There are two distinct clinical patterns of bleomycin pulmonary toxicity. Chronic progressive fibrosis is the most common; acute hypersensitivity reactions occur infrequently. Patients present with cough and dyspnea. The first physiologic abnormality seen is a decreased diffusing capacity of carbon monoxide.[118] Chest radiographs show a bibasilar reticular pattern, and gallium scans show marked uptake in the involved lung.[118] Chest radiographic changes lag behind pulmonary function abnormalities. Spirometry tests before each bleomycin dose are not predictive of toxicity. The single-breath diffusing capacity of carbon monoxide is the most sensitive indicator of bleomycin-induced lung disease. Although it is not absolutely predictive, a drop of 20% or greater in the diffusing capacity of carbon monoxide is an indication for using alternative therapies.[118] The prognosis of bleomycin lung toxicity has improved as a consequence of early detection, but the mortality rate is approximately 25%. Mild cases respond to discontinuation of bleomycin therapy.[107] Corticosteroid therapy appears to be helpful in patients with acute pneumonitis, although there have been no controlled trials. Patients with chronic fibrosis are less likely to respond. Although corticosteroids have been used for a number of drug-induced pulmonary problems, a study in mice showing a potential for worsening of lung damage when administered early during the repair stage should sound a word of caution against their indiscriminate use.[128] Current clinical trials do not support use of glucocorticoids in prevention, early, or late phases of acute lung injury or acute respiratory distress.[129]

Mitomycin

Mitomycin is an alkylating antibiotic that produces pulmonary fibrosis at a frequency of 3% to 12%.[118] The mechanism is unknown, but oxygen and radiation therapy appear to enhance the development of toxicity.[118] The clinical presentation and symptoms are the same as for bleomycin. The mortality rate is approximately 50%. Early withdrawal of the drug and administration of corticosteroids appear to improve the outcome significantly. In a prospective trial, routine pulmonary function test monitoring did not appear to be predictive of pulmonary toxicity.[130]

Alkylating Agents

A number of alkylating agents are associated with pulmonary fibrosis (see Table 30-5). The incidence of clinical toxicity is around 4%, although subclinical damage is apparent in up to 46% of patients at autopsy. The mechanism of toxicity is unknown; however, epithelial cell damage that triggers the arachidonic acid inflammatory cascade may be the initiating event.[118] The clinical presentation is insidious, with 4 years being the average duration of therapy before the onset of symptoms. Patients present with low-grade fever, weight loss, weakness, dyspnea, cough, and rales.[118] Pulmonary function tests initially show abnormal diffusion capacity followed by a restrictive pattern (low vital capacity). The histopathologic findings are nonspecific. The prognosis is one of slow progression with a mean survival of 5 months following diagnosis.[118] Although there is no direct dose-dependent correlation, patients receiving less than 500 mg of busulfan do not develop the syndrome without concomitant radiation or use of other pulmonary toxic chemotherapeutic agents.[118] There are anecdotal reports of beneficial responses to corticosteroids, but no controlled studies have been done.

Cyclophosphamide infrequently produces pulmonary toxicity.[1] More than 20 well-documented cases have been reported to date. In animal models, cyclophosphamide produces reactive oxygen radicals. High oxygen concentrations produce synergistic toxicity with cyclophosphamide. The duration of therapy before the onset of symptoms is highly variable, and there may be a delay of several months between the onset of symptoms and discontinuation of the drug.[118] Cyclophosphamide may potentiate carmustine lung toxicity.[118] Clinical symptoms usually consist of dyspnea on exertion, cough, and fever. Inspiratory crackles and the bibasilar reticular pattern typical of cytotoxic drug-induced radiographic changes are present. Histopathological changes are also nonspecific. Approximately 60% of patients recover. Corticosteroid therapy has been reported to be beneficial; however, death despite corticosteroid administration has also been reported.

Chlorambucil, melphalan, and uracil mustard are also associated with pulmonary fibrosis. Of the alkylating agents, only nitrogen mustard and thiotepa have not been reported to cause fibrotic pulmonary toxicity.[118]

Antimetabolites

Methotrexate was first reported to induce pulmonary toxicity in 1969.[118] The pulmonary toxicity to methotrexate is unique in that discontinuation is not always necessary, and reinstitution of the drug may not produce recurrence of symptoms.[8] Methotrexate pulmonary toxicity most commonly appears to result from hypersensitivity,[1, 111] and it can occur 3 or more years following methotrexate therapy.[131] Age, sex, underlying pulmonary disease, duration of therapy, or smoking is not associated with an increased risk of pneumonitis with methotrexate.[131] Serial pulmonary function tests did not help identify pneumonitis in patients receiving methotrexate before the onset of clinical symptoms.[131] Reductions in diffusing capacity of carbon monoxide and lung volumes are the most common manifestations of methotrexate lung toxicity.[107] Pulmonary edema and eosinophilia are common, and fibrosis occurs in only 10% of the patients who develop acute pneumonitis.[118] Systemic symptoms of chills, fever, and malaise are common before the onset of dyspnea, cough, and

acute pleuritic chest pain. Methotrexate is also associated with granuloma formation.[118]

The prognosis of methotrexate-induced pulmonary toxicity is good, with a 1% or less mortality rate.[111] Pulmonary toxicity has followed intrathecal as well as oral administration and has occurred after single doses as well as long-term daily and intermittent administration. Pneumonitis has been reported to occur up to 4 weeks following discontinuation of therapy.[118] Numerous anecdotal reports have claimed dramatic benefit from corticosteroid therapy. It is unknown whether intermittent (weekly) dosing, as is done for rheumatoid arthritis, decreases the risk of methotrexate-induced pulmonary toxicity because pneumonitis has occurred with this form of dosing.

Rarely, azathioprine and its major metabolite 6-mercaptopurine have been reported to produce an acute restrictive lung disease. Procarbazine, a methylhydrazine associated more commonly with Löffler syndrome, rarely has been associated with pulmonary fibrosis.[111] The vinca alkaloids vinblastine and vindesine have been reported to produce severe respiratory toxicity in association with mitomycin. The incidence with the combination is 39% and may represent a true synergistic effect between these agents.[118] The safety profile of gemcitabine was reviewed in 22 completed clinical trials with more than 900 patients and pulmonary toxicity was rare at a rate of 1.4%.[132] Gemcitabine has been reported to cause noncardiogenic pulmonary edema and use of corticosteroids and diuretics should be considered early on to prevent mortality.[133]

Noncytotoxic Drugs

Pulmonary fibrosis associated with the ganglionic-blocking agent hexamethonium was first reported in 1954 (see Table e30-6).[8] Patients developed extreme dyspnea after several months on the drug. Pathological findings were consistent with bronchiectasis, bronchiolectasis, and fibrosis.[8] This phenomenon has occurred occasionally with use of the other ganglionic blockers (ie, mecamylamine and pentolinium).[8]

In 1959, radiographic changes characteristic of diffuse pulmonary fibrosis were reported in 27 (87%) of 31 patients who had taken phenytoin for 2 years or more.[105] Since then, studies have been conflicting. If phenytoin does produce chronic fibrosis, it would appear to be a relatively rare event.

Gold salts (sodium aurothiomalate) used in the treatment of rheumatoid arthritis have produced pulmonary fibrosis with cough, dyspnea, and pleuritic pain 5 to 16 weeks following institution of therapy.[105] Pulmonary function tests show a restrictive defect, and patients generally have an eosinophilia. The reactions improve on discontinuation of the gold therapy and recur promptly on reexposure. The pulmonary deficit may not resolve completely.

Biological Agents

With recent increase in approval of biological including monoclonal antibody agents, the reports of interstitial lung diseases (with no identified pattern) are increasing; some of these agents include tumor necrosis factor-α class of medication, recombinant interferons, rituximab, cetuximab,

bevacizumab, alemtuzumab or traztuzumab.[134,135,136]

Amiodarone

Amiodarone, a benzofuran derivative, produces pulmonary fibrosis when used for supraventricular and ventricular arrhythmias (see Table e30-6).[137] The duration of amiodarone therapy before the onset of symptoms has ranged from 4 weeks to 6 years.[105,137,138] The estimated incidence is 1 in 1,000 to 2,000 treated patients per year. Approximately 6% of the patients taking amiodarone will have pulmonary abnormalities with mortality rate of 10% to 20%.[1] The clinical course is variable, ranging from acute onset of dyspnea with rapid progression into severe respiratory failure and death caused by slowly developing exertional dyspnea over a few months. Patients generally improve on discontinuation of the drug.[137,138] The majority of patients develop reactions while taking maintenance doses greater than 400 mg daily for more than 2 months or smaller doses for more than 2 years. The risk of amiodarone pulmonary toxicity is higher during the first 12 months of therapy even at a low dosage.[139] Other risk factors include cardiopulmonary surgery combined with the administration of high concentrations of oxygen,[139] maintenance dose, cumulative dose of amiodarone, and age.[140] The prevalence of lung toxicity increases from 4.2% to 10.6% from the first to the fifth year of amiodarone use. Patients 60 years or older have a threefold increase in risk of toxicity for each subsequent decade compared to those younger than 60 years.[140] Pulmonary function including DLCO at baseline and routinely or for unexpected pulmonary symptoms is recommended. A reduction in DLCO of 15% has a sensitivity of 68% to 100% and a specificity of 69% to 95% to diagnose pulmonary toxicity.[141,142] Clinical findings include exertional dyspnea, nonproductive cough, weight loss, and occasionally low-grade fever.[105,138] Radiographic changes are nondiagnostic and consist of diffuse bilateral interstitial changes consistent with a pneumonitis. Pulmonary function abnormalities include hypoxia, restrictive changes, and diffusion abnormalities.

The mechanism of amiodarone-induced pulmonary toxicity is multifactorial. Amiodarone and its metabolite can damage lung tissue directly by a cytotoxic process or indirectly by immunologic reactions.[139,140] Amiodarone is an amphiphilic molecule that contains both a highly apolar aromatic ring system and a polar side chain with a positively charged nitrogen atom.[137] Amphiphilic drugs characteristically produce a phospholipid storage disorder in the lungs of experimental animals and humans.[119] Chlorphentermine, an anorectic, is the prototype amphiphilic compound. The mechanism is currently believed to be the inhibition of lysosomal phospholipases.[119] The inflammation and fibrosis are thought to be a late finding resulting from nonspecific inflammation following the breakdown of phospholipid-laden macrophages.[137]

In a review of 39 cases, 9 patients died, and the remaining 30 patients had resolution of abnormalities after withdrawal of the drug.[137] Some patients have had resolution with lowering of the dosage, and therapy has been reinstituted at lower doses without problems in others. Of the patients who died, one half had received corticosteroids. There are reports of a protective effect with prophylactic corticosteroids and other reports of patients developing amiodarone lung toxicity while on corticosteroids.[137] The use of corticosteroids for months to 1 year after stopping amiodarone is

recommended, despite the lack of controlled trials.[143]

Miscellaneous Pulmonary Toxicity

Drugs may produce serious pulmonary toxicity as part of a more generalized disorder. The pleural thickening, effusions, and fibrosis that occur as an extension of the retroperitoneal fibrotic reactions of methysergide and practolol or as part of a drug-induced lupus syndrome are the most common examples (**Table e30-8**).

TABLE e30-8 Drugs That May Induce Pleural Effusions and Fibrosis

	Relative Frequency of Reactions
Idiopathic	
Methysergide	F
Practolol	F
Pindolol	R
Methotrexate	R
Nitrofurantoin	R
Drug-induced lupus syndrome	
Procainamide	F
Hydralazine	F
Isoniazid	R
Phenytoin	R
Mephenytoin	R
Griseofulvin	R
Trimethadione	R
Sulfonamides	R
Phenylbutazone	R
Streptomycin	R
Ethosuximide	R
Tetracycline	R
Pseudolymphoma syndrome	
Cyclosporine	R
Phenytoin	R

F, frequent; I, infrequent; R, rare.

Pleural and pulmonary fibrosis has been reported in one patient taking pindolol, a β-blocker structurally similar to practolol, an agent known to produce fibrosis.[73] Acute pleuritis with pleural effusions and fibrosis is a prominent manifestation of drug-induced lupus syndrome. Procainamide is associated with the largest number of pulmonary reactions, with 46% of patients with the lupus

syndrome developing pulmonary complications.[8] Symptoms include pleuritic pain and fever with muscle and joint pain. Chest radiographs show bilateral pleural effusions and linear atelectasis. Patients have a positive antinuclear antibody test. Symptoms usually resolve within 6 weeks of drug withdrawal.[8]

Hydralazine is the next most common cause of lupus syndrome. Most patients who develop pleuropulmonary manifestations have antecedent symptoms of generalized lupus.[8] Other drugs that produce the lupus syndrome include isoniazid and phenytoin. Phenytoin can also produce hilar lymphadenopathy as part of a generalized pseudolymphoma or lymphadenopathy syndrome.[8]

Monitoring Therapeutic Outcomes

Monitoring for drug-induced pulmonary diseases consists primarily of having a high index of suspicion that a particular syndrome may be drug induced. Presently, there is no defined diagnostic workup in patient with suspected drug-induced pulmonary disease. Most hypersensitivity or allergic reactions (bronchospasm) occur rapidly, within the first 2 weeks of therapy with the offending agent, and reverse rapidly with appropriate therapy (eg, withdrawal of the offending agent and administration of corticosteroids and bronchodilators). Dyspnea associated with Löffler syndrome and acute pulmonary edema syndromes also improve rapidly in 1 to 2 days. However, some residual defect in diffusion capacity and the roentgenogram may persist for a few weeks. It is probably unnecessary to do follow-up spirometry or diffusion capacity determinations in these patients unless there is some concern that the syndrome will progress to pulmonary fibrosis (through the use of bleomycin or nitrofurantoin).[1]

The routine monitoring of patients receiving known pulmonary toxins with dose-dependent toxicity such as amiodarone, bleomycin, or carmustine is still controversial. For chronic fibrosis, the diffusing capacity of carbon monoxide is the most sensitive test and may be useful in patients receiving bleomycin for detecting and preventing further deterioration of lung function with continued administration. Carmustine lung toxicity may be delayed up to 10 years following administration, and routine monitoring has not proved preventive. Monitoring patients receiving amiodarone in doses greater than 400 mg/day every 4 to 6 months may prove useful in detecting early disease that requires lowering the amiodarone or stopping the drug. Because there is no evidence of a cumulative dose effect once it has been established that the patient can tolerate the elevated dose, continued routine monitoring past the first year is unnecessary.

ABBREVIATIONS

Chapter e31: Evaluation of the Gastrointestinal Tract

Keith M. Olsen; Rachael V. McCaleb

INTRODUCTION

KEY CONCEPTS

- 1 The patient history is key to evaluating gastrointestinal (GI) tract disorders and should include the problem onset, the setting in which it developed, and its presentation. Patient warning signs and alarm symptoms should be identified quickly and referral for further evaluation should be obtained in a prompt manner.
- 2 A complete physical examination should be performed, the severity and location of symptoms directing the focus of the examination.
- 3 Contrast agents, barium sulfate and Gastrografin® (diatrizoate meglumine and diatrizoate sodium solution), have gradually been replaced by endoscopy, but allow evaluation of the hollow organs of the digestive tract for mucosally based lesions as well as narrowing or strictures involving the GI tract.
- 4 The upper GI series involves radiographic visualization of the esophagus, stomach, and duodenum; whereas, the lower GI series involves visualization of the colon and rectum.
- 5 Enteroclysis is used to evaluate the small bowel by introducing contrast agents by tube through the nose or mouth directly into the small intestine.
- 6 Transabdominal ultrasound, computed tomography, and magnetic resonance imaging provide images of the gallbladder, liver, pancreas, and abdominal wall.
- 7 Radionuclide imaging is sometimes useful to visualize and evaluate the liver, spleen, bile ducts, and gallbladder.
- 8 The endoscope, an illuminated optical instrument, remains the cornerstone of GI diagnosis

and most importantly therapy. Common examples of endoscopic procedures include esophagogastroduodenoscopy, colonoscopy, enteroscopy, endoscopic retrograde cholangiopancreatography, and endoscopic ultrasound.

- [9] Capsule endoscopy, a newer less invasive endoscopic technique, takes pictures of the GI tract in the assessment of the small bowel in particular.

- [10] Ambulatory esophageal pH measurement is an important diagnostic test for gastroesophageal reflux disease and is often performed in conjunction with upper endoscopy. Most systems today are completely wireless and patient friendly.

- [11] Multichannel intraluminal impedance and pH monitoring combines acid exposure with impedance changes in resistant flow to aid the diagnosis of reflux in patients receiving a proton pump inhibitor and other antisecretory medications.

The gastrointestinal (GI) tract is an organ system responsible for nutrient absorption, waste excretion, and immunity. It is composed of the upper GI tract (oral cavity, esophagus, and duodenum), lower GI tract (small intestine, cecum, colon, rectum, and anus), and associated glandular organs (gallbladder, pancreas, and liver). A variety of symptoms can arise from GI tract dysfunction, including heartburn, dyspepsia, abdominal pain, nausea, vomiting, diarrhea, constipation, and GI bleeding. Signs and symptoms of malabsorption, hepatitis, and GI infection are also commonly seen. All clinicians must recognize warning symptoms that include weight loss, intractable vomiting, anemia, dysphagia, odynophagia, and bleeding; and a patient presenting with any of these symptoms should be immediately referred for further diagnostic interventions.

Despite the rapid proliferation of technology for the diagnosis of digestive diseases, the patient history and physical examination remain important for initial assessment, triage, and guidance of further diagnostic interventions. When combined with a thorough patient history and physical examination, diagnostic procedures are essential in the evaluation of GI disorders. This chapter describes the most commonly used clinical tools to evaluate patients with GI tract-related diseases.

PATIENT HISTORY

[1] A comprehensive patient history is the cornerstone in the evaluation of a patient with digestive complaints. The purpose of history taking is to obtain a clear and detailed account of the patient's complaints. It is considered the first step in the diagnostic workup and used to narrow the focus of the diagnostic and therapeutic plan for the patient. In addition to collecting information on current complaints, a thorough patient history should gather information concerning medical history, social and family history, and current medications. The healthcare professional should ask guided question focused on determining the symptom's onset, location, severity, and duration, setting in which symptoms developed, aggravating and alleviating factors, and associated symptoms of the complaint. The symptom onset often provides important information that helps formulate a differential diagnosis. For example, biliary colic or pain, such as that encountered with symptomatic gallstone disease, typically evolves over minutes and is present for hours, but pain caused by

pancreatitis evolves over hours and lasts for days. The setting is always relevant as it provides clues to the possible origin of the disorder. For example, in the patient with complaints of reflux or ulcer disease, obtaining information as to whether the pain is alleviated or worsened by food or diminished when administered acid-suppressive therapy can help guide diagnostic and therapeutic interventions. For instance, ingesting a meal often relieves the pain of duodenal ulcer, but worsens pain due to a gastric ulcer. The healthcare professional should ask questions that address potential etiologic possibilities, including motility disorders, structural diseases, malignancies, infections, psychosocial factors, dietary factors, and travel-associated diseases.[1,2] A good cardiopulmonary history is also extremely relevant and should be performed during the overall history. Questions concerning medical and family history detailing illnesses, surgical interventions, injuries, foreign travel, living conditions, and habits are valuable (**Table e31-1**). A complete medication use history including over-the-counter, herbal, and traditional Chinese medicines is vital as many agents cause GI injury (**Table e31-2**).

TABLE e31-1 General Questions in a GI History

1. Where is your pain located? Please point to the area where you feel pain. How rapidly did the pain come on? Is your pain constant or intermittent? What factors exacerbate or alleviate your pain? Does the pain awaken you at night?
2. Tell me about the problem that you are experiencing. When did it start? What were you doing when the symptoms began?
3. Have you recently had a change in bowel habits? Have you experienced any diarrhea or constipation lately? Do you experience painful bowel movements?
4. Have you experienced any nausea or vomiting lately? If so, please describe conditions centered on this event.
5. Have you experienced any recent change in weight? Was this intentional? How many pounds have you gained or lost and over what time period did this occur? How has your appetite been?
6. Have you passed any blood from your rectum or vomited blood? Have you noticed any dark, tarry stools?
7. Have you had any acid indigestion?
8. Do you have difficulty swallowing?
9. Have you had these symptoms in the past?
10. What medications are you taking to help alleviate the pain? How much do you take? Do these medications work?
11. Have you recently had a change in dietary intake? If so, please describe. Can you draw any correlation between the foods that you eat and your GI complaint?

12. Describe your medical history, including illnesses and surgeries.
13. Please describe any past injuries that you have experienced.
14. What other medications are you currently taking? Why are you taking them?
15. Has anyone in your family experienced similar GI complaints? If so, please describe. Does anyone in your family have a history of GI disorders, including cancer of the GI tract?
16. Have you recently traveled outside of the United States? If so, where? When? How long did you stay? What kind of living conditions did you experience? What foods and drinks did you ingest?

GI, gastrointestinal.

TABLE e31-2 Drugs That May Cause GI Injury[20,21,22,23,24]

GI mucosal injury	
Aspirin	Iron preparations
Bisphosphonates	Nonsteroidal anti-inflammatory agents
Chemotherapeutic agents	Pancreatic enzymes
Corticosteroids	Potassium chloride
Ethacrynic acid	Reserpine
Ethanol	Warfarin
Jaundice	
Acetohexamide	Ethanol
Androgens	Gold salts
Chlorpropamide	Nitrofurantoin
Corticosteroids	Phenothiazines
Erythromycin	Warfarin
Estrogens	
Liver damage	
Acetaminophen	Nifedipine
Allopurinol	Nitrofurantoin
Amiodarone	Phenazopyridine

Aminosalicylic acid

Dapsone

Erythromycin

Ethanol

Glyburide

Isoniazid

Ketoconazole

Lovastatin

Methotrexate

Methyldopa

Monoamine oxidase inhibitors

Nevirapine

Niacin

Phenytoin

Propylthiouracil

Quinolone antibiotics

Rifampin

Salicylates

Sulfonamides

Telithromycin

Tetracycline

Valproic acid

Verapamil

Warfarin

Zidovudine

Herbal products

Ayurvedic herbal products

Atractylis gummifera

Callilepsis laureola

Chaparral

Chinese herbal medicines

Jin Bu Huan (*Lypocodium serratum*)

Ma huang (*Ephedra sinica*)

Dai-saiko-to (Sho-saiko-to, TJ-19)

Geniposide

Germander

Greater celandine

Green tea

Kava

Pennyroyal pyrrolizidine alkaloids

Pancreatitis

Azathioprine

Corticosteroids

Didanosine

Estrogens

Metronidazole

Opiates

Pentamidine

Sulfonamides

Ethacrynic acid	Tetracycline
Ethanol	Tigecycline
Furosemide	Thiazides

GI, gastrointestinal.

PHYSICAL EXAMINATION

2 A thorough physical examination, not limited to the GI tract, is necessary to provide important diagnostic data and determine the need for acute intervention.[3] A comprehensive evaluation of the patient should be performed with notable attention to physical appearances and vital signs as they may suggest signs of systemic conditions eliciting GI symptoms. An abdominal examination is an essential part of the GI workup and classically includes inspection, auscultation, percussion, and palpation in this order. Inspection of the abdomen may reveal scars, hernias, bulges, or peristalsis. Auscultation is mainly focused on analysis of bowel sounds and identification of bruits and should be performed prior to percussion and/or palpation. Percussion of the abdomen allows for detection of tympany, measurement of visceral organ size, and detection of ascites. Palpation may allow the examiner to identify tenderness, rigidity, masses, and hernias. Moving from the abdominal examination, the digital rectal examination is used to detect rectal masses and tenderness, and to assess muscle tone. Stool on the examiner's glove obtained during rectal examination is often subjected to testing for detection of occult blood.[2,3] Additionally, once cardiovascular disease is eliminated, patients with chest pain may have a GI source to their symptoms and further diagnostic workup may be needed.

LABORATORY AND MICROBIOLOGIC TESTS

Laboratory and microbiologic tests may be used to assess organ function, to screen for certain GI disorders, and to evaluate the effectiveness of therapy. Laboratory testing should be viewed largely as supportive to an accurate history and physical examination. To achieve an accurate diagnosis and provide the best care, it is important to assess the patient's fluid and electrolyte status, nutritional status, inflammatory markers, and abdominal organ function. A complete blood cell count should be completed early in the evaluation to provide information concerning infection, malignancy, bone marrow suppression, anemia, and blood loss.[4] A serum chemistry panel provides valuable information—involving several organ systems. For example, serum creatinine and blood urea nitrogen are often used as a measure of hydration status, as well as, serving as indicators for renal function. Elevations in serum creatinine and blood urea nitrogen may be indicative of renal dysfunction or dehydration, and bleeding from the upper GI tract may lead to elevations in blood urea nitrogen. Albumin and prealbumin levels can be used to assess the patient's nutritional and hydration status and provide information concerning hepatic and renal function. Specifically, low albumin may be indicative of malnutrition, hepatic dysfunction, nephrotic syndromes, or protein-losing enteropathies. Serum measurements of sodium, chloride, and potassium are useful to

determine electrolyte abnormalities associated with diarrheal illnesses. The erythrocyte sedimentation rate and C-reactive protein are nonspecific inflammatory markers that are useful for the diagnosis and management of patients with inflammatory bowel disease.

More specific laboratory blood tests are often useful for classifying pancreaticobiliary disorders. Measurements of serum aspartate transaminase and alanine transaminase are elevated in most diseases of the liver, and serum alkaline phosphatase and bilirubin are often elevated in hepatobiliary disorders involving bile duct blockage. Prothrombin time and international normalized ratio are related to hepatocyte synthesis of vitamin K-dependent clotting factors and serve as indirect measurements of hepatic function. When evaluating patients with suspected pancreatitis, serum and urine measurements of amylase and lipase are important, because these will be elevated in many patients with acute pancreatitis (see Chapter 39).

Microbiologic and related studies are useful in evaluating patients with unexplained diarrhea, abdominal pain, and suspected GI infections. Stool may be examined to detect the presence of bacteria, parasites, or toxins. Pathogens most often responsible for infectious diarrhea and enteritis include bacteria such as *Shigella*, *Salmonella, Escherichia coli, Yersinia*, and *Clostridium difficile*. Viruses such as cytomegalovirus, especially in patients with acquired immune deficiency syndrome (AIDS), and parasites such as *Entamoeba histolytica* and *Giardia lamblia* are occasionally seen.[5] Patients presenting with watery diarrhea following antibiotic exposure within the previous 3 months should have their stool checked for *C difficile* toxins A and B. An additional organism *Helicobacter pylori* is a significant factor associated with peptic ulcer disease and mucosa-associated lymphoid tissue (MALT) lymphomas; identification of this organism is critical in patients experiencing upper GI symptoms and is often tested for during upper endoscopy (see Chapter 33).[5]

DIAGNOSIS

The patient's history, physical examination, and routine laboratory tests are valuable in establishing a diagnosis, but frequently more specific studies are required to confirm a clinical suspicion. The most appropriate diagnostic study depends on the anatomic region involved, the suspected abnormality, the reliability of the test (eg, sensitivity vs specificity), the patient's overall condition, and the clinical manifestations of the patient. The next sections outline the most frequently used diagnostic studies and procedures and their roles in evaluating the GI tract.

Noncomputer-Assisted Radiologic Studies

Radiologic procedures rely on the differential absorption of radiation of adjacent tissues to highlight anatomy and pathology. It is useful to divide radiologic testing into noncomputer- and computer-assisted procedures. Noncomputer-assisted radiologic procedures important in evaluating the GI tract include plain radiography, upper GI series with small bowel follow-through, lower GI series, and enteroclysis.[6,7]

Plain Radiography of the Gastrointestinal System

Radiographic evaluation of the GI tract often starts with plain films of the abdomen, which are noncontrast radiographs.[7] Specific abdominal structures that may be identified include the kidneys, ureters, and bladder. In addition, the esophagus, stomach, small and large intestine, and stones may be seen. Stones located within the gallbladder body and within the kidney are sometimes seen on plain abdominal films. Plain films are often used initially to evaluate abdominal pain. Clinicians frequently employ plain radiographic fluoroscopy to guide and position other instruments that are used to evaluate and treat GI disorders; an example is the manipulation of dilation devices to treat esophageal strictures. Bowel obstruction and perforation can be seen using plain radiographic techniques; however, the widespread availability of computed tomography (CT) scanning is gradually replacing these techniques.

Contrast Radiography of the Gastrointestinal System

Oral, rectal, and intravenous contrast agents are used in a variety of ways for radiographic imaging of the GI system. Oral contrast agents, such as barium sulfate and other water soluble contrasts are commonly used for radiographic studies, such as pharyngographic studies, upper GI series, and small bowel follow-through examinations. In addition, oral contrast agents are routinely used to opacity the GI tract in CT, magnetic resonance imaging (MRI), CT and MRI enterography, and CT- and MRI-positron emission tomography. Barium sulfate enema technique is an established method for evaluating the colon and to opacity the colonic lumen during abdominal and pelvis CT imaging. Lastly, intravascular contrast agents allows for visualization of biliary and pancreatic ducts during endoscopic retrograde cholangiopancreatography.

3 Barium sulfate is a water soluble contrast agent that improves the visualization of the esophagus, stomach, and intestine in a radiographic image.[7] The area where barium localizes appears white on the radiographic film, creating distinctive definition and visual contrast between an organ and the surrounding tissues. Radiographic studies using barium sulfate are commonly referred to as barium esophagram (*barium swallow*) or barium enema studies as barium sulfate is only administered via the oral or rectal route. Barium sulfate is not generally absorbed, and constipation is the most frequent adverse effect reported with its use. Its use is contraindicated in the setting of known or suspected GI tract perforation due to increased risk of peritonitis. Diatrizoate meglumine and diatrizoate sodium solution (Gastrografin®) is an alternative oral contrast agent for use in patients that are unable to tolerate or are allergic to barium sulfate. Barium sulfate and/or Gastrografin® can reveal mucosal defects and lumen size, and are helpful in diagnosing hiatal hernias, strictures along the GI tract, polyps, tumors, and in some cases ulcers. Upper endoscopy is largely replacing contrast studies in the diagnosis of upper GI tract disorders, but in certain instances they can be a tool in establishing a diagnosis prior to endoscopic evaluation. The barium esophagram should not serve as a primary diagnostic tool for patients with heartburn.

Upper Gastrointestinal Series

4 The upper GI series refers to the radiographic visualization of the esophagus, stomach, and duodenum. Patient preparation for an upper GI series usually consists of instructing patients to

refrain from eating or drinking 8 to 12 hours prior to testing, which allows the upper GI tract to empty. A contrast agent such as barium sulfate or Gastrografin® is administered to the patient at the beginning of the study. The observed swallowing of the contrast agent permits visualization and monitoring of esophageal structural and motor functions. A gastrointestinal radiologist sometimes uses double contrast techniques to enhance the visualization of the inside wall lining of the esophagus, stomach, and duodenum. The double contrast technique uses a gas, such as air or a carbonated substance, in addition to barium sulfate. The gas expands the organs and allows for the barium sulfate to coat the inner surface of the organ, providing sharpened visualization.[8]

The upper GI series can be continued as the contrast agent moves from the stomach and duodenum into the small intestine, referred to as the *small bowel follow-through*. The single contrast agent technique, with either barium sulfate or a water soluble contrast, is utilized during a small bowel follow-through. An upper GI series with small bowel follow-through commonly uncovers gastric cancer, peptic ulcer disease, esophagitis, gastric outlet obstruction, and can be suggestive of Crohn disease (**Fig. e31-1**). In general, the barium swallow is plagued by low sensitivity and specificity for many GI disorders and as mentioned is being replaced by upper endoscopic techniques.

FIGURE e31-1

Upper GI series with small bowel follow-through demonstrating narrowed distal terminal ileum and separation of small bowel loops (*arrow*). These findings are consistent with Crohn disease.

Lower Gastrointestinal Series

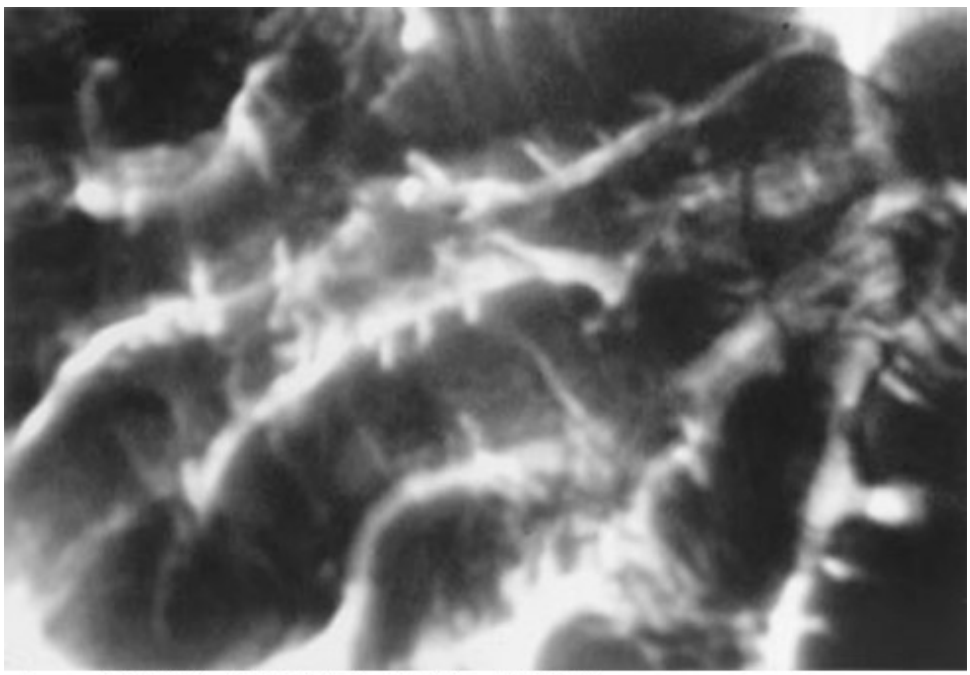
The lower GI series is used to examine the colon and rectum and is particularly useful if a colonic obstruction is suspected. Patients complaining of lower abdominal pain, constipation, or diarrhea are often referred for a lower GI series, also called a barium enema. The colon is prepared for the procedure by instructing the patient to refrain from eating or drinking 8 to 12 hours before the procedure, and by administering bowel-cleansing agents such as bisacodyl, magnesium citrate, magnesium hydroxide, or polyethylene glycol electrolyte (PEG) solution. During a lower GI series, a barium sulfate enema is given to contrast the terminal large intestine and rectum. The lower GI series is sometimes useful to detect and evaluate enterocolitis, obstructions, volvulus, and mucosal and structural lesions.[7] Similar to the upper GI series, the double contrast technique with air may be used to enhance imaging of the colon.

Small Bowel Enteroclysis

5 Enteroclysis, or small bowel enema, refers to the technique of direct small bowel introduction of a contrast agent through a tube inserted through the patient's mouth or nose directly into the small intestine. Sequential radiographic films are taken of the small bowel as the contrast agent flows distally (**Fig. e31-2**). The enteroclysis technique allows for optimal distention of the small bowel lumen and enables visualization of subtle mucosal abnormalities. Enteroclysis is not widely performed due to operator inexperience and is rapidly being replaced by improved radiologic techniques such as CT or MRI enterography or more recently by small intestinal endoscopy known as single and double balloon enteroscopy and capsule endoscopy.

FIGURE e31-2

Normal small bowel enteroclysis. Contrast agents are instilled into the small bowel to highlight tumors, strictures, or other lesions. In this image, one can identify the normal circular folds.



Computer-Assisted Radiologic Studies

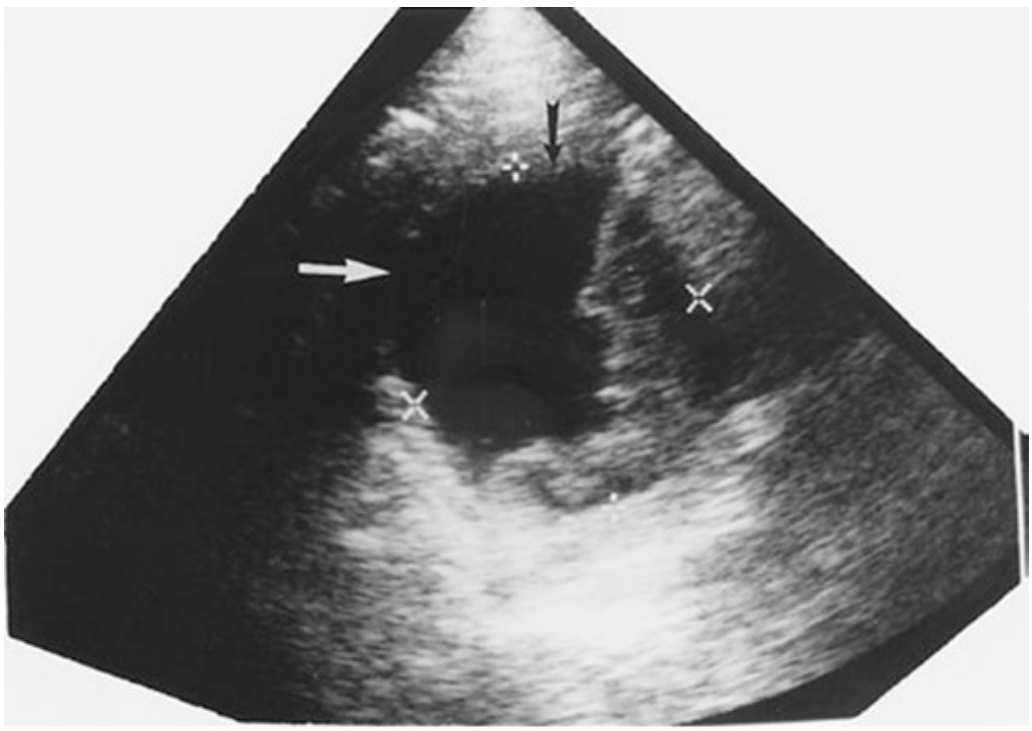
The second category of radiologic evaluation of the GI tract involves computer-assisted techniques, which allow a cross-sectional radiographic image of the body to be performed. Transabdominal ultrasonography, CT, radionuclide scanning, and MRI are frequently used imaging procedures for evaluating digestive disorders.[6,7]

Ultrasonography

Ultrasonography provides images of deeper structures such as the gallbladder, liver, and kidneys and can also be useful in helping define vascular abnormalities in the intra-abdominal cavity. Ultrasound involves the direction of a narrow beam of high-energy sound waves into the body and recording the reflections from the various organs and structures. In general, ultrasonography is a well-accepted, noninvasive, and relatively inexpensive method for evaluating GI pathology that requires no ionizing radiation and can be performed at bedside with a portable unit. It accurately depicts the presence of gallstones within the gallbladder, helps define liver morphology, and serves as a first test to evaluate the absence or presence of biliary ductal dilation in a jaundiced patient (**Fig. e31-3**). When combined with Doppler technologies, ultrasonography can image GI vascularity, in particular portal venous flow, and identify aneurismal dilations of the abdominal aorta. The images produced by ultrasonography are not as sharp and clear as those produced by CT and the quality of the images produced relies heavily on the operator. Moreover, ultrasonography is limited by the presence of bowel gas and excessive amounts of body fat, particularly when evaluating deeper organs such as the pancreas.[6,7]

FIGURE e31-3

Abdominal ultrasonogram demonstrating a chronic pancreatic pseudocyst (*arrows*).



Computed Tomography

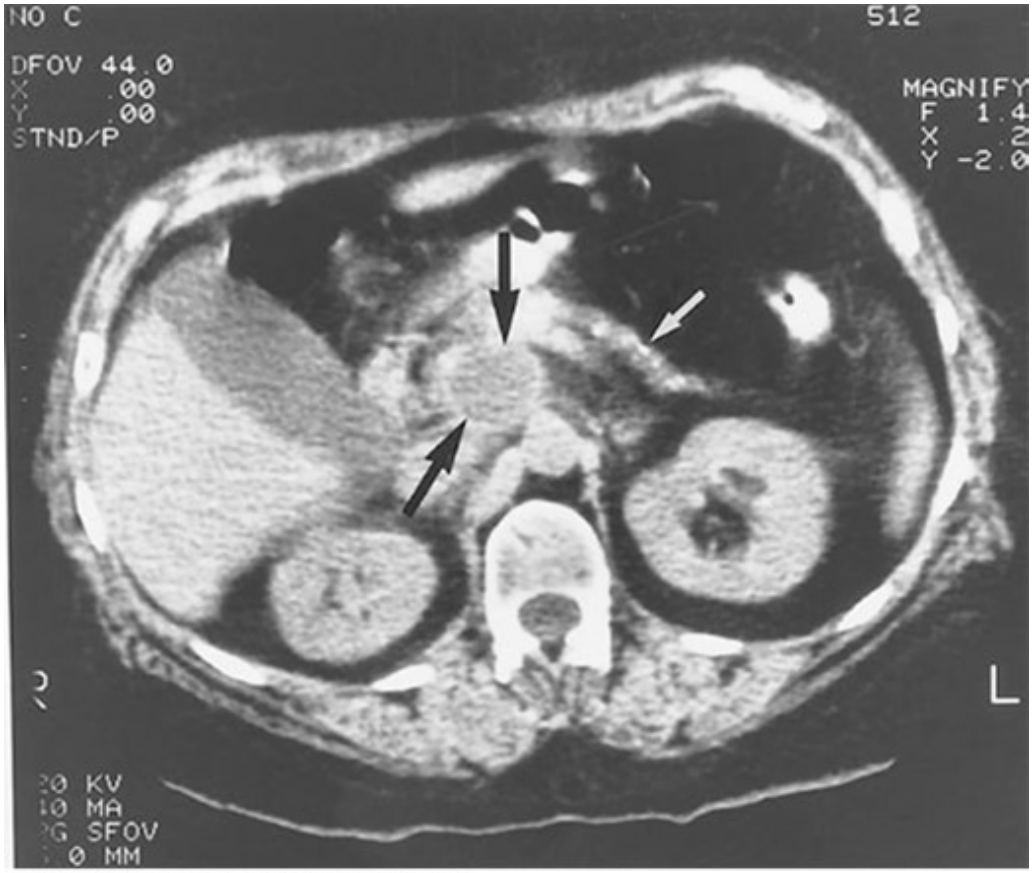
Advances in CT or computed axial tomography (CAT) scanning have resulted in a paradigm shift for chest and abdominal-pelvic imaging, providing improved resolution and faster acquisition of radiographic information. A CT examination provides detailed images of the GI system in which

transverse planes of tissue are swept by a radiographic beam and a computer analysis of the variance in absorption produces a precise reconstructed image of that area.[6] Contrast agents may be added during a CT procedure to enhance the difference in density of various structures. Oral and rectal administration of a contrast agent, such as barium sulfate or a water soluble contrast agent, will help delineate the GI tract; while intravenous administration of a water soluble contrast agent will illuminate the vascularity of the GI tract.

The abdominal CT displays organs from the diaphragm down to the pelvic brim, and is especially valuable for detecting GI diseases of the liver, pancreas, spleen, and colon. Patient preparation for CT includes refraining from eating or drinking for a minimum of 4 hours before the test. The remarkable detail that CT offers in imaging of organs and tissues adds to its popularity for evaluation of the GI tract. CT scanning is rapidly replacing plane radiography of the abdomen due to its widespread availability, diminishing cost, and wealth of information provided. CT is also useful in the identification of suspected intra-abdominal malignancy, pancreatitis, intraabdominal abscesses, and cysts (**Fig. e31-4**).[6,7] Unlike ultrasonography, patient body size or the presence of gas does not limit the quality of imaging with CT. Contrast agents used during CT scanning are nephrotoxic and close attention to a patient's renal function is mandatory in these patients.

FIGURE e31-4

Computed tomography (CT) scan of the abdomen showing pancreatitis with calcification (*white arrow*) and pancreatic pseudocyst (*black arrows*).



Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

CT enteroclysis combines the methods of barium enteroclysis and abdominal CT into one technique. It is highly accurate in depicting mucosal abnormalities in Crohn disease and diagnosing of low-grade small bowel obstructions. During CT enteroclysis, the small bowel is expanded by introduction of a contrast agent through a nasoduodenal tube directly into the small intestine with or without intravenous contrast. CT enterography uses the same method as CT enteroclysis; however, the patient orally ingests the contrast agent without the use of a nasoduodenal tube. For the investigation of small-bowel disease, CT enteroclysis is considered a complementary addition to capsule endoscopy technique discussed later in this chapter.[9]

Radionuclide Imaging

7 Radionuclide imaging, commonly referred to as nuclear medicine, is a well-suited diagnostic tool that allows for structural and functional visualization of the GI tract. It involves IV injections of a radiopharmaceutical imaging agent and the use of a computerized detection camera to gather images. A secretory agent is sometimes given in addition to the radiopharmaceutical agent to improve sensitivity. Although the choice of a radiopharmaceutical agent depends on the specific organ or function being studied, the most commonly used agent is technetium (^{99m}Tc) tagged to a carrier molecule. Radionuclide imaging is sometimes useful to visualize the liver and spleen (liver–spleen scan), bile ducts, gallbladder (hepatoiminodiacetic acid [HIDA] scan), and gut (tagged red blood cell).[6,7] Cysts, abscesses, tumors, and obstructions are detected and displayed as areas of differential uptake of radioactivity.[6] Radionuclide bleeding scans may detect hemorrhages and may

assist with localization of therapeutic interventions. Patient preparation for radionuclide imaging includes refraining from eating or drinking for a minimum of 8 hours before the test. Contrast agent nephrotoxicity in patients with preexisting renal impairment remains a clinically significant problem. Pretest treatment in high-risk patients with pharmacologic agents has demonstrated mixed results.

Magnetic Resonance Imaging

MRI allows for a comprehensive evaluation of intra-abdominal solid organs including, the liver, pancreas, and spleen, without the use of ionizing radiation. An MRI places the patient in close proximity to a high-strength magnetic field through which pulses of radiofrequency radiation are projected, thereby exciting the nuclei of hydrogen, phosphorus, oxygen, and other elements. The radiofrequency signals are manipulated and recorded by a computer, and a two-dimensional image representing a section of the patient is produced.[6,7] MRI has greater sensitivity for identifying liver tumors than do ultrasonography, CT, and radionuclide imaging. Patient preparation for an MRI includes refraining from eating or drinking for a minimum of 4 hours before the test. Significant advances in MRI technology and imaging capabilities often make it a preferred diagnostic test, particularly in the evaluation of pancreaticobiliary disorders when secretin is added to enhance bile and pancreatic duct visualization.[6,7] Magnetic resonance cholangiopancreatography (MRCP) is used for evaluating the biliary tract and pancreatic duct in a noninvasive manner without the need for exogenous contrast agents. In MRCP, static fluid in the ducts appears bright against the darker tissue.

Similar to CT, Magnetic resonance enteroclysis and enterography are used to evaluate and monitor patients with Crohn disease. Due to the lack of radiation exposure, magnetic resonance enteroclysis offers an advantage over CT enteroclysis particularly in younger patients that will likely require numerous examinations over their lifetime. However, it appears to be less accurate than CT enteroclysis which has higher sensitivity.[9]

Arteriography

Arteriography of the gut depicts the configuration of visceral blood vessels after intravascular administration of an iodinated contrast agent. Arteriography may be employed for vascular anomalies such as an aneurismal dilation and in the evaluation of obscure bleeding lesions. The therapeutic applications for arteriography include, embolization of bleeding vessels, fistulas, and inoperable tumors.[6,7]

Endoscopy

8 Refinement in optical engineering and fiber optics led to the development of the endoscope, which has revolutionized the management of GI disorders. Most endoscopic equipment today uses a computer chip device to provide high definition, detailed images of the particular lumen being examined. An endoscope is an illuminated white light and non-white light optical instrument designed to inspect the interior of the GI tract. Endoscopes enable the practitioner to inspect intraluminal mucosal lesions and to obtain biopsies and washings for cytology studies. Standard upper GI tract endoscopy (ie, esophagogastroduodenoscopy [EGD]) is capable of inspecting the

esophagus, stomach, and proximal small bowel. Lower GI tract endoscopic evaluation of the rectum and colon may be accomplished by colonoscopy or flexible-sigmoidoscopy. In addition to standard upper and lower endoscopy many newer diagnostic and therapeutic endoscopic devices are now available.[10]

Patients should be instructed to refrain from eating or drinking for at least 8 to 12 hours prior to the endoscopic procedure. Bowel cleansing is necessary for colonoscopy and sigmoidoscopy using a variety of PEG-based solutions. Topical pharyngeal anesthetics, such as viscous lidocaine or benzocaine, usually improve patient acceptance of the upper endoscopic tube. Intravenous sedating agents, such as lorazepam and midazolam, are commonly used to induce a state of altered consciousness, referred to as conscious sedation that minimizes pain and discomfort during the endoscopic procedure. These sedating agents tend to improve patient acceptance and ease of the procedure. The agents should not be used without appropriate monitoring and the availability of flumazenil, a benzodiazepine antagonist. Propofol has been used to induce a deeper sedation than traditional sedation agents and improves patient comfort and shortens recovery and discharge time.[11] Propofol has a negative cardiac inotropic effect which can cause a decrease in cardiac output, vascular resistance, and arterial pressure, and can induce respiratory depression in a dose-dependent fashion. The potential for serious adverse events with these agents used for sedation during endoscopic procedure should be considered and patients should be monitored appropriately. Antimuscarinic agents, such as atropine sulfate, are occasionally used to increase a patient's heart rate and reduce duodenal and colonic motility. Likewise, glucagon may be used to reduce bowel motility. Endoscopy should be pursued with caution in patients with severe respiratory or cardiac failure, and endoscopy is contraindicated for patients with suspected perforated viscera. The most commonly used endoscopic studies are upper endoscopy (EGD), colonoscopy, flexible sigmoidoscopy, and endoscopic retrograde cholangiopancreatography (ERCP).[10] Newer endoscopic techniques include single or double balloon enteroscopy, capsule endoscopy, and endoscopic ultrasound (EUS). These techniques are outlined in detail below.

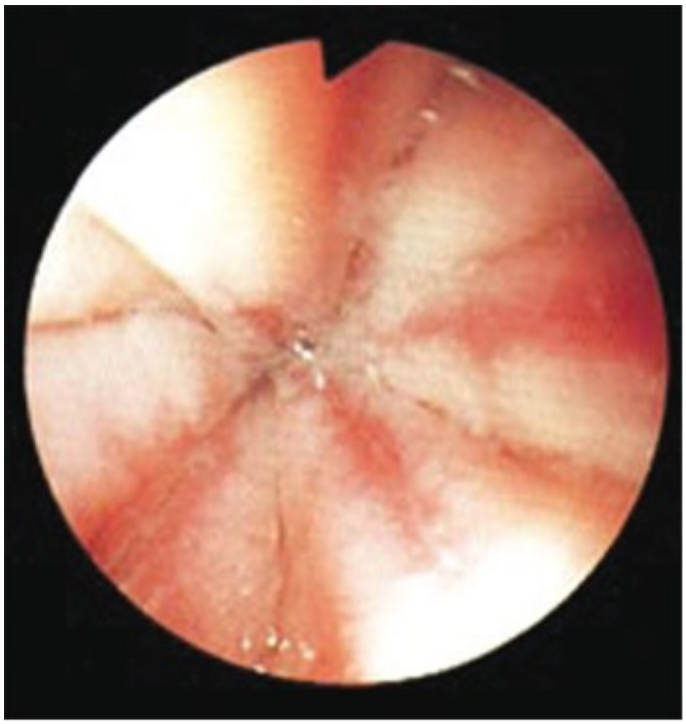
Upper Endoscopy

EGD, upper endoscopy, is used to examine the esophagus, stomach, and duodenum. Common indications for EGD include evaluation of suspected upper GI bleeding, obstructions, upper abdominal pain, and persistent vomiting, as well as, evaluation of radiographic abnormalities.[12] Patient preparation for EGD includes refraining from eating or drinking prior to the procedure and the administration of sedatives and topical anesthetics. EGD can also be used therapeutically in upper GI bleeding for ligation procedures involving esophageal varices, sclerosing, or vasoconstrictive agent administration at the site of the bleed in peptic ulcer-induced bleeding, or via the use of a thermal device such as a gold probe or heater probe on a bleeding vessel. In addition to its therapeutic potential, EGD commonly uncovers peptic ulcer disease and is the method of choice to diagnose Barrett esophagus, a premalignant condition of the esophagus and other esophageal ulcer erosive disorders (**Fig. e31-5**). Once viewed as the method of choice to diagnosis gastroesophageal reflux disease (GERD), EGD, although commonly used, is often times not performed before a trial of a proton pump inhibitor (PPI) has been undertaken. PPIs are widely prescribed for the treatment of heartburn and other symptoms attributed to GERD due to their superior healing ability. However,

several studies have linked PPI use to uncommon but serious adverse events, including increased risk of bone fracture, enteric infection, pneumonia, and chronic kidney disease in patients with long-term use.[13] Primary care physicians usually refer patients for EGD only when they fail to respond to a course of PPI therapy, and by the time an endoscopy is performed the examination is likely to reveal normal-appearing mucosa. Even in patients undergoing upper endoscopy in the evaluation of reflux type symptomatology in the absence of PPI therapy, endoscopy will be normal in up to 50% of patients.[10]

FIGURE e31-5

Gastrointestinal Endoscopy. In: Kasper DL, Braunwald E, Hauser S, et al., eds. Harrison's Principles of Internal Medicine, 16th ed. New York: McGraw-Hill, 2005.)*



Colonoscopy

Colonoscopy, lower GI endoscopy, permits direct examination of the large intestine and rectum and in addition allows for therapeutic removal of polyps and biopsy diagnosis of suspicious colonic lesions. Colonoscopy represents the main screening modality for the early detection and management of colonic polyps, which, in some cases, represent the precursor lesions for colorectal cancer development. To prepare for colonoscopy, the patient should refrain from eating or drinking for at least 8 to 12 hours prior to the examination, and bowel cleansing should be completed. Bowel preparations have traditionally involved a PEG-based or phosphate-based solution. However, due to

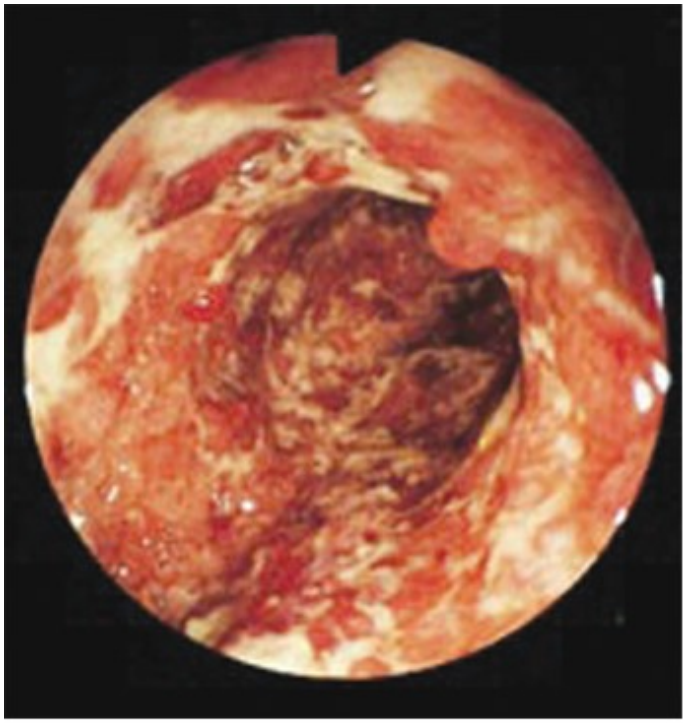
concerns regarding phosphate-induced nephropathy, there has been a return to standard PEG-based solutions. Newer trends in bowel preparation mainly include the advent of split dose bowel preparation involving the ingestion of approximately two-thirds of the bowel preparation the night before and the additional one-third 6 hours prior to the schedule procedure. This improves bowel visualization, particularly visualization of the right colon. A benzodiazepine is often given to produce conscious sedation and improve patient comfort. Propofol is often administered to provide a deeper level of sedation in patients who are refractory or intolerant to conscious sedation agents. As with upper GI endoscopy, indications for lower GI endoscopy can be either diagnostic or therapeutic in nature. Common indications include evaluation and detection of abnormalities visualized by radiography, as well as diagnosis and therapy of GI hemorrhage, and importantly, screening patients for colorectal carcinoma. Additionally, colonoscopy remains an invaluable procedure in the diagnosis, staging, and therapy of patients with inflammatory bowel disease (eg, ulcerative colitis and Crohn disease).[14]

Sigmoidoscopy

Flexible sigmoidoscopy is used to evaluate the sigmoid colon via the anorectum (**Fig. e31-6**). Flexible sigmoidoscopy has virtually replaced rigid sigmoidoscopy because of increased patient comfort and superior performance. The major indication for this examination is to evaluate symptoms related to the distal colon or rectum, such as hematochezia, painful defecation, and unexplained diarrhea. Flexible sigmoidoscopy is gradually being replaced by full colonoscopy in the evaluation and screening of patients for colorectal carcinoma. Patient preparation involves instructing patients to refrain from eating or drinking for at least 8 hours prior to the procedure and the administering of bowel-cleansing agents. Anoscopy is especially useful in evaluating the anus. The major indications for anoscopic examination include symptoms related to the anus and rectum, such as bleeding, protruding anorectal lesions, pain with defecation, and severe itching. Patients undergoing sigmoidoscopy or anoscopy generally do not require sedation.

FIGURE e31-6

In: Kasper DL, Braunwald E, Hauser S, et al., eds. Harrison's Principles of Internal Medicine, 16th ed. New York: McGraw-Hill, 2005.)*

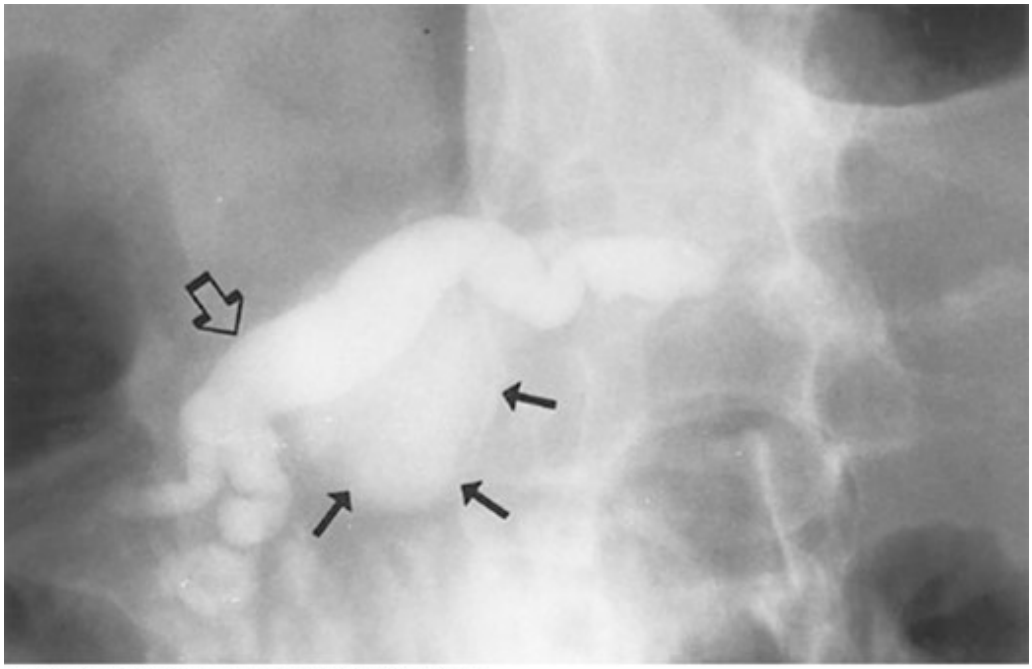


Endoscopic Retrograde Cholangiopancreatography

ERCP is an important therapeutic procedure that combines endoscopy and fluoroscopic imaging techniques to evaluate and treat diseases of the pancreaticobiliary tree. Common indications for ERCP include common bile duct stone management and bile and pancreatic duct stricture management, as well as, diagnosis and therapy of biliary tract and/or pancreatic malignancies. Cannulation of the bile or pancreatic duct is achieved through the wire-guided approach. Once the location of the guide wire has been confirmed, an intravenous contrast agent is injected which can reveal abnormalities such as obstruction due to malignancy, confirm presence of biliary or pancreatic duct calculi, and improved characterization of biliary strictures. ERCP also provides therapeutic modalities such as biliary or pancreatic sphincterotomy, removal of ductal stones from the common bile duct or main pancreatic duct, and stenting of biliary or pancreatic strictures. ERCP is also a useful method for tissue acquisition in the pancreaticobiliary tract using a variety of brush and biopsy devices. Recent advances in ERCP include the addition of direct bile duct or pancreatic duct visualization (cholangioscopy and/or pancreatoscopy), a procedure which has greatly aided in the diagnosis and therapy of pancreaticobiliary disorders. Preparation for ERCP consists of glucagon to relax gut motility and conscious sedation which often requires the use of an anesthesiologist due to the complex and long procedural times associated with ERCP (**Fig. e31-7**).[7,14]

FIGURE e31-7

Endoscopic retrograde cholangiopancreatography (ERCP) demonstrating a dilated, irregular pancreatic duct with areas of stricturing (*large arrow*). A pancreatic pseudocyst is visible immediately adjacent to the spine (*small arrows*).



Endoscopic Ultrasound

EUS is a newer, exciting endoscopic technology, which represents a marriage between upper endoscopy and standard ultrasound techniques. A high frequency ultrasound probe is attached to the working end of a diagnostic (radial array) or therapeutic (linear array) oblique viewing echoendoscope. EUS is commonly used to stage and diagnose upper GI tract malignancies such as those involving the esophagus, stomach, and pancreas. Upper GI tract locoregional tumor staging and tissue acquisition is highly sensitive and specific and provides a less invasive manner of tissue acquisition in many cases. Expanded uses of EUS include diagnosis and management of pancreatic fluid collections such as pancreatic cystic neoplasms (nonpseudocystic), celiac plexus block versus neurolysis in pancreatic malignant and chronic pancreatitis patients, and in some centers, direct instillation of antitumor agents into pancreatic malignancies. The development of ultrasound contrast agents, referred to as contrast-enhanced EUS, allows for better visualization of the vasculature and more accurate characterization of detected lesions. Ultrasound contrast agents consist of gas-filled microbubbles encapsulated by a phospholipid shell which oscillate to sound pressure and cause back-scattering of the ultrasound signal.[15] EUS-guided bile duct access is an additional indication gaining popularity in those patients in whom access at ERCP fails or is not technically feasible. Lower GI tract EUS is commonly performed in the diagnosis and locoregional staging of anorectal carcinoma and in evaluation of the anal sphincters. EUS is an invaluable tool in the management of GI tract disorders but its use remains centered largely in academic, tertiary care referral institutions.

Enteroscopy

Enteroscopy, or direct visualization of the small intestine, has traditionally been limited to examination of the proximal most portions of the duodenum/jejunum because of excessive endoscope looping and discomfort to the patient during the examination. To overcome these

difficulties two newer techniques, single and double balloon enteroscopy, have been developed. Sometimes referred to as "deep enteroscopy," these particular endoscopic procedures involve sequential inflation and deflation of balloon attachment devices in order to sequentially "walk" the enteroscope down the small or large intestine. A combination of inflation, deflation, and endoscope reduction via torque and withdrawal allow for a pleating of the mucosal surface being examined. Complete traversal of the small intestine is routinely achieved via the oral route and significant traversal of the colon and distal small intestine is now possible from the rectal route. Common indications for these procedures include the evaluation of obscure GI bleeding, the diagnosis and evaluation of possible inflammatory bowel disease, and the evaluation of radiologically discovered lesions such as mass or bowel wall thickening. Numerous studies, including some head-to-head trials, have yielded a high sensitivity and specificity for these technologies. The added advantage of deep enteroscopy is the ability to directly observe lesions of interest, to biopsy readily during the procedure, and in cases of obscure GI bleeding to add therapeutic maneuvers such as the application of thermal therapy or argon plasma coagulation to lesions felt to be responsible for ongoing blood loss.

Capsule Endoscopy

9 Capsule endoscopy allows the visualization of the esophagus, stomach, and small intestine. This device consists of a vitamin pill-sized video camera that is swallowed and acts as an endoscope (**Fig. e31-8**). As the video capsule travels naturally through the digestive tract, images are transmitted to a recording device placed on the patient's hip. Patients return the recording device to the practitioner so that the images can be downloaded to a computer and evaluated. Eventually, the camera is naturally excreted and not retrieved.[16] Capsule endoscopy represents a noninvasive means to evaluate the upper and lower GI tracts but unfortunately lacks therapeutic capability. Capsule endoscopy is often used in the evaluation of obscure GI bleeding and in the evaluation of suspected inflammatory bowel disease and is often times used in conjunction with single or double balloon enteroscopy. Capsule endoscopy continues to represent a powerful diagnostic tool in the management of many GI tract disorders.

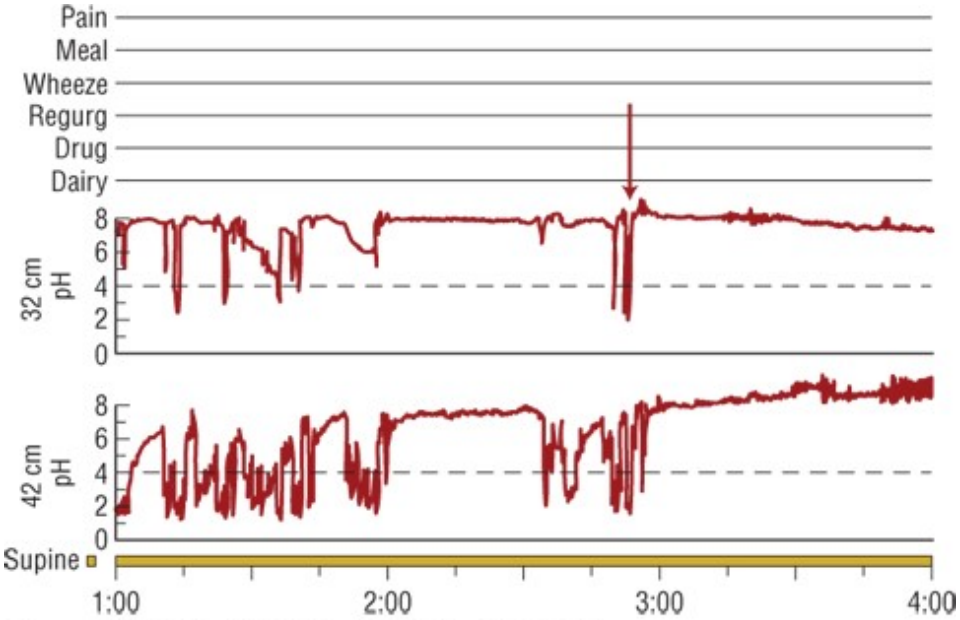
MISCELLANEOUS GASTROINTESTIONAL TESTS

Ambulatory Esophageal pH Monitoring

10 Esophageal pH monitoring is considered by many clinicians as the gold standard in the evaluation of patients who complain of gastroesophageal reflux. The evaluation of dyspepsia, whether it be organic or functional, is an extremely prevalent GI tract complaint and the use of ambulatory 24-hour pH monitoring is an elegant way to link esophageal acid exposure, as detected by a probe in the esophagus, with patient symptoms. The pH probe is transnasally placed approximately 5 cm above the distal esophagus. Intraesophageal pH is normally higher (pH 6) than that of the stomach (pH approximately 1-3), the pH probe will continuously record any decreases in pH if gastroesophageal reflux occurs. The most accepted method to identify gastroesophageal reflux during monitoring is the sudden decrease in pH below 4.0. The ambulatory 24-hour pH study links the patient's symptom to an acid event (**Fig. e31-9**). Wireless pH monitoring systems have gradually replaced the older methods that required a wire probe placement. A capsule is attached to the distal esophagus by a delivery system. The capsule then transmits measured pH data to a receiver by a radiotelemetry technique. Wireless systems offer the advantage of better patient acceptance and extended monitoring of up to 96 hours versus 24 hours of the wire method. There are limitations to ambulatory pH monitoring in patients receiving PPI therapy or in the detection of nonacidic or weakly acidic refluxate.[17]

FIGURE e31-9

Ambulatory pH monitoring. The pH recordings from two esophageal probes are plotted over a 3-hour interval. Notice that the patient's symptom of regurgitation correlates with a low pH (<4) event (*arrow*).



Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

11 Multichannel intraluminal impedance monitoring is an emerging technique to study acid and nonacid reflux. The method combines pH measurements with manometry that enables the measurement of and distinction between swallowing and reflux. In patients whose symptoms have not responded to empiric PPI therapy in GERD, impedance test can separate those in whom symptoms are associated with acid reflux from those in whom symptoms are associated with nonacid reflux. Outcomes studies are required to further evaluate the usefulness of this diagnostic method; however, accumulating data are extremely promising.[12,18]

The Bernstein test, an older procedure that is used to measure gastric fluid pH, has largely been replaced by ambulatory pH monitoring. The procedure requires inserting a nasogastric tube and administrating alternating dripped solutions of normal saline and 0.1 N hydrochloric acid (HCl) into the esophagus via the nasogastric tube. If patient symptoms are reproduced by the acid perfusion and not the saline, the study is considered abnormal and indicative of acid hypersensitivity.[19]

Esophageal Manometry

Esophageal manometry is used to evaluate diseases of the esophagus by assessing esophageal motor functions. Common indications for this procedure include dysphagia and obscure chest pain. A special catheter equipped with pressure transducers is placed into the esophagus to measure esophageal pressures and peristalsis. Provocative testing with pharmacologic agents such as edrophonium chloride, a cholinergic muscle stimulant, may be used to precipitate esophageal pain during this procedure. Typical indications for esophageal manometry include, evaluating suspected esophageal dysmotility, nonobstructive dysphagia, obscure chest pain, intestinal pseudo-obstruction, achalasia, and aiding in the positioning instruments such as pH probes. Esophageal manometry is almost always performed following endoscopic evaluation of the upper GI tract and can be a valuable tool in diagnosing many nonspecific disorders of the upper GI tract.

Laparoscopy

Laparoscopy uses a tube-like device with an elaborate optical system that permits distinct visualization of the peritoneal cavity. General anesthesia is often required and a surgical incision is made in the abdomen to allow the passage of the laparoscope. The exterior of the liver, gallbladder, spleen, peritoneum, diaphragm, and pelvic organs may be examined during the laparoscopic examination. Similar to the other endoscopic techniques mentioned, biopsies and therapeutic interventions may be performed during the laparoscopy. Laparoscopy, it is important to remember, is extremely invasive. Indications for laparoscopy include the evaluation patients with abdominal masses, chronic abdominal pain of unclear etiology, abnormalities indicated on liver-spleen scan, such as acute or chronic cholecystitis, and the diagnosis and management of intraabdominal malignancy.

Chapter 32: Gastroesophageal Reflux Disease

Dianne May; Michael Thiman; Satish S.C. Rao

INTRODUCTION

KEY CONCEPTS

- 1 Gastroesophageal reflux disease (GERD) can be described on the basis of either esophageal symptoms or esophageal tissue injury. The common symptoms include heartburn, acid brash, regurgitation, chest pain, and dysphagia.
- 2 Endoscopy is commonly used to evaluate mucosal injury from GERD and to assess for the presence of Barrett's esophagus or other complications such as strictures.
- 3 Whereas ambulatory reflux monitoring only measures acid reflux, combined impedance–pH monitoring measures both acid and nonacid reflux.
- 4 The goals of GERD treatment are to alleviate symptoms, decrease the frequency of recurrent disease, promote healing of mucosal injury, and prevent complications.
- 5 GERD treatment is determined by disease severity and includes lifestyle changes and patient-directed therapy, pharmacologic treatment, and antireflux surgery.
- 6 Patients with typical GERD symptoms should be treated with lifestyle modifications as appropriate and a trial of empiric acid suppression therapy. Those who do not respond to empiric therapy or who present with alarm symptoms such as dysphagia, weight loss, or GI bleeding should undergo endoscopy.
- 7 Surgical intervention is a viable alternative treatment for select patients when long-term pharmacologic management is undesirable or when patients have complications.
- 8 Acid suppression is the mainstay of GERD treatment. Proton pump inhibitors provide the greatest symptom relief and the highest healing rates, especially for patients with erosive disease or moderate to severe symptoms or with complications.

- 9 Many patients with GERD will relapse if medication is withdrawn; so long-term maintenance treatment may be required. A proton pump inhibitor is the drug of choice for maintenance of patients with moderate to severe GERD.

- 10 Patient medication profiles should be reviewed for drugs that may aggravate GERD. Patients should be monitored for adverse drug reactions and potential drug–drug interactions.

Gastroesophageal reflux disease (GERD) is a common medical disorder. A consensus definition of GERD is "symptoms or complications resulting from refluxed stomach contents into the esophagus or beyond, into the oral cavity (including the larynx) or lung."[1] The key is that these troublesome symptoms adversely affect the well-being of the patient. Episodic heartburn that is not frequent enough or painful enough to be considered bothersome by the patient is not included in this definition of GERD.

Gastroesophageal reflux disease can be further classified as either symptom-based or tissue injury-based depending on how the patient presents.[1] Symptom-based GERD may exist with or without esophageal injury and most commonly presents as heartburn, regurgitation, or dysphagia. Less commonly, odynophagia (painful swallowing) or hypersalivation may occur. The absence of tissue injury or erosions is commonly termed nonerosive reflux disease (NERD). Tissue injury-based GERD may exist with or without symptoms. The spectrum of injury includes esophagitis (inflammation of the lining of the esophagus), Barrett's esophagus (when tissue lining the esophagus is replaced by tissue similar to the lining of the intestine), strictures, and esophageal adenocarcinoma.[1] Esophagitis occurs when the esophagus is repeatedly exposed to refluxed gastric contents for prolonged periods of time. This can progress to erosion of the squamous epithelium of the esophagus (erosive esophagitis). Complications of long-term reflux may include the development of strictures, Barrett's esophagus, or possibly adenocarcinoma of the esophagus.

Gastroesophageal reflux symptoms associated with disease processes in organs other than the esophagus are referred to as extraesophageal reflux syndromes. Patients with extraesophageal reflux syndromes may present with chest pain, hoarseness of voice, chronic cough/throat clearing, or asthma. An association between these syndromes and GERD should only be considered when they occur along with esophageal GERD syndrome because these extraesophageal symptoms are nonspecific and have many other causes.[1]

Many patients suffering from mild GERD do not go on to develop erosive esophagitis and are often managed with lifestyle changes, antacids, and nonprescription histamine-2 (H_2)-receptor antagonists or nonprescription proton pump inhibitors. Those with more severe symptoms (with or without tissue injury) predictably follow a course of relapsing disease, requiring more intensive treatment with acid suppression therapy followed by long-term maintenance therapy. Antireflux surgery offers an alternative for select patients in whom prolonged medical management is undesirable or who have complications. Bariatric surgery may be an option in obese patients.

EPIDEMIOLOGY

GERD occurs in people of all ages but is most common in those older than age 40 years. Although mortality is rare, GERD symptoms may have a significant economic impact and impact on quality of life. The true prevalence of GERD is difficult to assess because many patients do not seek medical treatment, symptoms do not always correlate well with the severity of the disease, and there is no standardized definition or universal gold standard method for diagnosing the disease. However, the prevalence has risen significantly over the last 20 years with approximately 20% of adults in North America suffering from GERD symptoms on a weekly basis.[2,3] The prevalence of GERD varies depending on the geographic region but appears highest in Western countries and is on the rise.[2,3]

Except during pregnancy, there does not appear to be a major difference in incidence between men and women. Although gender does not generally play a major role in the development of GERD, it is an important factor in the development of Barrett's esophagus and esophageal adenocarcinoma, which are both more common in men. Adenocarcinoma of the esophagus is five-fold more common in those with chronic GERD symptoms than those who do not have GERD.[2] The relationship of adenocarcinoma to Barrett's esophagus, or even just long-standing GERD, which may be an independent risk factor for esophageal adenocarcinoma, remains to be clearly defined.

Other risk factors and comorbidities that may contribute to the development or worsening of GERD symptoms include family history, obesity, smoking, alcohol consumption, certain medications and foods, respiratory diseases, and reflux chest pain syndrome. Obese patients are 2.5 times more likely to experience GERD symptoms.[4] An increased prevalence of GERD was noted in patients with major depressive disorder in a population-based study conducted in a Taiwanese patient population. The exact mechanism of this association cannot be determined at this time.[5]

PATHOPHYSIOLOGY

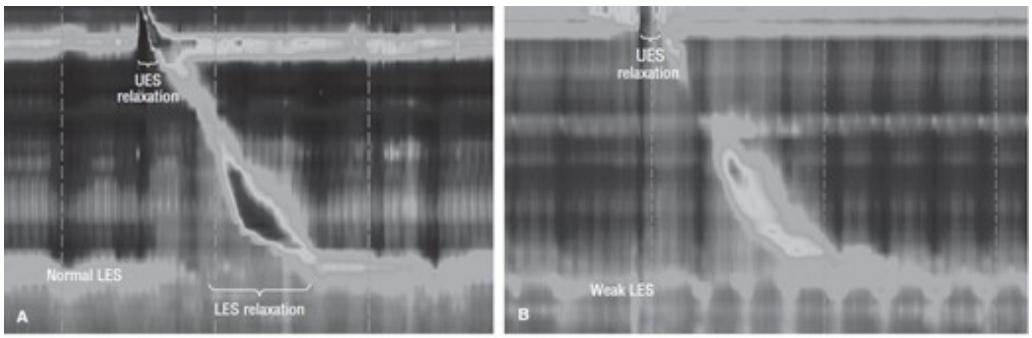
The key factor in the development of GERD is the abnormal reflux of gastric contents from the stomach into the esophagus, oral cavity, and/or the lung.[1] In some cases, gastroesophageal reflux is associated with defective lower esophageal sphincter (LES) pressure or function (**Fig. 32-1**). Patients may have decreased gastroesophageal sphincter pressures related to (a) spontaneous transient LES relaxations, (b) transient increases in intra-abdominal pressure, or (c) an atonic LES, all of which may lead to the development of gastroesophageal reflux. Problems with other normal mucosal defense mechanisms, such as abnormal esophageal anatomy, improper esophageal clearance of gastric fluids, reduced mucosal resistance to acid, delayed or ineffective gastric emptying, inadequate production of epidermal growth factor, and reduced salivary buffering of acid, may also contribute to the development of GERD. Substances that may promote esophageal damage on reflux into the esophagus include gastric acid, pepsin, bile acids, and pancreatic enzymes. Thus, the composition and volume of the refluxate, as well as duration of exposure, are important aggressive factors in determining the consequences of gastroesophageal reflux.

The presence of an "acid pocket" has gained attention as a potential explanation for postprandial reflux symptoms and may represent a target for treatment of reflux disease. While gastric acidity is buffered by food, pH monitoring has shown that this buffering effect may vary in different parts of the stomach and esophagus. The acid pocket is thought to be an area of unbuffered acid in the

proximal stomach that accumulates after a meal and may contribute to GERD symptoms postprandially.[6] It is thought to occur due to meal-stimulated acid not mixing well with the chyme in the proximal stomach. Gastric secretions form a distinct layer above the chyme.[6] GERD patients are predisposed to upward migration of acid from the acid pocket. In addition, the acid pocket may also be positioned above the diaphragm in patients, especially in those with hiatal hernia, which increases the risk for acid reflux.

FIGURE 32-1

Comparison of a normal esophageal high-resolution manometry showing normal upper esophageal sphincter and lower esophageal sphincter (LES) resting pressure and relaxations with a water bolus (*A*), compared with that seen in a patient with GERD and a weak resting LES (*B*).



Lower Esophageal Sphincter Pressure

The LES is a specialized thickening of the smooth muscle lining of the distal esophagus with an elevated basal resting pressure. The sphincter is normally in a tonic, contracted state, preventing the reflux of gastric material from the stomach, but relaxes on swallowing to permit the passage of food into the stomach. There are three mechanisms by which defective LES pressure may cause gastroesophageal reflux. First, and probably most importantly, reflux may occur following spontaneous transient LES relaxations that are not associated with swallowing. Although the exact mechanism is unknown, esophageal distension, vomiting, belching, and retching cause relaxation of the LES. While not thought to contribute significantly to erosive esophagitis, these transient relaxations, which are normal postprandially, may play an important role in symptom-based esophageal reflux syndromes. Transient decreases in sphincter pressure are responsible for more than half of the reflux episodes in patients with GERD. The propensity to develop gastroesophageal reflux secondary to transient decreases in LES pressure is probably dependent on numerous factors, including the degree of sphincter relaxation, efficacy of esophageal clearance, patient position (more common in recumbent position), gastric volume, and intragastric pressure. Secondly, reflux may occur following transient increases in intra-abdominal pressure (stress reflux). An increase in intra-abdominal pressure such as that occurring during straining, bending over, coughing, eating, or a Valsalva maneuver may overcome a weak LES, and thus may lead to reflux. Thirdly, the LES may be atonic, thus permitting free reflux as seen in patients with scleroderma.

Various foods and medications may aggravate esophageal reflux by decreasing LES pressure or by precipitating symptomatic reflux by direct mucosal irritation **(Table 32-1)**. Pregnancy is a condition in which reflux is common. There are many postulated reasons for the increased incidence of heartburn during pregnancy, including hormonal effects on esophageal muscle, LES tone, and physical factors (increased intra-abdominal pressure) resulting from an enlarging uterus. A decrease in LES pressure resulting from any of the previously mentioned causes is not always associated with gastroesophageal reflux. Likewise, individuals who experience decreases in sphincter pressures and subsequently reflux do not always develop GERD. The other natural defense mechanisms (anatomic factors, esophageal clearance, mucosal resistance, and other gastric factors) must be evoked to explain this phenomenon.

TABLE 32-1 Foods and Medications That May Worsen GERD Symptoms

Foods/Beverages	Medications
Decreased Lower Esophageal Sphincter Pressure	
Fatty meal	Anticholinergics
Carminatives (peppermint, spearmint)	Barbiturates
Chocolate	Caffeine
Coffee, cola, tea	Dihydropyridine calcium channel blockers
Garlic	Dopamine
Onions	Estrogen
Chili peppers	Nicotine
Alcohol (wine)	Nitrates
	Progesterone
	Tetracycline
	Theophylline
Direct Irritants to the Esophageal Mucosa	
Spicy foods	Aspirin
Orange juice	Bisphosphonates
Tomato juice	Nonsteroidal anti-inflammatory drugs (NSAIDs)
Coffee	Iron
Tobacco	Quinidine
	Potassium chloride

Anatomic Factors

Disruption of the normal anatomic barriers by a hiatal hernia (when a portion of the stomach protrudes through the diaphragm into the chest) was once thought to be a primary etiology of gastroesophageal reflux and esophagitis. Now it appears that a more important factor related to the presence or absence of symptoms in patients with hiatal hernia is the LES pressure. Patients with hypotensive LES pressures and large hiatal hernias are more likely to experience gastroesophageal

reflux following abrupt increases in intra-abdominal pressure compared with patients with a hypotensive LES and no hiatal hernia. Although anatomic factors are still considered significant by some, the diagnosis of hiatal hernia is currently considered a separate entity with which gastroesophageal reflux may simultaneously occur.

Esophageal Clearance

In many patients with GERD, the problem is not that they produce too much acid but that the acid spends too much time in contact with the esophageal mucosa. Contact time is dependent on the rate at which the esophagus clears the noxious material, as well as the frequency of reflux. Swallowing contributes to esophageal clearance by increasing salivary flow. Saliva contains bicarbonate that buffers the residual gastric material on the surface of the esophagus. The production of saliva decreases with increasing age, making it more difficult to maintain a neutral intraesophageal pH. In addition, swallowing is decreased during sleep, making nocturnal GERD a problem in many patients.

Mucosal Resistance

Within the esophageal mucosa and submucosa there are mucus-secreting glands that may contribute to the protection of the esophagus. Bicarbonate moving from the blood to the lumen can neutralize acidic refluxate in the esophagus. When the mucosa is repeatedly exposed to the refluxate in GERD, or if there is a defect in the normal mucosal defenses, hydrogen ions diffuse into the mucosa, leading to the cellular acidification and necrosis that ultimately cause esophagitis. In theory, mucosal resistance may be related not only to esophageal mucus but also to tight epithelial junctions, epithelial cell turnover, nitrogen balance, mucosal blood flow, tissue prostaglandins, and the acid–base status of the tissue. Saliva is also rich in epidermal growth factor, stimulating cell renewal.

Gastric Emptying/Increased Intra-abdominal Pressure

Delayed gastric emptying can contribute to gastroesophageal reflux. An increase in gastric volume may increase both the frequency of reflux and the amount of gastric fluid available to be refluxed. Gastric volume is related to the volume of material ingested, rate of gastric secretion, rate of gastric emptying, and amount and frequency of duodenal reflux into the stomach. Factors that increase gastric volume and/or decrease gastric emptying, such as smoking and high-fat meals, are often associated with gastroesophageal reflux. This partially explains the prevalence of postprandial gastroesophageal reflux. Fatty foods may increase postprandial gastroesophageal reflux by increasing gastric volume, delaying the gastric emptying rate, and decreasing the LES pressure. Patients with gastroesophageal reflux, particularly infants, may have a defect in gastric antral motility. The delay in emptying may promote regurgitation of feedings, which might, in turn, contribute to two common complications of GERD in infants (eg, failure to thrive and pulmonary aspiration).[7]

Increased GERD symptoms and complications have been seen in obese patients. Obesity is considered an independent risk factor for GERD due to increased intra-abdominal pressure. Interestingly, even weight gain in a non-obese patient has been associated with increased new-onset

GERD symptoms. Transient LES relaxations, incompetent LES and impaired esophageal motility have all been attributed to obesity.[8]

Composition of Refluxate

The composition, pH, and volume of the refluxate are important aggressive factors in determining the consequences of gastroesophageal reflux. If the pH of the refluxate is less than 2, esophagitis may develop secondary to protein denaturation. In addition, pepsinogen is activated to pepsin at this pH and may also cause esophagitis. Duodenogastric reflux esophagitis, or "alkaline esophagitis," refers to esophagitis induced by the reflux of bilious and pancreatic fluid. The term alkaline esophagitis may be a misnomer in that the refluxate may be either weakly alkaline or acidic in nature. Although bile acids have both a direct irritant effect on the esophageal mucosa and an indirect effect of increasing hydrogen ion permeability of the mucosa, symptoms are more often related to acid reflux than to bile reflux. Specifically, the percentage of time that the esophageal pH is less than 4 is greater for patients with severe disease as compared with that for patients with mild disease. Nevertheless, the combination of acid, pepsin, and/or bile is a potent refluxate in producing esophageal damage.

Complications

Several complications may occur with gastroesophageal reflux, including esophagitis, esophageal strictures, Barrett's esophagus, and esophageal adenocarcinoma. Strictures are common in the distal esophagus and are generally 1 to 2 cm in length. The use of nonsteroidal anti-inflammatory drugs or aspirin is an additional risk factor that may contribute to the development or worsening of GERD complications. Although GERD may lead to esophageal bleeding, the blood loss is usually chronic and low grade in nature, but anemia may occur. In some patients, the reparative process leads to the replacement of the squamous epithelial lining of the esophagus by specialized columnar-type epithelium (Barrett's esophagus), which increases the incidence of esophageal strictures by as much as 30%. Barrett's esophagus is most prevalent in white males in Western countries. The risk of esophageal adenocarcinoma may be higher for patients with Barrett's esophagus as compared with that for the general population, although not as high as previously thought. The absolute annual risk of esophageal adenocarcinoma was 0.12% in those with Barrett's esophagus.[9]

The pathophysiology of gastroesophageal reflux is a complex cyclic process. It is difficult, if not impossible, to determine which occurs first: gastroesophageal reflux leading to defective peristalsis with delayed clearing or an incompetent LES pressure leading to gastroesophageal reflux. Understanding the factors associated with the development of GERD provides insight into the treatment modalities currently used to manage patients suffering from this disease.

CLINICAL PRESENTATION

1 GERD can be described on the basis of either esophageal symptoms or esophageal tissue injury. The severity of the symptoms of gastroesophageal reflux does not always correlate with the degree

of esophageal tissue injury, but it does correlate with the duration of reflux. Similar frequency and severity of both heartburn and regurgitation have been found in patients with NERD compared with those with erosive esophagitis with some differences noted based on gender.[10] It is important to distinguish GERD symptoms from those of other diseases, especially when chest pain or pulmonary symptoms are present.

Diagnostic Tests

The most useful tool in the diagnosis of gastroesophageal reflux is the clinical history, including presenting symptoms and associated risk factors. Patients presenting with typical symptoms of reflux, such as heartburn or regurgitation, do not usually require invasive esophageal evaluation. These patients generally benefit from an initial empiric trial of acid-suppression therapy. A clinical diagnosis of GERD can be assumed in patients who respond to appropriate therapy.[1] Further diagnostic evaluation is useful to prevent misdiagnosis, identify complications, and assess treatment failures.[11] Diagnostic tests should be performed in those patients who do not respond to therapy and in those who present with alarm symptoms (eg, dysphagia, odynophagia, and weight loss), which may be more indicative of complicated disease.

Useful tests in diagnosing GERD include upper endoscopy, ambulatory reflux monitoring, combined impedance–pH monitoring, manometry/high-resolution esophageal pressure topography, and impedance manometry. 2 Endoscopy is commonly used to evaluate mucosal injury from GERD and to assess other complications, such as strictures, Barrett's esophagus or adenocarcinoma. It should be performed in patients not responding to twice daily proton pump inhibitor therapy, and those with dysphagia or unexplained weight loss. Currently endoscopic screening is only recommended in patients with chronic GERD and at least one additional risk factor for esophageal adenocarcinoma.[12]

A camera-containing capsule swallowed by the patient offers the newest technology for visualizing the esophageal mucosa via endoscopy. The PillCam ESO is less invasive than traditional endoscopy and takes less than 15 minutes to perform in the clinician's office. Images of the esophagus are downloaded through sensors placed on the patient's chest that are connected to a data collector. The camera-containing capsule is later eliminated in the stool. The main disadvantage of the PillCam is that biopsies cannot be obtained.

CLINICAL PRESENTATION GERD[1,11] Symptom-based GERD Syndromes (With or Without Esophageal Tissue Injury)

Typical symptoms (may be aggravated by activities that worsen gastroesophageal reflux such as recumbent position, bending over, or eating a meal high in fat):

- Heartburn (hallmark symptom described as a substernal sensation of warmth or burning rising up from the abdomen that may radiate to the neck; may be waxing and waning in character)
- Regurgitation/belching
- Reflux chest pain

Alarm symptoms (these symptoms may be indicative of complications of GERD such as Barrett's esophagus, esophageal strictures, or esophageal adenocarcinoma and require further diagnostic evaluation):

- Dysphagia (common)
- Odynophagia
- Bleeding
- Weight loss

Tissue Injury-based GERD Syndromes (With or Without Esophageal Symptoms)

Symptoms (may present with alarm symptoms such as dysphagia, odynophagia, or unexplained weight loss):

- Esophagitis
- Strictures
- Barrett's esophagus
- Esophageal adenocarcinoma

Extraesophageal GERD Syndromes

Symptoms (these symptoms have an association with GERD, but causality should only be considered if a concomitant esophageal GERD syndrome is also present):

- Chronic cough
- Laryngitis
- Wheezing
- Asthma (~50% with asthma have GERD)

Diagnostic Tests For Gerd

Clinical History:

- Generally sufficient to diagnose GERD in patients with typical symptoms

Endoscopy:

- Preferred for assessing for mucosal injury and to assess for complications, such as strictures. Biopsies needed to identify Barrett's esophagus, adenocarcinoma, and eosinophilic esophagitis (a nonacid-related esophageal disorder that generally does not respond well to proton pump inhibitor therapy).

- Non-inflammatory GERD and major motor disorders may be missed by endoscopy.

Ambulatory Reflux Monitoring:

- Identifies patients with excessive esophageal acid exposure and helps determine if symptoms are acid-related
- Useful for patients not responding to acid-suppression therapy
- Documents the percentage of time the intraesophageal pH is <4 and determines the frequency and severity of reflux
- Measures only acid reflux (not nonacid reflux)

Combined Impedance–pH Monitoring:

- Measures both acid and nonacid reflux

Manometry/High-Resolution Esophageal Pressure Topography (HREPT):

- Useful in those who have failed twice-daily proton pump inhibitor therapy with normal endoscopic findings to identify motor disorders, to evaluate peristaltic function in those who are candidates for antireflux surgery, and to assure proper placement of pH probes (the recent advancement of the tubeless pH monitoring system using endoscopic landmarks for placement may negate the need for manometry for ensuring proper placement of esophageal pH probes)

Impedance Manometry:

- Evaluates bolus transit esophageal clearance/retention
- Evaluates LES and upper esophageal sphincter pressures and peristalsis

Empiric Proton Pump Inhibitor as a Diagnostic Test for GERD:

- Less expensive and more convenient than ambulatory pH monitoring but lacks standardized dosing regimen and duration of the diagnostic trial

Barium Radiography:

- Not routinely used to diagnose GERD because it lacks sensitivity and specificity; cannot identify Barrett's esophagus. Can detect hiatal hernia.

Unfortunately, the presence or absence of mucosal damage does not prove the patient's symptoms are reflux related; for that, ambulatory reflux monitoring is useful. [3] Whereas ambulatory reflux monitoring only measures acid reflux, combined impedance–pH monitoring measures both acid and nonacid reflux.

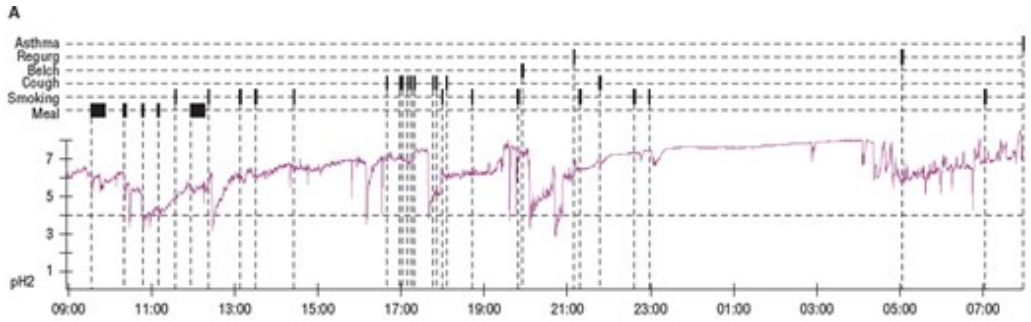
Ambulatory reflux monitoring can be performed by passing a small pH probe transnasally and

placing it approximately 5 cm above the LES. Patients are asked to keep a diary of symptoms that later are correlated with the pH measurement corresponding to the time the symptom was reported (**Fig. 32-2**). Approximately 24 hours of data can be obtained using this method. The wireless pH monitoring involves attaching a radiotelemetry capsule to the esophageal mucosa. The advantages of this method are that a longer period of monitoring is possible (48 hours), it may demonstrate superior recording accuracy compared with some catheter designs, and it is more comfortable for the patient because a nasogastric tube is unnecessary.[1] Proton pump inhibitor therapy should be withheld for 7 days prior to performing ambulatory catheter pH, impedance–pH, or wireless pH monitoring when evaluating patients who have failed an initial empiric therapy and who have normal findings on endoscopy and manometry. However, when testing for nonacid reflux, only impedance–pH monitoring should be performed and testing should be done while patient is still on a proton pump inhibitor.[1] Early referral for ambulatory pH monitoring reduced cost compared to long duration trials of proton pump inhibitors.[13]

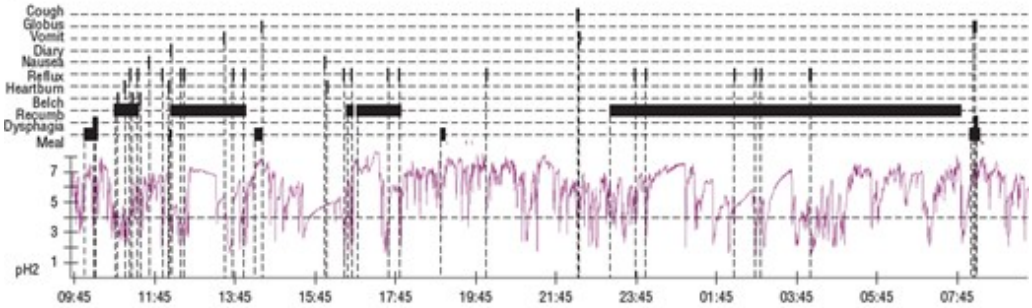
Manometry can be performed before ambulatory reflux/impedance testing. Manometry is useful for patients who are candidates for antireflux surgery and for ensuring proper placement of pH probes.

FIGURE 32-2

Graphical representation of a normal 24-hour ambulatory esophageal pH test profile in a healthy subject and a table summarizing key results (*A*) compared with an abnormal 24-hour ambulatory esophageal pH test (*B*) showing significant acid reflux (multiple events of pH drop below 4) and abnormal 24-hour profile in the table.



Normal 24 hour ambulatory esophageal pH test						
	Total	Normal	Upright	Normal	Supine	Normal
• Fraction time pH <4 (%)	1.9	<4.2	1.9	<6.3	0%	<1.2
• Number of refluxes	81		81		0	
• Number of long refluxes (>5 min)	0		0		0	
• Duration of longest reflux (min)	2.3		2.3		0	
• Time pH <4 (min)	25.9		25.9		0	



Abnormal 24-hour ambulatory esophageal pH test						
	Total	Normal	Upright	Normal	Supine	Normal
• Fraction time pH <4 (%)	16	<4.2	10.6	<6.3	20.6	<1.2
• Number of refluxes	332		143		189	
• Number of long refluxes (>5 min)	10		6		4	
• Duration of longest reflux (min)	7.9		7.1		7.9	
• Time pH <4 (min)	220.5		66.8		153.7

TREATMENT

Therapeutic modalities used in the treatment of gastroesophageal reflux are targeted at reversing the various pathophysiologic abnormalities.

Desired Outcomes

4 The goals of treatment are to (a) alleviate or eliminate the patient's symptoms, (b) decrease the frequency or recurrence and duration of gastroesophageal reflux, (c) promote healing of the injured mucosa, and (d) prevent the development of complications. Therapy is directed at augmenting defense mechanisms that prevent reflux and/or decrease the aggressive factors that worsen reflux or mucosal damage. Therapy is directed at (a) decreasing the acidity of the refluxate, (b) decreasing the gastric volume available to be refluxed, (c) improving gastric emptying, (d) increasing LES pressure, (e) enhancing esophageal acid clearance, and (f) protecting the esophageal mucosa.

General Approach to Treatment

5 GERD treatment is determined by disease severity and includes: (a) lifestyle changes and patient-directed therapy with antacids, nonprescription H_2-receptor antagonists, and/or nonprescription proton pump inhibitors; (b) pharmacologic treatment with prescription-strength acid suppression therapy; (c) and antireflux surgery (**Table 32-2**).[1,14] The initial therapeutic modality used is in part dependent on the patient's condition (frequency of symptoms, degree of esophagitis, and presence of complications) (**Table 32-3**). A step-down approach, starting with a proton pump inhibitor, instead of an H_2-receptor antagonist, and then stepping down to the lowest dose of acid suppression (either an H_2-receptor antagonist or proton pump inhibitor) needed to control symptoms, is most often advocated. The clinician should determine the most appropriate approach for the individual patient. Every attempt should be made to aggressively control symptoms and to prevent relapses early in the course of the patient's disease in order to prevent the complications. For patients with moderate to severe GERD, especially those with erosive disease, starting with a proton pump inhibitor as initial therapy is advocated because of its superior efficacy over H_2-receptor antagonists.

TABLE 32-2 Evidence-Based Treatment Recommendations for GERD in Adults[1,14]

Recommendation	Level of Evidence and Strength of Evidence[a]
Lifestyle modifications	
• Weight loss in overweight GERD patients or those who have recently gained weight.	Moderate, Conditional
• Elevation of the head end of the bed and avoidance of food 2-3 hours before bedtime if nocturnal GERD symptoms present.	Low, Conditional
• Routine elimination of foods that can trigger reflux is not recommended in the treatment of GERD.	Low, Conditional
Acid Suppression Therapy	
• Therapy of choice for symptom relief and healing of erosive esophagitis is an 8-week proton pump inhibitor course. There is similar efficacy among all proton pump inhibitors.	High, Strong
• For maximal pH control, delayed-release proton pump inhibitors should be administered 30-60 minutes before meals.	Moderate, Strong
• Proton pump inhibitors should be started at once daily dosing prior to the first meal each day.	Moderate, Strong
• Patients with Barrett's esophagus can be treated similarly to those with GERD who do not have Barrett's esophagus.	Moderate, Strong
• Flexibility with meal time administration may be seen with newer proton pump inhibitors (eg, dexlansoprazole).	Moderate, Conditional
• When clinically indicated, proton pump inhibitors are considered safe in pregnancy.	Moderate, Conditional
• Adjustments of dose timing and/or twice daily dosing may be beneficial in patients with night-time symptoms, variable schedules, and/or sleep	Low, Strong

Recommendation	Level of Evidence and Strength of Evidence[a]
disturbances who are partial responders to proton pump inhibitor therapy.	
• In patients with typical GERD symptoms who also have extraesophageal symptoms, a proton pump inhibitor trial is recommended.	Low, Strong
• Optimization of proton pump inhibitor therapy should be assessed in anyone with refractory GERD symptoms.	Low, Strong
• Increasing to twice daily dosing or switching proton pump inhibitor may be beneficial in partial responders to proton pump inhibitor therapy.	Low, Conditional
• Further evaluation is recommended for nonresponders to proton pump inhibitor therapy.	low, Conditional
• If adverse effects occur with proton pump inhibitor, may consider switching to an alternative proton pump inhibitor.	Low, Conditional
• Patients with osteoporosis can use a proton pump inhibitor.	Moderate, Conditional
• Concern for hip fracture with proton pump inhibitor should be considered in those with osteoporosis AND other risk factors for hip fracture.	Moderate, Conditional
• Proton pump inhibitors are a risk factor for development of *Clostridium difficile*.	Moderate, Moderate
• Proton pump inhibitors are a risk factor for development of Community-Acquired Pneumonia with short-term use (but not long-term use).	Moderate, Conditional
• Proton pump inhibitors can be used in patients on clopidogrel and there is not an increased risk for adverse cardiovascular events.	High, Strong
Promotility therapy and Other Nonacid Suppression Therapies	
• Prokinetic medications and/or baclofen should not be used to manage GERD without diagnostic evaluation.	Moderate, Conditional
• Sulcralfate is not generally recommended in nonpregnant GERD patients.	Moderate, Conditional
Maintenance therapy	
• Maintenance therapy is recommended for (1) patients with continued symptoms after proton pump inhibitor discontinuation; (2) patients with complications including erosive esophagitis and Barrett's esophagus.	Moderate, Strong
• The lowest effective dose should be used when long-term proton pump inhibitor therapy is indicated for maintenance. Strategies such as on-demand and intermittent therapy may be beneficial.	Low, Conditional
• H_2-receptor antagonists may be used as maintenance therapy in patients without erosive disease when the goal is heartburn relief.	Moderate, Conditional
Surgery	

Recommendation	Level of Evidence and Strength of Evidence[a]
• Surgery is a long-term treatment option in GERD patients.	High, Strong
• Surgery is not generally recommended in proton pump inhibitor nonresponders.	High, Strong
• Surgery is not generally recommended in patients with extraesophageal symptoms not responding to proton pump inhibitor therapy.	Moderate, Strong
• Endoscopic therapy or transoral incisionless fundoplication not recommended as alternative to medical or traditional surgical procedures.	Moderate, Strong
• Bariatric surgery (Gastric bypass) should be considered in obese patients contemplating surgical therapy.	Moderate, Conditional

[a]Level of evidence per Grades of Recommendation, Assessment, Development, and Evaluation (GRADE) system: High = further research not likely to change authors' confidence in the estimate of effect; Moderate = further research would likely have an impact on the confidence in the estimate of effect; Low = further research would be expected to have an important impact on the confidence in the estimate of the effect and would be likely to change the evidence.

Strength of evidence per GRADE system: Strong = desired effects of an intervention clearly outweigh the undesireable effects; Conditional = there is uncertainty about the trade-offs between desirable effects and undesirable effects. [1,14]

TABLE 32-3 Therapeutic Approach to GERD in Adults

Recommended Treatment Regimen	Brand Name	Oral Dose	Comments
Intermittent, mild heartburn (individualized lifestyle modifications + patient-directed therapy with antacids and/or nonprescription H_2-receptor antagonists *or* nonprescription proton pump inhibitor)			
Individualized lifestyle modifications			Lifestyle modifications should be individualized for each patient
Patient-directed therapy with antacids (≥12 years old)			
Magnesium hydroxide/aluminum hydroxide with simethicone	Maalox®	10-20 mL as needed or after meals and at bedtime	If symptoms are unrelieved with lifestyle modifications and nonprescription medications after 2 weeks, patient should seek medical attention; do not exceed 16 teaspoonfuls per 24 hours
Antacid/alginic acid	Gaviscon®	2-4 tablets or 10-20 mL after meals and at bedtime	Note: Content of alginic acid varies greatly among products; the higher the alginic acid the better

Recommended Treatment Regimen	Brand Name	Oral Dose	Comments
Calcium carbonate	Tums®	500 mg, 2-4 tablets as needed	
Patient-directed therapy with nonprescription H_2-receptor antagonists (up to twice daily) (≥12 years old)			
Cimetidine	Tagamet HB®	200 mg	If symptoms are unrelieved with lifestyle modifications and nonprescription medications after 2 weeks, patient should seek medical attention
Famotidine	Pepcid AC®	10-20 mg	
Nizatidine	Axid AR®	75 mg	
Ranitidine	Zantac®	75-150 mg	
Patient-directed therapy (>18 years old) with nonprescription proton pump inhibitors (taken once daily)			
Esomeprazole	Nexium® 24HR	20 mg	
Lansoprazole	Prevacid® 24HR	15 mg	If symptoms are unrelieved with lifestyle modifications and nonprescription medications after 2 weeks, patient should seek medical attention
Omeprazole	Prilosec OTC®	20 mg	
Omeprazole/sodium bicarbonate	Zegerid OTC®	20 mg/1,100 mg	
Symptomatic relief of GERD (individualized lifestyle modifications + prescription-strength H_2-receptor antagonists *or* prescription-strength proton pump inhibitors)			
Individualized lifestyle modifications			Lifestyle modifications should be individualized for each patient
Prescription-strength H_2-receptor antagonists (for 6-12 weeks)			
Cimetidine (off-label use)	Tagamet®	400 mg four times daily or 800 mg twice daily	• For typical symptoms, treat empirically with prescription-strength acid suppression therapy • If symptoms recur, consider maintenance therapy. Note: Most patients will require standard doses for maintenance therapy

Recommended Treatment Regimen	Brand Name	Oral Dose	Comments
Famotidine	Pepcid®	20 mg twice daily	
Nizatidine	Axid®	150 mg twice daily	
Ranitidine	Zantac®	150 mg twice daily	
Prescription-strength proton pump inhibitors (for 4-8 weeks)			
Dexlansoprazole	Dexilant®	30 mg once daily for 4 weeks	• For typical symptoms, treat empirically with prescription-strength acid suppression therapy • Patients with moderate to severe symptoms should receive a proton pump inhibitor as initial therapy • If symptoms recur, consider maintenance therapy
Esomeprazole	Nexium®	20-40 mg once daily	
Lansoprazole	Prevacid®	15mg once daily	
Omeprazole	Prilosec®	20 mg once daily	
Omeprazole/sodium bicarbonate	Zegerid®	20 mg once daily	
Pantoprazole (Off-label use)	Protonix®	40 mg once daily	
Rabeprazole	Aciphex®	20 mg once daily	
Healing of erosive esophagitis or treatment of patients with moderate to severe symptoms or complications (individualized lifestyle modifications + high-dose H_2-receptor antagonists *or* proton pump inhibitors *or* antireflux surgery)			
Individualized lifestyle modifications			Lifestyle modifications should be individualized for each patient.
Proton pump inhibitors (up to twice daily for up to 8 weeks)			
Dexlansoprazole	Dexilant®	60 mg daily	• For extraesophageal or alarm symptoms,

Recommended Treatment Regimen	Brand Name	Oral Dose	Comments
			obtain endoscopy with biopsy to evaluate mucosa
Esomeprazole	Nexium®	20-40 mg daily	• If symptoms are relieved, consider maintenance therapy. Proton pump inhibitors are the most effective maintenance therapy for patients with extraesophageal symptoms, complications, and erosive disease. Start with twice-daily proton pump inhibitor therapy if reflux chest syndrome present • Patients not responding to pharmacologic therapy, including those with persistent extraesophageal symptoms, should be evaluated via manometry and/or ambulatory reflux monitoring • Twice daily dosing of proton pump inhibitors is considered off-label use
Lansoprazole	Prevacid®	30 mg once or twice daily	
Omeprazole	Prilosec®	20 mg once or twice daily	
Rabeprazole	Aciphex®	20 mg once or twice daily	
Pantoprazole	Protonix®	40 mg once or twice daily	
High-dose H_2-receptor antagonists (for 8-12 weeks)			
Cimetidine	Tagamet®	400 mg four times daily or 800 mg twice daily	Note: If high-dose H_2-receptor antagonist needed, may consider using proton pump inhibitor to lower cost, increase convenience, and increase tolerability Note: Four times daily H_2-receptor antagonist is considered off-label use for Nizatidine
Famotidine	Pepcid®	20-40 mg twice daily	
Nizatidine	Aciphex®	150 mg two-four times daily	
Ranitidine	Zantac®	150 mg four times daily	
Interventional therapy			
Antireflux surgery			

While weight loss in obese patients and elevation of the head end of the bed are beneficial for most GERD patients, recommending all lifestyle modifications to all patients is not recommended.[1] Instead, education on lifestyle modifications should be tailored to the individual needs of the patient. **Table 32-4** lists some of the lifestyle modifications that can be recommended on an individualized basis.[11]

TABLE 32-4 Nonpharmacologic Treatment of GERD with Lifestyle Modifications[15]

- Elevate the head end of the bed (increases esophageal clearance). Use 6- to 8-in. (15-20 cm) blocks under the head side of the bed
- Weight reduction (reduces symptoms) in obese patients
- Avoid foods that may decrease lower esophageal sphincter pressure or increase transient lower esophageal sphincter relaxation (TLESR) (fats, chocolate, alcohol, peppermint, and spearmint)
- Include protein-rich meals in diet (augments lower esophageal sphincter pressure)
- Avoid foods that have a direct irritant effect on the esophageal mucosa (spicy foods, orange juice, tomato juice, and coffee)
- Behaviors that may reduce esophageal acid exposure:
    - Eat small meals and avoid sleeping immediately after meals (sleep after 3 hours if possible; decreases gastric volume)
    - Stop smoking (decreases spontaneous esophageal sphincter relaxation)
    - Avoid alcohol (increases amplitude of the lower esophageal sphincter, peristaltic waves, and frequency of contraction)
    - Avoid tight-fitting clothes
    - Always take drugs in the sitting upright or standing position and with plenty of liquid, especially for those that have a direct irritant effect on the esophageal mucosa (eg, bisphosphonates, tetracyclines, quinidine, potassium chloride, iron salts, aspirin, nonsteroidal anti-inflammatory drugs)

6 Initially, patients with typical GERD symptoms should be treated with lifestyle modifications and patient-directed therapy. Patients who do not respond to lifestyle modifications and patient-directed therapy after 2 weeks or those with alarm symptoms, such as dysphagia, should seek medical attention and are generally started on empiric therapy consisting of an acid suppression agent. Those who do not respond to empiric therapy or who present with alarm symptoms should undergo endoscopy. Acid suppression therapy with proton pump inhibitors or H_2-receptor antagonists is the mainstay of GERD treatment. Patients presenting with moderate to severe symptoms (with or without esophageal erosions) should be started on a proton pump inhibitor as initial therapy because it provides the most rapid symptomatic relief and healing in the highest percentage of patients.[1] H_2-receptor antagonists in divided doses are effective for patients with milder GERD symptoms. However, when standard doses of H_2-receptor antagonist therapy are not effective at relieving symptoms, it is considered more cost-effective and efficacious to switch to a proton pump inhibitor.

Promotility agents (such as metoclopramide) are not as effective as acid suppression agents. Combining a promotility agent with acid suppression medications offer only modest improvements in symptoms over standard doses of H_2-receptor antagonists and should not be routinely recommended. In addition, the availability of a promotility agent that has an acceptable adverse effect profile is lacking. Mucosal protectants, such as sucralfate, have a limited role in the treatment of GERD.

Maintenance therapy is generally necessary to control symptoms and to prevent complications. For patients with more severe symptoms (with or without esophageal erosions) or for patients with other complications, maintenance therapy with a proton pump inhibitor is most effective. Routine use of combination therapy has no role in GERD maintenance therapy. In cases of refractory GERD, the diagnosis should be confirmed through further diagnostic tests before long-term, high-dose therapy is considered.[1]

Nonpharmacologic Therapy

Nonpharmacologic treatment of GERD includes lifestyle modifications and antireflux surgery, which may be viable maintenance modalities in select patients. Endoscopic therapies, such as endoscopic sewing devices and endoluminal application of radiofrequency heat energy, have fallen out of favor and are not routinely recommended.

Lifestyle Modifications

The most common lifestyle modifications that a patient should be educated about include weight loss in obese patients and elevation of the head end of the bed, especially for those patients who have symptoms while in a recumbent position. Other lifestyle modifications should be individualized based on the patient's specific situation. These include consumption of smaller meals and not sleeping for at least 3 hours after eating, avoidance of foods or medications that exacerbate GERD, smoking cessation, avoidance of tight-fitting clothes, and avoidance of alcohol (see Table 32-4).[15]

Obesity increases the risk of GERD symptoms and complications including Barrett's esophagus. A clear association has been shown between body mass index (BMI), waist circumference and weight gain.[1] Surprisingly, weight gain in those considered to have a normal BMI has also been associated with new onset GERD symptoms.[1] Even more alarming is the potential association between BMI and cancer in the esophagus and gastric cardia.[1]

A high-fat meal will decrease LES pressure for 2 hours or more postprandially. In contrast, a high-protein, low-fat meal will elevate LES pressure. Consequently, weight loss and a low-fat diet may help to improve GERD symptoms.

Elevating the head end of the bed by approximately 6" to 8"(15-20 cm) with a foam wedge under the mattress (not just elevating the head with pillows) decreases nocturnal esophageal acid contact time and should be recommended. Many foods may worsen the symptoms of GERD. Some foods decrease LES pressure (eg, fats and chocolates), while other foods can act as direct contact irritants to the

esophageal mucosa (citrus juice, tomato juice, coffee, and pepper) (see Table 32-1).

Patient profiles should be evaluated to identify potential medications that may exacerbate GERD symptoms. Some medications decrease LES pressure, while other medications can act as direct contact irritants to the esophageal mucosa. Proper patient education can help prevent dysphagia or esophageal ulceration. Patients should be closely monitored for worsening symptoms when any of these medications are started. If symptoms worsen, alternative therapies may be warranted. The clinician must weigh the risks and benefits of continuing a medication known to worsen GERD and esophagitis.

Smoking can cause aerophagia (ie, air swallowing), which leads to increased belching and regurgitation. Smoking cessation has historically been recommended as an important lifestyle modification in the management of GERD patients; however, data are lacking to show that symptoms improve for patients who quit smoking and the current guidelines do not recommend this as an effective nonpharmacologic option for GERD. Nevertheless, patients with GERD should be encouraged to quit smoking. Alcohol, although not thought to play a role in severe disease, decreases LES pressure and may exacerbate symptoms such as heartburn.

Many patients are noncompliant with lifestyle modifications, and even those who do comply generally continue to have symptoms that require acid suppression therapy. Nonetheless, it is important to regularly stress the potential benefits of lifestyle modifications that would benefit each individual patient.

Interventional Approaches

Interventional approaches include antireflux surgery and endoscopic therapies. These are discussed in more detail below.

Antireflux Surgery

7 Surgical intervention is a viable alternative treatment for select patients when long-term pharmacologic management is undesirable or when patients have complications. The goal of antireflux surgery is to re-establish the antireflux barrier, to position the LES within the abdomen where it is under positive (intra-abdominal) pressure, and to close any associated defect in the diaphragmatic hiatus by reinforcing the crural muscles. Antireflux surgery should be considered for patients (a) who opt for surgery despite successful treatment because of lifestyle considerations, including age, time, or expense of medications, or (b) who have complications of GERD (eg, Barrett's esophagus and strictures). Current guidelines do not generally recommend surgery for patients who do not respond to proton pump inhibitor therapy.[1] The antireflux surgical procedure chosen depends on the surgeon's expertise and preference, as well as on anatomic considerations. In general, 90% of patients have symptom resolution following successful Nissen fundoplication. The major complications with antireflux surgery include gas bloat syndrome (inability to belch or vomit), dysphagia, vagal denervation, and splenic trauma. Antireflux surgery is superior to medical management with an H_2-receptor antagonist or a promotility agent. A meta-analysis comparing

fundoplication and medical management favored fundoplication at multiple quality of life endpoints; however a substantial number of patients remained on acid suppression medication following surgical intervention.[16] Long-term effectiveness of antireflux surgery is uncertain.

Bariatric surgery, specifically Roux-en-Y gastric bypass surgery, should be considered in obese patients contemplating surgery.[1] The consideration of bariatric surgery in obese patients for improvement of GERD symptoms is a result of the proposed difference in pathophysiology in this patient population. Abdominal pressure may play a greater role in the development of GERD in obese patients. Gastric banding may improve GERD through weight loss however, it may also precipitate acid reflux through other mechanisms. Studies evaluating the effect of gastric banding procedures on GERD have shown mixed results, while studies have more consistently demonstrated the benefits of gastric bypass in the management of GERD in obese patients.[17]

Endoscopic Therapies

Endoscopic approaches for the management of GERD have included endoscopic sewing devices and endoluminal application of radiofrequency heat energy resulting in tissue injury or nerve ablation (the Stretta procedure). Unfortunately, results from these endoscopic therapies have proven disappointing and are not routinely recommended. Currently in their infancy stages, natural orifice transluminal surgery and surgical techniques have been tested and may offer an option in the future. Endoscopic stapling has demonstrated improvement in quality of life scores but several limitations were noted in comparison to laparoscopic fundoplication.[18]

Other Therapies

Radiofrequency ablation is an endoscopic therapy used for the management of Barrett's esophagus primarily when dysplasia is present. Radiofrequency ablation is recommended in patients with Barrett's esophagus with high-grade dysplasia and current guidance additionally acknowledges radiofrequency ablation as a treatment option in low-grade dysplasia.[19] Radiofrequency ablation prompts reversal to normal squamous epithelium and reduces development of esophageal cancer in those with high-grade dysplasia.[19]

The FDA approved a device for magnetic sphincter augmentation to improve lower esophageal resistance and reduce symptoms of GERD. A study comparing magnetic sphincter augmentation with traditional laparoscopic fundoplication found similar improvement in symptoms and quality of life, with 67% of participants who underwent magnetic sphincter augmentation retaining the ability to belch in comparison to no patients who underwent fundoplication.[20] Postmarketing results have also demonstrated that a majority of patients can discontinue their proton pump inhibitor and have GERD-health-related quality of life (HRQL) scores similar to patients without GERD.[21] However concerns related to long-term safety of this approach have been raised.[22]

Pharmacologic Therapy

Pharmacologic treatment consists of (a) patient-directed therapy with nonprescription antacids, H_2-receptor antagonists, or proton pump inhibitors and (b) prescription-strength acid-suppression therapy or promotility medications.

Patient-Directed Therapy

Patient-directed therapy, where patients self-treat themselves with nonprescription medications, is appropriate for mild, intermittent symptoms. Patients with continuous symptoms lasting longer than 2 weeks should seek medical attention.

Antacids and Antacid–Alginic Acid Products

Patients should be educated that antacids are an appropriate component of treating milder GERD symptoms, even though documentation of their efficacy in placebo-controlled clinical trials is lacking. Antacids may offer immediate symptomatic relief and help maintain the intragastric pH greater than 4, which decreases the activation of pepsinogen to pepsin, a proteolytic enzyme. The neutralization of gastric fluid may also lead to increased LES pressure. Patients who require frequent use of antacids for chronic symptoms should be treated with prescription-strength acid suppression therapy.

Some antacid products are combined with alginic acid, which is not a potent neutralizing agent and does not enhance LES pressure; however, it does form a highly viscous solution or "raft" that floats on the surface of the gastric contents. This viscous solution is thought to serve as a protective barrier for the esophagus against reflux of gastric contents. It also reduces the frequency of the reflux episodes. The combination product may be superior to antacids alone in relieving the symptoms of GERD.[23] The alginic acid "raft" can adapt to the acid pocket, continuously floating above newly secreted acid near the esophagogastric junction. Weakly acidic or nonacidic reflux has been associated with refractory GERD symptoms. There are many Gaviscon® products with varying amounts of alginic acid. Products with a higher alginic acid component are preferred (eg, 500 mg). Patients should be encouraged to check medication labels for ingredients. Some of the Gaviscon® products contain lower amounts of alginic acid or list alginic acid under inactive ingredients with no amounts specified. Efficacy data indicating endoscopic healing are lacking.

Antacid or antacid combination products interact with a variety of medications by altering gastric pH, increasing urinary pH, adsorbing medications to their surfaces, providing a physical barrier to absorption, or forming insoluble complexes with other medications. Antacids have clinically significant drug interactions with tetracycline, ferrous sulfate, isoniazid, sulfonylureas, and quinolone antibiotics. Antacid–drug interactions are influenced by composition, dose, dosage schedule, and formulation of the antacid. They may also cause constipation or diarrhea depending on the magnesium or aluminum content.

Dosage recommendations for antacids in the management of GERD are somewhat difficult to derive from the literature. Doses range from hourly to an as-needed basis (see Table 32-3). In general, antacids have a short duration of action, which necessitates frequent administration throughout the day to provide continuous neutralization of acid. Taking antacids after meals can increase the

duration of action from about 1 to 3 hours; however, nighttime acid suppression cannot be maintained with bedtime doses.

Nonprescription H_2-Receptor Antagonists and Proton Pump Inhibitors

Nonprescription H_2-receptor antagonists (cimetidine, famotidine, nizatidine, and ranitidine) are effective in diminishing gastric acid secretion when taken prior to meals and decrease GERD symptoms associated with exercise. Antacids may have a slightly faster onset of action, while the H_2-receptor antagonists have a much longer duration of action compared with antacids.

The proton pump inhibitors esomeprazole, omeprazole (alone or combined with sodium bicarbonate) and lansoprazole are available without a prescription for the short-term treatment of heartburn. Patients who do not respond to lifestyle modifications and patient-directed therapy after 2 weeks should be seen by their clinician.

Acid Suppression Therapy

8 Acid suppression is the mainstay of GERD treatment. Proton pump inhibitors provide the greatest symptom relief and the highest healing rates, especially for patients with erosive disease, moderate to severe symptoms, or complications.

Proton Pump Inhibitors (Dexlansoprazole, Esomeprazole, Lansoprazole, Omeprazole [with or without Sodium Bicarbonate], Pantoprazole, and Rabeprazole)

Proton pump inhibitors are superior to H_2-receptor antagonists in treating patients with moderate to severe GERD and should be given empirically to those with troublesome symptoms. This includes not only patients with esophageal tissue injury (eg, Barrett's esophagus, strictures, or esophagitis) but also patients with symptom-based GERD syndromes. Twice-daily proton pump inhibitor use is indicated in those not responding to a standard once-daily course of therapy. Before increasing the frequency to twice daily, optimization of proton pump therapy should be assessed (eg, taken 30-60 minutes prior to largest meal each day, etc.). In patients who are partial responders to initial proton pump inhibitor therapy, a trial of an alternative proton pump inhibitor may also be considered. Patients with Barrett's esophagus should be treated similarly to patients without Barrett's esophagus.[1] Further diagnostic evaluation is indicated for patients not responding to twice-daily proton pump inhibitor therapy.

Proton pump inhibitors block gastric acid secretion by inhibiting gastric H^+/K^+-adenosine triphosphatase in gastric parietal cells. This produces a profound, long-lasting antisecretory effect capable of maintaining the gastric pH greater than 4, even during postprandial acid surges. A correlation exists between the percentage of time the gastric pH remains greater than 4 during the 24-hour period and healing erosive esophagitis.

In general, healing rates at 4 and 8 weeks are similar among proton pump inhibitors. Symptomatic relief is seen in approximately 83% of patients with endoscopic evidence of injury after 8 weeks

treated with a proton pump inhibitor, whereas the endoscopic healing rate at 8 weeks is 78%.[1] Symptom response to NERD has been found to be less robust with approximately 60% of patients experiencing complete relief with proton pump inhibitor therapy.[1]

Clinical Controversy…

With continued increased recognition of potential adverse effects associated with proton pump inhibitor therapy, there is a focus on ensuring de-escalation of therapy in appropriate patients. Appropriate patients for de-escalation of therapy are not well-defined.

The most cost common adverse effects associated with proton pump inhibitors include headache, diarrhea, constipation and abdominal pain. Community-acquired pneumonia has occurred with short-term use in GERD patients.[1] Enteric infections, vitamin B_{12} deficiency, hypomagnesemia, and bone fractures are potential long-term adverse effects associated with proton pump inhibitors (**Table 32-5**).[24,25,26,27,28,29] In one study, dysmotility and proton pump inhibitor use were found to be independent risk factors for not only for small intestinal bacterial overgrowth, but also small intestinal fungal overgrowth.[30] Overuse of proton pump inhibitors should be minimized as the clinical implications of chronic therapy are better elucidated.

TABLE 32-5 Drug Monitoring[23,24,25,26,27,28]

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
Antacids			
• Magnesium hydroxide/aluminum hydroxide • Antacid/alginic acid • Calcium carbonate	• Diarrhea or constipation (depending on product) • Alterations in mineral metabolism • Acid–base disturbances	• Periodic calcium and phosphate levels in patients on chronic therapy	• Use caution with aluminum- and calcium-containing antacids in patients with renal impairment • Aluminum-containing antacids may bind to phosphate in the gut and lead to bone demineralization
H_2-Receptor Antagonists			
• Cimetidine • Famotidine	• Headache, somnolence, fatigue, dizziness,	• Monitor for CNS effects, especially in the elderly	• May see increased CNS effects (rare) in those over 50

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
• Nizatidine • Ranitidine	and either constipation or diarrhea	• Monitor vitamin B_{12} serum concentrations in those on chronic, long-term therapy or in those on higher doses	years of age or in those with renal or hepatic dysfunction • May be associated with vitamin B_{12} deficiency with longer duration therapy and in higher doses
Proton Pump Inhibitors			
• Dexlansoprazole • Esomeprazole • Lansoprazole • Omeprazole • Omeprazole/sodium bicarbonate • Pantoprazole • Rabeprazole	*Most common adverse effects:* • Headache, dizziness, somnolence, diarrhea, constipation, flatulence, abdominal pain, and nausea *Other important adverse effects:* • Enteric infections (*C. difficile* infections) • Increased risk of pneumonia *Long-term adverse effects:* • Hypomagnesemia • Bone fractures • Vitamin B_{12} deficiency	• Number and type of diarrhea episodes • Periodic magnesium levels warranted in those on higher doses or who are on therapy for greater than 1 year • Routine bone density studies or calcium supplementation should only be considered if other risk factors for osteoporosis or bone fractures are present • Respiratory symptoms within first 30 days of therapy	• Acid suppression may result in loss of host defense against ingested spores and bacteria permitting a higher burden of exposure. Recent meta-analysis showed 65% increase in *Clostridium difficile*–associated diarrhea among those on proton pump inhibitors[23] • Hypomagnesemia is uncommon but can be life-threatening; has been seen as soon as 3 months after starting therapy but more likely in those on proton pump inhibitors >1 year

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
			• May increase risk for osteoporosis-related fractures of the hip, wrist or spine; Most common with high-dose (eg, multiple daily doses) and long-term use (eg, ≥1 year) Patients with known osteoporosis can remain on proton pump inhibitor
		• Periodic vitamin B_{12} serum concentration with long-term use	• Proton pump inhibitors may inhibit secretion of intrinsic factor, which potentially can lead to vitamin B_{12} deficiency; this is not common and usually associated with use for >3 years
			• May increase risk of community-acquired pneumonia, particularly within the first 30 days of therapy

Drug interactions with the proton pump inhibitors vary slightly with each agent. All proton pump inhibitors can decrease the absorption of medications such as ketoconazole or itraconazole, which require an acidic environment to be absorbed. While no drug interactions with lansoprazole, pantoprazole, or rabeprazole have been seen with CYP2C19 substrates such as diazepam, warfarin, and phenytoin, concerns have been raised regarding the concomitant use of proton pump inhibitors,

particularly omeprazole, with clopidogrel since it is the strongest inhibitor of CYP2C19.[31,32] Clopidogrel, a prodrug, is converted to its active metabolite via the CYP2C19 and CYP3A4 enzymes. Inhibition of CYP2C19 by proton pump inhibitors, specifically omeprazole, may decrease the effectiveness of clopidogrel. Careful review of the risk-to-benefit profile regarding the use of proton pump inhibitors for patients on clopidogrel should be considered. Selection of a proton pump inhibitor with less inhibition of CYP2C19 may limit the risk of interaction with clopidogrel.

Patients with upper GI bleeding or those with multiple risk factors for GI bleeding who require antiplatelet therapy would benefit from proton pump inhibitor therapy. Risk factors for GI bleeding include advanced age, use of anticoagulants, steroids or nonsteroidal anti-inflammatory drugs, presence of *Helicobacter pylori*, or previous history of bleeding or peptic ulcer disease complications.[33] Otherwise, using an alternative agent, such as an H_2-receptor antagonist, may be prudent in this patient population.

Esomeprazole does not appear to interact with warfarin or phenytoin, and an interaction with diazepam is generally not considered clinically relevant. Although generally not a problem, omeprazole has the potential to inhibit the metabolism of warfarin, diazepam, and phenytoin, and lansoprazole may decrease theophylline concentrations. Patients on potentially interacting medications, such as warfarin, should be monitored closely for potential problems.

The proton pump inhibitors degrade in acidic environments and are therefore formulated in a delayed-release capsule or tablet formulation. Dexlansoprazole, esomeprazole, lansoprazole, and omeprazole contain enteric-coated (pH-sensitive) granules in a capsule form. Dexlansoprazole is unique in that the capsule is a dual delayed-release formulation, with the first release occurring 1 to 2 hours after the dose and the second release occurring 4 to 5 hours after the dose. The clinical significance of this dual release is to allow the medication to have a longer lasting benefit, at least 16 to 18 hours. Patients taking pantoprazole or rabeprazole should be instructed not to crush, chew, or split the delayed-release tablets.

For patients who are unable to swallow the capsule or for pediatric patients, there are several alternative administration methods available. The contents of the delayed-release capsules can be mixed in applesauce or placed in orange juice. If a patient has a nasogastric tube, the contents of an omeprazole capsule can be mixed in 8.4% sodium bicarbonate solution. Esomeprazole granules can be dispersed in water. Esomeprazole, omeprazole, and pantoprazole are also available in a delayed-release oral suspension powder packet, and lansoprazole is available as a delayed-release, orally disintegrating tablet. Esomeprazole and pantoprazole are available in an IV formulation, which offers an alternative route of administration for patients who are unable to take an oral proton pump inhibitor. Importantly, the IV product is not more efficacious than oral proton pump inhibitors and is significantly more expensive. Careful patient selection is necessary to avoid the increased cost from the use of the IV product.

The newest dosage form of omeprazole is in a delayed-release tablet; it is also available in a combination product with sodium bicarbonate in an immediate-release capsule and oral suspension (Zegerid®). This is the first immediate-release proton pump inhibitor and it should be taken on an empty stomach at least 1 hour before a meal. Zegerid® powder for oral suspension offers an

alternative to the delayed-release capsules, powder for suspension, or IV formulation in adult patients with a nasogastric tube. The Zegerid® capsule should be swallowed whole and not opened, sprinkled on food, or administered via nasogastric tube. The 20 mg and 40 mg Zegerid® capsules have the same amount of sodium bicarbonate so two 20 mg capsules cannot be substituted for a 40 mg capsule.

Patients should be instructed to take their proton pump inhibitor in the morning, 30 to 60 minutes before breakfast or before their biggest meal of the day, to maximize efficacy, because these agents inhibit only actively secreting proton pumps. Dexlansoprazole can be taken without regards to meals. Patients with nocturnal symptoms may benefit from taking their proton pump inhibitor prior to the evening meal. If dosed twice daily, the second dose should be administered approximately 10 to 12 hours after the morning dose and prior to a meal or snack.

H_2-Receptor Antagonists (Cimetidine, Famotidine, Nizatidine, and Ranitidine)

H_2-receptor antagonists in divided doses are effective in treating patients with mild to moderate GERD.[15] The majority of the trials assessing the efficacy of standard doses of H_2-receptor antagonists indicate that symptomatic improvement is achieved in an average of 60% of patients after 12 weeks of therapy.[15] However, endoscopic healing rates tend to be lower, an average of 50% of patients at 12 weeks.[15]

The efficacy of H_2-receptor antagonists in the management of GERD is extremely variable and is frequently lower than desired. Response to the H_2-receptor antagonists is dependent on the (a) severity of disease, (b) dosage regimen used, and (c) duration of therapy. These factors are important to keep in mind when comparing clinical trials and/or assessing a patient's response to therapy. The severity of esophagitis at baseline has a profound impact on the patient's response to H_2-receptor antagonists. For symptomatic relief of mild GERD, low-dose, nonprescription H_2-receptor antagonists or standard doses given twice daily may be beneficial. Patients who do not respond to standard doses may be hypersecreters of gastric acid and will require higher doses. Although higher doses of H_2-receptor antagonists may provide higher symptomatic and endoscopic healing rates, limited information exists regarding the safety of these regimens, and they can be less effective and more costly than once-daily proton pump inhibitors. Unlike duodenal ulcer disease, in which the duration of therapy is relatively short (eg, 4- 6 weeks), prolonged courses of H_2-receptor antagonists are frequently required in the treatment of GERD.

Because all of the H_2-receptor antagonists have similar efficacy, selection of the specific agent to use in the management of GERD should be based on factors such as differences in pharmacokinetics, safety profile, and cost. Patients should be monitored for the presence of adverse effects as well as potential drug interactions, especially when on cimetidine. Cimetidine may inhibit the metabolism of theophylline, warfarin, phenytoin, nifedipine, and propranolol, among others. An alternate H_2-receptor antagonist should be selected if the patient is on any of these medications. Headache, fatigue, dizziness, and constipation/diarrhea are the most common adverse effects associated with the use of H_2-receptor antagonists.

Promotility Agents

Promotility agents may be useful as an adjunct to acid suppression therapy for patients with a known motility defect (eg, LES incompetence, decreased esophageal clearance, and delayed gastric emptying). Unfortunately, all available promotility agents are fraught with undesirable adverse effects and are not generally as effective as acid suppression therapy.

Metoclopramide

Metoclopramide, a dopamine antagonist, increases LES pressure in a dose-related manner and accelerates gastric emptying in gastroesophageal reflux patients. However, it does not improve esophageal clearance. Metoclopramide provides symptomatic improvement for some patients with GERD; however, substantial data supporting endoscopic healing are lacking. In addition, metoclopramide's adverse effect profile, including extrapyramidal effects, tardive dyskinesia, and other CNS effects, limits its usefulness in treating many patients with GERD. The risk of adverse effects is much greater for elderly patients and for patients with renal dysfunction because the drug is primarily eliminated by the kidneys. Contraindications include Parkinson's disease, mechanical obstruction, concomitant use of other dopamine antagonists or anticholinergic agents, and pheochromocytoma.

Bethanechol

Bethanechol, a promotility drug, has limited value in the treatment of GERD because of unwanted adverse effects, such as urinary retention, abdominal discomfort, nausea, and flushing. It is not routinely recommended for the treatment of GERD.

Other Promotility Drugs Under Investigation

Other promotility drugs under investigation include itopride and baclofen. Because domperidone does not cross the blood–brain barrier, it does not cause the CNS effects seen with metoclopramide. However, it is not currently available in the United States. Baclofen, a gamma aminobutyric acid (GABA) receptor type B agonist, may decrease esophageal acid exposure and the number of reflux episodes by decreasing the number of transient relaxations of the LES. However, this agent has many adverse effects, limiting its usefulness in GERD. Other GABA type B agonists, as well as metabotropic glutamate type 5 (mGluR5) receptor antagonists are under development as potential prokinetic agents; however their effectiveness has not been promising to date.[34]

Mucosal Protectants

Sucralfate, a nonabsorbable aluminum salt of sucrose octasulfate, has limited value in the treatment of GERD. It may not be useful in the routine treatment of acid reflux but may useful in the management of radiation esophagitis and bile or nonacid reflux GERD.

Combination Therapy

Combination therapy with an acid suppression agent and a promotility agent or a mucosal protectant agent would seem logical given the multifactorial nature of the disease, particularly in light of the disappointing results seen with many monotherapy regimens. However, data to support combination therapy are limited, and this approach should not routinely be recommended unless a patient has GERD plus motor dysfunction occurring. The effectiveness of the addition of an H_2-receptor antagonist at bedtime to proton pump inhibitor therapy for the treatment of nocturnal symptoms may decrease over time due to tachyphylaxis with H_2-receptor antagonists. In light of this, "as needed" use of bedtime H_2-receptor antagonist may be a more appropriate approach if combination with a proton pump inhibitor is deemed necessary. Using the omeprazole–sodium bicarbonate immediate-release product in addition to once-daily proton pump inhibitors may offer an alternative for nocturnal GERD symptoms.

Clinical Controversy…

The use of a bedtime H_2-receptor antagonist in addition to daytime proton-pump inhibitor therapy is sometimes encountered in clinical practice to manage nocturnal GERD symptoms; however the long-term efficacy of this regimen is not well-established and a low-level of evidence exists.

Maintenance Therapy

Many patients with GERD will relapse if medication is withdrawn; so long-term maintenance treatment may be required. A proton pump inhibitor is the drug of choice for maintenance of patients with moderate to severe GERD, erosive disease, or other complication.

Although healing and/or symptomatic improvement may be achieved via many different therapeutic modalities, a large percentage of patients with gastroesophageal reflux will relapse following discontinuation of proton pump inhibitor or H_2-receptor antagonist therapy, especially those with more severe disease. Patients who have symptomatic relapse following discontinuation of therapy or lowering of medication doses, including patients with complications such as Barrett's esophagus, strictures, or erosive esophagitis, should be considered for long-term maintenance therapy to prevent complications or worsening of esophageal function.[15] The goal of maintenance therapy is to improve quality of life by controlling the patient's symptoms and preventing complications. Patients should be counseled on the importance of complying with lifestyle changes and long-term maintenance therapy in order to prevent recurrence or worsening of disease.[15]

Clinical Controversy…

While trials exist supporting the efficacy of "on-demand" use of proton pump inhibitors as maintenance therapy—reliable methods for identifying most appropriate patients for this approach are not available.

H_2-receptor antagonists may be effective maintenance therapy for patients with mild disease.[1] Proton pump inhibitors are the drugs of choice for maintenance treatment of moderate to severe esophagitis or symptoms. Low doses of a proton pump inhibitor or alternate-day dosing may be effective in some patients with mild symptoms, thereby allowing dose reduction in some cases.

"On-demand" maintenance therapy, by which patients take their proton pump inhibitor only when they have symptoms, may be effective for patients with endoscopy-negative GERD.[1] Although not well studied, many patients with only mild to moderate symptoms may decide on their own to use "on-demand" for the financial benefit. However, patients with persistent symptoms and/or complications generally require standard doses of proton pump inhibitors.

Long-term chronic use of proton pump inhibitor doses, higher than standard treatment doses, is not indicated unless the patient has complicated symptoms, has erosive esophagitis per endoscopy, or has had further diagnostic evaluation to determine the level of acid exposure. Metoclopramide is not approved for maintenance therapy, and its use is limited by adverse effect profile. Antireflux surgery may also be considered a viable alternative to long-term drug therapy for maintenance of healing for patients who are candidates.

Maintenance Therapy with H_2-Receptor Antagonist

The studies evaluating the efficacy of the H_2-receptor antagonists in maintaining GERD patients in remission have been disappointing. Currently, ranitidine 150 mg twice daily is the only H_2-receptor antagonist regimen that is FDA approved for maintenance of healing of erosive esophagitis.

Maintenance Therapy with Proton Pump Inhibitors

Long-term use of the proton pump inhibitors is associated with adverse effects such as hypomagnesemia, enteric infections, and risk for bone fractures; however, there is no evidence of carcinoid tumors directly linked to their use. Prolonged hypergastrinemia leading to the development of colonic polyps, and potentially adenocarcinoma, was also a concern that has proven unfounded with long-term use.

However, the role of *H. pylori* status for patients with GERD has been questioned. As a consequence of the controversy surrounding *H. pylori* and GERD, specific guidelines on how to handle patients who are *H. pylori* positive are lacking. Most clinicians would probably opt to eradicate *H. pylori* infections once detected. However, routine screening for *H. pylori* is not recommended as part of the diagnosis and management of GERD. Further studies are needed to determine the role of *H. pylori* for patients with GERD.

Special Populations

There are several special populations that should be considered when discussing GERD, such as patients with extraesophageal symptoms, pediatric patients, elderly patients, and patients with refractory symptoms.

Patients with Extraesophageal GERD

Extraesophageal symptoms (such as asthma, laryngitis, or chest pain) should prompt investigation for other possible causes outside of GERD. Patients presenting with extraesophageal symptoms, with

concomitant typical GERD symptoms, should receive a trial of proton pump inhibitor therapy. Patients with extraesophageal symptoms without the presence of typical GERD symptoms should undergo esophageal reflux monitoring prior to initiation of proton pump inhibitor therapy. If symptoms continue, patients should be evaluated with manometry, ambulatory reflux monitoring, or impedance–pH monitoring to rule out dysmotility or refractory symptoms.[1] Because there are many causes of asthma and laryngeal symptoms, a concomitant esophageal GERD syndrome must also be present to associate these symptoms with GERD. A trial of proton pump inhibitor therapy is recommended for those with extraesophageal symptoms with concurrent typical GERD symptoms. The optimal dose of proton pump inhibition is not well-defined. For patients not responding to empiric therapy, ambulatory reflux monitoring may be beneficial in determining acid exposure as it relates to symptoms. Maintenance therapy is generally indicated for patients who respond to the therapeutic trial or have endoscopic evidence of reflux. Antireflux surgery may be an option in select patients but is generally not recommended for management of extraesophageal symptoms that persist despite proton pump inhibitor therapy.

Pediatric Patients with GERD

Many infants have physiologic reflux with little or no clinical consequence. Uncomplicated gastroesophageal reflux usually manifests as regurgitation or "spitting up" and resolves without incident by about 12 months of life.[7] It usually responds to supportive therapy, including dietary adjustments, postural management, and reassurance for the parents. Thickened feedings may be useful in milder cases. While this does not decrease reflux episodes, it may decrease the incidence of regurgitation.[7] This strategy of thickening feedings may be appropriate for full-term infants, however may be associated with necrotizing enterocolitis in preterm infants. Chronic vomiting associated with gastroesophageal reflux must be distinguished from other causes, such as neurologic, metabolic, eating, and rumination disorders. Smaller, more frequent feedings may be beneficial. In formula-fed infants, an extensively hydrolyzed protein may help identify milk protein sensitivity as the cause of unexplained GERD-like symptoms, likewise, exclusion of milk and eggs in the maternal diet for breastfeeding infants may be appropriate.[7]

Developmental immaturity of the LES is one suspected cause of gastroesophageal reflux in infants. Like adults, transient LES relaxations seem to be the most common cause of gastroesophageal reflux in children. Other causes include impaired luminal clearance of gastric acid, neurologic impairment, and type of infant formula. Complications, although rare, include distal esophagitis, failure to thrive, esophageal peptic strictures, Barrett's esophagus, and pulmonary disease. Further diagnostic evaluation is indicated in all who experience apnea or an apparent life-threatening event.

The benefits of using promotility medications, such as metoclopramide, erythromycin, bethanechol, and baclofen, are outweighed by the potential adverse effects that may occur and, therefore, cannot be routinely recommended.[7] Careful consideration should be made before medication is recommended, especially in children younger than 1 year of age. Overprescribing of acid suppression therapy may lead to increased risk of infection and other adverse effects in premature infants.[35,36] When medication is deemed necessary, ranitidine is commonly used at a dose of 5 to 10 mg/kg/day in 2 to 3 divided doses in pediatric patients aged 1 month to 16 years.[7] Tachyphylaxis may develop

making the effectiveness of H_2-receptor antagonists less than optimal.

Proton pump inhibitor use in children is increasing, especially in those with esophagitis. Most patients will respond to once-daily proton pump inhibitor dosing. Lansoprazole and omeprazole are indicated for treating symptomatic and erosive GERD for pediatric patients older than age 1 year, while esomeprazole is indicated in patients older than 1 month of age. Omeprazole has been used off-label for children younger than 1 year of age at a dose of 1 mg/kg/day. Rabeprazole is indicated for short-term treatment of symptomatic GERD in adolescents 12 years and older and for treatment of GERD in pediatric patients 1 to 11 years of age.

Table 32-6 details indications and dosing of proton pump inhibitors in pediatric patients. Dexlansoprazole and pantoprazole have not been adequately studied in pediatric patients. A review of the current evidence for use of proton pump inhibitor therapy in infants and children found little efficacy in infants with better evidence in children and adolescents particularly with omeprazole, rabeprazole, and lansoprazole.[37] When examining adverse effect data from currently available trial data the authors noted that overall proton pump inhibitor therapy was well tolerated with mostly mild to moderate adverse effects in the short-term. Adverse effects with individual agents included diarrhea, abdominal pain, and vomiting with headache noted in older age groups and upper and lower respiratory tract infections noted in infants. It was stated that additional long-term data is needed in this population and that overall data was limited in infants younger than 1 year of age.[37] Long-term use of a proton pump inhibitor without a clear diagnosis of GERD is not recommended.[7]

TABLE 32-6 Oral Proton Pump Inhibitor Therapy in Pediatric Patients

	Indication	Recommended Oral Dose (daily)		
Lansoprazole	GERD, erosive esophagitis	1-11 years	≤30 kg	15 mg
			>30 kg	30 mg
	Erosive esophagitis	12-17 years		30 mg
	Nonerosive GERD	12-17 years		15 mg
Esomeprazole	Erosive esophagitis	1 month-1 year	3-5 kg	2.5 mg
			>5 to 7.5 kg	5 mg
			>7.5 to 12 kg	10 mg
		1-11 years	<20 kg	10 mg
			≥20 kg	10-20 mg
		12-17 years		20-40 mg
	Symptomatic GERD	1-11 years		10 mg
		12-17 years		20 mg
Omeprazole	GERD, maintenance of healing of erosive esophagitis	1-16 years	5 to <10 kg	5 mg

	Indication	Recommended Oral Dose (daily)		
			10 to <20 kg	10 mg
			≥20 kg	20 mg
Pantoprazole	Short-term treatment of erosive esophagitis	≥5 years	≥15 to <40 kg	20 mg
			≥40 kg	40 mg
Rabeprazole	GERD	1-11 years	<15 kg	5-10 mg
			≥15 kg	10 mg
		≥12 years		20 mg

Elderly Patients with GERD

Many elderly patients have decreased host defense mechanisms, such as saliva production. In addition, they have more comorbidities, medications, and physiologic changes that put them at higher risk. Often these patients do not seek medical attention because they feel their symptoms are part of the normal aging process. They may also present with atypical symptoms such as chest pain, asthma, poor dentition, or jaw pain. Decreased GI motility is a common problem in elderly patients. Unfortunately, there are no good promotility agents available to these patients. Elderly patients are especially sensitive to the CNS effects of metoclopramide. They may also be sensitive to the CNS effects of H_2-receptor antagonists. Proton pump inhibitors appear to be the most useful treatment modality because they have superior efficacy and are dosed once daily, which is beneficial in all patients, but is especially beneficial in the elderly. Long-term risk of bone fractures may be of concern in this population. Patients at risk for bone fractures should be monitored appropriately.

Patients with Refractory GERD

What constitutes refractory GERD is not well-defined. Prior to increasing the dose to twice daily, adherence and proper timing of proton pump inhibitor therapy should be optimized. Refractory GERD should be considered in patients who have not responded to a standard course of twice-daily proton pump inhibitor therapy. In this case, other causes for the patient's symptoms should be evaluated. The majority of patients with refractory symptoms experience nocturnal acid breakthrough. Other reasons for refractory symptoms may be related to compliance, timing of proton pump inhibitor, and drug metabolism differences in certain patients. Switching to another proton pump inhibitor may be effective for refractory symptoms in some patients. Manometry or ambulatory esophageal reflux monitoring is useful for patients who are not responding to therapy with normal endoscopic findings. If tests are negative, ISERT the patient is unlikely to have GERD and proton pump inhibitor therapy should be discontinued.[1] The addition of an H_2-receptor antagonist at bedtime for nocturnal symptoms has been suggested; however, the effect may be short-lived due to tachyphylaxis. Eosinophilic esophagitis or dysmotility syndromes may be causes of nonacid-related esophageal symptoms.[38]

PERSONALIZED PHARMACOTHERAPY

Significant liver impairment may result in a seven-fold to nine-fold increase in area under the serum concentration versus time curve and increase serum half-life of proton pump inhibitors. While clear recommendations are not available, it may be prudent to consider a lower dose in this population.

The hepatic enzyme CYP2C19 is involved in the metabolism of many medications, including proton pump inhibitors, particularly omeprazole. Further evaluation is needed to determine the role of polymorphic gene variation in the hepatic activity of CYP2C19.

Drug interactions with omeprazole are of particular concern for patients who are considered "slow metabolizers" of omeprazole, which is more common in the Asian population but also found in approximately 3% of the white population. Unfortunately, it is unclear which patients have the polymorphic gene variation that makes them slow metabolizers. Like omeprazole, the metabolism of esomeprazole may also be altered for patients with this polymorphic gene variation.

EVALUATION OF THERAPEUTIC OUTCOMES

The long-term benefits of treatment are difficult to assess because of the limited information known about the epidemiology and natural history of GERD. Consequently, successful outcomes are generally measured in terms of three separate end points: (a) relieving symptoms, (b) healing the injured mucosa, and (c) preventing complications.

The short-term goal of therapy is to relieve symptoms such as heartburn and regurgitation to the point at which they do not impair the patient's quality of life. Patients should be educated regarding specific lifestyle modifications that are applicable to their individual situation including weight loss and raising the head end of the bed. [10] In addition, patient medication profiles should be reviewed for medications that may aggravate GERD. Patients should be monitored for adverse drug reactions. Table 32-5 reviews common adverse drug reactions and monitoring of medications used in GERD. Drug-drug interactions should also be assessed and these agents should be avoided if possible. **Table 32-7** lists recommendations for providing pharmaceutical care to patients with GERD.

TABLE 32-7 Recommendations for Providing Pharmaceutical Care to Patients with GERD

1. Assess the patient's symptoms to determine if patient-directed therapy is appropriate or whether patient should be evaluated by a clinician. Determine the type of symptoms, frequency, and exacerbating factors. Refer any patient with alarm or atypical symptoms to a clinician for further diagnostic workup
2. Obtain a thorough history of prescription, nonprescription, and natural drug product use
3. Counsel the patient on lifestyle modifications that will improve symptoms
4. Recommend appropriate drug therapy based on patient presentation
5. Develop a plan to assess effectiveness of acid-suppression therapy after an appropriate amount of time (8-16 weeks). Recommend alternative therapy if necessary

6. Assess improvement in quality-of-life measures such as physical, psychological, and social functioning and well-being

7. Evaluate patient for the presence of adverse drug reactions, allergies, and drug interactions

8. Stress the importance of compliance with the therapeutic regimen, including lifestyle modifications. Recommend a therapeutic regimen that is easy for the patient to accomplish

9. Provide patient education with regard to disease state, lifestyle modifications, and drug therapy. Patients should be counseled on:

    - What causes GERD and what things to avoid
    - When to take their medications
    - What potential adverse effects or drug interactions may occur
    - What alarm signs they should report to their clinician

The frequency and severity of symptoms should be monitored, and patients should be counseled on symptoms that suggest the presence of complications requiring immediate medical attention, such as dysphagia. Patients should also be monitored for the presence of extraesophageal symptoms, such as laryngitis asthma or chest pain. These symptoms require further diagnostic evaluation. Long-term maintenance treatment is indicated for patients who have strictures because the strictures commonly recur if reflux esophagitis is not treated.

The second goal is to heal the injured mucosa. Again, individualized lifestyle modifications and the importance of complying with the therapeutic regimen chosen to heal the mucosa should be stressed. Patients should be educated about the risk of relapse and the need for long-term maintenance therapy to prevent recurrence or complications.

The final, long-term goal of therapy is to decrease the risk of complications (esophagitis, strictures, Barrett's esophagus, and esophageal adenocarcinoma). A small subset of patients may continue to fail treatment despite therapy with high doses of H_2-receptor antagonists or a proton pump inhibitor. Patients should be monitored for the presence of continual pain, dysphagia, or odynophagia.

ABBREVIATIONS

BMI	body mass index
CYP	cytochrome P450
GABA	gamma aminobutyric acid
GERD	gastroesophageal reflux disease
H_2	histamine-2
HREPT	high-resolution esophageal pressure topography
HRQL	health-related quality of life

LES	lower esophageal sphincter
mGluR5	metabotropic glutamate type 5
NERD	nonerosive reflux disease
TLESR	transient lower esophageal sphincter relaxation

Chapter 33: Peptic Ulcer Disease and Related Disorders

Bryan L. Love; Phillip L. Mohorn

INTRODUCTION

KEY CONCEPTS

- 1 Psychological stress, cigarette smoking, nonsteroidal anti-inflammatory drug (NSAID) use and certain foods/beverages can exacerbate ulcer symptoms and should be avoided.
- 2 Eradication of *Helicobacter pylori* is recommended in all patients who test positive, especially in those patients with an active ulcer, a documented history of a prior ulcer, or a history of ulcer-related complications.
- 3 The selection of an *H. pylori* eradication regimen should be based on several factors, including: efficacy, safety, antibiotic resistance, cost, and the likelihood of medication adherence. The preferred initial treatment is a proton pump inhibitor (PPI)–based three-drug regimen. Subsequent salvage treatment for *H. pylori* should contain different antibiotics due to potential resistance.
- 4 PPI co-therapy reduces the risk of NSAID-related gastric and duodenal ulcers and is at least as effective as recommended dosages of misoprostol and superior to the histamine-2 receptor antagonists (H2RAs).
- 5 Standard PPI dosages and a nonselective NSAID are as effective as a selective cyclooxygenase-2 (COX-2) inhibitor in reducing the risk of NSAID-induced ulcers and upper gastrointestinal (GI) complications.
- 6 Patients with peptic ulcer disease (PUD), especially those receiving *H. pylori* eradication or misoprostol cotherapy, require patient education regarding their disease and drug treatment to successfully achieve a positive therapeutic outcome.
- 7 Treatment for severe peptic ulcer bleeding after appropriate endoscopic treatment includes IV administration of a PPI loading dose followed by a 72-hour continuous infusion.
- 8 Coagulopathy and respiratory failure requiring mechanical ventilation are two of the highest risk factors for developing stress-related mucosal bleeding (SRMB). Prophylactic drug therapy should be

administered to critically ill patients with one of these complications.

- 9 Since there are limited data to support the selection of a PPI over an IV H2RA for SRMB prophylaxis, agent selection should be based on appropriate individual patient characteristics (eg, nothing by mouth, presence of nasogastric tube, thrombocytopenia, renal failure).

PEPTIC ULCER DISEASE

Gastric-acid is a critical component of upper gastrointestinal (GI) tract complications including gastritis, erosions, and peptic ulcer.[1,2,3] Peptic ulcer disease (PUD) differs from gastritis and erosions in that ulcers are larger (greater than or equal to 5 mm) and extend deeper into the muscularis mucosa.[1] The three common forms of peptic ulcers can be grouped according to their etiology: *Helicobacter pylori*-positive, nonsteroidal anti-inflammatory drug (NSAID)-induced, and stress-related mucosal damage (SRMD) (**Table 33-1**).

TABLE 33-1 Comparison of Common Forms of Peptic Ulcer

Characteristic	*H. pylori*-Induced	NSAID-Induced	SRMD
Condition	Chronic	Chronic	Acute
Site of damage	Duodenum > stomach	Stomach > duodenum	Stomach > duodenum
Intragastric pH	More dependent	Less dependent	Less dependent
Symptoms	Usually epigastric pain	Often asymptomatic	Asymptomatic
Ulcer depth	Superficial	Deep	Most superficial
GI bleeding	Less severe, single vessel	More severe, single vessel	More severe, superficial mucosal capillaries

GI, gastrointestinal; NSAID, nonsteroidal anti-inflammatory drug; SRMD, stress-related mucosal damage.

H. pylori-positive and NSAID-induced ulcers are chronic peptic ulcers that differ in etiology, clinical presentation, and tendency to recur (see Table 33-1). These ulcers develop most often in the stomach and duodenum of ambulatory patients (**Fig. 33-1**). Occasionally, ulcers develop in the esophagus, jejunum, ileum, or colon. The natural course of chronic PUD is characterized by frequent ulcer recurrence. The cause of ulcer recurrence is often multifactorial, although *H. pylori* infection and NSAID use are commonly associated. In addition, cigarette smoking, alcohol use, gastric acid hypersecretion, and medication nonadherence are frequently related.

FIGURE 33-1

Anatomic structure of the stomach and duodenum and most common locations of gastric and duodenal ulcers.

Other conditions such as Zollinger-Ellison syndrome (ZES), radiation, chemotherapy, vascular insufficiency, and other chronic diseases (**Table 33-2**) are associated with development and recurrence of peptic ulcers.[1,2] Although a strong association exists between chronic pulmonary diseases, chronic renal failure including hemodialysis, and cirrhosis, the pathophysiologic mechanisms of these associations remain unclear.[1] In contrast, SRMD occurs primarily in the stomach of critically ill patients (see Table 33-1).[1]

TABLE 33-2 Potential Causes of Peptic Ulcer

Common causes
Helicobacter pylori infection
NSAIDs
Critical illness (stress-related mucosal damage)
Uncommon causes of chronic peptic ulcer
Idiopathic (non–*H. pylori*, non-NSAID peptic ulcer)
Hypersecretion of gastric acid (eg, Zollinger-Ellison syndrome)
Viral infections (eg, cytomegalovirus)
Vascular insufficiency (eg, crack cocaine associated)
Radiation therapy
Chemotherapy (eg, hepatic artery infusions)
Infiltrating disease (eg, Crohn disease)
Diseases and medical conditions associated with chronic peptic ulcer
Cirrhosis

Chronic renal failure

Chronic obstructive pulmonary disease

Cardiovascular disease

Organ transplantation

NSAIDs, nonsteroidal anti-inflammatory drugs.

This chapter focuses on issues surrounding chronic PUD due to *H. pylori* and NSAIDs. A brief discussion of other PUD-related disorders (ZES, upper GI bleeding, and SRMD) is also included.

EPIDEMIOLOGY

The epidemiology of PUD is complicated and the prevalence is difficult to estimate given the variability in *H. pylori* infection, NSAID use, and cigarette smoking. In addition, endoscopy, radiology, symptoms, or other methods have different sensitivity and specificity to detect ulcers.[1,4] The prevalence and incidence of PUD in the United States also reflects improvements in drug therapy, the dramatic shift to ambulatory management, and changes in the criteria and coding system for mortality and hospitalization data reflected by continued declines in mortality, hospitalization, and age-adjusted ambulatory care visits. Mortality rates are higher among those older than or 65 years and in males compared to females.[4] Despite continued improvements, PUD remains one of the most common GI diseases, resulting in impaired quality of life, work loss, and high-cost medical care.

Helicobacter pylori

The prevalence of *H. pylori* varies by geographic location, socioeconomic conditions, ethnicity, and age. In industrialized countries, *H . pylori* prevalence is less common than in developing countries and correlates with socioeconomic levels.[2,5,6] The prevalence of *H. pylori* in the United States is 30% to 40% but is much higher in individuals older than 60 years (50%-60%) than in children younger than 12 years (10%-15%).[2,5] Although most individuals in the United States acquire *H. pylori* in childhood, the rate of acquisition in children is declining and most likely will continue to fall as a consequence of improved socioeconomic conditions.[2] Whites are infected with *H. pylori* less frequently than African Americans and Hispanic persons, but this is thought to be related to lower socioeconomic status and living conditions. Infection rates do not differ with gender or smoking status.

Nonsteroidal Anti-Inflammatory Drugs

Gastroduodenal ulcers develop in up to 15% to 30% of chronic NSAID users with continued use.[7] Gastric ulcers are most common, occur primarily in the antrum, and are of greater concern because of their potential to cause ulcer-related upper GI complications. Between 2% and 4% of patients with an NSAID ulcer will bleed or perforate.[7] In the United States at least 100,000 hospitalizations and between 7,000 and 10,000 deaths are directly attributed to NSAIDs each year.[7,8,9] Ulcer-related complications and death among regular NSAID users are 3 to 10 times higher compared with nonusers.

ETIOLOGY

H. pylori infection and NSAID use are the most common risk factors for PUD. Less common factors including ZES with hypersecretion of acid (see Table 33-2) can also be involved.[1] Disruptions in normal mucosal defense and healing mechanisms allow acid and pepsin to reach the gastric epithelium.[1] Benign gastric ulcers, erosions, and gastritis can occur anywhere in the stomach, although the antrum and lesser curvature represent the most common locations (see Fig. 33-1). Most duodenal ulcers occur in the first part of the duodenum (duodenal bulb).

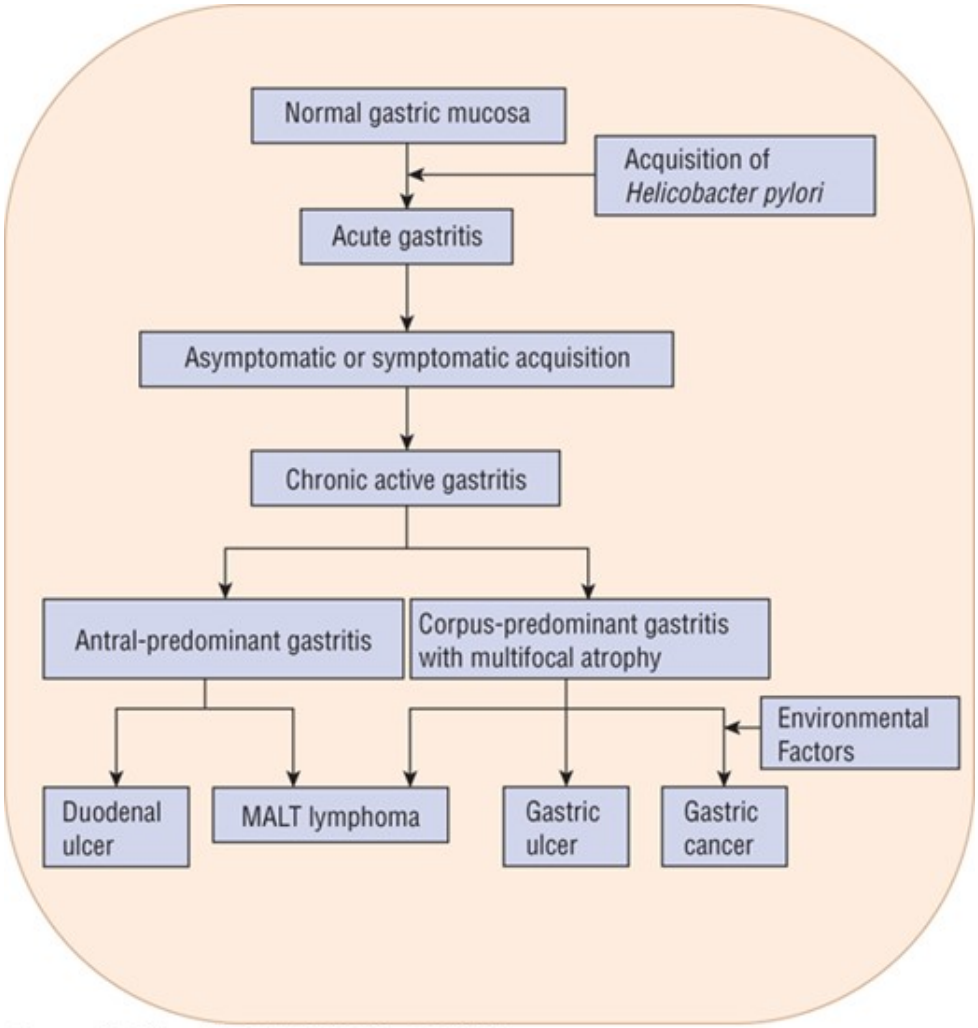
H. pylori

H. pylori is a gram-negative, microaerophilic, urease producing bacteria most commonly found in the stomach or duodenum. Bacterial urease production, to alkalinize the microenvironment, and flagella that allows for motility enable the bacterium to survive in the acidic environment of the stomach. *H. pylori* is primarily transmitted via person to person routes by either gastro–oral (vomitus) or fecal–oral (diarrhea) contact. Risk factors for acquiring *H. pylori* include close contact within households, low socioeconomic status, and country of origin.[2]

H. pylori infection can cause both acute and chronic gastritis in infected individuals and is associated with multiple GI complications. PUD, mucosa-associated lymphoid tissue (MALT) lymphoma, and gastric cancer (**Fig. 33-2**) have all been linked to *H. pylori* infection.[1,2,5,6,10,11] Most infected individuals remain asymptomatic, but 10% to 20% will develop PUD during their lifetime and about 1% will develop gastric cancer.[1,2] Environmental factors, host genetics and *H. pylori* strain virulence factors play an important role in the pathogenesis of PUD and gastric cancer.[2] *H. pylori* infection increases the risk of GI bleeding and peptic ulcers by threefold to sevenfold.[5] No specific link has been established between *H. pylori* and dyspepsia, nonulcer dyspepsia (NUD), or gastroesophageal reflux disease (GERD).[5,10,12] However, some patients with dyspepsia and NUD may have symptom improvement from *H. pylori* eradication.[5] Conversely, eradication of *H. pylori* may worsen GERD symptoms in some patients, but eradication should be attempted due to the known gastric cancer risk.[5,10] *H. pylori* is also associated with iron deficiency anemia, although the benefit of eradication remains unknown.[5,12]

FIGURE 33-2

The natural history of Helicobacter pylori infection in the pathogenesis of gastric ulcer and duodenal ulcer, mucosaassociated lymphoid tissue (MALT) lymphoma, and gastric cancer.



Nonsteroidal Anti-Inflammatory Drugs

Prescription and nonprescription NSAIDs (**Table 33-3**), are widely used in the United States, and have been linked to PUD. There is overwhelming evidence linking chronic NSAID (including low-dose aspirin) use to upper GI tract injury, PUD, gastritis, and superficial erosion.[1,7,13,14,15,16,17] In susceptible individuals, NSAIDs cause superficial mucosal damage consisting of petechiae (intramucosal hemorrhages) within minutes of ingestion, and progress to erosions with continued use.[1] These lesions typically heal within a few days and rarely cause ulcers or acute upper GI bleeding. NSAID-induced ulcers occur less frequently in the esophagus, small bowel, and colon.[17,18] The mechanisms by which NSAIDs damage the lower GI tract is not clear, but the enteropathy is associated with lower GI bleeding.

TABLE 33-3 Selected NSAIDs and COX-2 Inhibitors

Nonsalicylates[a]

Nonselective (traditional) NSAIDs: indomethacin, piroxicam, ibuprofen, naproxen, sulindac, ketoprofen, ketorolac, flurbiprofen

Partially selective NSAIDs: etodolac, nabumetone, meloxicam, diclofenac, celecoxib

Selective COX-2 inhibitors: rofecoxib,[b] valdecoxib[b]

Salicylates

Acetylated: aspirin

Nonacetylated: salsalate, trisalicylate

COX-2, cyclooxygenase-2; NSAIDs, nonsteroidal anti-inflammatory drugs.

[a]Based on COX-1-to-COX-2 selectivity ratio.

[b]Withdrawn from US market.

Table 33-4 lists the risk factors associated with NSAID-induced ulcers and upper GI complications. Combinations of factors confer an additive risk.[7,14,15,16,17,19] Advanced age is an independent risk factor, and the incidence of NSAID-induced ulcers increases linearly with the age of the patient.[1] The high incidence of ulcer complications in older individuals may be explained by age-related changes in gastric mucosal defense. The relative risk of NSAID complications is increased for patients with a previous peptic ulcer and may be as high as 14-fold in those with a history of an ulcer-related complication.[1,17] Although the risk of ulcer complications is greatest during the first few months after initiating continuous NSAID therapy, it does not vanish with long-term treatment.[7]

TABLE 33-4 Risk Factors Associated with lNSAID–Induced Ulcers and Upper GI Complications[a]

Age > 65
Previous peptic ulcer
Previous ulcer-related upper GI complication
High-dose NSAIDs
Multiple NSAID use
Selection of NSAID (eg, COX-1 vs COX-2 inhibition)
NSAID-related dyspepsia
Aspirin (including cardioprotective dosages)
Concomitant use of
NSAID plus low-dose aspirin
Oral bisphosphonates (eg, alendronate)
Corticosteroids
Anticoagulant or coagulopathy
Antiplatelet drugs (eg, clopidogrel)

Selective serotonin reuptake inhibitor

Chronic debilitating disorders (eg, cardiovascular disease, rheumatoid arthritis)

Helicobacter pylori infection

Cigarette smoking

Alcohol consumption

COX-2, cyclooxygenase-2; GI, gastrointestinal; NSAIDs, nonsteroidal anti-inflammatory drugs.

[a]Combinations of risk factors are additive.

Data from references 1, 7, 8, and 13 to 16.

NSAID ulcers and related complications are dependent upon the dose, duration of use, and type of NSAID. Although dose is important, low doses of nonprescription NSAIDs and low cardioprotective dosages of aspirin (81-325 mg/day) can also be attributed to increased risk of ulcer formation.[1,7,14,15,16,17] Factors such as NSAID potency, longer duration of effect, and a greater propensity to inhibit cyclooxygenase-1 (COX-1) versus cyclooxygenase-2 (COX-2) isoenzymes are associated with increased risk (see Table 33-3).[1,17,19,20] NSAID-related dyspepsia, in itself, does not correlate directly with mucosal injury or clinical events. However, new-onset dyspepsia, changes in severity, or dyspepsia not relieved by antiulcer medications may suggest an ulcer or ulcer complication.[1] Nonacetylated salicylates (eg, salsalate) may be associated with decreased GI toxicity.[1] Buffered or enteric-coated aspirin confers no added protection from upper GI events.[14]

NSAID ulcer and GI complication risk are increased with the use of multiple NSAIDs or the concomitant use of low-dose aspirin, oral bisphosphonates, corticosteroids, anticoagulants, antiplatelet drugs, and selective serotonin reuptake inhibitors.[1,7,14,15,16,17,21] The risk of an ulcer-related GI complication is greater when an NSAID or COX-2 inhibitor (see Table 33-3) is coadministered with low-dose aspirin than when either drug is taken alone.[1,14,17] The NSAID may also reduce the antiplatelet effects of aspirin, although NSAIDs vary in their effects on platelet function.[14,15,16] Corticosteroids, when used alone, do not potentiate the risk of ulcer or complications, but the relative risk is increased twofold in corticosteroid users who are also taking concurrent NSAIDs.[1,17] The relative risk of GI bleeding increases up to 20-fold when NSAIDs are taken concomitantly with anticoagulants (eg, warfarin) and up to sixfold with the concurrent use of serotonin reuptake inhibitors.[17,18] Coadministration of clopidogrel in combination with aspirin, an NSAID, or an anticoagulant significantly increases the risk of GI bleeding compared with either agent taken alone.[14,17] Even when prescribed as monotherapy, clopidogrel increases the risk of rebleeding for patients with a history of a bleeding ulcer.[14,15,17] Prasugrel and ticagrelor have more potent platelet inhibition than clopidogrel and are associated with a greater risk of bleeding.[14,22]

H. pylori and NSAIDs act independently to increase ulcer risk and ulcer-related bleeding and appear to have additive effects.[5,17] Thus, the incidence of peptic ulcer is higher in *H. pylori*–positive NSAID users. Whether *H. pylori* infection is actually a risk factor for NSAID ulcers remains controversial.[1,5,17] However, eradication is reported to reduce the incidence of peptic ulcer if undertaken prior to starting the NSAID but does not reduce the risk for patients who were previously taking an NSAID.[1,5,17]

Cigarette Smoking

Cigarette smoking has been linked to PUD, but it is uncertain whether smoking causes peptic ulcers.[1] The prevalence of ulcer disease is nearly double in current and former smokers (11.43% and 11.52%) compared to those who never smoked (6%). The risk of peptic ulcers in smokers with a large daily use, but ulcer risk is modest when fewer than 10 cigarettes are smoked per day.[23] Cigarette smoking impairs ulcer healing, promotes ulcer recurrence, and increases ulcer risk.[1] However, the underlying mechanisms by which cigarette smoking exerts these adverse effects remains unclear. Possible mechanisms include mucosal ischemia, inhibition of pancreatic bicarbonate secretion, and increases in gastric acid and mucous secretion, but these effects are inconsistent.[24]

Psychological Stress

The importance of psychological factors in the pathogenesis of PUD remains controversial.[1] Clinical observation suggests that ulcer patients are adversely affected by stressful life events. However, results from controlled trials are conflicting and have failed to document a cause-and-effect relationship.[1] Emotional stress may induce behavioral risks such as smoking and the use of NSAIDs or alter the inflammatory response or resistance to *H. pylori* infection. The role of stress and how it affects PUD is complex and probably multifactorial.

Dietary Factors

The effects of diet and nutrition on the pathophysiology PUD is uncertain. Carbonated beverages, coffee, tea, beer, milk, and spices often cause dyspepsia, but they do not appear to increase the risk of PUD.[1] Dietary interventions such as bland or restricted diets do not alter the frequency of ulcer recurrence. Although caffeine is a gastric acid stimulant, constituents in decaffeinated coffee or tea, caffeine-free carbonated beverages, beer, and wine may also increase gastric acid secretion. In high concentrations, alcohol ingestion is associated with acute gastric mucosal damage and upper GI bleeding; however, there is insufficient evidence to confirm that alcohol causes ulcers.[1]

PATHOPHYSIOLOGY

The pathophysiology of gastric and duodenal ulcers is determined by the balance between aggressive (gastric acid and pepsin) and protective (mucosal defense and repair) factors.[1,3] Gastric acid is secreted by the parietal cells, which contain receptors for histamine, gastrin, and acetylcholine.[1] Acid (as well as *H. pylori* infection and NSAID use) is an independent factor that contributes to the disruption of mucosal integrity.[1] Increased acid secretion has been observed for patients with duodenal ulcers and may be a consequence of *H. pylori* infection.[2,25] In contrast, patients with gastric ulcer usually have normal or reduced rates of acid secretion (hypochlorhydria).

The amount of acid secreted under basal or fasting conditions is referred to as basal acid output (BAO); after maximal stimulation, maximal acid output (MAO).[1] Basal and maximal acid secretion varies with time of day and the individual's psychological state, age, gender, and health status. The BAO follows a circadian rhythm, with the highest acid secretion occurring at night and the lowest in the morning. An increase in the BAO:MAO ratio suggests a basal hypersecretory state such as ZES.

Pepsin is an important enzyme cofactor in the proteolytic activity involved in ulcer formation.[21] Pepsinogen, the inactive precursor of pepsin, is secreted by the chief cells in the gastric fundus (see Fig. 33-1). Pepsin activity is determined by pH as it is activated by acid pH (optimal pH of 1.8-3.5), reversibly inactivated at pH 4, and irreversibly destroyed at pH 7.

Mucus and bicarbonate secretion, intrinsic epithelial cell defense, and mucosal blood flow protect the gastroduodenal mucosa from noxious endogenous and exogenous substances.[1,21] The viscous nature and near-neutral pH of the mucus–bicarbonate barrier protect the stomach from the acidic contents in the gastric lumen. Mucosal repair after injury is related to epithelial cell restitution, growth, and regeneration. Endogenous prostaglandins' (PGs) production facilitate mucosal integrity and repair. The term *cytoprotection* is often used to describe this process, but *mucosal defense* and *mucosal protection* are more accurate terms, as PGs prevent deep mucosal injury and not superficial damage to individual cells. Gastric hyperemia and increased PG synthesis characterize adaptive cytoprotection, the short-term adaptation of mucosal cells to mild topical irritants that enables the stomach to initially withstand the damaging effects of irritants. Alterations in mucosal defense that are induced by *H. pylori* or NSAIDs are the most important cofactors in the formation of peptic ulcers.

Helicobacter pylori

In infected people, *H. pylori* resides between the gastric mucus layer and surface epithelial cells, or any location where gastric-type epithelium is found.[2,25] Its spiral shape and flagellum permits it to move from the lumen of the stomach, where the pH is low, to the mucus layer, where the local pH is neutral. *H. pylori* produces large amounts of urease, which hydrolyzes urea in the gastric juice and converts it to ammonia and carbon dioxide.[2] The local buffering effect of ammonia creates a neutral microenvironment within and surrounding the bacterium, protecting it from the lethal effect of gastric acid. *H. pylori* also produces acid-inhibitory proteins, which allow it to adapt to the low-pH environment of the stomach.[2]

H. pylori binds to gastric-type epithelium by adherence pedestals, which prevent the organism from being shed during cell turnover and mucus secretion.[2] Colonization of the antrum and corpus (body) of the stomach is associated with gastric ulcer and cancer.[1,25] Antral organisms colonize gastric tissue that develops in the duodenum secondary to changes in gastric acid or bicarbonate secretion leading to duodenal ulcer (see Fig. 33-2).[1,2] Although *H. pylori* causes chronic gastric mucosal inflammation in all infected individuals, only a minority actually develop an ulcer or gastric cancer.[1] The difference in the diverse clinical outcomes is related to variations in bacterial pathogenicity and host susceptibility.[2,25]

Bacterial enzymes (urease, lipases, and proteases), bacterial adherence, and *H. pylori* virulence factors produce gastric mucosal injury.[2,25] Lipases and proteases degrade gastric mucus, ammonia produced by urease may be toxic to gastric epithelial cells, and bacterial adherence enhances the uptake of toxins into gastric epithelial cells. *H. pylori* induces gastric inflammation by altering the host inflammatory response and damaging epithelial cells directly by cell-mediated immune mechanisms or indirectly by activated neutrophils or macrophages attempting to phagocytose bacteria or bacterial products.[2,25] However, *H. pylori* strains are genetically diverse and account for differences in adaptation within the human host. Two of the most important are cytotoxin-associated gene protein (CagA) and vacuolating cytotoxin (VacA). About 60% of *H. pylori* strains in the United States possess CagA, but CagA-positive strains increase the risk for severe PUD, gastritis, and gastric cancer compared with CagA-negative strains.[2,26] The VacA gene

codes for the VacA cytotoxin, a vacuolating toxin. Although VacA is present in most *H. pylori* strains, strains vary in cytotoxicity and increased risk for peptic ulcer and gastric cancer.[2] Host polymorphisms are important markers of disease susceptibility and may identify high-risk patients.[2,25]

Nonsteroidal Anti-Inflammatory Drugs

NSAIDs, including aspirin (see Table 33-3), cause gastric mucosal damage by direct or topical irritation of the gastric epithelium and systemic inhibition of endogenous mucosal PG synthesis.[1,13] The onset of injury is initiated by the acidic properties of many of the NSAIDs while systemic inhibition of the protective PGs limits the ability of the mucosa to defend against injury and thus plays the predominant role in the development of gastric ulcer.[1,13]

Acidic NSAIDs (eg, aspirin) have topical irritant properties and they decrease the hydrophobicity of the mucous gel layer in the gastric mucosa. Most nonaspirin NSAIDs have topical irritant effects, but aspirin is the most damaging. Although NSAID prodrugs, enteric-coated aspirin tablets, salicylate derivatives, and parenteral or rectal preparations are associated with less acute gastric mucosal injury, they can cause ulcers and related GI complications as a result of systemic inhibition of endogenous PGs.[1]

COX is the rate-limiting enzyme in the conversion of arachidonic acid to PGs and is inhibited by NSAIDs (**Fig. 33-3**). Two similar COX isoforms have been identified: COX-1 is found in most body tissue, including the stomach, kidney, intestine, and platelets; COX-2 is undetectable in most tissues under normal physiologic conditions, but its expression can be induced during acute inflammation and arthritis (**Fig. 33-4**).[1,13] COX-1 produces protective PGs that regulate physiologic processes such as GI mucosal integrity, platelet homeostasis, and renal function. COX-2 is induced (unregulated) by inflammatory stimuli such as cytokines and produces PGs involved with inflammation, fever, and pain. It is also constitutionally expressed in organs such as the brain, kidney, and reproductive tract. Adverse effects (eg, GI or renal toxicity) of NSAIDs are primarily associated with the inhibition of COX-1, whereas anti-inflammatory actions result primarily from NSAID inhibition of COX-2.[1,13]

FIGURE 33-3

Metabolism of arachidonic acid after its release from membrane phospholipids. Broken arrow indicates inhibitory effects. (ASA, aspirin; HPETE, hydroperoxyeicosatetraenoic acid; NSAIDs, nonsteroidal antiinflammatory drugs; PG, prostaglandin.)

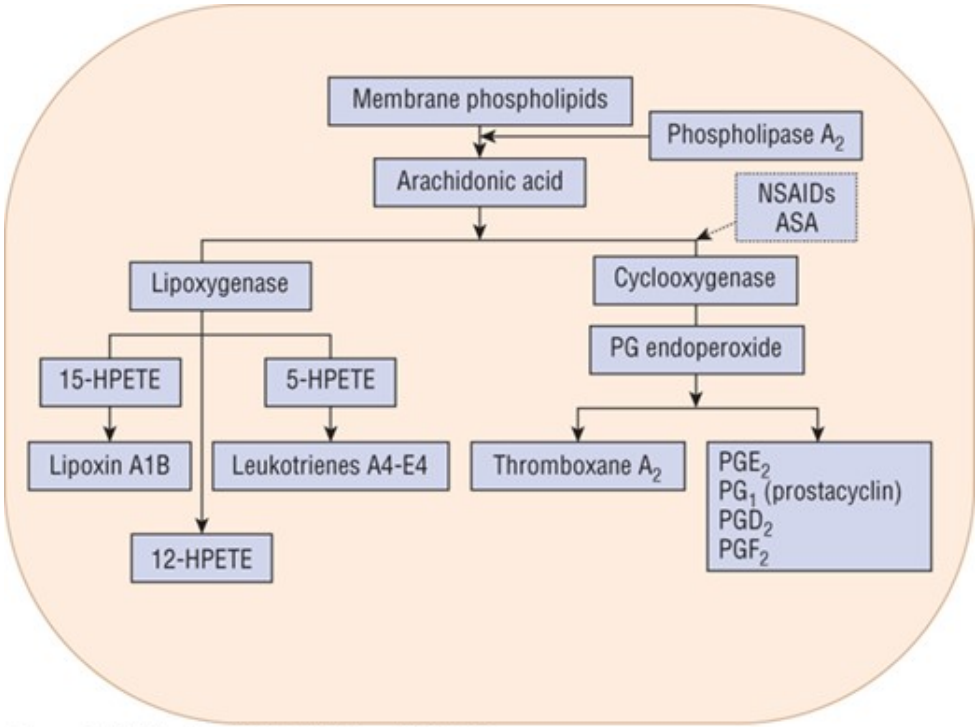


FIGURE 33-4

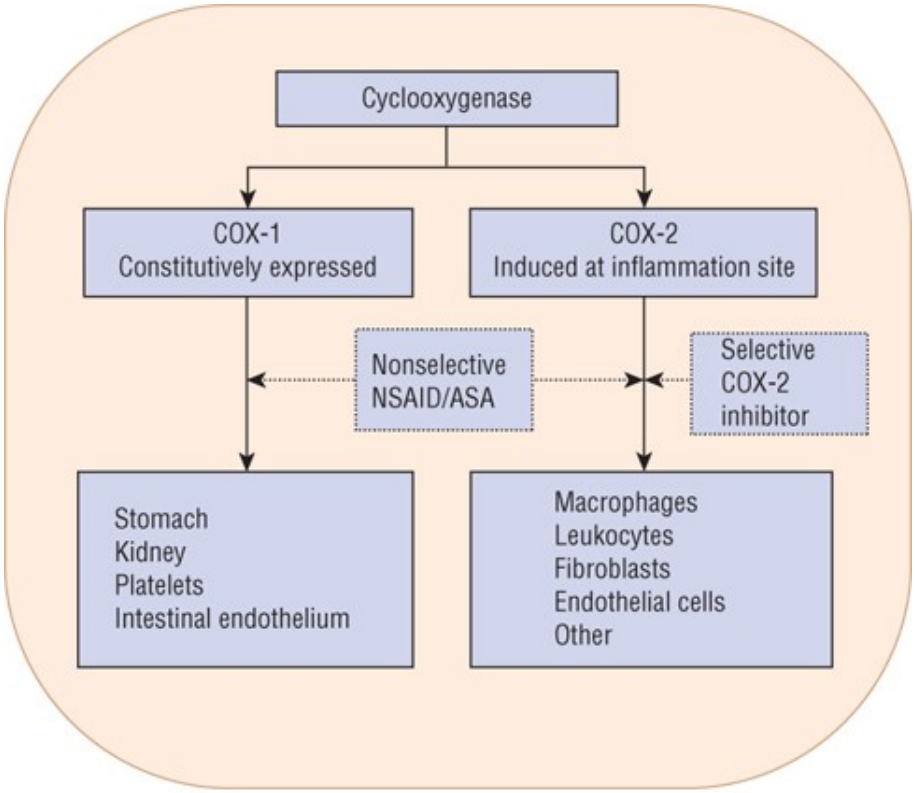
Tissue distribution and actions of cyclooxygenase (COX) isoenzymes. Nonselective nonsteroidal antiinflamatory drugs (NSAIDs) including aspirin (ASA) inhibit COX-1 and COX-2 to varying degrees; COX-2 inhibitors inhibit only COX-2. Broken arrow indicates inhibitory effects.



The COX-1-to-COX-2 inhibitory ratio determines the relative GI toxicity of a specific NSAID. Nonselective NSAIDs, including aspirin (see Table 33-3), inhibit both COX-1 and COX-2 to varying degrees and are associated with an increased propensity to cause gastric ulcers.[1,13] In contrast, the selective COX-2 inhibitors have a reduced risk of ulcers and related GI complications, but the benefit of celecoxib is less than that of rofecoxib and valdecoxib (see Table 33-3). The addition of aspirin to a selective COX-2 inhibitor reduces its ulcer-sparing benefit and increases ulcer risk.[1,13] Aspirin and nonaspirin NSAIDs irreversibly inhibit platelet COX-1, resulting in decreased platelet aggregation and prolonged bleeding times, thereby increasing the potential for upper and lower GI bleeding.[1,13,15] Coadministration of NSAIDs may reduce the antiplatelet effects of aspirin.[13,15,16] Clopidogrel and other medications that impair angiogenesis do not cause ulcers, per se, but may impair healing of gastric erosions leading to ulceration.[13,15]

Complications

The most serious, life-threatening complications of chronic PUD are upper GI bleeding, perforation, and obstruction.[1,27] Bleeding is caused by the erosion of an ulcer into an artery. It may be occult (hidden) and insidious or may present as melena (black-colored stools) or hematemesis (vomiting of blood). NSAID use (especially in older adults) is the most important risk factor for upper GI bleeding. Deaths occur primarily in patients who continue to bleed or in those patients who rebleed after the initial bleeding has stopped (see section "Upper GI Bleeding" below).

Gastric perforation into the peritoneal cavity is the second most common ulcer-related complication, occurring in up to 7% of patients with PUD.[1,27] The ulcer may penetrate into an adjacent structure (pancreas, biliary tract, or liver) rather than opening freely into a cavity. The incidence of perforation

appears to be increasing in elderly possibly due to increased use of NSAIDs. The pain of perforation is usually sudden, sharp, and severe, beginning first in the epigastrium, but quickly spreading over the entire abdomen. Most patients experience ulcer symptoms prior to perforation. However, older patients who experience perforation in association with NSAID use may be asymptomatic. Gastric outlet obstruction is mechanical obstruction caused by scarring, muscular spasm, or edema of the duodenal bulb usually resulting from chronic ulceration.[23] Symptoms occur over several months and include early satiety, bloating, anorexia, nausea, vomiting, and weight loss. Perforation, penetration, and gastric outlet obstruction occur most often with long-standing PUD. As a result of improvements in PUD treatment, rates of obstruction have decreased significantly, occurring in fewer than 2% of patients.[1] Intractability to drug therapy is an infrequent manifestation of PUD and an infrequent indication for surgery.

CLINICAL PRESENTATION

There is significant variability in the clinical presentation of PUD depending on the severity of epigastric pain and the presence of complications (**Table 33-5**).[1] Pain related to duodenal ulcer often occurs 1 to 3 hours after meals and is usually relieved by food, but this is variable. Food may precipitate or accentuate gastric ulcer pain. Antacids usually provide immediate pain relief in most ulcer patients. Pain usually diminishes or disappears during treatment; however, recurrence of epigastric pain after healing often suggests an unhealed or recurrent ulcer.

TABLE 33-5 Clinical Presentation of PUD

General

- Mild epigastric pain or acute life-threatening upper GI complications

Symptoms

- Abdominal pain that is often epigastric and described as burning but may present as vague discomfort, abdominal fullness, or cramping
- A typical nocturnal pain that awakens the patient from sleep (especially between 12 and 3 AM)
- The severity of ulcer pain varies from patient to patient and may be seasonal, occurring more frequently in the spring or fall; episodes of discomfort usually occur in clusters, lasting up to a few weeks and followed by a pain-free period or remission lasting from weeks to years
- Changes in the character of the pain may suggest the presence of complications
- Heartburn, belching, and bloating often accompany the pain
- Nausea, vomiting, and anorexia are more common for patients with gastric ulcer than with duodenal ulcer but may also be signs of an ulcer-related complication

Signs

- Weight loss associated with nausea, vomiting, and anorexia
- Complications including ulcer bleeding, perforation, penetration, or obstruction

GI, gastrointestinal; PUD, peptic ulcer disease.

The presence or absence of epigastric pain does not define an ulcer[1] and ulcer healing does not necessarily render the patient asymptomatic. Symptoms may remain because of sensitization of afferent nerves in response to mucosal injury.[1] Conversely, the absence of pain does not preclude an ulcer diagnosis especially in the elderly who may present with a "silent" ulcer complication possibly related to differences in the way the elderly perceive pain or the analgesic effect of NSAIDs.

Dyspepsia alone is of little clinical value when assessing subsets of patients who are most likely to have an ulcer. Patients taking NSAIDs often report dyspepsia, but these symptoms do not always correlate with an ulcer. Non-ulcer dyspepsia, or NUD, refers to the lack of an ulcer upon endoscopy in a patient with ulcer-like symptoms.[28] *H. pylori* gastritis or duodenitis may cause ulcer-like symptoms in the absence of peptic ulceration. There is no one sign or symptom that differentiates between *H. pylori*–positive and NSAID-induced ulcer.

DIAGNOSIS

Imaging and Endoscopy

Routine blood tests are not helpful in establishing the diagnosis of PUD (see Table 33-5).[1] The diagnosis of PUD depends on visualizing the ulcer crater by either upper GI radiography or upper endoscopy (see Table 33-5).[1] Upper endoscopy has replaced radiography as the diagnostic procedure of choice because it provides a more accurate diagnosis and permits direct visualization of the ulcer and implementation of therapeutic maneuvers such as injection of epinephrine or deployment of hemostatic clips to control bleeding.

Tests for *Helicobacter pylori*

The diagnosis of *H. pylori* infection can be made using endoscopic or nonendoscopic tests (**Table 33-6**).[2,5,29] Testing that requires upper endoscopy is invasive, more expensive, and usually requires a mucosal biopsy for histology, culture, or detection of urease activity. The updated Sydney system recommends taking five tissue samples from different sites within the stomach, as patchy distribution of *H. pylori* infection can lead to false-negative results.[30] Because antibiotics and bismuth salts may decrease the sensitivity of rapid urease test, they should be withheld for 4 weeks and proton pump inhibitors (PPIs) for 2 weeks prior to endoscopic testing.[2,5,29,31] If the patient has been taking these medications, then a gastric biopsy for histology should be performed.[5]

TABLE 33-6 Tests for Detection of *Helicobacter pylori*

Test	Description	Comments
Endoscopic tests		
Histology	Microbiologic examination using various stains	Gold standard; greater than 95% sensitive and specific; permits classification of gastritis; results are not immediate; not recommended for initial diagnosis; tests for active *H. pylori* infection

Test	Description	Comments
Culture	Culture of biopsy	Enables sensitivity testing to determine appropriate treatment or antibiotic resistance; 100% specific; results are not immediate; not recommended for initial diagnosis; used after failure of second-line treatment; tests for active *H. pylori* infection
Biopsy (rapid) urease	*H. pylori* urease generates ammonia, which causes a color change	Test of choice at endoscopy; greater than 90% sensitive and specific; easily performed; rapid results (usually within 24 hours); tests for active *H. pylori* infection
Polymerase chain reaction	*H. pylori* DNA detected in gastric tissue	Test is highly specific and sensitive; high rate of false-positives and false-negatives; positive DNA does not directly equate to presence of the organism; considered a research technique
Nonendoscopic tests		
Antibody detection (laboratory-based)	Detects antibodies to *H. pylori* in serum using laboratory-based ELISA tests and latex agglutination techniques	Quantitative; less sensitive and specific than endoscopic tests; more accurate than in office; unable to determine if antibody is related to active or cured infection; antibody titers vary markedly among individuals and take 6 months to 1 year to return to the uninfected range; not affected by PPIs or bismuth; antibiotics given for unrelated indications may cure the infection, but antibody test will remain positive
Antibody detection (can be performed in office or near patient)	Detects IgG antibodies to *H. pylori* in whole blood or finger stick	Qualitative; quick (within 15 minutes); unable to determine if antibody is related to active or cured infection; most patients remain seropositive for at least 6 months to 1 year after *H. pylori* eradication; not affected by PPIs, bismuth, or antibiotics
Urea breath test	*H. pylori* urease breaks down ingested labeled C-urea, patient exhales labeled CO_2	Tests for active *H. pylori* infection; 95% sensitive and specific; results take about 2 days; antibiotics, bismuth, PPIs, and H2RAs may cause false-negative results; withhold PPIs or H2RAs (1-2 weeks) and bismuth or antibiotics (4 weeks) prior to testing; recommended test to confirm posttreatment eradication of *H. pylori*
Fecal antigen	Identifies *H. pylori* antigen in stool by enzyme immunoassay using polyclonal anti–*H. pylori* antibody	Tests for active *H. pylori* infection; sensitivity and specificity comparable to urea breath test when used for initial diagnosis; antibiotics, bismuth, and PPIs may cause false-negative results, but to a lesser extent than with the urea breath test; may be used posttreatment to confirm eradication, but patients may have a reluctance to obtain stool samples

ELISA, enzyme-linked immunosorbent assay; H_2RA, H_2-receptor antagonist; PPIs, proton pump inhibitors.

Data from references 2, 5, and 35.

Nonendoscopic tests may identify active infection or detect antibodies (see Table 33-6) and are less invasive, more convenient, and less expensive than the endoscopic tests.[2,5,29] Antibody tests do not differentiate between active infection and previously eradicated *H. pylori*. The nonendoscopic tests include the urea breath test (UBT), serologic antibody detection tests, and the fecal antigen test.

The UBT is the most accurate noninvasive test and is based on *H. pylori* urease activity.[30] The ^{13}Carbon (nonradioactive isotope) and ^{14}Carbon (radioactive isotope) tests require that the patient ingest radiolabeled urea, which is then hydrolyzed by *H. pylori* (if present in the stomach) to ammonia and radiolabeled bicarbonate. The radiolabeled bicarbonate is absorbed in the blood and excreted in the breath. In addition to being noninvasive, another advantage of UBT over biopsy is that it overcomes the possible sampling error associated with endoscopic biopsy secondary to irregular distribution of *H. pylori*.[30] The fecal antigen test is less expensive and easier to perform than the UBT, and may be useful in children.

Serologic tests are a cost-effective alternative for the initial diagnosis of *H. pylori* infection in the untreated patient.[25] Antibodies to *H. pylori* usually develop about 3 weeks after infection and remain present after successful eradication.[5] Therefore, serology should not be used to confirm *H. pylori* eradication.[25] Office-based tests are less expensive, widely available, and provide rapid results, but the results are less accurate and more variable than the laboratory-based tests. Salivary and urine antibody tests are under investigation.

Testing for *H. pylori* is only recommended if eradication therapy is planned. Serologic antibody testing is a reasonable choice if endoscopy is not planned. The diagnostic accuracy of *H. pylori* tests for patients with an active bleeding ulcer has been questioned because of the potential for false-negative results. However, endoscopic biopsy-based tests such as the rapid urease test have a high degree of specificity in these patients (see "Peptic Ulcer–Related Bleeding").[5]

Confirmation of eradication is indicated post-treatment of active ulcers, previous ulcers, MALT lymphoma, endoscopic resection of gastric cancer, and uninvestigated dyspepsia. Routine testing for all patients is not recommended, and the cost-effectiveness needs to be further studied.[5] However, as resistance and treatment failures increase, the decision to confirm post-treatment eradication will also increase. The decision to test post-treatment should be patient-specific and take into consideration the patient's diagnosis, age, and ulcer history. The UBT and fecal antigen are the preferred nonendoscopic tests to confirm *H. pylori* eradication but must be delayed at least 4 weeks after the completion of treatment to avoid confusing bacterial suppression with eradication. The term *eradication* or *cure* is used when post-treatment tests conducted 4 weeks after the end of treatment do not detect the organism. Quantitative antibody tests are impractical for post-treatment confirmation as antibody titers remain elevated for long periods of time. A negative post-treatment antibody test, however, is considered reliable.

CLINICAL COURSE AND PROGNOSIS

PUD is characterized by periods of exacerbations and remissions.[1] Ulcer pain is usually recognizable and episodic, but symptoms are variable, especially in older adults and for patients taking NSAIDs. Antiulcer medications, including the histamine-2 receptor antagonists (H2RAs), PPIs, and sucralfate, relieve symptoms, accelerate ulcer healing, and reduce the risk of ulcer recurrence, but they do not cure the disease. Both duodenal and gastric ulcers recur unless the underlying cause (*H. pylori* or NSAID) is

removed. Successful *H. pylori* eradication markedly decreases ulcer recurrence and complications. Prophylactic co-therapy or a COX-2 inhibitor decreases the risk of upper GI events for patients who are taking NSAIDs. GI bleeding, perforation, and obstruction remain troublesome complications of chronic PUD. Mortality for patients with gastric ulcer is slightly higher than in duodenal ulcer and the general population. The development of gastric cancer in *H. pylori*–infected individuals is a slow process that occurs over 20 to 40 years and is associated with a lifetime risk of less than 1%.[11]

TREATMENT

Desired Outcome

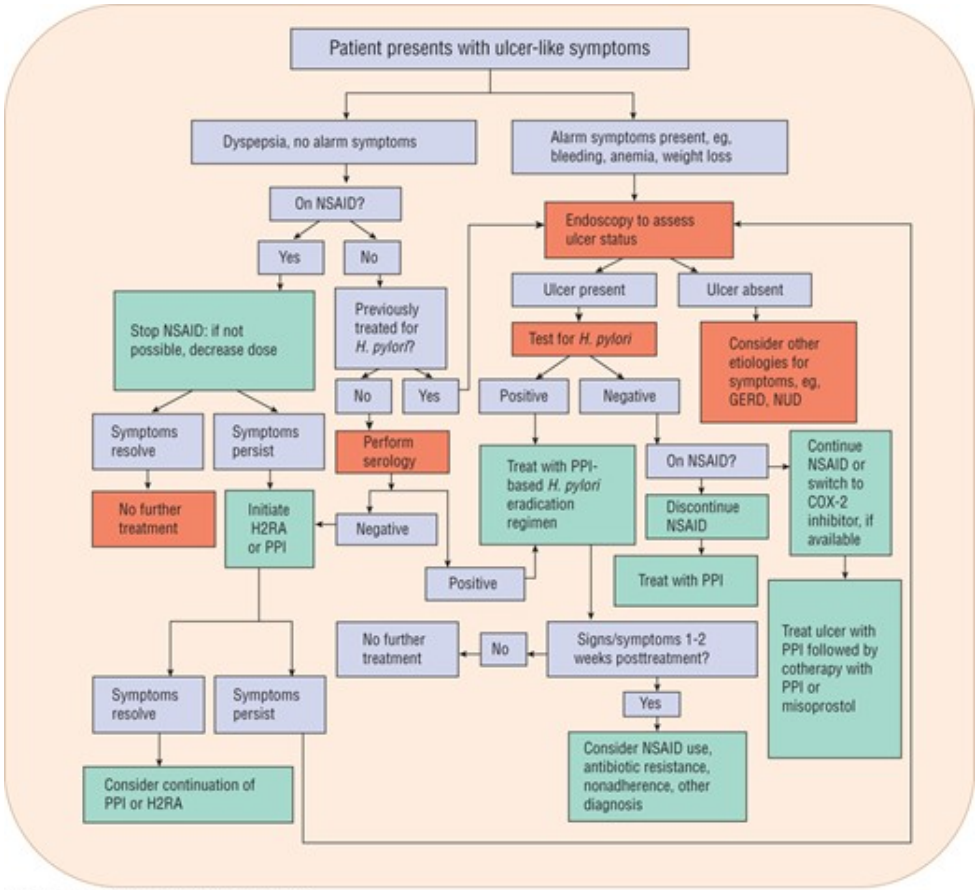
The goal of therapy for *H. pylori*–positive patients with an active ulcer, a previously documented ulcer, or a history of an ulcer-related complication is to eradicate *H. pylori*, heal the ulcer, and cure the disease. Successful eradication heals ulcers and reduces the risk of recurrence for most patients. The goal of therapy for a patient with an NSAID-induced ulcer is to heal the ulcer as rapidly as possible. Patients who are at high risk of developing NSAID ulcers should receive prophylactic co-therapy or be switched to a selective COX-2 inhibitor NSAID when possible to reduce ulcer risk and related complications.

General Approach to Treatment

The treatment of chronic PUD varies depending on the etiology of the ulcer (*H. pylori* or NSAID), whether the ulcer is initial or recurrent, and whether complications have occurred (**Fig. 33-5**). Treatment is aimed at relieving ulcer pain, healing the ulcer, preventing ulcer recurrence, and reducing ulcer-related complications. Antimicrobials such as clarithromycin, metronidazole, amoxicillin, bismuth salts, and antisecretory drugs (PPIs or H2RAs) eradicate *H. pylori* infection healing the ulcer and relieving ulcer symptoms. PPIs are preferred to H2RAs or sucralfate for healing *H. pylori*-negative NSAID-induced ulcers because they accelerate ulcer healing and provide more effective relief of symptoms.

FIGURE 33-5

Algorithm. Guidelines for the evaluation and management of a patient who presents with dyspeptic or ulcer-like symptoms. (COX-2, cyclooxygenase-2; GERD, gastroesophageal reflux disease; H_2 RA, H_2-receptor antagonist; NSAID, nonsteroidal antiinflammatory drug; NUD, nonulcer dyspepsia; PPI, proton pump inhibitor.)



Dietary modifications are important for patients who are unable to tolerate certain foods and beverages. Lifestyle modifications such as reducing stress and smoking cessation are encouraged. Surgery is reserved for patients with ulcer-related complications.

Nonpharmacologic Therapy

1 Patients with PUD should eliminate or reduce psychological stress, cigarette smoking, and the use of NSAIDs (including aspirin). Although there is no "antiulcer diet," the patient should avoid foods and beverages (eg, spicy foods, caffeine, and alcohol) that cause dyspepsia or that exacerbate ulcer symptoms. If possible, alternative agents such as acetaminophen or nonacetylated salicylate (eg, salsalate) should be used for relief of pain. Elective surgery for PUD is rarely performed today because of highly effective medical management. A subset of patients, however, may require emergency surgery for bleeding, perforation, or obstruction. In the past, surgical procedures were performed for medical treatment failures and included vagotomy with pyloroplasty or vagotomy with antrectomy.[1] Vagotomy (truncal, selective, or parietal cell) inhibits vagal stimulation of gastric acid. A truncal or selective vagotomy frequently results in postoperative gastric dysfunction and requires a pyloroplasty or antrectomy to facilitate gastric drainage. When an antrectomy is performed, the remaining stomach is anastomosed with the duodenum (Billroth I) or with the jejunum (Billroth II). A vagotomy is unnecessary when an antrectomy is performed for gastric ulcer. Postoperative consequences include postvagotomy diarrhea, dumping syndrome, anemia, and recurrent ulceration.

Pharmacologic Therapy

Recommendations

Table 33-7 presents guidelines for the eradication of infection in *H. pylori*–positive individuals. **Table 33-8** lists regimens used to eradicate *H. pylori* infection.

TABLE 33-7 Guidelines for the Eradication of *Helicobacter pylori* Infection

Indications for treatment of *H. pylori* infection

- Established indications for the treatment of *H. pylori* include gastric or duodenal ulcer, MALT lymphoma, after endoscopic resection of gastric cancer, and uninvestigated dyspepsia
- Controversial indications for the treatment of *H. pylori* infection include nonulcer dyspepsia, gastroesophageal reflux disease, individuals taking NSAIDs, individuals at high risk for gastric cancer, and unexplained iron deficiency anemia

Initial treatment of *H. pylori* infection

- Use only those eradication regimens that are of proven effectiveness in the United States
- In the United States, first-line treatment should include a PPI, clarithromycin, and either amoxicillin or metronidazole (PPI-based triple therapy) for 10-14 days
- The PPI-based triple-therapy amoxicillin-containing regimen is preferred initially because bacterial resistance to amoxicillin is almost absent, it has fewer adverse effects, and it leaves metronidazole as a backup agent for second-line therapy
- In penicillin-allergic patients, metronidazole should be substituted for amoxicillin in the PPI-based triple-therapy regimen and yields similar results when combined with clarithromycin
- An alternate initial strategy includes a PPI or H_2RA, bismuth salt, tetracycline, and metronidazole (bismuth-based quadruple therapy) for 10-14 days
- Sequential therapy consisting of a PPI and amoxicillin for 5 days followed by a PPI, clarithromycin, and metronidazole for 5 days is an alternative to PPI-based triple therapy or PPI-based quadruple therapy, but requires further validation before it can be recommended as first-line therapy in the United States

Eradication of *H. pylori* after initial treatment failure

- Avoid antibiotics that have been used in previous eradication regimens
- Bismuth-based quadruple therapy with a bismuth salt, tetracycline, metronidazole, and a PPI or H_2RA for 10–14 days is an acceptable treatment regimen for persistent *H. pylori* infections
- PPI-based triple therapy with levofloxacin and amoxicillin for 10 days may be more effective and better tolerated than PPI-based quadruple therapy with a bismuth salt, tetracycline, and metronidazole, but it requires further validation in the United States

MALT, mucosa-associated lymphoid tissue; NSAIDs, nonsteroidal anti-inflammatory drugs, PPI, proton

pump inhibitor.

Data from references 5, 8, 35, 37, 38, 39.

TABLE 33-8 Drug Regimens Used to Eradicate *Helicobacter pylori*

Drug #1	Drug #2	Drug #3	Drug #4
PPI-Based Triple Therapy[a]			
PPI once or twice daily[b]	Clarithromycin 500 mg twice daily	Amoxicillin 1 g twice daily *or* metronidazole 500 mg twice daily	
Bismuth-Based Quadruple Therapy[a]			
PPI or H2RA once or twice daily[b,c]	Bismuth subsalicylate[d] 525 mg four times daily	Metronidazole 250-500 mg four times daily	Tetracycline 500 mg four times daily
Non-Bismuth Quadruple or "Concomitant" Therapy[e]			
PPI once or twice daily on days 1 through 10[b]	Clarithromycin 250-500 mg twice daily on days 1-10	Amoxicillin 1 g twice daily on days 1 through 10	Metronidazole 250-500 mg twice daily on days 1 through 10
Sequential Therapy[e]			
PPI once or twice daily on days 1 through 10[b]	Amoxicillin 1 g twice daily on days 1 through 5	Metronidazole 250-500 mg twice daily on days 6 through 10	Clarithromycin 250-500 mg twice daily on days 6 through 10
Hybrid Therapy[e]			
PPI once or twice daily on days 1 through 14[b]	Amoxicillin 1 g twice daily on days 1 through 14	Metronidazole 250-500 mg twice daily on days 7 through 14	Clarithromycin 250-500 mg twice daily on days 7 through 14
Second-Line (Salvage) Therapy for Persistent Infections			
PPI or H2RA once or twice daily[b,c]	Bismuth subsalicylate[d] 525 mg four times daily	Metronidazole 250-500 mg four times daily	Tetracycline 500 mg four times daily
PPI once or twice daily[b,f]	Amoxicillin 1 g twice daily	Levofloxacin 250 mg twice daily	

H2RA, H_2-receptor antagonist; PPI, proton pump inhibitor.

[a]Although treatment is minimally effective if used for 7 days, 10-14 days is recommended. The antisecretory drug may be continued beyond antimicrobial treatment for patients with a history of a complicated ulcer, for example, bleeding, or in heavy smokers.

[b]Standard PPI peptic ulcer healing dosages given once or twice daily.

[c]Standard H2RA peptic ulcer healing dosages may be used in place of a PPI.

[d]Bismuth subcitrate potassium (biskalcitrate) 140 mg, as the bismuth salt, is contained in a prepackaged capsule (Pylera), along with metronidazole 125 mg and tetracycline 125 mg; three capsules are taken with each meal and at bedtime; a standard PPI dosage is added to the regimen and taken twice daily. All

medications are taken for 10 days.

[e]Requires validation as first-line therapy in the United States.

[f]Requires validation as rescue therapy in the United States.

Data from references 5, 8, 35, 37, 38, 39.

3 The most cost-effective drug regimen should be used whenever feasible. First-line therapy is usually initiated with a PPI-based three-drug regimen for 14 days. If a second course of treatment is required, the salvage regimen should contain different antibiotics or a four-drug regimen with a bismuth salt, metronidazole, tetracycline, and a PPI should be used.

Patients with NSAID-induced ulcers should be tested to determine their *H. pylori* status. If *H. pylori*-positive, treatment should be initiated with a PPI-based three-drug regimen. If *H. pylori*-negative, the NSAID should be discontinued, and the patient treated with a PPI, H2RA, or sucralfate (see **Table 33-9**). If the NSAID is continued, treatment should be initiated with a PPI (if *H. pylori*-negative) or with a PPI-based three-drug regimen (if *H. pylori*-positive). Co-therapy with a PPI or misoprostol or switching to a selective COX-2 inhibitor (if available) is recommended for patients at risk of developing an ulcer-related complication.

TABLE 33-9 Drug Dosing Table

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
Proton Pump Inhibitors					
Omeprazole, sodium bicarbonate	Prilosec, Zegerid	40 mg daily	20-40 mg/day	Consider adjustment for hepatic disease	Pregnancy Category C
Lansoprazole	Prevacid, various	30 mg daily	15-30 mg/day	Consider adjustment for hepatic disease	Pregnancy Category B
Rabeprazole	Aciphex	20 mg daily	20-40 mg/day	Use with caution in severe hepatic disease	Pregnancy Category B
Pantoprazole	Pantoprazole, various	40 mg daily	40-80 mg/day	Consider adjustment for severe hepatic disease	Pregnancy Category B
Esomeprazole	Nexium	40 mg daily	20-40 mg/day	Limit dose to 20 mg/day in severe hepatic disease	Pregnancy Category B
Dexlansoprazole	Dexilant	30-60 mg daily	30-60 mg/day	Consider dose limit of 30 mg/day in moderate hepatic impairment, dose not established in severe hepatic disease	Pregnancy Category B
H_2-Receptor Antagonists					
Cimetidine	Tagamet, various	300 mg four times daily,	800-1,600 mg/day in	Adjust dose for renal and severe hepatic	Pregnancy Category B

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Other
		400 mg twice daily, or 800 mg at bedtime	divided doses	impairment	
Famotidine	Pepcid, various	20 mg twice daily, or 40 mg at bedtime	20-40 mg/day	Adjust dose for renal impairment	Pregnancy Category B
Nizatidine	Axid, various	150 mg twice daily, or 300 mg at bedtime	150-300 mg/day	Adjust dose for renal impairment	Pregnancy Category B
Ranitidine	Zantac, various	150 mg twice daily, or 300 mg at bedtime	150-300 mg/day	Adjust dose for renal impairment	Pregnancy Category B
Mucosal Protectants					
Sucralfate	Carafate, various	1 g four times daily, or 2 g twice daily	2-4 g/day		Aluminum may accumulate in renal failure, Pregnancy Category B
Misoprostol	Cytotec	100-200 mcg four times daily	400-800 mcg/day		Pregnancy Category X

Data from references 79, 81, and 82.

Maintenance therapy with a PPI or H2RA should be limited to high-risk patients with ulcer complications, patients who fail eradication, and those with *H. pylori*-negative ulcers. Treatment failure is associated with poor medication adherence, antimicrobial resistance, NSAID use, cigarette smoking, acid hypersecretion, or tolerance to the antisecretory effects of an H2RA.

Treatment of *Helicobacter pylori*–Positive Ulcers

This chapter focuses on the eradication of *H. pylori* in adults. A discussion of the treatment of *H. pylori* infection in children is found elsewhere.[32]

The treatment of *H. pylori*–positive PUD should be effective, well tolerated, easy to adhere to, and cost-effective. Historically, none of these factors have been addressed in a systematic way making it difficult to identify the best evidence-based treatment regimens.[1] Successful eradication depends on the drug regimen, resistance to the antibiotics used, duration of therapy, medication adherence, and genetic polymorphism.[33,34] *H. pylori* regimens should have eradication (cure) rates of at least 80% based on intention-to-treat analysis or at least 90% based on per-protocol analysis, and they should minimize the potential for antimicrobial resistance.[1,8,35] Not one antibiotic, bismuth salt, or antiulcer drug achieves this goal, but clarithromycin has been considered the single most effective antibiotic. Two-drug regimens that combine a PPI and either amoxicillin or clarithromycin have yielded marginal and variable eradication rates

in the United States and are not recommended.[1,5] In addition, the use of only one antibiotic is associated with a higher rate of antimicrobial resistance and is therefore not recommended.

Several drug regimens (see Table 33-8) are available that offer combination therapy with an antisecretory drug, with two or more antibiotics, or a bismuth salt. When selecting an initial eradication regimen, an antibiotic combination should be used that permits second-line treatment (if necessary) with different antibiotics. The antibiotics that have been most extensively studied and found to be effective in various combinations include clarithromycin, amoxicillin, metronidazole, and tetracycline.[1] Because of insufficient data, ampicillin should not be substituted for amoxicillin, doxycycline should not be substituted for tetracycline, and azithromycin or erythromycin should not be substituted for clarithromycin.[36] Antisecretory drugs enhance antibiotic activity and stability by increasing intragastric pH and by decreasing intragastric volume thereby enhancing the topical antibiotic concentration.[37]

Proton Pump Inhibitor–Based Three-Drug Regimens

PPI-based triple therapy (see Table 33-8) is the initial treatment of choice for eradicating *H. pylori* (see Table 33-7).[5,8,35,37,38,39] The regimens that combine either clarithromycin and amoxicillin or clarithromycin and metronidazole are more effective than the amoxicillin–metronidazole regimen. In most cases, increasing the antibiotic dosage does not improve eradication rates. The clarithromycin–amoxicillin regimen is preferred initially (see Table 33-7), but metronidazole should be substituted for amoxicillin for penicillin-allergic patients unless alcohol is consumed.[5,35,37,38,39] Unfortunately, eradication rates for PPI-based triple therapy have declined substantially in recent years in North America and Europe due primarily to an increase in clarithromycin-resistant *H. pylori* strains (see "Factors that Predict H. pylori Eradication Outcomes" below).[5,8,35,37,38,39] Other antibiotics and antibiotic combinations have been investigated, but these regimens should not be used as initial treatment in the United States until well-designed trials confirm their effectiveness.[5,37]

Since the first treatment regimen offers the highest likelihood of *H. pylori* eradication, the recommended duration of triple-therapy in the United States is 14 days due to decreasing eradication rates with the PPI-based triple-therapy regimens containing clarithromycin, particularly with shorter durations.[5] Although a 7-day course has been approved by the FDA and is used in Europe, higher eradication and lower resistance rates are generally associated with longer treatment durations.[5,8,35,37,38,39]

The PPI is an integral part of the three-drug regimen and should be taken 30 to 60 minutes before a meal (see Table 33-8).[5] Prolonged PPI treatment beyond 2 weeks after eradication is usually not necessary for ulcer healing. A single daily dose of a PPI may be less effective than a twice-daily dose.[40,41] Substitution of one PPI for another is acceptable and does not enhance or diminish *H . pylori* eradication.[41] An H2RA should not be substituted for a PPI unless there are significant tolerability issues, as H2RA is associated with lower eradication rates.[42,43] Pretreatment with a PPI does not influence *H. pylori* eradication regardless of the pretreatment duration.[44]

Bismuth-Containing Quadruple Therapy

Bismuth-based quadruple therapy (see Table 33-8) is recommended as an alternative first-line eradication therapy (see Table 33-7) for those allergic to penicillin.[5,35,37,38,39] Although this regimen may be used

initially, it is often reserved as a second-line therapy after treatment failure with the PPI-based clarithromycin–amoxicillin regimen (see "Eradication of H. pylori After Initial Treatment Failure" below). Eradication rates for bismuth-based quadruple therapy (bismuth salicylate, metronidazole, tetracycline, and either a PPI or H2RA) are similar to those achieved with PPI-based triple therapy.[5,37,45] Eradication rates are comparable when bismuth subcitrate potassium (biskalcitrate) is substituted for bismuth subsalicylate (see Table 33-8).[46] Bismuth salts have a topical antimicrobial effect.[1] The antisecretory drug hastens ulcer healing and relieves pain in patients with an active ulcer. All medications except the PPI should be taken with meals and at bedtime.

The original bismuth-based regimens contained an H2RA but have largely been replaced by PPI as the antisecretory agent due to greater efficacy. Although shorter treatment durations have been studied, a 10- to 14-day duration is recommended in the United States as it generally provides higher eradication rates.[5,47] When treating an active ulcer, the antisecretory drug is usually continued for 2 (PPI) to 4 (H2RA) weeks after stopping bismuth and antibiotics. Bismuth-based quadruple therapy is the treatment of choice when medication costs are of overriding importance. However, major concerns include a four-times-a-day dosing regimen (see Table 33-8), poor medication adherence, and frequent adverse effects. A simplified twice-daily quadruple regimen has been piloted with high eradication rates (90%) and improved adherence.[48] Adverse effects are similar compared to those reported for the PPI-based triple therapy.[47]

Sequential Therapy

Sequential therapy is a form of eradication therapy in which the antibiotics are administered in a sequence rather than together.[5,8,38] The basis for sequential therapy is to initially treat with antibiotics that rarely promote resistance (eg, amoxicillin) to reduce the bacterial load and any preexisting resistant organisms that are susceptible. The second sequence follows with different antibiotics (eg, clarithromycin and metronidazole) to kill any remaining organisms. Treatment typically consists of a PPI and amoxicillin for 5 days followed by a PPI, clarithromycin, and tinidazole (or metronidazole) for an additional 5 days (see Table 33-8).[5,38,49] Although this regimen has achieved eradication rates that are superior to the PPI-based three-drug regimens containing clarithromycin,[49] the regimen requires a change in medication midtreatment, which may contribute to nonadherence.[50] Though promising, the advantages of sequential therapy have yet to be fully validated in the United States, and has yet to be incorporated into guidelines as a first-line *H. pylori* eradication therapy (see Table 33-7).[5,37,38]

Clinical Controversy…

Although sequential, hybrid, and non-bismuth quadruple therapies have higher overall eradication rates than traditional triple-therapy regimens, current guidelines do not recommend these as first-line therapy. Although these treatment strategies need to be validated in North American populations before they can be recommended as first-line therapy, they are more likely to be beneficial in situations where antibiotic (particularly clarithromycin) resistance is high.

Non-Bismuth Quadruple "Concomitant" Therapy and Hybrid Therapy

Non-bismuth quadruple therapy, also called "concomitant" therapy, is a regimen with a PPI, amoxicillin, clarithromycin, and metronidazole taken together at standard doses for 10 days. Hybrid therapy combines the strategies of concomitant and sequential therapy. Patients take 7 days of dual therapy (PPI and

amoxicillin) followed by 7 days of quadruple therapy (PPI, amoxicillin, clarithromycin, and metronidazole). Both hybrid and non-bismuth quadruple therapies have demonstrated higher eradication rates when compared with traditional triple-therapy,[51,52] although similar eradication rates are likely in areas of low antimicrobial resistance.[34,49,53]

Eradication of *Helicobacter pylori* After Initial Treatment Failure

H. pylori eradication is often more difficult after initial treatment fails and successful eradication after retreatment is extremely variable.[5,54] Treatment failures should be referred to a gastroenterologist for further diagnostic evaluation. Second-line (salvage) treatment should (a) use antibiotics that were not previously used during initial therapy; (b) use antibiotics that are not associated with resistance; (c) use a drug that has a topical effect such as bismuth; and (d) extend the duration of treatment to 14 days.[5,55] The most commonly used second-line therapy, after unsuccessful initial treatment with a PPI–amoxicillin–clarithromycin regimen, is a 14-day course of the PPI-based bismuth-containing quadruple therapy (see Table 33-8).[5,37,38,55] A levofloxacin-based triple therapy regimen (see Table 33-8) containing amoxicillin and a PPI may be an alternative second-line eradication regimen and may be better tolerated than PPI-based bismuth-containing quadruple therapy (see Table 33-7).[56] A 10-day therapy containing PPI, bismuth, tetracycline, and levofloxacin achieved a high eradication rate after failure of first-line treatment with sequential therapy.[57] However, concerns about using fluoroquinolones to treat *H. pylori* include development of resistance and adverse effects (eg, tendonitis and hepatotoxicity).[38] Other salvage regimens that include rifabutin and furazolidone are also effective, but these are discussed in more detail elsewhere.[5,38] European guidelines recommend obtaining antimicrobial sensitivity information following the second failed attempt to eradicate *H. pylori* when available.

Factors that Predict *Helicobacter pylori* Eradication Outcomes

Factors that predict *H. pylori* eradication outcomes include antibiotic resistance, poor medication adherence, short duration of therapy, CagA status, high bacterial load, low intragastric pH, and genetic polymorphism.[5,26,55,58] Medication adherence decreases with multiple medications, increased frequency of administration, intolerable adverse effects, and costly drug regimens. Tolerability varies with different regimens, but common adverse effects include nausea, vomiting, abdominal pain, diarrhea, and taste disturbances (metronidazole and clarithromycin). Adverse effects with metronidazole are dose-related (especially when more than 1 g/day) and include a disulfiram-like reaction with alcohol. Tetracycline may cause photosensitivity and should not be used in children because of possible tooth discoloration. Bismuth salts may cause darkening of the stool and tongue. Antibiotic-associated diarrhea and *Clostridium difficile*–associated disease can occur. Oral thrush and vaginal candidiasis may also occur.[1,5]

An important predictor of *H. pylori* eradication is the presence or absence of resistant microorganisms.[5,34,59] A worldwide meta-analysis including North American data from 2000 to 2008 reveal resistance rates among *H. pylori* strains (n = 818 isolates) for clarithromycin (30.8%), metronidazole (30.5%), amoxicillin (2%), tetracycline (0%), and levofloxacin (14.2%).[59] While amoxicillin and tetracycline resistance remains low, these data represent notable increases in resistance for metronidazole (25%) and clarithromycin (13%) compared to prior studies.[60,61] It is possible that the increased rate of clarithromycin resistance partially explains the decrease in efficacy of triple therapy clarithromycin-containing regimens. Prior antibiotic exposure is likely a factor in the development of resistance as was seen in one study where

the proportion of clarithromycin resistance increased from 7% resistance with no prior macrolide exposure to 80% resistance with more than or equal to five courses.[62] Therefore, prior antibiotic use should prompt consider for possible *H. pylori* resistance. The clinical importance of metronidazole resistance remains uncertain, as resistance can be overcome by using higher dosages and by combining metronidazole with other antibiotics.[5] Resistance to tetracycline and amoxicillin is uncommon.[5] Resistance to bismuth has not been reported. Although the role of antibiotic sensitivity testing prior to initiating *H. pylori* treatment has not been formally established, newly developed molecular-based tests may offer quick and easy determination of *H. pylori* resistance to macrolides and fluoroquinolones which allows for optimal regimen selection.[63]

Probiotics

Probiotics (eg, strains of *Lactobacillus* and *Bifidobacterium*) and foodstuffs (eg, cranberry juice and some milk proteins) with bioactive components have been used proactively to control *H. pylori* colonization in at-risk individuals. Although the quality of the data in this area is not optimal, probiotics taken as a supplement to antibiotic therapy, increases eradication rates compared to placebo and may reduce the adverse effects of PPI-based triple therapy.[64,65,66] However, the administration of probiotics alone does not eradicate *H. pylori* infection. In the future, the regular intake of probiotics may constitute a low-cost alternative for individuals who are at risk for *H. pylori* infection and, in combination with antibiotics, augment eradication rates. These preliminary data are encouraging and warrant more research in this area.

Treatment of Nonsteroidal Anti-Inflammatory Drug-Induced Ulcers

Nonselective NSAIDs should be discontinued (when possible) on confirmation of an active ulcer. If the NSAID is stopped, most uncomplicated ulcers heal with standard 4-week regimens of an H2RA, PPI, or sucralfate (see Table 33-9).[1,8,13,14] However, PPIs are usually preferred because they provide more rapid symptom relief and ulcer healing. If the NSAID is continued despite ulceration, consideration should be given to reducing the NSAID dose, switching to acetaminophen or a nonacetylated salicylate, or using a more selective COX-2 inhibitor (see Table 33-3). PPI treatment duration should be extended from 4 to 8-12 weeks if the NSAID must be continued. PPIs are the drugs of choice when the NSAID is continued, as potent acid suppression is required to accelerate ulcer healing.[1,8,13,14] If the ulcer is *H. pylori*-positive, eradication should be initiated with a regimen that contains a PPI.[1,8,13,14]

Strategies to Reduce the Risk of NSAID Ulcer and GI Complications

There are three therapeutic approaches to reducing the risk of NSAID ulcers and related upper GI complications (see **Table 33-10**). Medical co-therapy with either a PPI or misoprostol decreases ulcer risk and GI complications in high-risk patients.[7,8,13,14,16,17] The use of a selective COX-2 inhibitor instead of a nonselective NSAID also decreases risk of ulcers and upper GI events.[7,8,13,14,16,17] Unfortunately, these strategies do not completely eliminate ulcers and complications for patients at the "highest risk." When selecting a gastroprotective strategy, the GI benefits must be balanced against the cardiovascular risks associated with selective COX-2 inhibitor NSAIDs, nonselective NSAIDs, and concomitant antiplatelet therapy.[7,13,14,15,16,17] Strategies aimed at reducing the topical irritant effects of nonselective NSAIDs, for example, prodrugs, slow-release formulations, and enteric-coated products, do not prevent ulcers or GI complications.

TABLE 33-10 Drug Monitoring Table

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
PPIs	Headache, N/V/D, flatulence Less common: thrombocytopenia, neutropenia, hypomagnesemia, hypocalcemia, liver function abnormalities, renal impairment	Baseline and periodic CBC, serum electrolytes, renal/liver function	Well tolerated; may be associated with increased risk of fractures, pneumonia, *Clostridium difficile* infection
H_2RA	Headache, dizziness, diarrhea, somnolence, gynecomastia (cimetidine) Less common: thrombocytopenia, neutropenia, liver function abnormalities, renal impairment, pancreatitis	Baseline and periodic CBC, serum electrolytes, renal/liver function	
Sucralfate	Constipation		
Misoprostol	Diarrhea, abdominal pain, headache, nausea/vomiting, flatulence, dysmenorrhea, hypophosphatemia	Pregnancy test Serum phosphate	Avoid in pregnancy

CBC, complete blood count; H_2RA, H_2-receptor antagonists; PPIs, proton pump inhibitors.

Data from references 79, 81, 82, 95, 96, 97, 98, 99, 100, 101, 102.

Misoprostol Cotherapy

Misoprostol, 200 mcg orally four times per day, reduces the risk of NSAID-induced gastric and duodenal ulcer, and related upper GI complications, but diarrhea and abdominal cramping limit its use.[7,17,67] Because a dosage of 200 mcg three times per day is comparable in efficacy to 800 mcg/day, the lower dosage should be considered for patients unable to tolerate the higher dose.[7,17] Reducing the misoprostol dosage to 400 mcg/day or less to minimize diarrhea compromises its gastroprotective effects. A fixed combination of misoprostol 200 mcg and diclofenac (50 or 75 mg) may enhance compliance, but the flexibility to individualize drug dosage is lost. A large clinical trial in rheumatoid arthritis patients provided the most compelling evidence that misoprostol reduces the risk of upper GI complications for high-risk patients.[68]

Proton Pump Inhibitor Cotherapy

4 PPI cotherapy reduces NSAID-related gastric and duodenal ulcer risk and is better tolerated than misoprostol.[7,13,14,16,67] All PPIs are effective when used in standard dosages (see Table 33-9). Although head-to-head comparative trials are lacking, observational data indicate that PPIs are superior to H2RA at standard dosages.[7,14,17] When lansoprazole (15 or 30 mg/day) was compared with misoprostol 800 mcg/day or placebo, both dosages of lansoprazole and misoprostol effectively reduced ulcer recurrence, although the PPI was better tolerated.[69] A greater proportion of those in the misoprostol group reported

treatment-related adverse events and withdrew early from the study. Results from observational studies and meta-analyses indicate the PPIs reduce the risk of NSAID-related ulcer bleeding.[7,17,70,71]

H_2-Receptor Antagonist Cotherapy

Standard H2RA dosages (eg, famotidine 40 mg/day) are effective in reducing NSAID-related duodenal ulcer but not gastric ulcer (the most frequent type of ulcer associated with NSAIDs).[7,14,17] Higher dosages (eg, famotidine 40 mg twice daily, ranitidine 300 mg twice daily) may reduce the risk of gastric and duodenal ulcer, but studies comparing double dosages with PPIs or misoprostol are not available.[7,14] One study suggests that famotidine 20 mg twice daily may be an alternative to PPIs for patients taking low cardioprotective dosages of aspirin, but additional studies are required to confirm these findings.[72] The H2RAs are not recommended as prophylactic co-therapy because it is likely that they are not as effective as the PPIs or misoprostol in preventing NSAID-induced gastric ulcer and related GI complications.[17] An H2RA, however, may be used to relieve NSAID-related dyspepsia.

Cyclooxygenase-2 Inhibitors

Two large outcome trials have compared celecoxib[73] and rofecoxib with nonselective NSAIDs. Patients in the Celecoxib Long-Term Arthritis Safety Study (CLASS) trial who were taking celecoxib and required cardioprotection (antiplatelet effects of aspirin) were permitted to take low-dose aspirin. Although a 6-month analysis found a non-significant reduction in ulcer complications with celecoxib when compared with ibuprofen and diclofenac, results after 1 year found no difference between the groups.[73] Today, celecoxib is not considered a selective COX-2 inhibitor (Table 33-3) by the FDA as it contains the same GI warnings as the nonselective and partially selective NSAIDs.[74] Gastroprotective benefits of celecoxib were negated in aspirin users. Similar effects have been observed with rofecoxib. Additionally, an increased number of nonfatal myocardial infarctions and thrombotic stroke were observed in studies of rofecoxib leading to its withdrawal from the market.[75] Subsequently, valdecoxib was withdrawn from the market amid concerns about cardiovascular risk.[76]

Cardiovascular safety was also evaluated in the CLASS trial, but serious cardiovascular thromboembolic events were no different between celecoxib and the comparative nonselective NSAIDs. In contrast, the results of a meta-analysis of randomized trials of COX-2 inhibitor NSAIDs reported a dose-dependent increase in cardiovascular events with all COX-2 inhibitor NSAIDs, including celecoxib.[65] Increased cardiovascular risk appears to be dependent on a number of factors including increased COX-2 selectivity, higher dosages, and a longer duration of treatment.[7,19,20] Thus, the lowest effective celecoxib dose should be used for the shortest duration of time. Dyspepsia and abdominal pain, fluid retention, hypertension, and renal toxicity are associated with the COX-2 inhibitors and nonselective NSAIDs.[1]

COX-2 Inhibitor versus NSAID Plus PPI

5 For high-risk, *H. pylori*-negative patients, a COX-2 inhibitor NSAID may be as beneficial as a nonselective NSAID plus a PPI in reducing NSAID-related ulcer complications.[7,19,20] However, neither the COX-2 inhibitor NSAID nor the NSAID plus a PPI will eliminate upper GI events for these patients. Combining a COX-2 inhibitor NSAID with a PPI may be considered for very high-risk patients, but this

regimen is likely to be of modest benefit.[7,19]

Gastrointestinal and Cardiovascular Safety Issues

There is no difference in cardiovascular risk between the selective COX-2 inhibitor NSAIDs and the nonselective or partially selective NSAIDs, with the exception of naproxen.[7,19] Thus, individual patient risk factors for NSAID-related GI bleeding and cardiovascular events must be weighed when determining treatment (see **Table 33-11**). Naproxen is preferred compared with other nonselective NSAIDs and COX-2 inhibitors because of its comparative cardiovascular safety and not because of its GI safety profile. There is insufficient evidence regarding the preferred NSAID for patients also taking low-dose aspirin.[19] Clopidogrel should not be substituted for low-dose aspirin in order to reduce recurrent GI bleeding as it is inferior to a PPI plus low-dose aspirin.[14] Despite limited evidence to suggest an interaction via the hepatic cytochrome P450 (CYP450) pathway, combining a PPI and clopidogrel with or without low-dose aspirin results in less GI bleeding.[14] Ongoing studies for patients with cardiovascular disease should provide the necessary information to help resolve these issues. The lowest possible daily dose of a COX-2 inhibitor should be used as the cardiovascular risk may be dose dependent. However, no studies, to date, have evaluated the safety of low-dose COX-2 inhibitor NSAIDs for patients with or at risk for cardiovascular disease. In the future, there will be new formulations and classes of NSAIDs and COX-2 inhibitors with an improved GI and cardiovascular safety profile.[77] Until then patients who take NSAIDs or COX-2 inhibitors should be counseled about the signs and symptoms of upper GI bleeding and major cardiovascular events and what they should do if they occur.

TABLE 33-11 Guidelines for Reducing GI Risk for Patients Receiving Chronic NSAID Therapy

Cardiovascular Risk	No or Low GI Risk (No Risk Factors)	Moderate GI Risk (1-2 Risk Factors)	High GI Risk (Greater than 2 Risk Factors or Prior Ulcer or Ulcer-Related Complication)
GI Risk Factors (see Table 33-4)			
	Age < 65 years	Age ≥ 65 years High-dose NSAIDs Concomitant use of aspirin, corticosteroids, or anticoagulants	Age ≥ 65 years Concomitant use of aspirin corticosteroids, or anticoagulants Dual antiplatelet therapy
No or low CV risk (patient does not require low-dose aspirin)	Nonselective NSAID or partially selective NSAID (see Table 33-3)	Nonselective NSAID or partially selective NSAID + PPI or misoprostol Selective COX-2 inhibitor NSAID (if available)	Avoid NSAID or selective COX-2 inhibitor, if possible; use alternative therapy Nonselective NSAID or partially selective NSAID + PPI or misoprostol Selective COX-2 inhibitor NSAID (if available) + PPI or misoprostol
High CV risk (patient requires low-dose aspirin), no NSAID	No prophylaxis required	PPI or misoprostol	PPI or misoprostol

Cardiovascular Risk	No or Low GI Risk (No Risk Factors)	Moderate GI Risk (1-2 Risk Factors)	High GI Risk (Greater than 2 Risk Factors or Prior Ulcer or Ulcer-Related Complication)
High CV risk (patient requires low-dose aspirin) and NSAID	Naproxen + PPI or misoprostol	Naproxen + PPI or misoprostol	Avoid NSAID or selective COX-2 inhibitor If antiinflammatory drug is needed and CV risk is >GI risk, use naproxen and aspirin + PPI or misoprostol If antiinflammatory drug and aspirin are needed and GI risk is >CV risk, use selective COX-2 inhibitor + PPI or misoprostol

COX-2, cyclooxygenase-2 inhibitor; CV, cardiovascular; GI, gastrointestinal; NSAID, nonsteroidal anti-inflammatory drug; PPI, proton pump inhibitor.

Treatment of Non–*Helicobacter pylori*, Non-Nonsteroidal Anti-Inflammatory Drug Ulcers

Few individuals have non–*H. pylori*, non-NSAID (idiopathic) ulcers.[8,78] Patients should be double-checked to verify that they are *H. pylori*-negative and that they are not taking ulcerogenic medications. Possible explanations for *non–H. pylori*, non-NSAID ulcers include gastric hypersecretion, gastric outlet obstruction, genetic predisposition, concomitant diseases (see Table 33-2), and heavy tobacco use. Treatment should be initiated with conventional ulcer healing therapy (see Table 33-9). Although standard H2RA or sucralfate dosage regimens heal the majority of gastric and duodenal ulcers in 6 to 8 weeks, PPIs provide comparable ulcer healing rates in 4 weeks.[79] A higher daily dose or a longer treatment duration is sometimes needed to heal larger gastric ulcers. Antacids are not used as single agents to heal ulcers because of the high volume and frequent doses required. When conventional antiulcer therapy is discontinued after ulcer healing, most patients develop a recurrent ulcer within 1 year.[79] Maintenance therapy may be required to prevent ulcer recurrence.

Long-Term Maintenance of Ulcer Healing

Long-term maintenance of ulcer healing and the prevention of ulcer-related complications may be necessary in some patients. Because *H. pylori* eradication dramatically decreases ulcer recurrence, continuous maintenance therapy is primarily used to treat high-risk patients who failed *H. pylori* eradication, have a history of ulcer-related complications, have frequent recurrences of *H. pylori*-negative ulcers, and are heavy smokers or NSAID users. For most patients, standard maintenance dosages (see Table 33-9) are effective.[79]

Treatment of Refractory Ulcers

Ulcers are considered refractory to therapy when symptoms, ulcers, or both persist beyond 8 to 12 weeks

despite conventional treatment or when several courses of *H. pylori* eradication fail.[1,55] Poor patient compliance, antimicrobial resistance, cigarette smoking, NSAID use, gastric acid hypersecretion, or tolerance to the antisecretory effects of an H2RA (see "Antiulcer Agents" below) may contribute to refractory PUD. Patients with refractory ulcers should undergo upper endoscopy to confirm a nonhealing ulcer, exclude malignancy, and assess *H. pylori* status. *H. pylori*-positive patients should receive eradication therapy (see "Treatment of H. pylori–Positive Ulcers" above). In *H. pylori*-negative patients, higher PPI dosages (eg, omeprazole 40 mg/day) heal the majority of ulcers. Continuous treatment with a PPI is often necessary to maintain healing, as refractory ulcers recur when therapy is discontinued or the dose is reduced. Switching from one PPI to another is not beneficial. Patients with refractory gastric ulcer may require surgery because of the possibility of malignancy.

Antiulcer Agents

Proton Pump Inhibitors

PPIs (omeprazole, esomeprazole, lansoprazole, dexlansoprazole, rabeprazole, and pantoprazole) dose-dependently inhibit basal and stimulated gastric acid secretion.[79] The duration of acid suppression is a function of binding to the H^+/K^+-adenosine triphosphatase (ATPase) enzyme.[79] When PPI therapy is initiated, the degree of acid suppression increases over the first 3 to 4 days of therapy, as more proton pumps are inhibited.[79] PPIs inhibit only those proton pumps that are actively secreting acid, thus they are most effective when taken 30 to 60 minutes before meals.[79] Symptomatic acid rebound on withdrawal of a PPI has been reported in healthy volunteers after 8 weeks of treatment.[80]

PPIs are formulated as delayed-release enteric-coated dosage forms that have pH-sensitive granules contained in gelatin capsules (omeprazole, esomeprazole, prescription and nonprescription lansoprazole, and dexlansoprazole), rapidly disintegrating tablets (lansoprazole), and delayed-release enteric-coated tablets (rabeprazole, pantoprazole, and nonprescription omeprazole) (see **Table 33-12**).[79] The pH-sensitive enteric coating prevents degradation and premature protonation of the drug in stomach allowing the drug to be dissolved then absorbed in the duodenum at a higher pH. Dexlansoprazole is formulated with a dual-release mechanism that provides inhibition of proton pumps that become activated after initial release of the medication while omeprazole is also available as an immediate-release formulation (oral suspension, oral capsule) containing sodium bicarbonate, which can control intragastric pH in the absence of food.[81,82] IV products available in the United States include pantoprazole and esomeprazole.

TABLE 33-12 PPI Formulations and Options for Administration

	Omeprazole	**Esomeprazole**	**Lansoprazole**	**Pantoprazole**	**Rabeprazole**	**Dexlansoprazole**
Commercially available oral formulations

Oral disintegrating tablet			X			

	Omeprazole	Esomeprazole	Lansoprazole	Pantoprazole	Rabeprazole	Dexlansoprazole
Packet for oral suspension	X[d]	X[d]				
Extemporaneous oral preparations						
Pellets from capsule in water		X				
Pellets from capsule in applesauce	X		X			X
Pellets from capsule in juice	X	X[e]	X			
Extemporaneous preparation of delayed-release PPI in bicarbonate (omeprazole-sodium bicarbonate)	X		X	X		
Parenteral formulations						
IV	Not available in the United States	X		X		

PPI, proton pump inhibitor; X, product is available.

[a]Omeprazole is available as delayed-release enteric-coated pellets in a capsule or as immediate-release capsule that contains 20 or 40 mg of omeprazole with 1,100 mg sodium bicarbonate (equivalent to 304 mg of sodium). Because 20 and 40 mg dosages contain the same amount of bicarbonate, two 20 mg capsules should not be substituted for the 40 mg immediate-release omeprazole-sodium bicarbonate capsule.

[b]Dexlansoprazole is available as a dual delayed-release formulation in capsules for oral administration. The capsule contains dexlansoprazole in a mixture of two types of enteric-coated granules with different pH-dependent dissolution profiles.

[c]Omeprazole oral tablets are available as 20 mg delayed-release nonprescription tablets.

[d]Omeprazole oral suspension is available as 20 or 40 mg omeprazole with 1,680 mg sodium bicarbonate (equivalent to 460 mg of sodium). Because 20 and 40 mg dosages contain the same amount of bicarbonate, two 20 mg packets should not be substituted for the 40 mg immediate-release omeprazole-bicarbonate packet.

[e]No published information; based on omeprazole data.

Data from references 79, 81, and 82.

Five of the PPIs provide similar rates of ulcer healing (omeprazole, esomeprazole, lansoprazole, rabeprazole, and pantoprazole), maintenance of ulcer healing, and symptom relief when used in recommended dosages (see Table 33-9). Higher than indicated daily doses should be divided in order to obtain better 24-hour control of intragastric pH. Older adults and patients with renal impairment do not require dosage reductions, but dosage reductions should be considered in patients with severe hepatic disease.[79] Short-term adverse effects of the PPIs are similar to those observed with the H2RAs (headache, nausea, and abdominal pain).[79] Immediate-release formulations contain sodium bicarbonate, and thus are contraindicated for patients with metabolic alkalosis and hypokalemia. Sodium content in these immediate-release products should also be taken into consideration for patients who are on sodium-restricted diets (eg, congestive heart failure patients, chronic kidney disease patients).

Drug Interactions

Since PPIs increase intragastric pH, they may alter the bioavailability of orally administered drugs that are weak bases (eg, ketoconazole), digoxin, or pH-dependent dosage forms.[79,83] This interaction is especially important with atazanavir, a protease inhibitor used for treatment of HIV. Concomitant use with a PPI can significantly reduce the oral bioavailability of atazanavir leading to therapeutic failure and viral resistance in patients infected with HIV.[84] Omeprazole and esomeprazole selectively inhibit the hepatic CYP2C19 pathway and may decrease the elimination of several drugs (eg, phenytoin, warfarin, diazepam, and carbamazepine).[79] PPIs may increase the metabolic clearance and decrease the GI absorption of levothyroxine resulting in increased thyroid-stimulating hormone levels and a corresponding increase in the levothyroxine dose.[85] Clinically significant drug interactions with PPIs are rare and usually do not constitute a major clinical risk.[86,87]

Clinical Controversy…

PPIs have been linked with various enteric infections, but the most convincing data are with *C. difficile*. PPIs provide elevations in intragastric pH which facilitate the survival of *C. difficile* spores. Even though a possible association exists, the magnitude of risk varies and causality is difficult to establish prompting the need for large prospective studies.

A controversial PPI drug interaction involves the antiplatelet drug clopidogrel. Clopidogrel is converted to its active form through CYP2C19. PPIs may attenuate the antiplatelet effect of clopidogrel by inhibiting or competing for this metabolic pathway. FDA safety guidelines recommend that the coadministration of omeprazole, omeprazole/sodium bicarbonate, or esomeprazole with clopidogrel be avoided because they reduce the effectiveness of clopidogrel.[88] Warnings regarding omeprazole, esomeprazole, and other interacting drugs (eg, cimetidine), are contained in the clopidogrel package insert as well.[89] A reduced antiplatelet effect of clopidogrel may also result from genetic polymorphisms of the CYP2C19 pathway leading to decreased biotransformation of the drug to its active form which complicates the drug interaction.[90,91] Whether the use of other PPIs such as pantoprazole, lansoprazole, dexlansoprazole, and rabeprazole interacts with clopidogrel remains uncertain as the capacity to inhibit CYP2C19 varies among these PPIs.[92,93] Some reports suggest a “class effect” among the different PPIs. Other pharmacodynamic studies suggest an interaction with omeprazole and esomeprazole but not with pantoprazole.[92,93] The only

randomized double-blind trial comparing clopidogrel with or without omeprazole yielded no apparent increase in cardiovascular events due to clopidogrel and omeprazole cotherapy; however, there was a significant reduction in the rate of upper GI bleeding.[94] This trial has been criticized for the low number of cardiovascular events, formulation of omeprazole used, and premature termination of the study due to loss of funding by the sponsor. Patients should have an acceptable indication for a PPI recognizing that risk versus benefit must be weighed on an individual basis. If a PPI is absolutely necessary with clopidogrel, avoiding the use of omeprazole or esomeprazole may be warranted.

Potential Risks and Long-Term Safety Issues

Prolonged hypergastrinemia and chronic hypochlorhydria from long-term PPI use has been associated with numerous potential risks and safety issues (see **Table 33-13**).[79,95,96,97,98] In most cases, causality is difficult to ascertain because of the study design, confounding variables, and subject selection. All of the PPIs dose-dependently increase serum gastrin concentrations twofold to fourfold as a function of their potent acid-inhibitory effect.[79,95] Fasting gastrin elevations are usually within the normal range and return to baseline within 1 month of discontinuing the drug. In humans, PPIs may lead to enterochromaffin-like (ECL) hyperplasia, but there is no evidence that these changes result in dysplasia, carcinoid tumors, or gastric adenocarcinoma.[95,96] Long-term PPI therapy in *H. pylori*–positive individuals is associated with progressive atrophic gastritis, but there are insufficient data to link chronic PPI use with gastric cancer in *H. pylori*–positive patients.[95,96] There is also no evidence to support an association between PPIs and colonic polyps or colorectal cancer.[95,96] Bacterial overgrowth can occur in the stomach as a consequence of hypochlorhydria, but the full biological significance of this change in quantity and diversity of bacteria in the stomach and small intestine of PPI users remains unclear.[95,98]

TABLE 33-13 Potential Risks and Safety Issues Associated with the PPIs

Gastric cancers or malignancy
Carcinoid tumors
Atrophic gastritis
Adenocarcinoma
Bacterial overgrowth
Increase in *N*-nitroso compounds from ingested nitrates (carcinogenic)
Enteric infections (*Clostridium difficile, Salmonella typhimurium*, and *Campylobacter jejuni*)
Community-acquired pneumonia
Decreased nutrient absorption:
Iron
Calcium
Cyanocobalamin (vitamin B_{12})

Magnesium

Osteoporosis and related fractures

PPI, proton pump inhibitor.

Data from references 79, 95, 96, 97, 98.

Chronic PPI therapy may be associated with an increased risk of infection and nutritional deficiences.[95,96,97] Gastric acid plays an important role in the defense against bacterial colonization of the stomach and in nutrient absorption. Acid suppression has been implicated as a risk factor for community-acquired pneumonia (CAP) and enteric infections (*C. difficile*, *Salmonella*, *Campylobacter*).[96] Several studies, including one meta-analysis, demonstrate a higher adjusted relative risk of CAP for patients currently using PPIs compared with controls particularly in patients receiving higher doses or within the first 30 days of therapy.[99,100,101] The results of these retrospectively designed studies, however, need to be interpreted cautiously because of the variability in the length of therapy for current PPI users and the inclusion of older (older than 60 years) patients with concomitant comorbidities. A systematic review of the literature has linked PPIs with various enteric infections, but the most convincing data were with *C. difficile*.[102] It is likely that sustained elevations in intragastric pH facilitate the survival of *C. difficile* spores. However, the magnitude of risk varies and causality is difficult to establish. The risk of various infections associated with PPI therapy cannot be firmly established until the results of large prospective studies are made available.

The absorption of vitamin B_{12}, dietary iron, and calcium requires an acidic environment and may be adversely affected by long-term use of PPIs (see Table 33-10).[96] Although this adverse effect has been investigated, the clinical importance of their effect on absorption has not been established, and routine monitoring of B_{12} and iron levels cannot be recommended.[96] Adequate supplementation and monitoring should be considered in high-risk populations (eg, older patients, vegetarians, alcoholism) who may be already depleted.[95,96] High PPI dosage and long-term therapy have been associated with an increased risk of hip, wrist, and spine fractures related to reduction in calcium absorption.[38,103] The FDA has revised the warnings and precautions of prescription and nonprescription PPIs to reflect this potential risk.[103] Routine bone density tests for osteoporosis screening, calcium supplementation, or other precautions cannot be recommended solely based on chronic PPI therapy.[87] However, it is appropriate to screen and treat older patients for osteoporosis regardless of whether they are receiving long-term PPI therapy.

Hypomagnesemia, both symptomatic and asymptomatic, has been reported with PPI use with serious adverse events including tetany, arrhythmias, and seizures (see Table 33-10). In most cases it occurs in patients taking PPIs more than 1 year, but can occur with as little as 3 months of therapy. The FDA has revised the warnings and precautions of prescription and nonprescription PPIs.

H_2-Receptor Antagonists

Ulcer healing is comparable among H2RAs (cimetidine, famotidine, nizatidine, and ranitidine) with equipotent multiple daily doses or a single full dose given after dinner or at bedtime (see Table 33-9), but tolerance to their antisecretory effect may occur.[104] Twice-daily administration may be beneficial in patients with daytime ulcer pain while cigarette smokers may require higher doses or a longer duration of treatment. H2RAs are renally eliminated thus a dosage reduction is recommended for patients with

moderate-to-severe renal failure.[3] The short- and long-term safety of all four H2RAs is similar. Thrombocytopenia is a common yet likely overestimated hematologic adverse effect that occurs with all H2RAs and is reversible (see Table 33-10). The H2RAs decrease acid secretion and may alter the bioavailability of orally administered drugs, similar to that seen with the PPIs. Cimetidine inhibits several CYP450 isoenzymes, resulting in numerous drug interactions (eg, theophylline, lidocaine, phenytoin, warfarin, and clopidogrel). Ranitidine has less potential for hepatic CYP450 drug interactions, while famotidine and nizatidine do not interact with drugs metabolized by the hepatic CYP450 pathway.[3]

Sucralfate

Sucralfate heals peptic ulcers, but is not widely used today for this indication.[1] Deterrents to its use include the requirement for multiple doses per day, large tablet size, and the need to separate the drug from meals and potentially interacting medications. Drug interactions can be minimized by giving the interacting drug at least 2 hours before sucralfate. Alternative therapy is warranted for patients taking oral fluoroquinolones. Constipation may be troublesome especially in older individuals. Seizures may occur in dialysis patients taking aluminum-containing antacids. Hypophosphatemia may develop with long-term treatment. Gastric bezoar formation has also been reported (see Table 33-10).

Prostaglandins

Misoprostol, a synthetic PGE_1 analogue, moderately inhibits acid secretion and enhances mucosal defense.[1,3] Antisecretory effects are dose dependent over the range of 50 to 200 mcg, and cytoprotective effects occur in humans at doses of greater than 200 mcg. Because protective effects occur at higher doses, it is difficult to establish the protective effect independent of the antisecretory action. A dose of 200 mcg four times daily or 400 mcg twice daily (although not recommended in the United States) heals duodenal ulcers and gastric ulcers comparable to standard H_2RA or sucralfate regimens. The most troublesome adverse effect is diarrhea which is dose-dependent; develops in 10% to 30% of patients; and is accompanied by abdominal cramping, nausea, flatulence, and headache.[1,3] Taking the drug with or after meals and at bedtime may and avoidance of magnesium containing antacids minimize the diarrhea (see Table 33-10). Misoprostol is contraindicated in pregnant women because it produces uterine contractions that may endanger pregnancy. If misoprostol is prescribed to women in their childbearing years, contraceptive measures must be confirmed and a negative serum pregnancy test should be documented within 2 weeks of initiating treatment (see Table 33-10).[3]

Bismuth Preparations

Bismuth subsalicylate and bismuth subcitrate potassium (biskalcitrate) are the only available bismuth salts in the United States.[1] Possible ulcer healing mechanisms include an antibacterial effect, a local gastroprotective effect, and stimulation of endogenous PGs. Bismuth salts do not inhibit or neutralize acid. Bismuth subsalicylate is regarded as safe and has few adverse effects when taken in recommended dosages. Bismuth salts should be used with caution in older patients and in renal failure as renal insufficiency may decrease bismuth elimination. Bismuth subsalicylate may cause salicylate sensitivity or bleeding disorders and should be used with caution for patients receiving concurrent salicylate therapy. Bismuth salts impart a black color to stool and possibly the tongue with liquid preparations. Long-term use of bismuth salts is not recommended due to the potential for bismuth toxicity.

Antacids neutralize gastric acid, inactivate pepsin, and bind bile salts.[1] Aluminum-containing antacids also suppress *H. pylori* and enhance mucosal defense. The GI adverse effects are most common and are dose dependent: Aluminum-containing antacids cause constipation, and magnesium salts can cause an osmotic diarrhea. Aluminum-containing antacids (except aluminum phosphate) form insoluble salts with dietary phosphorus and interfere with phosphorus absorption. Hypophosphatemia occurs most often for patients with low dietary phosphate intake (eg, malnutrition or alcoholism). Combined treatment with sucralfate may amplify the hypophosphatemia and aluminum toxicity.

Magnesium excretion is impaired in patients with a creatinine clearance of less than 30 mL/min (0.5 mL/s) which may lead to toxicity; thus, magnesium-containing antacids should be avoided in these patients. Hypercalcemia may occur for patients with normal renal function taking more than 20 g/day of calcium carbonate and for patients with renal failure who are taking more than 4 g/day. The milk-alkali syndrome (ie, hypercalcemia, alkalosis, renal stones, increased blood urea nitrogen, and increased serum creatinine concentration) occurs with high calcium intake for patients with systemic alkalosis produced by either ingestion of absorbable antacids (sodium bicarbonate) or prolonged vomiting. Antacids may alter the absorption and excretion of drugs when administered concomitantly (eg, iron, warfarin, tetracycline, digoxin, quinidine, isoniazid, ketoconazole, or the fluoroquinolones).[1] Most interactions can be avoided by separating the antacid from the oral drug by at least 2 hours.

PERSONALIZED PHARMACOTHERAPY

The metabolism of PPIs occurs primarily through CYP2C19 and polymorphisms of CPY2C19 result in significant differences in enzymatic activity (poor, intermediate, or rapid metabolizers). For example, approximately 85% of white and nearly 100% of Asian populations have polymorphisms resulting in poor metabolism of substrates for CYP2C19. Eradication response rates of *H. pylori* are influenced by pharmacogenomics, with poor metabolizers achieving 100% eradication, intermediate metabolizers achieving 60%, and rapid metabolizers achieving 30% eradication.[105] Prior knowledge of CYP2C19 genotype may help to optimize the PPI dose and interval to minimize therapeutic failure. Rapid metabolizers may need more frequent PPI dosing, up to four times daily, to ensure an optimal gastric pH. Further studies are required to determine if increased AUC achieved in poor metabolizers translates to an additional risk of adverse effects.[106] Pharmacologic properties such as bioavailability and plasma concentrations of individual PPIs differ between individuals, but it remains unclear whether these differences impact the efficacy of *H. pylori* eradication.

Patients with high body-mass index have reduced antibiotic concentration at the gastric mucosal level and may result in higher risk of treatment failure. Likewise, prior allergy information and history of antimicrobial use is important in tailoring a regimen for *H. pylori* eradication. Tailoring eradication therapy based on *H. pylori* clarithromycin sensitivities is gaining popularity as molecular diagnostic testing improves. In one study, eradication rates improved from 70% in the control group to 94.3% in the treatment arm by tailoring eradication therapy from detection of clarithromycin-resistant *H. pylori* in feces.[107]

Smoking is a risk factor for treatment failure or ulcer recurrence; therefore, patients should be encouraged to quit smoking.

EVALUATION OF THERAPEUTIC OUTCOMES

Table 33-14 lists the recommendations for treating and monitoring patients with PUD. Relief of epigastric pain should be monitored throughout the course of treatment for patients with either *H. pylori*- or NSAID-related ulcers. Ulcer pain typically resolves in a few days when NSAIDs are discontinued and within 7 days upon initiation of antiulcer therapy. Patients with uncomplicated PUD are usually symptom free after treatment with any of the recommended antiulcer regimens. Persistent or recurrent symptoms within 14 days following treatment completion suggests failure of ulcer healing or *H. pylori* eradication or presence of an alternate diagnosis such as GERD. Most patients with uncomplicated *H. pylori*-positive ulcers do not require confirmation of ulcer healing or *H. pylori* eradication. However, eradication should be confirmed after treatment in individuals who are at risk for complications, for example, individuals who had a prior bleeding ulcer. The UBT and fecal antigen are the preferred methods to confirm *H. pylori* eradication when endoscopy is not indicated. Medication adherence should be assessed for patients who fail therapy. Many at-risk patients treated with NSAIDs do not receive adequate prophylaxis for GI complications; however, therapeutic outcomes can be improved by advocating preventive strategies. Any signs or symptoms of bleeding, obstruction, penetration, or perforation require prompt investigation to avoid complications. A follow-up endoscopy is justified for patients with frequent symptomatic recurrence, refractory disease, complications, or suspected hypersecretory states.

TABLE 33-14 Recommendations for Treating and Monitoring Patients with *Helicobacter pylori*–Associated and NSAID-Induced Ulcers

***H. pylori*-associated ulcer**

1. Recommend drug treatment as presented in the chapter text. See Tables 33-7 and 33-8
2. Assess patient allergies to determine if allergic to penicillin (or other antibiotics) so that drug regimens that contain penicillin (or other antibiotics) can be avoided. Avoid regimens that contain tetracycline in children
3. Assess patient use of alcohol or alcohol-containing products with metronidazole and oral birth control medications with antibiotics and counsel appropriately
4. Assess likelihood of nonadherence to the drug regimen as a cause of treatment failure
5. Recommend a different antibiotic combination if *H. pylori* eradication fails and a second treatment is planned
6. Inform the patient of change in stool color when bismuth salicylate is included in an *H. pylori* eradication regimen
7. Assess and monitor patients for potential adverse effects, especially those associated with metronidazole, clarithromycin, and amoxicillin
8. Assess and monitor patients for potential drug interactions, especially those receiving metronidazole, clarithromycin, or cimetidine
9. Monitor patients for salicylate toxicity, especially patients receiving cotherapy with other salicylates and anticoagulants and patients with renal failure

10. Monitor patients for persistent or recurrent symptoms within 14 days after completion of a course of *H. pylori* eradication therapy

11. Provide patient education to patients who are receiving *H. pylori* eradication therapy and include why antibiotic and antiulcer combinations are used; when and how to take medications; adverse effects; alarm symptoms; the importance of adherence to the entire course of drug treatment; and contact their healthcare provider if alarm symptoms develop (eg, blood in the stools, black tarry stools, vomiting, severe abdominal pain), or if symptoms persist or return after *H. pylori* eradication

NSAID-induced ulcer

1. Recommend drug treatment as presented in the chapter text

2. Assess risk factors for NSAID-induced ulcers and ulcer-related complications and recommend appropriate strategies for reducing ulcer risk (see Table 33-11)

3. Weigh patient risk factors for NSAID-related GI bleeding and cardiovascular events when selecting a strategy to reduce ulcer risk

4. Recommend eradication treatment for *H. pylori*-positive patients taking NSAIDs

5. Monitor patients for signs and symptoms of NSAID-related upper GI complications

6. Assess and monitor patients for potential drug interactions and adverse effects (especially misoprostol)

7. Provide patient education to patients who are at risk of NSAID-induced ulcers or GI-related complications and include why cotherapy is used with nonselective NSAIDs, when and how to take medications, adverse effects, alarm symptoms, when to contact their healthcare provider, and the importance of adherence to drug treatment

RELATED DISORDERS

Upper Gastrointestinal Bleeding

Upper GI bleeding is one of the most common GI emergencies with more than 300,000 hospital admissions annually. There are about 48 to 160 cases of upper GI bleeding per 100,000 adults annually in the United States, and the mortality rate associated with acute hemorrhage remains relatively high between 6% and 14% despite a decreased incidence of PUD and improvements in the management of upper GI bleeding. Upper GI bleeding is categorized as variceal or nonvariceal bleeding. A complete discussion of variceal bleeding is found elsewhere (Chapter 37). Two common types of nonvariceal bleeding are bleeding from chronic peptic ulcers and bleeding from stress-related mucosal damage (SRMD).[108] Upper GI bleeding associated with chronic PUD usually precedes hospital admission. Bleeding associated with SRMD develops in severely ill patients during hospitalization.[108,109,110,111] The underlying pathophysiology of bleeding from a peptic ulcer or from SRMD is similar in that impaired mucosal defense in the presence of gastric acid and pepsin leads to mucosal damage. In chronic PUD, *H. pylori* infection and NSAID use are the most important etiologic factors. The primary pathogenic factor of SRMD in critically ill

patients is thought to be mucosal ischemia, which is a result of reduced gastric blood flow resulting from splanchnic hypoperfusion.[108,109,110,111] Stress-related mucosal lesions are characteristically asymptomatic, numerous, located in the proximal stomach, and unlikely to perforate. Bleeding from SRMD occurs from superficial mucosal capillaries, whereas bleeding associated with chronic PUD usually results from a single vessel.[108,109,110,111] The mortality rate associated with clinically important stress-related mucosal bleeding (SRMB) is approximately 50% and is related to disease severity and comorbidities in this patient population. The mortality associated with chronic PUD-related bleeding is approximately 10% but can increase dramatically in select patient populations.[108,109,110,111] Initial management of acute upper GI bleeding focuses on aggressive resuscitation and hemodynamic stability.

Peptic Ulcer-Related Bleeding

Clinical Presentation and Diagnosis

Hematemesis (vomiting up blood), melena (dark, tarry stools), or both are most common presenting signs and symptoms of PUD-related bleeding. Risk for adverse outcomes must be rapidly assessed in order to determine if the patient's condition constitutes a medical emergency.[112,113] Two risk stratification tools exist for early assessment and triage. The Blatchford score is used to evaluate the need for urgent endoscopic intervention for patients presenting with PUD-related bleeding. The scale values range from 0 to 23, with higher scores indicating higher risk. The Rockall Score is composed of two assessments: the clinical score, which is performed prior to endoscopy, and the endoscopic score. The use of these risk stratification tools can reduce the requirement of endoscopic procedures and lead to early discharge for low-risk patients while ensuring rapid intervention for patients at higher risk.[112,113] When considering the risk of death due to PUD bleeding, the following patients generally have poorer prognoses and usually require more aggressive intervention including admission to an intensive care unit (ICU): age older than 65 years, shock, poor overall health, comorbid conditions, low initial hemoglobin/hematocrit, active bleeding (red blood per rectum or hematemesis), sepsis, and elevated serum creatinine or serum transaminases.[109] Diagnostic endoscopy is usually performed within 24 hours of presentation to identify the source of the bleeding, assess the potential risk for rebleeding using the Forrest classification of lesions, and, if appropriate, employ therapeutic interventions to promote hemostasis.[108,109,112,113]

The appearance of the ulcer at the time of endoscopy is a prognostic indicator for the risk of rebleeding. Clean-based (Forrest type III) and flat spot (pigmented; Forrest type IIc) ulcers are most commonly seen and are associated with a low risk of rebleeding (5% and 10%, respectively). In most cases, patients with clean-based ulcers can be treated as an outpatient after endoscopy on antiulcer therapy, while patients with flat spot ulcers may be admitted to the general hospital ward for brief observation.[108,112] Patients with an adherent clot overlying the ulcer base (Forrest type IIb) are at intermediate risk of rebleeding (22%-33%), and controversy exists as to the appropriate management of these patients. Patients with a visible vessel (Forrest type IIa) or active bleeding (Forrest type Ia or Ib) are at the highest risk of rebleeding (43%-50% and 55%-90%, respectively) and should receive ICU care for at least 24 hours followed by monitoring on a general medical/surgical service for an additional 48 hours as rebleeding significantly increases mortality.[108,112]

Treatment

Initial therapy for patients with defined hemostatic instability should focus on correcting fluid volume loss

though appropriate volume resuscitative measures. This is usually accomplished with a continuous 0.9% sodium chloride infusion or blood products if clinically indicated.[112,113] The use of nasogastric (NG) tubes remains controversial but may aid in early assessment and gastric lavage.[109,113] Several endoscopic treatment approaches (eg, thermocoagulation, argon plasma coagulation therapy, injection sclerotherapy, hemoclipping, and ligation) can be used. To maximize the likelihood of positive outcomes, patients should be treated with a combination of at least two endoscopic modalities, such as thermocoagulation and injection of lesions with epinephrine.[108,109,112,113]

Antisecretory agents are often used as adjuvant therapy to endoscopic procedures to prevent PUD rebleeding in high-risk patients because acid impairs clot stability. PPIs reduce the incidence of rebleeding and need for surgery but have no significant impact on overall mortality.[109,112,114] Historically, practice guidelines recommended that high-dose continuous-infusion PPI therapy (equivalent to omeprazole 80 mg given IV as a loading dose, followed by 8 mg/h continuous infusion for 72 hours) be used to reduce the risk of rebleeding in high risk patients who have undergone endoscopy hemostasis. A Cochrane Review comparing different regimens of PPIs and a meta-analysis comparing intermittent and continuous PPI therapy for high-risk bleeding ulcers showed no benefit in high dose or continuous therapy respectively.[114,115] Thus intermittent IV dosing of PPIs (at cumulative daily doses of 80-160 mg) may be a therapeutic option that provides a greater ease of administration. PPI therapy is not a replacement for interventional endoscopy in patients with a high risk of rebleeding, as data demonstrate that the combination of a PPI with therapeutic endoscopy is superior to either strategy alone.[109,112,113] The risk of rebleeding is greatest within the first 72 hours, and thus antisecretory therapy to prevent rebleeding in high-risk patients should be employed in this time frame. Patients should be transitioned to an oral PPI on completion of IV therapy.[109,112,113]

Patients with upper GI bleeding should be tested for *H. pylori* at the time of endoscopy (see "Tests for H. pylori" above). However, the tests are associated with an increased rate of false-negatives when obtained during acute bleeding episodes. If the initial results of the rapid urease test and/or histology are negative, a confirmatory test should be performed following the acute bleeding episode.[109] Ulcer treatment, including *H. pylori* eradication, if appropriate, should be initiated after the acute bleeding episode has resolved (see "Treatment of H. pylori–Positive Ulcers and Treatment of NSAID-Induced Ulcers" above).

Stress-Related Mucosal Bleeding

Epidemiology and Risk Factors

Clinically important bleeding increases ICU length of stay, results in excessive healthcare costs, and is associated with increased mortality. Thus, attempts to prevent SRMB are warranted in high-risk patients. Prophylactic therapy to prevent bleeding is most effective if initiated early in the patient's course.[111] Majority (75%-100%) of critically ill patients develop SRMD within the first 1 to 3 days of admission to an ICU, but the incidence of clinically important SRMB (defined as overt bleeding with concomitant hemodynamic instability and likely requirement for blood products) is 1% to 6%.[111]

Patients who are at risk for SRMB include those with respiratory failure (need for mechanical ventilation for longer than 48 hours), coagulopathy (INR greater than 1.5, platelet count less than 50,000 mm^3[less than 50×10^9 /L]), hypotension, sepsis, hepatic failure, acute renal failure, high-dose corticosteroid therapy (more than 250 mg/day hydrocortisone or equivalent), multiple trauma, severe burns (more than 35% of

body surface area), head injury, traumatic spinal cord injury, major surgery, prolonged ICU admission (more than 7 days), or history of GI bleeding.[116] The relative importance of the various risk factors remains controversial, but most clinicians concur that patients with respiratory failure or coagulopathy should receive prophylaxis, as these two factors are independent risk factors for SRMB.[117]

Prevention and Treatment

Prevention of SRMB includes resuscitative measures that restore mucosal blood and pharmacotherapy that either maintains an intragastric pH of greater than 4 or provides gastric mucosal protection.[111,116] Although the benefits of enteral nutrition to patient outcome (eg, improved nutritional status enhances mucosal integrity) are of overall clinical importance, its precise role as a sole modality to prevent SRMB remains controversial. Two meta-analyses suggest that patients receiving enteral nutrition may not require SRMB prophylaxis and that such therapies may increase the risk of adverse complications of these therapies.[118,119] Therapeutic options for the prevention of SRMB include antacids (which are no longer used because of cumbersome dosage schedules and side effects), antisecretory drugs (H2RAs and PPIs), and sucralfate.[111,116]

Sucralfate is an evidence-based option but requires multiple daily dosage administration (up to four times daily), which may occlude nasogastric (NG) tubes, cause constipation, interact with several medications, or increase the potential for aluminum toxicity in patients with renal dysfunction and is thus not used very frequently for SRMB prophylaxis.[116] Antisecretory therapy is generally preferred for SRMB prophylaxis. The PPIs are more potent than H2RAs in inhibiting acid secretion and, unlike H2RAs, tolerance does not develop. PPIs have become the most widely used therapy despite conflicting evidence of their superiority over H2RAs for SRMB prophylaxis.[111,120,121,122,123] In addition, adverse events that have been described when the PPIs are used for SRMB prophylaxis include an increased risk of enteric infections, including *C. difficile*–associated diarrhea and nosocomial pneumonia thus potentially increasing hospital-associated costs and providing an argument against their routine use for SRMB prophylaxis.[111,116,121,122,123] Based on available evidence, several PPI dosing regimens for SRMB prophylaxis exist (see Table 33-15).[111,116]

TABLE 33-15 Pharmacotherapy Options for Prophylaxis of Stress-Related Mucosal Bleeding

Drug and Route	Dosage
Parenteral H2RAs	
Cimetidine	300 mg IV loading dose followed by 50 mg/h as a continuous infusion[a] or 300 mg IV every 6-8 hours
Ranitidine	6.25 mg/h as a continuous infusion or 50 mg IV every 6-8 hours
Famotidine	1.7 mg/h as a continuous infusion or 20 mg IV every 12 hours
Oral/NG Tube PPIs	
Omeprazole	20-40 mg orally/NG tube[b] every 12-24 hours
Omeprazole/bicarbonate powder for oral suspension	40 mg orally/NG tube to start, then followed by an additional 40 mg in 6-8 hours as a loading dose, and then 40 mg every 24 hours
Lansoprazole	30 mg orally/NG tube[b,c] every 12-24 hours
Pantoprazole	40 mg orally/NG tube[b] every 12-24 hours
Parenteral PPIs	

Drug and Route	Dosage
Pantoprazole	40-80 mg IV every 12-24 hours
Esomeprazole	40 mg IV every 12-24 hours

H_2RA, histamine-2 receptor antagonist; NG, nasogastric; PPI, proton pump inhibitor.

[a]Product is FDA approved for the prevention of stress-related mucosal bleeding.

[b]Administered as an extemporaneously compounded suspension made with sodium bicarbonate.

[c]Administered as a rapidly disintegrating tablet given orally or by NG tube dissolved in 10 mL of water.

Even though PPIs have become the most widely used prevention therapy, numerous studies and years of experience support the use of H2RAs, and they remain a recommended option for the prevention of SRMB.[111,116,121,122] Parenteral H2RAs may be administered as either continuous infusions or intermittent bolus doses (see Table 33-15). Cimetidine, given as a continuous IV infusion, is the only FDA-labeled H_2RA for the prevention of SRMB. Drug interactions are more common with cimetidine, thus the other H2RAs (famotidine, ranitidine) are used more frequently.[111,116] Adverse events associated with the use of H2RAs for the critically ill patient include thrombocytopenia, mental status changes (more common in older patients or individuals with renal or hepatic compromise), and tachyphylaxis (especially with parenteral or high-dose therapy). Given that the H2RAs are renally eliminated, dosage reductions are recommended for patients with renal dysfunction.[116]

When deciding on the most appropriate pharmacotherapy plan for the prevention of SRMB for a specific patient, the clinical presentation of the patient and medication costs should be used as a guide. Patients who can take oral medication or have a working NG tube in place may be placed on an oral H_2RA or PPI suspension as a cost-effective measure. For most patients who are not able to utilize one of these routes, an IV H_2RA is appropriate. However, if the patient has any relative or absolute contraindications to an H_2RA, then an IV PPI may be the most appropriate prophylaxis option.

Improvement in the patient's overall medical condition (resolution of risk factors, discharge from the ICU, extubation, and oral intake) suggests that prophylactic therapy can be discontinued. Often patients are continued on SRMB prophylaxis on transition to the general medical/surgical unit and are often discharged on oral PPI therapy without an appropriate indication. This results in unnecessary costs for the patient and the healthcare system.[122,123] Patients in whom SRMB prophylaxis is no longer indicated should be identified. If a patient develops clinically important bleeding, endoscopic evaluation of the GI tract is indicated along with aggressive antisecretory therapy (see "Peptic Ulcer–Related Bleeding" above).

Clinical Controversy…

The precise role of enteral nutrition as a sole modality to prevent SRMB remains controversial. Two meta-analyses suggest that patients receiving enteral nutrition may not require SRMB prophylaxis thus preventing adverse complications of these therapies. However, more randomized-controlled trials are needed to confirm benefit.

Zollinger-Ellison Syndrome

ZES, characterized by hypersecretion of gastric acid and severe gastroesophageal PUD, is caused by a neuroendocrine tumor (gastrinoma) that is present in the duodenum or pancreas.[124,125,126,127] Gastrinoma has a yearly incidence of approximately one to three cases per million in the United States with ZES being the underlying cause of PUD in 0.1% to 1% of patients.[126] ZES occurs spontaneously in 75% to 80% of patients, but 20% to 25% of patients have the familial form associated with multiple endocrine neoplasia type 1 (MEN1), an autosomal-dominant syndrome due to defects in the *MEN1* gene.[125,126] MEN1 patients commonly develop hyperparathyroidism, pituitary adenomas, and neuroendocrine tumors. Half (50%) of patients with MEN1 have ZES making gastrinoma and ZES the most common functional neuroendocrine tumor and syndrome in MEN1.[125,126] Gastrinomas are usually slow growing, but approximately 60% to 90% are malignant with metastases to regional lymph nodes, liver, and other distant sites at time of diagnosis.[126]

Pathophysiology

Gastrinomas are derived from the enteroendocrine cells, form tumors mainly in the pancreas and proximal small intestine, and are generally classified under the larger term of neuroendocrine tumors. Most gastrinomas arise in the duodenum. Gastrinomas located in the pancreas carry a greater malignant potential.[127] ZES pathophysiology is related to the trophic action of gastrin on parietal cells of the gastric antrum and the resulting hypersecretion of gastric acid. A majority of patients consequently develop large peptic ulcers frequently in the distal duodenum and even proximal jejunum which is an uncommon location for ulcers resulting from *H. pylori* or the use of NSAIDs.[127]

Clinical Presentation and Diagnosis

Historically, patients with ZES presented with refractory PUD or complications of acid hypersecretion (perforation, penetration, bleeding, and esophageal stricture). Due to the widespread use of PPIs and H2RAs, this form of presentation has decreased drastically.[125] Currently, patients commonly present with severe refractory heartburn, epigastric pain, and profound diarrhea. Diarrhea maybe the only symptom in 10% to 20% of patients and is due to the osmotic load of high gastric acid, inhibition of sodium and water reabsorption by the intestinal brush border of high gastric acid secretion, and a malabsorptive component from inactivation of pancreatic digestive enzymes by gastric acid.[125,127]

ZES diagnosis is established when the serum gastrin is greater than 1,000 pg/mL (ng/L; greater than 481 pmol/L) and the basal acid output (BAO) is more than or equal to 15 mEq/h (more than or equal to 15 mmol/h) for patients with an intact stomach (BAO more than or equal to 5 mEq/h [greater than or equal to 5 mmol/h] for patients with previous gastric surgery) or when hypergastrinemia is associated with a gastric pH value of more than or equal to 2.[126,127] In situations in which the serum gastrin is between 100 and 1,000 pg/mL (ng/L; 48 and 481 pmol/L) and gastric pH is less than or equal to 2, a secretin or calcium proactive test is used to aid the diagnosis. Identification of the location of the tumor with imaging techniques is essential, as early surgical resection prior to liver metastases is often curative.[124,125,126,127] The widespread use of PPIs, although effective in reducing symptoms, may mask the clinical presentation and PPI-related hypergastrinemia may further complicate the diagnosis.[124,125]

Treatment

Historically, only total gastrectomy was effective at controlling gastric acid hypersecretion. With the development of H2RAs and PPIs, medical management of ZES is now feasible in almost all patients. Because of their long duration of action and potency, PPIs are now the drugs of choice for treating gastric acid hypersecretion in patients with ZES.[124,125,126] Many of the PPIs (omperazole, esomeprazole, lansoprazole, esomeprazole, rabeprazole, and pantoprazole) are effective in ZES. Initial doses of 80 mg/day for pantoprazole (or an equivalent dose of other available PPIs) given every 8 to 12 hours is most effective at controlling gastric acid hypersecretion and reliving symptoms. IV PPIs can be used for those patients who do not tolerate oral therapy. PPIs must be dose adjusted in patients with ZES to normalize BAO levels to less than 15 mEq/h (less than 15 mmol/h) or less than 5 mEq/h (5 mmol/h) in patients with reflux esophagitis or prior operations to reduce acid secretion, such as subtotal gastrectomy. PPI therapy can be gradually decreased after adequate control of hypersecretion is achieved.[124,125,126] Since 60% to 90% of gastrinomas are malignant, management of advanced disease may include surgical resection of primary and metastatic gastrinomas. Nonsurgical therapy may include treatment with chemotherapy, somatostatin analogues such as octreotide, interferon, and targeted-molecular therapies such as a mTor inhibitor (everolimus) or a tyrosine-kinase inhibitor (sunitinib).[124,125,126]

ACKNOWLEDGMENT

This chapter is a revision of the chapter on Peptic Ulcer Disease in the 8th edition written by Rosemary R. Berardi and Randolph V. Fugit.

Chapter 34: Inflammatory Bowel Disease

Brian A. Hemstreet

INTRODUCTION

KEY CONCEPTS

- 1 The exact cause of inflammatory bowel disease (IBD) is unknown. Proposed causes include infectious, genetic, and environmental factors, as well as immune dysregulation.
- 2 Ulcerative colitis (UC) is confined to the rectum and colon, causes continuous lesions, and affects primarily the mucosa and the submucosa. Crohn's disease (CD) can involve any part of the GI tract, often causes discontinuous (skip) lesions, and is a transmural process that can result in fistulas, perforations, or strictures.
- 3 Common GI complications of IBD include rectal fissures, fistulas (CD), perirectal abscess (UC), toxic megacolon (UC), and colon cancer. Extraintestinal manifestations include hepatobiliary complications, arthritis, uveitis, skin lesions (including erythema nodosum and pyoderma gangrenosum), osteoporosis, anemia, and aphthous ulcerations of the mouth.
- 4 The severity of UC may be assessed by stool frequency, presence of blood in stool, fever, pulse, hemoglobin, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), abdominal tenderness, and radiologic or endoscopic findings. The severity of CD can be assessed using similar parameters, in addition to the CD Activity Index, which includes stool frequency, presence of blood in stool, endoscopic appearance, and physician's global assessment.
- 5 The goals of IBD treatment are resolution of acute inflammation and complications, alleviation of systemic manifestations, maintenance of remission, and improvement in quality of life (QOL).
- 6 The first line of treatment for mild to moderate extensive UC consists of oral aminosalicylates (ASAs) with oral controlled release budesonide as an alternative. Mesalamine or corticosteroid enemas or suppositories may be used for distal disease. Mesalamine is less effective for CD; however, certain delayed-release oral formulations of mesalamine may be used for Crohn's ileitis. Controlled-release budesonide is preferred as a first-line agent for CD

confined to the terminal ileum and/or ascending colon.

- 7 Systemic corticosteroids are often required for acute UC or CD. The duration of steroid use should be minimized and the dose tapered gradually over 3 to 4 weeks.

- 8 Infliximab, adalimumab, and golimumab are treatment options for patients with moderate to severe active UC and for those patients with UC who are corticosteroid dependent. Azathioprine or mercaptopurine may be used for maintenance of remission in UC as an alternative to or in combination with tumor necrosis factor-alpha (TNF-α) inhibitors, and in patients failing ASAs or with corticosteroid dependency. Vedolizumab may be used for patients failing TNF-α inhibitors.

- 9 IV continuous infusion of cyclosporine may be effective in treating severe colitis that is refractory to corticosteroids as an option to delay or prevent the need for surgery.

- 10 Aminosalicylates may prevent recurrence of acute UC in many patients, while corticosteroids are ineffective for this purpose.

- 11 Treatments for CD include infliximab, adalimumab, and certolizumab (for moderate to severe or fistulizing disease as both induction and maintenance therapies); methotrexate, azathioprine, or mercaptopurine (for inadequate response or to reduce steroid dosage and in combination with TNF-α inhibitors); metronidazole (for perineal or colonic disease); natalizumab or vedolizumab (for patients failing TNF-α antagonists); and cyclosporine (for refractory disease).

There are two forms of idiopathic inflammatory bowel disease (IBD): (a) ulcerative colitis (UC), a mucosal inflammatory condition confined to the rectum and colon, and (b) Crohn's disease (CD), a transmural inflammation of the GI tract that can affect any part, from the mouth to the anus.

EPIDEMIOLOGY

Inflammatory bowel disease is most prevalent in Western countries and in areas of northern latitude.[1] Rates of IBD are highest in North America, Northern Europe, and Great Britain.[1,2] The incidence of IBD is increasing worldwide.[2,3] CD has an incidence of 6 to 15.5 cases per 100,000 persons per year and a prevalence of 3.6 to 214 per 100,000 people per year.[1,2] The incidence of UC ranges from 1.2 to 20 cases per 100,000 persons per year with a prevalence of 7.6 to 246 per 100,000 persons per year.[1] Although most epidemiologic studies combine ulcerative proctitis with UC, 17% to 49% of cases are classified as proctitis.

Both sexes are affected somewhat equally with IBD, although 20% to 30% more women are affected with CD and slightly more males (60%) are affected with UC.[2] Both UC and CD have bimodal distributions in age of initial presentation. The peak incidence generally occurs in the second (CD) or third (UC) decade of life, with a second peak occurring between 60 and 70 years of age.[1,2,3] A higher

incidence of IBD occurs in the Jewish population, while black and Asian populations have a relatively similar, and possibly lower, incidence of IBD.[2]

ETIOLOGY

1 The exact etiology of UC and CD is unknown; however, there are similar factors believed responsible for both conditions. The major theories behind the cause of IBD involve a combination of infectious, genetic, environmental, and immunologic factors. This may involve abnormal regulation of the innate immune response or a reaction to various antigens.[4,5,6] The microflora of the GI tract may provide an environmental trigger to activate inflammation and are highly implicated in the development of IBD.[5,6]

Infectious Factors

Microorganisms are proposed to be a major factor in the initiation of inflammation in IBD. In general, there is thought to be shift toward the presence of more proinflammatory bacteria in the GI tract, often referred to as dysbiosis.[4,7] However, no one definitive infectious cause of IBD has been found. Patients with IBD have an increased density of intestinal microbiotica compared with those without IBD, including increased numbers of mucus, mucosal, and intraepithelial bacteria.[1,4] The development and composition of the intestinal microbiotica may be influenced by dietary factors.[5] The pathogenesis of IBD may involve a loss of tolerance toward normal GI bacterial flora.[1] Other supporting evidence for an infectious etiology are that colitis does not appear to occur in genetically altered germ-free animals, intestinal lesions in IBD predominate in areas of highest bacterial exposure, and differences are observed in the makeup of the resident luminal and mucosal bacterial flora in healthy subjects versus those with IBD.[7,8]

Microorganisms may play a key role in the development of IBD. Suspect infectious agents include viruses, protozoans, mycobacteria such as *Mycobacterium paratuberculosis* or *avium*, and other bacteria such as *Ruminococcus gnavus*, *Ruminococcus torques*, *Listeria monocytogenes*, *Chlamydia trachomatis*, and *Escherichia coli*.[4,5,6,7,8,9] Patients with CD typically have circulating antibodies to *Saccharomyces cerevisiae*, which demonstrates some immunologic response to intestinal organisms.[4] Bacterial gene products may promote alteration of the intestinal barrier while bacterial antigens or ligands may include and propagate the inflammatory response.[4,5,10]

Genetic Factors

Genetic factors play a significant role in the predisposition to IBD. Studies of monozygotic twins demonstrate a high concordance rate of IBD in both individuals (particularly CD).[1,11] First-degree relatives of patients with IBD may have up to a 20-fold increase in the risk of disease and risk is extended to second and third degree relatives.[4,12] Several genetic markers and loci have been identified that occur more frequently in patients with IBD. Genes may not act independently, but rather function in an integrated manner. This is referred to as the “limited pathway model.”[4] The

nucleotide-binding oligomerization domain protein 2 (NOD2), a key component involved in pathogen recognition in the innate immune system, is the major contributor of genetic predisposition to CD.[11,12] Other genes involved in the innate immune system autophagy, such as ATG16L1 and IRGM, as well as genes involved in the interleukin (IL) biologic pathway such as polymorphisms of the IL-23 receptor IL-23R, and IL-12B, STAT3, and CCR6, are strongly associated with CD and possibly UC (IL-23R).[1,10,11,12] The major genetic region for UC is on chromosome 6p21, in the major histocompatibility region, near human leukocyte antigen (HLA) class II genes.[11] Alterations in the genes encoding for IL-10 and the IL-10 receptor have been implicated in UC.[11,12] Other possible high-risk loci involved in epithelial barrier function, such as ECM1, HNF4A, CDH1, and LAMB1, and Th1 and Th17, involved with helper T-cell types, are implicated in the pathophysiology of UC.[1] Lastly, an emerging area of interest in IBD pathogenesis is in the role of microRNAs, which are small noncoding RNAs that regulate gene expression.[15]

Immunologic Mechanisms

The immune system plays a critical role in the pathogenesis of IBD. Potential immunologic mechanisms include both autoimmune and nonautoimmune phenomena. The innate immune system largely involves the intestinal wall epithelial barrier and its associated secretions in response to contact with organisms.[4] NOD proteins (for recognition of organisms) and toll-like membrane receptors (TLRs) are involved in intestinal surveillance and can lead to release of antibacterial peptides such as defensins, among other functions.[4] Reduction in defensin secretion by Paneth cells is thought to be one contributing factor in the loss of effective barrier function.[4,10] Consequently, the bowel wall in CD is infiltrated with lymphocytes, plasma cells, mast cells, macrophages, and neutrophils, often leading to formation of granulomas. Similar infiltration has been observed in the colonic mucosal layer in patients with UC. Given that inflammation is limited to the colon in UC, dysfunction of colonocytes is highly implicated.[1] The colonic mucosal layer in UC may be thinner and less effective in protecting the epithelial cells. This may be due to reduced mucin secretion secondary to defective goblet cell differentiation.[4,10,14] Autoimmune features may be directed against mucosal epithelial cells or against neutrophil cytoplasmic elements.

Antineutrophil cytoplasmic antibodies are found in a high percentage of patients with UC (70%) and less frequently in CD.[6,14] Circulating antibodies to goblet cells and anti-tropomyosin are present in UC, although their contribution to the disease process is not fully elucidated.[10] Overproduction of circulating IgG1 antibodies in UC may react with epithelium in the eyes, skin, joints, and biliary tract.[1] Dysfunction or reduced expression of the peroxisome proliferator–activated receptor γ in colonocytes may play a role in this process.[1]

Dysregulation of cytokines is a key component of IBD. Specifically, Th1 cytokine activity is excessive in CD and increased expression of interferon-γ in the intestinal mucosa and production of IL-12 production are features of the immune response in CD.[6,10] In contrast, Th2 cytokine activity is excessive with UC.[1,14,16] This is mediated by excess production of IL-13, which contributes to epithelial cell dysfunction by enhancing natural killer T-cell cytotoxicity, and IL-5, which is involved

with eosinophil recruitment and activation.[1,10,14] Upregulation of the IL-13 receptor-2α occurs as well.[1,10,14,16] Activated epithelial cells secrete a variety of substances involved in the recruitment of inflammatory cells. These include IL-1β, epithelial neutrophil-activating peptide 78, IL-8, and monocyte chemoattractant protein 1.[1] Neutrophils produce proteolytic enzymes, such as matrix metalloproteinase-8 and neutrophil elastase, which further contribute to epithelial damage.[14]

Lastly, tumor necrosis factor-alpha (TNF-α) is a pivotal proinflammatory cytokine that is increased in the mucosa and intestinal lumen of patients with CD and UC. TNF-α can recruit inflammatory cells to inflamed tissues, activate coagulation, promote the formation of granulomas in patients with CD, and possibly modify epithelial cell apoptosis.[1,14,16]

Psychological Factors

Mental health changes, particularly stress, appear to possibly correlate with disease flares in IBD, but whether psychological factors are true etiologic factors in the pathophysiologic process is unclear.[17,18,19] Given the complex nature of the disease process and lack of standard measurement processes, documenting the effects of stress in IBD is difficult.[18] Some studies demonstrate that perceived stress and negative mood is significantly different between patients in remission and those experiencing a disease flare.[18,19] Mood-related components, such as anxiety and depression, may contribute to exacerbations of CD.[20] Approximately 50% of patients with IBD reported some type of significant stress during any 3-month period.[21] Additionally, subjects with IBD matched by sex, age, and geographic region to control subjects reported significantly worse psychological well-being and more distress compared with controls.[22] Stress-related interventions in another study did not appear to alter disease course for patients with IBD, but may result in improved quality of life (QOL).[23] While stress and psychological factors may not be a direct cause of IBD, they may significantly affect QOL. This is compounded by the fact that many patients are young at the time of diagnosis, and may require surgical intervention and temporary or permanent ostomy placement.[24]

Lifestyle, Dietary, and Drug-Related Causes

Several theories regarding dietary influence on the development of IBD have been proposed. Intake of refined sugars has been associated with development of CD, while increased protein intake has been associated with a higher risk of developing IBD.[13] Diet composition may directly influence the makeup of the gut microbiotica, possibly triggering IBD.[25,26] The “hygiene hypothesis” proposes that cleaner conditions in more industrialized countries expose patients to fewer microorganisms at an early age. The immune response to these organisms is altered when encountered later in life.[13,26] Diets low in fruits and vegetables and high in ω-6 polyunsaturated fats have been suggested to increase the risk of CD.[25] Changes in expression of the aryl hydrocarbon receptor, a transcription factor activated by dietary ligands and involved in the maintenance of the innate immune response, may increase development of IBD.[27] Recent interest has arisen in vitamin D deficiency as a possible cause of IBD given that vitamin D is involved with NOD2 gene induction.[28]

Smoking plays an important but contrasting role in UC and CD. It appears to be protective for UC and is associated with fewer disease flare-ups and reduced disease severity. The risk of developing UC is increased for 2 to 3 years after smoking cessation in patients without IBD.[24] In contrast, smoking is associated with increased frequency and severity of CD, and appears to worsen ileal disease more than colonic.[25] Patients with CD who stop smoking have a disease severity that is similar to nonsmokers. Smoking cessation should be offered to all patients. There are data to support transdermal nicotine replacement as an adjunctive therapy in UC.[29]

Use of nonsteroidal anti-inflammatory drugs (NSAIDs) may trigger disease occurrence or lead to disease flares.[25,30,31] Inhibition of prostaglandin production through cyclooxygenase inhibition may impair mucosal barrier protective mechanisms. Alteration in platelet function, release of inflammatory mediators, and alteration in the microvascular response to stress are other potential mechanisms of worsening of IBD. Cyclooxygenase-2 inhibitors and cyclooxygenase-1 inhibitors increase risk; however, it is unclear whether cyclooxygenase-2 inhibitors may be safer in select patients with IBD.[2] A large cohort study in U.S. women revealed an increase in risk of developing IBD with NSAID use; however, no association was found with use of aspirin.[30] Use of NSAIDs may be warranted in some patients with IBD, particularly those with arthritic symptoms, if the benefit outweighs the potential risk of disease flare.

An association with development of IBD following use of antibiotics has been found, but a direct causal relationship remains unclear.[25,31] Since antibiotics alter the intestinal flora, this appears to be a viable mechanism; however, delineating antibiotics as a causative factor is difficult given that symptoms may not manifest for several weeks to years following a treatment course. Furthermore, antibiotics may induce *Clostridium difficile* infection, which is a cause of colitis.[25,31] Patients presenting with severe diarrhea for whom a diagnosis of IBD is being entertained should be asked about recent antibiotic use.

Oral contraceptives and isotretinoin have been implicated in the development of IBD as well.[25,32]

PATHOPHYSIOLOGY

Ulcerative colitis and CD differ in two general respects: the extent and distribution of inflammation within the GI tract and depth of involvement within the bowel wall. A small fraction of patients have features of both diseases. Confusion can occur, particularly when the inflammation is limited to the colon. For patients in whom it cannot be determined whether they have UC or CD, they are often classified as indeterminate colitis.[1] **Table 34-1** compares pathologic and clinical findings of the two diseases.

TABLE 34-1 Comparison of the Clinical and Pathologic Features of Crohn's Disease and Ulcerative Colitis

Feature	Crohn's Disease	Ulcerative Colitis
Clinical		
Malaise, fever	Common	Uncommon

Feature	Crohn's Disease	Ulcerative Colitis
Rectal bleeding	Common	Common
Abdominal tenderness	Common	May be present
Abdominal mass	Common	Absent
Abdominal pain	Common	Unusual
Abdominal wall and internal fistulas	Common	Absent
Distribution	Discontinuous	Continuous
Aphthous or linear ulcers	Common	Rare
Pathologic		
Rectal involvement	Rare	Common
Ileal involvement	Very common	Rare
Strictures	Common	Rare
Fistulas	Common	Rare
Transmural involvement	Common	Rare
Crypt abscesses	Rare	Very common
Granulomas	Common	Rare
Linear clefts	Common	Rare
Cobblestone appearance	Common	Absent

Ulcerative Colitis

2 Ulcerative colitis is confined to the rectum and colon and affects the mucosal and the submucosal layers. In some instances, a short segment of terminal ileum may be inflamed; this is referred to as *backwash ileitis*. Unlike CD, the deeper longitudinal muscular layers, serosa, and regional lymph nodes are not usually involved.[1] Fistula, perforation, or obstruction is uncommon because this is a superficial inflammation.

In UC, abscess formation in the crypts of the mucosa occurs (crypts of Lieberkuhn) secondary to infiltration of lymphocytes, plasma cells, and granulocytes.[1] Crypt abscesses are usually visible only with microscopy but may be visible when coalescence results in ulceration. Reduced crypt density, distorted crypt architecture and atrophy, and depletion of goblet cells are typical findings.[1,33] Extension and coalescence of ulcers may surround areas of uninvolved mucosa, causing *pseudopolyp* formation. Mucosal damage and friability in UC can result in significant diarrhea and bleeding, although a small percentage of patients experience constipation.

3 Complications of UC may be local, including hemorrhoids, anal fissures, or perirectal abscesses, and are more likely to be present during active colitis. Extraintestinal manifestations (not directly associated with the colon) may occur and are discussed later.

A major complication is toxic megacolon, which is a segmental or total colonic distension of greater

than 6 cm with acute colitis and signs of systemic toxicity.[1,34] It occurs in up to 7.9% of UC patients admitted to hospitals and results in death rates of up to 50%. With toxic megacolon, ulceration extends below the submucosa, sometimes reaching the serosa. Vasculitis, swelling of the vascular endothelium, and thrombosis of small arteries occur. Involvement of the muscularis propria causes loss of colonic tone, leading to dilation and potential perforation. Patients typically have a high fever, tachycardia, distended abdomen, elevated white blood cell count, and a dilated colon observed on x-ray.[7,34] Colonic perforation may occur with or without toxic megacolon and is a greater risk with the first episode. Another infrequent major complication is massive colonic hemorrhage. Colonic stricture, sometimes with clinical obstruction, may also complicate long-standing UC.

The risk of colonic dysplasia with transition to colorectal carcinoma (CRC) is fivefold greater for patients with chronic UC with colonic involvement compared with the general population.[35] Patients with ulcerative proctitis or proctosigmoiditis are generally not considered to be at increased risk.[35,36] The cumulative risk of developing CRC in patients with chronic UC may be as high as 20% to 30% at 30 years.[1] Risk factors for CRC include young age at onset (<50 years), severe inflammation, a positive family history, and presence of primary sclerosing cholangitis (PSC) or inflammatory polyps.[1,35,36] Screening colonoscopy with multiple biopsies should be performed at 8 years after onset of symptoms in patients with left-sided or extensive colitis, with subsequent screenings at 1 to 2 years if negative.[36] Patients with PSC should undergo yearly colonoscopy.[36]

Crohn's Disease

Crohn's disease is characterized as a transmural inflammatory process. The terminal ileum is the most common site of the disorder, but it may occur in any part of the GI tract from mouth to anus.[37,38] Patients often have normal bowel separating segments of diseased bowel resulting in discontinuous disease. The mesentery first becomes thickened and edematous, and then fibrotic. Ulcers are typically deep and elongated and extend along the longitudinal axis of the bowel, at least into the submucosa. The "cobblestone" appearance of the bowel wall results from deep mucosal ulceration intermingled with nodular submucosal thickening.

Bowel wall injury is generally extensive, and the intestinal lumen is often narrowed. Small bowel stricture and subsequent obstruction is a complication that may require surgery. Fistula formation is also common, occurring much more frequently than with UC, and is reported as a 20% to 40% lifetime risk in CD.[37] Fistulas often occur in highly inflamed areas, where loops of bowel become matted together by fibrous adhesions. Fistulas may connect a segment of the GI tract to skin (enterocutaneous), two segments of the GI tract (enteroenteric), or the intestinal tract with the bladder (enterovesicular) or vagina. Fistulae associated with CD frequently require surgical treatment.

Bleeding with CD is usually not as severe as with UC, although patients with CD may develop hypochromic anemia. The risk of carcinoma is increased but not as greatly as with UC.[36]

Nutritional deficiencies are common with CD.[39,40] Reported deficiencies include folate, vitamin B_{12}, vitamins A-D, calcium, magnesium, iron, and zinc.[40] Major contributing factors include decreased

food intake, intestinal loss, malabsorption, hypermetabolic state, drug-nutrient interactions, and those receiving long-term total parenteral nutrition.[40]

Extraintestinal Manifestations of IBD

Both forms of IBD are associated with development of symptoms and organ involvement outside of the GI tract referred to as extraintestinal manifestations.

Hepatobiliary Complications

Approximately 11% of patients with UC are reported to have hepatobiliary complications with overall frequencies ranging from 5% to 95% for patients with IBD.[1,41,42] Hepatic complications include fatty liver, pericholangitis, autoimmune hepatitis, and cirrhosis. Biliary complications include PSC, cholangiocarcinoma, and cholelithiasis.[1,41]

Fatty infiltration of the liver may result from malabsorption, protein-losing enteropathy, or corticosteroid use. Pericholangitis (acute inflammation surrounding the intrahepatic portal venules, bile ducts, and lymphatics) occurs in up to one third of UC patients. PSC is associated with progressive fibrosis of intrahepatic and extrahepatic bile ducts in 3% to 7% of patients with UC.[41] Cirrhosis may result from cholangitis or chronic active hepatitis. Often the severity of hepatic disease does not correlate with GI disease activity. Gallstones occur in 13% to 34% of patients with CD (particularly with terminal ileal disease) and are related to bile salt malabsorption.[41]

Joint Complications

Arthritis in IBD is typically asymmetric (unlike rheumatoid arthritis) and migratory, involving one or a few usually large joints. The severity parallels IBD disease activity.[1,42] Arthritis may be peripheral or axial in nature and includes sacroiliitis, ankylosing spondylitis, and IBD-associated spondyloarthropathy. Patients positive for HLA-B27 often exhibit axial arthropathy, such as ankylosing spondylitis. Rheumatoid factors are generally not detected and the arthritis is nondeforming and nondestructive. Patients may exhibit enthesopathy, tenosynovitis, or dactylitis.[42]

Ocular Complications

Ocular complications including iritis, uveitis, episcleritis, and conjunctivitis occur in up to 2% to 29% of patients with IBD.[1,42] Commonly reported symptoms with iritis and uveitis include blurred vision, eye pain, and photophobia. Episcleritis is associated with scleral injection, burning, and increased secretions. These complications may parallel the severity of intestinal disease, and recurrence after colectomy with UC is uncommon.

Dermatologic and Mucocutaneous Complications

Skin and mucosal lesions associated with IBD include erythema nodosum, pyoderma gangrenosum, aphthous ulceration, and Sweet's syndrome.[42] Raised, red, tender nodules on the tibial surfaces of

the legs and arms that vary in size from 1 cm to several centimeters are manifestations of erythema nodosum, and may occur in 2% to 20% of patients with IBD.[42] These lesions are more commonly observed in CD patients and often correlate with disease severity.

Pyoderma gangrenosum occurs in 0.5% to 2% of patients with IBD and is characterized by discrete skin ulcerations that have a necrotic center and a violaceous color of the surrounding skin.[1,42] They can be seen on any part of the body but commonly occur on the lower extremities.

Oral lesions are found in 4% to 20% of patients with IBD.[37,42] The most common lesion seen with CD is aphthous stomatitis. The severity of these lesions tends to parallel the disease course. Sweet's syndrome, also known as acute febrile neutrophilic dermatosis, is characterized by tender erythematous skin lesions secondary to dermal neutrophil infiltration, and is often associated with fever and a distribution on the upper trunk, face, neck, and arms.[42]

Hematologic, Coagulation, and Metabolic Abnormalities

Patients with IBD may develop anemia, with a prevalence reported up to 74%.[1,40,42] The anemia may present as iron deficiency related to chronic blood loss, ongoing inflammation, malnutrition, hemolysis, or bone marrow suppression from drug treatment.[40,42] Alternatively, it may be more characteristic of anemia of chronic disease secondary to chronic inflammation and overproduction of cytokines. Patients with IBD are at a 1.5 to 3.6 times higher risk of venous thromboembolism (VTE) compared with the general population.[43] This is secondary to activation of the clotting cascade and platelet activation secondary to inflammation.[42,43] Occurrence of VTE is higher during disease flares and occurs more often in peripheral veins.[1,43] Patients should be considered for pharmacologic VTE prophylaxis when admitted to the hospital for a disease flare. Patients with IBD may be at increased risk for metabolic bone disease and development of osteoporosis. Osteomalacia is less common in IBD.[42,44] Bone disease may be related to a combination of nutritional deficiencies, especially calcium and vitamin D, chronic cytokine-related inflammatory effects on bone, disease-associated hypogonadism, and use of corticosteroids.[42,44]

CLINICAL PRESENTATION

The patterns of clinical presentation of IBD can vary widely. Patients may have a single acute episode that resolves and does not recur, but most patients experience acute flares with alternating periods of remission.

Ulcerative Colitis

There is a wide range of presentation in UC, ranging from mild abdominal cramping with frequent small-volume bowel movements to profuse diarrhea (**Table 34-2**). Most patients with UC experience intermittent bouts of illness after varying intervals of remission with symptoms. A small percentage of patients have continuous unremitting symptoms or a single acute attack with no subsequent symptoms.

TABLE 34-2 Clinical Presentation of Ulcerative Colitis

Signs and symptoms

- Abdominal cramping
- Frequent bowel movements, often with blood in the stool
- Weight loss
- Fever and tachycardia in severe disease
- Blurred vision, eye pain, and photophobia with ocular involvement
- Arthritis
- Raised, red, tender nodules that vary in size from 1 cm to several centimeters

Physical examination

- Hemorrhoids, anal fissures, or perirectal abscesses may be present
- Iritis, uveitis, episcleritis, and conjunctivitis with ocular involvement
- Dermatologic findings with erythema nodosum, pyoderma gangrenosum, or aphthous ulceration

Laboratory tests

- Decreased hematocrit/hemoglobin
- Increased ESR or CRP
- Leukocytosis and hypoalbuminemia with severe disease
- (+) perinuclear antineutrophil cytoplasmic antibodies

4 While various disease classifications are available for UC, a standard disease severity scoring system is not universally accepted.[45] The arbitrary distinctions of mild, moderate, severe, and fulminant disease activity are generally used in treatment guideline recommendations, and are determined largely by clinical signs and symptoms:[1,33,45]

1. Mild: Fewer than four stools daily, with or without blood, with no systemic disturbance and a normal erythrocyte sedimentation rate (ESR)
2. Moderate: More than four stools per day but with minimal systemic disturbance
3. Severe: More than six stools per day with blood, with evidence of systemic disturbance as shown by fever, tachycardia, anemia, or ESR of greater than 30 mm/h (8.3 µm/s)

4. Fulminant: More than 10 bowel movements per day with continuous bleeding, toxicity, abdominal tenderness, requirement for transfusion, and colonic dilation

With severe disease, the patient typically has profuse bloody diarrhea with a high fever, leukocytosis, and hypoalbuminemia. The patient may be dehydrated with tachycardia and hypotension. This presentation may have a sudden onset with rapid progression.

Determining disease extent, that is, which sections of the colon are involved, is important. This is accomplished via endoscopy. Patients with "distal" disease have inflammation limited to areas distal to the splenic flexure (also referred to as *left-sided* disease), while those with "extensive disease" have inflammation extending proximal to the splenic flexure.[1,33] Inflammation confined to the rectal area is referred to as *proctitis*, while disease involving the rectum and sigmoid colon is referred to as *proctosigmoiditis*. Inflammation of the majority of the colon is called *extensive disease*, sometimes referred to as *pancolitis*.

The diagnosis of UC is made on clinical suspicion and confirmed by biopsy, stool examinations, sigmoidoscopy or colonoscopy, or barium radiographic contrast studies. The presence of extracolonic manifestations may also aid in establishing the diagnosis.[1,33,42]

Crohn's Disease

As with UC, the presentation of CD is highly variable. The time between the onset of complaints and the initial diagnosis may be as long as 3 years. The patient typically presents with diarrhea and abdominal pain. Hematochezia occurs in about one half of patients with colonic involvement and much less frequently when there is no colonic involvement. A patient may first present with a perirectal or perianal lesion (**Table 34-3**). The diagnosis should also be suspected in children with growth retardation, especially with abdominal complaints.

TABLE 34-3 Clinical Presentation of Crohn Disease

Signs and symptoms
• Malaise and fever
• Abdominal pain
• Frequent bowel movements
• Hematochezia
• Fistula
• Weight loss and malnutrition
• Arthritis
Physical examination

- Abdominal mass and tenderness
- Perianal fissure or fistula

Laboratory tests

- Increased white blood cell count, ESR, and CRP
- (+) anti–*Saccharomyces cerevisiae* antibodies

Much like UC, global classification guidelines for scoring severity of active CD are not available. For patients with luminal nonfistulizing CD, the Crohn's Disease Activity Index (CDAI) is used most often to gauge response to therapy and determine remission and is employed mostly in the research setting.[46] This score system ranges from 0 to 600, with score great than 150 defined as active disease. The Harvey-Bradshaw Index (HBI) is another scoring system that is also used for CD, and tends to correlate well with the CDAI.[46] A decrease of 3 points in the HBI is defined as a clinical response with complete remission defined as a score of less than 4. Treatment guidelines use the presence of signs and symptoms as their marker for disease activity and severity.[37] Patients with mild to moderate CD are typically ambulatory and have no evidence of dehydration, systemic toxicity, loss of body weight, or abdominal tenderness, mass, or obstruction. Moderate to severe disease is considered in patients who fail to respond to treatment for mild to moderate disease or those with fever, weight loss, abdominal pain or tenderness, vomiting, intestinal obstruction, or significant anemia. Severe to fulminant CD is classified as the presence of persistent symptoms or evidence of systemic toxicity despite corticosteroid or biologic treatment or presence of cachexia, rebound tenderness, intestinal obstruction, or abscess. Disease activity may be assessed and correlated by evaluation of serum C-reactive protein (CRP) concentrations.

The course of CD is characterized by periods of remission and exacerbation. Patients may be symptom-free for years, while others experience chronic symptoms in spite of medical therapy. As with UC, the diagnosis of CD involves a thorough evaluation using laboratory, endoscopic, and radiologic testing to detect the extent and characteristic features of the disease. Small bowel involvement, strictures detected on radiographs, and presence of fistulae are characteristic of CD. A clinical decision support tool which contains recommendations and algorithms for initial laboratory, radiologic, and physical assessment of CD, has been published by the American Gastroenterological Association and is available for use on their website.[47]

TREATMENT

Desired Outcomes

5 The clinician must have a clear concept of realistic therapeutic goals for each patient with IBD. Goals may relate to resolution of acute inflammatory processes, resolution of complications (eg, fistulae and abscesses), alleviation of extraintestinal manifestations, maintenance of remission, or surgical palliation or cure.

When determining goals of therapy and selecting therapeutic regimens, it is important to understand the natural history of IBD.[1,13,33,37] Some cases of acute UC are self-limited. With mild to moderate acute colitis without systemic symptoms, 20% of patients may experience spontaneous improvement in their disease within a few weeks; however, a small percentage of patients may go on to experience more serious disease. With severe colitis, improvement without treatment cannot be expected. The response to medical management of toxic megacolon is variable and emergent colectomy may be required. When remission of UC is achieved, it is likely to last at least 1 year with medical therapy; however, long-term sustained remission rates are typically less than 50%.[45] In the absence of medical therapy, one half to two-thirds of patients relapse within 9 months.[33]

Approximately 20% of patients with CD will experience a relapse annually.[37] Sustained remission is impacted by response to treatment. Patients remaining in remission for 1 year have an 80% chance of remaining in remission the subsequent year, while 70% of patients will continue to have active disease in the year following a 12-month period in which they had active disease.[37] Thus, inducing and maintaining remission is an important aspect of treatment to improve outcomes and QOL and reduce complications. There has been recent interest in mucosal healing as a more objective end point or goal for the treatment of IBD.[48,49] Mucosal healing is accessed via endoscopy; however, there is not a universal scoring system that has been adopted for either CD or UC. The natural course of the disease may be altered and outcomes improved, such as sustained remission and reduced hospitalization, if mucosal healing is achieved.[48,49] Mucosal healing is directly related to the efficacy of drug therapies used in the treatment of IBD and may be used to determine the need for escalation or de-escalation of drug therapy.[48,49] At this time mucosal healing is a promising end point; however, as more studies incorporate this end point, it can be better determined if this is achievable in all patients, particularly those with CD whose disease typically penetrates below the mucosal layer.

General Approach To Treatment

Treatment of IBD centers on agents used to relieve the inflammatory process and induce disease remission. Aminosalicylates (ASAs), corticosteroids, antimicrobials, immunosuppressive, and biologic agents are commonly used to treat active disease and for some agents to maintain disease remission. The severity and extent of the disease should be taken into account, as this will often dictate the dose, route, frequency, and formulation of drug therapy that will be most effective. Patient preference for different drug formulations and cost of therapies should also be taken into account.

Surgical procedures are sometimes performed when active disease is inadequately controlled with drugs or when the required drug dosages pose an unacceptable risk of adverse effects. Nutritional considerations are also important because many patients may develop malnutrition. A variety of adjunctive therapies may be used to address complications or symptoms of IBD.

Nonpharmacologic Therapy

Nutritional Support

Proper nutritional support is an important aspect of the treatment of patients with IBD. Specific types of diets are not useful in alleviating the inflammatory conditions; however, patients with moderate to severe disease are often malnourished.[39,40,50] Malabsorption or maldigestion may occur secondary to the catabolic effects of the disease process. Elevated activity of IL-6 and TNF-α increases protein turnover, resulting in protein loss and muscle wasting.[40] Malabsorption and malnutrition may occur more often in the patient with CD with involvement of the small bowel, as this is where many nutrients are absorbed.[50] Protein–energy malnutrition and suboptimal weight is reported in up to 85% of patients with CD.[50] Patients who have undergone multiple small bowel resections may have reduction in the absorptive surface of the intestine (ie, "short gut"). Maldigestion with accompanying diarrhea can also occur if there is a bile salt deficiency in the gut.

Many specific diets have been tried to improve nutritional status and symptoms in IBD, but none has gained widespread acceptance. On an individual patient basis, elimination of specific foods that appear to exacerbate symptoms can be tried; however, exclusion diets are generally not endorsed, even in the setting of severe disease.[51] If attempted, the elimination process must be conducted cautiously, as patients may exclude a wide range of nutritious products without adequate justification. Some patients with IBD may have lactase deficiency as well; therefore, diarrhea may be associated with intake of dairy products. For these patients, avoidance of dairy products or supplementation with lactase generally improves the patient's symptoms.[51] Patients with small bowel strictures due to CD should avoid excessive high-residue foods, such as citrus fruits and nuts, in order to prevent obstruction.

The nutritional needs of patients with IBD may be adequately addressed with oral supplementation or use of enteral supplementation in acute or chronic situations.[39,40,50] Use of enteral nutrition has favorable effects on reducing inflammation and intestinal cytokine production.[50] This may lead to a greater chance of induction and maintenance of remission as well as facilitation of mucosal healing, particularly in patients with CD.[50] No specific enteral formula is recommended, so initiation of polymeric feeds may be tried first.[50] Monitoring for efficacy of the enteral feeding is similar to other patient populations receiving enteral nutrition.

Parenteral nutrition has a more limited role in CD or UC. It is generally reserved for patients with severe malnutrition or those who fail enteral therapy or have a contraindication to receiving enteral therapy, such as perforation, protracted vomiting, short-bowel syndrome, or severe intestinal stenosis.[50] Parenteral therapy is not preferred as primary therapy for IBD even in the setting of acute disease flares in hospitalized patients.[51] Home parenteral nutrition may be necessary for patients requiring long-term therapy, particularly those with short-bowel syndrome. Parenteral nutrition is more costly and is associated with more complications, such as serious infections, compared with enteral nutrition.

Given that the intestinal microbiotica may play a key role in IBD pathogenesis, probiotic administration as an adjunctive treatment of IBD has been explored. Postulated mechanisms for using probiotics in IBD include reestablishment of normal bacterial flora within the gut, reduction in bacterial adhesion and competition for nutrients with pathogenic bacteria, production of antibacterial

substances, and promotion of favorable effects on the host immune response.[52,53,54] Probiotic preparations often contain various organisms such as nonpathogenic *E. coli Nissle*, bifidobacteria, lactobacilli, *Streptococcus thermophilus*, *or Saccharomyces boulardii*. Probiotics have demonstrated some effectiveness in inducing and maintaining remission in some trials for patients with UC; however, differences in methodology, probiotics used, and underlying treatments for IBD make comparison of trials difficult.[52,53,54,55,56,57] A formulation of *Bifidobacterium*, lactobacilli, and streptococci (VSL #3) is marketed specifically for use in UC as an adjunctive therapy and for patients who have a surgically constructed ileal pouch anal anastomosis (IPAA) to prevent or treat pouchitis.[33,52,53,54] Use of probiotics as adjunctive agents to avoid stepping up drug therapy to potentially more toxic agents is another potential use.[52] Evidence of probiotic use in the induction and maintenance of CD is less compelling and has led to recommendations not supporting widespread use, but rather further investigation.[52,53,54,55,56,57] While probiotics are considered to be generally safe in patients with IBD, the added cost and requirement to often take multiple doses per day, coupled with the lack of quality data to support their use, should also weigh into the decision to use them in IBD.

Surgery

Despite the availability of medications to treat IBD, many patients will often require surgery. Surgical procedures may involve resection of segments of intestine that are affected, as well as correction of complications (eg, fistulas) or drainage of abscesses.

Rates of colectomy for UC are 5% to 30%.[1,33,58,59] Colectomy may be necessary when the patient has disease uncontrolled by maximum medical therapy or when there are complications of the disease such as colonic perforation, toxic megacolon, uncontrolled colonic hemorrhage, or colonic strictures.[1,33,59] Colectomy may be indicated for patients with long-standing disease (greater than 8-10 years), as a prophylactic measure against the development of CRC, and for patients with premalignant changes (severe dysplasia) on surveillance mucosal biopsies.[35,36,59] Proctocolectomy, after which the patient is left with a permanent ileostomy, is generally considered curative for UC; however, the decision to perform this should take into account the effects on the patient's QOL. Restorative proctocolectomy with construction of an IPAA is the most common surgical procedure performed in UC and is typically well tolerated with a reported failure rate of less than 10%.[59] Patients may develop inflammation of the IPAA, often referred to as pouchitis.[56]

Indications for surgery with CD are not as well established as for UC. Surgery is usually reserved for patients with complications of the disease. A recognized problem with intestinal resection for CD is the high rate of recurrence. Surgery may be appropriate in well-selected patients who have severe or incapacitating disease or obstruction in spite of aggressive medical management. The surgical procedures performed most often include resections of the major intestinal areas of involvement. Patients who undergo multiple resections of the small intestine may develop malabsorption related to short-bowel syndrome. For some patients with severe rectal or perianal disease, particularly abscesses, diversion of the fecal stream is performed with a colostomy. Other indications for surgery include resection of strictures or performance of stricturoplasty, or presence of colon cancer, an

inflammatory mass, intestinal perforation, or fistulas.[37]

Pharmacologic Therapy

Drug therapy plays an integral role in the treatment of IBD. None of the drugs used for IBD are curative; therefore, reasonable goals of drug therapy are resolution of acute disease symptoms and induction and maintenance of remission. The major types of drug therapy used in IBD include ASAs, corticosteroids, immunosuppressive agents (azathioprine, mercaptopurine, cyclosporine, and methotrexate), antimicrobials (metronidazole and ciprofloxacin), and agents to inhibit TNF-α (anti–TNF-α antibodies) or leukocyte adhesion and migration (natalizumab and vedolizumab).[58]

Sulfasalazine is the prototypical ASA, and is composed of a sulfonamide moiety (sulfapyridine) and mesalamine (5-aminosalicylate acid [5-ASA]) joined by a diazo bond in the same molecule.[60] Sulfasalazine has been used for years to treat IBD but was originally intended to treat arthritis. It is cleaved by gut bacteria in the colon to sulfapyridine (which is mostly absorbed and excreted in the urine) and mesalamine (which mostly remains in the colon and is excreted in stool).[60,61,62,63]

The active component of sulfasalazine is mesalamine, which exerts its effects locally in the GI tract; however, the mechanism of action is not completely understood. Beneficial effects of mesalamine may include scavenging of free radicals, inhibition of leukocyte motility, interference with TNF-α, transforming growth factor-β (TGF-β) and nuclear factor κ B (NF-κ β), suppression of IL-1 production, and inhibition of leukotriene and prostaglandin production.[60,61,62,63]

Because the effectiveness of sulfasalazine is not related to the sulfapyridine component and since sulfapyridine is believed to be responsible for many of the adverse reactions to sulfasalazine, mesalamine can be administered alone. Given that mesalamine is rapidly and completely absorbed in the small intestine but poorly absorbed in the colon, drug formulations must be designed to deliver mesalamine to the affected areas in the GI while preventing premature absorption.[58,59,60,61,62,63,64] Mesalamine can be used topically as an enema, to treat left-sided disease, or as a suppository for treatment of proctitis (**Fig. 34-1**). In general, the use of topical mesalamine preparations, such as enemas and suppositories, is more effective than oral preparations.[64,65] Likewise, these therapies may be used concomitantly with the oral mesalamine preparations, which may result in additive efficacy in patients with UC.[65] Oral slow-release formulations will deliver mesalamine to the small intestine and/or colon based on the product design (**Table 34-4**). Slow-release oral formulations of mesalamine, such as Pentasa, release mesalamine from the duodenum to the ileum, with up to 59% of the drug passing into the colon.[60,61] Some dose forms (Asacol, Asacol HD, Delzicol) utilize a pH-dependent coating that releases in response to intestinal pH.[62] Another tablet formulation of mesalamine (Lialda) uses a pH-dependent coating that releases at a pH of 7, in combination with a polymeric matrix core, referred to as the Multi-MatriX (MMX) system, and releases drug evenly throughout the colon also allowing for once-daily dosing.[63] A capsule formulation of mesalamine (Apriso) utilizes enteric-coated mesalamine granules in a polymer matrix for delayed and extended delivery of mesalamine to the colon and also allows for once-daily dosing.[61,62] Use of once-daily oral mesalamine preparations may enhance adherence, which may help to prevent relapse.[61,62] Olsalazine

is a dimer of two 5-ASA molecules linked by an azo bond. Mesalamine is released in the colon after colonic bacteria cleave the azo bond.[60] Balsalazide is a mesalamine prodrug that couples mesalamine with the inert carrier molecule 4-aminobenzoyl-β-alanine and is also enzymatically cleaved in the colon to release mesalamine.[60] The recommended daily doses of the oral mesalamine derivatives are intended to approximate the molar equivalent of mesalamine present in 4 g of sulfasalazine. Because the oral mesalamine formulations are delayed-release coated tablets or granules, they should not be crushed or chewed. Unlike sulfasalazine, all of these agents are safe to use for patients with sulfonamide allergies.

FIGURE 34-1

Site of activity of various agents used to treat inflammatory bowel disease.

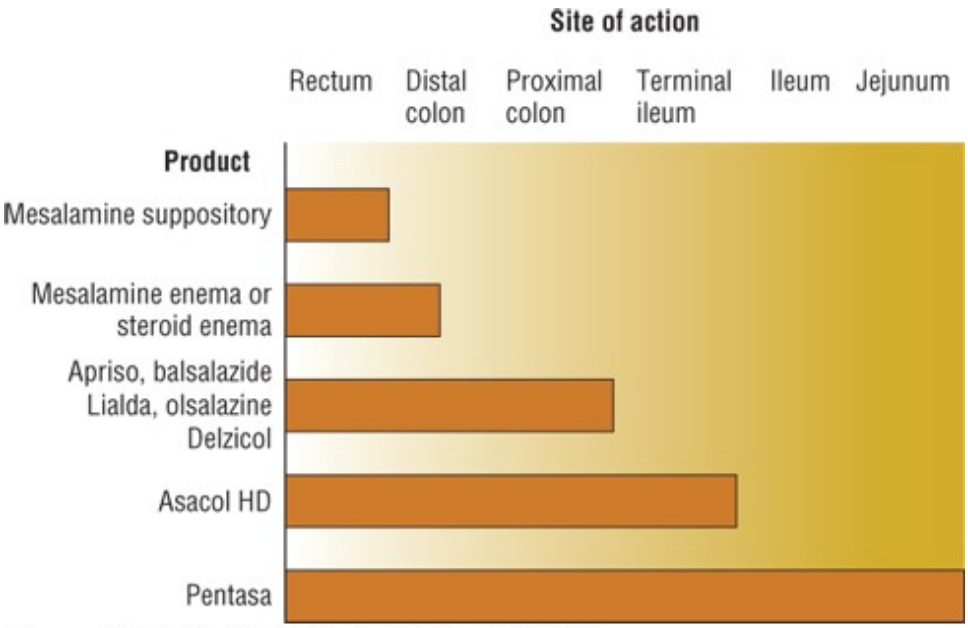

TABLE 34-4 Agents for the Treatment of Inflammatory Bowel Disease

Drug	Brand Name	Initial Dose (g)	Usual Range
Sulfasalazine	Azulfidine	500 mg-1 g	4-6 g/day
	Azulfidine EN	500 mg-1 g	4-6 g/day
Mesalamine suppository	Rowasa	1 g	1 g daily to three times weekly
Mesalamine enema	Canasa	4 g	4 g daily to three times weekly
Mesalamine (oral)	Asacol HD	1.6 g/day	2.8-4.8 g/day
	Apriso	1.5 g/day	1.5 g/day once daily
	Lialda	1.2-2.4 g/day	1.2-4.8 g/day once daily

Drug	Brand Name	Initial Dose (g)	Usual Range
	Pentasa	2 g/day	2-4 g/day
	Delzicol	1.2 g/day	2.4-4.8 g/day
Olsalazine	Dipentum	1.5 g/day	1.5-3 g/day
Balsalazide	Colazal	2.25 g/day	2.25-6.75 g/day
Azathioprine	Imuran, Azasan	50-100 mg	1-2.5 mg/kg/day
Cyclosporine	Gengraf	2-4 mg/kg/day IV	2-4 mg/kg/day IV
	Neoral, Sandimmune	2-8 mg/kg/day oral	
Mercaptopurine	Purinethol	50-100 mg	1-2.5 mg/kg/day
Methotrexate	No branded IM injection	15-25 mg IM weekly	15-25 mg IM weekly
Adalimumab	Humira	160 mg SC day 1	80 mg SC 2 (day 15), and then 40 mg every 2 weeks
Certolizumab	Cimzia	400 mg SC	400 mg SC weeks 2 and 4, and then 400 mg SC monthly
Infliximab	Remicade	5 mg/kg IV	5 mg/kg weeks 2 and 6, 5-10 mg/kg every 8 weeks
Natalizumab	Tysabri	300 mg IV	300 mg IV every 4 weeks
Budesonide	Enterocort EC, Uceris	9 mg	6-9 mg daily
Vedolizumab	Entyvio	300 mg IV	300 mg IV weeks 2 and 6 and then every 8 weeks
Golimumab	Simponi	200 mg SC	100 mg SC weeks 2 and 4

SC, subcutaneous; IM, intramuscular.

7 Corticosteroids are used to suppress acute inflammation in the treatment of IBD, and may be given parenterally, orally, or rectally.[66] They modulate the immune system and inhibit production of cytokines and mediators. It is not clear whether the most important steroid effects are systemic or local (mucosal). Budesonide is a corticosteroid that is administered orally in a controlled-release formulation designed to release in the terminal ileum or the colon depending on the product. The drug undergoes extensive first-pass metabolism; so systemic exposure is thought to be minimized.[38,66]

Immunosuppressive agents such as azathioprine, mercaptopurine, methotrexate, or cyclosporine are also used for the treatment of IBD (see Table 34-4). Azathioprine and mercaptopurine are effectively used in long-term treatment of both CD and UC.[1,33,37,67,68,69] These agents are generally reserved for patients who fail ASA therapy or are refractory to or dependent on corticosteroids. They may be used

in conjunction with mesalamine derivatives, corticosteroids, and TNF-α antagonists, and must be used for extended periods of time, ranging from a few weeks up to 12 months, before benefits may be observed.[58,67,68,69]

Cyclosporine has a short-term benefit in the treatment of acute, severe UC to avoid colectomy in patients failing corticosteroids.[1,13,33,51,70] It is used initially as a continuous IV infusion of 2 to 4 mg/kg daily.[51,58,71] Cyclosporine poses a risk of nephrotoxicity and neurotoxicity. Studies evaluating tacrolimus for the treatment of IBD suggest a potential role for use for patients with luminal or perianal CD; however, results have been variable with few data to support its routine use.[72] Methotrexate 15 to 25 mg given intramuscularly or subcutaneously once weekly may useful for maintenance therapy of CD and may result in steroid-sparing effects, while data supporting use in UC are lacking.[13,37,64,58,67]

Clinical Controversy…

Treatment with thiopurines remains a viable option for maintenance of remission in patients with IBD either as monotherapy or in combination with anti–TNF-α inhibitors. While effective in many patients, the optimal duration of thiopurine use is unknown. Long-term use may be associated with development of significant adverse effects such as infection and lymphoma. The benefit of maintaining remission must be weighed against the potential for adverse effects and risk for relapse if therapy is discontinued. Relapse rates after thiopurine discontinuation are reported in up to 23% of patients with CD and 12% of patients with UC at 12 months.[73]

Antimicrobial agents, particularly metronidazole and ciprofloxacin, are frequently used as adjunctive therapies in IBD. Metronidazole and ciprofloxacin, often given in combination, have demonstrated some value in both induction of remission and decrease in relapse rates in CD with some data supporting use in UC as well.[13,38,46,58,74] Antibiotics are often used in patients with perineal CD or when fistulas or abscesses are present or for pouchitis.[5,58] Rifamycin antibiotics have demonstrated some efficacy in treatment of both UC and CD.[58,74] Risks of long-term antibiotic use include the development of antibiotic resistance, predisposition to *C. difficile* infection, and adverse effects such as neurotoxicity secondary to metronidazole use.

Biologic agents that target TNF-α have become a key class of agents in the treatment and maintenance of IBD.[58,75,76,77] Infliximab is an IgG1 chimeric monoclonal antibody that is administered IV and binds TNF-α and inhibits its inflammatory effects. In addition, it lyses activated T cells and macrophages and induces T-cell apoptosis.[58,76,77] Infliximab is useful for moderate to severe active CD and UC disease, as well as steroid-dependent or fistulizing disease, as both an induction and a maintenance therapy. Adalimumab is also an IgG1 antibody to TNF-α; however, this agent, unlike infliximab, is fully humanized and contains no murine sequences. Theoretically, the lack of a murine component in adalimumab reduces antibody development seen with use of infliximab. This agent is administered subcutaneously and is a treatment option for patients with moderate to severe active UC and CD and those previously treated with infliximab who have lost response. Certolizumab pegol is a humanized pegylated Fab fragment directed against TNF-α that is also administered subcutaneously. Golimumab is similar in structure to adalimumab and offers similar efficacy to the

currently approved agents. Lastly, natalizumab and vedolizumab are a novel biologic agent that inhibits leukocyte adhesion and migration by targeting the α_4 subunit of integrin.[76,77] Vedolizumab works similar to natalizumab but is more specific for the $\alpha_{4\beta7}$ subunit of integrin, which targets leukocyte trafficking in the gut.[58,77]

Clinical Controversy…

The optimal management of corticosteroid refractory patients with acute severe UC remains unclear. The sequential use of TNF-α inhibitors, cyclosporine or tacrolimus in this patient population has traditionally yielded conflicting results, and may have more risk than benefit. However, if effective these agents may prevent the need for colectomy. Recent data suggest report the risk of severe adverse effects 23.0% (95% CI, 17.7%-28.3%) with these therapies versus remission rates of 39.9% (95% CI, 33.5%-44.3%).[78] Based on these data use of TNF-α inhibitors, cyclosporine or tacrolimus should be considered prior to colectomy.

Treatment of Ulcerative Colitis

Mild to Moderate Active Disease Most patients with mild to moderate active UC can be managed on an outpatient basis with oral and/or topical ASAs (**Fig. 34-2**; **Table 34-5**). For patients with extensive disease, oral sulfasalazine or an oral mesalamine derivative is preferred, with rates of induction of remission reported as 36% to 60% in 2 to 4 weeks after initiating therapy.[1,33,64,65,79,80] Topical mesalamine in an enema or suppository formulation is more effective than oral mesalamine or topical steroids for distal disease.[64,65] The combination of oral and topical mesalamine is more effective than either alone for patients with left-sided or extensive disease; however, patients may be less willing to use these formulations.[64,65] Usually 4 to 6 g/day of sulfasalazine given in four divided doses is required to suppress active inflammation.[33] There does not appear to be an increased rate of response with dosages over 6 g/day, although adverse effects typically increase.

FIGURE 34-2

Treatment approaches for ulcerative colitis.

*Can be considered as an alternative to TNF-alpha inhibitors.

TABLE 34-5 Levels of Evidence for Therapeutic Interventions in Inflammatory Bowel Disease

Interventions	Evidence Grades[a]
Ulcerative Colitis	
Mild to moderate active distal disease may be treated with oral aminosalicylates, topical mesalamine, or topical steroids	A
Combined oral and topical aminosalicylates are more effective than either is alone for mild to moderate active distal disease	A
Oral prednisone in doses of 40-60 mg/day or 1 mg/kg/day may be used in patients with mild to moderate distal disease unresponsive to oral or topical aminosalicylates	B
Sulfasalazine in doses of 4-6 g/day or an alternate aminosalicylate in doses of up to 4.8 g/day of the active 5-aminosalicylate moiety is effective for induction of mild to moderate extensive colitis	A

Interventions	Evidence Grades[a]
Infliximab, adalimumab, and golimumab are effective for moderate to severe disease in those patients not responding to corticosteroids or an immunosuppressive agent	A
Systemic corticosteroids are effective in moderate to severe active disease	A
Hospitalization for parenteral steroids is indicated for patients with severe disease or those failing to respond to oral steroids	A
Failure to demonstrate improvement following 3 days of parenteral steroids in patients with severe disease is an indication for cyclosporine or colectomy	1B
Sulfasalazine, mesalamine, or balsalazide is effective in maintenance of remission of distal disease; combining oral and topical mesalamine is more effective than is either alone	A
Sulfasalazine, olsalazine, mesalamine, and balsalazide are effective in preventing relapses in patients with mild to moderate extensive disease	A
Corticosteroids are not effective as maintenance treatment	A
Azathioprine, mercaptopurine, infliximab, and adalimumab are effective in lowering or eliminating corticosteroid use in corticosteroid-dependent patients	A
Azathioprine, mercaptopurine, or infliximab may be effective in patients with severe disease flares or those requiring retreatment with corticosteroids within 1 year	C
Oral cyclosporine is effective for patients with corticosteroid refractory disease but requires concomitant administration of azathioprine or mercaptopurine	C
Infliximab, adalimumab, and golimumab therapy is effective for maintenance if there is an initial response	A
Infliximab combined with azathioprine are effective for induction therapy in active moderately severe disease	B
Budesonide is effective for induction in mild-moderate active colonic disease	A
Vedolizumab is effective in moderate to severe disease in patients failing other therapies	B
Crohn's Disease	
Oral aminosalicylates are effective for mild to moderate ileal, ileocolonic, or colonic active disease	D
Metronidazole may be effective in patients not responding to sulfasalazine	D
Ileal release budesonide is effective for mild to moderate ileal or right-sided colonic disease	A
Topical hydrocortisone is effective for distal colonic inflammation	A
Systemic corticosteroids are effective in moderate to severe active disease	A
Systemic corticosteroids are not effective for patients with perianal fistulas	C
Hospitalization for parenteral steroids is indicated for patients with severe disease or those failing to respond to oral steroids	A

Interventions	Evidence Grades[a]
Parenteral methotrexate is effective for induction of remission in patients with active disease and for reducing corticosteroid dependency	B
Infliximab, adalimumab, and certolizumab are effective for moderate to severe disease in those patients not responding to corticosteroids or an immunosuppressive agent	A
Infliximab, adalimumab, and certolizimab are effective for those patients with fistulas who have not responded to antibiotics, immunosuppressive agents, or surgical drainage	A
High-dose oral cyclosporine (7.6 mg/kg) has short-term efficacy in patients with active disease	B
IV cyclosporine is effective for the treatment of fistulizing disease	B
Corticosteroids are not effective as maintenance treatment	A
Budesonide is effective as short-term maintenance therapy (3 months) but not long term	A
Azathioprine, mercaptopurine, infliximab, adalimumab, and certolizumab are effective in lowering or eliminating corticosteroid use in corticosteroid-dependent patients	A
Azathioprine or mercaptopurine is effective for maintenance of remission regardless of disease distribution	A
Azathioprine or mercaptopurine may be effective for treating perianal or enteric fistulae	C
Methotrexate maintenance therapy (15-25 mg IM weekly) is effective for patients whose active disease has responded to IM methotrexate	A
Methotrexate 25 mg IM for up to 16 weeks followed by 15 mg IM weekly is effective for patients with chronic active disease	A
Infliximab, adalimumab, and certolizumab therapy is effective for maintenance if there is an initial response	A
Natalizumab is effective in moderate to severe disease in patients failing other therapies	B
Vedolizumab is effective in moderate to severe disease in patients failing other therapies	B
Infliximab combined with azathioprine are effective for induction therapy in active moderately severe disease	A

[a]A, homogenous evidence from multiple well-designed, randomized (therapeutic) or cohort (descriptive) controlled trials, each involving a number of participants to be of sufficient statistical power; B, evidence from at least one large well-designed clinical trial with or without randomization from cohort or case-control analytic studies or well-designed meta analysis; C, evidence based on clinical experience, descriptive studies, or reports of expert committees; D, not rated.

Data from references 33, 37, 48, 77, 87, 88, 89, 91.

Oral mesalamine derivatives (see Table 34-2) are alternatives to sulfasalazine for treatment of mild to moderate UC with similar rates of efficacy. Mesalamine preparations are typically better tolerated than sulfasalazine and thus are often chosen preferentially as first-line therapies. Mesalamine suppositories will only reach to approximately 10 to 20 cm within the lower GI tract and thus are reserved for patients with proctitis.[1] Enemas will reach to the splenic flexure and can be used for left-sided disease.[64] The various oral mesalamine products generally have similar rates of efficacy and the effective daily dose range is 2.4 to 4.8 g/day. Doses greater than 2.4 g/day generally do not demonstrate significant additional benefit; however, patients with moderate disease may respond better to higher doses.[1,13,58,71,79] The choice of oral formulations may be dictated by patient-specific factors, such as use of a once-daily formulation to help improve patient adherence and reduce pill burden, or use of a generically available product in patients with limited financial resources.[60,61,62,63,81] Controlled release budesonide (Uceris) is an alternative for mild-moderate UC. Oral corticosteroids in doses of 40 to 60 mg/day prednisone equivalent can be used for patients with moderate extensive disease who are refractory to oral ASAs or require more rapid control of symptoms.[33,66] Topical corticosteroids, given as foams, enemas, and suppositories, while effective for patients with distal disease, are generally less effective than mesalamine but can be used for patients with tenesmus.[33]

Moderate to Severe Active Disease Patients with moderate to severe active disease require prompt initiation of therapies to quickly suppress inflammation. Systemic corticosteroids are used in the treatment of moderate to severe active UC regardless of disease location or in those patients who are unresponsive to maximal doses of oral and/or topical mesalamine derivatives.[22,33] Oral doses of 40 to 60 mg prednisone equivalent daily are recommended.[33]

Use of TNF-α inhibitors is an option for patients with moderate to severe disease who are unresponsive to ASAs, corticosteroids, or other immunosuppressive agents and is generally the next step in therapy. In general infliximab, adalimumab, and golimumab have similar rates of efficacy when used as monotherapy in UC.[58,77] Certolizumab is not approved for use in UC in the United States. Some data demonstrate that combining infliximab and azathioprine is more effective in inducing corticosteroid-free remission in patients with acute severe colitis.[69,77] Vedolizumab can be used for patients who fail immunosuppressive and TNF-α inhibitors, or for as an alternative those patients with contraindications to TNF-α inhibitors.[77] Vedolizumab should not be used in combination with any immunosuppressive agents or TNF-α inhibitors.

Severe or Fulminant Disease Patients with uncontrolled severe colitis or those with incapacitating symptoms require hospitalization for effective management. Under these conditions, patients generally receive nothing by mouth to promote bowel rest. Medications are given by the parenteral route and oral sulfasalazine or mesalamine derivatives are not typically beneficial in this setting because of rapid elimination of these agents from the colon with diarrhea.

Systemic corticosteroids are used in the treatment of severe disease and may allow some patients to avoid colectomy. IV hydrocortisone 300 mg daily in three divided doses or methylprednisolone 60 mg once daily is considered a first-line agent.[33,71] Methylprednisolone is typically preferred due to its

lesser mineralocorticoid effects. A trial of corticosteroids is warranted in most patients before proceeding to colectomy, unless the condition is grave or rapidly deteriorating. The length of corticosteroid therapy before consideration of surgery is open to debate, with recommendations ranging from 3 to 7 days.[1,33,51] Steroids do increase surgical risk, particularly infectious, if an operation is required later.

8 Patients, who are unresponsive to parenteral corticosteroids after 3 to 7 days, have the option of receiving higher-potency agents such as cyclosporine or infliximab. Seventy-six percent to 85% of hospitalized patients who are unresponsive to corticosteroids will typically respond to IV cyclosporine.[70] A continuous IV infusion of cyclosporine 2 to 4 mg/kg/day is the typical dose range utilized and may delay the need for colectomy.[1,33,51,70,71] Persistent fever, tachycardia, elevated CRP, hypoalbuminemia, and deep colonic ulcerations may be predictors of failure to respond to cyclosporine.[33,70] Patients who are controlled on IV cyclosporine can then be switched to an oral cyclosporine (4-8 mg/kg/day) tapered regimen with transition to azathioprine or MP.[1,33,51,71,82] Infliximab is an alternative to cyclosporine at a dose of 5 mg/kg and has demonstrated similar results regarding delaying the need for colectomy for patients with severe disease unresponsive to steroids.[1,51,71] Patients who respond to infliximab should be considered for additional doses at 2 and 6 weeks later.[51] The sequential use of cyclosporine and infliximab, or the drugs given in reverse order, is not generally recommended.[51] The adverse effects of both cyclosporine and infliximab are potentially serious and should be taken into consideration when using either therapy for patients with severe disease.[70,71]

Clinical Controversy...

Patients with IBD manifesting arthritic symptoms may benefit from the use of anti-inflammatory agents such as NSAIDs or corticosteroids. However, NSAIDs may exacerbate IBD symptoms by compromising the intestinal barrier. The ability of COX-2 specific NSAIDs, such as celecoxib, to exacerbate IBD compared to traditional NSAIDs is unclear. Few studies of COX-2 inhibitors have been conducted in patients with IBD. A recent Cochrane analysis reveals risk may be low with the use of COX-2 inhibitors; however, the ability to draw clinically relevant conclusions is hampered by the low number of patients and studies included. Both NSAIDs and COX-2 inhibitors should be used with caution in patients with IBD.[83]

Maintenance of Remission

9 After remission from active disease is achieved, the goal of therapy is to maintain remission. The major agents used for maintenance of remission are sulfasalazine and the newer mesalamine derivatives, infliximab, adalimumab, golimumab, and azathioprine or MP.

Oral agents, including sulfasalazine, mesalamine, and balsalazide, are all effective options for maintenance therapy. The optimal dose to prevent relapse is 2 to 2.4 g/day of mesalamine equivalent, with rates of relapse over 6 to 12 months reported as 40%.[13,33,76,79,80] The newer mesalamine derivatives are generally better tolerated than sulfasalazine and are associated with

fewer adverse effects often making them a preferred choice.[33,79] For patients with left-sided disease or proctitis, mesalamine enemas or suppositories are preferred.[64] The frequency of administration of topical agents may possibly be lessened to every third night over time.[31,64,65] The combination of topical and oral mesalamine is superior to either regimen alone for maintenance therapy.[65]

Corticosteroids do not have a role in the maintenance of remission with UC because they are ineffective and are associated with serious adverse effects with long-term use.[1,33] Steroids should be gradually withdrawn after 2 to 4 weeks after induction of remission. For patients who require chronic steroid use and are steroid dependent, there is a strong justification for use of alternative therapies. Azathioprine is effective in preventing relapse of UC for patients who fail ASAs or who are steroid dependent.[1,13,67,68,69] Approximately one third of patients will maintain remission on azathioprine; however, the onset of action is slow and 3 to 6 months may be required before beneficial effects are noted.[58,68] As mentioned earlier, azathioprine is also recommended for patients with severe UC who are transitioned to oral cyclosporine.[1,13,33,51,68,70,82]

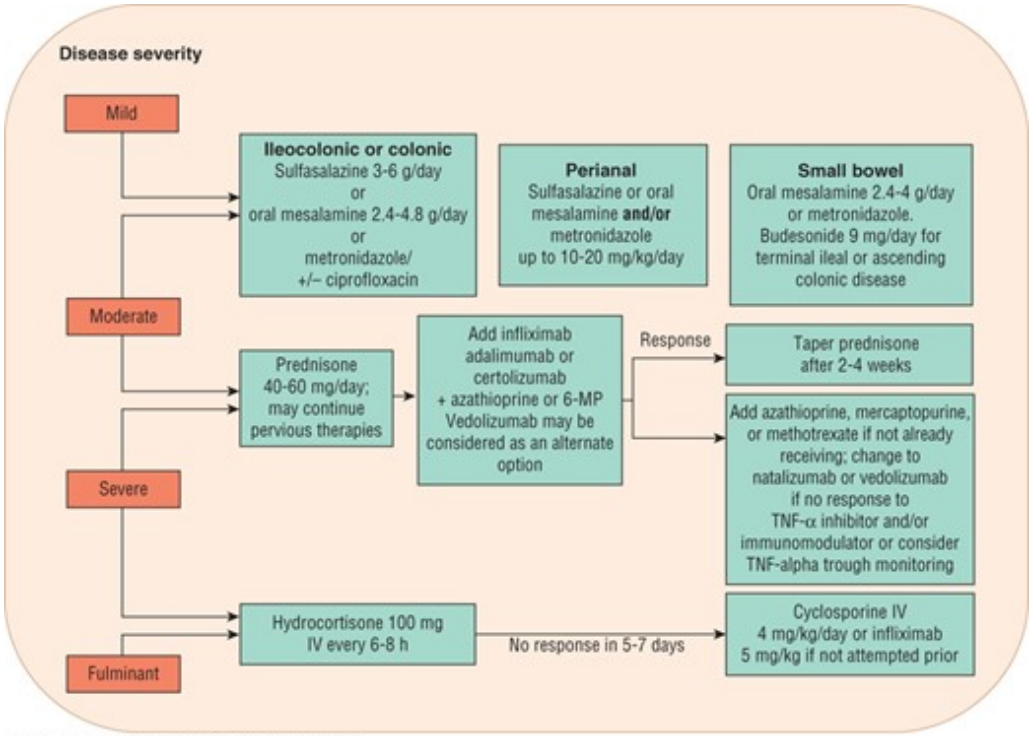
The TNF-α inhibitors are options for maintenance in patients with moderate to severe UC following induction, and in those who are steroid dependent or have failed azathioprine. Clinically up to one third of patients may not respond and those that do may lose effectiveness over time due to antibody development.[58,77]

Crohn's Disease

Management of CD often proves more difficult than management of UC because of the greater complexity of presentation (**Fig. 34-3**; see Table 34-3). There is a greater potential for reliance on drug therapy with CD because resection of involved areas of the GI tract may not be possible. Recurrence of CD is common following surgery with reported rates of endoscopic recurrence reported as up to 75% at 1 year.[84]

FIGURE 34-3

Treatment approaches for Crohn's disease.



The drug treatment of CD involves many of the same agents used for UC. While the treatment strategy for CD has often followed a similar "step-up" pattern as seen with UC, which involves initiating therapy with ASAs first, there has been interest in using higher-potency agents first, such as TNF-α inhibitors in a "top-down" approach in patients with severe disease.[38]

Mild to Moderate Active Crohn's Disease

While effective in UC, ASAs have not demonstrated significant efficacy in CD. Sulfasalazine is reported to have marginal efficacy when compared with placebo for patients with mild to moderate CD, while the newer mesalamine derivatives are generally considered to have minimal efficacy.[13,37,38,46,76,85] Despite limited and variable effectiveness, the mesalamine derivatives are often tried as an initial therapy for mild to moderate CD given their favorable adverse effect profile. Since CD often involves the small intestine, formulations such as Pentasa, which release in the small intestine, may be used.

Systemic corticosteroids are frequently used for the treatment of moderate to severe active CD; however, controlled-release budesonide (Entocort) at a dose of 9 mg daily is a viable first-line option for patients with mild to moderate ileal or right-sided (ascending colonic) disease.[13,37,38,46,66] This agent is superior to placebo and has demonstrated superiority to mesalamine and is preferred for patients with ileal disease.[13,46,76,86]

Antibiotics may have some roles in the treatment of CD. Metronidazole, given orally as 10 to 20 mg/kg/day in divided doses, has demonstrated variable efficacy but may possibly be useful in some patients with CD, particularly for patients with colonic or ileocolonic involvement, those with perineal disease, or those who are unresponsive to sulfasalazine.[13,37,38,74] For patients with colonic or perineal disease, metronidazole can be added to a mesalamine product or steroids as adjunctive therapy

when satisfactory control of CD is not gained with first-line agents, or in attempts to reduce steroid dosage.[38] Ciprofloxacin 1 g/day is another antibiotic used in CD, often in combination with metronidazole for patients with perianal disease or pouchitis; however, results have been variable due to differences in study design and patient numbers.[37,43,46,58,74,87] Other antibiotics, such as rifaximin and clofazimine, have also been studied with variable efficacy reported.[46,74] While there has been some demonstrated efficacy with antibiotics in mild to moderate CD, they are generally not recommended as a first-line therapy.[37,38,46,58,74]

Moderate to Severe Active Crohn's Disease

Patients with moderate to severe active CD require rapid suppression of inflammation for symptom improvement and prevention of complications. Oral corticosteroids, such as prednisone 40 to 60 mg/day, are generally considered first-line therapies for moderate to severe active CD who are unresponsive to ASAs and are effective in inducing remission for up to 70% of patients.[13,38,66] Traditional oral systemic steroids have greater efficacy in inducing remission compared with budesonide in patients with moderate disease; however, the potential for adverse effects is greater.[66,76] Hospitalized patients with moderate to severe disease who are unable to tolerate oral therapy are candidates for administration of parenteral steroids, with methylprednisolone or hydrocortisone being first-line options.[38,51] Systemic steroids do not appear to be effective for treatment of perianal fistulas.[38,76]

10 Immunomodulators (azathioprine and MP) are not recommended to induce remission in moderate to severe CD; however, they are effective in maintaining steroid-induced remission, in patients not achieving adequate response to standard medical therapy or those with steroid dependency, or in combination with TNF-α inhibitors.[13,38,67,88] Clinical response to azathioprine and mercaptopurine may be related to whole-blood concentrations of the metabolite 6-thioguanine (TGN). Concentrations of TGN greater than 230 to 260 pmol/8 × 10^8 erythrocytes have been demonstrated to have beneficial effects, but monitoring is not routinely performed or may not be available at some sites.[68]

11 Although mostly used in the setting of maintenance therapy as an alternative to azathioprine, methotrexate given weekly intramuscularly or subcutaneously in doses of 15 to 25 mg has demonstrated some efficacy in induction of remission in CD and corticosteroid-sparing effects; however, its use as a first line agent for induction is not recommended.[58,88]

The TNF-α inhibitors are the most effective and thus the preferred agents in the management of moderate to severe CD.[88,89] All agents in this class, with the exception of golimumab, which is not approved for use in CD in the United States, have similar rates of efficacy. The choice of agent depends on patient preference, route of administration, and cost. Adalimumab and certolizumab have the advantage of subcutaneous administration and may be considered alternates to infliximab as initial therapy or in those patients losing response to infliximab. Collectively these agents have demonstrated higher likelihood of induction of remission compared to placebo: RR 1.6 (95% CI 1.17-2.36).[89]

The use of TNF-α inhibitors in combination with thiopurines has quickly become the preferred approach to treatment of moderate to severe CD. Combination therapy results in added efficacy and reduction in antibody formation to the TNF-α inhibitor, which extends the duration of efficacy. Studies comparing infliximab with azathioprine and the combination of infliximab and azathioprine demonstrated significantly greater rates of remission of 57% at week 26 with the combination and infliximab alone (44%) compared with azathioprine alone (30%) in immunomodulator and biologic naive patients with CD.[88,89,90,91] For this reason the combination of TNF-α inhibitors and thiopurines is the recommended treatment approach.[88]

The integrin antagonists are options for patients who do not respond to steroids or TNF-α inhibitors (vedolizumab may as an alternative to TNF-alpha inhibitors for moderate to sever disease).[58,77,92] Vedolizumab is preferred over natalizumab due to the reduced risk of adverse effects, particularly progressive multifocal leukoencephalopathy (PML). These agents should not be used in combination with other immunosuppressants or biologic agents.

Severe/Fulminant Active Disease

Patients with severe or fulminant disease require prompt management in the inpatient setting and are often considered for surgical intervention. Parenteral corticosteroids at a dose equivalent of 40 to 60 mg prednisone should be instituted once the presence of abscess has been excluded.[38] Unresponsive cyclosporine has been tried at doses of 2 to 4 mg/h via IV infusion with reported in-hospital colectomy rates of 12.5%; however, despite these findings, there are few data to support its use in this setting.[13,93] It may also be effective as a last-line option for patients with severe fistulizing disease.[93]

Maintenance of Remission

Maintaining remission is typically more difficult with CD than with UC. There is minimal evidence that sulfasalazine and oral mesalamine derivatives are effective therapies for maintenance of CD following medically induced remission.[37,80,84,85] Despite these findings, an attempt to maintain remission with sulfasalazine or oral mesalamine following a medically induced remission may be carried out given the favorable side-effect profile and cost of these drugs compared with those of immunosuppressive and biologic agents. Mesalamine appears to have some efficacy in preventing postsurgical relapse following resection, with absolute risk reductions of approximately 14% for relapse in some studies, and can be considered in patients who do not qualify for or have a contraindication to immunosuppressive therapy.[84]

Systemic corticosteroids have no place in the prevention of recurrence of CD. These agents do not alter the long-term course of the disease and predispose patients to serious adverse effects with long-term use.[38] Budesonide has been studied at maintenance doses of 6 mg/day for up to 52 weeks with minimal efficacy in maintaining remission.[13,80,86] Despite this recommendation, use of budesonide as maintenance therapy for up to 1 year can be considered, particularly in patients who have become corticosteroid dependent, for whom switching to budesonide is an option.[13]

Azathioprine and mercaptopurine are most effective in maintaining corticosteroid induced remission in CD.[58,68,80,82] Patients who may also benefit from these agents include those with quiescent disease who are steroid dependent or refractory, postsurgical patients to prevent recurrence, those with frequent flares requiring steroid bursts, and those with perianal or enteric fistulas.[13,68,80] Methotrexate may be considered as an alternative to thiopurines to maintain corticosteroid induced remission; however, the evidence for its use is weak.[58,88]

All of the TNF-α inhibitors currently approved for use in CD are viable options for maintenance of remission.[87,91] If induction of remission was obtained via combination therapy with a thiopurine, the decision will need to be made as to whether both drugs should be continued, or one of the two agents discontinued to promote use of monotherapy given the risk of adverse effects increases with continued use of both agents.[88]

Selected Complications

Toxic Megacolon

The treatment required for toxic megacolon includes general supportive, consideration for early surgical intervention, and drug therapy.[34,38] Perforation is reported in up to 36% of patients and can significantly worsen outcomes.[51] Aggressive fluid and electrolyte management is required for dehydration. Transfusion may be necessary if significant blood loss has occurred. Opiates and medications with anticholinergic properties should be discontinued because these agents enhance colonic dilation, thereby increasing the risk of bowel perforation.[51] Broad-spectrum antimicrobials that include coverage for gram-negative bacilli and intestinal anaerobes should be used as preemptive therapy in the event that perforation occurs.[34] If the patient is not receiving corticosteroids, then high-dose IV therapy should be administered to reduce acute inflammation. Emergent surgical intervention, mainly an abdominal colectomy with formation of an ileostomy, is an important consideration for patients with toxic megacolon and prevents death in some patients.[51]

Extraintestinal Manifestations

For some extraintestinal manifestations of IBD, specific therapies can be instituted, whereas for others the treatment that is used for the GI inflammatory process also addresses the systemic manifestations.

Anemia secondary to blood loss from the GI tract can be treated with oral ferrous sulfate. If the patient is unable to take oral medication and the patient's hematocrit is sufficiently low, blood transfusions or IV iron infusions may be required.[42] Anemia may also be related to malabsorption of vitamin B_{12} or folic acid, particularly for patients who have had ileal resection, so supplementation may be required. Screening for osteoporosis via dual x-ray absorptiometry is recommended for patients using steroids for more than 3 months, in postmenopausal females, patients of age over 60, and those who have sustained a low-stress fracture.[44] If the patient is deemed high risk for osteoporosis or exhibits a reduced serum vitamin D concentration, vitamin D and calcium should be

instituted. If osteoporosis is present, then calcium, vitamin D, and a bisphosphonate or possibly teriparatide are recommended.[42,44] Corticosteroid use should be avoided or limited, and weight-bearing exercise initiated if possible.

There are no consistently recommended therapies for aphthous ulcers; however, topical viscous lidocaine may provide symptom relief while topical corticosteroids may promote healing.[42] Episcleritis or uveitis is often worse during exacerbations of the intestinal disease, and measures improving intestinal disease will improve these systemic manifestations. Cool compresses and topical corticosteroids may provide symptomatic relief, while TNF-α inhibitors when in use may also provide benefit.[42] For arthritis associated with IBD, aspirin or another NSAID may be beneficial, as are corticosteroids. However, NSAID use may exacerbate the underlying IBD and predispose patients to GI bleeding. Intraarticular corticosteroids may be tried to limit the adverse effects of systemically administered agents.[42] Skin manifestations often require local wound care and use of topical or systemic corticosteroids.[42] Anti–TNF-α therapies may also improve severe dermatologic manifestations. Although ursodiol may improve liver enzymes in patients with IBD-associated PSC, it has not been demonstrated to have favorable effects on outcomes.[41,42] Liver transplantation is being used more frequently for definitive treatment of PSC.

Special Considerations

Pregnancy and Breastfeeding

The occurrence or consideration of pregnancy may cause significant concerns for the patient with IBD. Patients with IBD have similar infertility rates as the general female population. The rate of normal childbirth is similar to that for healthy populations.[94,95] Some studies have noted a greater risk of spontaneous abortion, low birth weight, caesarian section, congenital abnormalities, low Apgar scores, preterm rupture of membranes, and preeclampsia.[94,95,96] However, most patients can conceive normally and have a normal pregnancy.[94,95,96,97,98,99] There is a small risk of preterm labor or low-gestational-weight infants.[94,98,99] Preconception counseling is key for female patients with IBD who are considering becoming pregnant. This includes improving prepregnancy nutrition, implementing supplementation with folate, calcium, and vitamin D, ceasing alcohol and tobacco use, and inducing disease remission if possible.[94] Overall, pregnancy appears to have minimal effects on the course of IBD.[93,94,95,96,97,98] Likewise, IBD appears to have little effect on the course of pregnancy, particularly if the IBD is quiescent at the time of conception.[94,95,98] Patients who are pregnant experience IBD recurrence rates similar to those of nonpregnant females.[98] Patients are recommended to wait until their disease is in remission for 3 months prior to conceiving if possible.[93] Patients requiring colectomy for UC should preferentially receive rectal-sparing surgery if they are considering conceiving, followed by IPAA after delivery.[94]

Most classes of medications used in IBD are relatively safe in pregnancy. Sulfasalazine is generally well tolerated; however, it does interfere with folate absorption, so supplementation with folic acid 1 mg twice daily should be used during the pregnancy.[94,95] Sulfasalazine causes decreased sperm

counts and reduced fertility in males and corticosteroids may adversely affect fertility as well.[100] This effect is reversible on discontinuation of the drug, and it is not reported with mesalamine. Other ASAs can be used as well; however, there are concerns regarding the presence of dibutyl phthalate in the coating of Asacol.[94] Mesalamine preparations not containing dibutyl phthalate should be preferentially used. Steroids given systemically do not appear to be detrimental to the fetus, with the exception of dexamethasone, and should be limited in duration.[94,98,100] Maternal cortisol is generally inactivated by placental 11β-hydroxysteroid dehydrogenase type 2; however, dexamethasone is not inactivated by this enzyme and may accumulate in fetal tissue. Therefore, dexamethasone should be avoided in pregnancy.[94] Immunosuppressive drugs (azathioprine and mercaptopurine) may be associated with fetal deformities in humans and are classified as pregnancy category D; however, they have been used commonly in IBD without detriment for most patients.[94,98] Infliximab, adalimumab, and certolizumab appear to be relatively safe for use in pregnant patients.[94,95,96,97,98,99] Use of infliximab should be restricted to the first and second trimesters if possible due to placental transfer of infliximab and the potential for neonatal adverse effects.[99] There is a similar concern with adalimumab, although this agent is more difficult to detect in the neonatal bloodstream. Consideration can be given to stopping it 8 to 10 weeks prior to delivery.[99] Natalizumab was formerly pregnancy category C drug and not much is known about its safety in pregnancy, and thus may be used if benefit is thought to outweigh risk.[91] Vedolizumab was a pregnancy category B drug and pregnancies occurring while receiving this agent should be reported to the manufacturers pregnancy exposure registry. Metronidazole may be used for short courses for treatment of trichomoniasis, but prolonged use should be avoided due to potential mutagenic effects.[98] Methotrexate should not be used during pregnancy, as it is a known abortifacient (former category X).[94,95,96,97,98,99] Cyclosporine has been used in pregnant patients with success and therefore is an option for patients with severe disease.[94,98]

Use of agents in breastfeeding women is also a consideration. Sulfasalazine does pose a small risk of kernicterus, as levels of sulfapyridine in breast milk are low or undetectable, and thus monitoring for this symptom should be implemented.[94] Other mesalamine derivatives are considered safe in breastfeeding.[94,98] Corticosteroids can be detected in breast milk, with fetal levels approximately 10% to 12% of maternal levels.[95] However, breastfeeding is believed to be safe for the infant when doses of prednisone less than 40 mg are used.[95] Optimally mothers should wait at least 4 hours after an oral dose of systemic corticosteroids before breastfeeding to limit exposure to the child.[94,98] The anti–TNF-α agents are generally considered safe for use in breastfeeding and carry minimal risk of adverse effects.[95,99] Metronidazole and cyclosporine should not be given to nursing mothers because these agents are excreted into breast milk and may cause adverse effects.[94,95,96,97,98]

Adverse Drug Effects

Drug intolerance often limits the usefulness of agents used to treat IBD. In some cases, adverse effects can be significant and require discontinuation of the therapy. Knowledge of the common or important adverse reactions will assist in avoiding or minimizing their effects.

Compared with mesalamine, sulfasalazine is more often associated with adverse drug effects, and these effects may be classified as either dose related or idiosyncratic (**Table 34-6**).[58,101] The sulfapyridine portion of the sulfasalazine molecule is believed to be responsible for much of the sulfasalazine toxicity.[33] Dose-related side effects usually include GI disturbances such as nausea, vomiting, diarrhea, or anorexia but may also include headache and arthralgia. These adverse reactions tend to occur more commonly on initiation of therapy and decrease in frequency as therapy is continued. Approaches to the management of these adverse effects include discontinuing the agent for a short period and then reinstituting therapy at a reduced dosage with subsequent slower dose escalation, administration with food, or substituting another enteric-coated 5-ASA product. Folic acid absorption is impaired by sulfasalazine, which may lead to anemia, so oral folic acid supplementation should be administered.

TABLE 34-6 Drug Monitoring Guidelines

Drug(s)	Adverse Drug Reaction	Monitoring Parameters	Comments
Sulfasalazine	Nausea, vomiting, headache		
	Rash, anemia, pneumonitis	Folate, complete blood count	Increase the dose slowly, over 1-2 weeks
	Hepatotoxicity, nephritis	Liver function tests, Scr, BUN	
	Thrombocytopenia, lymphoma		
Mesalamine	Nausea, vomiting, headache	GI disturbances	
Corticosteroids	Hyperglycemia, dyslipidemia	Blood pressure, fasting lipid panel	Avoid long-term use if possible or consider budesonide
	Osteoporosis, hypertension, acne	Glucose, vitamin D, bone density	
	Edema, infection, myopathy, psychosis		
Azathioprine/mercaptopurine	Bone marrow suppression, pancreatitis	Complete blood count	Check TPMT activity
	Liver dysfunction, rash, arthralgia	Scr, BUN, liver function tests, genotype/phenotype	May monitor TGN
Methotrexate	Bone marrow suppression, pancreatitis	Complete blood count, Scr, BUN	Check baseline pregnancy test
	Pneumonitis, pulmonary fibrosis, hepatitis	Liver function tests	Chest x-ray

Drug(s)	Adverse Drug Reaction	Monitoring Parameters	Comments
Infliximab	Infusion-related reactions (infliximab), infection	Blood pressure/heart rate (infliximab)	Need negative PPD and viral serologies
Adalimumab	Heart failure, optic neuritis, demyelination, injection site reaction, signs of infection	Neurologic exam, mental status	
Certolizumab	Lymphoma	Trough concentrations (infliximab)	
Golimumab		Antidrug antibodies (all agents)	
Natalizumab	Infusion-related reactions	Brain MRI, mental status, progressive multifocal leukoencephalopathy	Vedolizumab not associated with PML
Vedolizumab			

Idiosyncratic effects commonly include rash, fever, or hepatotoxicity, as well as relatively uncommon but serious reactions such as bone marrow suppression, thrombocytopenia, pancreatitis, pneumonitis, interstitial nephritis, and hepatitis. For most patients with idiosyncratic reactions, sulfasalazine must be discontinued. In some patients who have experienced allergic reactions to sulfasalazine, a desensitization procedure can be instituted. By gradually increasing sulfasalazine dosage over weeks to months, patient tolerance has been improved.[33]

Oral mesalamine derivatives may impose a lower frequency of adverse effects as compared with sulfasalazine.[33,78] Up to 80% of patients who are intolerant to sulfasalazine will tolerate oral mesalamine derivatives.[33] The most commonly encountered adverse effects are nausea, vomiting, and headache.[79] However, olsalazine may cause watery diarrhea in up to 25% of patients, often requiring drug discontinuation.

There is a greater potential for adverse effects from corticosteroids when used for the treatment of IBD because there is often a requirement for use of high doses for extended periods of time. Adverse effects of corticosteroids include hyperglycemia, hypertension, osteoporosis, acne, fluid retention, electrolyte disturbances, myopathies, muscle wasting, increased appetite, psychosis, infection, and adrenocortical suppression.[33,66] To minimize corticosteroid effects, clinicians have used alternate-day steroid therapy; however, some patients do not do well clinically on the days when no steroid is given. For most patients a single daily corticosteroid dose suffices, and divided daily doses are unnecessary. Adrenal insufficiency after abrupt steroid withdrawal often necessitates gradual tapering of steroid therapy for patients using these agents daily for more than 2 to 3 weeks. Due to its lower bioavailability and lower potential for adverse effects, budesonide may be used as alternate steroid therapy in CD involving the ileum or right colon, or in UC, or may be substituted for prednisone in CD patients who are steroid dependent or require long-term therapy.[37,38,66]

Azathioprine and mercaptopurine may be associated with serious adverse effects such as lymphomas,

pancreatitis, or nephrotoxicity.[33,38,68,69] Adverse events to thiopurines are typically divided into two groups: type A and type B.[68,101,102] Type A are dose related and include malaise, nausea, infectious complications, hepatitis, and myelosuppression. Complete blood counts with differential should be monitored every 2 weeks while doses are being titrated. Type B reactions are considered idiosyncratic and include fever, rash, arthralgia, and pancreatitis (3%-15% of patients).[100,101] Predisposition to development of these adverse effects may be related to polymorphisms in the enzyme thiopurine methyltransferase (TPMT), which is partially responsible for activation and metabolism of these drugs. Determination of TPMT activity is recommended prior to initiation of therapy to determine which patients require lower doses of these agents.[38,68,102] Alternatively, evaluating TPMT genotype or phenotype can also assist in assessing a patient's risk for toxicity.[67,68,69,102] Doses may need to be reduced by 30% to 70% if low TPMT activity is present.[102] Adjusting azathioprine and MP doses by measuring concentrations of metabolites, particularly TGN, may be useful, with higher levels associated with greater remission rates.[67,68,69,101,102]

With the advent of coadministration of azathioprine with infliximab, development of hepatosplenic T-cell lymphoma (HSTCL) has become a concern. The overall impact of using both drugs together, the contribution of drug classes to the development of lymphoma, and the risk and effects of both drugs are unclear. Those most at risk appear to be younger male patients and most of the risk is thought to be conferred by the thiopurine component.[67,103,104,105] Methotrexate is associated with the development of nausea, vomiting, pulmonary fibrosis, pneumonitis, hepatotoxicity, anemia, and renal dysfunction, and is a known abortifacient. Patients should have baseline liver function tests, serum creatinine, BUN, complete blood count, and chest x-ray prior to use. Female patients should have a negative pregnancy test prior to use. Some patients may require supplementation with folic acid.

Most patients receiving metronidazole for CD tolerate the agent fairly well; however, mild adverse effects occur frequently. They commonly include nausea, metallic taste, urticaria, and glossitis.[34,37] More serious effects that occur with long-term use include development of paresthesias and reversible peripheral neuropathy. Other effects include a disulfiram-like reaction if alcohol is ingested in conjunction.

The TNF-α inhibitors may be associated with development of serious adverse effects and carry similar adverse effect profiles for the available agents. Patients who receive infliximab often develop antibodies to infliximab (ATIs), also referred to as antidrug antibodies (ADAs). These ADAs can develop in response to administration of the other TNF-α inhibitors as well. Overall up to 50% of patients may lose efficacy after 1 year of treatment due to ADA development.[106] The development of ADAs also results in increases in the occurrence of serious infusion-related reactions and loss of response to the drug. Up to 10% of patients per year require discontinuation of infliximab due to adverse effects and loss of efficacy related to development of ATIs.[76,88,106]

Strategies to reduce ATI formation include administration of a second dose within 8 weeks of the first dose, concurrent administration of steroids (hydrocortisone 200 mg IV on the day of the infusion or oral prednisone the day prior), and use of concomitant immunosuppressive agents such as

thiopurines.[76,97,106] Loss of efficacy may be managed by a dose escalation to 10 mg/kg, reducing the dosing interval, or switching to another TNF-α inhibitor.[87,88,106] Delayed hypersensitivity reactions may also occur up to 14 days after administration, with 5 to 7 days being the most common time frame.[87,104] Autoimmune phenomena, such as lupus and hemolytic anemia, may also occur during infliximab therapy but are uncommon, as are adverse neurologic events such as optic neuritis and demyelinating syndrome.[77,86,104] For these reasons patients with a history of demyelinating disease, optic neuritis, or lymphoma should avoid use of TNF-α antagonists.[104] Infliximab may also cause worsening of heart failure and thus is contraindicated for patients with New York Heart Association Class III or IV heart failure.[91] While the mechanism is unclear, it may relate in part to the cytoprotective effects of TNF on ischemic cardiac tissue, increases in production of nitric oxide and increased peripheral perfusion secondary to TNF, or TNF's role in cardiac remodeling and repair. Due to administration via the subcutaneous route, adalimumab, certolizumab, and golimumab may be more associated with injection site reactions versus infusion-related reactions.

All TNF-α inhibitors predispose patients to development of serious infections, including fungal, bacterial, and viral. Patients with clinically significant active infections should not receive TNF-α inhibitors. While the overall risk of hospitalization for serious infections may be less than previously suspected, development of infection remains a serious concern.[107] Reactivation of latent mycobacterial infections may occur because of the inhibition of TNF-protective mechanisms; therefore, patients should receive a tuberculin skin test (purified protein derivative [PPD] test) and a chest x-ray prior to initiating therapy to rule out undiagnosed tuberculosis.[93,107] Reactivation of hepatitis B may occur; thus, patients should also be screened for hepatitis B virus infection prior to initiating therapy. Patients should also be screened for hepatitis C infection, although it does not appear that use of TNF-α inhibitors is unsafe or significantly alters the disease course. Lastly, use of natalizumab is associated with development of PML and is only available via the manufacturer's TOUCH prescribing program.[95] Patients receiving natalizumab should be monitored for development of adverse neurologic events and undergo MRI of the brain should development of PML be suspected. Vedolizumab has not been associated with development of PML to date.

PERSONALIZED PHARMACOTHERAPY

The approach to treatment of IBD should consider all aspects of each individual patient in order to maximize therapy, improve patient symptoms and QOL, and prevent complications. To ensure optimal drug therapy, an assessment of each patient's health literacy and potential barriers to understanding and adherence should be performed. Involving the patient in the care process will help to keep him or her engaged. For the drug classes that are used in the management of IBD, there are several aspects of individualization that may improve efficacy and safety. Since patients with IBD are often seen by GI specialists or surgeons, ensuring that each provider has a current, accurate, and complete medication list will help to prevent potential medication errors. Female patients of childbearing age should discuss with their providers their goals for becoming pregnant, as this may dictate the choice of drugs used.

For the ASAs, picking the appropriate formulation and dose of drug for the disease severity and

extent is key. Enemas and suppositories, while generally more effective than oral preparations, may not be as acceptable for use, particularly by younger patients. Therefore, individuating the patient's preference for a specific formulation should be taken into account when choosing ASA preparations.[57] Consideration can be given to the use of once-daily products if there is evidence that multiple-daily dosing is affecting patient adherence.[61,62,63] This must be weighed against the higher cost of these preparations. If expense is an issue, use of generically available agents may be preferred.

Patients receiving systemic corticosteroids for extended periods of time should be assessed for risk of bone loss and fracture and the need for vitamin D and calcium supplementation. In addition, a review of the patient's medical history should be performed to identify other conditions that may be worsened by corticosteroids, such as diabetes or hypertension. Adjustment of medications for these types of conditions may need to be made based on the dose and duration of corticosteroid use.

Patients in whom azathioprine or mercaptopurine is being considered should undergo TPMT activity testing or have a genotype or phenotype test performed to determine if dose adjustments are required. Since the initial dosing of these agents is weight based, obtaining a current accurate weight for the patient is necessary as well. Obtaining a family history regarding lymphoproliferative disorders or lymphoma is important for determining if the potential risks outweigh the benefits of long-term use. For female patients in whom methotrexate is being considered, a pregnancy test should be obtained and the potential desire to become pregnant in the future should be discussed. Female patients of childbearing age opting to use methotrexate should have a safe and effective method of birth control available that is based on their preference.

For patients receiving TNF-α inhibitors, baseline screening for latent infections should be performed. Obtaining an accurate weight will assist in the dosing of infliximab. Likewise use of infliximab requires administration in an observed infusion center or clinic. If patients are unable to afford to get to their appointment, use of a self-administered agent, such as adalimumab or certolizumab, may be preferred. If patients appear to be losing response to infliximab, evaluating for ADAs, if assays are available, in addition to evaluating serum trough concentrations may assist the clinician in determining if dose and frequency need to be altered. Trough concentrations of 3 to 7 mcg/mL (mg/L) are considered optimal, while ADA concentrations specific for infliximab are considered high if greater than 9.1 U/mL (kU/L).[106]

From a health maintenance standpoint, patients should be evaluated for use of recommended vaccines; however, if patients are receiving immunosuppressants or biologic agents, the use of live or attenuated vaccines may be contraindicated. Patients who currently use tobacco should be encouraged to undergo tobacco cessation, as tobacco use will worsen CD. Since nicotine often improves symptoms in UC, it may be more difficult to cease tobacco use in this patient population. Choice of tobacco cessation products should also be based on current amount and patient preference. Nutritional status of patients should also be routinely assessed and patient-specific diets or delivery, such as enteral or parenteral nutrition, should be implemented.

EVALUATION OF THERAPEUTIC OUTCOMES

The success of therapeutic regimens to treat IBD can be measured by patient-reported complaints, signs, and symptoms; by direct clinician examination (including endoscopy); by history and physical examination; by selected laboratory tests; and by QOL measures. Evaluation of IBD severity is difficult because much of the assessment is subjective. Disease rating scales, such as the CDAI or other indices, have been created to try and make disease assessment more objective. The CDAI is a commonly used scale for patients with nonfistulizing disease and for evaluation of patients during clinical trials.[46] The scale incorporates eight elements: (a) number of stools in the past 7 days, (b) sum of abdominal pain ratings from the past 7 days, (c) rating of general well-being in the past 7 days, (d) use of antidiarrheals, (e) body weight, (f) hematocrit, (g) finding of abdominal mass, and (h) a sum of extraintestinal symptoms present in the past week. Elements of this index provide a guide for those measures that may be useful in assessing the effectiveness of treatment regimens. A decrease in CDAI of 100 points is considered a clinically significant response, with a score of less than 150 considered to be disease remission.[46] A subsequent scale was developed specifically for perianal CD, known as the *Perianal Crohn's Disease Activity Index* (PDAI).[46] The PDAI includes five items: presence of discharge, pain, restriction of sexual activity, type of perianal disease, and degree of induration. The HBI may also be used in place of the CDAI.

Standardized assessment tools have also been constructed for UC.[45] Elements in these scales vary and include (a) stool frequency, (b) presence of blood in the stool, (c) mucosal appearance (from endoscopy), and (d) physician's global assessment based on physical examination, endoscopy, and laboratory data. While these tools are often used for assessment of patients in clinical trials, they are sometimes used in the clinical setting as well.

Additional studies that are often useful include direct endoscopic examination of affected areas and/or radiocontrast studies. As mentioned earlier, mucosal healing is being explored as a major end point for patients with luminal disease.[48] For patients with acute disease, assessment of fluid and electrolyte status is important, because these may be lost during diarrheal episodes. Other laboratory tests, such as serum albumin, transferrin, or other markers of visceral protein status as well as markers of inflammation such as ESR or CRP, may be used to monitor disease and drug therapy. Lastly assessing for both trough concentrations of infliximab and presence of ADAs can help guide therapy in patients who are not responding to normal doses.

Assessment of the IBD patient must include consideration of adverse drug effects. Because many of the agents used have a relatively high probability of causing adverse effects, particularly corticosteroids and other immunosuppressive agents, patient assessment should include collection of history and physical and laboratory data that are necessary to prevent or recognize adverse drug effects.

Finally, a patient QOL assessment should be performed regularly.[45,46] Inquiry should be made regarding patient's general well-being, emotional function, and social function. Social function may include assessment of the ability to perform routine daily functions and to maintain occupational activities, sexual function, and recreation. The most common tool used to assess QOL is the Inflammatory Bowel Disease Questionnaire (IBDQ), a 32-item questionnaire that covers four disease dimensions: bowel function, emotional status, systemic symptoms, and social function. The IBDQ has

shown good correlation with the CDAI.[46] The standard short form-36 is often used as a measure of QOL in IBD intervention trials.[45,46]

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ADA	antidrug antibody
ASA	aminosalicylate
ATI	antibody to infliximab
CD	Crohn's disease
CDAI	Crohn's Disease Activity Index
CRC	colorectal carcinoma
CRP	C-reactive protein
ESR	erythrocyte sedimentation rate
HBI	Harvey-Bradshaw Index
HLA	human leukocyte antigen
HSTCL	hepatosplenic T-cell lymphoma
IBD	inflammatory bowel disease
IBDQ	Inflammatory Bowel Disease Questionnaire
IL	interleukin
IPAA	ileal pouch anal anastomosis
MMX	Multi-MatriX
MP	mercaptopurine
NF-κ B	nuclear factor κ B
NOD2	nucleotide-binding oligomerization domain protein 2
NSAID	nonsteroidal anti-inflammatory drug
PDAI	Perianal Crohn's Disease Activity Index
PML	progressive multifocal leukoencephalopathy
PPD	purified protein derivative
PSC	primary sclerosing cholangitis
QOL	quality of life
TGF-β	transforming growth factor-β
TGN	thioguanine
TLR	toll-like membrane receptor
TNF-α	tumor necrosis factor-α
TPMT	thiopurine methyltransferase
UC	ulcerative colitis

VTE venous thromboembolism

Chapter 35: Nausea and Vomiting

Leigh Anne Hylton Gravatt; Krista L. Donohoe; Cecily V. DiPiro

INTRODUCTION

Key Concepts

- 1 Nausea and/or vomiting is often a part of the symptom complex for a variety of gastrointestinal (GI), cardiovascular, infectious, neurologic, metabolic, or psychogenic processes.
- 2 Nausea or vomiting is caused by a variety of medications or other noxious agents.
- 3 The overall goal of treatment should be to prevent or eliminate nausea and vomiting regardless of etiology.
- 4 Treatment options for nausea and vomiting include drug and non-drug modalities such as relaxation, biofeedback, and self-hypnosis.
- 5 The primary goal with chemotherapy-induced nausea and vomiting (CINV) is to prevent nausea and/or vomiting and the emetic risk of the chemotherapeutic regimen is a major factor to consider when selecting a prophylactic regimen.
- 6 Patients at high risk of vomiting should receive prophylactic antiemetics for postoperative nausea and vomiting (PONV).
- 7 Patients undergoing radiation therapy (RT) to the upper abdomen or receiving total or hemibody irradiation should receive prophylactic antiemetics for radiation-induced nausea and vomiting (RINV).
- 8 Beneficial therapy for patients with balance disorders can most reliably be found among the antihistaminic–anticholinergic agents.

Nausea and vomiting are common complaints from individuals of all ages. Management can be simple or detailed and complex, depending on the etiology. This chapter provides an overview of nausea and vomiting, two multifaceted problems.

Nausea is defined as the inclination to vomit or as a feeling in the throat or epigastric region alerting an individual that vomiting is imminent. Vomiting is the ejection or expulsion of gastric contents through the mouth and is often a forceful event. Either condition may occur transiently with no other associated signs or symptoms; however, these conditions also may be only part of a more complex clinical presentation.

ETIOLOGY

Nausea and vomiting may be associated with a variety of conditions, including gastrointestinal (GI), cardiovascular, infectious, neurologic, or metabolic disease processes. Nausea and vomiting may be a feature of such conditions as pregnancy, or may follow operative procedures or administration of certain medications, such as those used in cancer chemotherapy. Psychogenic etiologies of these symptoms may be present. Anticipatory etiologies may be involved, such as in patients who have previously received cytotoxic chemotherapy. **Table 35-1** lists specific etiologies associated with nausea and vomiting.[1]

TABLE 35-1 Specific Etiologies of Nausea and Vomiting

GI mechanisms
Mechanical obstruction
Gastric outlet obstruction
Small bowel obstruction
Functional GI disorders
Gastroparesis
Nonulcer dyspepsia
Chronic intestinal pseudoobstruction
Irritable bowel syndrome
Organic GI disorders
Peptic ulcer disease
Pancreatitis
Pyelonephritis
Cholecystitis
Cholangitis
Hepatitis
Acute gastroenteritis
Viral
Bacterial
Cardiovascular diseases
Acute myocardial infarction
Congestive heart failure
Radio-frequency ablation
Neurologic processes
Increased intracranial pressure

Migraine headache

Vestibular disorders

Metabolic disorders

Diabetes mellitus (diabetic ketoacidosis)

Addison's disease

Renal disease (uremia)

Psychiatric causes

Psychogenic vomiting

Anxiety disorders

Anorexia nervosa

Therapy-induced causes

Cytotoxic chemotherapy

Radiation therapy

Theophylline preparations

Anticonvulsant preparations

Digitalis preparations

Opiates

Antibiotics

Volatile general anesthetics

Drug withdrawal

Opiates

Benzodiazepines

Miscellaneous causes

Pregnancy

Noxious odors

Operative procedures

Adapted from reference 1.

The etiology of nausea and vomiting may vary with the age of the patient. For example, vomiting in the newborn during the first day of life suggests upper digestive tract obstruction or an increase in intracranial pressure. [2] Drug-induced nausea and vomiting are of particular concern, especially with the increasing number of patients receiving cytotoxic treatment. A four-level classification system defines the risk for emesis with agents used in oncology (**Table 35-2**).[2] Although some agents may have greater emetic risk than others, combinations of agents, high doses, clinical settings, psychological conditions, prior treatment experiences, and unusual stimulus of sight,

smell, or taste may alter a patient's response to drug treatment. In this setting, nausea and vomiting may be unavoidable and some patients experience these problems so intensely that chemotherapy is postponed or discontinued.

TABLE 35-2 Emetic Risk of Agents Used in Oncology

Emetic Risk (If No Prophylactic Medication Is Administered)	Cytotoxic Agent (in Alphabetical Order)
High (>90%)	Combination of either doxorubicin or epirubicin + cyclophosphamide
	Carmustine
	Cisplatin (>50 mg/m^2)
	Cyclophosphamide (≥1,500 mg/m^2)
	Dacarbazine
	Ifosfamide (>10 g/m^2)
	Mechlorethamine
	Streptozotocin
Moderate (30%-90%)	Aldesleukin (>12-15 million units/m^2)
	Amifostine (>300 mg/m^2)
	Arsenic trioxide
	Azacitidine
	Bendamustine
	Busulfan
	Carboplatin
	Cisplatin (<50 mg/m^2)
	Clofarabine
	Cytarabine (>200 mg/m^2)
	Cyclophosphamide (<1,500 mg/m^2)
	Daunorubicin
	Dactinomycin
	Fluorouracil
	Gemcitabine
	Interferon alfa (<10 million units/m^2)
Low (10%-30%) (Continued)	Ixabepilone
	Lapatinib
	Methotrexate (<250 mg/m^2)
	Mitomycin
	Mitoxantrone
	Paclitaxel
	Paclitaxel albumin
	Pemetrexed
	Pentostatin
	Romidepsin
	Sorafenib
	Sunitinib
	Thiotepa
	Topotecan
	Trastuzumab
	Alemtuzumab
	Asparaginase
Minimal (<10%)	Bevacizumab
	Bleomycin
	Bortezomib

Emetic Risk (If No Prophylactic Medication Is Administered)	Cytotoxic Agent (in Alphabetical Order)	Emetic Risk (If No Prophylactic Medication Is Administered)	Cytotoxic Agent (in Alphabetical Order)
	Doxorubicin		
	Epirubicin		Cladribine
	Idarubicin		Cytarabine (<200 mg/m^2)
	Ifosfamide		Decitabine
	Interferon alfa (10 million units/m^2)		Denileukin diftitox
	Irinotecan		Dexrazoxane
	Melphalan		Fludarabine
	Methotrexate (>250 mg/m^2)		Ipilimumab
	Oxaliplatin		Nelarabine
	Procarbazine		Ofatumumab
	Temozolomide		Panitumumab
	Cabazitaxel		PEG-asparaginase
	Capecitabine		Rituximab
	Cetuximab		Temsirolimus
Low (10%-30%)	Cytarabine (≤200 mg/m^2)		Trastuzumab
	Docetaxel		Valrubicin
	Eribulin		Vinblastine
	Erlotinib		Vincristine
	Etoposide		Vinorelbine
	Floxuridine		

Data from references 2 and 30.

PATHOPHYSIOLOGY

The three consecutive phases of emesis include nausea, retching, and vomiting. Nausea, the imminent need to vomit, may be considered a separate and singular symptom. Retching is the labored movement of abdominal and thoracic muscles before vomiting. The final phase of emesis is vomiting, the forceful expulsion of gastric contents caused by GI retroperistalsis. The act of vomiting requires the coordinated contractions of the abdominal muscles, pylorus, and antrum, a raised gastric cardia, diminished lower esophageal sphincter pressure, and esophageal dilation.[1] Vomiting should not be confused with regurgitation, an act in which the gastric or esophageal contents

rise to the pharynx but is not usually associated with forceful ejection seen with vomiting. Accompanying autonomic symptoms of pallor, tachycardia, and diaphoresis account for many of the distressing feelings associated with emesis.

Vomiting is triggered by afferent impulses to the vomiting center (VC), a nucleus of cells in the medulla. Impulses are received from sensory centers, which include the chemoreceptor trigger zone (CTZ), cerebral cortex, and visceral afferents from the pharynx and GI tract. The VC integrates the afferent impulses, resulting in efferent impulses to the salivation center, respiratory center, and the pharyngeal, GI, and abdominal muscles, leading to vomiting.

The CTZ, located in the area postrema of the fourth ventricle of the brain, is a major chemosensory organ for emesis and is usually associated with chemically induced vomiting. Because of its location, bloodborne and cerebrospinal fluid toxins have easy access to the CTZ. Cytotoxic agents primarily stimulate this area rather than the cerebral cortex and visceral afferents. Similarly, pregnancy-associated vomiting probably occurs through stimulation of the CTZ.

Numerous neurotransmitter receptors are located in the VC, CTZ, and GI tract, including cholinergic, histaminic, dopaminergic, opiate, serotonergic, neurokinin (NK), and benzodiazepine receptors. Chemotherapeutic agents, their metabolites, or other emetic compounds theoretically trigger the process of emesis through stimulation of one or more of these receptors. Antiemetics have been developed to antagonize or block these emetogenic receptors.

CLINICAL PRESENTATION

Nausea and vomiting are commonly seen in many clinical situations. Patients may present in varying degrees of distress summarized in **Table 35-3** as *simple* or *complex* in presentation.

TABLE 35-3 Clinical Presentation of Nausea and Vomiting

General	
Depending on severity of symptoms, patients may present in mild to severe distress	
Symptoms	
Simple: Self-limiting, resolves spontaneously, and requires only symptomatic therapy	
Complex: Not relieved after administration of antiemetics; progressive deterioration of patient secondary to fluid-electrolyte imbalances; usually associated with noxious agents or psychogenic events	
Signs	
Simple: Patient complaint of queasiness or discomfort	
Complex: Weight loss; fever; abdominal pain	
Laboratory tests	
Simple: None	
Complex: Serum electrolyte concentrations; upper/lower GI evaluation	
Other information	
Fluid input and output	
Medication history	
Recent history of behavioral or visual changes, headache, pain, or stress	

Family history positive for psychogenic vomiting

TREATMENT

Desired Outcomes

3 The overall goal of antiemetic therapy is to prevent or eliminate nausea and vomiting. This should be accomplished without adverse effects or with clinically acceptable adverse effects. In addition to these clinical goals, appropriate cost issues should be considered, particularly in the management of chemotherapy-induced nausea and vomiting (CINV) and postoperative nausea and vomiting (PONV).

General Approach to Treatment

4 Treatment options include drug and non-drug modalities such as relaxation, biofeedback, and self-hypnosis. Initially patients may choose to not treat or to self-medicate with nonprescription drugs. As symptoms become worse or are associated with more serious medical problems, patients are more likely to utilize prescription antiemetic drugs. When prescribed and used appropriately, these agents can provide relief; however, some patients will never be totally free of symptoms. This lack of relief is most disabling when it is associated with an unresolved medical problem or when the necessary therapy for this condition is the cause of the nausea or vomiting, as in the case of patients who are receiving chemotherapy of moderate or high emetic risk.

Nonpharmacologic Management

Nonpharmacologic management of nausea and vomiting involves dietary, physical, or psychological strategies that are consistent with the etiology of nausea and vomiting. For patients who are suffering due to excessive or disagreeable food or beverage consumption, avoidance or moderation in dietary intake may be lead to symptom resolution. Patients suffering symptoms of systemic illness may quickly improve as their underlying condition resolves. Finally, patients in whom these symptoms result from labyrinthine changes produced by motion may benefit quickly by assuming a stable physical position.

Nonpharmacologic interventions are classified as behavioral interventions and include relaxation, biofeedback, hypnosis, cognitive distraction, optimism, guided imagery, acupuncture, yoga, and systematic desensitization.[3,4] Some of these modalities, such as with P6 acupuncture bands, have shown to be effective at preventing nausea and vomiting in the surgical population.[5] Other therapies, such as ginger and pyridoxine, are beneficial in specific situations as with chemotherapy-induced nausea and vomiting (CINV) and nausea and vomiting related to pregnancy.

Pharmacologic Therapy

Although many approaches to the treatment of nausea and vomiting have been suggested, antiemetic drugs (nonprescription and prescription) are most often recommended. These agents work in various ways that may be used singularly or in conjunction with each other and represent a number of delivery mechanisms.

Factors that enable the clinician to choose the appropriate regimen include: (a) the suspected etiology of the symptoms; (b) the frequency, duration, and severity of the episodes; (c) the ability of the patient to use oral, rectal, injectable, or transdermal medications; and (d) the success of previous antiemetic medications. Please see **Table 35-4** for dosing information of commonly available antiemetic preparations.

TABLE 35-4 Common Antiemetic Preparations and Adult Dosage Regimens

Drug	Adult Dosage	Availability	Adverse	Monitoring	Comments

	Dosage Regimen	Form/Route		Drug Reactions	Parameters	
Antacids						
Antacids (various)	15-30 mL every 2-4 hours prn	Liquid/oral	OTC	Magnesium products: diarrhea Aluminum or calcium products: constipation	Assess for symptom relief	Useful with simple nausea/vomiting
Antihistaminic–Anticholinergic Agents						
Dimenhydrinate (Dramamine)	50-100 mg every 4-6 hours prn	Tab, chew tab, cap	OTC	Drowsiness, confusion, blurred vision, dry mouth, urinary retention	Assess for episodic relief of motion sickness or nausea/vomiting	Especially problematic in the elderly Increased risk of complications in patients with BPH, narrow angle glaucoma, or asthma
Diphenhydramine (Benadryl)	25-50 mg every 4-6 hours prn	Tab, cap, liquid	Rx/OTC			
	10-50 mg every 2-4 hours prn	IM, IV				
Hydroxyzine (Vistaril, Atarax)	25-100 mg every 4-6 hours prn	IM (unlabeled use)	Rx			
Meclizine (Bonine, Antivert)	12.5-25 mg 1 hour before travel; repeat every 12-24 hours prn	Tab, chew tab	Rx/OTC			
Scopolamine (Transderm Scop)	1.5 mg every 72 hours	Transdermal patch	Rx			
Trimethobenzamide (Tigan)	300 mg three to four times daily	Cap	Rx			
	200 mg three to four times daily	IM				
Benzodiazepines						
Alprazolam (Xanax)	0.5-2 mg three times daily prior to	Tab	Rx (C-IV)	Dizziness, sedation, appetite	Assess for episodes of ANV	Place in therapy: ANV

	chemotherapy			changes, memory impairment		
Lorazepam (Ativan)	0.5-2 mg on night before and morning of chemotherapy	Tab	Rx (C-IV)			
Butyrophenones						
Haloperidol (Haldol)	1-5 mg every 12 hours prn	Tab, liquid, IM, IV	Rx	Sedation, constipation, hypotension	Observe for additive sedation especially if used with narcotic analgesics	Place in therapy: palliative care
Droperidol (Inapsine)[a]	2.5 mg; additional 1.25 mg may be given	IM, IV	Rx	QT prolongation and/or torsade de pointes	12-Lead electrocardiogram prior to administration, followed by cardiac monitoring for 2-3 hours after administration	Limited use outside of clinical trials
Cannabinoids						
Dronabinol (Marinol)	5-15 mg/m^2 every 2-4 hours prn	Cap	Rx (C-III)	Euphoria, somnolence, xerostomia	Assess for symptom relief	May be useful with refractory CINV
Nabilone (Cesamet)	1-2 mg twice daily	Cap	Rx (C-II)	Somnolence, vertigo, xerostomia		
Corticosteroids						
Dexamethasone	See Table 35-6 for CINV dosing and Table 35-8 for PONV dosing	Tab, IV	Rx	Insomnia, GI symptoms, agitation, appetite stimulation	Assess for efficacy as prophylactic agent: episodes of nausea/vomiting and hydration status	Useful as single-agent or combination therapy for prophylaxis of CINV and PONV
Histamine (H2) Antagonists						
Cimetidine (Tagamet HB)	200 mg twice daily prn	Tab	OTC	Headache	Assess for symptom relief	Useful when nausea due to heartburn or GERD
Famotidine (Pepcid AC)	10 mg twice daily prn	Tab	OTC	Constipation, diarrhea		
Nizatidine (Axid AR)	75 mg twice daily prn	Tab	OTC	Diarrhea, headache		

Ranitidine (Zantac 75)	75 mg twice daily prn	Tab	OTC	Constipation, diarrhea		
5-Hydroxytryptamine-3 Receptor Antagonists						
	See Table 35-6 for CINV dosing and Table 35-8 for PONV dosing	Tab, IV	Rx	Asthenia, constipation, headache	Assess for efficacy as prophylactic agent: episodes of nausea/vomiting and hydration status	Useful as single-agent or combination therapy for prophylaxis of CINV and PONV
Miscellaneous Agents						
Metoclopramide (Reglan)	10 mg four times daily	Tab	Rx	Asthenia, headache, somnolence	Assess for symptom relief	Prokinetic activity useful in diabetic gastroparesis
Olanzapine (Zyprexa)	2.5-5 mg twice daily	Tab	Rx	Sedation	Assess for decrease in episodes of nausea/vomiting	Use with caution in elderly. May be useful in breakthrough CINV
Phenothiazines						
Chlorpromazine (Thorazine)	10-25 mg every 4-6 hours prn	Tab, liquid	Rx	Constipation, dizziness, tachycardia, tardive dyskinesia	Assess for decrease in episodes of nausea/vomiting	Useful with simple nausea/vomiting
	25-50 mg every 4-6 hours prn	IM, IV		See above		
Prochlorperazine (Compazine)	5-10 mg three to four times daily prn	Tab, liquid	Rx	Prolonged QT interval, sedation, tardive dyskinesia	Assess for decrease in episodes of nausea/vomiting	Useful with simple nausea/vomiting and for breakthrough CINV
	5-10 mg every 3-4 hours prn	IM				
	2.5-10 mg every 3-4 hours prn	IV	Rx			
	25 mg twice daily prn	Supp	Rx			
Promethazine (Phenergan)	12.5-25 mg every 4-6 hours prn	Tab, liquid, IM, IV, supp	Rx	Drowsiness, sedation	Assess for decreased nausea/vomiting episodes and improvement in	

					hydration status	
Substance P/Neurokinin 1 Receptor Antagonist						
Aprepitant	See Table 35-6 for CINV dosing and Table 35-8 for PONV dosing	Cap, IV	Rx	Constipation, diarrhea, headache, hiccups	Assess for efficacy as prophylactic agent: episodes of nausea/vomiting and hydration status	Useful in combination therapy for prophylaxis of CINV and PONV
Fosaprepitant		IV	Rx			
Netupitant/palonosetron		Cap	Rx	Same as above plus dyspepsia and fatigue		
Rolapitant		Cap	Rx			Long half-life and no drug interactions

ANV, anticipatory nausea and vomiting; C-II, C-III, and C-IV, controlled substance schedule 2, 3, and 4, respectively; cap, capsule; chew tab, chewable tablet; CINV, chemotherapy-induced nausea and vomiting; GERD, gastroesophageal reflux disease; liquid, oral syrup, concentrate, or suspension; OTC, nonprescription; PONV, postoperative nausea and vomiting; Rx, prescription; supp, rectal suppository; tab, tablet.

[a]See text for current warnings.

The treatment of simple nausea and vomiting often involves self-care from a list of nonprescription products. Both nonprescription and prescription drugs are useful in the treatment of simple nausea and vomiting in small, infrequently administered doses and are associated with minimal side effects. Changes in diet such as restricting oral intake, eating smaller meals, avoiding spicy or fried foods and instead eating bland foods such as with the BRAT diet (Bananas, Rice, Applesauce and Toast) can help alleviate symptoms. As the symptoms persist or become worse, prescription medications may be chosen, either as single-agent therapy or in combination.

The management of complex nausea and vomiting, such as in patients who are receiving cytotoxic chemotherapy, may require initial combination therapy. In combination regimens, the goal is to achieve symptomatic control through administration of agents with different pharmacologic mechanisms of action.

Antacids

Patients who are experiencing simple nausea and vomiting may initially use antacids, as many of these products are readily available without a prescription. In this setting, single or combination products, especially those containing magnesium hydroxide, aluminum hydroxide, and/or calcium carbonate, may provide rapid relief, primarily through gastric acid neutralization. These agents are most effective for those with symptoms related to acid reflux or heartburn and must be used with caution in those who experience acute or chronic kidney disease due to the risk of accumulation. These agents may exacerbate other GI complaints that accompany nausea and vomiting, such as diarrhea or constipation, so attention must be paid to which of these agents may worsen these other conditions.

Antihistamine–Anticholinergic Drugs

Antiemetic drugs from the antihistaminic–anticholinergic category work on muscarinic and histamine receptors in the VC and the vestibular system that stimulates nausea and vomiting. As such, these agents are frequently initiated

as self-care to prevent nausea and vomiting associated with motion disturbances such as vertigo and motion sickness.

Benzodiazepines

Benzodiazepines are relatively weak antiemetics and are primarily used for their anxiolytic activity to prevent anxiety or anticipatory nausea and vomiting (ANV) that is common in patients receiving highly emetogenic chemotherapy. Either agent, alprazolam, or lorazepam, may be used as adjuncts to other antiemetics in patients treated with cisplatin-containing regimens. Both agents may be used orally, with alprazolam and the sublingual formulation of lorazepam having an onset of action of 60 minutes.

Butyrophenones

Haloperidol and droperidol work to block dopaminergic stimulation of the CTZ, which in turn decreases the incidence of nausea and vomiting. Although each agent is effective in relieving nausea and vomiting, these agents are limited due to their propensity to cause extra-pyramidal symptoms and risk of QTc prolongation. For these reasons, haloperidol is not considered first-line therapy for uncomplicated nausea and vomiting but has been used in palliative care situations.[6] The labeling of droperidol recommends that all patients should undergo a 12-lead electrocardiogram prior to administration, followed by cardiac monitoring for 2 to 3 hours after administration because of the possibility of the development of potentially fatal QT prolongation and/or torsade de pointes.[7] The clinical use of droperidol has effectively ceased outside of clinical trials in anesthesia.

Cannabinoids

Cannabinoids have complex effects on the CNS and their effects at receptors in neural tissues may explain efficacy in CINV. Oral dronabinol and nabilone are therapeutic options when CINV is refractory to other antiemetics. These agents are limited by their route of administration and slow onset of action; however, a newer agent, nabiximol, which is available as a oromucosal spray, is currently being investigated in the prevention of CINV and resolves some of the key limitations of the currently available products.[8] Cannabinoids have the advantage of being effective for other cancer related side effects such as serving as a treatment of cancer related pain and an appetite stimulant.[9,10,11] Despite these advantages, cannabinoids are not indicated as first-line agents.

Corticosteroids

Corticosteroids have demonstrated antiemetic efficacy since the initial recognition that patients who received prednisone as part of their Hodgkin's disease protocol appeared to develop less nausea and vomiting than did those patients who were treated with protocols that excluded this agent. Methylprednisolone has also been used as a component of an antiemetic regimen, but the majority of trials have studied dexamethasone. The site and mechanism of action of corticosteroids for CINV and PONV is unknown.

Dexamethasone is the most commonly used corticosteroid in the management of CINV and PONV, either as a single agent or in combination with 5-hydroxytryptamine-3 receptor antagonists (5-HT3-RA). Dexamethasone is effective in the prevention of both CINV acute emesis and delayed nausea and vomiting when used alone or in combination.[12,13] Given the risk of corticosteroids such as hyperglycemia, fluid retention and even psychosis, steroids are not indicated for the treatment of simple nausea and vomiting.

H2-Receptor Antagonists (H2RA)

Histamine2-receptor antagonists work by decreasing gastric acid production and are used to manage simple nausea and vomiting associated with heartburn or gastroesophageal reflux. Except for potential drug interactions with

cimetidine, these agents cause few side effects when used for episodic relief.

5-Hydroxytryptamine-3 Receptor Antagonists

5-Hydroxytryptamine-3 receptor antagonists block serotonin receptors on sensory vagal fibers in the gut wall, thus blocking the acute phase of CINV. These agents do not completely block the acute phase of CINV and are less efficacious in preventing the delayed phase, but they are considered the standard of care in the management of CINV, PONV, and radiation-induced nausea and vomiting (RINV). Issues involved in the use of dolasetron, granisetron, ondansetron, and palonosetron are reviewed in detail in the sections that follow.

Metoclopramide

Metoclopramide works by blocking dopaminergic receptors centrally in the CTZ. It also increases lower esophageal sphincter tone, aids gastric emptying, and accelerates transit through the small bowel, possibly through the release of acetylcholine. The prokinetic activity of metoclopramide makes it useful in patients with nausea and vomiting associated with diabetic gastroparesis.

Olanzapine

Olanzapine is an antipsychotic that blocks several neurotransmitters including dopamine, serotonin, adrenergic, histamine (H1) and 5-HT3-RA. Use of olanzapine, in combination with palonosetron and dexamethasone, effectively controlled acute and delayed CINV in patients receiving highly emetogenic chemotherapy as compared with aprepitant, palonosetron, and dexamethasone in a randomized, phase 3 clinical trial.[14] It has also been studied as an option for those who have failed their initial antiemetic prophylactic therapy. When compared to metoclopramide, olanzapine had significantly lower nausea or vomiting rates in this population.[15] The National Comprehensive Cancer Network (NCCN) antiemesis practice guideline includes olanzapine as one of many options in patients who experience breakthrough nausea and/or vomiting following prophylaxis for CINV.[16] Sedation, constipation, and restlessness are the most common side effects with olanzapine; it should be used with caution in the elderly.

Phenothiazines

Phenothiazines have been the most widely prescribed antiemetic agents and appear to block dopamine receptors, most likely in the CTZ. They are marketed in an array of dosage forms, none of which appears to be more efficacious than another. These agents may be most practical for long-term treatment and are inexpensive in comparison with newer drugs. Rectal administration is a reasonable alternative in patients in whom oral or parenteral administration is not feasible.

Phenothiazines are most useful in adult patients with simple nausea and vomiting. Intravenously administered prochlorperazine provided quicker and more complete relief with less drowsiness than IV promethazine in adult patients treated in an emergency department for nausea and vomiting associated with uncomplicated gastritis or gastroenteritis.[17]

Neurokinin 1 Receptor Antagonists

Substance P is a peptide neurotransmitter in the NK family whose preferred receptor is the NK1 receptor. The acute phase of CINV is believed to be mediated by both serotonin and substance P, where substance P is believed to be the primary mediator of the delayed phase. Aprepitant and fosaprepitant are the first NK1 receptor antagonists in clinical use; however, newer agents are available such as the new combination NK1 receptor antagonist/5-HT3-RA product, netupitant/palonosetron (NEPA) and the NK1 receptor antagonist, rolapitant.[18]

Agents, such as rolapitant, aprepitant, or fosaprepitant, are used in patients receiving moderate to highly

emetogenic chemotherapy as part of a three drug combination consisting of an NK1 receptor antagonist, dexamethasone, and a 5-HT3-RA. This combination is now considered the standard of care for CINV and has shown improved protection from vomiting for up to 5 days after chemotherapy administration as compared with dual therapy of dexamethasone and a 5-HT3-RA inhibitor.[16]

Aprepitant has the potential for numerous drug interactions because it is a substrate, moderate inhibitor, and an inducer of cytochrome isoenzyme CYP3A4 as well as an inducer of CYP2C9. It can increase serum concentrations of many drugs, including many chemotherapeutic agents, metabolized by CYP3A4, including docetaxel, paclitaxel, etoposide, irinotecan, ifosfamide, imatinib, vinorelbine, vincristine, and vinblastine. Other significant drug interactions include decreased effectiveness of oral contraceptives, and a decrease in the international normalized ratio when used with warfarin.[19] The dose of oral dexamethasone should be reduced 50% when coadministered with aprepitant, because of the 2.2-fold increase in observed area under the plasma-concentration-versus-time curve.[20]

Fosaprepitant, an injectable form of aprepitant, has been approved by the FDA as an IV substitute for oral aprepitant on day 1 of the standard 3-day CINV prevention regimen, with oral aprepitant administered on days 2 and 3.[21]

Rolapitant is the newest NK1 receptor antagonist and has the unique advantage over other NK1 receptor antagonist in that it has a significantly longer half-life in comparison with aprepitant, 7 days versus 9 hours. This allows less frequent administration with this drug only being administered in one dose prior to chemotherapy in combination with a 5-HT3-RA and dexamethasone.[18] Another unique advantage of rolapitant is that it has no effects on CYP3A4, which could be useful in those regimens that would otherwise have significant drug interactions with aprepitant.[22]

Netupitant/palonosetron (NEPA) is an oral, coformulated product that when given in just one dose combination with dexamethasone, was superior to a combination regimen of aprepitant, oral palonosetron, and dexamethasone regimen in individuals receiving highly emetogenic chemotherapy. NEPA prevented both acute and delayed nausea and vomiting; this effect was sustained up to 5 days from chemotherapy administration.[23,24] As with aprepitant, it is also a moderate inhibitor of CYP3A4, and also requires a significant decrease in the dexamethasone dose when used together. The most common side effects of NEPA were headache, asthenia, fatigue, and dyspepsia.[25]

CHEMOTHERAPY-INDUCED NAUSEA AND VOMITING

There are five categories of CINV: acute, delayed, anticipatory, breakthrough, and refractory. Nausea and vomiting that occurs within 24 hours of chemotherapy administration is defined as acute CINV, whereas when it starts more than 24 hours after chemotherapy administration, it is defined as delayed CINV.

Nausea or vomiting that occurs prior to receiving chemotherapy is termed anticipatory nausea and vomiting (ANV). ANV is believed to be a learned, conditioned, or psychological response that occurs in about 25% of patients by the fourth cycle of chemotherapy.[26] ANV triggers include tastes, odors, sights, or thoughts associated with chemotherapy. Risk factors associated with ANV include age under 50, nausea and/or vomiting after the previous chemotherapy session, anxiety, sweating and a feeling of warmth after the last chemotherapy cycle, and susceptibility to motion sickness.[27]

In the setting of optimal antiemetic prophylaxis and no prior history of emesis, reported chemotherapy-induced ANV is rare. Use of newer antiemetic regimens appears to have resulted in a decreased rate of ANV.[28]

Breakthrough nausea and vomiting is defined as emesis occurring despite prophylactic administration of antiemetics and requiring the use of rescue antiemetics. Breakthrough emesis occurs in 10% to 40% treated with modern-day antiemetics.[29]

Refractory nausea and vomiting is evident when there is a poor response to multiple antiemetic regimens. It is also

important to rule out other potential causes of nausea and vomiting in the cancer population such as with brain metastases, electrolytes imbalances, infections, uremia, treatment with opioids, anxiety or bowel obstruction.[16]

5 The primary goal with CINV is to prevent nausea and/or vomiting and the emetic risk of the chemotherapeutic regimen is a major factor to consider when selecting a prophylactic regimen.[16]

Clinical practice guidelines for the use of antiemetics in CINV have been published by the NCCN,[16] the Multinational Association of Supportive Care in Cancer/European Society of Oncology (MASCC/ESMO),[30] and the American Society of Clinical Oncology (ASCO).[31] The NCCN guidelines are updated annually, while the ASCO and ESMO guidelines are updated less frequently. Despite the demonstrated improvement in outcomes with the use of these practice guidelines, they are underutilized by a high percentage of practitioners.[30] Furthermore, product availability and recommended doses are often institution-specific and may vary considerably from the doses listed in **Table 35-6**.

TABLE 35-6 Dosage Recommendations for CINV for Adult Patients

Emetogenic Risk	Acute NV Prevention (Day 1)—Prior to Chemotherapy			Delayed NV Prevention (Days 2-4)		
High[b,c,g]	***Option 1—NK1 + 5-HT3 + Steroid***					
	NK1 Antagonist	*5-HT3 Antagonist*	*Steroid*	*Day 2*	*Day 3*	*Day 4*
	Aprepitant 125 mg PO × 1	Dolasetron 100 mg PO × 1	Dexamethasone 12 mg PO/IV × 1[a]	Aprepitant 80 mg PO + Dexamethasone 8 mg IV/PO	Aprepitant 80 mg PO + Dexamethasone 8 mg IV/PO	Dexamethasone 8 mg IV/PO
	Fosaprepitant 150 mg IV × 1	Granisetron 2 mg PO × 1 OR 1 mg PO twice daily OR 0.01 mg/kg (Max 1 mg) IV OR 3.1 mg/h transdermal patch applied 24-48 hours prior to chemo		Dexamethasone 8 mg IV/PO	Dexamethasone 8 mg IV/PO twice daily	Dexamethasone 8 mg IV/PO twice daily
	Rolapitant 180 mg PO × 1	Ondansetron 16-24 mg PO × 1 OR 8-16 mg IV × 1	Dexamethasone 20 mg PO/IV × 1	Dexamethasone 8 mg IV/PO twice daily	Dexamethasone 8 mg IV/PO twice daily	Dexamethasone 8 mg IV/PO twice daily
		Palonosetron 0.25 mg IV × 1				
	Option 2—NK1/5-HT3 + Steroid			*Day 2*	*Day 3*	*Day 4*
	Netupitant 300 mg PO/Palonosetron 0.5 mg PO × 1 + Dexamethasone 12 mg PO/IV × 1			Dexamethasone 8 mg IV/PO	Dexamethasone 8 mg IV/PO	Dexamethasone 8 mg IV/PO
	Option 3—Olanzapine + 5-HT3 + Steroid			*Day 2*	*Day 3*	*Day 4*
	Olanzapine 10 mg PO × 1+ Palonosetron 0.25 mg IV + Dexamethasone 20 mg IV × 1			Olanzapine 10 mg PO	*Olanzapine 10 mg PO*	*Olanzapine 10 mg PO*
Moderate[b,c]	***Option 1-5—HT3 (Palonosetron Preferred) + Steroid (Same doses as listed above) ± NK1***			***Option 1-5—HT3 Monotherapy, Days 2-3***		
				Dolasetron 100 mg PO daily Granisetron 1-2 mg PO daily OR 1 mg PO twice daily OR 0.01 mg/kg (Max 1 mg) IV Ondansetron 8 mg PO twice daily OR 16 mg PO daily OR 8-16 mg IV daily		
				Option 2—Steroid Monotherapy, Days 2-3		
				Dexamethasone 8 mg IV/PO daily		
				Option 3—NK1 + Steroid, as listed with High-Risk Delayed Regimen		
	Option 2—NK1/5-HT3 + Steroid at Doses listed above			± Dexamethasone 8 mg IV/PO daily, Days 2-3		

Emetogenic Risk	Acute NV Prevention (Day 1)—Prior to Chemotherapy	Delayed NV Prevention (Days 2-4)
	Option 3—Olanzapine +5-HT3 + Steroid at Doses listed above	Olanzapine 10 mg PO daily, Days 2-3
Low[b,c]	Dexamethasone 12 mg IV/PO IV daily Metoclopramide 10-40 mg IV/PO, then every 4-6 hours prn Prochlorperazine 10 mg IV/PO, then every 6 hour prn (max 40 mg/day) 5-HT3 Antagonist Dolasetron 100 mg PO daily Granisetron 1-2 mg PO daily Ondansetron 8-16 mg PO daily	None
Minimal	None	None

[a]Use a lower dose of Dexamethasone if Aprepitant or Fosaprepitant is used

[b]± Use of H2RA or Proton Pump Inhibitor See References 16, 24, and 27 for the above information.

[c]± Use of Lorazepam 0.5-2 mg PO/IV/SL every 6 hours prn on Days 1-4

Principles of Antiemetic Use for CINV

The ASCO, MASCC, and NCCN consensus groups share several of the principles listed below that appear to be important for the effective prevention of CINV in adults:[32,33]

1. The primary goal of emesis prevention is no nausea and/or vomiting throughout the period of emetic risk.
2. The duration of emetic risk is 2 days for patients receiving moderately emetogenic chemotherapy and 3 days for highly emetogenic chemotherapy. Emetic prophylaxis should be provided through the entire period of risk.
3. The selection of the antiemetic regimen should be based on the chemotherapy drug with highest emetogenicity (see Table 35-2). Prior emetic experience and patient-specific factors should also be considered.
4. When given in equipotent doses, oral and IV 5-HT3-RAs are equivalent in efficacy.
5. The toxicities of antiemetics should be considered and managed appropriately.

Prophylaxis of Acute CINV

Each of the practice guidelines states that the most effective classes of drugs for the prevention of acute emesis are the 5-HT3-RAs, NK1 receptor antagonists, olanzapine and glucocorticoids (especially dexamethasone). Treatment recommendations for the different categories of emesis are outlined in Table 35-6.

High Emetogenic Chemotherapy

Patients receiving high emetogenic chemotherapy (HEC) have three different options that may be used. The first option includes an initial three drug antiemetic regimen that is initiated prior to the administration moderate/low

emetogenic chemotherapy, day 1, which includes a 5-HT3-RA agent, dexamethasone, and an NK1 receptor antagonist. Due to the CYP3A4 interactions, lower doses of dexamethasone are used for aprepitant or fosaprepitant versus a standard dose of dexamethasone with a rolapitant regimen; steroids may be continued for days 2 to 4 as outlined in Table 35-6.

The second option includes a two drug regimen containing the NK1 receptor antagonist/5-HT3 antagonist combination of NEPA, in addition to reduced dose dexamethasone due to the drug interactions with CYP3A4, similar to the dose used with aprepitant. As with the first option, dexamethasone is continued on days 1 to 3.

The third option includes an olanzapine based therapy in combination with a 5-HT3-RA, specifically palonosetron, along with dexamethasone. This regimen is unique in that it is steroid sparing and only the olanzapine is continued through days 2 to 4 as outlined in Table 35-6.

Any of the 5-HT3-RAs may be used on day 1; however, the ASCO and NCCN guidelines prefer IV palonosetron.[30,31] In regards to dolasetron, in 2010 the FDA released a statement that IV dolasetron should not be used for treatment of CINV due to an increased risk of QTc prolongation and other cardiac conduction abnormalities. Only the oral formulation of dolasetron should be used for CINV.[34] Non-oral/IV options do exist such as the granisetron transdermal patch, which should be applied 24 to 48 hours prior to chemotherapy. This patch continues to work for up to 7 days. The final choice of 5-HT3-RA should be based on route of administration, potential side effects and cost concerns.

Clinical Controversy…

Is QT prolongation a concern for 5-HT3-RAs? 5-HT3-RAs are widely used antiemetics in oncology; however, QT prolongation has been observed. Only a few studies have addressed ECG changes in cancer patients treated for CINV. Further studies are needed in this population as patients are often older, have a higher incidence of comorbidities and polypharmacy, as well as the potential for more drug-drug interactions than those who have previously been included in clinical trials for PONV. The incidence of cardiac adverse effects in cancer patients who have known heart disease needs to be addressed in those who may receive a 5-HT3-RA for the prophylaxis of CINV.[35]

Moderate Emetogenic Chemotherapy

Patients receiving moderate emetogenic chemotherapy (MEC) also have three options of antiemetic regimens. The first is a two-drug regimen 5-HT3-RA on day 1 with dexamethasone and either a 5-HT3-RA or dexamethasone continued through day 3. Both ASCO and NCCN guidelines recommend IV palonosetron as the preferred 5-HT3-RA for MEC.[30,31] The exception to this recommendation is in patients who are receiving combination chemotherapy with the following therapies: carboplatin, cisplatin, doxorubicin, epirubicin, ifosfamide, irinotecan, or methotrexate. It is recommended that these patients be given an NK1 receptor antagonist in addition the 5-HT3-RA and dexamethasone.[16]

The second option is the combination of an NK1 receptor antagonist/5-HT3 receptor antagonist, NEPA plus dexamethasone on day 1 of therapy, with dexamethasone continued through days 2 to 3. The third and final option is the same as with the HEC based olanzapine therapy in combination with palonosetron and dexamethasone, with only olanzapine continued for days 2 to 3.[16]

For chemotherapy regimens that are of low emetic risk, dexamethasone or any of the following may be used: prochlorperazine, metoclopramide, or a 5-HT3-RA such as dolasetron, granisetron or ondansetron alone.[16]

Prophylaxis of Delayed CINV

The best strategy for preventing delayed CINV, nausea and/or vomiting occurring 24 or more hours after chemotherapy, is to control acute CINV and provide adequate prophylaxis for delayed CINV. As with prevention of acute CINV, the agent used is highly dependent on the emetogenic potential of the regimen. It is also imperative to realize that the regimen used in the prevention of acute CINV in each patient will often dictate the regimen to be used for delayed nausea and vomiting. These regimens frequently include continuing dexamethasone or olanzapine for up to 3 days for those receiving HEC.[16,30,31] For those who use aprepitant for prevention of acute CINV, aprepitant must be continued for 3 days in addition to dexamethasone. This is the only NK1 antagonist that is recommended for continued dosing for prevention of CINV, and other NK1 antagonists do not require repeated dosing administrations.[16] Those receiving MEC can often continue with just a single drug therapy with options with 5-HT3-RAs, dexamethasone, olanzapine, or potentially use a combination of these agents. Further details including agents and days of therapy are outlined in Table 35-6.

Any of the above regimens, whether it be HEC, MEC, or low risk, may be used in combination with an acid suppressing agent such as an H2RA or a proton pump inhibitor. These patients may also use lorazepam 0.5-2 mg PO/IV every 6 hours as needed for additional nausea relief.[16,30,31]

Prophylaxis and Treatment of Anticipatory Nausea and Vomiting

All three guidelines, MASCC, ASCO, as well as the NCCN, are all in agreement that prevention of CINV from the beginning of chemotherapy is essential in preventing ANV.[16,30,31] There are some nonpharmacologic options, such as use of behavioral therapy, hypnosis, acupuncture/acupressure or music therapy, may be of use for ANV. Benzodiazepine therapy may be used the decrease the occurrence of ANV; however, these therapies may become less effective over time.[28] If ANV occurs, options such as oral alprazolam 0.5-1 mg or oral lorazepam 0.5-2 mg starting the evening prior to chemotherapy and then an addition dose 1 to 2 hours prior to chemotherapy administration may be used.[16]

Treatment of Breakthrough CINV

A general principle in all patients receiving chemotherapy is to prescribe an antiemetic from a different pharmacologic class for rescue of breakthrough nausea and vomiting. Rescue medications used in adult patients include prochlorperazine, promethazine, lorazepam, metoclopramide, haloperidol, 5-HT3-RAs, dexamethasone, cannabinoids, or olanzapine.[16,31,36]

Around-the-clock dosing of rescue antiemetics should be considered rather than as-needed administration. If the rescue antiemetics are useful, there should be consideration of changing the current antiemetic therapy to a higher level of primary treatment for the subsequent cycles.[16,31] The choice of agent should be based on patient-specific factors, including potential adverse drug reactions and cost. Chlorpromazine, lorazepam, and dexamethasone are recommended for pediatric patients.[37]

Treatment of Refractory Nausea and Vomiting

The general approach to the management of refractory CINV is to upgrade the antiemetic strategy to the next level of prophylaxis or to add breakthrough antiemetics to the regimen.[16] Some patients will experience nausea and vomiting despite optimal acute and delayed prophylaxis and failure of rescue antiemetics. Addition of another agent from a different pharmacologic class is recommended and routes other than the oral route may be required.

Treatment of Multiday Chemotherapy

Chemotherapy regimens are occasionally administered over multiple days. The MASCC guidelines state that the combination of a 5-HT3-RA plus daily dexamethasone is the standard of care.[30] For HEC or MEC, it is recommended

that dexamethasone be administered either IV or PO and be continued for up to 2 to 3 days after the chemotherapy has ended and that 5-HT3-RA administration should be started prior to start of chemotherapy.[16] When using NK1 antagonist for HEC regimens, there is some data supporting the use of aprepitant for up to 4 to 5 days; there is another trial that suggests that for 5-day cisplatin therapy, initiate aprepitant on day 3 and continue a lower dose of aprepitant through day 7 along with a 5-HT3-RA on days 1 to 5 along with dexamethasone on days 1 to 2.[38] Dexamethasone should not be prescribed for patients receiving a corticosteroid in their chemotherapy regimen or with regimens containing interferon alpha or interleukin-2.[33]

POSTOPERATIVE NAUSEA AND VOMITING

Postoperative nausea and vomiting in adults occurs in 30% of patients and usually within 24 hours of undergoing anesthesia.[39] Patients with multiple risk factors are at highest risk for PONV (**Table 35-7**). Patients with zero or one of the four risk factors present in Table 35-7 are at lowest risk (10%-20%) and those with three to five risk factors are at highest risk for PONV (50%-80%). Moderate risk is defined by this model as the presence of two to three risk factors and high risk is defined as greater than three risk factors. The use of a risk assessment tool can help identify patients most likely to benefit from prophylaxis.[40,41,42]

TABLE 35-7 Risk Factors for Postoperative Nausea and Vomiting (PONV)

Patient-related factors
Age less than 50 years old
Female gender (two to three times greater incidence of PONV vs males)
Nonsmoker
History of PONV or motion sickness (threefold increase in incidence of PONV)
Hydration status
Factors related to anesthesia
Use of general anesthesia
Use of volatile anesthetics
Nitrous oxide
Use of opioids (intraoperative or postoperative)
Factors related to surgery
Type of surgical procedure (laparoscopic, gynecological, cholecystectomy)
Duration of surgery

Data from references 45 and 47.

In addition to using prophylactic antiemetics in moderate and high-risk patients, other strategies to prevent PONV include using regional rather than systemic anesthesia, propofol, and hydration, as well as avoiding the use of nitrous oxide, volatile anesthetics, or opioids.[41]

Prophylaxis of PONV

Adherence to consensus guidelines for prophylaxis and treatment of PONV decreases emetic episodes.[41] Patients at highest risk of vomiting should receive two or more prophylactic antiemetics from different pharmacologic classes, while those at moderate risk should receive one or two drugs.[41] Timing the administration of the antiemetic is dependent on the agent used. Scopolamine patches must be initiated the evening before the surgery or at least 2 hours prior, whereas NK1 antagonists should be given during the induction of anesthesia; all other agents are recommended to be given at the end of the surgery. Pharmacological options for the prevention of PONV include 5-HT3-RAs, NK1 antagonist, corticosteroids, droperidol, haloperidol, antihistamines, and anticholinergics.

Of the available 5-HT3-RAs available, ondansetron is still considered the "gold standard" agent and has the most data supporting its use at the end of surgical procedures. Ondansetron has greater anti-vomiting activity versus anti-nausea activity and is as effective as dexamethasone, droperidol, and IV haloperidol. It was however found to be less effective than the NK1 antagonist, aprepitant, in decreasing emesis and less effective than fellow 5-HT3-RA, palonosetron for decreasing the incidence of PONV.[41,43,44] Palonosetron is a second generation 5-HT3-RA, which is unique with a prolonged half-life of 40 hours and it is one of the only 5-HT3-RAs that does not affect the QT interval. Granisetron is as effective as other first generation 5-HT3-RAs, but this agent may not be as effective in those who are ultra-metabolizers of CYP2D6 pathway.[45]

Steroids, such as dexamethasone and methylprednisolone are useful low cost agents used in preventing PONV. Utilizing higher doses of dexamethasone (more than 0.1 mg/kg) has been associated with a decrease in nausea and vomiting, and improvement in other important postoperative complications such as decreasing pain, need for opiates, and improvement in sleep. Dexamethasone should be administered after the induction of anesthesia, and due to its effects on glycemic control, its use should be avoided in patients with uncontrolled diabetes.[41,46,47]

When the different combinations of antiemetics were compared, no differences were found between 5-HT3-RA plus droperidol, 5-HT3-RA plus dexamethasone, and droperidol plus dexamethasone.[48] However, QT prolongation and/or torsade de pointes has been reported in some cases, with some fatalities in patients receiving droperidol at doses at or below recommended doses. Droperidol should be avoided in patients who have a history of QT prolongation, are over 65 years old, or have a history of alcohol abuse, or when used concomitantly with benzodiazepines, volatile anesthetics, and IV opiates.[7] Low-dose haloperidol has also been studied as a potential alternative to droperidol therapy and is beneficial in PONV. This agent also carries a risk for potential QTc prolongation and should be used with caution in individuals at high risk for this complication.[41]

Monotherapy with perphenazine, metoclopramide, scopolamine are as effective as placebo for the prophylaxis of PONV.[41] The guidelines advocate the use of combination therapy versus monotherapy; however, an optimal combination of antiemetics for PONV has not been established. The agents with the most data supporting their use includes dexamethasone plus either a 5-HT3-RA or droperidol or a 5-HT3-RA plus droperidol.[41] The choice should be based on use of different mechanisms of action, agents with different adverse effects along with cost considerations. **Table 35-8** summarizes the doses for prophylactic antiemetics from the consensus guidelines.[41]

TABLE 35-8 Recommended Prophylactic Doses of Selected Antiemetics for Postoperative Nausea and Vomiting in Adults and Postoperative Vomiting in Children

Drug	Adult Dose	Pediatric Dose (IV)	Timing of Dose[a]
Aprepitant[b]	40 mg orally	Not labeled for use in pediatrics	Within 3 hours prior to induction
Dexamethasone	4-5 mg IV	150 mcg/kg up to 5 mg	At induction
Dimenhydrinate	1 mg/kg IV	0.5 mg/kg up to 25 mg	Not specified
Dolasetron	12.5 mg IV	350 mcg/kg up to 12.5 mg	At end of surgery
Droperidol[c]	0.625-1.25 mg IV	10-15 mcg/kg up to 1.25 mg	At end of surgery

Drug	Adult Dose	Pediatric Dose (IV)	Timing of Dose[a]
Granisetron	0.35-3 mg IV	40 mcg/kg up to 0.6 mg	At end of surgery
Haloperidol	0.5-2 mg (IM or IV)	*d*	Not specified
Methylprednisolone	40 mg IV	*d*	At induction
Ondansetron	4 mg IV, 8 mg ODT	50-100 mcg/kg up to 4 mg	At end of surgery
Palonosetron[b]	0.075 mg IV	*d*	At induction
Promethazine[c]	6.25-12.5 mg IV	*d*	At induction
Scopolamine	Transdermal patch	*d*	Prior evening or 4 hours before surgery

[a]Based on recommendations from consensus guidelines.

[b]Labeled for use in PONV but not included in consensus guidelines.

[c]See FDA "black box" warning.

[d]Pediatric dosing not included in consensus guidelines.

Data from reference 47.

Aprepitant, an NK1 antagonist, was approved for the prevention of PONV when given orally within 3 hours prior to induction of anesthesia.[19] Aprepitant is equivalent to ondansetron 4 mg IV in reducing the incidence of nausea and the need for rescue in the 24 hours after surgery, but was significantly better than ondansetron for preventing vomiting in the 24 and 48 hours after surgery.[49] It has also been studied in combination with dexamethasone in comparison with an ondansetron plus dexamethasone combination and the aprepitant combination was more effective than the ondansetron combination group.[50] The newest and longest acting NK1-antagonist, rolapitant, is currently being investigated for prophylaxis of PONV and was found to be more effective than placebo in a small trial, but currently only has an indication for CINV.[51]

Treatment of PONV

Patients who experience PONV after receiving prophylactic treatment with a combination of 5-HT3-RA plus dexamethasone should be given rescue therapy from a different drug class such as a phenothiazine, metoclopramide, or droperidol.[41] Repeating the agent given for PONV prophylaxis within 6 hours of surgery offers no additional benefit.[52] Furthermore, a repeated dose of a 5-HT3-RA is not effective in treatment of PONV.[53,54] An emetic episode occurring more than 6 hours postoperatively can be treated with any of the drugs used for prophylaxis except dexamethasone and transdermal scopolamine.[41]

If no prophylaxis was given initially, the recommended treatment is low-dose 5-HT3-RA such as ondansetron 1 mg. Alternative treatments for established PONV include dexamethasone 2 to 4 mg IV, droperidol 0.625 mg IV, or promethazine 6.25 to 12.5 mg IV.[55]

RADIATION-INDUCED NAUSEA AND VOMITING

Nausea and vomiting associated with radiation therapy (RT) is not well understood and often underestimated by radiation oncologists.[56] RINV is neither as predictable nor as severe as CINV, and many patients receiving RT will not experience nausea or vomiting. The incidence of RINV ranges from 50% to 80%, is site dependent, and can have a substantial impact on a patient's quality of life. Risk factors associated with the development of RINV include combination chemoradiotherapy, prior CINV, upper abdomen RT, and field size.[57]

Four radiotherapy-induced emesis risk groups have been defined by the Antiemetic Subcommittee of the MASCC and the ASCO antiemetic practice guidelines:[30,31]

1. Highest risk: Total-body or nodal irradiation (TBI/TNI)
2. Moderate risk: Upper body or abdomen and hemibody RT
3. Low risk: Cranial, craniospinal, head and neck, lower thorax, and pelvic RT
4. Minimal risk: Extremity or breast RT

Prophylaxis of RINV

7 Patients undergoing RT to the upper abdomen or receiving total or hemibody irradiation should receive prophylactic antiemetics for RINV. Several randomized trials have demonstrated that the combination of prophylactic 5-HT3-RA plus dexamethasone is more effective than placebo,[57] which was confirmed by a meta-analysis.[57] In addition, 5-HT3-RAs were more effective than placebo or non-5-HT3-RAs (prochlorperazine or metoclopramide), even in patients undergoing TBI.[57,58]

The ASCO, ESMO/MASCC, and NCCN recommend preventive therapy with a 5-HT3-RA throughout RT and dexamethasone on fractions 1 through 5 in patients who are receiving TBI (high emetic risk).[16,30,31] Patients undergoing RT procedures with moderate emetic risk should receive a 5-HT3-RA prior to each fraction and dexamethasone on fractions 1 through 5. Those receiving low emetic risk radiotherapy may be given a 5-HT3-RA either throughout RT or only as needed for rescue. For minimal emetic risk, a 5-HT3-RA, metoclopramide, or prochlorperazine may be offered.[16,30,31]

There has not a study of prophylactic NK1 antagonists, palonosetron, or transdermal granisetron in the setting of RINV.

DISORDERS OF BALANCE

Disorders of balance include vertigo, dizziness, and motion sickness. The etiology of these complaints may include diseases that are infectious, postinfectious, demyelinative, vascular, neoplastic, degenerative, traumatic, toxic, psychogenic, or idiopathic. Symptoms of imbalance perceived by the patient present a particular clinical challenge.

8 Beneficial therapy for patients with balance disorders can most reliably be found among the antihistaminic–anticholinergic agents. However, the precise mechanisms of action of these agents are currently unknown. Oral regimens of antihistaminic–anticholinergic agents given one to several times each day may be effective, especially when the first dose is administered prior to motion.

Motion sickness may be associated with nausea and vomiting. A Cochrane review of 14 randomized controlled trials showed that scopolamine is effective for the prevention of motion sickness and is considered first-line for this indication.[59] The usefulness of scopolamine in preventing motion sickness was enhanced with the development of the transdermal system (patch) that increased patient satisfaction and decreased untoward side effects. The patch should be placed several hours before the anticipated motion exposure. First-generation sedating antihistamines are also effective. However, second-generation non-sedating antihistamines, ondansetron, and ginger root are not effective in the prevention and treatment of motion sickness.[60]

ANTIEMETIC USE DURING PREGNANCY

As many as 75% of pregnant women experience nausea and vomiting to some degree during the first trimester of pregnancy. The severity of the symptoms varies considerably, from mild nausea to incapacitating nausea and vomiting. The etiology of nausea and vomiting of pregnancy (NVP) is not well understood. Symptoms are self-limited for a majority of women, although approximately 1% develop hyperemesis gravidarum, a serious condition marked by severe physical symptoms and/or medical complications requiring hospitalization. In its most severe state, hyperemesis gravidarum may result in volume contraction, starvation, and electrolyte abnormalities.

Initial management of NVP often involves dietary changes and/or lifestyle modifications, such as eating smaller, more frequent meals and avoiding foods or odors that trigger symptoms. Ginger has also been shown to be beneficial in reducing nausea.[61,62] Persistent nausea and/or vomiting leads to the consideration of drug therapy at a time when teratogenic potential of each agent must be considered.

Treatment recommendations for the management of NVP are available from the American College of Obstetricians and Gynecologists (ACOG).[62] Pyridoxine, with or without doxylamine is recommended as first-line therapy.[62,63] The U.S. Food and Drug Administration approved a delayed-release formulation of doxylamine and pyridoxine hydrochloride (Diclegis[R]) in April 2013.[64]

Patients with persistent NVP or who show signs of dehydration should receive IV fluid replacement with thiamine. Ondansetron, promethazine, and metoclopramide have similar effectiveness for hyperemesis gravidarum, although ondansetron may be better tolerated due to less adverse effects.[63,65,66] Metoclopramide should not be used for more than 12 weeks due to the risk of tardive dyskinesia. Glucocorticoids may be used in patients with severe NVP or hyperemesis gravidarum, but should be used only after 10 weeks of gestation due to the increased risk of cleft lip.[63]

Clinical Controversy...

Which antiemetic is best to use during breastfeeding? There is a paucity of clinical trials to determine the most effective, safest medication to use for nausea and/or vomiting in breastfeeding. More studies are needed to look at the extent antiemetics are excreted into breast milk and the adverse effects to infants if the drugs are excreted. An important clinical consideration is to try to minimize exposure to medications and use them for the shortest duration possible. LactMed provides information on individual antiemetics in breastfeeding.[67]

ANTIEMETIC USE IN SPECIAL POPULATIONS

Chemotherapy-Induced Nausea and Vomiting in Children

Updated practice guidelines recommend that a corticosteroid (such as dexamethasone) plus a 5-HT3-RA be administered as prophylaxis of acute CINV to children receiving chemotherapy of high or moderate emetic risk.[68] Consensus guidelines suggest that there are no differences between 5-HT3-RAs in safety or efficacy. 5-HT3-RAs are more efficacious and have less adverse effects than metoclopramide, phenothiazines, and cannabinoids in children for the prevention of CINV.[68]

One small study has evaluated the safety and efficacy of aprepitant in adolescents. Patients were randomized to dexamethasone and ondansetron with or without aprepitant, using the recommended oral adult 3-day regimen. The emetogenicity of the chemotherapy administered was not discussed. Patients in the aprepitant arm had higher complete response rates and a parallel pharmacokinetic study suggests that the adult dose regimen was appropriate for adolescents.[69]

Gastroenteritis in Children

Nausea and vomiting associated with pediatric gastroenteritis is usually self-limited and improves with correction of dehydration. The majority of patients can be successfully treated with oral rehydration therapy. Pediatric practitioners may prescribe antiemetics for intractable vomiting due to gastroenteritis. The use of promethazine is contraindicated in patients less than 2 years old and should be used in caution in older children due to the potential risk of fatal respiratory depression.[70] Administration of ondansetron is associated with deceased vomiting and a reduced need for intravenous therapy and hospital admissions.[71,72,73]

Antiemetic Use in Geriatric Patients

Many of the commonly used antiemetics are on the Beers Criteria list, which are considered medications that may be considered potentially inappropriate in the older adults due to the risks outweighing the benefits.[74] These include first-generation antihistamines and scopolamine due to their highly anticholinergic side effects. Metoclopramide is also a Beers Criteria medication that may cause extrapyramidal effects including tardive dyskinesia especially in frail older adults. Ondansetron may be considered a preferred antiemetic in older adults; however, consider drug–drug interactions and potential side effects before prescribing.[75]

PERSONALIZED PHARMACOTHERAPY

Antiemetics are 70% to 80% effective in the prevention of CINV. One potential factor that might explain a less than optimal response is the variability in genetic enzymes responsible for the metabolism, transport, and receptor affinity of antiemetics.[76] The literature on the pharmacogenetics of antiemetic drugs is limited regarding the impact of the polymorphic variability in the drug transport mechanisms such as the ABCB1 or multidrug resistance gene (MDR1), or polymorphisms of metabolism with either CYP2D6 genes, which all may impact the efficacy of the 5-HT3-RAs. Individuals who are either rapid or ultra-metabolizers of the CYP2D6 enzymes generally respond poorly to 5-HT3-RAs and dopamine D2 receptor antagonists (prochlorperazine and metoclopramide).[77] Those patients with specific polymorphisms of the ABCB1 transporter, which is found in 5-HT3-RAs such as ondansetron, and are found to have the 3435T variant had a better response of short-term nausea and vomiting control versus those with the 3435C variant.[78] There are many limitations given the relatively small number of individuals studied in these trials, typically less than 300 patients, studied in limited ethnic populations and the fact that there are no tests readily available to test for these genetic polymorphisms. Given that granisetron is the only 5-HT3-RA available that does not require metabolism via CYP2D6, this agent should be used as an alternative if a patient is less responsive to initial 5-HT3-RA therapy with other agents.[77] Until there are confirmatory studies of these results, it is premature to utilize genomic analysis for personalized clinical decision-making for use of 5-HT3-RAs.

EVALUATION OF EMETIC OUTCOMES

In assessing emetic outcomes, standardized monitoring criteria should include a subjective assessment and objectives parameters including:

1. Severity of nausea
2. Change in patient weight
3. Number of vomiting episodes each day
4. Estimated fluid loss
5. Acid-base balance
6. Serum sodium, potassium, and chloride concentrations

7. Serum BUN and creatinine concentrations

8. Daily urine volume and urine-specific gravity

Physical assessment should include evaluation of mucous membranes and skin turgor. For patients on chemotherapy, evaluation of emetic outcomes should occur after the administration of each chemotherapy cycle. Adherence to outpatient antiemetic regimens occurs in only about 65% of patients. Patients receiving high-risk regimens are most likely to report symptoms of nausea and vomiting on day 3 after chemotherapy.[79] Documentation of nausea and/or vomiting events will assist the clinician in modifying the antiemetic regimen for the next cycle of chemotherapy.

Chapter 36: Diarrhea, Constipation, and Irritable Bowel Syndrome

Patricia H. Fabel; Kayce M. Shealy

DIARRHEA

KEY CONCEPTS

- 1 Diarrhea is caused by many viral and bacterial organisms. It is most often a minor discomfort, not life-threatening, and usually self-limited.
- 2 The four pathophysiologic mechanisms of diarrhea have been linked to the four broad diarrheal groups, which are secretory, osmotic, exudative, and altered intestinal transit. The three mechanisms by which absorption occurs from the intestines are active transport, diffusion, and solvent drag.
- 3 Management of diarrhea focuses on preventing excessive water and electrolyte losses, dietary care, relieving symptoms, treating curable causes, and treating secondary disorders.
- 4 Bismuth subsalicylate is marketed for indigestion, relieving abdominal cramps, and controlling diarrhea, including traveler's diarrhea, but may cause interactions with several components if given excessively.
- 5 Constipation is defined as difficult or infrequent passage of stool, at times associated with straining or a feeling of incomplete defecation.
- 6 Underlying causes of constipation should be identified when possible and corrective measures taken (eg, alteration of diet or treatment of diseases such as hypothyroidism).
- 7 The foundation of treatment of constipation is dietary fiber or bulk-forming laxatives that provide 20 to 25 g/day of raw fiber.
- 8 Irritable bowel syndrome (IBS) is one of the most common GI disorders characterized by lower abdominal pain, disturbed defecation, and bloating. Many non-GI manifestations also

exist with IBS. Visceral hypersensitivity is a major culprit in the pathophysiology of the disease.

- 9 Diarrhea-predominant IBS should be managed by dietary modification and drugs such as loperamide when diet changes alone are insufficient to promote control of symptoms.

- 10 Several drug classes are involved in the treatment of the pain associated with IBS including tricyclic compounds and the gut-selective calcium channel blockers.

Diarrhea is a troublesome discomfort that affects most individuals in the United States at some point in their lives and can be thought of as both a symptom and a sign. Usually diarrheal episodes begin abruptly and subside within 1 or 2 days without treatment. This chapter focuses primarily on noninfectious diarrhea, with only minor reference to infectious diarrhea (see Chapter 113 for a discussion of gastrointestinal infections). Diarrhea is often a symptom of a systemic disease, and not all possible causes of diarrhea are discussed in this chapter. Acute diarrhea is commonly defined as less than 14 days' duration, persistent diarrhea as more than 14 days' duration, and chronic diarrhea as more than 30 days' duration.

To understand diarrhea, one must have a reasonable definition of the condition; unfortunately, the literature is extremely variable on this. Simply put, diarrhea is an increased frequency and decreased consistency of fecal discharge as compared with an individual's normal bowel pattern. Frequency and consistency are variable within and between individuals. For example, some individuals defecate as often as three times per day, whereas others defecate only two or three times per week. A Western diet usually produces a daily stool weighing between 100 and 300 g, depending on the amount of nonabsorbable materials (mainly carbohydrates) consumed. Patients with serious diarrhea may have a daily stool weight in excess of 300 g; however, a subset of patients experience frequent small, watery passages. Additionally, vegetable fiber-rich diets, such as those consumed in some Eastern cultures (eg, those in Africa), produce stools weighing more than 300 g/day.

Diarrhea may be associated with a specific disease of the intestines or secondary to a disease outside the intestines. For instance, bacillary dysentery directly affects the gut, whereas diabetes mellitus causes neuropathic diarrheal episodes. Furthermore, diarrhea can be considered as acute or chronic disease. Infectious diarrhea is often acute; diabetic diarrhea is chronic. Congenital disorders in GI ion transport mechanisms are another cause of chronic diarrhea.[1] Whether acute or chronic, diarrhea has the same pathophysiologic causes that help in identification of specific treatments.

Epidemiology

The epidemiology of diarrhea varies in developed versus developing countries.[2] In the United States, diarrheal illnesses are usually not reported to the Centers for Disease Control and Prevention (CDC) unless associated with an outbreak or an unusual organism or condition. For example, the acquired immune deficiency syndrome (AIDS) has been identified with protracted diarrheal illness. Diarrhea is a major problem in daycare centers and nursing homes, probably because early childhood and senescence plus environmental conditions are risk factors. Although an exact epidemiologic profile in the United States is not available through the CDC or published literature, chronic diarrhea affects

approximately 5% of the adult population and ranges from 3% to 20% in children worldwide.[2,3,4] In developing countries, diarrhea is a leading cause of illness and death in children, creating a tremendous economic strain on health care costs.

1 Most cases of acute diarrhea are caused by infections with viruses, bacteria, or protozoa and are generally self-limited.[5] Although viruses are more commonly associated with acute gastroenteritis, bacteria are responsible for more cases of acute diarrhea.

Evaluation of a noninfectious cause is considered if diarrhea persists and no infectious organism can be identified, or if the patient falls into a high-risk category for metabolic complications with persistent diarrhea. Common causative bacterial organisms include *Shigella*, *Salmonella*, *Campylobacter*, *Staphylococcus*, and *Escherichia coli*. Foodborne bacterial infection is a major concern, as several major food poisoning episodes have occurred that were traced to poor sanitary conditions in meat processing plants. Acute viral infections are attributed mostly to the Norwalk and rotavirus groups.

Physiology

In the fasting state, 9 L of fluid enters the proximal small intestine each day. Of this fluid, 2 L is ingested through diet, while the remainder consists of internal secretions. Because of meal content, duodenal chyme is usually hypertonic. When chyme reaches the ileum, the osmolality adjusts to that of plasma, with most dietary fat, carbohydrate, and protein being absorbed. The volume of ileal chyme decreases to about 1 L/day on entering the colon, which is further reduced by colonic absorption to 100 mL daily. If the small intestine water absorption capacity is exceeded, chyme overloads the colon, resulting in diarrhea. In humans, the colon absorptive capacity is about 5 L daily. Colonic fluid transport is critical to water and electrolyte balance.

Absorption from the intestines back into the blood occurs by three mechanisms: active transport, diffusion, and solvent drag. Active transport and diffusion are the mechanisms of sodium transport. Because of the high luminal sodium concentration (142 mEq/L [mmol/L]), sodium diffuses from the sodium-rich gut into epithelial cells, where it is actively pumped into the blood and exchanged with chloride to maintain an isoelectric condition across the epithelial membrane.

Hydrogen ions are transported by an indirect mechanism in the upper small intestine. As sodium is absorbed, hydrogen ions are secreted into the gut. Hydrogen ions then combine with bicarbonate ions to form carbonic acid, which then dissociates into carbon dioxide and water. Carbon dioxide readily diffuses into the blood for expiration through the lung. The water remains in the chyme.

Paracellular pathways are major routes of ion movement. As ions, monosaccharides, and amino acids are actively transported, an osmotic pressure is created, drawing water and electrolytes across the intestinal wall. This pathway accounts for significant amounts of ion transport, especially sodium. Sodium plays an important role in stimulating glucose absorption. Glucose and amino acids are actively transported into the blood via a sodium-dependent cotransport mechanism. Cotransport absorption mechanisms of glucose–sodium and amino acid–sodium are extremely important for treating diarrhea.

Gut motility influences absorption and secretion. The amount of time in which luminal content is in contact with the epithelium is under neural and hormonal control. Neurohormonal substances, such as angiotensin, vasopressin, glucocorticoid, aldosterone, and neurotransmitters, also regulate ion transport.

Pathophysiology

2 Four general pathophysiologic mechanisms disrupt water and electrolyte balance, leading to diarrhea, and are the basis of diagnosis and therapy. These are (a) a change in active ion transport by either decreased sodium absorption or increased chloride secretion; (b) change in intestinal motility; (c) increase in luminal osmolarity; and (d) increase in tissue hydrostatic pressure. These mechanisms have been related to four broad clinical diarrheal groups: secretory, osmotic, exudative, and altered intestinal transit.

Secretory diarrhea occurs when a stimulating substance either increases secretion or decreases absorption of large amounts of water and electrolytes. Substances that cause excess secretion include vasoactive intestinal peptide (VIP) from a pancreatic tumor, unabsorbed dietary fat in steatorrhea, laxatives, hormones (such as secretion), bacterial toxins, and excessive bile salts. Many of these agents stimulate intracellular cyclic adenosine monophosphate and inhibit Na^+/K^+-adenosine triphosphatase (ATPase), leading to increased secretion. Also, many of these mediators inhibit ion absorption simultaneously. Secretory diarrhea is recognized by large stool volumes (more than 1 L/day) with normal ionic contents and osmolality approximately equal to plasma. Fasting does not alter the stool volume in these patients.

Poorly absorbed substances retain intestinal fluids, resulting in osmotic diarrhea. This process occurs with malabsorption syndromes, lactose intolerance, administration of divalent ions (eg, magnesium-containing antacids), or consumption of poorly soluble carbohydrate (eg, lactulose). As a poorly soluble solute is transported, the gut adjusts the osmolality to that of plasma; in so doing, water and electrolytes flux into the lumen. Clinically, osmotic diarrhea is distinguishable from other types, as it ceases if the patient resorts to a fasting state.

Inflammatory diseases of the GI tract discharge mucus, serum proteins, and blood into the gut. Sometimes bowel movements consist only of mucus, exudate, and blood. Exudative diarrhea affects other absorptive, secretory, or motility functions to account for the large stool volume associated with this disorder.

Altered intestinal motility produces diarrhea by three mechanisms: (1) reduction of contact time in the small intestine, (2) premature emptying of the colon, and (3) bacterial overgrowth. Chyme must be exposed to intestinal epithelium for a sufficient time period to enable normal absorption and secretion processes to occur. If this contact time decreases, diarrhea results. Intestinal resection or bypass surgery and drugs (such as metoclopramide) cause this type of diarrhea. On the other hand, an increased time of exposure allows fecal bacteria overgrowth. A characteristic small intestine diarrheal pattern is rapid, small, coupling bursts of waves. These waves are inefficient, do not allow absorption, and rapidly dump chyme into the colon. Once in the colon, chyme exceeds the colonic capability to absorb water.

Etiologic Examination of the Stool

Stool characteristics are important in assessing the etiology of diarrhea. A description of the frequency, volume, consistency, and color provides diagnostic clues. For instance, diarrhea starting in the small intestine produces a copious, watery or fatty (greasy), and foul-smelling stool; contains undigested food particles; and is usually free from gross blood. Colonic diarrhea appears as small, pasty, and sometimes bloody or mucoid movements. Rectal tenesmus with flatus accompanies large intestinal diarrhea.

Clinical Presentation

Table 36-1 outlines the clinical presentation of diarrhea, and Table 36-2 shows common drug-induced causes of diarrhea. A medication history is extremely important in identifying drug-induced diarrhea. Many agents, including antibiotics and other drugs, cause diarrhea or, less commonly, pseudomembranous colitis. Self-inflicted laxative abuse for weight loss is popular.

TABLE 36-1 Clinical Presentation of Diarrhea

General

- Usually, acute diarrheal episodes subside within 72 hours of onset, whereas chronic diarrhea involves frequent attacks over extended time periods

Signs and symptoms

- Abrupt onset of nausea, vomiting, abdominal pain, headache, fever, chills, and malaise
- Bowel movements are frequent and never bloody, and diarrhea lasts 12-60 hours
- Intermittent periumbilical or lower right quadrant pain with cramps and audible bowel sounds is characteristic of small intestinal disease
- When pain is present in large intestinal diarrhea, it is a gripping, aching sensation with tenesmus (straining, ineffective, and painful stooling). Pain localizes to the hypogastric region, right or left lower quadrant, or sacral region
- In chronic diarrhea, a history of previous bouts, weight loss, anorexia, and chronic weakness are important findings

Physical examination

- Typically demonstrates hyperperistalsis with borborygmi and generalized or local tenderness

Laboratory tests

- Stool analysis studies include examination for microorganisms, blood, mucus, fat, osmolality, pH, electrolyte and mineral concentration, and cultures

- Stool test kits are useful for detecting GI viruses, particularly rotavirus
- Antibody serologic testing shows rising titers over a 3- to 6-day period, but this test is not practical and is nonspecific
- Occasionally, total daily stool volume is also determined
- Direct endoscopic visualization and biopsy of the colon may be undertaken to assess for the presence of conditions such as colitis or cancer
- Radiographic studies are helpful in neoplastic and inflammatory conditions

Misoprostol

Colchicine

Proton pump inhibitors

H_2-receptor blockers

Most acute diarrhea is self-limiting, subsiding within 72 hours. However, infants, young children, the elderly, and debilitated persons are at risk for morbid and mortal events in prolonged or voluminous diarrhea. These groups are at risk for water, electrolyte, and acid–base disturbances, and potentially cardiovascular collapse and death. The prognosis for chronic diarrhea depends on the cause; for example, diarrhea secondary to diabetes mellitus waxes and wanes throughout life.

TREATMENT

Prevention

Acute viral diarrheal illness often occurs in daycare centers and nursing homes. Because person-to-person contact is the mechanism by which viral disease spreads, isolation techniques must be initiated. For bacterial, parasitic, and protozoal infections, strict food handling, sanitation, water, and other environmental hygiene practices can prevent transmission. If diarrhea is secondary to another illness, controlling the primary condition is necessary. Antibiotics and bismuth subsalicylate are advocated to prevent traveler's diarrhea, in conjunction with treatment of drinking water and caution with consumption of fresh vegetables.[6,7]

Desired Outcome

3 If prevention is unsuccessful and diarrhea occurs, therapeutic goals are to (a) manage the diet; (b) prevent excessive water, electrolyte, and acid–base disturbances; (c) provide symptomatic relief; (d) treat curable causes; and (e) manage secondary disorders causing diarrhea (**Figs. 36-1** and **36-2**).

FIGURE 36-1

Recommendations for treating acute diarrhea. Follow the following steps: (a) Perform a complete history and physical examination. (b) Is the diarrhea acute or chronic? If chronic diarrhea, go to Fig. 36-2. (c) If acute diarrhea, check for fever and/or systemic signs and symptoms (ie, toxic patient). If systemic illness (fever, anorexia, or volume depletion), check for an infectious source. If positive for infectious diarrhea, use appropriate antibiotic/anthelmintic drug and symptomatic therapy. If negative for infectious cause, use only symptomatic treatment. (d) If no systemic findings, then use symptomatic therapy based on severity of volume depletion, oral or parenteral fluid/electrolytes, antidiarrheal agents (see Table 36-4), and diet (RBC, red blood cells; WBC, white blood cells).

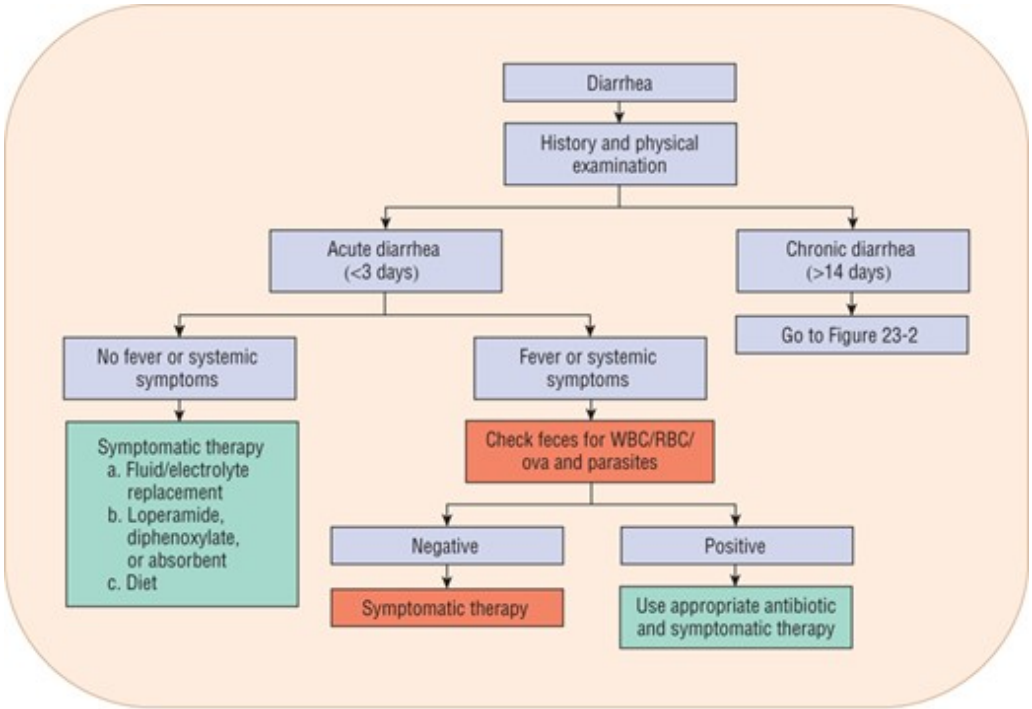

FIGURE 36-2

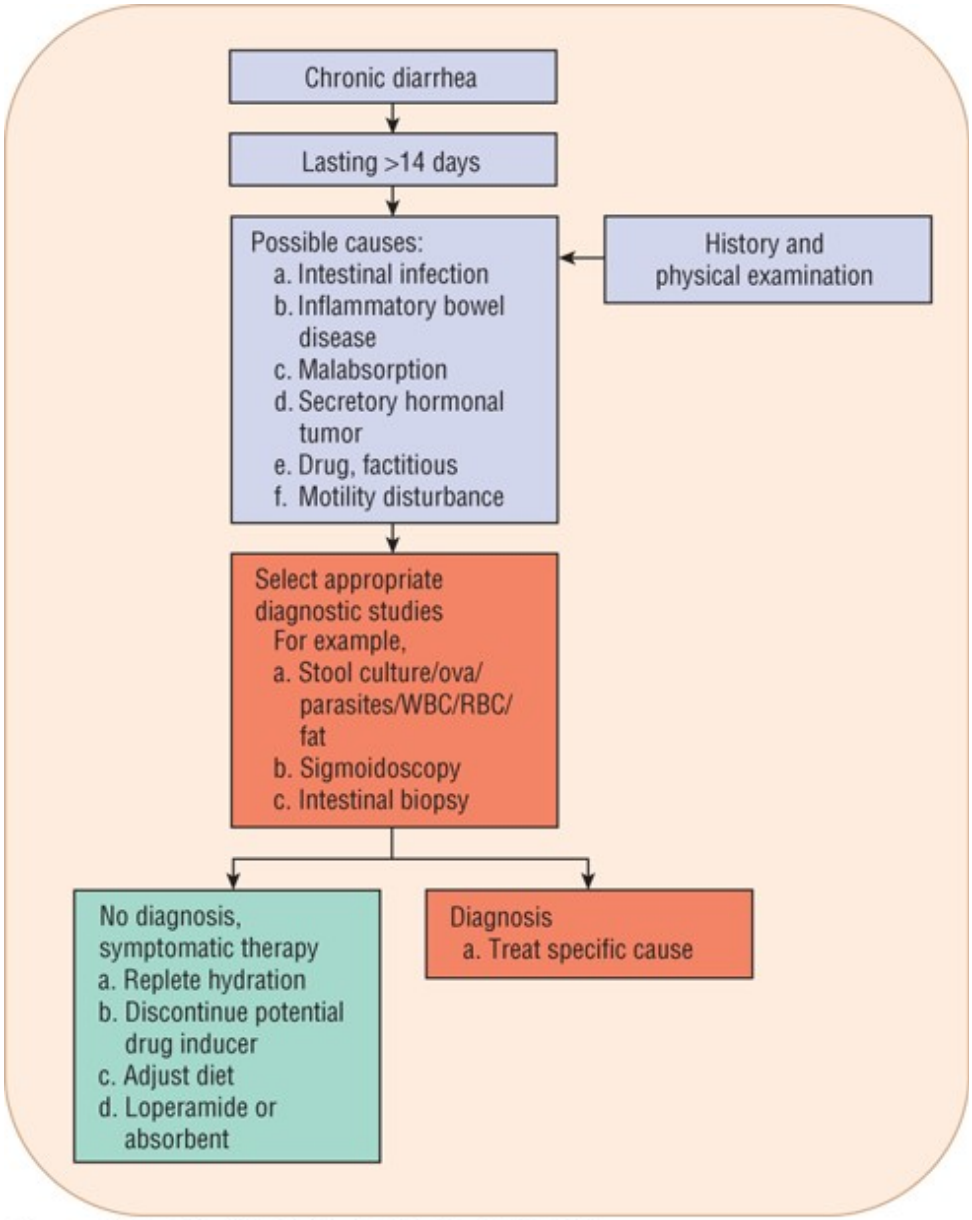
Recommendations for treating chronic diarrhea. Follow the following steps: (a) Perform a careful history and physical examination. (b) The possible causes of chronic diarrhea are many. These can be classified into intestinal infections (bacterial or protozoal), inflammatory disease (Crohn's disease or ulcerative colitis), malabsorption (lactose intolerance), secretory hormonal tumor (intestinal carcinoid tumor or vasoactive intestinal peptide-secreting tumor [VIPoma]), drug (antacid), factitious (laxative abuse), or motility disturbance (diabetes mellitus, irritable bowel syndrome, or hyperthyroidism). (c) If the diagnosis is uncertain, selected appropriate diagnostic studies should be ordered. (d) Once diagnosed, treatment is planned for the underlying cause with symptomatic antidiarrheal therapy. (e) If no specific cause can be identified, symptomatic therapy is prescribed (RBC, red blood cells; WBC, white blood cells).



Clinicians must clearly understand that diarrhea, like a cough, may be a body defense mechanism for ridding itself of harmful substances or pathogens. The correct therapeutic response is not necessarily to stop diarrhea at all costs.

Nonpharmacologic Management

Dietary management is a first priority in the treatment of diarrhea. Feeding should continue in children with acute bacterial diarrhea. Fed children have less morbidity and mortality, whether or not they receive oral rehydration fluids. Studies are not available in the elderly or in other high-risk groups to determine the value of continued feeding in bacterial diarrhea.

Clinical Controversy…

Most clinicians recommend discontinuing consumption of solid foods and dairy products for 24 hours in patients with acute diarrhea. However, withholding food is considered inappropriate in patients with no signs of severe dehydration. In osmotic diarrhea, it may control the problem. If the mechanism is secretory, diarrhea persists. For patients who are experiencing nausea and/or vomiting, a mild, digestible, low-residue diet should be administered for 24 hours. If vomiting is present and uncontrollable with antiemetics (see Chapter 35), nothing is taken by mouth. As bowel movements decrease, a bland diet is begun.

Water and Electrolytes

Rehydration and maintenance of water and electrolytes are primary treatment goals until the diarrheal episode ends. If the patient is volume depleted, rehydration should be directed at replacing water and electrolytes to normal body composition. Then water and electrolyte composition are maintained by replacing losses. Many patients will not develop volume depletion and therefore will only require maintenance fluid and electrolyte therapy. Parenteral and enteral routes may be used for supplying water and electrolytes. If vomiting and dehydration are not severe, enteral feeding is the less costly and preferred method. In the United States, many commercial oral rehydration preparations are available (**Table 36-3**).

TABLE 36-3 Oral Rehydration Solutions

	WHO-ORS[a]	Pedialyte[b] (Ross)	CeraLyte (Cera Products)	Enfalyte (Mead Johnson)
Osmolality (mOsm/kg or mmol/kg)	245	250	220	167

Magnesium	—	—	—	—
Sulfate	—	—	—	—
Phosphate	—	—	—	—

[a]World Health Organization reduced osmolarity oral rehydration solution.

[b]Carbohydrate is glucose.

[c]Rice syrup solids are carbohydrate source.

Because of concerns about hypernatremia, physicians continue to hospitalize patients and use IV fluids to correct fluid and electrolyte deficits in severe dehydration. Oral solutions are strongly recommended.[8,9,10] In developing countries, the World Health Organization oral rehydration solution (WHO-ORS) saves the lives of millions of children annually.

During diarrhea, the small intestine retains its ability to actively transport monosaccharides such as glucose. Glucose actively carries sodium with water and other electrolytes. The WHO now recommends an ORS with a lower osmolarity, sodium content, and glucose load (see Table 36-3).[11] A separate oral supplement of zinc 20 mg daily for 10 days in addition to ORS significantly reduces the severity and duration of acute diarrhea in developing countries.[2] ORS is a lifesaving treatment for millions afflicted in developing countries. Acceptance in developed countries is less enthusiastic; however, the advantage of this product in reducing hospitalizations may prove its use as a cost-effective alternative, saving millions of dollars in health care expenditures.

Pharmacologic Therapy

Various drugs have been used to treat diarrheal attacks (**Table 36-4**), including antimotility agents, adsorbents, antisecretory compounds, antibiotics, enzymes, and intestinal microflora. Usually these drugs are not curative but palliative.

TABLE 36-4 Selected Antidiarrheal Preparations

	Dose Form	Adult Dose
Antimotility		
Diphenoxylate	2.5 mg/tablet	5 mg four times daily; do not exceed 20 mg/day
	2.5 mg/5 mL	
Loperamide	2 mg/capsule	Initially 4 mg, and then 2 mg after each loose stool; do not exceed 16 mg/day
	2 mg/capsule	
Paregoric	2 mg/5 mL (morphine)	5-10 mL one to four times daily
Opium tincture	10 mg/mL (morphine)	0.6 mL four times daily
Difenoxin	1 mg/tablet	Two tablets, and then one tablet after each loose stool; up to eight tablets per day
Adsorbents		
Kaolin-pectin mixture	5.7 g kaolin + 130.2 mg pectin/30 mL	30-120 mL after each loose stool
Polycarbophil	500 mg/tablet	Chew 2 tablets four times daily or after each loose stool; do not exceed 12 tablets per day

	Dose Form	Adult Dose
Attapulgite	750 mg/15 mL 300 mg/7.5 mL 750 mg/tablet 600 mg/tablet 300 mg/tablet	1,200-1,500 mg after each loose bowel movement or every 2 hours; up to 9,000 mg/day
Antisecretory		
Bismuth subsalicylate	1,050 mg/30 mL 262 mg/15 mL 524 mg/15 mL 262 mg/tablet	Two tablets or 30 mL every 30 minutes to 1 hour as needed up to eight doses per day
Enzymes (lactase)	1,250 neutral lactase units/4 drops 3,300 FCC lactase units per tablet	Three to four drops taken with milk or dairy product
Bacterial replacement (*Lactobacillus acidophilus*, *Lactobacillus bulgaricus*)		Two tablets or one granule packet three to four times daily; give with milk, juice, or water
Octreotide	0.05 mg/mL 0.1 mg/mL 0.5 mg/mL	Initial: 50 mcg subcutaneously One to two times per day and titrate dose based on indication up to 600 mcg/day in two to four divided doses

Opiates and Their Derivatives

Opiates and opioid derivatives (a) delay the transit of intraluminal contents or (b) increase gut capacity, prolonging contact and absorption. Enkephalins, which are endogenous opioid substances, regulate fluid movement across the mucosa by stimulating absorptive processes. Limitations to the use of opiates include an addiction potential (a real concern with long-term use) and worsening of diarrhea in selected infectious diarrhea.

Most opiates act through peripheral and central mechanisms with the exception of loperamide, which acts only peripherally. Loperamide is antisecretory; it inhibits the calcium-binding protein calmodulin, controlling chloride secretion. Loperamide, available as 2 mg capsules or 1 mg/5 mL solution (both are nonprescription products), is suggested for managing acute and chronic diarrhea. The usual adult dose is initially 4 mg orally, followed by 2 mg after each loose stool, up to 16 mg/day. Used correctly,

this agent has rare side effects, such as dizziness and constipation. If the diarrhea is concurrent with a high fever or bloody stool, the patient should be referred to a physician. Also, diarrhea lasting 48 hours beyond initiating loperamide warrants medical attention. Loperamide can also be used in traveler's diarrhea. It is comparable to bismuth subsalicylate for treatment of this disorder.[6]

Diphenoxylate is available as a 2.5 mg tablet and as a 2.5 mg/5 mL solution. A small amount of atropine (0.025 mg) is included in the product to discourage abuse. In adults, when taken as 2.5 to 5 mg three or four times daily, not to exceed a 20 mg total daily dose, diphenoxylate is rarely toxic. Some patients may complain of atropinism (blurred vision, dry mouth, and urinary hesitancy). Like loperamide, it should not be used in patients who are at risk of bacterial enteritis with *E. coli*, *Shigella*, or *Salmonella*.

Difenoxin, a diphenoxylate derivative also chemically related to meperidine, is also combined with atropine and has the same uses, precautions, and side effects. Marketed as a 1 mg tablet, the adult dosage is 2 mg initially, followed by 1 mg after each loose stool, not to exceed 8 mg/day.

Paregoric, camphorated tincture of opium, is marketed as a 2 mg/5 mL solution and is indicated for managing both acute and chronic diarrhea. It is not widely prescribed today because of its abuse potential.

Adsorbents

Adsorbents are used for symptomatic relief. These products, many not requiring a prescription, are nontoxic, but their effectiveness remains unproven. Adsorbents are nonspecific in their action; they adsorb nutrients, toxins, drugs, and digestive juices. Polycarbophil absorbs 60 times its weight in water and can be used to treat both diarrhea and constipation. It is a nonprescription product and is sold as a 500 mg chewable tablet. This hydrophilic, nonabsorbable product is safe and may be taken four times daily, up to 6 g/day in adults. See Table 36-4 for selected antidiarrheal preparations.

Antisecretory Agents

Bismuth subsalicylate appears to have antisecretory, antiinflammatory, and antibacterial effects. As a nonprescription product, it is marketed for indigestion, relieving abdominal cramps, and controlling diarrhea, including traveler's diarrhea. Bismuth subsalicylate dosage strengths are a 262 mg chewable tablet, 262 mg/5 mL liquid, and 524 mg/15 mL liquid. The usual adult dose is two tablets or 30 mL every 30 minutes to 1 hour up to eight doses per day.

4 Bismuth subsalicylate contains multiple components that might be toxic if given excessively to prevent or treat diarrhea. For instance, an active ingredient is salicylate, which may interact with anticoagulants or may produce salicylism (tinnitus, nausea, and vomiting). Bismuth reduces tetracycline absorption and may interfere with select GI radiographic studies. Patients may complain of a darkening of the tongue and stools with repeat administration. Salicylate can induce gout attacks in susceptible individuals.

Bismuth subsalicylate suspension has been evaluated in the treatment of secretory diarrhea of

infectious etiology as well. In a dose of 30 mL every 30 minutes for eight doses, unformed stools decrease in the first 24 hours. Bismuth subsalicylate may also be effective in preventing traveler's diarrhea.

Octreotide, a synthetic octapeptide analog of endogenous somatostatin, is effective for the symptomatic treatment of carcinoid tumors and other peptide-secreting tumors, dumping syndrome, and chemotherapy-induced diarrhea.[12] It has had limited success in patients with AIDS-associated diarrhea and short-bowel syndrome, does not appear to have an advantage over various opiate derivatives in the treatment of chronic idiopathic diarrhea, and has the disadvantage of being administered by injection.[13] Metastatic intestinal carcinoid tumors secrete excessive amounts of vasoactive substances, including histamine, bradykinin, serotonin (5-hydroxytryptamine, 5-HT), and prostaglandins. Primary carcinoid tumors occur throughout the GI tract, with most in the ileum. Predominant signs and symptoms experienced by patients with these tumors are attributable to excessive concentrations of 5-hydroxytryptophan and 5-HT. The totality of their clinical effects is termed the carcinoid syndrome. Some patients have a violent, watery diarrhea with abdominal cramping. Initially, diarrhea might be managed with various agents such as codeine, diphenoxylate, cyproheptadine, methysergide, phenoxybenzamine, or methyldopa. But octreotide is now considered first-line therapy for carcinoid syndrome.

Octreotide blocks the release of 5-HT and many other active peptides and has been effective in controlling diarrhea and flushing. It is reported to have direct inhibitory effects on intestinal secretion and stimulatory effects on intestinal absorption. Non–gastrin-secreting adenomas of the pancreas are tumors associated with profuse watery diarrhea. This condition has been referred to as Verner–Morrison syndrome, WDHA (watery diarrhea, hypokalemia, and achlorhydria) syndrome, pancreatic cholera, watery diarrhea syndrome, and vasoactive intestinal peptide-secreting tumor (VIPoma). Excessive secretion of VIP from a retroperitoneal or pancreatic tumor produces most of the clinical features. Surgical tumor dissection is the treatment of choice. In nonsurgical candidates, the profuse watery diarrhea and other symptoms commonly encountered are managed with octreotide.

The dose of octreotide varies with the indication, disease severity, and patient response.[12] For managing diarrhea and flushing associated with carcinoid tumors in adults, the initial dosage range is 100 to 600 mcg/day in two to four divided doses subcutaneously for 2 weeks. For controlling secretory diarrhea of VIPomas, the dosage range is 200 to 300 mcg/day in two to four divided doses for 2 weeks. Some patients may require higher doses for symptomatic control. Patients responding to these initial doses may be switched to Sandostatin LAR Depot, a long-acting octreotide formulation. This product consists of microspheres containing the drug. Initial doses consist of 20 mg given intramuscularly intragluteally at 4-week intervals for 2 months. It is recommended that during the first 2 weeks of therapy the short-acting formulation also be administered subcutaneously. At the end of 2 months, patients with good symptom control may have the dose reduced to 10 mg every 4 weeks, while those without sufficient symptom control may have the dose increased to 30 mg every 4 weeks. For patients experiencing recurrence of symptoms on the 10 mg dose, dosage adjustment to 20 mg should be made. It is not uncommon for patients with carcinoid tumors or VIPomas to experience periodic exacerbation of symptoms. Subcutaneous octreotide for several days should be reinstituted in these individuals. In so-called carcinoid crisis, octreotide is given as an IV infusion at 50

mcg/h for 8 to 24 hours.

Because octreotide inhibits many other GI hormones, it has a variety of intestinal side effects. With prolonged use, gallbladder and biliary tract complications such as cholelithiasis have been reported. Approximately 5% to 10% of patients complain of nausea, diarrhea, and abdominal pain. Local injection pain occurs with about an 8% incidence. With high doses, octreotide may reduce dietary fat absorption, leading to steatorrhea.

Two other somatostatin analogs, lanreotide and vapreotide, have been studied.[13,14] Lanreotide is approved for use in the United States for acromegaly. The starting dose is 90 mg subcutaneously every 4 weeks for 3 months, and then the dose is adjusted based on growth hormone and insulin-like growth factor levels.[15] Vapreotide is an orphan drug that is indicated for pancreatic and GI fistulas as well as esophageal variceal bleeding.

Miscellaneous Products

Probiotics are microorganisms that have been used for many years to replace colonic microflora. This supposedly restores normal intestinal function and suppresses the growth of pathogenic microorganisms. *Saccharomyces boulardii*, *Lactobacillus* GG, and *Lactobacillus acidophilus* decrease the duration of infectious and antibiotic-induced diarrhea in adults and children.[16] A meta-analysis suggests that probiotics may prevent antibiotic-associated diarrhea (AAD).[17] However, a randomized control trial in hospitalized patients over the age of 65 years found no difference in cases of AAD between a probiotic preparation (two strains of lactobacillus acidophilus and Bifidobacterium) and placebo.[18] The dosage of probiotic preparations varies depending on the brand used. Intestinal flatus is the primary patient complaint experienced with this modality.

Anticholinergic drugs such as atropine block vagal tone and prolong gut transit time. Drugs with anticholinergic properties are present in many nonprescription products. Their value in controlling diarrhea is questionable and limited because of side effects. Angle-closure glaucoma, selected heart diseases, and obstructive uropathies are relative contraindications to the use of anticholinergic agents.

Lactase enzyme products are helpful for patients who are experiencing diarrhea secondary to lactose intolerance. Lactase is required for carbohydrate digestion. When a patient lacks this enzyme, eating dairy products causes an osmotic diarrhea. Several products are available for use each time a dairy product, especially milk or ice cream, is consumed.

Clinical Controversy…

The use of probiotics to treat and prevent AAD is controversial. A meta-analysis published in 2012 concluded that adjunctive probiotics significantly reduce the risk of acquiring AAD, but individual studies, including a well-designed randomized control trial published in 2013, have been unable to show a difference when compared with placebo. Additional studies are needed to compare different probiotic formulations, determine optimal dosing, and evaluate whether efficacy differs based on the antibiotic used. Additional safety data are also required before probiotics can be recommended

routinely for this purpose.

Vaccines

Vaccines are a new therapeutic frontier in controlling infectious diarrheas, especially in developing countries.[19,20] An oral vaccine for cholera is licensed and available in other countries (Dukoral from SBL Vaccines) and appears to provide somewhat better immunity and has fewer adverse effects than the previously available parenteral vaccine. However, the CDC does not recommend cholera vaccines for most travelers, nor is the vaccine available in the United States.

Oral *Shigella* vaccine, although effective under field conditions, requires five weekly oral doses and repeat booster doses, thereby limiting its practicality for use in developing nations. With about 1,500 serotypes for *Salmonella*, a vaccine is not currently available for humans. There are two newer typhoid vaccine formulations, one a parenteral inactivated whole-cell vaccine and the other an oral live-attenuated (Ty21a) vaccine that is administered in four doses on days 1, 3, 5, and 7, to be completed at least 1 week before exposure. Two rotavirus vaccines have been shown to prevent gastroenteritis due to rotavirus infection in infants and children.[21] The pentavalent human-bovine reassortant vaccine (RotaTeq from Merck) is administered as a three-oral-dose sequence, and the monovalent human vaccine (Rotarix from GlaxoSmithKline) is administered as a two-oral-dose sequence. A rotavirus vaccine program has been formed to reduce child morbidity and mortality from diarrheal disease by accelerating the availability of rotavirus vaccines appropriate for use in developing countries.

Evaluation of Therapeutic Outcomes

Therapeutic outcomes are directed toward key symptoms, signs, and laboratory studies. Constitutional symptoms usually improve within 24 to 72 hours. Monitoring for changes in the frequency and character of bowel movements on a daily basis in conjunction with vital signs and improvement in appetite are of utmost importance. Also, the clinician needs to monitor body weight, serum osmolality, serum electrolytes, complete blood cell counts, urinalysis, and culture results (if appropriate).

Acute Diarrhea

Most patients with acute diarrhea experience mild to moderate distress. In the absence of moderate to severe dehydration, high fever, and blood or mucus in the stool, this illness is usually self-limiting within 3 to 7 days. Mild to moderate acute diarrhea is usually managed on an outpatient basis with oral rehydration, symptomatic treatment, and diet. Elderly persons with chronic illness as well as infants may require hospitalization for parenteral rehydration and close monitoring.

Severe Diarrhea

In the urgent/emergent situation, restoration of the patient's volume status is the most important outcome. Toxic patients (fever dehydration, hematochezia, or hypotension) require hospitalization, IV

fluids and electrolyte administration, and empiric antibiotic therapy while awaiting culture and sensitivity results. With timely management, these patients usually recover within a few days.

CONSTIPATION

5 Constipation is a common complaint among the general population and accounts for many medical visits each year in the United States.[22] It is generally defined by the American Gastroenterology Association (AGA) as difficult or infrequent passage of stool, at times associated with straining or a feeling of incomplete defecation.[23]

Constipation may be further defined by quantitative or qualitative measures. For instance, physicians often use stool frequency to define constipation (most commonly fewer than three bowel movements per week); however, the "normal" frequency of bowel movement is not well established and can vary from person to person. Patients more often describe constipation in terms of symptoms or a combination of quantitative and qualitative descriptors that are difficult to quantify: bowel movement frequency, stool size or consistency (hard or lumpy stools), straining on defecation, inability to defecate at will, and symptoms such as sensation of incomplete evacuation. The condition is considered chronic if symptoms last for at least 3 months. Many people believe that daily bowel movements are required for normal health or that accumulation of toxic substances will occur with infrequent defecation. Inappropriate laxative use by the general public may result from these misconceptions.

Though often considered more of a minor uncomfortable or unpleasant problem, constipation can have serious consequences and be costly to the health care system. Costs for medical evaluation of constipation alone have been estimated at more than $2,500 per patient, and patients spend more than $800 million each year on nonprescription laxatives.[22,24]

Epidemiology

The prevalence of constipation depends on the definition used and whether the condition is self-reported or provider-diagnosed. A systematic review of 45 studies reported the prevalence of chronic constipation in adults (elder than or equal to 15 years old) worldwide to be 14%.[23] The highest incidence was found in South America (16%) and the lowest incidence in Southeast Asia. A review of the epidemiology of constipation in North America found a prevalence up to 27%, with most reported estimates ranging from 12% to 19%.[25] Similarly, in a multinational survey of 13,879 adults from seven countries, the rate of self-reported constipation was 12.3% overall (range 5%-18%).[25,26]

Constipation is more common in women (2.4-fold more likely) and the elderly.[23] Other factors associated with constipation in some reports include inactivity, lower socioeconomic class, lower income, non-white race, symptoms of depression, and history of physical or sexual abuse.

Pathophysiology

Constipation may be primary or secondary. Primary, or idiopathic, constipation occurs without an identifiable underlying cause, whereas secondary constipation may be the result of constipating drugs, lifestyle factors, or medical disorders (**Table 36-5**).[27] Primary constipation can be further divided into three categories—normal transit, slow transit, and pelvic floor dysfunction, or disordered defecation.[28] Normal transit constipation, often referred to as functional, is the most common type. These patients have normal GI motility and stool frequency but may experience difficulty evacuating, passage of hard stools, or bloating and abdominal discomfort. Slow transit constipation represents an abnormality of GI transit time that leads to infrequent defecation. Dysfunction of the pelvic floor muscles and/or anal sphincter is the most frequently encountered reason for disordered defecation. In patients with defecatory disorders, these muscles or sphincter contract during defecation instead of relax and impede evacuation of stool. It is common for patients to have and present with more than one type of constipation.

TABLE 36-5 Possible Causes of Constipation

Conditions	Possible Causes
GI disorders	Irritable bowel syndrome
	Diverticulitis
	Upper GI tract diseases
	Anal and rectal diseases
	Hemorrhoids
	Anal fissures
	Ulcerative proctitis
	Tumors
	Hernia
	Volvulus of the bowel
	Syphilis
	Tuberculosis
	Helminthic infections
	Lymphogranuloma venereum
	Hirschsprung's disease
Metabolic and endocrine disorders	Diabetes mellitus with neuropathy
	Hypothyroidism
	Panhypopituitarism
	Pheochromocytoma
	Hypercalcemia
	Enteric glucagon excess
Cardiac disorders	Heart failure
Pregnancy	Depressed gut motility
	Increased fluid absorption from colon

Conditions	Possible Causes
	Use of iron salts
Lifestyle factors	Dietary changes
	Inadequate fluid intake
	Low dietary fiber
	Decreased physical activity
Neurogenic causes	CNS diseases
	Trauma to the brain (particularly the medulla)
	Spinal cord injury
	CNS tumors
	Cerebrovascular accidents
	Parkinson's disease
Psychogenic causes	Ignoring or postponing urge to defecate
	Psychiatric diseases
Drug induced	See Table 36-6

Factors associated with the increased prevalence of constipation in the elderly include a higher number of daily medications, particularly anticholinergic agents, increased incidence of chronic comorbidities, and changes in mobility status.[24] Changes in diet such as decreased fluid and/or fiber intake, diminished physical activity, and institutionalization can lead to constipation. Physiologic changes such as mesenteric dysfunction and changes in anorectal function, including loss of rectal wall elasticity, are also thought to predispose elderly patients to constipation.

Drug-Induced Constipation

Use of drugs that inhibit the neurologic or muscular function of the GI tract, particularly the colon, may result in secondary constipation.[27] Medications that are commonly associated with causing constipation include opiates, anticholinergic agents, and certain antacids.[24] With most of the agents listed in **Table 36-6**, the inhibitory effects on bowel function may be dose dependent, with larger doses causing constipation more frequently.

TABLE 36-6 Drugs Causing Constipation

Analgesics

Inhibitors of prostaglandin synthesis

Opiates

Anticholinergics

Antihistamines

Antiparkinsonian agents (eg, benztropine or trihexyphenidyl)

Phenothiazines

Tricyclic antidepressants

Antacids containing calcium carbonate or aluminum hydroxide

Barium sulfate

Calcium channel antagonists

Clonidine

Diuretics (non–potassium-sparing)

Ganglionic blockers

Iron preparations

Muscle blockers (D-tubocurarine, succinylcholine)

Nonsteroidal antiinflammatory agents

Polystyrene sodium sulfonate

Opiates have effects on all segments of the bowel, but effects are most pronounced on the colon.[23] The major mechanism by which opiates produce constipation has been proposed to be prolongation of intestinal transit time by causing spastic, nonpropulsive contractions. Additionally, anal sphincter tone may be increased with an accompanying decrease in reflex relaxation leading to difficult rectal evacuation.[29]

While all opiate derivatives are associated with constipation, the degree of intestinal inhibitory effects seems to differ between agents. Orally administered opiates appear to have greater inhibitory effects than parenterally administered products. In some reports, transdermal fentanyl has been associated with less constipation than oral sustained-release morphine.[30]

Other medications may increase the risk of constipation by a variety of mechanisms. Anticholinergic agents decrease contractility of intestinal muscle while calcium channel blockers are thought to cause rectosigmoid dysfunction, leading to constipation. Nonsteroidal antiinflammatory drugs (NSAIDs) may lead to constipation due to their inhibition of prostaglandin synthesis.[24]

Clinical Presentation

A symptom-based system for classifying functional constipation (and other functional GI disorders) is often used to define constipation in clinical trials. The Rome criteria encompass both quantitative (frequency) and qualitative (stool consistency, etc.) symptoms associated with constipation.[31] **Table**

36-7 outlines general clinical presentation of patients with constipation. According to the Rome III criteria, patients should have at least two of the signs and symptoms listed in Table 36-7 apply to a minimum of 25% of bowel movements.

TABLE 36-7 Clinical Presentation of Constipation

Signs and symptoms

- Infrequent bowel movements (<3 per week)
- Stools that are hard, small, or dry
- Difficulty or pain of defecation
- Feeling of abdominal discomfort or bloating, incomplete evacuation, etc.

Alarm signs and symptoms

- Hematochezia
- Melena
- Family history of colon cancer
- Family history of inflammatory bowel disease
- Anemia
- Weight loss
- Anorexia
- Nausea and vomiting
- Severe, persistent constipation that is refractory to treatment
- New-onset or worsening constipation in elderly without evidence of primary cause

Physical examination

- Perform rectal exam for presence of anatomical abnormalities (such as fistulas, fissures, hemorrhoids, rectal prolapse) or abnormalities of perianal descent
- Digital examination of rectum to check for fecal impaction, anal stricture, or rectal mass

Laboratory and other diagnostic tests

- No routine recommendations for lab testing—as indicated by clinical discretion
- In patients with signs and symptoms suggestive of organic disorder, specific testing may be

performed (ie, thyroid function tests, electrolytes, glucose, complete blood count) based on clinical presentation

- In patients with alarm signs and symptoms or when structural disease is a possibility, select appropriate diagnostic studies:

    1. Protoscopy
    2. Sigmoidoscopy
    3. Colonoscopy
    4. Barium enema

Evaluation of constipation should attempt to clarify the patient's specific symptoms (ie, exactly what the patient means by constipation).[31] A complete and thorough history should be obtained from the patient, including frequency of bowel movements and duration of symptoms. Constipation occurring abruptly in an adult may indicate significant colon pathology such as malignancy. Constipation present since early infancy may be indicative of neurologic disorders. The patient should also be carefully questioned about usual diet and laxative regimens. Does the patient have a diet consistently deficient in high-fiber items and containing mainly high refined foods? What laxatives or cathartics has the patient used to attempt relief of constipation? The patient should be questioned about other concurrent medications, with interest focused on agents that might cause constipation.

Evaluation should also include perianal and anal examinations to identify fecal impaction or other anatomical obstructions that may be contributing to or causing constipation. General health status, signs of underlying medical illness (ie, hypothyroidism), and psychological status (eg, depression or other psychological illness) should also be assessed. Laboratory tests may be performed, particularly if the patient is presumed to suffer from secondary causes and is still experiencing symptoms after a trial of fiber supplementation or other nonprescription therapies.[28]

Specific attention should be given to identify any "alarm symptoms" that would warrant further diagnostic workup (see Table 36-7).[32] Patients with alarm symptoms, a family history of colon cancer, or those more than 50 years old with new symptoms may need further diagnostic evaluation.

TREATMENT

Desired Outcome

The major goals of treatment are to (a) relieve symptoms; (b) reestablish normal bowel habits; and (c) improve quality of life by minimizing adverse effects of treatment.

General Approach to Treatment

Table 36-8 presents a general treatment algorithm for the management of constipation.

TABLE 36-8 Constipation Treatment Algorithm

Diagnosis

1. Treat specific cause
2. No underlying diagnosis, then choose symptomatic therapy
    A. Dietary modification to increase fiber ± supplementation (bulk agents)
    B. Add Osmotic laxative (ie, PEG) if no relief; trial 2-4 weeks
    C. Add stimulant laxative (ie, bisacodyl) if no relief or no BM in 2 days
    D. Lubiprostone or linaclotide trial
    E. Opioid-receptor antagonists if opioid-induced constipation

6 Approaches to the treatment of constipation should begin with attempts to determine its cause. If an underlying disease is recognized as the cause of constipation, attempts should be made to correct it. GI malignancies may be removed via surgical resection. Endocrine and metabolic derangements should be corrected by the appropriate methods. For example, when hypothyroidism is the cause of constipation, cautious institution of thyroid replacement therapy is the most important treatment measure. If a patient is consuming medications known to cause constipation, consideration should be given to alternative agents. If a patient must remain on constipating medications, then more attention must be given to general measures for prevention of constipation, as discussed in the next section. Also, patients with opioid-induced constipation (OIC) may require the routine use of pharmacologic agents, also discussed below.

The proper management of constipation will require a combination of nonpharmacologic and pharmacologic therapies. Osmotic laxative therapy is considered the preferred first line for the treatment of constipation, in addition to increasing dietary fiber or using fiber supplementation.[28] Patients are often encouraged to increase daily fluid intake and physical activity as well dedicate time to respond to the urge to defecate, although efficacy data are conflicting for these measures.[33]

Nonpharmacologic Therapy

Dietary Modification

The most important aspect of therapy for constipation for the majority of patients is dietary modification to increase the amount of fiber consumed. Fiber, the portion of vegetable matter not digested in the human GI tract, increases stool bulk, retention of stool water, and rate of transit of stool through the intestine. The result of fiber therapy is an increased frequency of defecation. Also, fiber decreases intraluminal pressures in the colon and rectum, which is thought to be beneficial for diverticular disease and for irritable bowel syndrome (IBS).

7 The specific physiologic effects of fiber are not well understood. Patients should be advised to gradually increase daily fiber intake to 20 to 25 g, through either dietary changes or fiber supplement products (see Bulk-Forming Agents below), a grade B recommendation from the American College of Gastroenterology.[34] Fruits, vegetables, and cereals typically have the highest fiber content. Bran, a by-product of milling of wheat, is often added to foods to increase fiber content and contains a high amount of soluble fiber, which may be extremely constipating in larger doses. Raw bran is generally 40% fiber. A small randomized controlled trial revealed that adding prunes (approximately 6 g fiber/day), or dried plums, to daily diet was more effective than adding psyllium (6 g fiber/day) in treating mild to moderate constipation.[35]

A trial of dietary modification with high-fiber content should be continued for at least 1 month before effects on bowel function are determined. Most patients begin to notice effects on bowel function 3 to 5 days after beginning a high-fiber diet, but some patients may require a considerably longer period of time. Patients should be cautioned that abdominal distension and flatulence may be particularly troublesome in the first few weeks of fiber therapy, especially with high bran consumption. Gradually increasing dietary fiber over a few weeks to the goal of 20 to 25 g may help reduce some of the adverse abdominal effects, as well as ensuring adequate fluid intake. In most cases these problems resolve with continued use.

Surgery

In a small percentage of patients who present with complaints of constipation, surgical procedures are necessary because of the presence of colonic malignancies or GI obstruction from a number of other causes. Patients who have slow-transit-type primary constipation that is refractory to treatment are also surgical candidates.[33] Surgery may be required in some endocrine disorders that cause constipation, such as pheochromocytoma, which requires removal of a tumor. In each case, the involved segment of intestine may be resected or revised.

Biofeedback

Patients with constipation due to pelvic floor dysfunction/disordered defecation may have a less favorable response to fiber therapy than other constipation subtypes.[34] Many adult patients with functional defecatory disorders appear to benefit from pelvic floor retraining with biofeedback therapy. The goals of biofeedback are to improve pelvic floor relaxation to facilitate the passage of stool and the procedure is typically performed over 4- to 6-hour-long sessions. Success rates of 65% to 80% have been reported in controlled and uncontrolled studies, and improvement has been sustained for up to 1 year. The value of biofeedback in children with chronic constipation has not been well demonstrated.

Electrical Stimulation

Sacral nerve stimulation is a minimally invasive technique that has been used for treatment of fecal incontinence and there are some reports of its use in severe refractory chronic constipation.[36] However, clinical data supporting the use of electrical stimulation for this purpose are limited and

there are currently no recommendations for general practice.

Pharmacologic Therapy

Three general classes of laxatives are discussed in this section: (a) those causing softening of feces in 1 to 3 days; (b) those that result in soft or semifluid stool in 6 to 12 hours; and (c) those causing watery evacuation in 1 to 6 hours (**Table 36-9**). Other pharmacologic agents available for the treatment of constipation include a calcium channel activator, guanylate cyclase C agonist, and serotonergic agents.

TABLE 36-9 Dosage Recommendations for Laxatives and Cathartics

Agent	Recommended Dose
Agents that Cause Softening of Feces in 1-3 Days	
Bulk-forming agents/osmotic laxatives	
Methylcellulose	4-6 g/day
Polycarbophil	4-6 g/day
Psyllium	Varies with product
Emollients	
Docusate sodium	50-360 mg/day
Docusate calcium	50-360 mg/day
Docusate potassium	100-300 mg/day
Polyethylene glycol 3350	17 g/dose
Lactulose	15-30 mL orally
Sorbitol	30-50 g/day orally
Agents that Result in Soft or Semifluid Stool in 6-12 Hours	
Bisacodyl (oral)	5-15 mg orally
Senna	Dose varies with formulation
Magnesium sulfate (low dose)	<10 g orally
Agents that Cause Watery Evacuation in 1-6 Hours	
Magnesium citrate	18 g 300 mL water
Magnesium hydroxide	2.4-4.8 g orally
Magnesium sulfate (high dose)	10-30 g orally
Sodium phosphates	Varies with salt used
Bisacodyl	10 mg rectally
Polyethylene glycol-electrolyte preparations	4 L

Bulk-Forming Agents

Medicinal products, often called “bulk-forming agents,” such as psyllium hydrophilic colloids, methylcellulose, or polycarbophil, have properties similar to those of dietary fiber and may be taken

as tablets, powders, or granules.[24] These agents increase the water content of stool to increase stool bulk and weight and relieve the symptoms of constipation within 3 days of initiating therapy.

Bulk-forming laxatives have few adverse effects. The most common effects include flatulence, abdominal bloating, and distention. Rarely, these agents may lead to bowel obstruction. Patients should also be cautioned to consume sufficient fluid while supplementing with bulk-forming agents to avoid obstruction of the esophagus, stomach, small intestine, and colon.

Emollient Laxatives

Emollient laxatives, including docusate in its various salts, are surfactant agents that work by facilitating mixing of aqueous and fatty materials within the intestinal tract; these are commonly referred to as stool softeners.[37] They may increase water and electrolyte secretion in the small and large bowel. Increased stool moisture content should lead to a softer, easier-to-pass stool. These products are generally given orally, although docusate potassium has also been used rectally. With these products, softening of stools occurs within 1 to 3 days of therapy.

Emollient laxatives are ineffective in treating constipation but are used mainly to prevent this condition. They may be helpful in situations in which straining at stool should be avoided, such as after recovery from myocardial infarction (MI), with acute perianal disease, or after rectal surgery. It is unlikely that these agents would be effective in preventing constipation if major causative factors (eg, heavy opiate use, uncorrected pathology, or inadequate dietary fiber) are not concurrently addressed. The use of mineral oil is generally not recommended due to safety concerns.

Although docusates are generally safe, a few adverse effects have been noted. They may increase the intestinal absorption of agents administered concurrently and alter toxic potential. Reports of increased fecal soiling associated with docusate use in elderly patients may limit their use in this population.[37]

Hyperosmolar Agents

Lactulose and Sorbitol Lactulose is a nonabsorbable disaccharide that is metabolized by colonic bacteria to low-molecular-weight acids, resulting in an osmotic effect whereby fluid is retained in the colon.[37] The fluid retained in the colon lowers the pH and increases colonic peristalsis within 2 to 3 days of use. Lactulose increases stool frequency and consistency in patients with chronic constipation (vs placebo) and may be more effective than fiber alone. In comparison to polyethylene glycol (PEG), lactulose is slightly less effective in increasing stool frequency per week and patients are more likely to need additional products for constipation relief.[38] The most common adverse effects include flatulence, nausea, and abdominal discomfort or bloating—although lactulose can be useful in some patients. It may be justified as an alternative for acute constipation or in patients with an inadequate response to increased dietary fiber and bulking agents. In some patients with more complex disease or nonmodifiable risk factors for constipation (such as bedridden, elderly patients with chronic or debilitating illnesses and constipating medications), lactulose may be required on a more regular basis.[37] In addition to the adverse abdominal effects associated with lactulose, diarrhea and

electrolyte imbalances can occasionally occur. Sorbitol, a monosaccharide, also exerts its effect by osmotic action and has been recommended as a cost-effective alternative to lactulose. It is as effective as lactulose but may cause less nausea and is much less expensive.

Polyethylene Glycol PEG is FDA-approved for treatment of constipation at low doses and is expected to produce a bowel movement in 1 to 3 days.[37,38] For this indication, PEG is administered in smaller volumes (10-30 or 17-34 g per 120-240 mL) usually once (or twice) daily. PEG is not absorbed systemically or metabolized by colonic bacteria, and therefore has a lower incidence of adverse effects compared with other osmotic laxatives. Daily use in low dose (17 g) may be safe and effective for up to 6 months.[39] PEG has a grade A recommendation from the American College of Gastroenterology for the treatment of chronic constipation and is available as a nonprescription drug.[31] It is also preferred by the American Gastroenterology Association if fiber supplementation is insufficient due to high efficacy based on high quality of evidence available.[28] The most common adverse effects are GI-related and include nausea, vomiting, flatulence, and abdominal cramping.[37] PEG solutions with electrolytes are used as bowl cleansing regimens prior to GI-related procedures, and should not be used routinely for treatment of constipation.

Magnesium Salts Magnesium salts, including hydroxide, phosphate, and citrate, and sodium phosphate are categorized as saline cathartics.[37] These agents are frequently used as bowel preparations prior to diagnostic procedures such as colonoscopy.[27] Milk of magnesia (an 8% suspension of magnesium hydroxide), though, may be used occasionally to treat constipation in otherwise healthy adults, but efficacy data are limited. Saline cathartics should not be used on a routine basis. These agents may cause fluid and electrolyte depletion. Also, magnesium or sodium accumulation may occur in patients with renal dysfunction or congestive heart failure. These risks increase with long-term use.

Glycerin Glycerin is usually administered as a suppository and exerts its effect by osmotic action in the rectum. As with most agents given as suppositories, the onset of action is usually less than 30 minutes. Glycerin is considered a safe laxative, although it may occasionally cause rectal irritation. Its use is acceptable on an intermittent basis for constipation or fecal impaction, particularly in children.[40]

Stimulant Laxatives

Stimulant laxatives such as diphenylmethane (bisacodyl) and anthraquinone (senna and others) derivates primarily affect the colon.[37] These agents stimulate the mucosal nerve plexus of the colon and may also affect intestinal fluid secretion by altering fluid and electrolyte transport, and are expected to cause a bowel movement within 8 to 12 hours of administration. Stimulant laxatives may cause severe abdominal cramping and electrolyte imbalances, particularly with chronic use. Compared with placebo, bisacodyl is effective in treatment of constipation;[40] however, stimulant laxatives are not recommended as first-line treatment. These agents are typically reserved for intermittent use or in patients who fail to respond adequately to bulking and osmotic laxatives. Some patients, though, with severe chronic constipation and nonmodifiable risk factors may use these

agents on a more regular basis.[28,41]

Clinical Controversy…

The long-term use of stimulant laxatives is controversial. Newer studies do not report damage to the enteric nervous system like earlier studies. Nerve damage may actually be the cause of the constipation rather than the result of using laxatives. Patients requiring regular use of laxatives, though, may still need to be monitored for these effects.

Intestinal Secretagogues

Lubiprostone

Lubiprostone (Amitiza) is a chloride channel activator that acts locally in the gut to open chloride channels on the GI luminal epithelium, which, in turn, stimulates chloride-rich fluid secretion into the intestinal lumen. Increased intraluminal fluid secretion helps to soften stool and accelerate GI transit time.[23] Lubiprostone is FDA-approved for adults with chronic idiopathic constipation as well as treatment of patients with constipation-predominant irritable bowel syndrome (IBS-C) at a recommended dose of one 24 mg capsule twice daily with food. Patients treated with lubiprostone have a significant increase in spontaneous bowel movements versus placebo as well as improvement in straining, stool consistency, and overall constipation severity.[42] Lubiprostone appears safe and effective for long-term treatment (up to 48 weeks). For most patients, bowel movements occur within 24 to 48 hours of lubiprostone administration. Common adverse effects include nausea, headache, and diarrhea and may be dose dependent.[27] Because of its high cost (especially relative to other available laxative agents) and lack of comparative data with other laxative therapies, lubiprostone is reserved for patients with chronic constipation who fail conventional first-line agents such as osmotic laxatives and fiber supplementation, or for those with OIC.

Linaclotide

Linaclotide (Linzess) is approved for the treatment of constipation and IBS-C.[43] It is a synthetic 14-amino-acid peptide that binds to and activates the guanylate cyclase C receptor found on the intestinal epithelium. This increases intestinal fluid secretion and quickens intestinal motility. In two randomized controlled trials involving approximately 1,276 patients, linaclotide 145 and 290 mcg daily was more effective than placebo at increasing spontaneous bowel movements in patients with chronic constipation at 12 weeks.[44] Only the 145 mcg dose is approved for treatment of constipation due to the lack of improved efficacy with the higher dosing. Diarrhea was the most commonly reported adverse event in clinical trials, followed by flatulence and abdominal pain. Linaclotide should not be used in patients under the age of 18.[43]

Opioid Receptor Antagonists

Alvimopan (Entereg) is an oral GI-specific μ-opioid antagonist approved for short-term use in hospitalized patients to accelerate recovery of bowel function after large or small bowel resection.[45]

It antagonizes the GI (peripheral) effects of opioids without affecting analgesia because it does not cross the blood–brain barrier. Alvimopan is only available through a special use program (ENTEREG access support and education [EASE]), which requires hospitals to register and meet all requirements before the drug can be administered. Additionally, alvimopan is contraindicated in patients receiving therapeutic doses of opioids for more than 7 consecutive days prior to surgery as they may be more sensitive to the drug's effects. Dosing for alvimopan is as follows: 12 mg capsule administered 30 minutes to 5 hours before surgery and then 12 mg twice daily for up to 7 days or until discharge (maximum of 15 doses).

Methylnaltrexone (Relistor) is μ-receptor antagonist approved for OIC in patients with advanced disease receiving palliative care or when response to laxative therapy has been insufficient.[45] This agent does not cross the blood–brain barrier or antagonize analgesia; it acts on peripheral μ-receptors to block unwanted opioid side effects such as constipation. It is administered at a weight-based dose as a subcutaneous injection, usually every other day (no more than once daily), and is contraindicated in patients with known or suspected GI obstruction.

Naloxegol (Movantik) was approved by the FDA in September 2014 for the treatment of OIC in adult patients with noncancer pain.[46] It is an oral pegylated naloxone molecule and antagonizes the μ-receptor. Pegylation reduces naloxegol's passive permeability of the blood–brain barrier. The recommended dose is 25 mg by mouth once daily, 1 hour before or 2 hours after a meal. The dose should be reduced by half in patients with diminished renal function (CrCl <60 mL/min [<1.0 mL/s]) or in those unable to tolerate 25 mg. The most common side effects are abdominal pain, diarrhea, and nausea. In clinical trials, naloxegol significantly increased the number and frequency of bowel movements compared to placebo at 12 weeks.[29]

Other Agents

Prucalopride is a selective 5-hydroxytryptamine-4 (5-HT_4) receptor agonist approved for treatment of chronic constipation in Europe.[47] It demonstrates proenterokinetic effects (increased colonic motility and transit), specifically in the GI tract. Prucalopride, however, is more selective than the previously available serotonergic agonists cisapride and tegaserod with higher affinity for the 5-HT_4 receptor. Receptor selectivity is thought to improve the safety profile of prucalopride over cisapride and tegaserod, which were removed from the market due to concerns for adverse cardiovascular events. In clinical trials, prucalopride significantly increased the number of complete, spontaneous bowel movements in adults with chronic constipation. Constipation symptoms and quality of life were also improved with prucalopride. This agent has been safely tolerated in clinical trials with no adverse cardiovascular effects versus placebo (although data are limited). Prucalopride has not yet been approved by the FDA.

Probiotics may be useful in the treatment of constipation. Five randomized controlled trials conducted in children and adults revealed that certain strains of probiotics increased weekly stool frequency.[48] However, these trials were small (370 patients total) and only slight improvement was realized (one additional stool per week). More studies are needed to strengthen evidence involving probiotics, but these may be an option for patients seeking alternative treatment.

Prevention

For patients recovering from MI or rectal surgery, straining at defecation should be avoided. The basis of preventive therapy in these patients should be bulk-forming laxatives. Additionally, the use of docusate is popular, although its effectiveness is debated. In pregnant patients, constipation may result because of alterations in hormones or iron supplementation. As described earlier, bulk-forming laxatives and docusates should be the first line of prevention.

Evaluation of Therapeutic Outcomes

The ultimate goal of treatment for constipation is to prevent further episodes of constipation. Short-term goals include alleviation of acute constipation with relief from symptoms. For patients with chronic constipation, the goals include use of proper diet and decreased reliance on laxatives in addition to relief of symptoms for the patient so that quality of life is not diminished. Effective treatment of constipation requires the patient to become more knowledgeable about the causes of constipation, proper diet, and appropriate use of laxatives.

IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome is a GI syndrome characterized by chronic abdominal pain and altered bowel habits in the absence of any organic cause. It is the most commonly diagnosed GI condition.

Epidemiology

The prevalence of IBS is approximately 5% to 15% based on North American and European population-based studies; however, there is a wide variation in prevalence by individual country.[49,50,51] IBS affects men and women, young patients, and the elderly with an overall 2:1 female predominance in North America.[52] However, younger patients and women are more likely to be diagnosed with IBS. Although only 15% of those affected actually seek medical attention, IBS is the cause of between 25% and 50% of all referrals to gastroenterologists.[49]

Pathophysiology

Although the exact pathophysiologic abnormalities with IBS are still being actively investigated, IBS likely results from altered somatovisceral and motor dysfunction of the intestine from a variety of causes. Abnormal CNS processing of afferent signals may lead to visceral hypersensitivity, with the specific nerve pathway affected determining the exact symptomatology expressed. This visceral hypersensitivity is a neuroenteric phenomenon that is independent of motility and psychological disturbances.[51] Factors known to contribute to these alterations include genetics, motility factors, inflammation, colonic infections, mechanical irritation to local nerves, stress, and other psychological factors.

The enteric nervous system contains a significant percentage of the body's 5-HT receptors.[53] Two

types of 5-HT receptors exist within the gut: serotonin type 3 (HT_3) and serotonin type 4 (HT_4), which are responsible for secretion, sensitization, and motility. There is an increase in the postprandial levels of 5-HT in the GI tract in those who suffer from diarrhea-predominant IBS when compared with nonsufferers.[53] Therefore, stimulation and antagonism of these 5-HT receptors have become a focused area for research on new drug therapies for both diarrhea- and constipation-predominant diseases.

Clinical Presentation

8 Irritable bowel syndrome presents as either diarrhea- or constipation-predominant disease and can be defined as lower abdominal pain, disturbed defecation (constipation, diarrhea, or an alternating pattern of both), and bloating in the absence of structural or biochemical factors that might explain these symptoms (**Table 36-10**). Because IBS can have variable signs and symptoms, two diagnostic criteria "checklists" are commonly used to aid in the workup of a patient suspected of having IBS.[54] The Manning criteria were first proposed in 1978, whereas the Rome criteria were initially proposed in 1999 and revised as recently as 2006 by an international working group in an effort to help standardize the diagnostic criteria used in clinical research protocols. **Table 36-11** shows the symptom criteria for both of the Manning[55] and Rome III[31] symptom-based criteria.

TABLE 36-10 Clinical Presentation of Irritable Bowel Syndrome

Signs and symptoms

- Lower abdominal pain
- Abdominal bloating and distension
- Diarrhea symptoms, >3 stools/day
- Extreme urgency
- Passage of mucus
- Constipation symptoms, <3 stools/wk, straining, incomplete evacuation
- Psychological symptoms such as depression and anxiety

Non-GI symptoms

- Urinary symptoms
- Fatigue
- Dyspareunia

Other concurrent conditions

- Fibromyalgia
- Functional dyspepsia
- Chronic fatigue syndrome

Reduced health-related quality of life

TABLE 36-11 Symptom-Based Criteria for Irritable Bowel Syndrome

The Manning criteria[56]

Chronic or recurrent abdominal pain for at least 6 months and two or more of the following:

1. Abdominal pain relieved with defecation
2. Abdominal pain associated with more frequent stools
3. Abdominal pain associated with looser stools
4. Abdominal distension
5. Feeling of incomplete evacuation after defecation
6. Mucus in stools

Rome III diagnostic criteria for irritable bowel syndrome[33]

Recurrent abdominal pain or discomfort at least 3 days per month in the last 3 months associated with two or more of the following:

1. Relieved with defecation
2. Onset associated with a change in frequency of stool
3. Onset associated with a change in form (appearance) of stool

Additional diagnostic steps that can be taken include sigmoidoscopy or colonoscopy, examination of the stool for occult blood and ova and parasites, complete blood cell count, erythrocyte sedimentation rate, and serum electrolytes. In some cases, radiographic imaging studies, such as computed tomography scans or barium swallows or enemas, may also be necessary if the findings of the foregoing assessment are not typical for IBS.[49]

TREATMENT

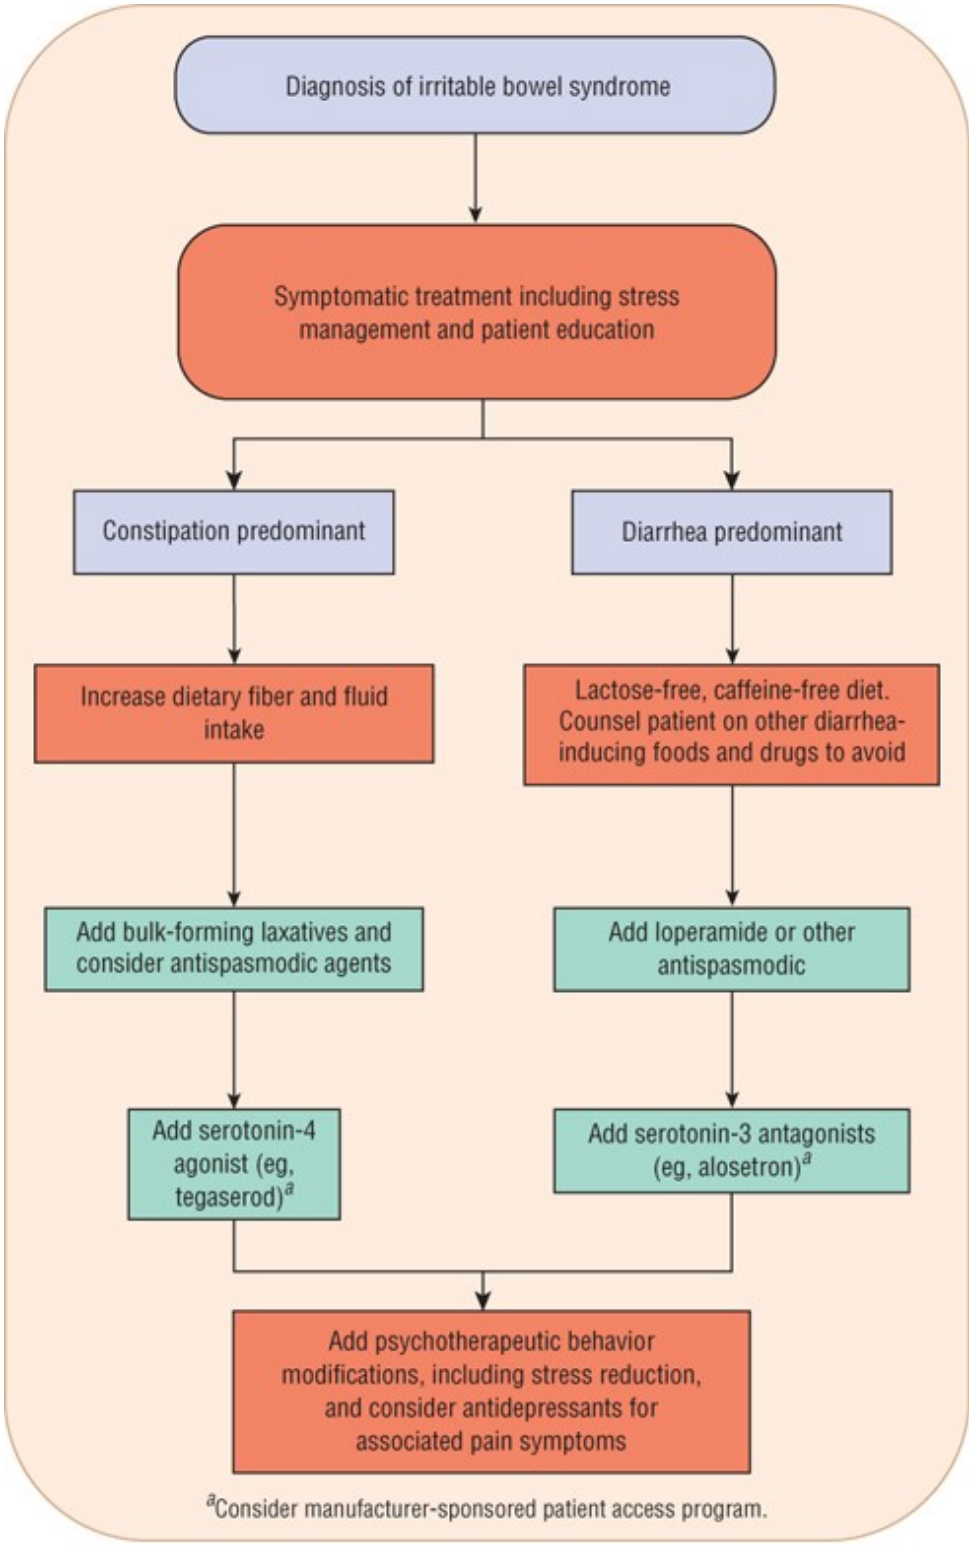
General Approach to Treatment

The treatment approach to IBS is based on the predominant symptoms and their severity (**Fig. 36-3**).

Milder, less frequent episodes can be managed with lifestyle changes such as dietary restrictions, a higher-fiber diet, physical activity, and relaxation techniques.[56] More persistent disease may require as-needed uses of various antispasmodic or antidiarrheal agents such as loperamide. Lastly, the most severe forms of this disease may call for pharmacologic agents directed specifically at the underlying neurohormonal imbalance, such as the 5-HT_4 agonists (eg, tegaserod), or the 5-HT_3 receptor antagonists (eg, alosetron).

FIGURE 36-3

A general stepwise approach to the management of both constipation- and diarrhea-predominant irritable bowel syndrome.



Alosetron, a 5-HT_3 receptor antagonist, was withdrawn from the U.S. market in 2000 as a result of serious adverse effects, including severe constipation and ischemic colitis that did not appear in the initial clinical trials. It was reintroduced in 2002 and is now limited to an FDA-approved restricted-use program in lower initial doses, and requires extensive postmarketing surveillance. Results of these trials are necessary to definitively determine alosetron's true safety profile, especially with regard to

its association with or causation of fatal ischemic colitis.

Constipation-Predominant Disease

In the constipation-predominant patient, dietary fiber may be beneficial. Patients should be instructed to begin with one tablespoonful of fiber with one meal daily and gradually increase the dose to include fiber with two and three meals a day until the desired outcome is achieved. End points that the patient should aim for include bulkier and more easily passed stools. For patients unable to tolerate dietary bran, bulking agents such as psyllium may be substituted.[56] PEG laxatives may be used; however, other laxatives should only be used in the smallest dose for the least amount of time. When lifestyle modifications alone do not control symptoms, linaclotide should be recommended.[52]

The 5-HT_4 partial agonist tegaserod was the first therapy approved by the FDA specifically for short-term, intermittent treatment of IBS-C in women.[57,58,59] Tegaserod is available in the United States through a restricted-access program due to a small, yet significant, increase in ischemia events (MI, cerebrovascular accident [CVA], and unstable angina) in patients with preexisting cardiovascular disease and/or cardiovascular risk factors. It is given as 2 or 6 mg doses given twice daily 30 minutes prior to a meal with water for up to 12 weeks.[58] Stimulation of the 5-HT_4 receptors by tegaserod increases gastric secretions and promotes motility, with improvement in symptoms generally occurring within the first week of therapy. Diarrhea was the most common adverse effect, resulting in drug discontinuation in 1.6% of study subjects.

Diarrhea-Predominant Disease

9 For patients in whom diarrhea is the primary complaint, avoidance of certain food products may be necessary. Caffeine, alcohol, and artificial sweeteners (sorbitol, fructose, and mannitol) are known to irritate the gut and produce a laxative effect. Lactose intolerance should be considered in certain patients; however, the prevalence of this condition may be exaggerated.

Herbal medicines or teas often contain senna, which may produce diarrhea. In patients with disease persistence following dietary modification, loperamide may be used for episodic management of urgent diarrhea, or in situations in which the patient wishes to avoid the possibility of an acute onset of symptoms.[52] Loperamide decreases intestinal transit, enhances water and electrolyte absorption, and strengthens rectal sphincter tone. Some patients may require continuous therapy, and careful dosage titration can usually be undertaken to prevent the development of constipation.

Diarrhea-predominant IBS caused by excessive stimulation of the 5-HT_3 receptor can be relieved by the drug alosetron. Alosetron was the first effective treatment for diarrhea-predominant IBS.[52] Alosetron is only available via an FDA-approved restricted-use program due to severe GI adverse effects. Additional information can be found at http://www.lotronex.com. It is indicated for women with diarrhea-predominant symptoms of longer than 6 months' duration that are not relieved by conventional therapy at a dose of 0.5 mg twice daily.

Two new agents, eluxadoline and rifaximin, were approved for use in IBS-D by the FDA in 2015.[60] Rifaximin is a rifamycin antibacterial indicidated for the treatment of travelers' diarrhea that is indicated for the treatment of IBS-D in adults based on several randomized control trials demonstrating improvement in abdominal pain, stool consistency, and bloating.[52,61] The recommended dose is 550 mg orally three times a day for 2 weeks. Recurrences may be retreated up to two times; however, there is no evidence to support repeating the regimen. Eluxadoline is a μ-opiod receptor agonist indicated for adults with IBS-D. The recommended dose is 100 mg orally twice a day with food. A lower dose of 75 mg twice daily is recommended for patients without a gallbladder, who cannot tolerate the 100 mg dose and if they have hepatic impairement.[62] It was approved based on two randomized clinical trials that suggested an improved in abdominal pain and stool consistency. The main side effect observed was constipation.

Use of Antidepressants in Irritable Bowel Syndrome

Tricyclic antidepressants have shown some benefit in treatment of diarrhea-predominant IBS associated with moderate to severe abdominal pain, by modulating perception of visceral pain, altering GI transit time, and treating underlying comorbidities.[63,64] Selective 5-HT reuptake inhibitors are less well studied, with only one report with paroxetine showing some improvement in stool passage and "well-being" but no decrease in abdominal pain.[65,66,67]

Figure 36-3 shows a general stepwise approach to the management of both constipation and diarrhea-predominant IBS.

Pain in Irritable Bowel Syndrome

10 Some patients with IBS suffer significant pain associated with their disease. Data supporting the use of antispasmodic agents in these patients are conflicting.[49] A trial of low-dose antidepressant therapy is indicated, especially if pain is associated with eating. Both tricyclic antidepressants and 5-HT reuptake inhibitors produce analgesia and may relieve depressive symptoms if present. Preprandial doses of drugs containing anticholinergic properties may suppress pain (and/or diarrhea) associated with an overactive postprandial gastrocolonic response. Tricyclic antidepressants should be avoided in patients with pain and constipation. In addition, psychotherapy, including cognitive behavioral therapy, relaxation therapy, and hypnotherapy, has been shown to decrease IBS symptoms.[68]

Evaluation of Therapeutic Outcomes

Irritable bowel syndrome is usually classified as constipation-predominant, diarrhea-predominant, or IBS with abdominal pain and bloating. Therapeutic goals in IBS should focus on the patient's primary complaint. Dietary and drug therapy goals should focus on end-organ treatment to relieve abdominal pain (antispasmodic drugs) or disturbed bowel habits (antidiarrheals and bulk-forming agents). Additionally, severe symptoms from CNS dysregulation should be treated with antidepressants, psychotherapy, relaxation/stress management, cognitive behavior treatment, and/or

hypnosis aimed at specific affective disorders.[49] Lastly, the 5-HT receptor agonists and antagonists can be used in carefully selected patients whose symptoms are not adequately controlled with other agents. The AGA recommends that patients with severe IBS consider psychological treatments such as psychotherapy, relaxation/stress management, and/or cognitive behavior treatment.

Chapter 37: Portal Hypertension and Cirrhosis

Julie M. Sease; Jennifer N. Clements

INTRODUCTION

KEY CONCEPTS

- 1 Cirrhosis is a severe, chronic, irreversible disease associated with significant morbidity and mortality. However, the progression of cirrhosis secondary to alcohol abuse can be interrupted by abstinence. It is therefore imperative for the clinician to educate and support abstinence from alcohol as part of the overall treatment strategy of the underlying liver disease.
- 2 Patients with cirrhosis should receive endoscopic screening for varices, and certain patients with varices should receive primary prophylaxis with nonselective β-adrenergic blockade therapy to prevent variceal hemorrhage.
- 3 When nonselective β-adrenergic blocker therapy is used to prevent rebleeding, therapy can be titrated to achieve a goal heart rate of 55 to 60 beats/min or the maximal tolerated dose.
- 4 Octreotide is the preferred vasoactive agent for the medical management of variceal bleeding. Endoscopic band ligation is the primary therapeutic tool for the management of acute variceal bleeding.
- 5 The combination of spironolactone and furosemide is the recommended initial diuretic therapy for patients with ascites.
- 6 All patients who have survived an episode of spontaneous bacterial peritonitis (SBP) should receive long-term antibiotic prophylaxis.
- 7 The mainstay of therapy of hepatic encephalopathy (HE) involves therapy to lower blood ammonia concentrations and includes diet therapy, lactulose, and antibiotics alone or in combination with lactulose.

Chronic liver injury causes damage to normal liver tissue resulting in the development of regenerative nodules surrounded by fibrous bands.[1] Cirrhosis is an advanced stage of liver fibrosis that leads to

shunting of the portal and arterial blood supply directly into hepatic outflow through the central veins with compromised exchange between hepatic sinusoids and hepatocytes. Clinical consequences of cirrhosis include impaired hepatocyte function, the increased intrahepatic resistance of portal hypertension, and hepatocellular carcinoma. Circulatory irregularities, such as splanchnic vasodilation, vasoconstriction and hypoperfusion of the kidneys, water and salt retention, and increased cardiac output, also occur. The word *cirrhosis* is derived from the Greek *kirrhos*, meaning orange-yellow, and refers to the color of the cirrhotic liver as seen on autopsy or during surgery.[2]

1 While cirrhosis has many causes (**Table 37-1**), in the Western world, excessive alcohol intake and hepatitis C are the most common causes.[1,3] Nonalcoholic steatohepatitis is also an important cause of cirrhosis in the end diagnosis of cirrhosis without an apparent cause occurs infrequently today.[1] This chapter elucidates the pathophysiology of cirrhosis and the resultant effects on human anatomy and physiology. Treatment strategies for managing the most commonly encountered clinical complications of cirrhosis are discussed.

TABLE 37-1 Etiology of Cirrhosis

Chronic alcohol consumption
Chronic viral hepatitis (types B and C)
Metabolic liver disease
Hemochromatosis
Wilson's disease
α_1-antitrypsin deficiency
Nonalcoholic steatohepatitis ("fatty liver")
Immunologic disease
Autoimmune hepatitis
Primary biliary cirrhosis
Vascular disease
Budd–Chiari
Cardiac failure
Drugs
Isoniazid, methyldopa, amiodarone, amoxicillin-clavulanate, nitrofurantoin, diclofenac, methotrexate, nevirapine, propylthiouracil, valproate

Data from references 1 and 3.

EPIDEMIOLOGY

The exact prevalence of cirrhosis is unknown, but a reasonable estimate is that 1% of populations have histologically diagnosable cirrhosis.[1] Chronic liver disease and cirrhosis were responsible for nearly 35,000 deaths in America in 2012 making it the 11th leading cause of death among whites, 15th leading cause of death among blacks, 5th leading cause of death among American Indians and Alaska Natives and 13th leading cause of death among Asians and Pacific Islanders.[4] Acute variceal bleeding and spontaneous bacterial peritonitis (SBP) are among the immediately life-threatening complications of cirrhosis. Associated conditions causing significant morbidity include ascites and hepatic encephalopathy (HE). Approximately 50% of patients with cirrhosis develop ascites during 10 years of observation and, within 2 years, nearly half of patients who develop ascites will die.[5]

PATHOPHYSIOLOGY OF CIRRHOSIS

Any discussion of cirrhosis must be based on a firm understanding of hepatic anatomy and vascular supply. Conceptually, the liver can be thought of as an elaborate blood filtration system receiving blood from the hepatic artery and the portal vein (**Fig. 37-1**), with portal blood originating from the small intestines.[6] Blood enters the liver via the portal triad, which contains branches of the portal vein, hepatic artery, and bile ducts. It then drains through the sinusoidal spaces (also known as the space of Disse) of the hepatic lobule (**Fig. 37-2**), which are lined by the workhorses of the liver, the hepatocytes. Individual hepatocytes are arranged in plates that are one cell thick and organized around individual central veins. The six or more surfaces of each individual hepatocyte make contact with adjacent hepatocytes, border the bile canaliculi, or are exposed to the sinusoidal space. Filtered blood travels into the terminal hepatic venules, also called central veins, and then empties into larger hepatic veins and eventually into the inferior vena cava. Functional gradients of hepatocytes based on oxygen saturation have been reported. Hepatocytes closest to the portal triad, which contains the hepatic artery, have greater oxygen saturation than those hepatocytes nearer to the terminal hepatic venule. Blood flows past hepatocytes in zone one, then zone two, and finally zone three before entering the central vein. Hepatocytes in zone one are involved in gluconeogenesis, urea synthesis, and oxidative energy metabolism while those in zone three carry out the functions of glycolysis and lipogenesis.

FIGURE 37-1

The portal venous system.

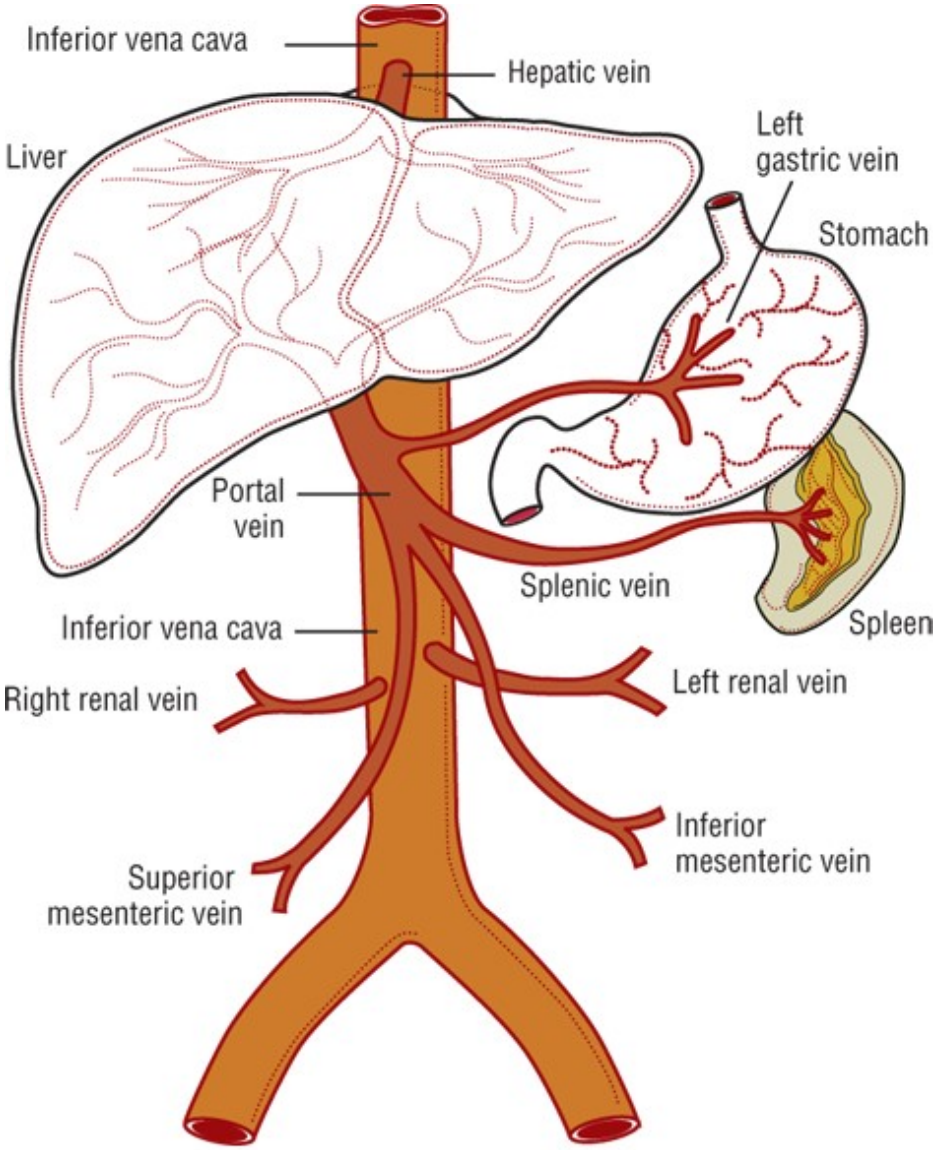

FIGURE 37-2

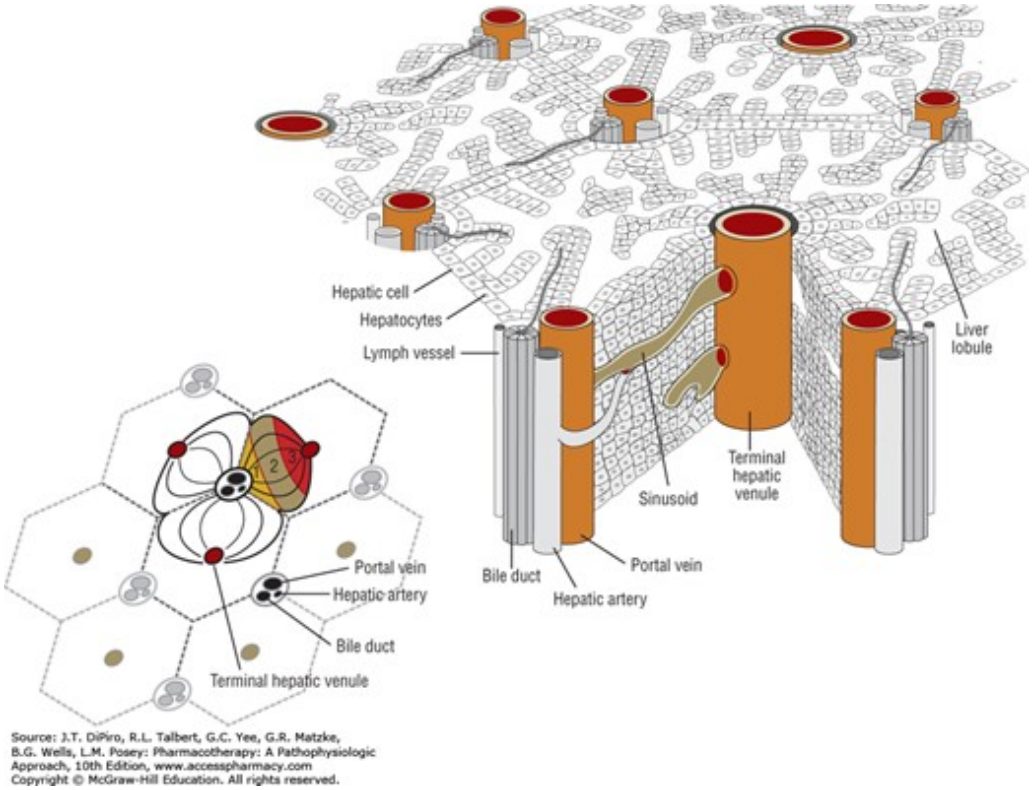
The hepatic lobule.



Normally, hepatic stellate cells function to store vitamin A and help to maintain the normal matrix in the sinusoidal space.[7] During chronic liver disease, however, hepatic stellate cells undergo an "activation" process, which is the central event in the development of hepatic fibrosis. Activation causes stellate cells to lose vitamin A, become highly proliferative, and synthesize fibrotic scar tissue, which accumulates in the sinusoidal space. This leads to loss of hepatocyte microvilli, loss of sinusoidal endothelial fenestrae, deterioration of hepatocyte function, and, if fibrosis progresses, eventual cirrhosis.

Cirrhosis causes changes to the splanchnic vascular bed as well as the systemic circulation.[8] Splanchnic vasodilation, decreased responsiveness to vasoconstrictors, and the formation of new blood vessels contribute to an increased splanchnic blood flow, formation of gastroesophageal varices, and variceal bleeding. All of these components are part of the portal hypertensive syndrome. Portal hypertension is characterized by hypervolemia, increased cardiac index, hypotension, and decreased systemic vascular resistance. This is so-called hyperkinetic syndrome that leads to a marked activation of neurohumoral vasoactive factors, a response that occurs in an effort to maintain the arterial blood pressure within normal limits. Activation of neurohumoral vasoactive factors is a main component in the pathophysiology of the ascites and renal dysfunction that often accompany chronic liver disease. Portal-systemic shunting may also occur and is involved in HE and other complications.

ANATOMIC AND PHYSIOLOGIC EFFECTS OF CIRRHOSIS

Cirrhosis and the pathophysiologic abnormalities that cause it result in the commonly encountered problems of ascites, portal hypertension, esophageal varices, HE, and coagulation disorders. Other less commonly seen problems in patients with cirrhosis include hepatorenal syndrome,

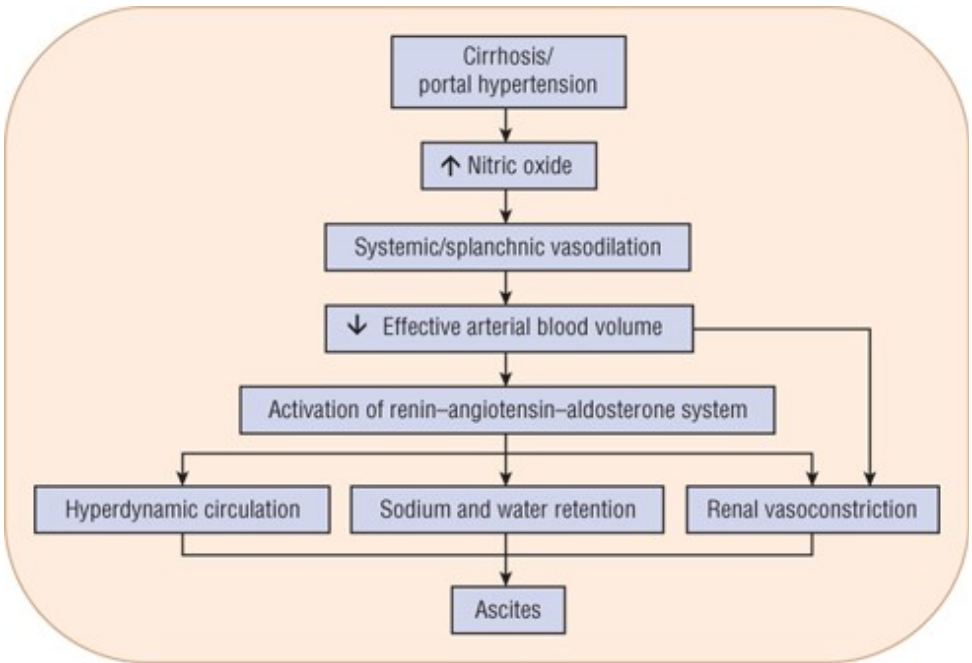
hepatopulmonary syndrome, and endocrine dysfunction. These are discussed under heads Management of Portal Hypertension and Variceal Bleeding.

Ascites

Ascites is the accumulation of an excessive amount of fluid within the peritoneal cavity.[9] It is the most commonly occurring major complication of cirrhosis.[5] Approximately half of all cirrhotic patients develop ascites within 10 years of diagnosis. Several hypotheses have been offered to explain the mechanism for the development of ascites in decompensated cirrhosis.[9] Most acceptable theories state that ascites formation begins as a result of the development of sinusoidal hypertension and portal hypertension. Portal hypertension activates vasodilatory mechanisms that are mediated mostly by nitric oxide overproduction. This leads to splanchnic and peripheral arteriolar vasodilation and, in advanced disease, a drop in arterial pressure. Baroreceptor-mediated activation of the renin–angiotensin–aldosterone system, activation of the sympathetic nervous system, and release of antidiuretic hormone occur in response to the resulting arterial hypotension in an effort to restore normal blood pressure (**Fig. 37-3**). These changes cause renal sodium and water retention. Additionally, ongoing splanchnic vasodilation increases splanchnic lymph production beyond the capacity of the lymph transportation system. Leakage of lymphatic fluid into the peritoneal cavity occurs. Persistent renal sodium and water retention, increased splanchnic vascular permeability, and lymphatic leakage into the peritoneal cavity combine to create the sustained ascites formation of end-stage liver disease.

FIGURE 37-3

Pathogenesis of ascites.



Portal Hypertension and Varices

Sinusoidal portal hypertension is most often caused by cirrhosis.[10] It is associated with acute variceal bleeding, a medical emergency which is among the most severe complications of cirrhosis.[11] Portal hypertension is defined by the presence of a gradient of greater than 5 mm Hg (0.7 kPa) between the portal and central venous pressures (see Fig. 37-1).[10] This gradient is called the hepatic venous pressure gradient (HVPG). Esophageal and gastric varices and variceal bleeding may arise after an HVPG pressure gradient of 10 mm Hg (1.3 kPa) is reached.

Progression to bleeding can be predicted by Child-Pugh score, size of varices, and the presence of red wale markings on the varices. First variceal hemorrhage occurs at an annual rate of about 15% and carries a mortality of 7% to 15%. Rebleeding is common following initial hemorrhage with a median rate of 60% and carries a mortality rate as high as 33%. Prevention of bleeding is a major goal in the therapy of portal hypertension, and strategies include both pharmacologic and surgical approaches.

Hepatic Encephalopathy

Hepatic encephalopathy is a metabolically induced functional disturbance of the brain that is potentially reversible.[12] Symptoms of HE are thought to result from an accumulation of gut-derived nitrogenous substances in the systemic circulation as a consequence of decreased hepatic functioning and shunting through portosystemic collaterals bypassing the liver.[13] Once these substances enter the CNS, they cause alterations of neurotransmission that affect consciousness and behavior. Ammonia is the most commonly cited culprit in the pathogenesis of HE, but glutamine, benzodiazepine receptor agonists, aromatic amino acids, and manganese are also potential causes.[12,13] Arterial ammonia levels are increased commonly in both acute and chronic liver diseases, but an established correlation between blood ammonia levels and mental status does not exist.[13] Despite this, interventions to lower blood ammonia levels remain the mainstay of treatment for HE.

Hepatic encephalopathy is categorized as type A, B, or C based on nomenclature developed by the 11th World Congress of Gastroenterology.[12] Type A is HE induced by acute liver failure, type B is due to portal-systemic bypass without associated intrinsic liver disease, and type C is HE that occurs in patients with cirrhosis. Minimal HE refers to cirrhotic patients who do not suffer clinically overt cognitive dysfunction but who are found to have cognitive impairment on psychological studies. The onset of HE in a patient with liver failure may be related to the presence of several known precipitating factors. In cases of HE associated with a precipitant, if that precipitant can be cured or discontinued, it may also be possible to discontinue treatment for HE. In many cases, no precipitant is found and, therefore, long-term treatment of HE may be required.

Coagulation Defects

End stage chronic liver disease is associated with decreased synthetic capability of the liver leading to decreased levels of most procoagulant factors as well as the naturally occurring anticoagulants,

antithrombin and protein C.[14] However; two procoagulant factors, factor VIII, and von Willebrand factor, are actually elevated in chronic liver disease. Traditionally, it was thought that chronic liver disease induced an "autoanticoagulation" owing to the decrease in most procoagulant factors, but it is now believed that, thanks to the increased levels of factor VIII and von Willbrand factor and the decreased levels of antithrombin and protein C, these patients actually live in a tenuous state of hemostatic homeostasis. The rebalanced homeostasis seen in chronic liver disease can be tipped toward either thrombosis or clinically significant bleeding at any time depending on the circumstances experienced by the patient at the time. The prothrombin time (PT) is a standard component of the Child-Pugh scoring system and the international normalized ratio (INR) is utilized in the Model for End-Stage Liver Disease, a prognostic evaluation tool. The ability of the PT and INR to accurately measure bleeding risk and assist with estimation of the severity of a patient's liver disease has been called into question.

CLINICAL PRESENTATION Cirrhosis Signs and Symptoms

- Asymptomatic
- Hepatomegaly and splenomegaly
- Pruritus, jaundice, palmar erythema, spider angiomata, and hyperpigmentation
- Gynecomastia and reduced libido
- Ascites, edema, pleural effusion, and respiratory difficulties
- Malaise, anorexia, and weight loss
- Encephalopathy

Laboratory Tests

- Hypoalbuminemia
- Elevated prothrombin time (PT)
- Thrombocytopenia
- Elevated alkaline phosphatase
- Elevated aspartate transaminase (AST), alanine transaminase (ALT), and *γ*-glutamyl transpeptidase (GGT)

Both platelet number and function may be affected in cirrhosis. Thrombocytopenia, a common finding in cirrhosis, could promote bleeding. However, given the relatively high levels of von Willebrand factor present in cirrhosis, platelet function is actually increased. Cirrhotic patients with platelet counts as low as 60×10^9 per liter are able to preserve thrombin formation similar to the lower end of the normal range for healthy persons. Fibrinolysis is another process that is likely rebalanced in cirrhosis. While it has been observed that hyperfibrinolysis occurs in chronic liver

disease owing to increased levels of tissue plasminogen activator and thrombin-activatable fibrinolysis inhibitor, reduced levels of plasminogen and increased levels of plasminogen activator inhibitor are also observed, both of which promote a hypofibrinolytic state.

CLINICAL PRESENTATION

Cirrhotic patients may present in a variety of ways, from asymptomatic with abnormal radiographic or laboratory studies to decompensated with ascites, SBP, HE, or variceal bleeding.[15]

The approach to a patient with suspected liver disease begins with a thorough history and physical examination. Some presenting characteristics of patients with cirrhosis include anorexia, weight loss, weakness, fatigue, jaundice, pruritus, GI bleeding, coagulopathy, increasing abdominal girth with shifting flank dullness, mental status changes, and vascular spiders. Osteoporosis, as a result of vitamin D malabsorption and resultant calcium deficiency, can also occur.

A thorough history including risk factors that predispose patients to cirrhosis should be taken. Quantity and duration of alcohol intake should be determined. Risk factors for hepatitis B and C transmission should be inquired about. These include birthplace in endemic areas, sexual history, intranasal or IV drug use, body piercing or tattooing, and accidental contamination of body tissues or blood. Information concerning any history of transfusions, as well as any personal history of autoimmune or hepatic diseases, should be gathered. A family history should also be taken, looking especially for any family member with a prior history of autoimmune or hepatic diseases.

Laboratory Abnormalities

There are no laboratory or radiographic tests of hepatic function that can accurately diagnose cirrhosis. Despite this, liver function tests, a complete blood count with platelets, and a PT test should be performed if liver disease is suspected. Tests that measure the level of serum liver enzymes are usually referred to as liver function tests.[16] However, these tests actually reflect hepatocyte integrity or cholestasis, not liver function.

Routine liver tests include alkaline phosphatase, bilirubin, AST, ALT, and GGT. Additional markers of hepatic synthetic activity include albumin and PT. Liver function tests are often the first step in the evaluation of patients who present with symptoms or signs suggestive of cirrhosis.[15] The use of liver function tests in the diagnosis and management of cirrhosis is discussed in the following sections. It may be useful to group the tests into two broad categories: (1) markers of hepatocyte integrity such as the transaminases and (2) markers of liver function mass such as PT and albumin.[16]

Aminotransferases

The aminotransferases, AST and ALT, are enzymes that are highly concentrated in the liver. Liver injury, whether acute or chronic, results, at some point in the course of the disease, in increases in the serum concentrations of the aminotransferase enzymes. The degree of elevation, rate of rise, and nature of the course of alteration in aminotransferase serum levels are helpful in suggesting possible

etiologies. Liver function tests will typically be elevated to the highest levels in acute viral, ischemic, or toxic liver injury. Chronic hepatitis and cirrhosis patients may present with elevated aminotransferase levels, but they may also present with aminotransferase levels within the normal reference range. The degree of aminotransferase level elevation is dependent on the course of the hepatic injury being experienced by the patients and also depends on when the enzyme levels are tested. In a landmark study by Cohen and Kaplan, alcoholic liver disease resulted in AST elevations of only six to seven times the upper limit of normal in 98% of patients.[17] The ratio of AST to ALT also provides information in patients with suspected alcoholic liver disease. Seventy percent of patients with alcoholic liver disease in the study by Cohen and Kaplan had ratios greater than 2, whereas 92% of patients had ratios greater than 1.

Alkaline Phosphatase and γ-Glutamyl Transpeptidase

Elevated serum levels of alkaline phosphatase and GGT occur in cases of liver injury with a cholestatic pattern and therefore accompany conditions such as primary biliary cirrhosis, primary sclerosing cholangitis, drug-induced cholestasis, bile duct obstruction, autoimmune cholestatic liver disease, and metastatic cancer of the liver.[16] Neither alkaline phosphatase nor GGT is found solely in the liver, and elevations in either of these biomarkers can occur in a variety of disease states affecting other bodily tissues. However, the combination of an elevation in alkaline phosphatase level with a concomitant elevation in GGT level increases clinical suspicion of hepatic etiology.

Child-Pugh Classification and Model for End-Stage Liver Disease Score

The Child-Pugh classification system has gained widespread acceptance as a means of quantifying the myriad effects of the cirrhotic process on the laboratory and clinical manifestations of this disease.[18] Recommended drug dosing adjustments for patients in liver failure, when available, are normally based on the Child-Pugh score. The newer MELD scoring system is now the accepted classification scheme used by the United Network for Organ Sharing in the allocation livers for transplantation.[19] The Child-Pugh classification system employs a combination of physical and laboratory findings (**Table 37-2**), whereas the MELD score calculation takes into account a patient's serum creatinine, bilirubin, INR, and etiology of liver disease, omitting the more subjective reports of ascites and encephalopathy used in the Child-Pugh system.

TABLE 37-2 Criteria and Scoring for the Child–Pugh Grading of Chronic Liver Disease

Score	1	2	3
Total bilirubin (mg/dL)	<2 (<34.2 µmol/L)	2-3 (34.2-51.3 µmol/L)	>3 (>51.3 µmol/L)
Albumin (g/dL)	>3.5 (>35 g/L)	2.8-3.5 (28-35 g/L)	<2.8 (<28 g/L)
Ascites	None	Mild	Moderate
Encephalopathy (grade)	None	1 and 2	3 and 4
Prothrombin time (seconds prolonged)	<4	4-6	>6

Grade A, <7 points; grade B, 7-9 points; grade C, 10-15 points.

Data from reference 18.

The MELD scoring calculation* is as follows:[20]

$$\text{MELD score} = 0.957 \times \log_e(\text{creatinine [mg/dL]}) + 0.378 \times \log_e(\text{bilirubin [mg/dL]}) + 1.120 \times \log_e(\text{INR}) + 0.643$$

or using SI units:*

$$\text{MELD score} = 0.957 \times \log_e(\text{creatinine [}\mu\text{mol/L]} \times 0.01131) + 0.378 \times \log_e(\text{bilirubin [}\mu\text{mol/L]} \times 0.05848) + 1.120 \times \log_e(\text{INR}) + 0.643$$

These classification systems are important because they are used to assess and define the severity of the cirrhosis, and as a predictor for patient survival, surgical outcome, and risk of variceal bleeding.

*Multiply the score by 10 and round to the nearest whole number. (Laboratory values <1 are rounded up to 1 for the purposes of the MELD calculation.)

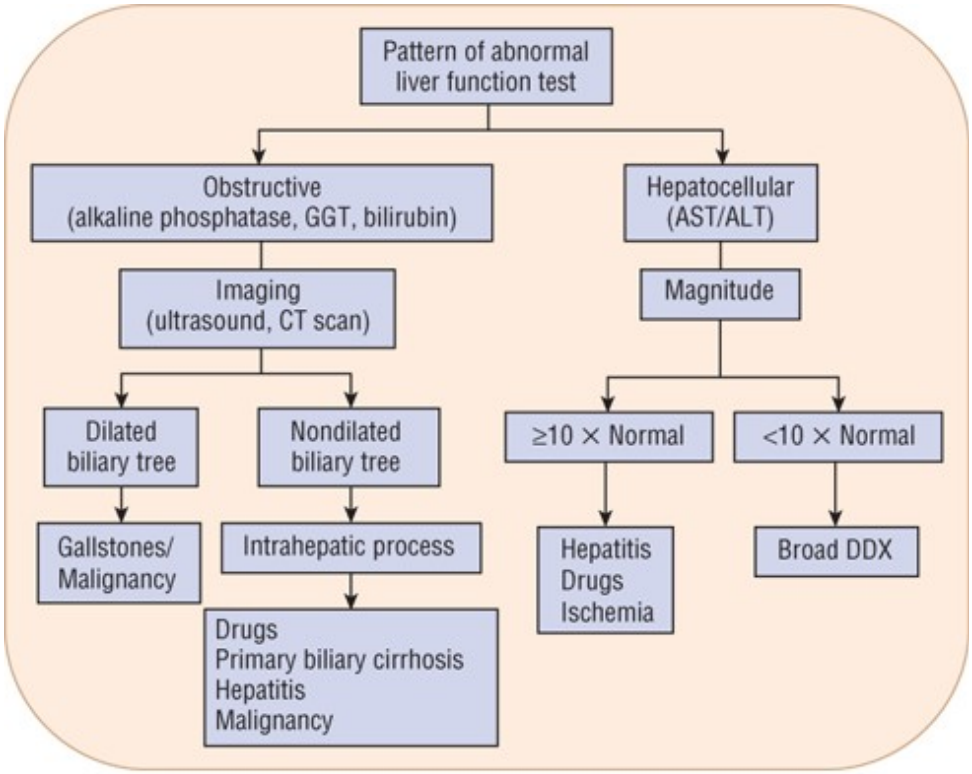
Bilirubin

Bilirubin is the product of the breakdown of hemoglobin molecules in the reticuloendothelial system.[16] Elevations in serum conjugated bilirubin indicate that the liver has lost at least half of its excretory capacity and are usually a sign of liver disease. When found in conjunction with markedly elevated AST and ALT, conjugated hyperbilirubinemia indicates the possible presence of acute viral hepatitis, autoimmune hepatitis, toxic liver injury, or ischemic liver injury. Elevated conjugated bilirubin levels with concomitant increases in alkaline phosphatase and normal aminotransferase levels are a sign of cholestatic disease and possible cholestatic drug reactions. Causes of elevations in unconjugated bilirubin include hemolysis, Gilbert's syndrome, hematoma reabsorption, and ineffective erythropoiesis. Causes of conjugated hyperbilirubinemia include bile duct obstruction, hepatitis, cirrhosis, primary sclerosing cholangitis, primary biliary cirrhosis, total parenteral nutrition, drug toxins, and vanishing bile duct syndrome. When cirrhosis has been established, the degree of bilirubin elevation has prognostic significance and is used as a component of the Child-Pugh and MELD scoring systems for quantifying the degree of cirrhosis.[18,20]

Figure 37-4 describes a general algorithm for the interpretation of liver function tests. The algorithm first separates the tests into two categories based on the underlying pathology (pattern of elevations): obstructive (alkaline phosphatase, GGT, and bilirubin) versus hepatocellular (AST and ALT). If a hepatocellular pattern predominates, the magnitude of elevation provides diagnostic assistance. If the degree of elevation is greater than 10 times normal, the etiology is likely a result of drugs or other toxins, ischemia, or acute viral hepatitis.[16] Elevations less than 10 times normal have a broad differential. Unfortunately, most liver enzyme abnormalities will fall into a mixed pattern providing limited diagnostic assistance.

FIGURE 37-4

Interpretation of liver function tests. (DDX, differential diagnosis)



Albumin and Coagulation Factors

Albumin and coagulation proteins are markers of hepatic synthetic activity and are therefore used to estimate the level of hepatic functioning in cirrhosis. Albumin and PT are used in the Child-Pugh system for quantifying liver disease, and the INR is used in the MELD scoring system as a marker of coagulation.[18,20] Albumin levels can be affected by a number of factors, including malnutrition, malabsorption, and protein losses from renal and intestinal sources.[16]

Thrombocytopenia

Thrombocytopenia is a common feature of chronic liver disease.[14] A platelet count below 160,000 per mm^3 (160×10^9/L) is indicative of cirrhosis in patients with hepatitis C with a sensitivity of 80%.[15] When liver abnormality is suspected, a complete blood cell count with platelets should be evaluated. Platelet count should also be evaluated prior to liver biopsy.

Endoscopic and Radiographic Abnormalities

While no radiographic test is considered a diagnostic standard for cirrhosis, radiographic studies may be used to detect ascites, hepatosplenomegaly, hepatic or portal vein thromboses, and hepatocellular carcinoma. Ultrasonography, because it does not require radiation exposure or IV contrast and is relatively low cost, should be the first radiographic study in the evaluation of a patient

with suspected cirrhosis. Hepatic nodularity, irregularity, increased echogenicity, and atrophy are all ultrasonographic findings indicative of cirrhosis. Ascites may also be detected on ultrasound. Computed tomography and magnetic resonance imaging can demonstrate liver nodularity as well as atrophic and hypertrophic changes. Ascites and varices may also be detected on computed tomography or magnetic resonance imaging scans. Portal vein patency can be assessed by computer tomography imaging.

Liver Biopsy

Liver biopsy should be considered after a thorough noninvasive workup has failed to confirm a diagnosis in suspected cirrhosis. Liver biopsy has a sensitivity and specificity of 80% to 100% for an accurate diagnosis of cirrhosis and its etiology. The success of biopsy as a diagnostic tool is dependent on the number of histologic samples retrieved as well as the sampling method used.

TREATMENT

General Approaches to Treatment

General approaches to therapy in cirrhosis should include the following:

1. Identify and eliminate, where possible, the causes of cirrhosis (eg, alcohol abuse).
2. Assess the risk for variceal bleeding and begin pharmacologic prophylaxis when indicated. Prophylactic endoscopic therapy can be used for patients with high-risk medium and large varices as well as in patients with contraindications or intolerance to nonselective β-adrenergic blockers. Endoscopic therapy is also appropriate for patients suffering acute bleeding episodes. Variceal obliteration with endoscopic techniques in conjunction with pharmacologic intervention is the recommended treatment of choice in patients with acute bleeding.
3. Evaluate the patient for clinical signs of ascites and manage with pharmacologic therapy (eg, diuretics) and paracentesis. Careful monitoring for SBP should be used in patients with ascites who undergo acute deterioration.
4. HE is a common complication of cirrhosis and requires clinical vigilance and treatment with dietary restriction, elimination of precipitating factors, and therapy to lower ammonia levels.
5. Frequent monitoring for signs of hepatorenal syndrome, pulmonary insufficiency, and endocrine dysfunction is necessary.

Desired Outcomes

The desired therapeutic outcomes can be viewed in two categories: *resolution of acute complications* such as tamponade of bleeding and resolution of hemodynamic instability for an episode of acute variceal hemorrhage and *prevention of complications* through lowering of portal pressure with medical therapy using non-selective β-adrenergic blocker therapy or supporting abstinence from alcohol. Treatment end points and desired therapeutic outcomes are presented for each of the

recommended therapies discussed.

Management of Portal Hypertension and Variceal Bleeding

The management of varices involves three strategies: (a) primary prophylaxis (prevention of the first bleeding episode); (b) treatment of acute variceal hemorrhage; and (c) secondary prophylaxis (prevention of rebleeding in patients who have previously bled).[11]

Primary Prophylaxis

***β*-Adrenergic Blockade** The mainstay of primary prophylaxis is the use of nonselective *β*-adrenergic blocking agents such as propranolol, nadolol, or carvedilol.[10,11,21] These agents reduce portal pressure by reducing portal venous inflow via two mechanisms: a decrease in cardiac output through β_1-adrenergic blockade and a decrease in splanchnic blood flow through β_2-adrenergic blockade.[10]

Endoscopic Variceal Ligation (EVL) EVL is an endoscopic therapy that consists of placing rubber bands around varices until the varices are obliterated.[21]

Treatment Recommendations: Variceal Bleeding—Primary Prophylaxis

2 All patients with cirrhosis should be screened for varices on diagnosis.[10,11,21] Transient elastography that shows liver stiffness below 20 kPa in patients with platelets over 150,000/mm^3 (150 × 10^9/L) do not require screening endoscopy.[10] Others should undergo screening endoscopy to identify and evaluate varices. *β*-Adrenergic blocker therapy is not indicated in patients without varices to prevent the formation of varices.[10,11,21] Patients with small varices plus risk factors for variceal hemorrhage including red wale marks or Child-Pugh grade C should receive prophylaxis therapy with a nonselective *β*-adrenergic blocker. *β*-Adrenergic blocker therapy is recommended preferentially to EVL in this situation due to the technical difficulty of EVL in the treatment of small varices. *β*-Adrenergic blocker therapy is not recommended for patients with small varices in the absence of risk factors as there is insufficient evidence to support this therapy to slow the growth of varices in this scenario. All patients found to have medium to large varices that have not bled should receive primary prophylaxis therapy with a nonselective *β*-adrenergic blocker or EVL. The choice of treatment should be based on a consideration of resources and expertise as well as patient preferences and characteristics with a particular emphasis on side effects and contraindications.[11] If *β*-adrenergic blocker therapy is chosen, initiate therapy with oral propranolol 20 mg twice daily, nadolol 20 to 40 mg once daily, or carvedilol 6.25 mg daily and titrate every 2 to 3 days to maximal tolerated dose to heart rates of 55 to 60 beats/min.[10,21,22] Once a patient is started on nonselective *β*-adrenergic blocker therapy, it should be continued indefinitely or until the occurrence of end-stage liver disease when the risks may outweigh the benefits.[11] Following initiation and appropriate titration of the *β*-adrenergic blocker, further endoscopic surveillance is not needed.[10,21,23] If EVL is chosen, it will be performed every 1 to 2 weeks until the obliteration of varices.[21] Follow-up surveillance will occur at 1 to 3 months and again every 6 to 12 months thereafter.

Patients with contraindications to therapy with nonselective β-adrenergic blockers (ie, those with asthma, insulin-dependent diabetes with episodes of hypoglycemia, and peripheral vascular disease) or intolerance to β-adrenergic blockers should be considered for alternative prophylactic therapy with EVL.[23] Also, EVL may be considered as a possible first option for primary prophylaxis in patients with high-risk medium to large varices. Nitrates are no longer recommended as alternative therapy for primary prophylaxis against variceal bleeding in patients with intolerance to nonselective β-adrenergic blocker due to a potential for higher mortality with this therapy.[21] At this time, there is also insufficient evidence to support the use of other therapies and procedures (such as combination nonselective β-adrenergic blocker therapy with isosorbide mononitrate, combination nonselective β-adrenergic blocker therapy with spironolactone, combination nonselective β-adrenergic blocker therapy with EVL, shunt surgery, and endoscopic sclerotherapy) for primary prevention of variceal hemorrhage.

Acute Variceal Hemorrhage

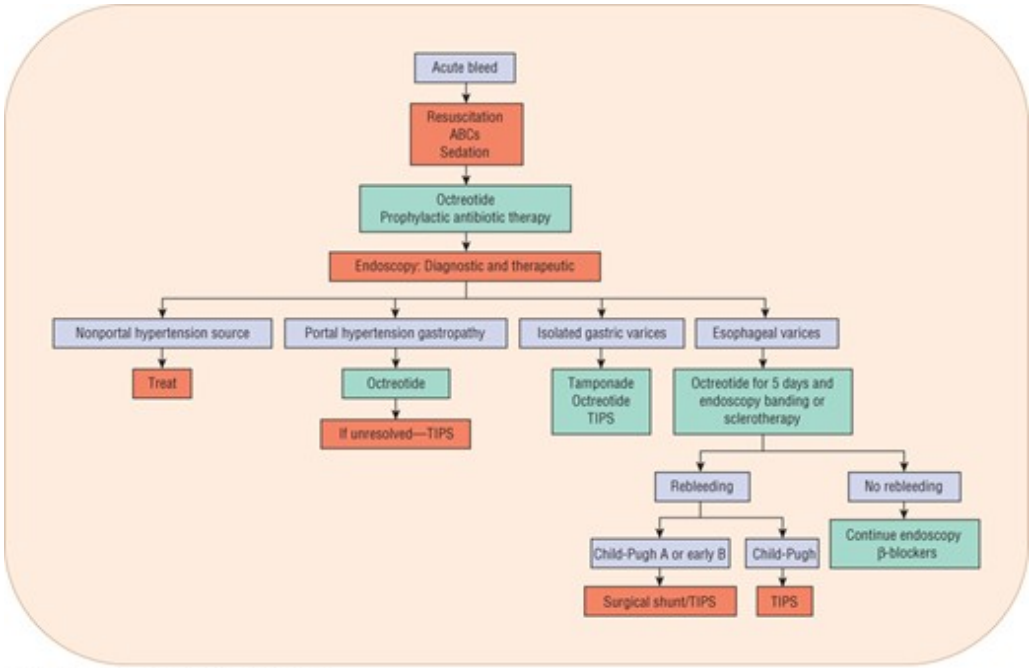
Variceal hemorrhage is a medical emergency that carries a mortality rate of 15% to 20%, requires admission to an intensive care unit, and is one of the most feared complications of cirrhosis.[10,21] Treatment of acute variceal bleeding includes general stabilizing and assessment measures as well as specific measures to control the acute hemorrhage and prevent complications.

Initial treatment goals include (a) adequate blood volume resuscitation, (b) protection of airway from aspiration of blood, (c) correction of significant coagulopathy and/or thrombocytopenia with fresh-frozen plasma and platelets, (d) prophylaxis against SBP and other infections, (e) control of bleeding, (f) prevention of rebleeding, and (g) preservation of liver function.[23] Prompt stabilization of blood volume with a goal of maintaining hemodynamic stability and a hemoglobin of 8 g/dL (80 g/L; 4.97 mmol/L) should be undertaken. Volume should be expanded to maintain a systolic blood pressure of 90 to 100 mm Hg and a heart rate of less than 100 beats/min, but vigorous resuscitation with saline solution should generally be avoided because this may lead to recurrent variceal hemorrhage or accumulation of ascites and/or fluid at other anatomic sites.[21,23] Use of recombinant factor VIIa therapy is not recommended in cirrhotic patients with GI hemorrhage at this time. Airway management is critical in patients with variceal hemorrhage, especially those with concomitant HE or severe bleeding.[23] Elective or more emergent intubation may be required prior to diagnostic endoscopy. Combination pharmacologic therapy plus endoscopic therapy with preferably EVL, or sclerotherapy if EVL is not technically feasible, is considered the most rational approach to the treatment of acute variceal bleeding.[10,21]

Vasoactive drug therapy (usually octreotide) is routinely used early to stop or slow bleeding for patient management as soon as a diagnosis of variceal bleeding is suspected, and potentially even before endoscopy. Antibiotic therapy to prevent SBP and other infections, as well as to prevent rebleeding and decrease mortality, should be implemented. **Figure 37-5** presents an algorithm for the management of variceal hemorrhage.

FIGURE 37-5

Management of acute variceal hemorrhage. TIPS, transjugular intrahepatic portosystemic shunt.



Drugs employed to manage acute variceal bleeding in the United States include (a) the somatostatin analogue octreotide and (b) vasopressin. These agents work as splanchnic vasoconstrictors, thus decreasing portal blood flow and pressure.[21] Agents available in other countries also include terlipressin, which is an analogue of vasopressin, and another somatostatin analogue, vapreotide.

Somatostatin and Octreotide

Somatostatin is a naturally occurring tetradecapeptide hormone, and octreotide is a synthetic octapeptide that shares a four amino acid segment with somatostatin and has similar pharmacologic activity with greater potency and longer duration of action as compared with somatostatin.[24] Somatostatin and octreotide cause a reduction in portal pressure and port-collateral blood flow through inducing splanchnic vasoconstriction without causing the systemic effects associated with vasopressin.[23,24] The splanchnic vasoconstriction found with somatostatin and octreotide therapy is due to inhibition of the release of vasodilatory peptides such as glucagon; however, octreotide has a local vasoconstrictive effect confined to the splanchnic vasculature.[23] Somatostatin and somatostatin analogues are associated with fewer side effects as compared with vasopressin. The side effects of somatostatin therapy may include sinus bradycardia, hypertension, arrhythmia, and abdominal pain.[10] The recommended dosing of octreotide for variceal bleeding consists of an initial IV bolus of 50 mcg followed by a continuous IV infusion of 50 mcg/h. Because octreotide is safe for continuation for multiple days and because around half of early recurrent bleeding occurs within the first 3 to 5 days, guidelines suggest continuation of octreotide for 5 days after acute variceal bleeding.[11,21]

Vasopressin

Vasopressin (also known as antidiuretic hormone) is a potent, nonselective vasoconstrictor that reduces portal pressure by causing splanchnic vasoconstriction, which reduces splanchnic blood flow.[24] Unfortunately, the vasoconstrictive effects of vasopressin are nonselective—the vasoconstriction is not restricted to the splanchnic vascular bed. Potent systemic vasoconstriction induces peripheral resistance, which reduces cardiac output, heart rate, and coronary blood flow. These effects on cardiac hemodynamics can lead to myocardial ischemia or infarction, arrhythmias, mesenteric ischemia, ischemia of the limbs, and cerebrovascular accidents. A meta-analysis comparing vasopressin and somatostatin in the management of acute esophageal variceal hemorrhage found somatostatin more efficacious for controlling acute hemorrhage from esophageal varices with significantly less adverse effects.[25] Only four patients must be treated with somatostatin over vasopressin for one to derive additional benefit in terms of initial control of bleeding, and only nine patients need to be treated with somatostatin instead of vasopressin in order for one to experience benefit in terms of avoidance of rebleeding. Although somatostatin is not available in the United States today, its analogue octreotide is commonly used instead of vasopressin for acute variceal hemorrhage.

A recommended dosing strategy for vasopressin is a continuous IV infusion of 0.2 to 0.4 units/min, which can be increased to a maximal dose of 0.8 units/min.[23] Vasopressin should only be used at the highest effective dose continuously for a maximum of 24 hours and should always be administered with IV nitroglycerin at a starting dose of 40 mcg/min (which can be increased to a maximum of 400 mcg/min and adjusted to maintain systolic blood pressure over 90 mm Hg) in order to minimize the risk of serious adverse events. With the addition of safer and equally effective treatment alternatives, vasopressin, alone or combined with nitroglycerin, can no longer be recommended as first-line therapy for the management of variceal hemorrhage.[10,23] Terlipressin, a synthetic analogue of vasopressin, has fewer side effects and a longer duration of action than vasopressin. It reduces mortality in acute variceal hemorrhage, but is not currently available in the United States.[10]

Cirrhotic patients with active bleeding are at high risk of severe bacterial infections such as SBP.[23] Short-term prophylactic antibiotic therapy to reduce the risk of infection during episodes of bleeding not only reduces the likelihood of development of SBP and other infections but also reduces the incidence of rebleeding and increases short-term survival.[21] Prophylactic antibiotic therapy should be prescribed for all patients with cirrhosis and acute variceal bleeding.[23] A short course (7 days maximum) of oral norfloxacin 400 mg twice daily or IV ciprofloxacin when the oral route is not available is recommended. Alternatively, in patients with severe cirrhosis in areas with high quinolone resistance, IV ceftriaxone 1 g/day may be preferable.[11]

Endoscopic Interventions: Sclerotherapy and Band Ligation

The Baveno VI Consensus Report recommends that endoscopy be performed as soon as possible following admission in cases of upper GI bleeding.[11] Endoscopy is used to diagnose variceal bleeding, and endoscopic techniques, such as EVL and sclerotherapy, can be used in an attempt to stop variceal bleeding. EVL consists of placement of rubber bands around the varix through a clear plastic channel attached to the end of the endoscope.[21] EVL can be repeated if hemorrhage is not

controlled or in the event of early recurrence of bleeding. Endoscopic sclerotherapy involves injection of 1 to 4 mL of a sclerosing agent into the lumen of the varices to tamponade blood flow. EVL is more effective than sclerotherapy with greater control of hemorrhage, less risk for rebleeding, lower likelihood of adverse events, and lower mortality.[10] Therefore, consensus recommendation calls for EVL (in conjunction with pharmacologic therapy) as the recommended form of endoscopic therapy for acute variceal bleeding.[11] Endoscopic injection of the tissue adhesive *N*-butyl cyanoacrylate is recommended to control acute *gastric* variceal bleeding from isolated gastric varices and gastroesophageal varices type 2 that extend beyond the cardia. EVL or tissue adhesive can be used for bleeding from gastroesophageal varices type 1. A pre-endoscopy infusion of erythromycin 250 mg IV, 30 to 120 minutes prior to the procedure, is recommended in the absence of QT interval prolongation.

Interventional and Surgical Treatment Approaches

Standard therapy fails to control initial bleeding or early rebleeding in 10% to 20% of patients with acute variceal hemorrhage.[21] In these cases, a salvage procedure, such as balloon tamponade or transjugular intrahepatic portosystemic shunt (TIPS), is necessary. Balloon tamponade is effective in controlling variceal bleeding temporarily; however, rebleeding is common after balloon deflation, and complications result in mortality rates of up to 20% with balloon tamponade. Sengstaken-Blakemore tubes are recommended for use in esophageal variceal bleeding. Linton tubes are preferred for bleeding from fundal gastric varices. Balloon tamponade should be reserved as a temporizing measure until a more definitive treatment, such as TIPS, can be performed.

The TIPS procedure involves the placement of one or more stents between the hepatic vein and the portal vein (**Fig. 37-6**). TIPS (preferably with polytetrafluoroethylene-covered stents) is recommended for patients who fail to achieve hemostasis despite combined endoscopic and pharmacologic therapy.[11] TIPS provides an effective decompressive shunt without laparotomy and can be employed regardless of Child-Pugh score, unlike shunt surgery, which is restricted to Child-Pugh grade A patients.[23] TIPS decreases the incidence of variceal rebleeding and decreases the incidence of deaths due to rebleeding.[26] There is a significantly increased rate of posttreatment encephalopathy found in TIPS-treated patients.

Treatment Recommendations: Variceal Hemorrhage

Patients require cautious resuscitation with colloids and blood products to correct intravascular losses and to reverse existing coagulopathies.[10,11,21,23] 4 Drug therapy with octreotide should be initiated early to control bleeding and facilitate diagnostic and therapeutic endoscopy. Therapy is initiated with an IV bolus of 50 mcg and is followed by a continuous infusion of 50 mcg/h for 3 to 5 days.[21,23] Monitor patients for bradycardia, hypertension, arrhythmia, and abdominal pain.[10] Endoscopy is recommended in any patient with suspected upper GI bleeding due to ruptured varices.[10,11,21,23] EVL is the recommended form of endoscopic therapy, but endoscopic sclerotherapy may be employed if EVL is technically difficult. An additional endoscopic therapy option is injection of the tissue adhesive *N*-butyl cyanoacrylate for gastric varices.[11] Short-term antibiotic prophylaxis (maximum 7 days) is recommended.[11,23] Appropriate choices include norfloxacin 400 mg twice daily or IV ciprofloxacin if the oral route is unavailable.[5,23] In patients with advanced cirrhosis in areas of high quinolone resistance, IV ceftriaxone 1 g daily may be preferred. Surgical shunts and TIPS are employed as salvage therapy in patients who have failed repeated endoscopy and vasoactive drug therapy.[11]

Secondary Prophylaxis

Because rebleeding after initial control of variceal hemorrhage occurs in a median of 60% of patients and because rebleeding carries a mortality rate of 33%, it is inappropriate to simply observe patients for evidence of further bleeding.[10,23] Only patients who underwent shunt surgery or TIPS to control their initial acute bleeding require no further intervention as secondary prophylaxis. Patients who underwent one of these procedures to treat their initial bleeding should be referred for transplantation if they are a candidate. Candidates include those with a Child-Pugh score greater

than or equal to 7 or MELD score greater than or equal to 15.[23] Combination therapy with β-adrenergic blockers and chronic EVL to eradicate varices is the best treatment option for secondary prophylaxis of variceal bleeding.[10,11,21,23] Secondary prophylaxis should be started once vasoactive drug therapy is discontinued and as soon as possible (as early as day 6) following the acute bleeding event.[10]

Clinical Controversy...

While carvedilol is now an accepted alternative β-adrenergic blocker for primary prophylaxis against variceal bleeding in patients with portal hypertension, it is not recommended for secondary prophylaxis against variceal bleeding in patients with a history of prior bleed.[11] Propranolol or nadolol should be chosen as the non-selective β-adrenergic blocker therapy in secondary prophylaxis since carvedilol has not been adequately studied in comparison to the current standard of care in this population.

Drug Therapy

The combination of EVL and a nonselective β-adrenergic blocking agent provides the most rational approach for secondary prophylaxis because nonselective β-adrenergic blocking agents can protect against variceal rebleeding before variceal obliteration can be accomplished through EVL, and β-adrenergic blocking agents will also delay variceal recurrence.[21,23] The addition of isosorbide mononitrate to nonselective β-adrenergic blocker therapy reduces portal pressure more than β-adrenergic blocker alone, but there is no difference in the overall rate of rebleeding with this combination and side effects are more likely than with β-adrenergic blocker monotherapy (namely, headache and light-headedness).[27] Pharmacologic therapy (either isosorbide mononitrate plus nonselective β-adrenergic blocker therapy or β-adrenergic blocker therapy alone) plus EVL is associated with lower rebleeding rates than either pharmacologic or EVL therapy alone.[28,29]

The lowest rate of variceal rebleeding occurs in patients when pharmacologic therapy leads to a reduction in HVPG of at least 10% of baseline or to a measurement less than or equal to 12 mm Hg (1.6 kPa).[11] Ideally, portal pressure monitoring would be used to assess the response to nonselective β-adrenergic blocker therapy and identify responders from nonresponders earlier in the treatment course. Nonselective β-blocker therapy should be utilized regardless of the possibility of HVPG monitoring.

Treatment Recommendations: Variceal Bleeding—Secondary Prophylaxis

The combination of EVL plus pharmacologic therapy to prevent rebleeding is currently considered the most rational therapeutic approach.[21,23] Pharmacologic therapy should be initiated with a nonselective β-blocker such as propranolol 20 mg twice daily or nadolol at a dose of 20 to 40 mg once daily.[21] 3 β-Blocker therapy can be titrated to achieve a goal heart rate of 55 to 60 beats/min or the maximal tolerated dose. Monitor patients for evidence of heart failure, bronchospasm, and glucose intolerance, particularly hypoglycemia in patients with insulin-dependent diabetes. EVL should be conducted every 1 to 2 weeks until variceal obliteration, and then the patient should be

followed by surveillance endoscopy in 1 to 3 months and then every 6 to 12 months. Patients who cannot tolerate or who fail pharmacologic and endoscopic interventions can be considered for TIPS or surgical shunting to prevent bleeding.[11] A summary of evidence-based treatment recommendations regarding portal hypertension and variceal bleeding is found in **Table 37-3**.

TABLE 37-3 Evidence-Based Table of Selected Treatment Recommendations: Variceal Bleeding in Portal Hypertension

Recommendation	Grade
Prevention of variceal bleeding	
Nonselective β-blocker therapy should be initiated in:	
Patients with small varices and criteria for increased risk of hemorrhage	IIaC
Patients with medium/large varices without high risk of hemorrhage	IA
Endoscopic variceal ligation (EVL) should be offered to patients who have contraindications or intolerance to nonselective β-blockers	IA
EVL may be recommended for prevention in patients with medium/large varices at high risk of hemorrhage instead of nonselective β-blocker therapy	IA
Treatment of variceal bleeding	
Short-term antibiotic prophylaxis should be instituted on admission	IA
Vasoactive drugs should be started as soon as possible, prior to endoscopy, and maintained for 3-5 days	IA
Endoscopy should be performed within 12 hours to diagnose variceal bleeding and treat bleeding with either sclerotherapy or EVL	IA
Secondary prophylaxis of variceal bleeding	
Nonselective β-blocker therapy plus EVL is the best therapeutic option for prevention of recurrent variceal bleeding	IA

Recommendation grading:

- Class I—Conditions for which there is evidence and/or general agreement
- Class II—Conditions for which there is conflicting evidence and/or a divergence of opinion
- Class IIa—Weight of evidence/opinion is in favor of efficacy
- Class IIb—Efficacy less well established
- Class III—Conditions for which there is evidence and/or general agreement that treatment is not effective and/or potentially harmful
- Level A—Data from multiple randomized trials or meta-analyses
- Level B—Data derived from single randomized trial or nonrandomized studies
- Level C—Only consensus opinion, case studies, or standard of care

Data from reference 23.

Management of Ascites and Spontaneous Bacterial Peritonitis

Patients with cirrhosis experience overt fluid retention and ascites as liver disease progresses.[9] The classic physical examination findings of ascites are a bulging abdomen with shifting flank dullness.[5] The development of ascites in patients with cirrhosis is an indication of advanced liver disease and is a poor prognostic sign.[5,9] The principle therapeutic goals for patients with ascites are to control the ascites; to prevent or relieve ascites-related symptoms such as dyspnea, abdominal pain, and abdominal distention; and to prevent life-threatening complications such as SBP and the hepatorenal syndrome.[9] Treatment of ascites is expected to have little effect on survival, however.[21] Workup includes a history and physical examination, abdominal paracentesis and/or ultrasound, and ascitic fluid analysis.[5] The treatment of ascites is based on oral diuretics and is carried out in a slow, stepwise fashion.[21] Treatment of ascites should be initiated only in stable patients (eg, those without ongoing variceal hemorrhage, bacterial infection, or renal dysfunction).

Spontaneous bacterial peritonitis is an infection of ascitic fluid that occurs in the absence of any evidence of an intraabdominal, surgically treatable source of infection.[5] It is a common complication that develops in 10% to 20% of patients hospitalized with severe liver disease, cirrhosis, and ascites.[21] The key mechanism behind the development of SBP is thought to be bacterial translocation.[30] Decreased motility of the GI tract with disturbances of the gut flora, changes in the structure of the GI tract, and reduced local and humoral immunity combine to lead to the free flow of microorganisms and endotoxins to the mesenteric lymph nodes. Most episodes of SBP are caused by *Escherichia coli*, *Klebsiella pneumonia*, and pneumococci.[5] Symptoms and signs of SBP include fever, abdominal pain, abdominal tenderness, rebound, encephalopathy, renal failure, acidosis, peripheral leukocytosis, and altered mental status.[5,30] Paralytic ileus, hypotension, and hypothermia are poor prognostic indicators.[30] Thirteen percent of patients with SBP present with no symptoms. For this reason, a diagnostic paracentesis with analysis of ascitic fluid should be performed in all patients admitted with ascites.[5] SBP is diagnosed when there is possible ascitic fluid bacterial culture and ascitic fluid cell counts show an absolute polymorphonuclear (PMN) leukocyte count of greater than or equal to 250 cells/mm^3 (0.25×10^9/L).

The following treatment guidelines for the management of adult patients with ascites and SBP were updated and approved by the Practice Guidelines Committee of the American Association for the Study of Liver Diseases (AASLD).

Ascites

In adult patients with new-onset ascites as determined by physical examination or radiographic studies, abdominal paracentesis should be performed, and ascitic fluid analysis should include a cell count with differential, ascitic fluid total protein, and a serum-ascites albumin gradient (SAAG). If infection is suspected, ascitic fluid cultures should be obtained at the time of the paracentesis. The SAAG can accurately determine whether ascites is a result of portal hypertension or another process.

If the SAAG is greater than or equal to 1.1 g/dL (11 g/L), the patient almost certainly has portal hypertension. The treatment of ascites secondary to portal hypertension is relatively straightforward and includes abstinence from alcohol, sodium restriction, and diuretics.

1 Abstinence from alcohol is an essential element of the overall treatment strategy. Abstinence from alcohol can result in improvement of the reversible component of alcoholic liver disease, resolution of ascites, or improved responsiveness of ascites to medical therapy. Patients with cirrhosis not caused by alcohol have less reversible liver disease, and, by the time ascites is present, these patients may be best managed with liver transplantation rather than protracted medical therapy.

Beyond avoidance of alcohol, the primary treatment of ascites due to portal hypertension and cirrhosis is salt restriction and oral diuretic therapy. Fluid loss and weight change depend directly on sodium balance in these patients. A goal of therapy is to increase urinary excretion of sodium to greater than 78 mmol/day. Evaluation of urinary sodium excretion, preferably utilizing a 24-hour urine[5] collection, may be helpful, although this collection can be difficult. A random spot urine sodium concentration that is greater than the potassium concentration correlates very well with a 24-hour urinary sodium excretion over 78 mmol/day and is an easier test to complete. Severe hyponatremia, defined as serum sodium less than a threshold of 120 to 125 mEq/L (mmol/L), does warrant fluid restriction.[5] However, hyponatremia of this severity is rare among patients with cirrhosis and ascites and, for this reason, rarely requires specific treatment.

Diuretic Therapy

The AASLD practice guidelines recommend that diuretic therapy be initiated with the combination of spironolactone and furosemide or spironolactone alone.[5] Due to the likelihood for development of drug-induced hyperkalemia with spironolactone when used as monotherapy, it is best to use spironolactone as a lone diuretic agent only in patients with minimal fluid overload. Furosemide as lone diuretic therapy is inferior to spironolactone in the treatment of ascites and is not recommended. If tense ascites is present, paracentesis should be performed prior to institution of diuretic therapy and salt restriction. For patients who respond to diuretic therapy, this approach is preferred over the use of serial paracenteses. In patients with refractory ascites, serial paracenteses may be employed. Albumin infusion postparacentesis is reasonable for extraction volumes exceeding 5 L.[5] Laboratory tests for renal function and electrolytes need to be monitored during therapy. Referral for liver transplantation should be made in patients with refractory ascites. TIPS is a therapeutic modality for the treatment of refractory ascites that may be considered in appropriately selected patients. Peritoneovenous shunting may be considered in treatment refractory patients who are not candidates for paracenteses, transplant, or TIPS.

Clinical Controversy...

Patients with cirrhosis and ascites should avoid nonsteroidal anti-inflammatory drugs, angiotensin converting enzyme inhibitors, and angiotensin receptor blockers except under special circumstances.[5] Angiotensin converting enzyme inhibitors and angiotensin receptor blockers should not be used in patients with refractory ascites. While these therapies are not part of the standard therapies of the

complications of cirrhosis, non-selective β-adrenergic blocker therapy is indicated for primary and secondary prophylaxis against variceal bleeding in portal hypertension. Unfortunately, non-selective β-adrenergic blocker therapy can cause hypotension in patients with refractory ascites making the condition worse. For this reason, the risks versus benefits of non-selective β-adrenergic blocker therapy in refractory ascites must be carefully weighed and non-selective β-adrenergic blockers avoided or not started in this population unless the benefit of bleeding prophylaxis is considered to outweigh the risk of worsening ascites.

Spontaneous Bacterial Peritonitis

Relatively broad-spectrum antibiotic therapy that adequately covers the three most commonly encountered pathogens (*E. coli*, *K. pneumoniae*, and pneumococci) is warranted in patients with documented or suspected SBP.[5,21,30] Empiric therapy should not be delayed while awaiting culture results. In some patients, signs and symptoms of infection are present such as fever, abdominal pain, and unexplained encephalopathy at the bacterascites stage (ie, signs and symptoms are present before the PMN count in the ascitic fluid is elevated).[5] In these patients, signs and symptoms of infection justify empiric antibiotic therapy until culture results are known, regardless of the PMN count in the ascitic fluid.

Cefotaxime 2 g every 8 hours, or a similar third-generation cephalosporin, is considered the drug of choice for SBP. A 5-day course of antibiotic therapy is as efficacious as 10 days of therapy. Ofloxacin 400 mg every 12 hours administered orally for an average of 8 days is an alternative for patients without vomiting, shock, significant HE, or serum creatinine over 3 mg/dL (265 µmol/L). IV ciprofloxacin offers another potential treatment alternative. Patients with SBP who previously received quinolone therapy as prophylaxis should be treated with an alternative agent since patients who have received quinolone therapy may become infected with quinolone-resistant flora.

Secondary bacterial peritonitis, ascitic fluid infection caused by a surgically treatable intraabdominal source, can masquerade as SBP. Free perforation should be considered when multiple or atypical organisms are cultured, a very high ascitic fluid PMN count is seen, or at least two of the following are seen on ascitic fluid analysis: total protein greater than 1 g/dL (10 g/L), lactate dehydrogenase greater than the upper limit of normal for serum, and glucose less than 50 mg/dL (2.8 mmol/L). A 48-hour follow-up PMN count that rises above pretreatment levels despite antibiotic treatment is indicative of secondary nonperforation peritonitis. Patients with free perforation or nonperforation secondary peritonitis should receive a third-generation cephalosporin plus anaerobic coverage in addition to undergoing laparotomy.

Treatment Recommendations: Ascites and Spontaneous Bacterial Peritonitis

Adult patients admitted to the hospital with new-onset ascites should have an abdominal paracentesis performed to establish the SAAG, the ascitic fluid cell count and differential, and the ascitic fluid total protein. If ascitic fluid infection is suspected, ascitic fluid should be cultured at the bedside. 1 Patients who drink alcohol should be strongly discouraged from further alcohol use. 5 Sodium restriction to 2,000 mg/day, together with spironolactone and furosemide, is the mainstay of

therapy. Diuretic therapy should be initiated with single morning doses of spironolactone 100 mg and furosemide 40 mg administered orally. Titrate diuretic therapy every 3 to 5 days using the 100:40 mg dose ratio to attain adequate natriuresis and weight loss (reasonable daily weight loss goal is 0.5 kg).[5] Maximum daily doses are 400 mg spironolactone and 160 mg furosemide. This combination ratio is used because it usually maintains normokalemia. Fluid restriction, unless the serum sodium is less than 120 to 125 mEq/L (mmol/L), and bedrest are not recommended. Utilize the random spot urine test to confirm a sodium concentration that is greater than the potassium concentration as this correlates very well with a 24-hour urinary sodium excretion over the goal of 78 mmol/day. Monitor serum potassium and renal function frequently. Avoid rapid correction of asymptomatic hyponatremia in patients with cirrhosis. If tense ascites is present, paracentesis should be performed prior to institution of diuretic therapy and salt restriction. For patients who respond to diuretic therapy, this approach is preferred over the use of serial paracenteses. Discontinue diuretic therapy in patients who experience uncontrolled or recurrent encephalopathy, severe hyponatremia (serum sodium <120 mEq/L [mmol/L]) despite fluid restriction, or renal insufficiency (serum creatinine >2 mg/dL [177 µmol/L]). Serial paracenteses may be considered for patients with refractory ascites and albumin infusion of 6 to 8 g/L of fluid removed can be considered postparacentesis when paracentesis volumes exceed 5 L.

Patients with ascitic fluid PMN counts greater than or equal to 250 cells/mm^3 (0.25 × 10^9/L) should receive empiric antibiotic therapy with IV cefotaxime 2 g every 8 hours or a similar third-generation cephalosporin. Oral ofloxacin 400 mg twice daily may be an alternative option in patients without prior exposure to quinolones, vomiting, shock, severe encephalopathy, or serum creatinine over 3 mg/dL (265 µmol/L).[5] Patients with ascitic fluid PMN counts less than 250 cells/mm^3 (0.25 × 10^9/L) but with signs and symptoms of infection (symptoms such as abdominal pain, abdominal tenderness, and fever) should also receive empiric antibiotic treatment. Patients with ascitic fluid PMN counts greater than or equal to 250 cells/mm^3 (0.250 × 10^9/L) and suspicion of SBP should also receive 1.5 g of albumin per kilogram body weight within 6 hours of detection and 1 g of albumin per kilogram body weight on day 3 if they also have a serum creatinine over 1 mg/dL (88 µmol/L), blood urea nitrogen over 30 mg/dL (10.7 mmol/L), or total bilirubin over 4 mg/dL (68.4 µmol/L).

6 All patients who have survived an episode of SBP should receive long-term antibiotic prophylaxis with daily norfloxacin 400 mg or double strength trimethoprim–sulfamethoxazole.[5] Long-term prophylaxis should also be considered for the prevention of SBP in patients with low-protein ascites (<1.5 g/dL [15 g/L]) who also have one of the following: serum creatinine greater than or equal to 1.2 mg/dL (106 µmol/L), blood urea nitrogen greater than or equal to 25 mg/dL (8.9 mmol/L), serum sodium less than or equal to 130 mEq/L (mmol/L), or Child-Pugh score of greater than or equal to 9 with bilirubin greater than or equal to 3 mg/dL (51.3 µmol/L). Short-term prophylaxis (7 days) is indicated in patients with cirrhosis and GI hemorrhage. A summary of evidence-based treatment recommendations regarding ascites and SBP is found in **Table 37-4**.

TABLE 37-4 Evidence-Based Table of Selected Treatment Recommendations: Ascites and Spontaneous Bacterial Peritonitis

Recommendation	Grade

Recommendation	Grade
Ascites	
Paracentesis should be performed in patients with apparent new-onset ascites	IC
Sodium restriction of 2,000 mg/day should be instituted as well as oral diuretic therapy with spironolactone and furosemide	IIaA
Diuretic-sensitive patients should be treated with sodium restriction and diuretics rather than serial paracentesis	IIaC
Refractory ascites	
Serial therapeutic paracenteses may be performed	IC
Postparacentesis albumin infusion of 6-8 g/L of fluid removed can be considered if more than 5 L is removed during paracentesis	IIaA
Treatment of SBP	
If ascitic fluid PMN counts are >250 cells/mm^3 (0.25 × 10^9/L), empiric antibiotic therapy should be instituted (cefotaxime 2 g every 8 hours)	IA
If ascitic fluid PMN counts are <250 cells/mm^3 (0.25 × 10^9/L), but signs or symptoms of infection exist, empiric antibiotic therapy should be initiated while awaiting culture results	IB
Ofloxacin 400 mg twice daily may be substituted for cefotaxime in patients without vomiting, shock, grade II or higher encephalopathy, or serum creatinine >3 mg/dL (265 µmol/L) and if there is no prior exposure to quinolones	IIaB
If ascitic fluid polymorphonuclear leukocyte counts are >250 cells/mm^3 (0.25 × 10^9/L), clinical suspicion of SBP is present, and the patient has a serum creatinine >1 mg/dL (88 µmol/L), blood urea nitrogen >30 mg/dL (10.7 mmol/L), or total bilirubin over 4 mg/dL (68.4 µmol/L), 1.5 g/kg albumin should be infused within 6 hours of detection and 1 g/kg albumin infusion should also be given on day 3	IIaB
Prophylaxis against SBP	
Short-term antibiotic prophylaxis should be used for 7 days to prevent SBP in cirrhosis patients with GI hemorrhage	IA
Patients who survive an episode of SBP should receive long-term prophylaxis with either daily norfloxacin or trimethoprim–sulfamethoxazole	IA
Patients with low-protein ascites (<1.5 g/dL [15 g/L]) plus at least one of the following: serum creatinine ≥ 1.2 mg/dL (106 µmol/L), blood urea nitrogen ≥25 mg/dL (8.9 mmol/L), serum sodium ≤ 130 mEq/L (mmol/L), or Child–Pugh score of ≥ 9 with bilirubin ≥ 3 mg/dL (51.3 µmol/L) may also justifiably receive long-term norfloxacin or sulfamethoxazole/trimethoprim as prophylaxis	IA

Recommendation grading:

- Class I—Conditions for which there is evidence and/or general agreement
- Class II—Conditions for which there is conflicting evidence and/or a divergence of opinion

- Class IIa—Weight of evidence/opinion is in favor of efficacy
- Class IIb—Efficacy less well established
- Class III—Conditions for which there is evidence and/or general agreement that treatment is not effective and/or potentially harmful
- Level A—Data from multiple randomized trials or meta-analyses
- Level B—Data derived from single randomized trial or nonrandomized studies
- Level C—Only consensus opinion, case studies, or standard of care

Data from reference 5.

Management of Hepatic Encephalopathy

Hepatic encephalopathy will occur in 30% to 40% of patients with cirrhosis at some point during the course of their disease.[31] The clinical manifestations of HE vary widely from subclinical alterations to coma. In addition to classification based upon underlying disease, HE is also classified based on severity, time course, and the presence of precipitating factors. To determine the severity of HE, a grading system that relates neurologic and neuromuscular signs can be used (**Table 37-5**). Time course of HE is classified as episodic, persistent, or recurrent. Recurrent HE refers to HE episodes which occur in time intervals less than 6 months apart. Persistent HE refers to behavioral symptoms which are always present and periodically interspersed with episodes of overt HE relapses. A precipitating factor or factors such as constipation, infection, diuretic overuse, GI bleeding, or electrolyte abnormalities can be identified in most episodic cases of HE related to cirrhosis, but spontaneous episodic HE can occur as well. The general approach to the management of HE is four pronged and includes the following: care for patients with altered consciousness, identify and treat any other causes besides HE for altered mental status, identify and treat any precipitating factors, and begin empirical HE treatment. Treatment for HE is primarily aimed at reducing ammonia blood concentrations through drug therapy aimed at inhibiting ammonia production or enhancing its removal. Additionally, treatment for HE should include avoidance and prevention of precipitating factors in an effort to avoid acute decompensation. In cases where a precipitant of episodic HE has been identified and adequately treated or removed, long-term prophylaxis against another acute HE episode may not be required. Otherwise, chronic therapy to prevent acute decompensation is often required.

TABLE 37-5 Grading System for Hepatic Encephalopathy

Grade	Level of Consciousness	Personality/Intellect	Neurologic Abnormalities
Unimpaired	Normal	Normal	Normal
Minimal	No clinical evidence of change	No clinical evidence of change/alterations identified on psychometric or neuropsychological	No clinical evidence of change

Grade	Level of Consciousness	Personality/Intellect	Neurologic Abnormalities
		testing	
I	Trivial lack of awareness; shortened attention span	Euphoria or anxiety; impairment of addition or subtraction	Altered sleep rhythm
II	Lethargic	Obvious personality changes; inappropriate behavior; apathy	Asterixis; dyspraxia; disoriented for time
III	Somnolent but arousable	Bizarre behavior	Responsive to stimuli; confused; gross disorientation to time and space
IV	Coma/unarousable	None	Does not respond to stimuli

Data from reference 31.

Hyperammonemia

7 Treatment interventions to reduce ammonia blood concentrations are recommended in patients with HE. Decreasing ammonia blood concentrations by reducing the nitrogenous load from the gut remains a mainstay of therapy for patients with HE. Treatment options most commonly used to decrease ammonia load from the gut include nutritional management, nonabsorbable disaccharides, and antibiotics.

Guidelines for nutritional support of patients with liver disease have been published by the International Society for Hepatic Encephalopathy and Nitrogen Metabolism.[32] Protein withdrawal is a cornerstone of treatment for patients during acute episodes of HE.[31] However, prolonged restriction can lead to malnutrition and poorer prognosis among HE patients. Therefore, once successful reversal of HE symptoms is achieved, protein is added back to the diet in combination with other therapies until a target of 1.2 to 1.5 g/kg/day is reached. Vegetable-source and dairy-source protein may be preferable to meat-source protein because the latter contains a higher calorie-to-nitrogen ratio. Also, the higher fiber content of vegetable protein lowers colonic pH, increasing catharsis. Oral branched-chain amino acid formulations have been shown to improve symptoms in episodic HE and may be considered as alternative or add-on therapy in patients who do not respond to conventional measures.[33]

The use of lactulose, a nonabsorbable disaccharide, is standard therapy for both acute and chronic HE.[31] Lactulose, when administered orally through ingestion or a nasogastric tube, passes through the GI tract and reaches the colon unchanged. It can also be administered by retention enema. Lactulose is metabolized by gut flora into acetic acid and lactic acid, which lower colonic pH and create a cathartic effect. Lactulose administration lowers ammonia levels in the blood in several ways: (a) through creation of a laxative effect that reduces the time period available for ammonia

absorption, (b) through leaching of ammonia from the circulation into the colon and increasing bacterial uptake of ammonia by colonic bacteria, and (c) through reducing ammonia production by the small intestine by interfering directly with the uptake of glutamine by the intestinal wall and its subsequent metabolism to ammonia.[34]

Inhibiting the activity of urease-producing bacteria with neomycin or metronidazole can decrease production of ammonia.[35] Additionally, neomycin inhibits glutaminase thereby further reducing ammonia production.[31] Neomycin at a dose of 1,000 mg every 6 hours for up to 6 days daily can be given during an acute episode of HE.[35] For persistent HE, a dose of 1 to 2 g daily could be used with periodic renal and annual auditory monitoring since, despite poor absorption, chronic use of neomycin can lead to irreversible ototoxicity and nephrotoxicity. Metronidazole initiated at 250 mg twice daily may also produce a favorable clinical response in HE. However, neurotoxicity caused by impaired hepatic clearance of the drug may be problematic.

Rifaximin is a synthetic antibiotic structurally similar to rifamycin with a systemic absorption of only 0.4%.[34] It lowers blood ammonia levels and improves neuropsychiatric symptoms in HE. In a randomized, double-blind, placebo-controlled trial, patients in remission from recurrent HE were randomized to either rifaximin 550 mg twice daily or placebo for 6 months.[36] Rifaximin significantly reduced the risk of a recurrent episode of HE as well as hospitalization due to HE. Lactulose was used concomitantly in 90% of patients in this study. The incidence of adverse effects was similar between rifaximin and placebo with the most common serious adverse events reported being nausea and diarrhea.

Zinc can be deficient in cirrhotic patients, especially in cases of alcoholism.[35] Supplementation with elemental zinc at doses of 11 mg/day for men and 8 mg/day for women is recommended for patients with zinc deficiency.

Drugs Affecting Neurotransmission

The GABA-receptor complex is the primary inhibitory neural network within the CNS. An enhanced GABA-ergic tone and an increased amount of endogenous benzodiazepines may contribute to HE. Flumazenil 1 mg IV bolus may be considered for short-term therapy in refractory patients with suspected benzodiazepine intake, but cannot be recommended for routine clinical use.[13,31,35]

Alterations of dopaminergic neurotransmission have also been thought to play a role in the symptoms of HE, particularly the extrapyramidal signs. Improvements of extrapyramidal symptoms have been reported with bromocriptine therapy. Bromocriptine 30 mg twice daily is indicated for chronic HE treatment in patients who are unresponsive to other therapies. Prolactin levels may become elevated during bromocriptine treatment.[13,35]

Treatment Recommendations: Hepatic Encephalopathy

7 The mainstay of therapy of HE involves measures to lower blood ammonia concentrations and includes diet therapy, lactulose, and antibiotics alone or in combination with lactulose.[13,31,35] Other

adjunctive therapies include zinc replacement in patients with zinc deficiency, flumazenil, and possibly bromocriptine.

In patients with episodic HE, protein is withheld or limited while maintaining the total caloric intake until the clinical situation improves. Then dietary protein is titrated back up based on tolerance, increasing gradually to a total of 1.2 to 1.5 g/kg/day.[31] Consider the substitution of meat-source protein with vegetable or dairy protein. Supplementation with elemental zinc at doses of 11 mg/day for men and 8 mg/day for women is recommended for long-term management in patients with cirrhosis who are zinc deficient.[35]

In episodic HE, lactulose is initiated at a dose of 45 mL orally every hour (or by retention enema: 300 mL lactulose syrup in 1 L water held for 60 minutes) until catharsis begins. The dose is then decreased to 15 to 45 mL orally every 8 to 12 hours and titrated to produce two to three soft stools per day for chronic therapy. The enema is retained for 1 hour with the patient in the Trendelenburg position. Monitor electrolytes periodically, follow patients for changes in mental status, and titrate to the number of stools as already described.

Rifaximin 550 mg twice daily plus lactulose has been proven superior to lactulose alone in patients with a history of recurrent HE.[36] Because of its more favorable adverse effect profile, rifaximin is now considered the next line of therapy for recurrent HE over either metronidazole or neomycin.[21] Rifaximin doses of 400 to 550 mg twice daily are utilized in chronic HE.[35] It is recommended that rifaximin be added on to lactulose therapy in recurrent HE following the second recurrence.[31]

Systemic Complications

In addition to the more common complications of chronic liver disease discussed earlier, other complications can occur, including hepatorenal syndrome, hepatopulmonary syndrome, coagulation disorders, and endocrine dysfunction.

Hepatorenal syndrome, which is a functional renal failure in the setting of cirrhosis, occurs in the absence of structural kidney damage.[37] It develops in patients with cirrhosis as a result of intense renal vasoconstriction, which results from extreme systemic vasodilation. The resultant reduction in blood supply to the kidneys causes avid sodium retention and oliguria. As liver disease progresses, systemic vasodilation worsens and, subsequently, increased renal vasoconstriction occurs and renal blood flow is further decreased. As this occurs, the heart's response becomes insufficient to maintain perfusion pressure, which the kidneys rely heavily on at this point to maintain adequate blood flow. Hepatorenal syndrome is common and develops in approximately 20% of hospitalized patients with cirrhosis.

Management of hepatorenal syndrome begins with a first step of discontinuing diuretics and any other medication that could potentially decrease effective blood volume and to expand the intravascular volume with IV albumin at a dose of 1 g/kg up to a maximum of 100 g.[21] Precipitating factors, such as infection, fluid loss, and blood loss, should be investigated and treated if found. Liver transplantation is the only definitive therapy for hepatorenal syndrome and the only therapy that will

prolong survival. Therapies used to bridge patients until transplantation include arteriolar vasoconstrictor-based treatments with terlipressin or midodrine plus octreotide used in addition to IV albumin infusion as already discussed.

Hepatopulmonary syndrome affects somewhere between 5% and 32% of patients with cirrhosis.[38] This abnormality is characterized by a defect in arterial oxygenation, which is caused by the pulmonary vascular dilation that occurs in the presence of liver disease. Less commonly, pleural and pulmonary arteriovenous shunting can occur as well as portopulmonary venous anastomoses. These patients present with dyspnea on exertion, at rest, or both. Cirrhotic patients with these findings should be evaluated for hepatopulmonary syndrome, which is diagnosed based on the presence of arterial hypoxemia. Arterial hypoxemia is defined based on measurements of the partial pressure of oxygen that are performed with patients sitting and at rest. Testing for an increased alveolar–arterial oxygen gradient is also particularly important as this gradient can rise abnormally before the patient's partial pressure of oxygen measurement becomes abnormally low. Long-term management requires supportive therapy with supplemental oxygen. The prognosis for these patients is poor. Ultimately, liver transplantation offers the best chance for long-term recovery.

Correction of the coagulopathy is essential for patients actively bleeding. The pathophysiology of the coagulopathy is complex and involves impaired synthesis of clotting factors, excessive fibrinolysis, disseminated intravascular coagulation, thrombocytopenia, and platelet dysfunction. Acute therapy involves platelet transfusions for thrombocytopenia and fresh-frozen plasma for prolongation of the PT because of clotting factor deficiencies.[21]

The presence of cirrhosis can produce abnormal circulating levels of various hormones.[39] Hypogonadism, diabetes mellitus, osteoporosis, and thyroid disorders are among the endocrine disorders that may develop related to advanced liver disease. Erectile dysfunction related to hypogonadism can be treated with the administration of testosterone and the removal of causative factors such as alcohol.

Liver Transplantation

The complications seen in patients with chronic liver disease are essentially functional as a secondary effect of the circulatory and metabolic changes that accompany liver failure. Consequently, liver transplantation is the only treatment that can offer a cure for complications of end-stage cirrhosis.

PERSONALIZED PHARMACOTHERAPY

Cirrhosis modulates the behavior of drugs in the body by inducing kinetic alterations in drug absorption, distribution, and clearance.[40] Additionally, patients with cirrhosis may exhibit pharmacodynamic changes with increased sensitivity to the effects of certain drugs, namely, opiates, benzodiazepines, and nonsteroidal anti-inflammatory drugs. These pharmacodynamic changes are separate and distinct from the enhancement of drug effects seen in cirrhosis patients as a result of pharmacokinetic changes. Hepatic drug clearance is primarily dependent on protein binding, hepatic blood flow, and metabolic enzyme activity. The pathophysiologic changes that occur in patients with

cirrhosis, including reduced liver blood flow, intrahepatic and extrahepatic portal-systemic shunting, diminished metabolic and synthetic function, and capillarization of the sinusoids, can have a significant impact on each of these factors. The consequence of these changes is a reduction in intrinsic metabolic activity, a reduction in the delivery of blood to the liver that decreases clearance and prolongs half-life, and a reduction in the degree of protein binding that increases the fraction of unbound drug in the serum. Finally, patients with cirrhosis frequently accumulate large amounts of interstitial fluid resulting in substantial changes in the volume of distribution, which also prolongs drug half-life. These changes occur most commonly in combination in patients with cirrhosis and are dynamic throughout the disease course. The effect that these changes will have depends on the drug and the type of biotransformation that the drug undergoes.

Drugs with a high extraction ratio (high-extraction drugs) are dependent on blood flow for metabolism, and the rate of metabolism will be sensitive to changes in blood flow. Drugs with a low extraction ratio (low-extraction drugs) are dependent on intrinsic metabolic activity for metabolism, and the rate of metabolism will reflect changes in intrinsic clearance and protein binding. Furthermore, hepatic biotransformation involves two types of metabolic processes: phase I reactions and phase II reactions. Phase I reactions involve the cytochrome P450 system and include hydrolysis, oxidation, dealkylation, and reduction reactions. Phase II reactions involve conjugation of the drug with an endogenous molecule, such as sulfate or amino acid, rendering it more water soluble and enhancing its elimination. Drugs metabolized by phase I reactions, especially oxidation, tend to be significantly impaired in patients with cirrhosis, whereas drugs eliminated by conjugation are relatively unaffected.

The variability and complexity of the interaction between the extent and severity of liver disease and individual characteristics of the drug make it difficult to predict the degree of pharmacokinetic perturbation in an individual patient. Unfortunately, there are no sensitive and specific clinical or biochemical markers that allow us to quantify the extent of liver insufficiency or the degree of metabolic activity. In addition, renal insufficiency and alterations that commonly accompany cirrhosis further complicate empiric dosing recommendations in these patients. Dosing recommendations are most commonly nonspecific, with recommendations labeled for patients with mild to moderate liver impairment. Dosing information for patients with more severe liver impairment is not available. As a result, when patients with cirrhosis require therapy with drugs that undergo hepatic metabolism (eg, benzodiazepines), monitoring response to therapy and anticipating drug accumulation and enhanced effects is essential. In the case of benzodiazepines, selection of an agent such as lorazepam, an intermediate-acting agent that is metabolized via conjugation and has no active metabolites, is easier to monitor than a drug such as diazepam, a long-acting benzodiazepine that is oxidized in the liver and has an active metabolite with a long half-life of its own.

EVALUATION OF THERAPEUTIC OUTCOMES

Table 37-6 summarizes the management approach for patients with cirrhosis and includes possible adverse drug effects. Cirrhosis is generally a chronic progressive disease that requires aggressive medical management to prevent or delay common complications. Table 37-6 also lists monitoring criteria that need to be carefully followed in order to achieve the maximum benefit from the medical

therapies employed and prevent adverse effects. A therapeutic plan including therapeutic end points for each medical and diet therapy needs to be developed and discussed with the patient.

TABLE 37-6 Drug Monitoring Guidelines

Drug	Adverse Drug Reaction	Monitoring Parameter	Comments
Nonselective β-adrenergic blocker	Heart failure, bronchospasm, glucose intolerance	BP, HR Goal HR: 55-60 beats/min or maximal tolerated dose	Nadolol, propranolol, carvedilol
Octreotide	Bradycardia, hypertension, arrhythmia, abdominal pain	BP, HR, EKG, abdominal pain	
Vasopressin	Myocardial ischemia/infarction, arrhythmia, mesenteric ischemia, ischemia of the limbs, cerebrovascular accident	EKG, distal pulses, symptoms of myocardial, mesenteric, or cerebrovascular ischemia/infarction	
Spironolactone/furosemide	Electrolyte disturbances, dehydration, renal insufficiency, hypotension	Serum electrolytes (especially potassium), SCr, blood urea nitrogen, BP Goal sodium excretion: >78 mmol/day	Spot urine sodium concentration greater than potassium concentration correlates well with daily sodium excretion >78 mmol/day
Lactulose	Electrolyte disturbances	Serum electrolytes Goal number of soft stools per day: 2-3	
Neomycin	Ototoxicity, nephrotoxicity	SCr, annual auditory monitoring	
Metronidazole	Neurotoxicity	Sensory and motor neuropathy	
Rifaximin	Nausea, diarrhea		

BP, blood pressure; HR, heart rate; beats/min, beats per minute; EKG, electrocardiogram; SCr, serum creatinine; mmol, millimole.

Chapter e38: Drug-Induced Liver Disease

William R. Kirchain; Rondall E. Allen

INTRODUCTION

KEY CONCEPTS

- 1 Through its normally functioning enzymes and processes the liver often causes a drug to become toxic through a process known as bioactivation.
- 2 Drug-induced liver disease (DILD) can have many different clinical presentations: idiosyncratic reactions, allergic hepatitis, toxic hepatitis, chronic active toxic hepatitis, toxic cirrhosis, and liver vascular disorders.
- 3 The mechanisms of DILD are diverse, representing many phases of biotransformation, and are susceptible to genetic polymorphism.
- 4 The assessment of a possible liver injury caused by drugs should include what is known in the literature, the timing involved, the clinical course, and, always, an exploration for preexisting conditions that may have encouraged the lesion's development.
- 5 Liver enzyme assays in serum can help to determine if a particular type of liver damage is present.
- 6 Monitoring for DILD must be tailored to the drug and the patient's potential risk factors.

The number of drugs associated with adverse reactions involving the liver is extensive, but in clinical practice is dominated by alcohol, antibiotics, antiseizure medications and acetaminophen.[1] Complementary (herbal) medicines contribute disproportionately as well to this disease burden Drug-induced liver disease (DILD) is potentially fatal, often debilitating outcome of drug treatment. DILD is thought to be responsible for 11% to 13% of all cases of acute liver failure in the United States.[1,2]

Drug-induced liver disease accounts for as much as 20% of acute liver failure in pediatric populations and a similar percentage of adults with acute liver failure.[3] In approximately 75% of these cases, liver

transplantation is ultimately required for patient survival.[4] Of patients who required liver transplantation according to the United Network for Organ Sharing, acetaminophen, isoniazid, antiepileptics, and antibiotics collectively account for just over 60% of cases.[5]

The liver's function affects every other organ system in the body; it in turn is exposed to every substance absorbed from the gut and every injected substance that enters the bloodstream. This chapter will first explore the underlying mechanisms in DILD. Then proceed to develop the key therapeutic skill required in recognizing and categorizing what is and what is not DILD.

MECHANSIMS OF DRUG-INDUCED DISEASES

Stimulation of Autoimmunity

Autoimmune injuries involve antibody-mediated cytotoxicity or direct cellular toxicity.[6,7] This type of injury occurs when enzyme–drug adducts migrate to the cell surface and form neoantigens. The liver plays host to all of the cells that make up the innate immune response system in the body along with Kupffer cells, which are a type of macrophage. These cells sit in anticipation around the hepatocytes, in the space of Disse and elsewhere waiting for antigens (or neoantigens) to present themselves. The neoantigens serve as targets for cytolytic attack by killer T-cells, and others.[8] Halothane, sulfamethoxazole, carbamazepine, nevirapine, fluoroquinolones, and antitumor necrosis factor (TNF) alpha inhibitors are associated with autoimmune injuries.[2,9] Stimulation of autoimmunity is often associated with fulminant presentations.

Dantrolene, isoniazid, phenytoin, nitrofurantoin, trazodone, and methyldopa are associated with a type of autoimmune-mediated disease in the liver called *chronic active hepatitis*.[10,11] Patients experience periods of symptomatic hepatitis followed by periods of convalescence, only to repeat the experience months later. It is a progressive disease with a high mortality rate and is more common in females than males. Antinuclear antibodies (ANA) appear in most patients. These drugs appear to form antiorganelle antibodies.[12] The exact identification of a causative agent is sometimes difficult as diagnosis requires multiple episodes occurring long after exposure to the offending drug.

Idiosyncratic Reactions

Idiosyncratic drug-related hepatotoxicity is rare and usually occurs in a small proportion of individuals. These adverse reactions are often categorized into allergic and nonallergic reactions. Allergic reactions represent 23% to 37% of all idiosyncratic drug-induce liver injuries and are characterized by fever, rash, eosinophilia, and granulomas.[11] They are usually dose-related and have a short latency period (less than 1 month). On re-exposure to the offending agent, there is a rapid recurrence of hepatotoxicity. Minocycline, nitrofurantoin, phenytoin, amoxicillin-clavulanate, sulfamethoxazole-trimethoprim, angiotensin-converting enzyme inhibitors, and allopurinol can cause allergic reactions.[2,11,13]

The nonallergic idiosyncratic reactions are devoid of the hypersensitivity features, usually have a long

latency period (several months), and are not associated with rapid reinjury with rechallenge.[2] These patients often have normal liver function tests for 6 months or longer and then suddenly develop hepatotoxicity. Dependent on the medication, the incident can be independent of dose or dose related. Amiodarone, isoniazid, and ketoconazole are associated with nonallergic drug-related hepatotoxicity.[13]

Disruption of Calcium Homeostasis and Cell Membrane Injury

Drug-induced damage to the cellular proteins that are involved with calcium homeostasis can lead to an influx of intracellular calcium that causes a decline in adenosine triphosphate levels and disruption of the actin fibril assembly.[14] The resulting impact on the cell is blebbing of the cell membrane, rupture, and cell lysis.[15] Lovastatin, venlafaxine, and phalloidin, which is the active component of mushrooms, impair calcium homeostasis.[7,14]

Metabolic Activation of the Cytochrome P450 Enzymes

1 Most hepatocellular injuries involve the production of high-energy reactive metabolites by the CYP450 system. These reactive metabolites are capable of forming covalent bonds with cellular proteins (enzymes) and nucleic acids that lead to adduct formation. In the case of acute toxicity, the enzyme–drug adduct can cause cell injury or cell lysis.[15] Adducts that form with DNA can cause long-term consequences such as neoplasia. Acetaminophen, furosemide, and diclofenac are examples of this mechanism of liver injury.[7] 3 Individual genetic differences can play a role in the significance of this process. Patients with a single nucleotide polymorphism (SNP) that codes for slow-reacting variants of CYP450 will react differently from those with a SNP that codes for very fast-reacting variants.

Stimulation of Apoptosis

Apoptosis represents a distinct pattern of cell lysis that is characterized by cell shrinkage and fragmentation of nuclear chromatin. Apoptotic pathways are triggered by interactions between death ligands (tumor necrosis factor and Fas ligand) and death receptors (tumor necrosis factor receptor 1 and Fas). These interactions activate caspases, which cleave cellular proteins and eventually lead to cell death.[15,46]

Mitochondrial Injury

Drugs that impair mitochondrial structure, function, or DNA synthesis can disrupt β-oxidation of lipids and oxidative energy production within the hepatocyte.[14] In acute disease, prolonged interruption of β-oxidation leads to microvesicular steatosis, whereas, in chronic disease, macrovesicular disease is present.[16] Severe damage to the mitochondria eventually leads to hepatic failure and death. Aspirin, valproic acid, and tetracycline cause mitochondrial injury by inhibiting β-oxidation and amiodarone via disruption of oxidative phosphorylation.[14] Inborn errors in

mitochondrial metabolism can predispose a patient to these types of disruptions in function.

Liver Neoplastic Disease

A large body of literature on adverse reactions and the liver addresses the development of neoplasms following drug therapy. Both carcinoma- and sarcoma-like lesions have been identified. Fortunately, hepatic tumors associated with drug therapy are usually benign and remit when drug therapy is discontinued. Except in rare instances, these lesions are associated with long-term exposure to the offending agent.[17] Androgens, estrogens, and other hormonal-related agents are the most frequently associated causes of neoplastic disease. The model for drug-induced hepatic cancer is polyvinyl chloride exposure. Used in the production of many types of plastic products, polyvinyl chloride induces angiosarcoma in exposed workers after as few as 3 years of exposure.[4,18]

ASSESSMENT: THE PATTERN OF LIVER ENZYME CHANGES

2 Drug-induced liver disease is categorized in two ways each with its own contribution to patient care strategies. The most common way to categorize DILD is by the pattern of liver enzyme changes. At this stage of recognition, two questions can be answered: (1) is this liver injury? and (2) what type of liver injury is likely emerging? In severe, puzzling, or unusual cases a liver biopsy is used to categorize DILD by the *Pattern of Histological Changes*.

5 For the majority of DILD cases, the first indicator of injury is the elevation of alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (Alk Phos) and the total bilirubin (TBL). Additional liver enzymes and other laboratory findings that will be useful include 5′-nucleotidase (5-NT), gama-glutamyltransferase (GGTP), lactic dehydrogenase (LDH), ANA, antismooth muscle antibodies (ASMA), liver kidney microsomal auto-antibodies (LKM-1) and micro-RNA 122. These laboratory findings break out into three primary categories of DILD: (1) hepatocellular damage, (2) cholestatic damage, and (3) mixed hepatocellular cholestatic damage. These laboratory findings will also indicate if the injury is an autoimmune or nonimmune process.

Hepatocellular Injury

2 Hepatocellular injury is characterized by significant elevations in the serum aminotransferases, which usually precede elevations in TBL levels and alkaline phosphatase levels.[19] 5 Hy's Law defines hepatocellular injury as an increase in ALT that is at least 3 times above the upper limit of normal (UNL) with concurrent rise in TBL to a point at least 2 UNL without a significant rise in the Alk Phos (**Table e38-1**).[20,21] The US Food and Drug Administration along with the Council for International Medical Sciences recommend evaluating the ratio of the ALT to the Alk Phos as well. Hepatocellular injury then becomes defined as ALT > 3 UNL plus TBL > 2 UNL plus R = (Measured ALT/Upper Normal Limit of ALT) ÷ (Measured Alk Phos/Upper Normal Limit of Alk Phos) where R > 5.[2,20,21]

TABLE e38-1 An Approach to Evaluating a Suspected Hepatotoxic Reaction

Points	–3	–1	0	+1	+2	+3

What is the temporal relationship? (days)						
From the start of therapy	—	—	??	<5	>90	5-90
From the end of therapy	>30	—	??	—	—	<30
Is there evidence of the concurrent use of a hepatotoxin[a]?	Yes	Maybe	??	—	—	No
Is there an alternate cause, such as viral hepatitis?	Yes	Most likely—Yes	??	Most likely—No		No
Are there extrahepatic signs or symptoms?						
Dermatologic: rash, palmar erythema, cutaneous vasculitis	—	—	No	Yes (+1 for each)	—	—
Dermatologic: spider nevi, white nails (aka Terry's nails)	—	—	No	Yes (+1 for each)	—	—
Hematologic: coagulation disorders	—	—	No	Yes (+1 for each)	—	—
Endocrine disorders: insulin resistance, thyroid dysfunction	—	—	No	Yes (+1 for each)	—	—
Endocrine disorders: adrenal insufficiency, hypogonadism	—	—	No	Yes (+1 for each)	—	—
Skeletal muscular: arthralgias, arthritis	—	—	No	Yes (+1 for each)	—	—
Neurological: encephalopathy	—	—	No	Yes (+1 for each)	—	—
Portopulmonary hypertension	—	—	No	Yes (+1 for each)	—	—
Does the literature support a connection with this drug?						
Listed in the product labeling	—	—	—	—	—	Yes
Published reports in the literature	—	—	—	—	Yes	—
No information available, reaction is undocumented	—	—	Yes	—	—	—
Results from a rechallenge with the drug	Negative	—	—	Inconclusive	—	Positive

??, Uncertain.

A total score <7 makes it unlikely that this is a hepatotoxic reaction.

As the score approaches 14; the possibility that this is a hepatotoxic reaction increases toward certainty.

[a]*Drug, herbal remedy, or other occupational exposure known to be potentially hepatotoxic.*

Most hepatocellular injuries occur within 1 year of starting drug therapy. Hepatocellular injury can lead to fulminant hepatitis with a corresponding 20% survival rate with supportive care.[16] For those patients who present with the combination of hepatocellular injury and jaundice, there is a 10% mortality rate.[22] Acarbose, allopurinol, fluoxetine, and *losartan* are capable of causing hepatocellular injury.[19]

Autoimmune hepatocellular injury is often accompanied by fever and elevations in ANA, ASMA, LKM-1, and gamma globulins. 5 Typically this type of DILD is more rapid in onset (less than 2 months from start of therapy) and fulminant. If identified early autoimmune hepatocellular injury may respond to high dose glucocorticoid treatment. This treatment must be carefully targeted however since glucocorticoid treatment can worsen underlying fatty liver disease.

Hepatocellular injuries can be further subdivided by specific histologic patterns and clinical presentations. Centrolobular necrosis, steatohepatitis (steatonecrosis), phospholipidosis, and generalized hepatocellular necrosis are each identifiable by particular biopsy results and subtle differences in clinical presentation.[23]

Cholestatic Injury

2 Cholestatic disease is more often seen in patients over the age of 60 (compared with underage 60) and is slightly more common in males.[9] 6 In cholestatic disease, disturbance of the subcellular actin filaments around the canaliculi prevents the movement of bile through the canalicular system.[14] Mutations in hepatic transporter genes can result in slower function prior to toxin exposure.[24] The inability of the liver to remove bile causes intrahepatic accumulation of toxic bile acids and excretion products.[14,24]

Alkaline phosphatase is the predominant elevated enzyme.[3] 5 Cholestatic injury would then be defined by an Alk Phos > 3 UNL plus TBL > UNL plus and R ≤ 2. The antibiotic erythromycin associated DILD is the prototype for this injury, along with amoxicillin–clavulanic acid, and carbamazepine.[16] An IV form of vitamin E, α-tocopheryl acetate, causes cholestatic jaundice, primarily involving the canalicular duct in premature infants. The incidence of this reaction in those receiving this formulation was high (more than 10%) and the mortality even higher (more than 50%).[25]

Cholestatic injury is also known as cholestatic jaundice or cholestasis and can be further classified by the area of the bile canalicular or ductal system that is impaired. Canalicular cholestasis is often associated with long-term, high-dose estrogen therapy. These patients are often asymptomatic and present with mild-to-moderate elevations of serum bilirubin.[26] An IV form of vitamin E, α-tocopheryl acetate, causes cholestatic jaundice, primarily involving the canalicular duct in premature infants. The incidence of this reaction in those receiving this formulation was high (more than 10%) and the mortality even higher (more than 50%).[25]

Mixed Hepatocellular and Cholestatic Injury

This pattern as the name implies is the result of both hepatocytes and bile canalicular cells bearing damage at near to the same time. Either the ALT or the Alk Phos can predominate but both will be significantly elevated.[2]

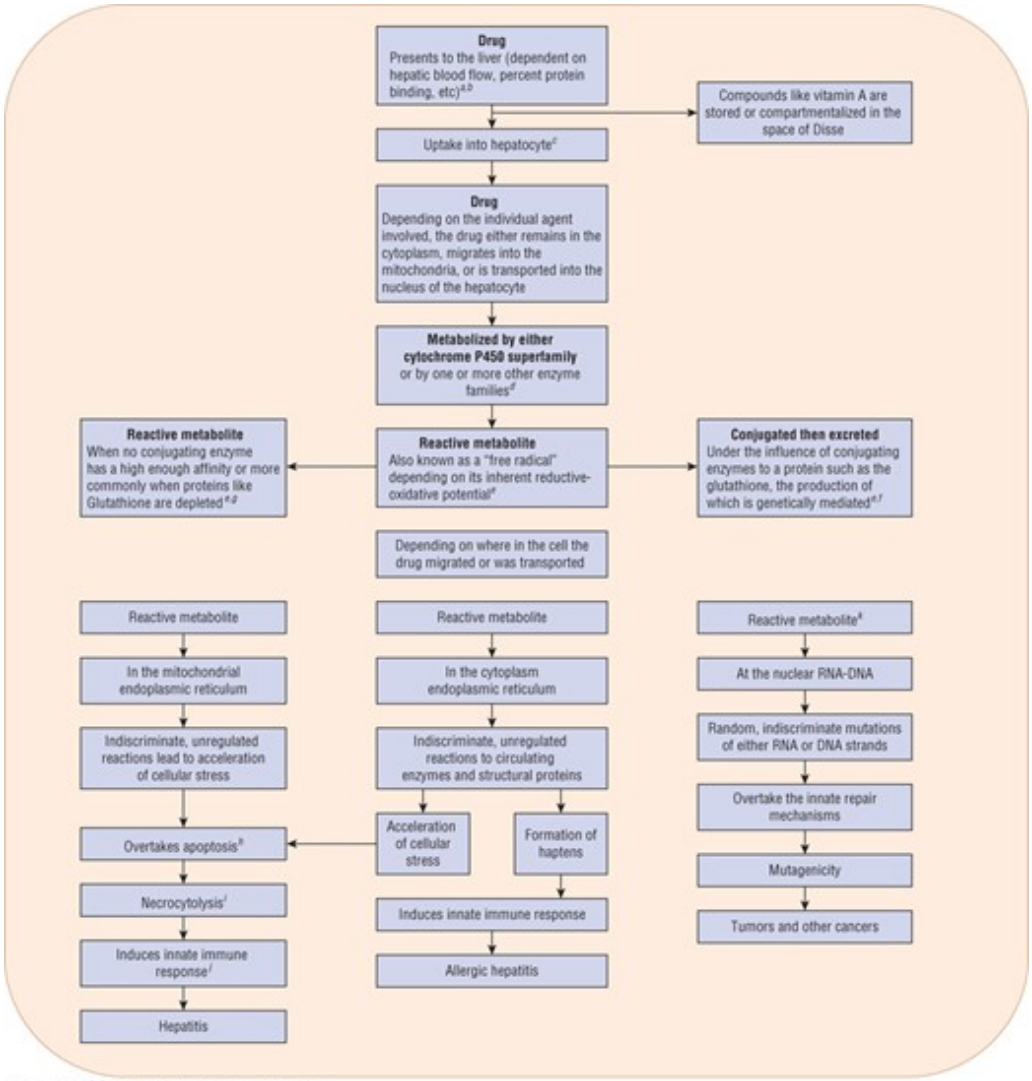
ASSESSMENT: THE PATTERN OF HISTOLOGIC CHANGES

Centrolobular Necrosis

Centrolobular necrosis is often a dose-related, predictable reaction; however, it also can be associated with idiosyncratic reactions. Also called direct or metabolite-related hepatotoxicity, centrolobular necrosis is usually the result of the production of a toxic metabolite (**Fig. e38-1**). The damage spreads outward from the middle of a lobe of the liver.

FIGURE e38-1

A general diagram of biotransformation. [a]Hepatic blood flow, which changes proportionately with changes in cardiac output, delivers the drug to the liver. [b]Protein binding is most affected by nutritional status and competing drugs. [c]The drug is actively transported into the hepatocyte by the organic anion transport pump, a transmembrane protein. [d]The metabolite (drug) interacts with one of a number of enzymes, the most common being CYP2C9, 2C19, 2D6, and 3A4. This family of enzymes is regulated by the complementary DNA xenobiotic receptor. The xenobiotic receptor is in turn upregulated by other drugs, changes in cholesterol catabolism, and bile acids. The immediate result of the action of these phase I enzymes is the production of a reactive metabolite. [e]The unstable metabolite then reacts with glucuronidase, various transferases, or hydroxylases to form a conjugated metabolite. The efficacy of these enzymes is affected by the patient's nutritional state and genetic polymorphism, leading to variations in individual risk for toxicity. [f]The conjugated metabolite is removed from the hepatocyte by the canalicular membrane export pump, one of a large family of membrane proteins (other members of this family pump conjugated metabolites back into the blood for excretion by the kidney). These proteins are subject to genetic polymorphism as well, again leading to some patients having an increased risk for toxicity. [g]If unable to form a conjugate, the unstable metabolite can participate in oxidative reactions that damage lipids, proteins, or even DNA. [h]The normal process of cellular aging, death, and reabsorption by surrounding cells. [i]Widespread, rapid cellular death with the creation of multiple antigens. [j]Activation Kupffer cells, killing cells, B-cells, and other T-cells with the associated production of inflammatory cytokines the relative numbers of which and the innate activity of each mediated by genetic polymorphism. [k]Drugs or active metabolites that are transported or diffuse into the mitochondria or the nucleus can damage DNA, leading to mutagenicity and ultimately hepatic cancers.



Patients suffering from centrolobular necrosis tend to present in one of two ways, depending on the extent of necrosis. Mild drug reactions, involving only small amounts of parenchymal liver tissue, may be detected as asymptomatic elevations in the serum aminotransferases. If the reaction is diagnosed at this stage, most of these patients will recover with minimal cirrhosis and thus minimal chronic liver impairment. More severe forms of centrolobular necrosis are accompanied by nausea, vomiting, upper abdominal pain, and jaundice.[10,27]

These reactions are predictable, often dose-related effects in the liver caused by specific agents. When taken in overdose, acetaminophen becomes bioactivated to a toxic intermediate known as *N*-acetyl-*p*-benzoquinone imine (NAPQI). NAPQI is very reactive, with a high affinity for sulfhydryl groups. The protein glutathione provides a ready source of available sulfhydryl groups within the hepatocyte. When the liver's glutathione stores are depleted and there are no longer sulfhydryl groups available to detoxify this metabolite, it begins to react directly with the hepatocyte (see Fig. e38-1). In addition, the depletion of glutathione changes the mitochondrial oxidized to reduced glutathione ratio resulting in catastrophic shifts in mitochondrial function, accelerating cell necrocytolysis.[28] Continuing mitochondrial damage leading to fragmentation of mitochondrial DNA leads directly to necrosis.[29] Replenishing the liver's sulfhydryl capacity through the administration of

N-acetylcysteine early after ingestion of the overdose halts this process.[28] During the first hours after ingestion, some patients report mild symptoms of nausea and vomiting, but no elevations of the commonly measured liver enzymes are seen. Serum elevations in the liver enzymes begin 40 to 50 hours after ingestion.[30] Circulating cell-free microRNA (liver-specific miR-122) begins to rise after only 1 hour in rat models of acetaminophen overdose. This may lead the way to earlier detection of many drug-induced liver disorders in the future.[31]

Nonalcoholic Steatohepatitis

2 Nonalcoholic steatohepatitis (NASH), also known as steatohepatitis and steatonecrosis, results from the accumulation of fatty acids in the hepatocyte. In the preacute stages, this is known as nonalcoholic fatty liver disease (NAFLD). Drugs or their metabolites that cause NAFLD do so by affecting fatty-acid esterification and oxidation rates within the mitochondria of the hepatocyte (see Fig. e38-1). Hepatic vesicles become engorged with fatty acids, eventually disrupting hepatocyte homeostasis. In patients with diabetes, various dyslipidemias and even hypertension, the de novo production of free fatty acids from excess circulating carbohydrates, accelerates this process of accumulation. The liver biopsy is marked by a massive infiltration by polymorphonuclear leukocytes, degeneration of the hepatocytes, and the presence of Mallory bodies.[32]

Alcohol is the drug that most commonly produces steatonecrotic changes in the liver. When alcohol is converted into acetaldehyde, the synthesis of fatty acids is increased.[33,34] The hepatocyte can become completely engorged with microvesicular fat, resulting in alcoholic fatty liver. Metabolically this type of de novo free fatty acid synthesis depletes NADPH in favor of $NADP^+$ and reduces the hepatocytes' ability to respond to stress, bypassing normal apoptosis, and increasing the rate of necrocytolysis. In NAFLD, the same end point is often achieved through oxidation of lipid peroxidases.[35] If the offending agent is withdrawn before significant numbers of hepatocytes become necrotic, the process is completely reversible without long-term sequelae. If not, then ever increasing rates of necrocytolysis will induce an innate immune response and result in hepatitis.

Tetracycline produces NAFLD and NASH.[36] The lesions are characterized by large vesicles of fat found diffused throughout the liver. The development of this reaction is related to the high concentrations achieved when tetracycline is given IV and in doses greater than 1.5 g/day. The mortality of tetracycline steatohepatitis is high (70%-80%), and those who do survive often develop cirrhosis. Sodium valproate also can produce steatonecrosis through the process of bioactivation. 3 Cytochrome P450 (CYP450) converts valproate to delta-4-valproic acid, a potent inducer of microvesicular fat accumulation.[37]

Patients experiencing steatohepatitis may present with abdominal fullness or pain as their only complaint. Patients with more severe steatonecrosis will present with all the symptoms characteristic of alcoholic hepatitis such as nausea, vomiting, steatorrhea, abdominal pain, pruritus, and fatigue.

Phospholipidosis

Phospholipidosis is the accumulation of phospholipids instead of fatty acids. The phospholipids usually engorge the lysosomal bodies of the hepatocyte.[38] Amiodarone is associated with this reaction. Patients treated with amiodarone who develop overt hepatic disease tend to have received higher doses of the drug. These patients also have higher amiodarone-to-*N*-desethylamiodarone ratios, indicating a greater accumulation of the parent compound. Amiodarone and its major metabolite *N*-desethylamiodarone remain in the liver of all patients for several months after therapy is stopped. Usually the phospholipidosis develops in patients treated for more than 1 year. The patient can present with either elevated aminotransferases or hepatomegaly; jaundice is rare.[12,32]

Generalized Hepatocellular Necrosis

Generalized hepatocellular necrosis mimics the changes associated with the more common viral hepatitis. The onset of symptoms is usually delayed as much as a week or more after exposure to toxin. Bioactivation is often important for toxic hepatitis to develop. Many drugs that are associated with toxic hepatitis produce metabolites that are not inherently toxic to the liver. Instead, they bind with proteins to create haptens, which serve as neoantigens and induce the innate immune response (see Fig. e38-1).[39]

The rate of bioactivation can vary between males and females and between individuals of the same sex.[40,41] The superfamily of CYP450 enzymes metabolizes lipophilic substrates that are actively pumped into the hepatocyte by an organic anion (or cation) transporting protein. The CYP450 subspecies 2C9, 2C19, 2D6, 3A4, and 4F8 are regulated by the highly inducible xenobiotic receptor on complementary DNA. The receptor is found in the liver, and to a lesser extent in the cells lining the intestinal tract, and is responsible for cholesterol catabolism and bile acid homeostasis. The activity of this receptor is subject to genetic polymorphism. This results in a wide variation in the sensitivity of the population to hepatic damage.[42]

The long-term administration of isoniazid can lead to hepatic dysfunction in 10% to 20% of those receiving the drug. Yet severe toxic hepatitis develops in only 1% or less of this population.[43] The *N*-acetyltransferase2 (NAT2) genotype appears to play a role in determining a patient's relative risk. A study of patients who developed elevated liver enzymes (defined as at least 2.5 times upper normal) or jaundice found that 29 out of 41 (70%) of these patients were slow acetylators.[44] Isoniazid is metabolized by several pathways, acetylation being the major pathway. It is acetylated to acetylisoniazid, which, in turn, is hydrolyzed to acetylhydrazine.[45] The acetylhydrazine, and to a lesser extent the acetylisoniazid, are directly toxic to the cellular proteins in the hepatocyte, but rapid acetylators detoxify acetylhydrazine very rapidly, converting it to diacetylhydrazine (a nontoxic metabolite). Therefore, it is the rate and efficiency of this reaction sequence that ultimately determines if hepatocellular damage will ensue.

Isoniazid simultaneously is an example of the potential predictability of DILD based on SNP and a lesson in the limitations of our current understanding. There are definite links to NAT2 genotype and toxicity.[46] The risk for this reaction is also influenced heavily by the age of the patient, with older

patients having a much higher risk than younger patients. In fact, age may be more important than genotype.[43,44,46] In one prospective series focused on DILD, cases involving isoniazid had a median onset at 6 months of therapy with around 30% of isoniazid-induced liver disease clustered between 6 and 8 months.[8]

Ketoconazole produces generalized hepatocellular necrosis or milder forms of hepatic dysfunction in 1% to 2% of patients treated for fungal infections. The onset is usually early in therapy. In immunocompromised patients in whom ketoconazole is used, special care should be taken to watch for changes in liver function.[47]

Toxic Cirrhosis or Fibrosis

The scarring effect of hepatitis in the liver leads to the development of cirrhosis through a process known as fibrosis. Some drugs tend to cause such a mild case of hepatitis that it may not be detected. Mild hepatitis can be easily mistaken for a more routine generalized viral infection. If the offending drug or agent is not discontinued, this damage will continue to progress. The patient eventually presents not with hepatitis, but with cirrhosis.

Methotrexate causes periportal fibrosis in most patients who experience hepatotoxicity. The lesion results from the action of a bioactivated metabolite produced by CYP450.[48] This process occurs most commonly in patients treated for psoriasis and arthritis. Periodic liver biopsies have a low yield in patients without other risk factors for liver disease, and should be reserved for select high-risk patients.[49] Vitamin A is normally stored in liver cells, and causes significant hypertrophy and fibrosis when taken for long periods in high doses. Hepatomegaly is a common finding, along with ascites and portal hypertension. In patients with vitamin A toxicity, gingivitis and dry skin are also very common. This is accelerated by ethanol, which competes with retinol for aldehyde dehydrogenase.[33]

Liver Vascular Disorders

Focal lesions in hepatic venules, sinusoids, and portal veins occur with various drugs. The most commonly associated drugs are the cytotoxic agents used to treat cancer, the pyrrolizidine alkaloids, and the sex hormones. A centralized necrosis often follows and can result in cirrhosis. Azathioprine and herbal teas that contain comfrey (a source of pyrrolizidine alkaloids) are associated with the development of venoocclusive disease. The exact incidence is rare and may be dose related.[32] Peliosis hepatitis is a rare type of hepatic vascular lesion that can be seen as both an acute and a chronic disease. The liver develops large, blood-filled lacunae (space or cavity) within the parenchyma. Rupture of the lacunae can lead to severe peritoneal hemorrhage. Peliosis hepatitis is associated with exposure of the liver to androgens, estrogens, tamoxifen, azathioprine, and danazol. Androgens with a methyl alkylation at the 17-carbon position of the testosterone structure are the most frequently reported agents that cause peliosis hepatitis, usually after at least 6 months of therapy.[50]

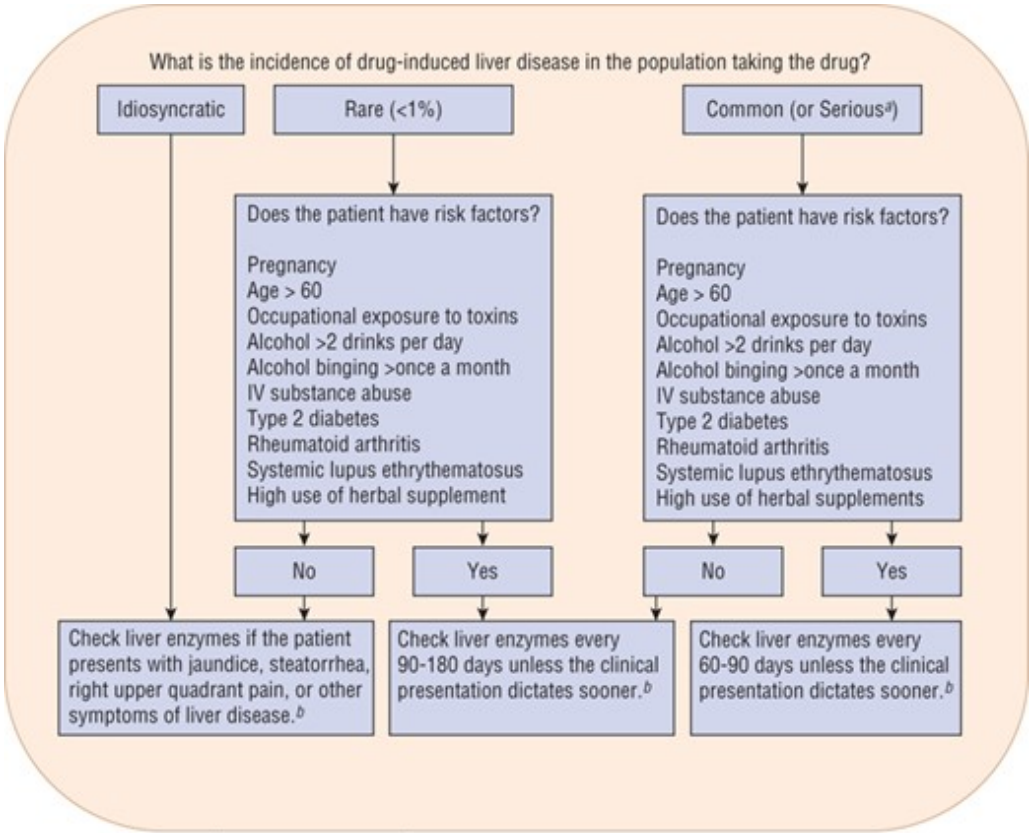
ASSESSMENT: DETERMINING THE MEDICATION RELATED PROBLEM

It is important to document the pattern of liver enzyme changes, the pattern of histologic changes if known to assess the medication related problem. Key information also comes from the patient's history. 4 All potential drug reactions should be judged as to the timing of the reaction and its known pharmacokinetics.

Questions addressing the patient's drug use are essential (**Fig. e38-2**).[51,52,53,54] Drugs for recreational purposes must not be overlooked. Cocaine has been directly linked to liver disease.[55] Methylenedioxymethamphetamine (MDMA or Ecstasy) has induced deadly fulminant hepatitis as have various combinations of so-called synthetic marijuana or Spice.[56,57] 6 The more pervasive but harder to detect impact of street drugs on the incidence of hepatic disease is the concomitant injection or ingestion of adulterants. Talc, heavy metals, and various solvents are used. Many of these adulterants are either directly toxic or serve to enhance the toxicity of the drug (see Table e38-1).

FIGURE e38-2

An approach to determining a drug monitoring plan for patients prescribed potentially hepatotoxic drugs. Notes: [a]Serious reactions would include those that occur rarely but have a very high morbidity or mortality rate. Common reactions would be reported in 1% or more patients taking the drug. [b]Concomitant therapy with another hepatotoxic drug will elevate the potential risk of a reaction and should lead to more frequent monitoring.



4 It is also important to determine nondrug hepatic disease risk from occupational or environmental exposure. Arsenic, for example, is known to induce both acute and chronic hepatic reactions.[56] Even if exposure to an environmental toxin does not produce a hepatic reaction, it may predispose a patient to a hepatic reaction when a drug is added.[51,52,53,54] **Table e38-2** lists some of the more common hepatic toxins found in occupational or environmental exposures that can add to the risk for developing a hepatic lesion.[58] Immune-mediated chronic liver diseases can often be tracked to geographic clusters that correspond to known toxic waste sites around the world.[58]

TABLE e38-2 Environmental Hepatotoxins and Associated Occupations at Risk for Exposure

Hepatotoxin	Associated Occupations at Risk for Exposure
Arsenic	Chemical plant, agricultural workers
Carbon tetrachloride	Chemical plant workers, laboratory technicians
Copper	Plumbers, sculpture artists, foundry workers
Dimethylformamide	Chemical plant workers, laboratory technicians
2,4-Dichlorophenoxyacetic acid	Horticulturists
Fluorine	Chemical plant workers, laboratory technicians
Toluene	Chemical plant, agricultural workers, laboratory tech
Trichloroethylene	Printers, dye workers, cleaners, laboratory technicians
Vinyl chloride	Plastics plant workers; also found as a river pollutant

The history of a person's use of alternative medicines must be solicited. [4] In the prospective series of cases noted earlier, from an area of the country where traditional medicine usage is commonplace, herbal remedies and other traditional medicines accounted for 14 of 132 cases of DILD.[8] [6] Comfrey tea is a common cause of hepatocellular damage. With the Chinese remedy *jinbuhuan*, or the more elegantly presented chaparral capsules containing grease wood leaves, the end of therapy with these types of agents is occasionally severe disability or death from fulminant hepatic failure.[59] Pennyroyal oil, margosa oil, and clove oil cause a dose-related hepatotoxicity.[59]

The nutritional status of a patient can be as important to the development of a DILD as the hepatotoxin itself.[51,52,53,54] [4] Patients who are malnourished because of illness or long-term alcohol abuse make up the most troublesome group.[60] Low serum levels of vitamins E and C along with lutein and the α- and β-carotenes are associated with asymptomatic elevations in transaminases. Conversely, high serum iron, transferrin, and selenium levels are also associated with asymptomatic elevations of transaminases.[61]

The inclusion of alternative nondrug causes and closes clinical observation when the drug in question is stopped. It is also important to keep in mind that most elevations in liver enzymes will not be associated with a drug. In a study of all patients admitted to a hospital in the United Kingdom with elevated liver aminotransferases, only 9% of cases involved a drug other than alcohol as the possible cause.[13] In all cases, titers of serum antibodies to hepatitis A, B, and C should be drawn. Even in cases in which the drug is absolutely targeted as the cause, viral hepatitis may be a complication.[51,52,53,54]

ASSESSMENT: SEVERITY OF THE MEDICATION RELATED PROBLEM

Serum bilirubin concentration is a sensitive indicator of most hepatic lesions and has significant prognostic value. [5] High peak bilirubin concentrations are associated with poor survival (Table e38-3). Other important findings that indicate poor survival are a peak prothrombin time greater than 40 seconds, elevated serum creatinine, and low arterial pH. The presence of encephalopathy or prolonged jaundice are not good signs for the survival of the patient and are strong indicators for transplantation.[62]

TABLE e38-3 Patterns of Enzyme Elevation in Liver Injury. R = (Measured ALT/Upper Normal Limit of ALT) ÷ (Measured Alk Phos/Upper Normal Limit of Alk Phos)

Enzyme		Hepatocellular	Cholestatic	Mixed Injury	Chronic
R-Values		5	2	3-4	—
Alkaline phosphatase	Alk Phos	↑	↑↑↑	↑↑↑	↑
5′-Nucleotidase	5-NC, 5NC	↑	↑↑↑	↑↑↑	↑
γ-Glutamyltransferase	GGT, GGTP	↑	↑↑↑	↑↑↑	↑↑
Aspartate aminotransferase	AST	↑↑↑	↑	↑↑↑	↑↑
Alanine aminotransferase	ALT	↑↑↑	↑	↑↑↑	↑↑

Enzyme		Hepatocellular	Cholestatic	Mixed Injury	Chronic
Lactate dehydrogenase	LDH	↑↑↑	↑	↑↑↑	↑

↑, <100% of normal; ↑↑, >100% of normal; ↑↑↑, >300% of normal.

Bilirubin concentrations and serum enzyme elevations give a static picture of the liver's condition and are not good indicators of hepatic function. Clinically available tests to predict hepatic function include measurement of serum proteins (albumin or transferrin). As a hepatic function decreases, serum protein concentrations in the body decrease at a rate determined by each protein's own elimination rate. Overhydration and starvation can also decrease serum protein concentrations. Albumin levels less than 2.8 g/dL (less than 28 g/L) where associated with significant mortality following the onset of DILD. The same study of 78 subjects with DILD (76% with hepatocellular disease) also noted that low levels of the interleukins, IL-9, IL-17; platelet-derived growth factor-bb and chemokine ligand 5 were also significantly associated with mortality.[63]

Changes in the prothrombin time as reported as the international normalized ratio (INR) often occur earlier than the changes in albumin or transferrin. It is a good predictor of liver function in acute liver failure.[64] The response of the INR to the administration of 10 mg of parenteral vitamin K has been used to differentiate between hepatic and extrahepatic disease.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ALT	Alanine Aminotransferase
ANA	antinuclear antibodies
ASMA	antismooth muscle antibodies
AST	Aspartate Aminotransferase
CYP450	Cytochrome P450 liver enzyme family
CYP2C9 or 2C9	CYP450 subspecies 2C9, >50 SNP identified*
CYP2C19 or 2C19	CYP450 subspecies 2C19, ≥8 SNP identified
CYP2D6 or 2D6	CYP450 subspecies 2D6, ≥5 SNP identified
CYP3A4 or 3A4	CYP450 subspecies 3A4, highly conserved less SNP affect*
CYP4F8 or 4F8	CYP450 subspecies 4F8, fatty acid metabolism
DILD	drug-induced liver disease
GGTP	gama-glutamyltransferase
IL-9	Interleukin–9, prevents apoptosis
IL-19	Interleukin–19, induces apoptosis
INR	International Normalized Ratio
LDH	lactic dehydrogenase

LKM-1	liver kidney microsomal auto-antibodies
miR-122	Circulating Micro-RNA–number 122
MDMA	Methylenedioxymethamphetamine
NAFLD	Nonalcoholic Fatty Liver Disease
NAPQI	*N*-Acetyl-*P*-benzoquinone Imine
NASH	Nonalcoholic Steatohepatitis
NAT2	*N*-Acetyltransferase 2 Genotype
SNP	Single Nucleotide Polymorphism
TBL	total bilirubin
TNF	Tumor Necrosis Factor
UNL	Upper Normal Limit for this laboratory test

*CYP 2C9 and 3A4 are the most common enzymes that metabolize.

"foreign" substrates in the liver—ie, drugs.

Chapter 39: Pancreatitis

Scott Bolesta; Patricia A. Montgomery

INTRODUCTION

KEY CONCEPTS

ACUTE PANCREATITIS

- 1 Factors that can contribute to acute pancreatitis should be identified and corrected, including discontinuation of medications that could be potential causes.
- 2 Patients with acute pancreatitis should receive aggressive fluid replacement to reduce the risks of persistent systemic inflammatory response syndrome (SIRS) and organ failure.
- 3 Parenteral opioid analgesics are used to control abdominal pain associated with acute pancreatitis despite a lack of high quality evidence to support the practice.
- 4 Use of prophylactic antibiotics is not recommended in patients with acute pancreatitis without signs or symptoms of infection, including those with necrosis.

CHRONIC PANCREATITIS

- 5 Chronic pain, malabsorption with resultant steatorrhea, and diabetes mellitus are the hallmark symptoms and complications of chronic pancreatitis.
- 6 Pain from chronic pancreatitis may initially be treated with opioid analgesics, but adjuvant agents may be necessary as the disease progresses.
- 7 Reduction in dietary fat intake and pancreatic enzyme supplementation are the primary treatments for malabsorption due to chronic pancreatitis.
- 8 Enteric-coated pancreatic enzyme supplements are the preferred dosage form in the treatment of malabsorption and steatorrhea due to chronic pancreatitis.
- 9 The addition of a histamine$_2$-receptor antagonist or proton pump inhibitor to pancreatic

enzyme supplementation may increase the effectiveness of enzyme therapy for malabsorption and steatorrhea due to chronic pancreatitis.

Pancreatitis is inflammation of the pancreas with variable involvement of regional tissues or remote organ systems.[1,2] Acute pancreatitis is characterized by severe pain in the upper abdomen and elevations of pancreatic enzymes in the blood.[2] In the majority of patients, acute pancreatitis is a self-limiting disease that resolves spontaneously without complications. Approximately 20% of adults with acute pancreatitis have a severe course.[1,2] Severe pancreatitis with either organ failure or infected necrosis is associated with a mortality of approximately 30% and it increases when both are present.[3] The risk for progression to chronic pancreatitis after an initial episode of acute pancreatitis is related to the etiology. Patients with acute pancreatitis due to gallstone disease have little risk for progression to chronic disease whereas patients with alcohol-related acute pancreatitis have a risk of 14% to 41% based on whether or not they continue to consume alcohol.[4]

Chronic pancreatitis is characterized by long-standing inflammation that eventually leads to a loss of pancreatic exocrine and endocrine functions.[5,6,7] It is a progressive disease that often goes unnoticed for many years. The usual initial presentation is complaints of chronic abdominal pain. Later in the disease process malabsorption with resultant steatorrhea occurs. This leads to malnutrition and weight loss. Finally, patients develop diabetes mellitus due to a loss of pancreatic endocrine function.[5,6]

EPIDEMIOLOGY

Acute pancreatitis is the most common gastrointestinal disorder causing hospitalization in the United States with admission rates of approximately 13 to 45 per 100,000 per year.[4,8] The risk for acute pancreatitis varies widely with geographic, etiologic (eg, alcohol consumption and smoking), environmental, and genetic factors. The incidence of acute pancreatitis has increased in the United States, which is likely related to an increase in obesity.[4] The annual incidence of chronic pancreatitis in the United States is 5 to 14 per 100,000, and the prevalence is 50 per 100,000.[7] The prevalence increases with age, with an average onset at 62 years, and it is 4.5 times more common in males than females.[7] Also, the prevalence of chronic pancreatitis varies widely based on geographic location.[5,6] There is also racial disparity with the disease, with African-Americans having 2 to 3 times the risk than Caucasians, and being more than twice as likely to be hospitalized.[7]

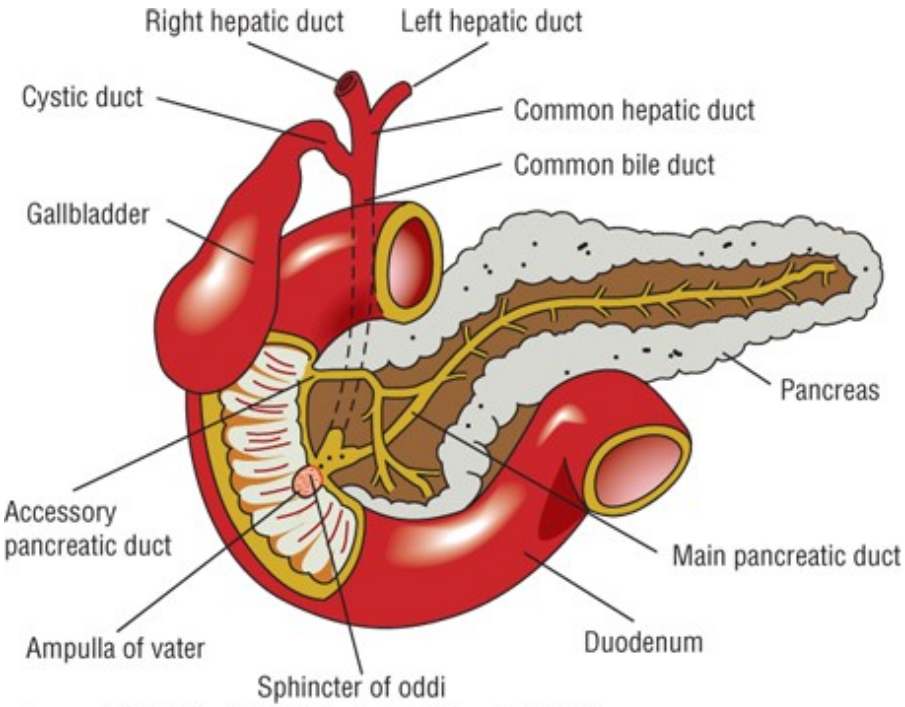
PANCREATIC EXOCRINE PHYSIOLOGY

The pancreas possesses both endocrine and exocrine functions. The islets of Langerhans, which contain the cells of the endocrine pancreas, secrete insulin, glucagon, somatostatin, and other polypeptide hormones. The exocrine pancreas is composed of acini and ductules that secrete about 2.5 L/day of isotonic fluid that contains water, electrolytes, and pancreatic enzymes necessary for digestion. Bicarbonate and other electrolytes are secreted primarily by the centroacinar (ductular) cells in order to neutralize gastric acid. Pancreatic juice is delivered to the duodenum via the

pancreatic ducts (**Fig. 39-1**) where the alkaline secretion neutralizes gastric acid and provides an appropriate pH for maintaining the activity of pancreatic enzymes.[9]

FIGURE 39-1

Anatomic structure of the pancreas and biliary tract.



The major pancreatic exocrine enzyme groups are as follows:

1. Amylolytic: amylase
2. Lipolytic: lipase, procolipase, prophospholipase A_2, and carboxylesterase
3. Proteolytic: trypsinogen, chymotrypsinogen, procarboxypeptidase, and proelastase
4. Nucleolytic: ribonuclease and deoxyribonuclease
5. Other: trypsin inhibitor

Amylase is responsible for digestion of starches and glycogen through hydrolysis. The lipolytic enzymes break down triglycerides, cholesterol, and other fats in the digestive tract. Specifically, lipase hydrolyzes triglycerides into fatty acids and monoglycerides. Colipase and bile acids facilitate this process by allowing lipase to act on the hydrophobic surface of fat droplets in the mainly hydrophilic environment. Phospholipase A_2 and carboxylesterase continue to break down fatty acids, cholesterol, monoglycerides, and other products of fat digestion. Proteolytic enzymes digest proteins into oligopeptides and free amino acids, while nucleases break down nucleic acids.[9]

The production of proteolytic enzymes in the pancreas occurs in a manner that prevents self-digestion of the pancreas. These enzymes are synthesized within the acinar cells, stored in vacuoles, and secreted into the duodenum as zymogens (inactive enzymes). Enterokinase secreted by the duodenal mucosa converts trypsinogen to trypsin, which then activates all other proteolytic zymogens along with procolipase and prophospholipase A_2. Thus, two important mechanisms protect the pancreas from the potential degradative action of its own digestive enzymes. First, the synthesis of proteolytic enzymes as zymogens requires extrapancreatic activation by trypsin. Second, pancreatic juice contains a low concentration of trypsin inhibitor, which inactivates any autocatalytically formed trypsin within the pancreas. Proteolytic activity of trypsin in the intestinal lumen is not inhibited because the concentration of trypsin inhibitor is minimal. Lipase, amylase, ribonuclease, and deoxyribonuclease are secreted by the acinar cells in their active form.[9]

The regulation of exocrine pancreatic secretion is a complex interplay of neurohormonal feedback with three distinct phases. The first phase is the cephalic phase where the sight, smell, and taste of food produce pancreatic enzyme secretion through stimulus of the vagus nerve. Vasoactive intestinal peptide (VIP) and gastrin-releasing peptide (GRP) released from efferent vagus nerve terminals bind to receptors on the acinar cells stimulating enzyme release.[9] Water and bicarbonate are also released from ductal cells due to VIP stimulation. The gastric phase occurs due to gastric distension from food entering the stomach. This results primarily in secretion of digestive enzymes from the pancreas. Once chyme enters the duodenum, the intestinal phase begins. The chyme causes secretin to be released from the duodenal mucosa when its pH is less than 4.5. Secretin results in water and bicarbonate secretion from the pancreas to increase intestinal pH for stable lipolytic enzyme activity. Digestive enzymes are released from the pancreas due to the presence of fatty acids, peptides, amino acids, and glucose in the duodenum.[9]

The feedback mechanism for continued release of pancreatic enzymes involves the hormone cholecystokinin (CCK). When products of fat, protein, and starch digestion enter the upper small intestine, they stimulate release of CCK from I cells into the blood. Elevated levels of CCK in the serum activate a vasovagal reflex causing further release of VIP and GRP, leading to enhanced pancreatic enzyme secretion. Inhibition of this feedback loop is thought to be due to trypsin. After digestion is complete, unoccupied trypsin is thought to inhibit the release of CCK.[9] A more in-depth discussion of pancreatic physiology can be found elsewhere.[9]

ACUTE PANCREATITIS

Acute pancreatitis may be mild or may be associated with complications including organ failure and pancreatic necrosis. Prognosis and management vary according to the severity of the disease. There are several classification systems for acute pancreatitis that can be used to predict disease severity and outcomes. Some of these systems predict outcomes, but none have demonstrated superiority to the other.[10] In addition, it is not clear how management should change based on classification of severity.

Etiology

Table 39-1 lists the etiologic risk factors associated with acute pancreatitis. Obstruction caused by gallstones is the most common cause of acute pancreatitis in the United States, with alcohol abuse being the second most common. Abdominal obesity increases the risk for both gallstone- and non-gallstone-related acute pancreatitis. Moderate elevations in lipid levels are associated with non-alcohol related pancreatitis.[11] There is also an autoimmune form of pancreatitis.[12] Diabetes mellitus is also associated with an increase in acute pancreatitis as are autoimmune disorders such as inflammatory bowel disease.[4,13] Most remaining cases are classified as idiopathic.[2] Acute pancreatitis can occur as a result from undergoing an endoscopic retrograde cholangiopancreatography (ERCP) procedure and is more common following therapeutic ERCP than diagnostic, with overall rates up to 5.4%. Pregnancy is not considered a cause of acute pancreatitis; however, pregnant women develop pancreatitis as a result of a coincident process, most commonly cholelithiasis.[14] The reported incidence of acute pancreatitis in children has increased in recent years, and the common etiologies are biliary disease, medications, idiopathic, systemic disease, and trauma.[15]

TABLE 39-1 Etiologic Risk Factors Associated with Acute Pancreatitis

Structural	Gallstone disease, sphincter of Oddi dysfunction, pancreas divisum, pancreatic tumors
Toxins	Alcohol (ethanol) consumption, scorpion bite, organophosphate insecticides
Infectious	Bacterial, viral (including HIV and H1N1 influenza), parasitic
Metabolic	Hypertriglyceridemia, chronic hypercalcemia
Genetic	Cystic fibrosis, α_1-antitrypsin deficiency, hereditary (trypsinogen gene mutations)
Medications	See Table 39-2 for specific drugs
Iatrogenic	Abdominal surgery, ERCP
Kidney disease	Chronic kidney disease, dialysis-related
Trauma	Blunt abdominal trauma
Vascular	Vasculitis, atherosclerosis, cholesterol emboli, coronary artery bypass surgery
Other etiologies	Congenital, Crohn's disease, autoimmune, tropical, solid organ transplantation (eg, liver, kidney, heart), refeeding syndrome
Idiopathic	Undetermined cause

HIV, human immunodeficiency virus; ERCP, endoscopic retrograde cholangiopancreatography.

Data from references 15, 16, 31, and 33, 34, 35.

Medications

1 Factors that can contribute to acute pancreatitis should be identified and corrected, including discontinuation of medications that could be potential causes. Drug-induced acute pancreatitis should be considered when other causes have been excluded and there is a temporal relationship with the initiation of a medication that has been implicated as a cause. Most experts consider drug-induced pancreatitis to be rare. Published reports have reported 5.3% to 12.5% of hospital

admissions for acute pancreatitis may be drug-induced.[17,18] However, it is possible that the difficulty in diagnosing drug-induced pancreatitis has led to an underestimation of the rate.[17,18] Most information on drug-induced acute pancreatitis is obtained from case reports, which do not provide reliable information on incidence. The most convincing case reports involve recurrence on rechallenge; however, rechallenge is rare, occurring only when alternative therapy is not available. Further complicating the evaluation of some reports is use of medications associated with pancreatitis in patient populations with an increased risk of pancreatitis.[19] Adverse events attributed to newly introduced medications may be reported more frequently.[20]

Many medications have been frequently reported to cause acute pancreatitis. There is a higher incidence of drug-induced acute pancreatitis in the United States in patients with human immunodeficiency virus (HIV) treated with antiretroviral therapy.[21] However, there was no increase in acute pancreatitis associated with antiretroviral use in a well-controlled trial including data from 33,742 person-years.[22] Pancreatitis due to azathioprine is reported more frequently in patients with Crohn's disease than patients taking the medication for other indications, suggesting an interaction between the disease and medication. Patients with Crohn's disease often take other medications that can cause pancreatitis, including 5-aminosalycilates, corticosteroids and sulfasalazine.[23] Patients with type 2 diabetes mellitus have an increased risk of acute pancreatitis. Case reports and some observational studies have linked antihyperglycemic agents, including metformin, sulfonylureas, and incretin mimetics, with pancreatitis. However, a meta-analysis did not find an increase in pancreatitis with incretin mimetics (such as exenatide and sitagliptin) compared to sulfonylureas, metformin or insulin.[24] Complicating comparisons between agents used to treat diabetes mellitus is that the medications are often used in obese patients and patients with different durations of disease, both of which may also influence disease-associated pancreatitis.[25,26]

There are numerous case reports of apparent drug-induced pancreatitis with statins. In contrast, a meta-analysis of lipid-lowering therapies found that statins were associated with a decreased number of acute pancreatitis cases.[27] However, pancreatitis was not a stated end point of any of the trials included and the issue remains controversial.

The onset of drug-induced pancreatitis after initiation of medications ranges from a few months to several years, with a median of 5 weeks; onset after rechallenge can occur within hours. The onset may differ according to the mechanism. Clinicians should be especially suspicious of a drug as a cause of acute pancreatitis in high-risk patients, such as those receiving immunomodulating drugs or who have HIV infection, the elderly, or those with diabetes mellitus.[28]

Mechanisms of drug-induced pancreatitis have been proposed for some medications but remain poorly defined. Possible mechanisms include direct toxic effects of the drug or its metabolites, hypersensitivity, drug-induced hypertriglyceridemia, and alterations of cellular function in the pancreas and pancreatic duct.[29] Ultimately, drug-induced pancreatitis causes damage to the pancreas, which produces a response similar to other causes of pancreatitis. It is prudent to withdraw a medication when an association is suspected.

Numerous drugs are believed to cause acute pancreatitis, but ethical and practical considerations

prevent rechallenge with suspected agents. **Table 39-2** lists specific agents associated with acute pancreatitis. Classification schemes consider factors such a case reports that include rechallenge, the number of case reports, consistency with respect to onset of symptoms following initiation of the suspect medication, and exclusion of other causes. Other classification systems have been developed that consider factors such as consistency in the temporal relationship.[30]

TABLE 39-2 Medications Associated with Acute Pancreatitis

Well-supported Association	Probable Association	Possible Association	
5-Aminosalicylic acid	Acetaminophen	Aldesleukin	Indinavir
Asparaginase	Atorvastatin	Amiodarone	Indomethacin
Azathioprine	Hydrochlorothiazide	Atorvastatin	Infliximab
Bortezomib	Ifosfamide	Asparaginase	Ketoprofen
Carbamazepine	Interferon α_{2b}	Calcium	Ketorolac
Cimetidine	Maprotiline	Ceftriaxone	Lipid emulsion
Corticosteroids	Methyldopa	Capecitabine	Liraglutide
Cisplatin	Oxaliplatin	Carboplatin	Lisinopril
Cytarabine	Simvastatin	Celecoxib	Mefenamic acid
Didanosine		Clozapine	Metformin
Enalapril		Cholestyramine	Metolazone
Erythromycin		Ciprofloxacin	Metronidazole
Estrogens		Clarithromycin	Nitrofurantoin
Furosemide		Clonidine	Omeprazole
Hydrochlorothiazide		Cyclosporine	Ondansetron
Mercaptopurine		Danazol	Paclitaxel
Mesalamine		Diazoxide	Pravastatin
Octreotide		Etanercept	Propofol
Olsalazine		Ethacrynic acid	Propoxyphene
Opiates		Exenatide	Rifampin
Pentamidine		Famciclovir	Sertraline
Pentavalent antimonials		Glyburide	Sitagliptin
Sulfasalazine		Gold therapy	Sorafenib
Sulfamethoxazole and trimethoprim		Granisetron	Sulindac
Sulindac		Ibuprofen	Zalcitabine
Tamoxifen		Imatinib	
Tetracyclines			
Valproic acid/salts

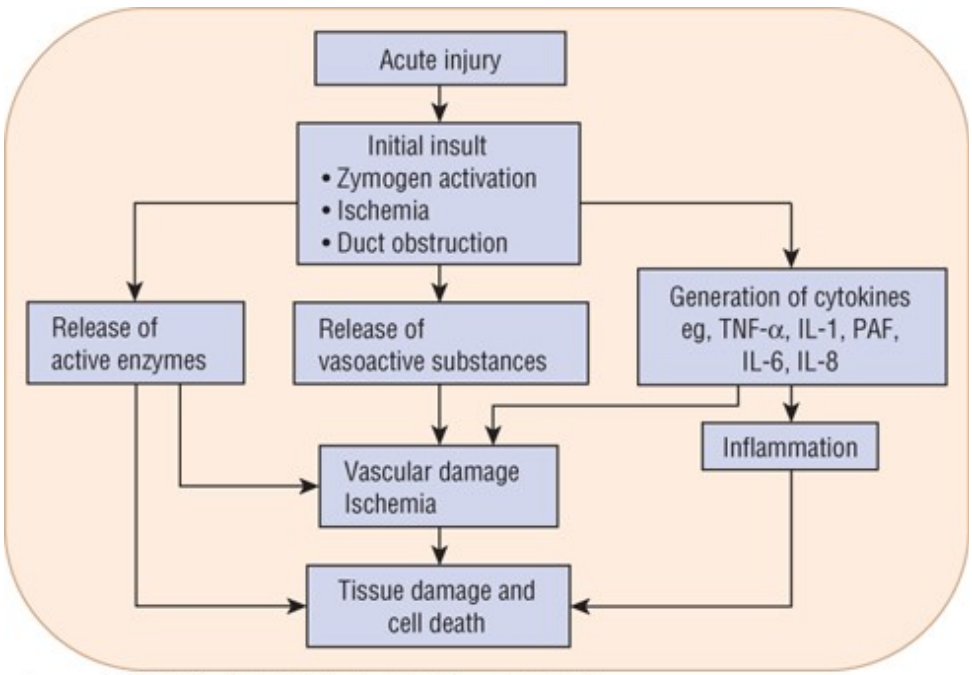
Pathophysiology

The pathophysiology of acute pancreatitis is based on events that initiate injury and secondary events that establish and perpetuate the injury (**Fig. 39-2**). Gallstones, alcohol abuse, and other causes of pancreatitis produce different initial insults to the pancreas. However, the resulting pathophysiologic process may be similar and include a combination of autodigestion and inflammatory response. In acinar cells, the separation of zymogens and lysosomes can be disrupted, resulting in exposure of trypsinogen to lysosomal enzymes such as cathepsin B. The premature activation of trypsinogen to trypsin within the pancreas leads to activation of other digestive enzymes and autodigestion of the gland.[2]

FIGURE 39-2

Pathophysiology of acute pancreatitis: initiating and secondary events. (IL-1β, interleukin-1β; IL-6, interleukin-6; IL-8, interleukin-8; PAF, platelet-activating factor; TNF-α, tumor necrosis factor-α.)



In addition to activation of digestive enzymes within the pancrease, enzymes are also released into surrounding fat, vascular endothelium and other surrounding tissues and structures causing further damage and necrosis. Lipase damages fat cells, producing noxious substances that cause further pancreatic and peripancreatic injury. There may be an independent response from intra-acinar activation of inflammatory factors. The release of cytokines by acinar cells directly causes their injury and enhances the inflammatory response.[31] Injured acinar cells liberate chemoattractants that recruit neutrophils, macrophages, and other cells to the area of inflammation. These immune responses cause a systemic inflammatory response syndrome (SIRS). Vascular damage and ischemia causes the release of kinins, which makes capillary walls permeable and promotes tissue edema. The release of

damaging oxygen-free radicals appears to correlate with the severity of pancreatic injury.[32] Finally, pancreatic infection may result from increased intestinal permeability and translocation of colonic bacteria.[33]

Clinical Presentation

Signs and Symptoms

The clinical presentation of acute pancreatitis varies depending on the severity of the inflammatory process and whether damage is confined to the pancreas or involves local and systemic complications (**Table 39-3**).[34]

TABLE 39-3 Presentation and Diagnosis of Acute Pancreatitis

General

- The patient may have acute mild symptoms or present with a severe acute attack with life-threatening complications.

Symptoms

- The patient may present initially with moderate abdominal discomfort to excruciating pain, nausea, shock, and respiratory distress.
- Abdominal pain occurs in 95% of patients. The pain is usually epigastric and radiates to either of the upper quadrants or the back in two thirds of patients. In gallstone pancreatitis, the pain is typically sudden and quite severe and the intensity is often described as "knife-like" or "boring." The pain usually reaches its maximum intensity within 30 minutes and may persist for hours or days. Repositioning the patient relieves very little of the pain. In alcohol abuse and other cases, the onset of pain may be less abrupt and poorly localized. Pain may not be the dominant symptom if it is masked by multiorgan failure.
- Nausea and vomiting occur in 85% of patients and usually follow the onset of abdominal pain. Vomiting does not provide relief of the abdominal pain.

Signs

- Marked epigastric or diffuse tenderness on palpation with rebound tenderness and guarding in severe cases. The abdomen is often distended and tympanic, with bowel sounds decreased or absent in severe disease.
- Vital signs may be normal, but hypotension, tachycardia, and low-grade fever are often observed, especially with widespread pancreatic inflammation and necrosis.
- Dyspnea and tachypnea are often signs of acute respiratory complications. Jaundice and altered mental status may be present and have multiple causes. Other signs of alcoholic liver disease may be present in patients with alcoholic pancreatitis.

APACHE, Acute Physiology and Chronic Health Evaluation; CECT, contrast-enhanced computed tomography; CT, computed tomography.

Data from reference 36.

Diagnosis

The diagnosis of acute pancreatitis requires two of the following three: upper abdominal pain, a serum lipase or amylase concentration at least three times greater than the upper limit of normal, or characteristic findings on imaging studies.[35,36] Lipase is more sensitive and specific than amylase and is the preferred laboratory test. Imaging studies are not necessary for diagnosis if the other two findings are positive. Contrast-enhanced computed tomography (CECT) of the abdomen may be used to confirm the diagnosis in patients with amylase or lipase that is not three times the upper limit of normal, or in sedated patients. The diagnosis of acute pancreatitis should also be considered when evaluating patients with SIRS (see Table 39-3).[36] For further information on laboratory tests and abdominal imaging, refer to Table 39-3. Pertinent history includes previous history of pancreatitis, gallstone disease, alcohol use, medication use, recent surgery or ERCP, hyperlipidemia, and family history. Magnetic resonance cholangiopancreatography (MRCP) is useful for detecting retained common bile duct stones. Laboratory tests should include liver enzymes, triglycerides and calcium. Transabdominal ultrasound of the right upper quadrant is recommended to assess for gallstones.[35,36]

Prediction of severity of acute pancreatitis is useful for decisions involving the need for aggressive treatment, including admission to an intensive care unit. The risk for severe acute pancreatitis should be assessed on admission and on an ongoing basis.[37] Several scoring systems have been developed to assess the likelihood of severe disease.

Multiple scoring systems have been used to predict which patients with acute pancreatitis are at greatest risk for persistent organ failure.[38] This would be useful in determining aggressiveness of initial therapy as well as in developing clinical trials of interventions. However, development and validation of such systems remain an ongoing area of research. Scoring systems are developed based on retrospectively identified associations between clinical and laboratory findings and morbidity and mortality.[1,39] Many are too complicated for bedside use or rely on measurements that are not widely available. Some scoring systems have not been validated in prospective trials or have poor predictive ability.[38]

Ranson's criteria assesses 11 variables that must be monitored at the time of admission and during the initial 48 hours of hospitalization.[32] Severe acute pancreatitis is characterized by three or more criteria. Two separate groups have released recommendations for new classifications. The revised Atlanta Classification defines acute pancreatitis as mild disease (not associated with organ failure, local complications or systemic complications), moderately severe (transient organ failure, local complications or systemic complications) and severe (persistent organ failure).[40] In contrast, an international multidisciplinary group proposed using factors that have a causal association with severity (ie, distant organ failure or pancreatic necrosis) rather than events that may be associated with severity.[41] This determinant-based classification includes mild (no organ dysfunction or

necrosis), moderate (sterile necrosis or transient organ dysfunction or both), severe (either infected necrosis or persistent organ dysfunction) and critical (infected necrosis and persistent organ dysfunction). The Acute Physiology and Chronic Health Evaluation II (APACHE II) system is a sensitive predictor of persistent organ failure in patients with acute pancreatitis; however, it is less specific than some scoring systems that were developed for acute pancreatitis.[42] Other tools for assessing the severity of acute pancreatitis include the Bedside Index of Severity in Acute Pancreatitis (BISAP), the Harmless Acute Pancreatitis Score (HAPS), and the Japanese Severity Score (JSS).

The accuracy of several scoring systems was assessed and none had consistent superiority to the others.[38] The IAP/APA guidelines recommend evaluation based on SIRS criteria.[36] Advantages of using SIRS criteria include ease of use and the widespread adoption of processes to ensure that it is routinely assessed.

Clinical Course and Prognosis

The clinical course of acute pancreatitis varies from a mild transitory disorder to a severe necrotizing disease. Mild acute pancreatitis is self-limiting and subsides spontaneously within 3 to 5 days. Mortality is influenced by etiology, as idiopathic and postoperative acute pancreatitis have higher rates than gallstone- or alcohol-related disease. First and second occurrences also carry a higher mortality than subsequent episodes. Mortality increases with unfavorable early prognostic signs, local complications, and organ failure. Persistent organ failure is a greater risk than transient organ failure.[3] Severe pancreatitis with either organ failure or infected necrosis is associated with a mortality of approximately 30%, and increases when both are present.[3] Death during the first few days results from SIRS and multiorgan failure. When death occurs after this period, it is usually a result of infected necrosis, pancreatic abscess, and sepsis.[35,36,43]

Complications

Early complications are a result of SIRS and organ failure. The most common systemic complication of acute pancreatitis is respiratory failure.[40] In addition, patients may experience systemic complications due to exacerbation of pre-existing renal, lung or heart disease.[40] A second phase occurs in patients with moderately severe or severe disease. These patients have persistent organ failure and may have local complication including fluid collections that may become necrotic.[40] Long-term complications include glucose intolerance and recurrence of acute pancreatitis.[44,45]

There are also local complications that may occur, including interstitial pancreatitis (acute peripancreatic fluid collection and pancreatic pseudocysts) and collection of necrosis. These develop approximately 3 to 4 weeks after the initial attack. Pancreatic infections occur in 15% to 30% of those with pancreatic necrosis and are usually secondary infections of necrotic tissue.[34]

TREATMENT

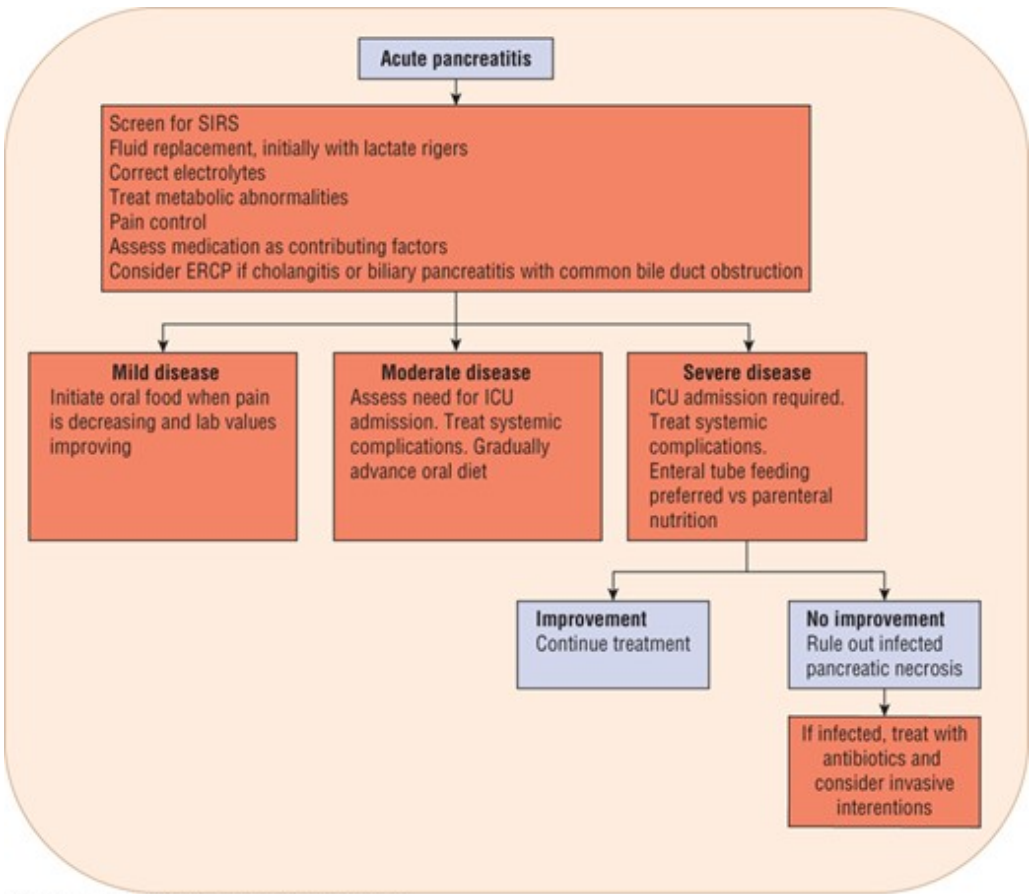
Acute Pancreatitis

Desired Outcome

Treatment of acute pancreatitis is aimed at relieving abdominal pain and nausea, replacing fluids, correcting electrolyte, glucose, and lipid abnormalities, minimizing systemic complications, and managing pancreatic necrosis and infection. Management varies depending on the severity of the attack (**Fig. 39-3**). Patients with mild acute pancreatitis respond very well to the initiation of supportive care. Patients with severe acute pancreatitis should be treated aggressively and monitored closely.

FIGURE 39-3

Algorithm of guidelines for evaluation and treatment of acute pancreatitis. (SIRS, systemic inflammatory response syndrome; ERCP, endoscopic retrograde cholangiopancreatography; ICU, intensive care unit.)



General Approach to Treatment

All patients with acute pancreatitis should receive supportive care, including IV fluid resuscitation, adequate nutrition, and effective relief of pain and nausea. Patients should be evaluated for admission to the intensive care unit. Patients predicted to follow a severe course may require treatment of systemic complications.[1] Fluid therapy is recommended and may help prevent organ

failure.[36,46,47,48,49,50,51,52] Patients with pancreatitis and SIRS should be treated according to SIRS guidelines. IV potassium, calcium, and magnesium are used to correct electrolyte deficiency states. Insulin is used to treat hyperglycemia. Local complications resolve as the inflammatory process subsides. However, patients with necrotizing pancreatitis may require antibiotics and procedural intervention.[36,53] Medications listed in Table 39-2 should be discontinued if possible.

Nonpharmacologic Therapy

Nonpharmacologic therapy includes ERCP for removal of any underlying biliary tract stones, procedural interventions, and nutritional support. The need for admission to an intensive care unit should be addressed. Advances in minimally invasive surgical techniques are changing practice with respect to timing and approach to managing infected necrotizing pancreatitis, and may help lower the risk of mortality in the most critical patients.[37,53]

Nutrition and Probiotics

Nutritional support plays an important role in the management of patients with mild or severe disease as acute pancreatitis creates a catabolic state that promotes nutritional depletion. This can impair recovery, increase the risk of complications, and prolong hospitalization.[54] Patients with mild acute pancreatitis can begin oral feeding when pain is decreasing an inflammatory markers are improving. It is not necessary to withhold oral nutrition until lipase normalizes.[55] In severe or complicated disease, nutritional deficits develop rapidly and are complicated by tissue necrosis, organ failure, and surgery. Nutritional support should begin when it is anticipated that oral nutrition will be withheld for more than 1 week.[54] In the past, there was concern that enteral feeding stimulated pancreatic enzyme secretion and exacerbated the underlying disease. However, randomized controlled trials found that enteral nutrition results in a decrease in morality, multiple organ failure, and need for surgical intervention compared with parenteral nutrition.[54] Possible mechanisms for this include protection of the gut barrier and prevention of colonization with pathogenic bacteria, both of which may prevent translocation of bacteria and subsequent infection.[37] Therefore, enteral nutrition delivered via a nasogastric or nasojejunal tube is preferred over parenteral nutrition in patients with severe acute pancreatitis provided it can be tolerated. If enteral feeding is not possible or if the patient is unable to obtain sufficient nutrients, total parenteral nutrition should be implemented before protein and calorie depletion become advanced. ASPEN guidelines state that IV lipids are considered safe unless the serum triglyceride concentration is greater than 400 mg/dL (4.52 mmol/L) and the patient has a history of hyperlipidemia.[56]

Clinical trials do not support the use of probiotics in the treatment of acute pancreatitis, as they have not shown a benefit. One prospective randomized trial in patients with predicted severe acute pancreatitis showed an increase in mortality with probiotics compared with placebo.[57]

Pharmacologic Therapy

Patients with acute pancreatitis often require IV antiemetics for nausea. Those requiring ICU

admission should be treated with antisecretory agents (such as famotidine or pantoprazole) if they are at risk of stress-related mucosal bleeding. Patients also require appropriate fluid resuscitation and pain management, but there is controversy surrounding both of these therapies. (see Fig. 39-3). Clinical trials have also failed to identify a group of patients that benefit from prophylactic antibiotics.

Fluid Resuscitation

Vasodilation from the inflammatory response, vomiting, and nasogastric suction contributes to hypovolemia and fluid and electrolyte abnormalities, thus necessitating replacement. Patients with acute pancreatitis should receive aggressive fluid replacement to reduce the risks of persistent SIRS and organ failure. The IAP/APA guidelines recommend goal directed intravenous fluid with lactated Ringer's at an initial rate of 5 to 10 mL/kg/h while the ACG guidelines recommend 250 to 500 mL/h with crystalloids. Goals for fluid therapy are one or more of the following: heart rate less than 120/min, mean arterial pressure 65 to 85 mm Hg, urinary output greater than 0.5 to 1 mL/kg/h, invasive measures of stroke volume or intrathoracic blood volume, or hematocrit 35% to 44% (0.35-0.44) with transfusion of blood.[35,36]

Observational studies have identified both benefit (decreased mortality and organ failure) and harm (abdominal compartment syndrome) associated with early aggressive fluid administration. Most studies have compared standard therapy with aggressive fluid therapy over the first 24 hours retrospectively. One trial found that administration during the first 24 hours of at least one third the cumulative volume given over the first 72 hours was associated with a decrease in mortality.[47] A similar trial found a decrease in SIRS, organ failure at 72 hours, and length of stay in patients who received more fluid during the first 24-hour period than subsequent 24-hour periods.[51] In contrast, another study found that patients who received more than 3.1 L of fluid during the first 24 hours had higher rates of persistent organ failure, respiratory failure, and renal failure than those who received smaller volumes.[46] In a prospective, randomized trial, goal-directed fluid replacement therapy of 3 mL/kg/h for the first 20 hours did not result in a reduction in SIRS or C-reactive protein (CRP).[52] Replacement at rates of 10 to 15 mL/kg/h was associated with more abdominal compartment syndrome, mechanical ventilation, and sepsis in the first 2 weeks following presentation than standard therapy in another trial.[48]

Interpretation of these trials is complicated by the likelihood that sicker patients were given larger volumes of fluid. Studies of fluid resuscitation in acute pancreatitis suggest that some patients may not require aggressive fluid resuscitation, while others may require gradual fluid administration. For example, those with reduced cardiac reserve may do better if fluid is replaced over 72 hours rather than 24 to 48 hours.[50]

In addition to questions about the rate and volume of fluid that should be administered to patients with acute pancreatitis, there is also debate regarding which fluid is most appropriate. A small randomized trial found that goal-directed resuscitation with lactated Ringer's produced a reduction in SIRS and CRP at 24 hours compared with normal saline.[52] The study protocol used aggressive replacement with a bolus of 20 mL/kg of lactated Ringer's followed by 150 to 300 mL/h for the first

24 hours. If patients responded to this therapy as assessed by BUN, the rate could be reduced to 2 mL/kg/h. Patients with SIRS or sepsis should be resuscitated according to sepsis guidelines.[49]

Relief of Abdominal Pain

Parenteral opioid analgesics are used to control abdominal pain associated with acute pancreatitis despite a lack of high quality evidence to support the practice 3. A Cochrane review found a lack of studies to support any specific agent or class of agents for pain management in acute pancreatitis.[58]

Parenteral morphine is often recommended for pain control because it provides a longer duration of pain relief than other opioids. Although morphine increases biliary pressure, there is no evidence to indicate that it is contraindicated for use in acute pancreatitis. Patient-controlled analgesia should be considered in patients who require frequent opioid dosing (eg, every 2-3 hours).

Limitation of Systemic Complications and Prevention of Pancreatic Necrosis

There is currently no specific therapy to prevent the complications and necorosis associated with acute pancreatitis. The use of parenteral histamine^2-receptor antagonists or proton pump inhibitors does not improve the overall outcome of patients with acute pancreatitis.[34] Also, although somatostatin and its synthetic analog octreotide have been used to interrupt the inflammatory process of acute pancreatitis, there are insufficient data to support their routine use, and they are not recommended by guidelines.[35,36]

Antimicrobial use in Acute Pancreatitis

Antimicrobials have been widely studied in patients with acute pancreatitis, but there are still areas of uncertainty. Selective digestive tract decontamination uses oral minimally absorbed antibiotics, including polymyxin E, tobramycin, and amphotericin B, to eradicate intestinal flora, thereby reducing the likelihood of translocation.[59,60] This alternative to systemic antibiotics may be of benefit in reducing the risk of pancreatic infection, but randomized controlled trials in patients with acute pancreatitis are needed to confirm its effectiveness when compared with parenteral antibiotic prophylaxis.[59] The IAP/APA guidelines state that it may be effective but more studies are needed.[36]

Clinical Controversy...

The IAP/APA guidelines give a 2B recommendation (weak recommendation and moderate quality evidence) to the use of gut decontamination based on one randomized controlled trial. Due to many unanswered questions regarding efficacy and development of resistant organisms with this practice, the use of gut decontamination has not been widely implemented in clinical practice. Additional studies are needed before most clinicians begin utilizing it in the treatment of acute pancreatitis.

Several small, randomized clinical trials have compared antibiotic prophylaxis with no prophylaxis in patients with acute necrotizing pancreatitis with varying results. A meta-analysis found that prophylactic antibiotics do not reduce infected necrosis or mortality.[61] In addition, overuse of

antibiotics increases microbial resistance. Use of prophylactic antibiotics is not recommended in patients with acute pancreatitis without signs or symptoms of infection, including those with necrosis 4 .[35,36] However, empiric antimicrobial therapy may be considered in patients with necrosis who deteriorate or fail to improve with in 7 to 10 days.[35]

Because the source of bacterial contamination is most likely the colon, the antibiotic regimen for patients with known or suspected infected pancreatitis should be broad-spectrum, covering the range of enteric aerobic gram-negative bacilli and anaerobic microorganisms. Therapy should be initiated as soon as possible and not delayed in order to obtain cultures.[35,62] Imipenem–cilastatin (500 mg IV every 8 hours) has been widely used because of its good penetration into the pancreas and one positive prophylaxis study.[63] However, it has been replaced on many hospital formularies by one of the newer carbapenems (eg, meropenem). Fluoroquinolones, such as ciprofloxacin or levofloxacin, combined with metronidazole should be considered for penicillin-allergic patients.[64] Patients with infected necrotic pancreatitis are generally treated with a combination of invasive interventions and antibiotics. Antibiotics alone may be sufficient in some cases or at least delay the need for an invasive procedure long enough for the necrotic areas to be walled off.[62,65]

A high mortality associated with candidal infections in severe acute pancreatitis has led investigators to study strategies for identifying patients who might benefit from antifungal prophylaxis.[66] In a series of 479 patients with acute pancreatitis treated at one medical center, the strongest predictor of fungal infection was use of an antibiotic on admission (OR, 1.6; 95% CI, 1.4-1.8).[67] At this point, prophylactic antifungal therapy is not recommended for patients with acute pancreatitis.[35]

PostERCP Pancreatitis

The clinical characteristics of postERCP pancreatitis are similar to those of acute pancreatitis from other causes. In most cases, the disease course is mild and resolves in several days. The incidence of postERCP pancreatitis has decreased over the past 15 years, most likely due to better patient selection. Use of a pancreatic duct stent during the procedure is effective in reducing postERCP pancreatitis.[68] Several classes of medications have been studied for prevention of postERCP pancreatitis. The best data are with non-steroidal anti-inflammatory agents (NSAID).[69] Indomethacin suppositories decreased the incidence of postERCP pancreatitis by 46% in a population at increased risk.[70] This therapy was not associated with an increase in bleeding or renal failure. However, patients at increased risk for adverse effects from NSAIDs were excluded. A posthoc analysis of the data suggested that rectal indomethacin alone could be more cost-effective than use of a stent or stent plus indomethacin.[71]

CHRONIC PANCREATITIS

Chronic pancreatitis results from long-standing pancreatic inflammation resulting in irreversible destruction of pancreatic tissue with fibrin deposition, leading to a loss of exocrine and endocrine functions.[5,6,7] It has four different stages beginning with a preclinical inflammatory stage where

patients remain asymptomatic or have indistinguishable symptoms.[5] In the second stage patients present with acute attacks that often resemble those of acute pancreatitis. The third stage consists of episodes of intermittent or constant abdominal pain. Finally, in the burnout stage patients present with diminished or absent pain, but develop malabsorption syndrome due to loss of pancreatic exocrine function and may develop diabetes mellitus from loss of endocrine function.

Etiology

Chronic alcohol consumption, especially heavy drinking, remains the leading cause of chronic pancreatitis in Western society, accounting for up to two-thirds of cases.[7,72,73] Generally, consumption of greater than or equal to 150 g/day of alcohol for greater than or equal to 15 years poses a significant risk of chronic pancreatitis.[7,73,74] Most of the remaining cases can be classified as idiopathic, while a small percentage of cases are due to rare causes, such as autoimmune, hereditary, and tropical pancreatitis.[6,7] Various genetic alterations have also been associated with the occurrence of chronic pancreatitis, including mutations of the following genes: protease serine 1 (trypsin 1) (*PRSS1*), serine peptidase inhibitor Kazal type 1 (*SPINK1*), and the cystic fibrosis transmembrane conductance regulator (*CFTR*).[6,7,73,74] There is also a demonstrated risk of chronic pancreatitis with cigarette smoking that appears to be dose-dependent and may contribute to mortality from chronic pancreatitis.[6,72,73,75,76] There are two classification systems for chronic pancreatitis that take into account the various risk factors associated with the disease (**Table 39-4**).[73]

TABLE 39-4 Classification of Etiology and Risk Factors for Chronic Pancreatitis

M-ANNHEIM	
Multiple	Risk factors
Alcohol	Excessive consumption (>80 g/day), increased consumption (20-80 g/day), moderate consumption (<20 g/day)
Nicotine	Quantitated in pack years for current smokers
Nutritional factors	High-fat and protein diet, hyperlipidemia (especially hypertriglyceridemia)
Hereditary factors	Hereditary pancreatitis, familial pancreatitis, early and late-onset idiopathic pancreatitis, tropical pancreatitis, possible gene mutations (eg, *PRSS1*, *SPINK1*, and *CFTR*)
Efferent duct factors	Pancreas divisum, annular pancreas/congenital abnormalities, pancreatic duct obstruction (eg, tumors), posttraumatic pancreatic duct scars, sphincter of Oddi dysfunction
Immunologic factors	Autoimmune pancreatitis
Miscellaneous and rare factors	Hypercalcemia and hyperparathyroidism, chronic kidney disease, medications, toxins
TIGAR-O	
Toxic-metabolic	Alcohol, tobacco smoking, hypercalcemia, hyperlipidemia, chronic kidney disease, medications, toxins

Idiopathic	Early onset, late onset, tropical pancreatitis
Genetic mutations	*PRSS1, CFTR, SPINK1*, others
Autoimmune	Isolated, syndromic
Recurrent and severe associated acute pancreatitis	Postnecrotic (severe AP), vascular disease/ischemic, postirradiation
Obstructive	Pancreas divisum, sphincter of Oddi dysfunction, pancreatic duct obstruction (eg, tumor), posttraumatic pancreatic duct scars

PRSS1, cationic trypsinogen; *SPINK1*, serine protease inhibitor Kazal type 1; *CFTR*, cystic fibrosis transmembrane conductance regulator.

Pathophysiology

Although the exact mechanism for the pathogenesis of chronic pancreatitis is unknown, several theories have been proposed. The oxidative stress theory proposes that the pancreas is exposed to by-products of mixed-function oxidases that lead to an inflammatory reaction.[74] Increased activity of hepatic and pancreatic oxidases may be due to increased exposure to substrates (eg, fat), inducers (eg, alcohol), or other substances. A toxic-metabolic theory focuses on alcohol as a primary causative agent where by-products of its metabolism in the pancreas lead to lipid accumulation in acinar cells and eventual fatty degeneration of the pancreas.[74] Ductal obstruction theories state that alcohol leads to obstruction of pancreatic ductals secondary to increased protein deposition and stone formation.[7,73] This leads to scarring of ductal epithelial cells, which potentiates further obstruction and eventually results in acinar atrophy and fibrin deposition. The final major theory suggests that periductular necrosis from repeated episodes of acute pancreatitis eventually leads to ductal obstruction and stone formation with subsequent acinar atrophy and fibrosis.[7,73]

Regardless of the pathophysiologic mechanism, several pieces of evidence now point to activation of pancreatic stellate cells as the cause of fibrin deposition in chronic pancreatitis. Various toxins, oxidative stress, and inflammatory mediators activate pancreatic stellate cells.[7,74,77] As an example, exposure of the pancreas to alcohol and its metabolites leads to the production of various mediators and proinflammatory cytokines, especially tumor necrosis factor-α and interleukin-1 and 6.[77] These then activate pancreatic stellate cells that initiate fibrinogenesis. Other mediators generated by the stellate cells themselves perpetuate continued stellate cell activation.

The pathogenesis of pain in chronic pancreatitis has long been thought to be the result of increased pancreatic parenchymal pressure from obstruction, inflammation, and necrosis.[7] However, evidence increasingly points to a neurogenic origin of pain. There is abnormal pain processing in the central nervous system of patients with chronic pancreatitis, with evidence of functional reorganization of

the insular cortex.[7] Also, visceral nerves in these patients are sensitized. This may explain the hyperalgesia often experienced by these patients, and the need for various methods of pain management. Patients with chronic pancreatitis may also experience pain in areas distant to the pancreas due to impaired inhibition of somatic and visceral pain pathways.

Clinical Presentation

Chronic pain, malabsorption with resultant steatorrhea, and diabetes mellitus are the hallmark symptoms and complications of chronic pancreatitis [5]. Although abdominal pain is the most common symptom at any stage, patients may present with various signs and symptoms depending on the stage of the disease. A more comprehensive list of the common signs and symptoms is presented in **Table 39-5**.

TABLE 39-5 Signs, Symptoms, and Diagnosis of Chronic Pancreatitis

Signs

- Malnutrition (especially in chronic alcoholism)
- Abdominal mass (may indicate a pancreatic pseudocyst)
- Jaundice may be seen
- Splenomegaly (rare)

Symptoms

- Abdominal pain
    - Commonly in epigastric area
    - May radiate to the back
    - Described as deep and penetrating
    - May be relieved by bending/leaning forward or bringing knees to the chest
    - Often occurs with meals and at night
    - May be associated with nausea and vomiting
- Steatorrhea
    - Patients describe bulky or foul-smelling stools often with obvious oil droplets
    - Usually have an average of three to four stools per day
    - May be associated with deficiencies in fat-soluble vitamins

- Watery diarrhea, excess gas, and abdominal cramps are uncommon

- Pancreatic diabetes mellitus
- Diarrhea (associated with steatorrhea)
- Weight loss
  - May be due to severe malabsorption or acute/chronic pain
  - Substantial loss may be due to associated or unrelated malignancy
- Osteoporosis (from vitamin D malabsorption and increased bone resorption)
- Dyspepsia

Laboratory studies

- CBC to rule out infection (ie, infected pseudocyst)
- Serum amylase and lipase
  - Low specificity for chronic pancreatitis
  - May be elevated in acute exacerbations
  - Usually are normal or only slightly elevated
- Total bilirubin, alkaline phosphatase, and hepatic transaminases may be elevated with ductal obstruction
- Fasting serum glucose
- Pancreatic function tests
  - Indirect
    - Serum trypsinogen (<20 ng/mL [or mcg/L] is abnormal)
    - Fecal elastase (<200 mcg/g of stool is abnormal)
    - Fecal chymotrypsin (<3 units/g of stool is abnormal)
    - Fecal fat estimation (>7 g/day is abnormal; need to collect 72 hours of stool)
    - ^{13}C-mixed triglyceride breath test (conducted over 6 hours; not available in United States)
  - Direct

        - Secretin stimulation (evaluates duodenal bicarbonate secretion)
        - Cholecystokinin stimulation (evaluates pancreatic lipase secretion)
- Serum albumin (may be low with malnutrition)
- Serum calcium (may be low with malnutrition)

Imaging studies

- Noninvasive
    - Abdominal ultrasound
    - Computed tomography (CT)
    - Magnetic resonance imaging (MRI) with Magnetic resonance cholangiopancreatography (MRCP)
- Invasive
    - Endoscopic ultrasonography (EUS)
    - Endoscopic retrograde cholangiopancreatography (ERCP)

CBC, complete blood count.

Diagnosis

The diagnosis of chronic pancreatitis is based primarily on presenting signs and symptoms in combination with either imaging or pancreatic function studies (see Table 39-5). Although histology would be the best diagnostic test, it is difficult and risky to perform and is generally not recommended.[74] Therefore, testing usually begins with noninvasive or invasive imaging studies. Abdominal ultrasonography and computed tomography (CT) may be used first, but are limited in their ability to produce detailed imaging of pancreatic ductal abnormalities.[73,78,79,80] Magnetic resonance imaging (MRI) with MRCP produces more detailed images of the pancreatic ducts.[73,78,79] While ERCP is the gold standard invasive study, it is rarely used due to inter- and intra-observer variability and the risk of postERCP pancreatitis, and endoscopic ultrasonography (EUS) is an equivalent alternative.[73,78,79] In addition to imagining studies, pancreatic function tests are used when imagining is inconclusive, as adjunctive diagnostic studies, or to quantify the degree of exocrine insufficiency.[78] The most sensitive studies are the secretin and CCK stimulation tests.[73,78,79] However, these are not widely available and are uncomfortable for patients. Indirect studies of pancreatic function are most sensitive during late chronic pancreatitis.[73]

Clinical Course and Prognosis

The clinical course of chronic pancreatitis depends on the etiology. Exocrine insufficiency occurs when lipase secretion is less than 10% of normal.[5,79] Patients with hereditary chronic pancreatitis typically have exocrine insufficiency occur at an early age, while those with alcohol related disease have exocrine insufficiency occur about 5 years after disease onset, with "burnout" of the pancrease in about 10 years.[79] Patients with early-onset idiopathic chronic pancreatitis have delayed progression to exocrine insufficiency compared to those with alcohol related or late-onset idiopathic disease.[79] Diabetes mellitus occurs later than exocrine insufficiency and has a reported prevalence of 70%.[81]

The life expectancy of patients with chronic pancreatitis is shorter than that of the general population.[4] However, death in patients with chronic pancreatitis most commonly results from other chronic diseases, infection, or malignancy.[4] One of the most significant complications of long-standing disease is pancreatic cancer. Patients with chronic pancreatitis are 13 times as likely as the general population to develop pancreatic cancer.[79] This risk increases depending on the etiology, with smokers having twice the risk.[79]

TREATMENT

Chronic Pancreatitis

Desired Outcome

The major goals in the treatment of uncomplicated chronic pancreatitis are relief of abdominal pain, treatment of any associated complications such as malabsorption and diabetes mellitus, and improvement in quality of life. Secondary goals include delaying development of complications and treating associated disorders such as depression and malnutrition.

General Approach to Treatment

Treatment of chronic pancreatitis and its complications involves various nonpharmacologic and pharmacologic interventions. Lifestyle modifications should include abstinence from alcohol and smoking cessation.[78,79,80,82] In addition, patients with steatorrhea may need to eat smaller, more frequent meals and reduce dietary fat intake.[5,79,83] The majority of patients require analgesics and pancreatic enzyme supplementation.[78,79,80,82] Pain can initially be controlled with medications, but may require more aggressive medical and surgical therapies as the disease progresses. Patients with malabsorption require pancreatic enzymes to reduce steatorrhea and maintain adequate nutrient absorption.[78,79,80] An antisecretory agent may be added to the regimen when enzymes alone provide an inadequate reduction in steatorrhea.[5,7,79,80]

Nonpharmacologic Therapy

In addition to medical management, the treatment of chronic pancreatitis includes both lifestyle and dietary modifications. Patients should be counseled to abstain from alcohol use, and smoking cessation should be advocated. Cessation of alcohol use may reduce pain in patients with alcoholic chronic pancreatitis, and hastens disease progression and reduces the risk of developing pancreatic cancer.[4,5,78,79,80,82] Smoking has been associated with more rapid progression of disease, so cessation should be advocated.[82] Patients with steatorrhea should be counseled to eat small and frequent meals.[79,83,84] A reduction in dietary fat is not needed routinely, but may be needed in those whose symptoms are uncontrolled with enzyme supplementation.[78] Consumption of a low-fat purified amino acid elemental diet may reduce pain in patients with chronic pancreatitis.[85] Supplementation with medium-chain triglycerides, which do not require lipolysis, should be considered for patients with steatorrhea who are unable to gain weight.[79,83] Enteral nutrition via a feeding tube is recommended for patients who cannot consume adequate calories, have continued weight loss, experience complications, or require surgery.[83] For patients with chronic pancreatitis requiring tube feeding, use of a jejunal feeding tube is the recommended.[83,84]

Invasive procedures and surgery are primarily used to treat uncontrolled pain and the associated complications of chronic pancreatitis. Stents placed via ERCP may be used to treat pancreatic duct strictures in order to relieve parenchymal pressure and reduce pain.[78,86] Extracorporeal shock wave lithotripsy can be used to break up pancreatic stones with ultrasonic vibration prior to removal by ERCP.[80,86] Blockade of pain signals through the celiac plexus may be achieved utilizing EUS.[78,80,86,87,88] The various complications of chronic pancreatitis that can be treated endoscopically include common bile duct strictures, duodenal obstructions, and pancreatic pseudocysts.[78,86] Various surgical techniques including total pancreatectomy may also be used to relieve pain associated with chronic pancreatitis.[78,80] Surgery is more effective at relieving pain than endoscopic procedures, but these trials have a number of limitations.[78,80,89] Finally, total pancreatectomy with transplantation of pancreatic islet cells to reduce the need for exogenous insulin is a possible option for the treatment of pain due to chronic pancreatitis.[78,80,90,91]

Pharmacologic Therapy

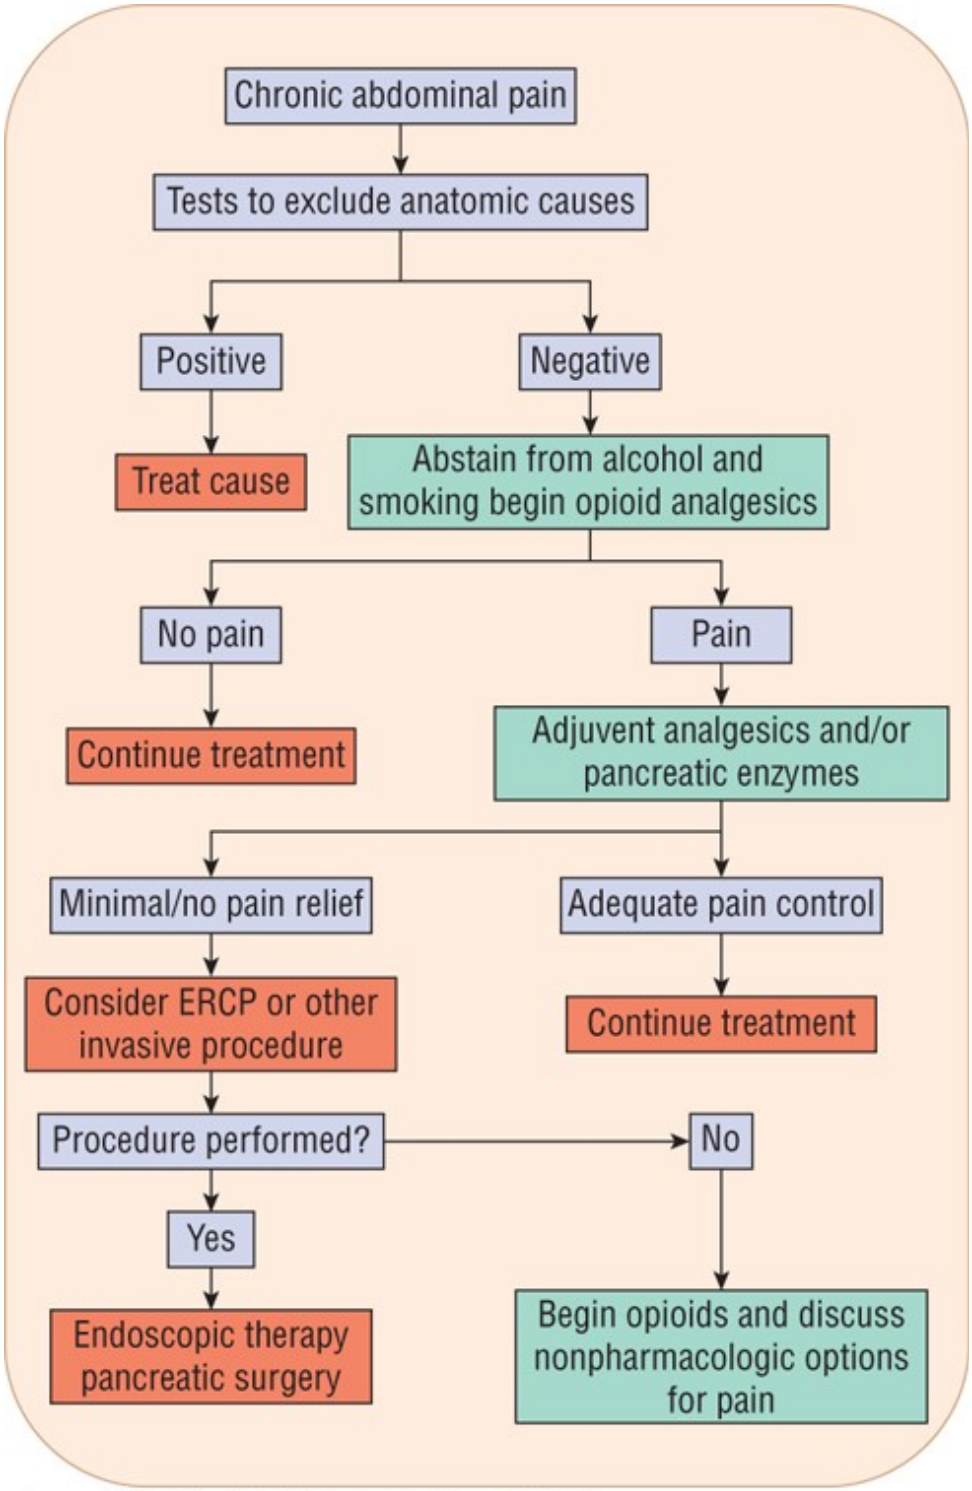
General Recommendations

Pharmacologic therapy of chronic pancreatitis is aimed at controlling pain, treating malabsorption and associated steatorrhea, and controlling diabetes mellitus. Once other causes have been excluded, weak opioid analgesics should be tried initially for pain management (**Fig. 39-4**).[5,78,79,80] Patients with inadequate relief from opioids should have adjuvant agents added to their regimen.[78,79,80,82] The addition of pancreatic enzyme supplements for pain control may also be considered in select patients.[5,78,79,80,82]

FIGURE 39-4

Algorithm for the treatment of abdominal pain in chronic pancreatitis. (ERCP, endoscopic retrograde

cholangiopancreatography.)

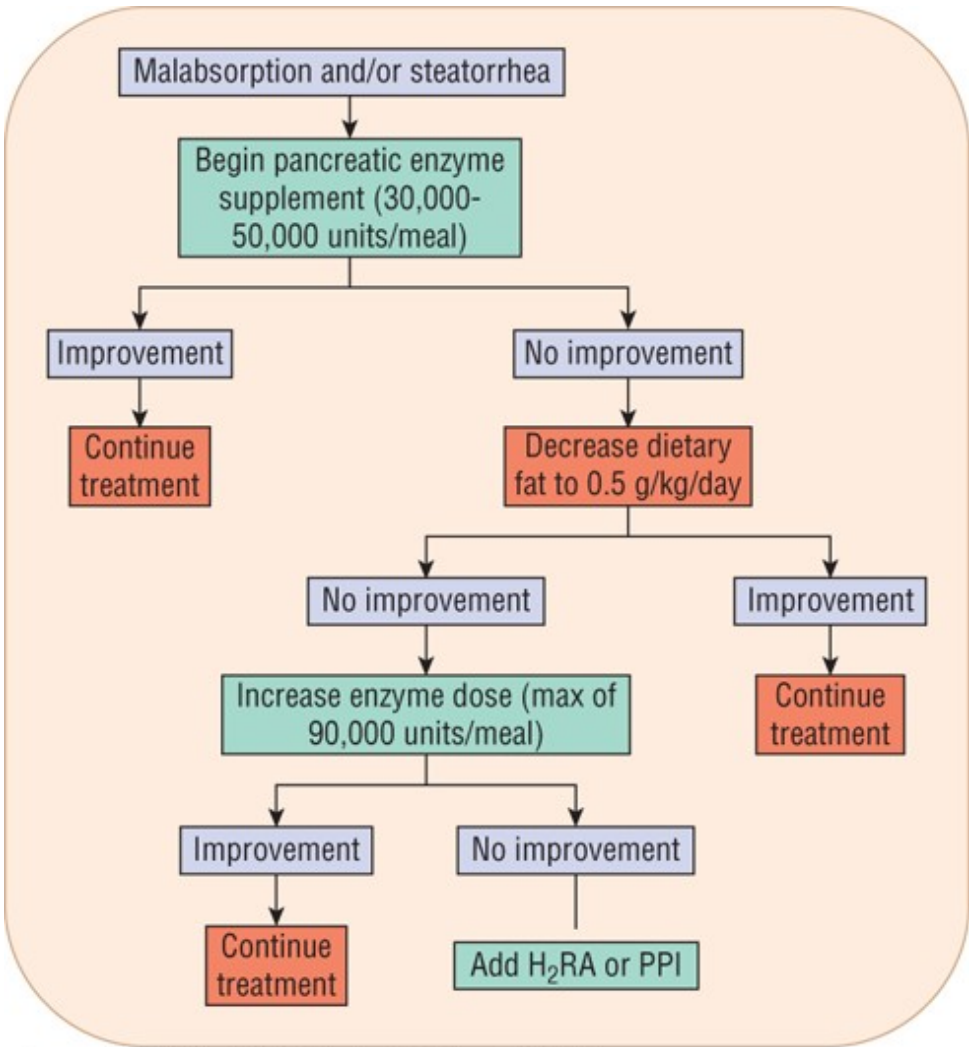


Most patients with malabsorption will require a modification in diet along with pancreatic enzyme supplementation in order to achieve adequate nutritional status and reduction in steatorrhea (**Fig. 39-5**). An antisecretory agent (such as ranitidine or omeprazole) should be added to the regimen when there is an inadequate response to enzyme therapy alone.[5,78,79,80] If these measures are

ineffective, documentation of the diagnosis and exclusion of other diseases should be undertaken. Exogenous insulin is the primary pharmacologic agent used in the treatment of diabetes mellitus associated with chronic pancreatitis.[5,80,81] However, metformin may be initiated in early chronic pancreatitis, and has the added benefit of significantly reducing the risk pancreatic cancer.[81]

FIGURE 39-5

Algorithm for the treatment of malabsorption and steatorrhea in chronic pancreatitis. (H_2RA, histamine$_2$-receptor antagonist; PPI, proton pump inhibitor.)



Relief of Chronic Abdominal Pain

Analgesics

Pain from chronic pancreatitis may initially be treated with opioid analgesics, but adjuvant agent may be necessary as the disease progresses [6]. Regimens should be individualized and should begin with

the lowest effective dose. The dosage regimen should be maximized before adding or substituting agents. Analgesics should be scheduled around the clock rather than as needed in order to maximize efficacy. Scheduling short-acting analgesics prior to meals should help decrease postprandial pain. Less potent opioids should be used initially, and tramadol successfully treated pain in patients with chronic pancreatitis, but at a higher dose than that approved in the United States.[5,78,79,80] Severe pain will require the use of more potent opioids, such as oxycodone. Although opioids carry about a 10% to 30% risk of addiction in this population, their use should not be withheld.[5] Unless contraindicated, oral opioids should be used before parenteral, transdermal, or other dosage forms. The choice of agent should be based on cost, compliance, and avoidance of adverse drug events (eg, allergic reactions).

Pancreatic Enzymes

Although pancreatic enzymes are primarily used to treat malabsorption associated with chronic pancreatitis, they are also used to treat pain from the disease. Relief of pain using pancreatic enzymes is thought to be due to their ability to break down CCK.[5,74,78,82] Normally, the release of CCK, which causes an increase in pancreatic secretion, is inhibited by trypsin. However, there is a decrease in the production of trypsin in patients with chronic pancreatitis. This leads to a loss of negative feedback on the release of CCK and thus an increase in pain due to unabated pancreatic secretion. The proteases in pancreatic enzyme supplements are thought to act as substitutes for endogenous trypsin, leading to a decrease in CCK release.

Despite this intuitive mechanism, mixed results have been found from trials investigating pancreatic enzyme supplements for the treatment of pain from chronic pancreatitis. This may be due to the differences between the various enzyme formulations used in the trials as well as the small number of subjects enrolled.[5,78,79,82] A Cochrane Collaborative review found no beneficial effect on pain relief.[92] However, trials that used non-enteric-coated enzyme formulations have demonstrated a benefit in the treatment of pain.[5,78,82] Enteric-coated formulations may not release enough proteases in the duodenum to inhibit CCK release. A trial of non-enteric-coated enzyme supplements may be used for patients with less advanced disease before more aggressive therapy is considered.[5,78,79,82] An alternative is to administer an enteric-coated product with an antisecretory agent in order to increase the amount of proteases available in the duodenum from these products (**Table 39-6**). However, no studies have been conducted using such a regimen for the treatment of pain from chronic pancreatitis.

TABLE 39-6 Recommendations for the Pharmacologic Treatment of Chronic Pancreatitis

Treatment of chronic pain (oral drug regimens)
Opioids
• Tramadol: 50-100 mg every 4-6 hours, not to exceed 400 mg/day; has opioid-like effect; contraindicated in alcohol or hypnotic intoxication; be aware of drug interactions; expensive
• Codeine 30-60 mg every 6 hours; hydrocodone 5-10 mg every 4-6 hours; morphine sulfate

(extended-release) 30-60 mg every 8-12 hours; oxycodone 5-10 mg every 6 hours; methadone 2.5-10 mg every 8-12 hours; hydromorphone 0.5-1 mg every 4-6 hours; fentanyl patch 25-100 mcg/h every 72 hours

- Risk of potentiation with alcohol; impaired respiration; constipation; hypotension; allergy
- Dosing is usually based on providing continuous pain relief; consider combining with acetaminophen; opioid dependence is common; abuse is a concern in alcoholics; tolerance may develop

Adjuvent agents

- Pregabalin: has the best evidence; begin with 75 mg twice daily; maximum dose of 300 mg twice daily
- Consider use selective serotonin reuptake inhibitors (eg, paroxetine), serotonin/norepinephrine reuptake inhibitors (eg, duloxetine) and tricyclic antidepressants in difficult-to-manage patients

Pancreatic enzymes

- Four to eight tablets/capsules of a preferred product (see Table 39-7) with each meal plus either a histamine$_2$-receptor antagonist or proton pump inhibitor; no clinical trials support such a regimen for pain management

Treatment of malabsorption and steatorrhea

- Start with pancreatic enzymes containing 30,000-50,000 USP units of lipase with each meal of a preferred product (see **Table 39-7**); administer dose during or just after meals
- Increase dose to a maximum of 90,000 USP units of lipase per meal
- Products containing enteric-coated microspheres or minimicrospheres may be more effective than other dose forms

Acid-suppression agents

- May improve efficacy of enzyme therapy for malabsorption and steatorrhea
- Use with either non-enteric-coated or enteric-coated formulations

USP, United States Pharmacopeia.

Data from references 5, 78, 79, 82, 93, and 99.

Other Agents

Various adjunctive agents are also used in patients experiencing pain from chronic pancreatitis. Selective serotonin reuptake inhibitors and tricyclic antidepressants are used both for treating the concomitant depression that often occurs in patients with chronic pancreatitis and for their potential effects on pain (see Table 39-6).[5] Gabapentin has been used as an adjunct to opioids.[5] Pregabalin significantly decreased maximum and average daily pain scores when studied in a prospective randomized trial in patients with chronic pancreatitis.[93] Evidence does not support use of octreotide for chronic pancreatitis pain.[5,78,82] There is evidence showing that patients with chronic pancreatitis have increased oxidative stress, and the use of antioxidants, such as selenium, vitamins C and E, and β-carotene, has demonstrated some benefit in relieving pain and improving quality of life in these patients.[94,95,96] However, evidence regarding their benefit remains variable and their widespread use in patients with chronic pancreatitis is not generally recommended.[78,79,82,97]

Treatment of Malabsorption

Reduction in dietary fat intake and pancreatic enzyme supplementation are the primary treatments for malabsorption due to chronic pancreatitis 7. Treatment should begin when steatorrhea is documented and persistent weight loss occurs despite initial dietary modifications. The combination of pancreatic enzymes and a reduction in dietary fat enhances the patient's nutritional status and reduces steatorrhea. Malabsorption is minimized if the concentration of lipase delivered to the duodenum with supplementation is about 10% of normal pancreatic output.[5] This requires that 30,000 to 50,000 units of lipase be administered with each meal to start (see Table 39-6).[78,80,98] In many cases the lipase dose will need to be increased due to insufficient lipolytic activity, but doses greater than 90,000 units per meal are not recommended.

There is little evidence regarding the optimal dosage form and administration of pancreatic enzyme supplements. Most studies have compared them with placebo rather than other enzyme products, and used quantitation of fat absorption or elimination as a primary measure of efficacy rather than weight gain.[99] Although they improve fat absorption, they may not completely eliminate steatorrhea.[99] However, they improve the quality of life of patients with chronic pancreatitis.[79] Since most exogenous lipase is rapidly and irreversibly destroyed at low intragastric pH, enteric-coated products are preferred for the treatment of malabsorption and steatorrhea 8. The enteric coating only dissolves at a pH greater than 5.5, which allows a sufficient quantity of enzymes to remain intact until dissolution of the coating in the duodenum.[79] However, enzymes must also be emptied from the stomach into the duodenum at the same rate and time as ingested food. The size of the enteric-coated enzyme preparation influences the rate of enzyme delivery to the duodenum.[5] Likewise, the administration time relevant to a meal influences the timing of enzyme delivery. Products that contain enzymes in small enteric-coated microspheres or minimicrospheres are often the best products because they are thought to mix effectively with chyme, thus leaving the stomach at a similar rate.[79,98] Also, the optimal administration time of enzymes containing minimicrospheres appears to be either with a meal or just after.[5,78,79,98]

Despite enzyme therapy, patients may continue to have steatorrhea and fail to gain sufficient weight.

Compliance should be assessed in these patients as the number of capsules required with each meal can lead to noncompliance. Alternative products with higher lipase content can be tried in order to reduce the number of capsules needed. If this fails, the dose of lipase should be increased. Finally, addition of an antisecretory agent may be tried to increase the availability of active enzymes in the duodenum.[79,98]

Pancreatic Enzyme Supplements

Six pancreatic enzyme products have been approved by the FDA since its 2004 mandate that any product marketed would need approval. Only two of these products are specifically approved for exocrine pancreatic insufficiency associated with chronic pancreatitis.[100,101] Dosage forms of approved products include regular-release tablets, enteric-coated beads, bicarbonate-buffered enteric-coated microspheres, enteric-coated minimicrospheres, and enteric-coated minitablets or microtablets encased in a cellulose or gelatin capsule (**Table 39-7**). Enzymes are easily administered to patients able to swallow the capsules or their contents. However, administration to patients with enteral feeding tubes presents a challenge. Products containing microspheres may be administered through feeding tubes in food or solutions with a pH of 4.5 or less.[98] Clinicians must be aware, however, that available products are not equivalent and should consider this before substituting products in patients who require administration through a nonoral route. Careful consideration should also be given to this issue in patient care facilities with limited formularies.

TABLE 39-7 Commercially Available Pancreatic Enzyme (Pancrelipase) Preparations

	Enzyme Content Per Unit Dose (USP Units)		
Product	**Lipase**	**Amylase**	**Protease**
Tablets			
Viokace™ 10,440 lipase units	10,440	39,150	39,150
Viokace™ 20,880 lipase units	20,880	78,300	78,300
Enteric-coated beads			
Zenpep® 3,000 lipase units	3,000	16,000	10,000

Adverse reactions from pancreatic enzyme supplements are generally benign. High doses can lead to nausea, diarrhea, and intestinal upset.[79] One of the more serious adverse effects of these products is fibrosing colonopathy. It occurs when the enzymes cause deposition of fibrin in the colon leading to colonic stricture. This reaction is uncommon and has been reported mostly in children with cystic fibrosis who received high doses of enzymes for prolonged periods.[79] Another concern with pancreatic enzymes is the risk of possible viral infection due to contamination of these porcine-derived products.[79,102] Finally, pancreatic enzymes and chronic pancreatitis have been associated with deficiencies in fat-soluble vitamins, and appropriate monitoring and supplementation, especially of vitamin D, should be instituted.[5,79]

Clinical Controversy…

Adjuvant agents (such as pregabalin) for pain control in patients with chronic pancreatitis have not been widely studied, but are often utilized. Pregabalin has the best evidence of efficacy in this population, but it has only been studied in one prospective randomized trial. There is debate about the utilization of such agents for the treatment of pain associated with chronic pancreatitis because well-designed clinical trials demonstrating their efficacy are sparse.

Adjuncts to Enzyme Therapy

The addition of a histamine$_2$-receptor antagonist or proton pump inhibitor to pancreatic enzyme supplementation may increase the effectiveness of enzyme therapy for malabsorption and

steatorrhea 9. The beneficial effects of these agents result from an increase in gastric and duodenal pH.[79,80,98] This is thought to result in an increase in the amount of active enzymes available in the duodenum. Traditionally, their use has been advocated with non-enteric-coated enzyme products.[5,78] In fact, the only non-enteric-coated formulation currently approved by the FDA is indicated for administration with a proton pump inhibitor.[101] However, they are recommended to enhance the efficacy of both nonenteric-coated and enteric-coated formulations.[79,80]

PERSONALIZED PHARMACOTHERAPY

Some cases of drug-induced pancreatitis are associated with elevated concentrations of the causative medications, and it is possible that genetic differences in drug metabolism contribute to this. A pharmacogenetic analysis was performed in one case of drug-induced pancreatitis that was associated with high concentrations of clozapine.[103] However, the patient was not found to have any genetic variants that would affect the metabolism of clozapine. Diagnosis of acute pancreatitis in pregnant patients is complicated by normal increases in amylase and lipase of up to three times the normal limit in this population. Lipase is considered to be a more sensitive measure than amylase in this population. Contrast should be avoided in pregnant patients with acute pancreatitis.[14]

Although several genetic variations have been associated with the occurrence of chronic pancreatitis, variation in response to therapy related to these factors has not been studied. One cautionary note regarding pancreatic enzyme supplements is that they are all porcine-derived and thus contain purines. Therefore, they may increase uric acid levels and should be used cautiously in patients prone to the effects of hyperuricemia. This would include patients with a history of gout, impaired kidney function, and known hyperuricemia. One physiologic parameter affecting the efficacy of pancreatic enzyme supplements is GI transit. Non-enteric-coated formulations are preferred for patients with rapid gastrojejunal transit secondary to pancreatectomy associated with partial gastrectomy or vagotomy and gastroenteroscopy. These patients have hyposecretion of gastric acid and enteric-coated formulations would not be released early enough in the small intestine to confer a beneficial effect.[79]

EVALUATION OF THERAPEUTIC OUTCOMES

Acute Pancreatitis

Hydration status, serum electrolytes, pain control, and nutritional status should be assessed periodically in patients with mild acute pancreatitis, depending on the degree of abdominal pain and fluid loss. Patients with severe acute pancreatitis should receive intensive care and close monitoring of vital signs, fluid and electrolyte status, white blood cell count, blood glucose, lactate dehydrogenase, aspartate aminotransferase, serum albumin, hematocrit, BUN, serum creatinine, and international normalized ratio. Continuous hemodynamic and arterial blood gas monitoring is essential. Serum lipase, amylase, and bilirubin require less frequent monitoring. The patient should also be monitored for signs of infection, relief of abdominal pain, and adequate nutritional status.

Severity of disease and patient response should be assessed using an evidence-based method.

Chronic Pancreatitis

The severity and frequency of abdominal pain should be assessed periodically in patients with chronic pancreatitis using a standardized scale in order to determine the efficacy of pain therapy. Patients receiving opioids should be prescribed laxatives on an as-needed or scheduled basis and be monitored for constipation. Patients receiving pancreatic enzymes for malabsorption should have their weight and stool frequency and consistency monitored periodically. More objective assessments of fecal fat content, such as the ^{13}C-mixed triglyceride breath test, can be utilized, but are usually unnecessary and impractical in general clinical practice.[5,79,93] Blood glucose must be closely monitored in patients with diabetes mellitus, and those with long-standing disease should receive appropriate monitoring for nephropathy, retinopathy, and neuropathy.[5]

Chapter 40: Viral Hepatitis

Paulina Deming

INTRODUCTION

KEY CONCEPTS

- 1 Hepatitis A is transmitted via the fecal–oral route, most often from through travel to countries with high rates of hepatitis A, poor sanitation and hygiene, and overcrowded areas.
- 2 Hepatitis A causes an acute, self-limiting illness and does not lead to chronic infection. There are three stages of infection: incubation, acute hepatitis, and convalescence. Rarely, the infection progresses to liver failure.
- 3 Hepatitis A is vaccine preventable. In cases of acute infection, treatment consists of supportive care.
- 4 Hepatitis B causes both acute and chronic infection. Chronic infections are responsible for high rates of liver disease, liver cancer, and death.
- 5 Vaccination can prevent hepatitis B and is the most effective strategy in preventing complications of hepatitis B virus (HBV) infections. Prevention of hepatitis B infections focuses on immunization of all children and at-risk adults.
- 6 The purpose of anti-HBV drug therapy is for viral suppression and immune control and to prevent progression of liver disease and the complications associated with hepatitis B infections.
- 7 Initial therapy of chronic hepatitis B is with tenofovir or entecavir because these agents have a high barrier to resistance. Therapy is often long-term.
- 8 Patients undergoing immunosuppressive therapy should be screened for hepatitis B infections and may require hepatitis B therapy to reduce the risks of reactivating their hepatitis B infection.

- Hepatitis C is an insidious, blood-borne infection. Increased screening of all patients born between 1945 and 1965 was implemented to help identify the many people unaware of their infection.
- Hepatitis C infections can cause significant morbidity (including extrahepatic manifestations) and mortality. Patients with chronic hepatitis C are at risk for end-stage liver disease, cirrhosis, liver transplant, and death as a result of their infection.
- The goal of anti-hepatitis C virus (HCV) drug treatment is cure. Drug therapy with direct acting antivirals optimized based on the infecting viral genotype, presence of cirrhosis and the patient's prior treatment experience.

The major hepatotrophic viruses responsible for viral hepatitis are hepatitis A, hepatitis B, hepatitis C, delta hepatitis, and hepatitis E. All share clinical, biochemical, immunoserologic, and histologic findings. Both hepatitides A and E are spread through fecal–oral contamination, whereas hepatitides B, C, and delta are transmitted parenterally. Infection with delta hepatitis requires coinfection with hepatitis B. Although the rates of acute infection have declined, viral hepatitis remains a major cause of morbidity and mortality with a significant impact on healthcare costs in the United States. Compared with human immunodeficiency virus (HIV), there are three to five times as many people infected with chronic viral hepatitis. In the United States, there is a general lack of knowledge among healthcare providers, social service providers, and the public regarding the risks of chronic hepatitis B and C infections.[1]

Unprecedented therapeutic advances have occurred with the treatment for hepatitis C with the approval of new agents, updated guidelines for care, and more novel therapies anticipated. For both hepatitides B and C, the challenge remains to increase awareness of the viral hepatic epidemic and to prevent the profound morbidity and mortality associated with chronic infection. This chapter focuses on hepatitides A, B, and C.

HEPATITIS A

Hepatitis A virus (HAV), or infectious hepatitis, is often a self-limiting and acute viral infection of the liver posing a health risk worldwide. The infection is rarely fatal. According to the Centers for Disease Control and Prevention (CDC), rates of reported cases of acute clinical hepatitis A infection in the United States continue to decline with 1,781 cases in 2013.[2] The significant declines in rates of acute HAV are associated with major vaccination campaigns that successfully reduced the incidence rate.

Epidemiology

Various patient groups are at increased risk for infection with HAV. Children pose a particular problem with the spread of the disease because they often remain asymptomatic and are infectious for longer periods of time than adults. The most likely patient group affected is household or close personal contacts of an infected person. Infection primarily occurs through the fecal–oral route, by person-to-person, or by ingestion of contaminated food or water. Incidentally, HAV's prevalence is

linked to regions with low socioeconomic status and specifically to those with poor sanitary conditions and overcrowding. International travel and immigration also mitigate potential exposure to the virus.

International travel, in particular travel to HAV endemic areas, continues to be a major risk factor for HAV infection. Other identified risk factors include sexual and household contact with an HAV-infected person, men who have sex with men (MSM), and persons who inject drugs (PWIDs).[2] Additional patient groups that are at risk include patients with chronic liver disease and persons working with nonhuman primates. In 2010, 75% of case reports of acute HAV reported no identifiable risk factor.[2] Among MSMs, specific sexual practices may be associated with an increased risk for infection.[3] Foodborne outbreaks also occur. In general, mortality rates are low but highest among persons 75 years or older.[2]

Despite low endemic rates and successful vaccination programs in the United States, travel to HAV endemic areas is a recognized risk for acquiring acute HAV infections. According to the CDC, the majority of travel-related cases correspond to travel to Central and South America and Mexico.[2] Most Americans traveling to Mexico do not consider that country to be a risk in part because of Mexico's proximity to the United States. Moreover, most tourists falsely believe that higher-end resorts imply safety and that short visits to foreign countries are not associated with a risk for infection. Travel related to international adoptions can also be of risk.

Etiology

Hepatitis A is an RNA virus of the *Picornaviridae* family. The virus is stable in the environment, including at low pH and in freezing to moderate temperatures.[4] Inactivation requires disinfecting with a 1:100 dilution of sodium hypochlorite (bleach) in tap water or heating foods to a minimum of 85°C (185°F) for 1 minute.[5] Transmission occurs primarily through the fecal–oral route because HAV is shed in the feces of infected people.[6] Contaminated water or ice are common modes of transmission, as are any foods which may be prepared using contaminated water, including shellfish harvested from contaminated water.

Pathophysiology

HAV infection is usually acute, self-limiting, and confers lifelong immunity. HAV's life cycle in the human host classically begins with ingestion of the virus. Absorption in the stomach or small intestine allows entry into the circulation and uptake by the liver. Replication of the virus occurs within hepatocytes and gastrointestinal (GI) epithelial cells. New virus particles are released into the blood and secreted into bile by the liver. The virus is then either reabsorbed to continue its cycle or excreted in the stool. The enterohepatic cycle will continue until interrupted by antibody neutralization.[6]

Clinical Presentation

2 The incubation period of HAV is approximately 28 days, with a range of 15 to 50 days. **Table 40-1** summarizes the clinical features of acute hepatitis A. Symptoms and severity of HAV vary according to age. Children younger than 6 years typically are asymptomatic and can shed the virus for long periods of time, serving as a reservoir for the spread of HAV. Peak fecal shedding of the virus precedes the onset of clinical symptoms and elevated liver enzymes. Acute hepatitis follows, beginning with the preicteric or prodromal period. The phase is marked by an abrupt onset of nonspecific symptoms; some very mild.[5] Other, more unusual symptoms include chills, myalgia, arthralgia, cough, constipation, diarrhea, pruritus, and urticaria. The phase generally lasts 2 months. There are no specific symptoms unique to HAV. Liver enzyme levels rise within the first weeks of infection, peaking approximately in the fourth week and normalizing by the eighth week. Conjugated bilirubinemia, clinically evident as dark urine, precedes the onset of the icteric period. GI symptoms may persist or subside during this time and some patients may have hepatomegaly. Duration of the icteric period varies and corresponds to disease duration, averaging between 7 and 30 days.[6]

TABLE 40-1 Clinical Presentation of Acute Hepatitis A

Signs and symptoms

- The preicteric phase brings nonspecific influenza-like symptoms consisting of anorexia, nausea, fatigue, and malaise.
- Abrupt onset of anorexia, nausea, vomiting, malaise, fever, headache, and right upper quadrant abdominal pain with acute illness.
- Icteric hepatitis is generally accompanied by dark urine, alcoholic (light-colored) stools, and worsening of systemic symptoms.
- Pruritus is often a major complaint of icteric patients.

Physical examination

- Icteric sclera, skin, and secretions
- Mild weight loss of 2-5 kg
- Hepatomegaly

Laboratory tests

- Positive-serum Ig M anti–HAV
- Mild elevations of serum bilirubin, *γ*-globulin, and hepatic transaminase (ALT and AST) values to about twice normal in acute anicteric disease
- Elevations of alkaline phosphatase, *γ*-glutamyl transferase, and total bilirubin in patients with cholestatic illness

ALT, alanine transaminase; AST, aspartate transaminase; HAV, hepatitis A virus; Ig, immunoglobulin.

The diagnosis of acute HAV is made through the immunoglobulin (Ig) M antibody to HAV (anti-HAV). IgM anti-HAV is detectable 5 to 10 days prior to symptomatic HAV infections in the majority of patients. The IgG anti-HAV replaces IgM and indicates host immunity following the acute phase of the infection.[5] Food and Drug Administration (FDA)-approved assays for serologic testing detect IgM anti-HAV only and total anti-HAV (IgM and IgG anti-HAV). Patients who have detectable total anti-HAV with a negative IgM have resolved their infection. Concentrations of antibody often fall to 10 to 100 times lower than what would be expected after a natural course of infection. Although a positive anti-HAV result confirms protection, undetectable concentration of anti-HAV may not necessarily imply that protective levels were not achieved.[5]

HAV does not lead to chronic infections. Some patients may experience symptoms for up to 9 months. Rarely, patients experience complications from HAV, including relapsing hepatitis, cholestatic hepatitis, and fulminant hepatitis. Fatalities from HAV are generally rare, although more likely in patients older than 50 years and in persons with preexisting liver disease.[5]

A diagnosis of HAV is based on clinical criteria of an acute onset of fatigue, abdominal pain, loss of appetite, intermittent nausea and vomiting, jaundice or elevated serum aminotransferase levels, and serologic testing for IgM anti-HAV. Serologic testing is necessary to differentiate the diagnosis from other types of hepatitis.

TREATMENT Desired Outcomes

The majority of people infected with HAV can be expected to fully recover without clinical sequelae.[6] Nearly all individuals will have clinical resolution within 6 months of the infection, and a majority will have done so by 2 months. Rarely, symptoms persist for longer or patients relapse. The ultimate goal of therapy is complete clinical resolution. Other goals include reducing complications from the infection, normalization of liver function, and reducing infectivity and transmission. Prevention of HAV infection is important because significant costs are accrued during acute HAV infections, both from direct costs of hospitalizations and indirect costs from loss of work days.

General Approach to Treatment

3 Prevention and prophylaxis are keys to managing this vaccine preventable virus. No specific treatment options exist for HAV infections. Instead, patients should receive general supportive care. The importance of good hand hygiene cannot be overemphasized in preventing disease transmission. Passive immunity with Ig is used for preexposure and postexposure prophylaxis. Active immunity is achieved through vaccination. Vaccines were approved for use in 1995 and implemented in the routine vaccination of children, as well as at-risk adults, to reduce the overall incidence of HAV.[5]

Prevaccination serologic testing to determine susceptibility is generally not recommended. In some cases, testing may be cost-effective if the cost of the test is less than that of the vaccine and if the person is from a moderate to high endemic area and likely to have prior immunity. Similarly, because

of high vaccine response, postvaccine serologic testing is not recommended.[5]

Prevention of Hepatitis A

HAV is easily preventable with vaccination. Because children often serve as reservoirs of the disease, vaccine programs have targeted children as the most effective means to control HAV. Two vaccines for HAV are available and are incorporated into the routine childhood vaccination schedule. In 2005, the FDA reduced the minimum age for the vaccines to 12 months. In response, the Advisory Committee on Immunization Practices (ACIP) recommended expanding vaccine coverage to all children, including catch-up programs for children living in areas without existing vaccination programs. The new recommendations were enacted in the attempt to further reduce HAV incidence rates and possibly to eradicate the virus.[5] Other updated ACIP guidelines included HAV vaccination for previously unvaccinated persons anticipating close personal contact with international adoptees from a country of high or intermediate endemicity. Complete HAV vaccination recommendations are available from the CDC (**Table 40-2**).

TABLE 40-2 Recommendations for Hepatitis A Virus Vaccination

All children at 1 year of age.
Children and adolescents between 2 and 18 years who live in states or communities where routine hepatitis A vaccination has been implemented because of high disease incidence.
Persons traveling to or working in countries that have high or intermediate endemicity of infection.[a]
MSM.
Illegal drug users.
Persons with occupational risk for infection (eg, persons who work with HAV-infected primates or with HAV in a research laboratory).
Persons who have clotting factor disorders.
Persons with chronic liver disease.
All previously unvaccinated persons anticipating close personal contact (eg, household contact or regular babysitter) with an international adoptee from a country of high or intermediate endemicity within the first 60 days following the arrival of the adoptee.

HAV, hepatitis A virus; MSM, men who have sex with men,

[a]Travelers to Canada, Western Europe, Japan, Australia, or New Zealand are at no greater risk for infection than they are in the United States. All other travelers should be assessed for HAV risk.

From Centers for Disease Control and Prevention[7]

Routine prevention of HAV transmission includes regular hand washing with soap and water after

using the bathroom, changing a diaper, and before food preparation. For travelers to countries with high endemic rates of HAV, even short-term stays in urban and upscale resorts are not risk-free.[5] In particular, contaminated water and ice, fresh produce, and any uncooked foods pose a risk.[6]

Vaccines to Prevent Hepatitis A

The inactivated virus vaccines licensed in the United States are the single-antigen HAVRIX® and VAQTA® and the combination of HAV and hepatitis B virus (HBV) antigen vaccine TWINRIX®. Both single-antigen vaccines are available for pediatric and adult use while the TWINRIX® is indicated for adults only (**Table 40-3**). The differences in the vaccines are in the use of a preservative and in expression of antigen content. VAQTA® is formulated without a preservative and uses units of HAV antigen to express potency. HAVRIX® and TWINRIX® use 2-phenoxyphenol as a preservative and antigen content is expressed as enzyme-linked immunosorbent assay (ELISA) units.[5] Although high seroconversion rates of more than or equal to 94% are achieved with the first dose, VAQTA® and HAVRIX® recommend a booster shot to achieve the highest possible antibody titers. Although seroconversion exceeds 90% for HAV after the first dose of TWINRIX®, the full three-dose series is required for maximal HBV seroconversion. An accelerated dosing schedule is available but requires four doses for optimal response. The combined vaccine offers the advantage of immunization against both types of hepatitis in a single vaccine.

TABLE 40-3 Recommended Dosing of Hepatitis A Vaccines

Vaccine	Age (Years)	Dose of Hepatitis A Antigen	No. of Doses	Schedule
HAVRIX	1-18	720 ELISA units	2	0, 6-12 months
	≥19	1,440 ELISA units	2	0, 6-12 months
VAQTA	1-18	25 units	2	0, 6-18 months
	≥19	50 units	2	0, 6-18 months
TWINRIX[a]	≥18	720 ELISA units	3	0, 1, 6 months
	≥18 (accelerated schedule)	720 ELISA units	4	0, 7 days, 21-30 days, +12 months

ELISA, enzyme-linked immunosorbent assay.

[a]Combination hepatitis A and B vaccine, also contains 20 µg of hepatitis B surface antigen and requires a three-dose schedule.

From Centers for Disease Control and Prevention[7]

In situations of postexposure prophylaxis, either the vaccine or Ig can be used. The use of the vaccine is advantageous as vaccination confers the benefit of long-term immunity against HAV; however, experience in patients older than 40 years or with underlying medical conditions is limited.[7] Both vaccines may be given concomitantly with Ig and the two brands are interchangeable for booster shots.[5]

Vaccine is recommended for international travel to areas of high or intermediate endemicity and can be given regardless of scheduled dates of departure. For older patients, immunocompromised, or any patients with chronic liver disease or any other chronic medical conditions traveling within 2 weeks, both Ig and vaccine are recommended.[7]

The most common side effects of the vaccines include soreness and warmth at the injection site, headache, malaise, and pain. More than 65 million doses of the vaccine have been administered and despite routine monitoring for adverse events, there are no data to suggest a greater incidence of serious adverse events among vaccinated people compared with nonvaccinated. The vaccine is considered safe.[5]

Immunoglobulin

Ig is used when preexposure or postexposure prophylaxis against HAV infection is needed in persons for whom vaccination is not an option. Vaccination is preferred for multiple reasons, including that it induces active immunity and therefore a longer time of protection against HAV than Ig.

A sterile preparation of concentrated antibodies against HAV, Ig provides protection by passive transfer of antibody. Ig is most effective if given in the incubation period of the infection. Receipt of Ig within the first 2 weeks of infection will reduce infectivity and moderate the infection in 85% of patients. Patients who receive at least one dose of the HAV vaccine at least 1 month prior to exposure do not need preexposure or postexposure prophylaxis with Ig.[5] Ig is available as both an intravenous (IV) and intramuscular (IM) injection, but for HAV exposure, only the IM is used.

Serious adverse events from Ig are rare. Anaphylaxis has been reported in patients with IgA deficiency. Patients who had an anaphylaxis reaction to Ig should not receive it. There is no contraindication for use in pregnancy or lactation.

Dosing of Ig is the same for adults and children. For postexposure prophylaxis and for short-term preexposure coverage of less than 3 months, a single dose of 0.02 mL/kg IM is given. For long-term preexposure prophylaxis of less than or equal to 5 months, a single dose of 0.06 mL/kg is used. Either the deltoid or gluteal muscle may be used. In children younger than 24 months, Ig can be given in the anterolateral thigh muscle.[5]

In most patients who were recently exposed to HAV and who had not been previously vaccinated, postexposure prophylaxis with vaccination is preferred. Ig prophylaxis is preferred in the following situations: patients are younger than 12 months or older than 40 years, are immunocompromised, have chronic liver disease or have underlying medical conditions, or for whom vaccine is contraindicated.[7]

Ig can be given concomitantly with the HAV vaccine. Although the antibody titer will be lower than if the vaccine were administered alone, the response is still protective and coadministration should be considered for the advantages of long-term HAV protection. However, Ig can interfere with the response of other live, attenuated vaccines and should be delayed.

Vaccine efficacy may be reduced in certain patient populations. In HIV-infected patients, greater immunogenic response may correlate with higher baseline CD4 cell counts. Patients with CD4 counts less than 200 cells/mm^3 (<0.200 × 10^9/L) at vaccination have a reduced response rate. Moreover, patients with HIV/HCV coinfection may also have a lowered response.[8]

HEPATITIS B

4 Hepatitis B is highly infectious, approximately 50 to 100 times more so than HIV.[9] Although a vaccine was made available in 1981, HBV has acutely infected more than 2 billion people globally, leading to chronic infection in more than 240 million people.[9,10] Chronic infection with HBV is a major public health issue as it serves as a reservoir for continued HBV transmission and poses a significant risk of death resulting from liver disease including liver cirrhosis and hepatocellular carcinoma (HCC). According to the World Health Organization (WHO), an estimated 650,000 people per year die as a result of complications from HBV.[10] In the United States, estimates of prevalence and incidence of viral hepatitis are difficult because there is no national chronic hepatitis surveillance program.[1]

Epidemiology

According to the WHO, chronic HBV infections disproportionately affect low and middle-income countries.[9,10] Prevalence can vary regionally; however, areas commonly associated with high infectivity rates include sub-Saharan Africa, East Asia, followed by the Amazon and southern parts of Eastern and Central Europe.[10] Areas of high prevalence, approximately 45% of the global population, are of special concern because most infections are of infants and children and more than 90% of cases lead to a chronic carrier state. Myths and misinformation about HBV abound and can result in discrimination and social injustice.[1] There are approximately 1.4 million chronically infected HBV people in the United States. Rates of acute infection in the United States continue to decline and in 2013, an estimated 19,800 people developed new infections.[2] In 2013, the highest incidence rate was among persons aged 30 to 39 years and among non-Hispanic blacks. Data from a limited chronic surveillance program indicate Asian/Pacific Islanders account for the highest proportion of chronic HBV infections and HBV-related mortality.[2] Annually, 3,000 people die from chronic liver disease attributable to HBV.[1]

HBV is transmitted sexually, parenterally, and perinatally. In areas of high HBV prevalence, perinatal transmission from mother to infant at birth is most common, whereas in areas of intermediate prevalence, horizontal transmission from child to child is most common. Sexual contact, both homosexual and heterosexual, and injection-drug use are the predominant forms of transmission in low endemic countries such as the United States.[9] Concentration of HBV is high in blood, serum, and wound exudates of infected persons. Transmission occurs via blood-to-blood contact or semen or vaginal fluid of an infected person. The virus can be stable in the environment for at least 7 days and can cause infection during this time.[9] In the United States in 2013, no risk factor could be identified for the majority of acute infections with HBV. Among patients with identifiable risk factors, the most

common risk is injection drug use, followed by sexual contact, specifically multiple sexual partners and MSM.[2] Other known risk factors include household contact of HBV-positive person.[2] Screening focuses on individuals at high risk for HBV (**Table 40-4**).[11]

TABLE 40-4 Persons at High Risk for HBV: Recommended Screening

Individuals From the Following Areas	Other Groups
Asia	US-born persons not vaccinated as infants whose parents were born in high HBV endemic regions
Africa	Household and sexual contacts of HBsAg-positive patients
South Pacific Islands	Persons who have ever injected drugs
Middle East (except Cyprus and Israel)	Persons with multiple sexual partners or history of STD
Malta	MSM
Spain	Inmates of correctional facilities
Arctic (indigenous populations of Alaska, Canada, Greenland)	Individuals with chronically elevated AST or ALT
South America: Ecuador, Guyana, Suriname, Venezuela, Amazon regions of Bolivia, Brazil, Colombia, Peru	Individuals with HIV or HCV
Eastern Europe (except Hungary)	Patients undergoing dialysis
Antigua and Barbuda, Dominica, Granada, Haiti, Jamaica, St. Kitts and Nevis, St. Lucia, Turks and Caicos	All pregnant women
	Persons requiring immunosuppressive therapy

ALT, alanine transaminases; AST, aspartate aminotransferase; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; MSM, men who have sex with men; STD, sexually transmitted disease.

Data from references 11 and 14.

The mode of transmission has clinical implications because chronic infections are associated with infection acquired in younger patients, especially those infected perinatally and in early childhood.[9]

Clinical Controversy…

Between 2008 and 2014, at least 23 healthcare-associated HBV outbreaks were identified, resulting in 175 outbreak associated cases and more than 10,700 people notified for screening. Most outbreaks occurred in long-term care facilities and were linked to lapses in infection control. Inappropriate use of glucose meters without cleaning and disinfection was the suspected mode of transmission in most cases.

Etiology

The HBV is a DNA virus that preferentially replicates within the liver.[12] There are at least 10 HBV genotypes (GTs) (A-J) with distinct geographic and ethnic distribution. GT prevalence may depend on mode of transmission as types B and C are found in areas where vertical transmission is the primary mode of infection.[13] Additionally, various subtypes of GTs exist with varying clinical outcomes. Correlations between clinical outcomes and HBV GTs suggest infections with GT C are associated with more severe liver injury, including liver cirrhosis and progression to HCC. Resistance mutations may contribute to GT virulence and hence impact severity of liver disease in infection.[13,14,15] Testing for HBV GT is not currently recommended for clinical practice.[14]

Pathophysiology

On infection, replication of the virus begins by attachment of the virion to the hepatocyte cell surface receptors. The particles are transported to the nucleus where the DNA is converted into closed, circular DNA that serves as a template for pregenomic RNA. Viral RNA is then transcribed and transported back to the cytoplasm where it can alternatively serve as a reservoir for future viral templates or bud into the intracellular membrane with the viral envelope proteins and infect other cells.[13] The viral genome has four reading frames coding for various proteins and enzymes required for viral replication. Several of these proteins are used diagnostically (**Table 40-5**). The hepatitis B surface antigen (HBsAg) is the most abundant of the three surface antigens and is detectable at the onset of clinical symptoms. Its persistence past 6 months after initial detection corresponds to chronic infection and indicates an increased risk for cirrhosis, hepatic decompensation, and HCC. Development of antibody to HBsAg (anti-HBsAg) confers immunity to the virus and clearance of HBsAg is associated with favorable outcomes.[16] The precore polypeptide encodes for the secretory protein hepatitis B e antigen (HBeAg) and the hepatitis B core antigen (HBcAg) proteins. HBeAg is present in an acute infection and is replaced by antibodies (anti-HBeAg) once an infection is resolved. HBeAg was assumed to be a marker of viral replication and infectivity; however, it is now known that some viral mutants exist that are unable to have or have downregulated expression of HBeAg, although their ability to replicate is not affected.[14] HBeAg-negative mutants pose a particular clinical challenge because they are refractory to treatment. The HBcAg is a nucleocapsid protein that, when expressed on hepatocytes, promotes immune-mediated cell death. High levels of antibodies (IgM anti-HBcAg) are detectable during acute infections. Patients who respond to vaccine will have anti-HBsAg only.[7]

TABLE 40-5 Interpretation of Serologic Tests in Hepatitis B Virus

Tests	Result	Interpretation
HBsAg	(–)	
Anti-HBc	(–)	Susceptible
Anti-HBs	(–)	
HBsAg	(–)	
Anti-HBc	(+)	Immune because of natural infection

Tests	Result	Interpretation
Anti-HBs	(+)	
HBsAg	(–)	
Anti-HBc	(c)	Immune because of vaccination (valid only if test performed 1-2 months after third vaccine dose)
Anti-HBs	(+)	
HBsAg	(+)	
Anti-HBc	(+)	
IgM anti-HBc	(+)	Acute infection
Anti-HBs	(–)	
HBsAg	(+)	
Anti-HBc	(+)	
IgM anti-HBc	(–)	Chronic infection
Anti-HBs	(–)	
HBsAg	(–)	Four interpretations possible: 1. Recovery from acute infection
Anti-HBc	(+)	2. Distant immunity and test not sensitive enough to detect low level of HBs in serum
Anti-HBs	(–)	3. Susceptible with false-positive anti-HBc 4. May have undetectable level of HBsAg in serum and be chronically infected

HBc, hepatitis B core; HBs, hepatitis B surface; HBsAg, hepatitis B surface antigen; IgM, immunoglobulin M.

From Centers for Disease Control and Prevention. Hepatitis B Serology. http://www.cdc.gov/ncidod/diseases/hepatitis/b/Bserology.htm.

HBV itself does not seem to be pathogenic to cells; rather, it is thought that the immune response to the virus is cytotoxic to hepatocytes.[13] The immune response is critical to viral clearance. If the response is weak, chronic infection is likely. Liver injury is likely caused by secondary, nonspecific inflammation activated by the initial cytotoxic lymphocyte response and as an attempt by the immune system to clear the virus by destroying HBV antigen—presenting hepatocytes. Destruction of hepatocytes results in release of circulating, and hence increased, alanine aminotransferase (ALT) levels.

Chronic Hepatitis B Virus

4 Patients who continue to have detectable HBsAg for more than 6 months have chronic HBV.[13]

Chronic infections can be controlled in many cases, but cure is not possible because the HBV template is integrated into the host genome. The most predictive factor for developing a chronic infection is age. Perinatal infections almost always result in chronic infections because of immune tolerance to the virus. The risks of chronicity decline to a rate of 30% in infants and to less than 5% in adult-onset infections. Importantly, chronic HBV infections are differentiated into phases with varied serologic patterns and patients can progress from one phase to the next or experience an active infection after being in an inactive state.[14]

Clinical Presentation and Phases of Infection

The clinical symptoms and course of an HBV infection are indistinguishable from other types of viral hepatitis. **Table 40-6** lists the clinical features of chronic HBV. Several phases of an HBV infection exist and are dynamic (**Table 40-7**).[15] During the initial or acute phase of an HBV infection in adults and older children, the HBV enters a 4- to 10-week incubation period, during which antibodies toward the HBV core are produced and the virus replicates profusely. Active viral replication results in high serum HBV DNA levels and HBeAg secretion. ALT levels may rise slightly, but most patients will remain asymptomatic. Symptoms, if they do occur, include fever, anorexia, nausea, vomiting, jaundice, dark urine, clay-colored or pale stools, and abdominal pain. Most neonates and children are anicteric and have no clinical symptoms; many adults are also asymptomatic.[9] HBsAg does not become detectable until after significant viremia. The initial phase is considered immunotolerant because no hepatic injury is sustained, as evidenced by generally normal ALT levels, and the virus replicates profusely. Patients are highly infectious during this time.[15] In perinatally acquired infections, and in young children, the phase can last for decades—until adulthood.[15] Infected children pose a particular risk because they are often asymptomatic, undiagnosed, and highly infectious.

TABLE 40-6 Clinical Presentation of Chronic Hepatitis B[a]

Signs and symptoms
• Easy fatigability, anxiety, anorexia, and malaise
• Ascites, jaundice, variceal bleeding, and hepatic encephalopathy can manifest with liver decompensation
• Hepatic encephalopathy is associated with hyperexcitability, impaired mentation, confusion, obtundation, and eventually coma
• Vomiting and seizures
Physical examination
• Icteric sclera, skin, and secretions
• Decreased bowel sounds, increased abdominal girth, and detectable fluid wave

- Asterixis
- Spider angiomata

Laboratory tests

- Presence of HBsAg >6 months
- Intermittent elevations of hepatic transaminase (ALT and AST) and HBV DNA >20,000 IU/mL (>20 × 10^6 IU/L)
- Liver biopsies for pathologic classification as chronic persistent hepatitis, chronic active hepatitis, or cirrhosis

ALT, alanine transaminase; AST, aspartate transaminase; DNA, deoxyribonucleic acid; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus.

[a]Chronic hepatitis B can be present even without all the signs, symptoms, and physical examination findings listed being apparent.

TABLE 40-7 Patterns of Chronic Hepatitis B Virus Phases

State	HBeAg Status	ALT Level	HBV DNA IU/mL[a]	Other
Immune tolerant	+	WNL	>20,000	
Immune active	+	High	>2,000	
Immune control	–	WNL	<2,000	Anti-HBe +
Immune escape	–	High	>20,000	Anti-HBe +
Reactivation	±	High	>20,000	Associated with immunosuppressive states or therapies

ALT, alanine transaminase; DNA, deoxyribonucleic acid; HBeAg, hepatitis B e antigen; HBV, hepatitis B virus; WNL, within normal limits.

[a]Conversion factor for IU/mL to IU/L is 1,000.

The immunoactive phase marks a decrease in HBV DNA levels with ongoing secretion of HBeAg. Patients are symptomatic with intermittent flares of hepatitis and marked increases in ALT levels. More frequent flares are associated with disease progression and reflect host immune response against HBV-infected hepatocytes, increased cell death in an attempt to clear the virus.[13] The phase can last a few weeks in acute disease, and for years in patients with chronic disease. As the host immune system attempts to gain control of the infection by stopping active viral replication, serum

HBV DNA levels drop to undetectable, ALT levels normalize, and liver necroinflammation resolves.[13]

If the infection is self-limiting, HBV DNA quickly subsides, HBeAg disappears within weeks, and HBsAg usually resolves within 4 months. The final phase is seroconversion and is defined by the replacement of HBeAg with anti-HBeAg. Factors favoring seroconversion include female sex, older age, biochemical activity, and genotype (GT). Flares of hepatitis with ALT levels more than 5 times the upper limits of normal, compared with less than 5 times the upper limits of normal, correspond to increased immune system activity and precede seroconversion. Spontaneous HBeAg clearance is possible and is associated with older age, higher ALT, and infection with HBV GT B.[14] Patients who have achieved immune control over HBV will be HBeAg-negative, with detectable HBsAg and anti-HBeAg, normal ALT, and either low or undetectable levels of HBV DNA. This patient population usually experiences a more benign course of disease, with the possibility of long-term remission, even seroconversion, although reactivation is possible with the progression to cirrhosis and HCC. Up to 20% of patients in the inactive carrier state may revert to detectable HBeAg, emphasizing the need for lifelong follow-up to confirm quiescence.[14]

In a subset of patients, often in patients who are older, another phase of infection may occur which is described as the immune escape or HBeAg-negative chronic infection. This phase is linked to mutations of the virus resulting in a lack of production of HBeAg and is associated with worse outcomes.[10] Patients may have long periods of disease remission, but recurring flares of hepatitis with increased frequency and severity can progress to cirrhosis and HCC.

Reactivation of hepatitis B, defined as the recurrence or abrupt rise in HBV replication by an increase in serum HBV DNA of at least 1 $\log_{10}$ and a marked increase in transaminase levels, can occur and is well described in the literature in patients receiving cancer chemotherapy, steroids, and other immunosuppressive agents.[16,17] Reactivation can occur in anyone with a prior or current HBV exposure, but patients who are HBsAg positive are most likely to experience a reactivation.[17] The causes of reactivation include spontaneous mutations of the virus that allow it to escape immune control, development of resistance to HBV drug therapy or the cessation of HBV therapy, or changes in immunity, such as those that occur in patients undergoing immunosuppressive therapies or coinfection with HIV. Antiviral prophylactic therapy is often indicated to prevent reactivation.[10]

Cirrhosis

Cirrhosis results as the liver attempts to regenerate while in an environment of persistent inflammation. Most patients with compensated cirrhosis either are asymptomatic or have mild symptoms of epigastric pain. During cirrhosis, the liver enters a cycle of ongoing liver damage, fibrosis, and attempts at regeneration. The classical appearance of a small and knobby liver reflects the irreversible effect of nodules of regenerating cells integrated with infiltrates of inflammation-induced fibrous tissue. Both viral and clinical factors affect the outcome of cirrhosis (**Table 40-8**). Cirrhosis develops at an annual incidence rate of 2.1% to 3.5%.[13] The development of cirrhosis is mostly insidious and patients can remain stable for years before disease progression. An estimated 20% of all chronic hepatitis B patients develop complications of hepatic insufficiency and portal hypertension as their compensated cirrhosis progresses to decompensated cirrhosis within a 5-year

period.[14]

TABLE 40-8 Factors Associated with Hepatitis B Virus Cirrhosis and Disease Progression

Persistence of HBV serum DNA
Infection with genotype C
Coinfection with HCV, delta hepatitis, or HIV
Age at diagnosis
Severity of liver disease at diagnosis
Male sex
Frequency of severe hepatic flares
Alcohol use
Laboratory/physical findings of abnormal liver function
Obesity and metabolic disorders
Smoking

Data from references 13, 14, and 19.

Hepatocellular Carcinoma

HBV is a known risk factor for the development of HCC and in areas of high HBV endemicity, a major complication of the infection.[9] The development of HCC can be insidious, occurring in the absence of cirrhosis or in the presence of clinically silent, compensated cirrhosis. Many patients with HCC have no signs of cirrhosis.[14] The virus itself is not likely the causative agent of the cancer. In most cases, HCC develops after years of inflammatory processes provoked by ongoing HBV infection however HBV itself is an oncogenic virus.[10] Several factors influence the development of HCC, as well as predict survival (see Table 40-8). HCC is more prevalent in males; in older patients; in patients coinfected with HCV or delta hepatitis; in patients coinfected with HIV; in patients with diabetes; and in patients with serologic markings of past or present HBV infection, preexisting cirrhosis, or continued alcohol ingestion. Risks for death and decompensation increase with underlying liver disease. Serum ALT levels, on-going viral replication, and family history of HCC are also associated with progression.[10] Smoking is a risk factor among European and Asian patients.[18,19]

Vaccine Prevention of Hepatitis B

5 The development of the HBV vaccine represented the first vaccine against a major human cancer.[10] Despite the availability of the HBV vaccine in 1982, rates of HBV did not decline in the early 1980s. Initial declines in incidence were likely attributable to behavioral changes among high-risk groups as a result of the acquired immune deficiency syndrome (AIDS) epidemic. A 94% decline in rates between 1990 and 2004 was seen in children and adolescents, which began with the initiation

of screening of pregnant women and subsequent immunizations of infants and recommendations set forth in the 1990s to immunize adolescents. Regulations enacted by Occupational Safety and Health Administration (OSHA) further reduced overall U.S. rates by 75%.[12]

5 Prophylaxis against HBV can be achieved by vaccination or by passive immunity in postexposure cases with hepatitis B Ig. Vaccination is the most effective strategy to prevent infection and a comprehensive vaccination strategy has been implemented in the United States (**Table 40-9**). Vaccines use HBsAg for the antigen via recombinant DNA technology using yeast to prompt active immunity. More than 60 million adolescents and more than 40 million infants and children have received an HBV vaccine in the United States since 1982. The vaccine is considered safe. Since 2000, vaccines licensed in the United States contain either none or trace amounts of thimerosal as a preservative. Available vaccines include two single-antigen products and three combination products. The two single-antigen products are Recombivax® HB and Engerix-B®. TWINRIX® is a combination vaccine for HAV and HBV in adults. Comvax® and Pediarix® are used for children and are used for HBV along with other scheduled vaccines. Unlike the HAV vaccine, the HBV vaccine response is generally lower and often requires at least three doses for optimal protection.

TABLE 40-9 Recommendations for Hepatitis B Virus Vaccination

Infants
Adolescents including all previously unvaccinated children <19 years
All unvaccinated adults aged 19-59 with diabetes mellitus
All unvaccinated adults at risk for infection
All unvaccinated adults seeking vaccination (specific risk factor not required)
Men and women with a history of other STDs and persons with a history of multiple sex partners (>1 partner/6 months)
MSM
Current or recent IDUs
Household contacts and sex partners of persons with chronic hepatitis B infection and healthcare and public safety workers with exposure to blood in the workplace
Clients and staff of institutions for the developmentally disabled
International travelers to regions with high or intermediate levels (HBsAg prevalence ≤2%) of endemic HBV infection
Recipients of clotting factor concentrates
STD clinic patients
HIV patient/HIV-testing patients
Drug abuse treatment and prevention clinic patients
Correctional facilities inmates
Chronic dialysis/ESRD patients including predialysis, peritoneal dialysis, and home dialysis patients
Persons with chronic liver disease

HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HIV, human immunodeficiency virus; ESRD, end-stage renal disease; IDUs, injection drug users; MSM, Men who have sex with men; STDs, sexually transmitted diseases.

Data from reference 11.

Passive immunity in the form of anti-HBsAg offers temporary protection against HBV and is used in conjunction with the hepatitis B vaccine for postexposure prophylaxis.[12]

TREATMENT Desired Outcomes

6 HBV infections are not curable; rather, the goals of therapy are to suppress HBV replication and prevent disease progression to cirrhosis and HCC. The loss of HBsAg is becoming an increasingly more important goal in therapy.

General Approach to Treatment

6 Response to therapy is monitored by biochemical, histologic, and virologic assessments (**Table 40-10**).[14] Maintenance of viral suppression is defined as durability of response. In HBeAg-positive patients, successful therapy includes loss of HBeAg status and seroconversion to anti-HBeAg. Other serologic markers are typically not evaluated in clinical trials. Recommendations for treatment consider the patient's age, serum HBV DNA and ALT levels, as well as histologic evidence and clinical progression of disease (**Figs. 40-1** and **40-2**). Not all chronic HBV patients are candidates for treatment. In general, treatment is indicated if the risk of liver-related morbidity and mortality is within the foreseeable future and the likelihood for achieving sustained viral suppression is high.[14] Some patients may be best managed with periodic monitoring for disease progression because the chances for therapeutic response are unlikely and do not outweigh the risks and costs associated with treatment. The major organizations providing guidelines on the management of HBV infections are the WHO, American Association for the Study of Liver Diseases (AASLD), the European Association for the Study of Liver Disease, and the Asian Pacific Association for the Study of the Liver.[10,13,14,15]

TABLE 40-10 Definitions of Response in Hepatitis B Virus Therapy

Biochemical	Normalization of ALT
Histologic	Decrease in histology activity by at least 2 points as compared with baseline biopsy
Virologic	Undetectable HBV DNA and, in patients previously HBeAg positive, loss of HBeAg

ALT, alanine transaminase; DNA, deoxyribonucleic acid; HBV, hepatitis B virus; HBeAg, hepatitis B e antigen.

Nonpharmacologic Therapy

All chronic HBV patients should be counseled on preventing disease transmission. Sexual and household contacts should be vaccinated. To minimize further liver damage, all chronic HBV patients should avoid alcohol and be immunized against HAV. No level of alcohol use has been established as safe.[14] Moreover, patients are encouraged to consult their medical provider before using any new medications, including herbals and nonprescription drugs.[14]

Herbal medicines are an intriguing option to many patients. Although some of the products may have some physiologic benefits, there are insufficient data and the methodologic qualities of the trials evaluating the herbs are poor. Randomized, placebo-controlled studies and long-term follow-up data are lacking.[20]

Pharmacologic Therapy

Because hepatic damage is sustained by ongoing viral replication, drug therapy aims to suppress viral replication by either immunomodulating agents or antivirals—the nucleos(t)ide agents (NAs). In the United States, the immune-mediating agents approved as first-line therapy are interferon (IFN)-alfa and pegylated (peg) IFN-alfa. The antiviral agents lamivudine, telbivudine, adefovir, entecavir, and tenofovir are all approved as first-line therapy options for chronic HBV.[14] A major difference in therapy is duration of use: IFN-based therapies are typically administered for a predefined duration, whereas NAs are used until a specific end point is achieved. For HBeAg-positive patients, treatment is recommended until HBeAg seroconversion and an undetectable HBV viral load are achieved and for 6 months of additional treatment. In HBeAg-negative patients, treatment should be continued until HBsAg clearance.[14]

Interferon

IFN-alfa therapy was the first approved therapy for treatment of HBV and improves long-term outcomes and survival. Acting as a host cytokine, it has antiviral, antiproliferative, and immunomodulatory effects in chronic HBV.[14] Several factors correlate with improved response to IFN therapy, including increased ALT and HBV DNA levels, high histologic activity score at biopsy, and being non-Asian. Asian patients tend to have more normal ALT levels in chronic infection; confounding the actual impact of ethnicity on infection.[14] The main mechanism of action of the IFNs is to enhance the host immune system to mount a defense against HBV.

Patients who respond to IFN therapy tend to have a more durable response than that seen with lamivudine, likely as a consequence of IFN's stimulation of the immune response for seroconversion. However, seroconversion with IFN therapy is most likely in patients with HBeAg positivity and who have persistent or intermittently elevated ALT. The duration of therapy is finite, although the optimal duration of treatment is unclear and some patients benefit from a prolonged course of therapy including up to 24 months.[14] Patients treated with IFN were historically treated with thrice-weekly IFN, which has largely been replaced by peg-IFN because of the benefits in ease of administration (once weekly injections) and improvements in efficacy. IFN-based therapies are still limited by multiple adverse effects. The high risk of infection precludes use of IFN in decompensated cirrhotic patients.[14] In patients with compensated cirrhosis, IFN appears to be safe and effective, although it can provoke hepatic flares and precipitate hepatic decompensation.[14] Because IFN is not directly acting on the virus and thus not susceptible to specific resistant mutations, it remains an option in treatment and ongoing clinical trials are investigating the use of either sequential or combination therapy with peg-IFN and NAs. The optimal role of IFN-based therapies in HBV treatment is not defined. IFN therapies remain an option in the United States.[14] However, due to the substantial side effects, need for monitoring, and toxicities of IFN-based therapies, IFN is not considered an option in resource-limited countries and not recommended as a first-line therapy by the WHO guidelines.[10]

Lamivudine

Lamivudine, an NA, has antiviral activity against both HIV and HBV but is not recommended as first-line therapy for chronic HBV infections. It is given at a dose of 100 mg by mouth daily and

inhibits HBV DNA synthesis by being incorporated into growing DNA chains causing premature chain termination.[14] Normalization of ALT levels occurs gradually over 3 to 6 months in most patients. Additionally, fibrotic changes are reduced and may be reversed in some cases. Response to lamivudine is dependent on baseline ALT levels, with higher levels corresponding to greater likelihood of seroconversion. Seroconversion rates increase with duration of therapy and are at 50% by the fifth year of therapy.[14] Patients who can maintain long-term viral suppression have reduced and possibly reversed cirrhotic changes. However, lamivudine therapy is not without problems. There is no clear duration of treatment. Patients who are HBeAg-negative have a less than 20% viral suppression rate after 12 months of therapy.[14] Seroconversion rates are less than 20% after 1 year of therapy and will relapse in up to 58% of patients. Resistance is inevitable and can undermine the value of treatment. The emergence of resistant mutants increases with each subsequent year of therapy, with rates approaching 80% after 5 years of therapy, and is associated with returns of serum HBV DNA and elevated ALT levels.[21] Relapse is associated with reversion of histologic benefits.[14] In HBeAg-negative chronic hepatitis B, where therapy is long-term and the exact duration of therapy unknown, resistance is an especially daunting problem.[14] Patients on lamivudine therapy require monitoring for breakthrough infection. If patients have confirmed lamivudine-resistant mutations, therapy should be changed to include agents with activity against lamivudine-resistant HBV.[14]

Adefovir

Adefovir dipivoxil is an acyclic NA of adenosine monophosphate. The drug acts by inhibiting HBV reverse transcriptase and DNA polymerase and is effective in both wild-type and lamivudine-resistant HBV. It is dosed at 10 mg daily for 1 year in adults, although the optimal duration of therapy is unknown and some patients may benefit from a prolonged course of therapy.[14] Patients who are HBeAg-negative in particular are likely to benefit from prolonged treatment courses. Adefovir is well tolerated at the 10 mg daily dose. Previous reports of nephrotoxicity were associated with clinical trials where adefovir was dosed at 30 mg/day. In patients treated chronically at a dose of 10 mg daily, the incidence of nephrotoxicity was the same as placebo. Routine monitoring of serum creatinine is recommended every 3 months in patients at risk for renal insufficiency and in all patients treated for more than a year with adefovir.[14]

Resistance to adefovir has not been seen within the first year of therapy.[21] Resistant mutants have been identified and may be more likely in patients with prior lamivudine resistance.[14] In contrast, combination therapy with lamivudine and adefovir may decrease the risk of adefovir resistance.[22] Neither the optimal duration for combination therapy nor the optimal drug therapy in adefovir resistance is known.[14]

Adefovir's role in HBV therapy is unclear. It is no longer recommended as monotherapy by international guidelines.[10]

Entecavir

7 Entecavir is a guanosine NA that acts by inhibiting HBV replication at three different steps. An

oral agent, it is more potent than lamivudine and adefovir in suppressing serum HBV DNA levels and is effective in lamivudine-resistant HBV.[14] Entecavir does have weak activity against HIV.[10] Rates of HBeAg seroconversion are higher in patients with elevated baseline ALT.[14] The drug is dosed at 0.5 mg daily for adults with treatment-naïve or non–lamivudine-resistant infections and at 1 mg daily in lamivudine-refractory patients. In treatment-naïve patients, entecavir resistance remains low, even after six years of therapy, demonstrating the high barrier to resistance of the drug.[21] However, treatment response in lamivudine-resistant patients is lower overall and more likely for the development of entecavir-resistant mutants especially if lamivudine is continued during entecavir therapy.[14] Patients on lamivudine who develop resistance and are switched to entecavir should stop lamivudine therapy.[14] Resistance to lamivudine is a risk factor for entecavir resistance.[21] In terms of safety, entecavir is comparable to lamivudine. Entecavir is considered to be a first-line agent for HBV therapy because of its efficacy and low rates of resistance.[10,14]

Telbivudine

Telbivudine is an HBV-specific NA that acts as a competitive inhibitor of viral reverse transcriptase and DNA polymerase to inhibit HBV DNA synthesis. Compared with lamivudine, telbivudine is a more potent suppressor of HBV DNA.[14] However, similar to lamivudine, telbivudine has a high rate of mutations that limits its efficacy. Moreover, telbivudine-resistant mutations are cross-resistant with lamivudine. Due to resistance concerns, telbivudine monotherapy has a limited role in the treatment of HBV and is not recommended as monotherapy by international guidelines.[10,14]

Tenofovir

7 Tenofovir is considered to be a first-line therapy in the treatment of HBV.[14] For HBV, it is available as a single-agent oral tablet. Tenofovir is similar to adefovir but without the nephrotoxicity seen with adefovir, permitting adult dosing to be 300 mg versus 10 mg of adefovir. The higher dosing strategy likely confers several advantages to tenofovir in comparison with adefovir. In lamivudine-resistant chronic hepatitis B, tenofovir showed an earlier and greater suppression of HBV DNA than adefovir. In studies of treatment-naïve patients on tenofovir for up to 3 years, no resistant mutations were detected.[27] Additional data suggest sustained viral suppression with regression of fibrosis and no resistance in patients treated with tenofovir for up to 7 years.[21,23] Viral suppression was seen in nearly all patients, regardless of HBeAg status.[23] No resistance was identified to tenofovir through the 7-year study period. Other studies have demonstrated good viral suppression with tenofovir in treatment-experienced patients. Tenofovir can overcome adefovir treatment failure, but adefovir mutants demonstrate some cross-resistance because viral suppression by tenofovir is reduced.[10,21]

Alternative Drug Treatments

Combination therapy has been proposed to increase drug effectiveness and to counter the issues of resistance. Potential disadvantages for combination therapy include costs, toxicity, and drug interactions. Currently no data exist that combination therapy of two antiviral agents improves

effectiveness. IFN-based therapy, because it acts on the host immune system rather than the virus itself, poses an interesting option in overcoming viral resistance. Data for preventing resistance are mixed as complete suppression of resistance has not been achieved with combination therapy. Combination therapy with IFN and lamivudine creates less resistance than lamivudine monotherapy, but the combination did not change the posttherapy viral response in comparison to IFN monotherapy.[14] Given the toxicity profile of IFN, it is unlikely a combination therapy with IFN will be used.

Combination therapy with NA agents may offer a way to bypass IFN-induced toxicity and minimize resistance concerns; however, combination therapy is not frequently used as initial therapy. Many studies examined the role of sequential or add-on therapy, rather than comparing the effectiveness of monotherapy versus combination therapy in an otherwise treatment-naïve patient population. There may be a role for combination therapy, especially in patients with high initial viral loads or multiple underlying HBV resistance mutations.[24,25] Furthermore, in resource-limited areas where access to monotherapy may be cost-prohibitive, combination therapy may offer a strategy to reduce resistance and provide optimal HBV viral suppression.[21] There is also increasing interest in the use of combination therapy to prevent HBV recurrence in patients undergoing immunosuppressive therapies.

Combination therapy is not recommended as initial therapy. Current guidelines suggest combination therapy with two or more agents in patients who develop antiviral resistant HBV.[13,14,15] The AASLD recommends combination therapy with lamivudine or telbivudine plus adefovir, tenofovir, or entecavir for decompensated cirrhotic patients with chronic HBV regardless of HBV DNA levels or HBeAg status.[14]

Special Populations

Cirrhosis

The decision to treat cirrhotic patients depends on disease progression. Patients with decompensated cirrhosis require referral for liver transplant. The AASLD guidelines suggest lamivudine, telbivudine, adefovir, tenofovir, and entecavir are possible agents for use in cirrhotic patients (see Fig. 40-2).[14]

Clinical Controversy…

There is a variability in practice recommendations regarding the need and indications for HBV screening and prophylaxis across medical specialties. Even if patients are screened and antiviral prophylaxis is initiated, the optimal duration of antiviral therapy is unclear.

Coinfection with Hepatitis C Virus

In patients coinfected with HCV, the clinical practice is to treat the more dominant form of the hepatitis virus. There are no current recommendations on management of HBV/HCV coinfection. Previously published recommendations suggested treating HCV according to published guidelines

and to consider the addition of entecavir or adefovir if HBV DNA levels remained stable or rose.[14]

Coinfection with Hepatitis D

Patients coinfected with hepatitis D, which requires infection with hepatitis B, may be treated with high-dose IFN-alfa or peg-IFN.[14] There is an overall paucity of data on HBV–HDV coinfection treatment. No NAs have demonstrated efficacy against HDV.[10]

Coinfection with Human Immunodeficiency Virus

In HIV-coinfected patients, therapy should be tailored specifically to the patient. Initiation of highly active antiretroviral therapy (HAART) in patients with cirrhosis is strongly recommended as it may improve overall survival. If the patient is being treated for HIV, certain regimens may be optimized to include drugs with efficacy against HBV, including tenofovir, emtricitabine, or lamivudine. [14]

Pediatric Patients

Although the majority of chronic HBV patients are adults, children may be treated. Lamivudine is indicated for children 2 years and older and IFN is approved for use in children 1 year and older. Entecavir is approved for children 2 years and older and adefovir for children 12 years and older. Tenofovir is approved for children 12 and older although for HIV, tenofovir may be used in children 3 years and older. Although peg-IFN-alfa does have indications for children 3 years and older, the approval is for the use in chronic hepatitis C infections.

Pregnant Females

Perinatal transmission of HBV is a major cause of chronic HBV. To prevent mother-to-child transmission, the use of lamivudine or telbivudine in the third trimester is recommended for women. Tenofovir is an alternative.[13]

Immunosuppressive or Cytotoxic Therapy

8 Patients who will undergo chemotherapy or immunosuppressive therapy should be assessed for risk of HBV. The American Gastroenterological Association publishes guidelines on antiviral prophylaxis.[26] According to their recommendations, patients who should receive antiviral prophylaxis because they are at high risk of HBV reaction are (1) HBsAg-positive or negative and anti-HBc-positive and undergoing B-cell depleting agents such as rituximab; (2) HBsAg-positive and anti-HBc-positive treated with anthracycline derivatives such as doxorubicin; (3) HBsAg-positive and anti-HBc-positive undergoing 10 to 20 mg prednisone daily or equivalent therapy or on high-dose (>20 mg prednisone daily or equivalent) corticosteroids for 4 weeks or more. Due to moderate risks of reactivation, other immunosuppressive therapies such as tumor necrosis factor alpha inhibitors, cytokine or integrin inhibitors, tyrosine kinase inhibitors, and corticosteroids are also identified as requiring antiviral prophylaxis in patients with specific HBV serological results.[26,27] The CDC

recommends testing for hepatitis B for all patients who are to receive chemotherapy or other immunosuppressive agents.

8 Prophylactic therapy is recommended prior to initiation of cancer chemotherapy or immunosuppressive therapy. Patients who have undetectable HBV DNA and who are expected to be on treatment for 1 year or less should be treated for 6 months after completion of chemotherapy or immunosuppressive therapy.[27]

Resistance Concerns

Current guidelines favor the use of potent agents with low rates of resistance. Resistance potential in HBV is evaluated by an antiviral agent's genetic barrier to resistance, or the number of primary mutations needed for antiviral drug resistance to occur. Other factors include cross-resistance and drug potency. Viral suppression is important because the HBV virus requires ongoing viral replication in the setting of antiviral drug pressure to mutate. HBV therapy can be cost-prohibitive for many patients and can favor the use of lamivudine. Unfortunately lamivudine-based therapies are prone to resistance and may have long-term implications on viral activity, notably the concerns for development of vaccine-resistant mutants.[12,21]

Hepatitis B Virus Mutations

Although a DNA virus, HBV uses reverse transcriptase, similar to a retrovirus such as HIV. The similarities between HIV reverse transcriptase and HBV polymerase prompted the development of NAs for the treatment of HBV. IFN-based therapies, because they are immune-modulating and not directly antiviral, are not associated with resistance. However, long-term therapy with the NAs is problematic because of the high likelihood of developing HBV viral resistance given HBV's high replication rate and an estimated 10[10,11,12] mutations generated daily.[10] In addition, HBV can archive drug-resistant mutations that allow the virus to quickly select the mutation if the antiviral agent is reintroduced. Cross-resistance amongst antiviral agents also occurs, further limiting therapeutic options. Lamivudine is most associated with resistance due to (1) its low barrier for developing resistance with a single mutation able to overcome the agent combined with (2) widespread use of lamivudine in some regions.[10]

Resistance to the NA agents occurs by alteration of the active site of the HBV DNA polymerase. Long-term use of lamivudine is associated with resistance mutations of this active site.[28] The incidence of lamivudine resistance increases with each subsequent year of therapy and may be associated with a more severe disease progression.[14] Cross-resistance occurs with HBV polymerase mutations to lamivudine also affecting telbivudine.[28] Other mutations include resistance to adefovir and entecavir. Based on clinical studies of NAs with up to 6 years of follow-up, patients on entecavir and tenofovir were the least likely to develop resistance.[21] As a result, both entecavir and tenofovir are the preferred first-line agents for HBV. The optimal management of patients with resistant HBV is not clear.

Another major factor in resistance is patient adherence to therapy. Studies on adherence suggest

suboptimal adherence is common with approximately 40% of patients missing doses.[29] Moreover, in patients experiencing virologic breakthrough, studies have shown that 40% of cases were not related to antiviral drug resistance, emphasizing the impact of medication adherence on viral suppression.[30]

Personalized Pharmacotherapy

Vaccination for HBV is less effective than for HAV and requires multiple doses for improved response. Several host factors are implicated in a reduced response. Patients who are immunocompromised and patients on hemodialysis may require additional doses to induce antibody response. Some patients may require repeat vaccination.[31] Sleep deprivation may also contribute to decreased antibody response.[32]

HEPATITIS C

In the United States, approximately 3.2 million people are chronically infected with HCV.[1] HCV is approximately 5 times as common as HIV and is responsible for an estimated 10,000 chronic liver disease–associated deaths per year.[1] Most acute infections are asymptomatic and the course of the infection is insidious. As a result, many patients are not diagnosed until significant disease progression. Today's HCV disease burden is associated to the high numbers of patients infected in the 1980s. HCV was not easily identified and testing for the virus was not commonly implemented until the early 1990s. Historically, HCV treatment was plagued by significant side effects and profound laboratory abnormalities. Beginning in late 2013, HCV therapies evolved dramatically with all-oral regimens that are curative in the overwhelming majority of patients.

Epidemiology

HCV is the most common blood-borne pathogen. Since 2010, the number of acute HCV cases increased by over 151%, due to both improved surveillance and increase in incidence. There were 29,718 new HCV infections in 2013, primarily among young, white persons, living in nonurban areas, with a history of injection and opioid agonist use.[2] Since 2007, the number of deaths attributable to HCV exceeded the number of deaths due to HIV.[2,33] Considering that HCV infection is prevalent in high-risk populations such as prisoners, injection drug users (IDUs), and the homeless, and that this population is generally excluded from most surveys, the actual number of chronically infected people is significantly higher. Estimates vary, but approximately 45% to 85% of infected people may not be identified.[1,33,34] 9 10 The impact of undiagnosed and untreated HCV is expected to increase dramatically over the next 40 to 50 years with 1.76 million persons developing cirrhosis, 400,000 developing HCC, and 1 million persons dying from HCV-associated complications.[35] 10 Since 2013, the number of HCV-related deaths among adults between ages 55 and 64 years continues to increase. Targeted testing for HCV of persons born between 1945 and 1965, a recommendation by the CDC and the United States Prevention Services Task Force (USPSTF), attempts to address this rising epidemic.[36]

Transmission of HCV occurs through percutaneous exposure.[37] Injection-drug use is a major factor in the cycle of HCV transmission and the most common reason for new infections. In Indiana in 2015, an outbreak of 135 new cases of HIV among PWIDs identified coinfection with HCV in over 84% of patients.[38] Some experts also consider other illicit drug use, for example, intranasal cocaine, as a risk factor because of the possible contamination of drug paraphernalia not limited to syringes and needles. Unsafe injection practices are associated with HCV transmission and include tattoos received in a nonregulated setting and needle stick injuries. Less common routes of transmission include sexual transmission in particular among HIV-positive MSM and infants born to HCV-infected women. No specific sexual practices are associated with an increased risk of transmission.[39] Although sexual contact is considered an inefficient means of HCV transmission, multiple sexual partners and coinfection with sexually transmitted diseases, including HIV, increase the risk for HCV sexual transmission. Historically, blood transfusion posed a major risk for infection. Improved screening of blood in 1992 decreased the risk of transfusion-related HCV.[37] Healthcare-associated transmission is rare; however, unsafe injection practices as often identified as the cause of HCV transmission.

Although acute HCV infections are often not recognized and many progress to chronic infections, routine screening for infection is not recommended. The AASLD, in conjunction with the Infectious Diseases Society of America (IDSA) and the International Antiviral Society-USA (IAS-USA), publish on-line guidelines for testing, managing, and treating HCV (see www.hcvguidelines.org).[37] In 2012, the CDC released recommendations to perform a one-time screening of all patients born between 1945 and 1965.[36] The recommendation was made due to the high rates of HCV in this birth cohort. The CDC estimates approximately 75% of adults with HCV were born in that age range.[36] Screening is also warranted in patients who are at high risk for infection, especially among PWIDs or who have a history of injection drug use (**Table 40-11**).[37] The risk of infection from other needle-borne exposures, such as tattooing and body piercing, is unclear and at this time not an indication for routine screening for HCV.[37]

TABLE 40-11 Recommendations for Hepatitis C Virus Screening

Anyone born between 1945 and 1965
Current or past use of injection drug use
Coinfection with HIV
Received blood transfusions or organ transplantations before 1992
Received clotting factors before 1987
Patients who have ever been on hemodialysis
Patients with unexplained elevated ALT levels or evidence of liver disease
Healthcare and public safety workers after a needle-stick or mucosal exposure to HCV-positive blood
Children born to HCV-positive mothers
Sexual partners of HCV-positive patients

ALT, alanine transaminase; HCV, hepatitis C virus; HIV, human immunodeficiency virus.

Data from reference 62.

The initial test for HCV infection is the anti-HCV or antibody test (**Table 40-12**). Patients who are antibody positive for HCV require confirmatory testing for HCV RNA to verify current HCV infection. Patients who are anti-HCV positive but who do not have a detectable HCV RNA do not have a current HCV infection and no further workup is required in the majority of cases.[40] Furthermore, it is important that the presence of antibody does not infer immunity and patients are at risk for HCV infection should they be reexposed.[41]

TABLE 40-12 Interpretation of Hepatitis C Virus Test Results

	Interpretation
HCV Antibody Nonreactive	No prior exposure to HCV If suspect recent HCV infection, test for HCV RNA
HCV Antibody Reactive	Prior or current exposure to HCV, requires further evaluation
HCV Antibody Reactive HCV RNA Negative	Prior HCV infection may indicate prior resolution or prior successful treatment
HCV Antibody Reactive HCV RNA Detectable	Indicates current, active infection

HCV, hepatitis C virus; RNA, ribonucleic acid.

Data from reference 40.

Etiology

HCV is a single-stranded RNA virus notable for lacking a proofreading polymerase and enabling frequent viral mutations.[41] The virus replicates within hepatocytes and, like hepatitis B, is not directly cytopathic. HCV replicates copiously posing an immense challenge for host immune control.[41] The implications of viral mutations on direct-acting antiviral (DAA) therapy for HCV is not well understood.

HCV is differentiated into six major GTs, numbered 1 to 6. GTs are further classified into subtypes (a, b, c, etc). The most widely distributed GTs are 1 and 2, with GT1 the most common. In the United States, most infections are caused by GT1a and GT1b, followed by GT2 and GT3. Although infection caused by any of the GTs can lead to cirrhosis, end-stage liver disease (ESLD), or HCC, the significance of the infecting GT is related to therapeutic response. Historically GT1 infections were least likely to respond to therapy, but with the release of DAAs, major advances in response are now possible. GT3 continues to pose a therapeutic challenge.

Pathophysiology

In most cases, an acute HCV infection leads to chronic infection. The immune response in an acute

HCV infection is mostly insufficient to eradicate the virus. HCV poses a daunting challenge for immune control because of its rapid viral diversification. HCV genomic mutations are detectable within 1 year of infection. Resolved cases of HCV are defined by a vigorous T-cell response with highly active CD8 and persistent CD4 cell response. CD8 activity mediates protective immunity but requires the aid of CD4 cells to maintain the response during viral mutations.[41]

Clinical Presentation

In an acute HCV infection, most patients are asymptomatic and undiagnosed. HCV RNA is detectable within 1 to 2 weeks of exposure and levels rise quickly during the initial weeks. Approximately one-third of adults will experience some mild and nonspecific symptoms, including fatigue, anorexia, weakness, jaundice, abdominal pain, or dark urine.[42] Acute infections rarely progress to fulminant hepatitis, although the course can be severe and prolonged. If the infection is self-limiting, symptoms last several weeks as ALT and HCV RNA levels subside. Almost all patients, including immunosuppressed patients, will develop antibodies to HCV. Typically, antibodies are not detectable until either at the time of or shortly after the development of symptoms, limiting their usefulness in diagnosing an acute infection.[37]

Up to 85% of acutely infected patients will go on to develop a chronic HCV infection, defined as persistently detectable HCV RNA for 6 months or more. HCV RNA levels and ALT levels can fluctuate and even have periods of undetectable HCV RNA and normal ALTs. Most patients will have few, if any, symptoms. The most common symptom is persistent fatigue. Additional symptoms include right upper quadrant pain, nausea, or poor appetite. On physical examination, hepatomegaly is usually present. With advanced disease, stigmata of liver disease are evident, such as spider nevi, splenomegaly, palmar erythema, testicular atrophy, and caput medusae. However, almost all patients with chronic HCV will have some degree of necroinflammatory disease on liver biopsy. Chronic inflammation of the liver from chronic HCV infection may result in fibrosis. Fibrosis is defined by altered hepatic perfusion creating a distorted structure and affecting normal function. Fibrosis leads to cirrhosis, although the speed of fibrosis progression can vary.

10 The development of HCV cirrhosis poses a 30% risk over 10 years for the development of ESLD, as well as a 1% to 2% risk per year of developing HCC.[34] Progression to cirrhosis is the primary concern in patients infected with HCV for two decades or longer. Disease progression is not uniform or linear, making it difficult to identify which patients will have progressive liver damage and when. Other concomitant viral infections, comorbidities, and lifestyle factors can contribute to disease progression. On-going alcohol use, obesity, and metabolic syndrome can potentiate fibrosis.[37] Viral load is not a factor for disease progression and not associated with degree of fibrosis. Coinfection with HIV or HBV is associated with disease progression as is infection with HCV GT3.[37,43]

10 Although HCV is thought of as a liver disease, HCV is associated with extrahepatic manifestations, or HCV-associated systemic disease. The most common is cryoglobulinemia, a local deposition of immune complexes that cause vasculitis.[37] Typical manifestations involve the skin and internal organ damage, predominantly affecting the kidneys and associated with worsening renal function. Other

systemic diseases associated with HCV include cardiovascular disease, diabetes, B-cell non-Hodgkin lymphoma, Sjögren syndrome, glomerulonephritis, arthritis, corneal ulcers, thyroid disease, neuropathies, and skin diseases such as vasculitis, porphyria cutanea tarda, and lichen planus.[44]

9 For many patients, a diagnosis of hepatitis C is incidental. Unfortunately, those patients who present with symptoms typically have advanced disease. Due to the profound morbidity and mortality associated with HCV, the overall lack of awareness of the HCV epidemic, and the advances in treatment, the CDC recommends testing for HCV for anyone born between 1945 and 1965.[36] Early diagnosis and treatment can prevent liver damage, cirrhosis, HCC, and death. The U.S. Preventative Task Force joined the CDC to recommend screening of HCV in the birth cohort and among high-risk individuals.[45]

TREATMENT Desired Outcomes

11 The primary goal of therapy is to eradicate HCV infection. Virologic cure, or sustained virologic response (SVR), is defined as a nondetectable HCV RNA at least 12 weeks after completing HCV therapy. The definition of SVR changed as prior to the release of the DAAs, SVR was defined as nondetectable HCV RNA 24 weeks after completing treatment. Patients who achieve SVR will continue to have detectable HCV antibody, though this does not imply HCV immunity. Resolving the infection prevents the development of chronic HCV infection sequelae including ESLD, HCC, and death. Patients with extrahepatic manifestations of HCV are expected to benefit with reductions in symptoms and disease severity of their extrahepatic disease while experiencing improvements in quality of life measures.[37] As more patients are cured, the risk of transmission is expected to decline and reduce the long-term HCV disease prevalence.[37]

General Approach to Treatment

Although treatment for HCV is recommended for all HCV-infected persons, patients with advanced fibrosis, compensated cirrhosis, liver transplant recipients, and patients with severe extrahepatic HCV are recommended for urgent treatment.[37] Patients with fibrosis, HIV-HCV coinfection, HBV-HCV coinfection, other coexisting liver disease, debilitating fatigue, diabetes mellitus, and porphyria cutanea tarda are listed as high priority of treatment because of high risk for developing HCV complications. Importantly, there are no longer any clearly identified contraindications for HCV therapy. In some patients at high risk of transmitting HCV, HCV treatment may help reduce rates of HCV transmission.[37]

Before therapy is initiated, quantitative HCV testing and genotyping are performed. Quantitative amplification assays for HCV RNA are performed to confirm chronic HCV infection, can serve to identify candidates for a shortened duration of therapy, and are used to monitor virologic response once therapy is initiated. Genotyping is also necessary because duration of therapy varies depending on the infecting GT. An assessment of underlying liver disease is necessary to guide treatment options and assess urgency for treatment. Although biopsy was previously recommended, less invasive tests can be used to stage liver disease. The less invasive tests include the use of routine tests and direct serum biomarkers and transient liver elastography. Moreover, the aspartate

aminotransferase-to-platelet ratio index (also known as the APRI) or fibrosis-4 index can help identify patients with advanced fibrosis or cirrhosis.[37]

Nonpharmacologic Therapy

All chronic HCV patients should be vaccinated against hepatitis A and B. Lifestyle changes are an important factor in reducing health consequences in hepatitis C. Continued alcohol use is a known risk factor for disease progression and severity. There is no established lower limit of alcohol consumption at which disease progression is not seen. Obesity is also a factor and patients should be encouraged to eat a balanced diet and exercise regularly to maintain a normal weight. Progression of fibrotic changes is associated with obesity. Smoking may also contribute to disease progression. Marijuana smoking, especially daily use, is a risk factor for progression of liver disease in patients with HCV.[46,47] The use of herbal therapy is ineffective. Patients should be counseled on minimizing HCV transmission risks.

Pharmacologic Therapy

11 The treatment of chronic HCV was revolutionized with the approval of DAAs. Previously the treatment backbone included the injection of peg-IFN and was associated with a substantial side-effect profile. The current standard of care for all chronic HCV infections, regardless of GT, is an all-oral regimen. **Table 40-13** lists current recommended therapeutic regimens for GT1 treatment-naïve patients. Current guidelines suggest a 12- or 24-week duration of therapy, depending on HCV GT and subtype (1a vs 1b). The need for concomitant ribavirin use varies. Patients who are treatment-experienced, in whom prior peg-IFN and ribavirin therapy failed, and who have cirrhosis may require either a longer treatment duration or the addition of ribavirin. There are few recommendations for patients who previously failed a protease inhibitor and the management of patients who failed DAAs is even less well understood. **Table 40-14** provides a comparison of the DAAs.

TABLE 40-13 AASLD/IDSA/IAS-USA Recommended Treatment Regimens for Treatment-Naïve Patients with Hepatitis C (in Alphabetical Order)

HCV Genotype	No Cirrhosis	Cirrhosis
1a	Daclatasvir[a] + sofosbuvir for 12 weeks	Daclatasvir[a] + sofosbuvir ± ribavirin for 24 weeks
	Ledipasvir/sofosbuvir for 12 weeks	Ledipasvir/sofosbuvir for 12 weeks
	Ombitasvir/paritaprevir/ritonavir + dasabuvir and ribavirin for 12 weeks	Ombitasvir/paritaprevir/ritonavir + dasabuvir and ribavirin for 24 weeks
	Simeprevir and sofosbuvir for 12 weeks	Simeprevir and sofosbuvir ± ribavirin for 24 weeks

HCV Genotype	No Cirrhosis	Cirrhosis
1b	Daclatasvir[a] + sofosbuvir for 12 weeks	Daclatasvir[a] + sofosbuvir ± ribavirin for 24 weeks
	Ledipasvir/sofosbuvir for 12 weeks	Ledipasvir/sofosbuvir for 12 weeks
	Ombitasvir/paritaprevir/ritonavir + dasabuvir for 12 weeks	Ombitasvir/paritaprevir/ritonavir + dasabuvir for 12 weeks
	Simeprevir and sofosbuvir for 12 weeks	Simeprevir and sofosbuvir ± ribavirin for 24 weeks
2	Daclatasvir[a] + sofosbuvir for 12 weeks	(Consider daclatasvir[a] + sofosbuvir for 24 weeks)
	Sofosbuvir + ribavirin for 12 weeks	Sofosbuvir + ribavirin for 16 weeks
3	Daclatasvir + sofosbuvir for 12 weeks	Daclatasvir + sofosbuvir ± ribavirin for 24 weeks
	Daclatasvir + ribavirin + pegylated interferon for 12 weeks	Daclatasvir + ribavirin + pegylated interferon for 12 weeks

HCV, hepatitis C virus.

[a]Daclatasvir only approved for HCV GT 3 infections in the United States.

Data from reference 37.

TABLE 40-14 Comparison of Hepatitis C Virus Direct Acting Antivirals

Drug	Class	Adult Dose	Use in Cirrhosis	Use in Renal Insufficiency	Adverse Effects	Comments
Daclatasvir	NS5A inhibitor	60 mg daily (available as 30 mg and 60 mg)	No dose adjustment needed	No dose adjustment needed	Headache, fatigue, nausea, diarrhea	FDA approved for GT3; AASLD recommendations in other GT
Ledipasvir	NS5A inhibitor	90 mg daily	No dose adjustment needed	No dose adjustment needed but limited by SOF component	Headache, fatigue	Only available in combination with SOF
Sofosbuvir	NS5B inhibitor	400 mg daily	No dose adjustment needed	Not recommended in eGFR<30 mL/min	Headache, fatigue	FDA approved for GT1-4

Drug	Class	Adult Dose	Use in Cirrhosis	Use in Renal Insufficiency	Adverse Effects	Comments
				/1.73m^2		
Simeprevir	NS3/4A inhibitor	150 mg daily	Not recommended in CTP Class B or C	No dose adjustment needed	Rash including photosensitivity, pruritus, nausea	Used in combination with sofosbuvir or pegylated interferon and ribavirin for GT1
Ombitasvir	NS5A inhibitor	2 tablets daily: each tablet contains 12.5 mg ombitasvir, 75 mg paritaprevir, and 50 mg ritonavir	Not recommended in CTP Class B; Contraindicated in CTP Class C	No dose adjustment needed	Nausea, pruritus, insomnia	Only available in combination with paritaprevir boosted with ritonavir with or without dasabuvir
Paritaprevir	NS3/4A inhibitor	2 tablets daily: each tablet contains 12.5 mg ombitasvir, 75 mg paritaprevir, and 50 mg ritonavir	Not recommended in CTP Class B; Contraindicated in CTP Class C	No dose adjustment needed	Nausea, pruritus, insomnia	Only available in combination with ombitasvir with or without dasabuvir; Boosted with ritonavir
Dasabuvir	NS5B inhibitor	250 mg daily	Not recommended in CTP Class B; Contraindicated in CTP Class C	No dose adjustment needed	Nausea, pruritus, insomnia	Only available in combination with ombitasvir and paritaprevir boosted with ritonavir

AASLD, American Association for the Study of Liver Diseases; CTP, Child-Turcotte Pugh; eGFR, estimated glomerular filtration rate; FDA, Food and Drug Administration; GT: genotype; SOF, sofosbuvir.

Clinical Controversy…

Due in part to the high number of patients with HCV and the high cost of the medications, access to

HCV therapies is often reserved for patients with more advanced liver disease. Patients with cirrhosis, however, often are more difficult to treat and may have lower SVR rates.

Ombitasvir/Paritaprevir/Ritonavir and Dasabuvir

The combination of ombitasvir/paritaprevir/ritonavir and dasabuvir is approved for HCV GT1 infections. Ritonavir does not have activity against HCV but is used to pharmacologically boost paritaprevir to allow for once daily dosing. The treatment duration of ombitasvir/paritaprevir/ritonavir and dasabuvir and need for concomitant ribavirin use varies depends on the infecting HCV subtype. Patients with HCV GT1a require the use of ribavirin and for patients with HCV GT1a and cirrhosis, treatment includes ribavirin and is extended to 24 weeks. The need for ribavirin in HCV GT1a infections was demonstrated in the *PEARL-IV* study which found a lower SVR in patients who did not receive ribavirin at 90.2% versus 97% in patients who did receive ribavirin.[48] The *Turquoise-II* study demonstrated an improved SVR among patients treated for 24 weeks versus 12 weeks (94.2% vs 88.6%, respectively).[49] In contrast, patients without cirrhosis who had HCV GT1b infections were able to achieve high SVR with or without ribavirin, 99.5% versus 99%, in the *PEARL-III* study.[48] For HCV1b infections and underlying cirrhosis, the use of ribavirin is recommended, however, there does not seem to be any additional improvements in SVR by extending the duration of therapy from 12 to 24 weeks.[49,50]

Ombitasvir/Paritaprevir/Ritonavir

The combination of ombitasvir/paritaprevir/ritonavir and ribavirin is approved for HCV GT4 infections. Unlike for HCV GT1, dasabuvir is not required for GT4 and thus the combination is packaged separately. The effectiveness of the regimen was studied in the PEARL-1 study, which showed SVR of 100% in patients treated with ribavirin, compared with 90.9% in patients without ribavirin.[51]

Overall, ombitasvir/paritaprevir/ritonavir with or without dasabuvir is well tolerated and has few laboratory abnormalities. Although ombitasvir/paritaprevir/ritonavir and dasabuvir can be used in cirrhosis, its use is limited to Class A cirrhosis as it is contraindicated in Class B and C cirrhosis. There are no dosing adjustments for renal insufficiency. Patients must discontinue any ethinyl estradiol-containing medications prior to starting therapy with ombitasvir/paritaprevir/ritonavir because of expected elevations in ALT. The concomitant use of ribavirin adds side effects and is expected to exacerbate fatigue and skin reactions, as well as require more frequent laboratory monitoring. The use of ritonavir as a pharmacological booster adds additional drug-drug interaction concerns.

Sofosbuvir

Sofosbuvir was approved in 2013 for HCV GT1-4. Its use in GT1 and 4 was supplanted by the combination of ledipasvir/sofosbuvir which allowed for an IFN-free treatment. For HCV GT2, sofosbuvir in combination with ribavirin is highly effective and was the first all-oral, IFN-free HCV drug regimen available in the United States. Treatment duration is 12 weeks, however, a 16-week course of therapy is recommended in patients with cirrhosis.[37] The use of sofosbuvir for the treatment of HCV GT3 with ribavirin was effective although at substantially reduced SVR as compared

to the treatment efficacy seen in other GTs. The preferred, most effective therapy for GT3 combines sofosbuvir and daclatasvir with or without ribavirin.[37] Sofosbuvir is well tolerated and has few drug-drug interactions. Symptomatic bradycardia was identified in patients treated with sofosbuvir and taking amiodarone in combination with other DAAs, thus this combination is not recommended.

Ledipasvir/Sofosbuvir

The fixed dose combination tablet of ledipasvir/sofosbuvir is approved for use in patients with HCV GT1. Ledipasvir is only available in combination with sofosbuvir. There are no differences in treatment whether patients have GT1a or 1b, however, there are differences in treatment duration depending on underlying cirrhosis.[52,53] Treatment-naïve patients with or without cirrhosis are recommended for a 12-week course of treatment; moreover, patients who are treatment-naïve and noncirrhotic who have a baseline viral load of less than 6 million IU/mL (6×10^9 IU/L)may be considered for an 8-week course of treatment with similar SVR as patients treated for 12 weeks (94% vs 95% SVR).[37,54] The use of ribavirin did not affect SVR rates and is not routinely recommended. In patients with underlying cirrhosis, ledipasvir/sofosbuvir is approved for 24 weeks of treatment, however, based on preliminary results of a multicenter study, the addition of ribavirin to ledipasvir/sofosbuvir allows for a 12-week course of therapy and is recommended by national guidelines.[37,55] National guidelines also recognize the use and efficacy of ledipasvir/sofosbuvir for treatment of HCV GT4 for a 12-week course of therapy.[37]

The combination of ledipasvir/sofosbuvir is well tolerated and can be used in patients with cirrhosis, including Child-Turcotte Pugh (CTP) Class A, B, and C cirrhosis. Its use in patients with renal insufficiency is limited to patients with an estimated glomerular filtration rate no less than 30 mL/min /1.73m^2. Headache and fatigue have been reported as side effects. Laboratory abnormalities are not frequently encountered. The drug-drug interaction potential is also limited although amiodarone use is not recommended because of the symptomatic bradycardia observed with the concomitant use of sofosbuvir, amiodarone, and other DAAs. Acid suppressive therapy poses a challenge to treatment because ledipasvir requires an acidic environment for absorption.

Daclatasvir

Daclatasvir is approved for use with sofosbuvir for HCV GT 1 and 3. It does have activity for other GTs, which is why it is an option for the treatment of GT 2. In both treatment-naïve and treatment-experienced patients with GT3, the combination was highly effective. In noncirrhotic patients the SVR was 96%.[56] The combination is recommended by national guidelines for a planned duration of therapy of 12 weeks.[37] Unfortunately, SVR rates were lower in patients with cirrhosis at 63%. As a result, the optimal management of GT3 patients with cirrhosis remains a challenge. In general, approaches to improving SVR include extending the treatment duration and adding ribavirin. The recommended options include sofosbuvir and daclatasvir for 24 weeks, with consideration to add ribavirin.[37]

Daclatasvir is well tolerated. There are no dosing adjustments for renal or hepatic impairment.

Daclatasvir is subject to various drug-drug interactions. Because it is used with sofosbuvir, it is also subject to warnings regarding serious bradycardia when co-administered with amiodarone. Daclatasvir is the first DAA available in varying dosage strengths: 30 mg and 60 mg, with option to combine for a 90-mg dose. The option to alter the strength allows for use with concomitant medications known or suspected affecting daclatasvir concentrations. The 30-mg strength allows for dosing in the presence of strong CYP3A inhibitors expected to increase the concentration of daclatasvir while the combined strength of 90 mg allows for use in the presence of moderate CYP3A inducers which would otherwise decrease daclatasvir concentrations.

Simeprevir

Simeprevir is a second-generation NS3/4A protease inhibitor which is highly effective for HCV GT1 infections. Originally used in combination with peg-IFN and ribavirin, it is approved for use with sofosbuvir for an all-oral treatment regiment. In patients with HCV GT1a considering simeprevir-based therapy, guidelines recommend pretreatment-resistance testing for the *Q80K* mutation, a baseline resistance which may render simeprevir ineffective.[37]

Ribavirin

Ribavirin continues to be used in combination with DAAs, especially in difficult to treat patients such as those with prior treatment experience or with underlying cirrhosis. The mechanism of action of ribavirin is not well understood. Ribavirin is a synthetic guanosine analog and is ineffective as a monotherapy for HCV. The most common side effect of ribavirin is hemolytic anemia, necessitating close monitoring during HCV therapy. In addition, ribavirin is a teratogenic agent, Pregnancy Category X, and women of childbearing age who undergo HCV treatment with ribavirin need to practice two forms of contraception during HCV treatment and for 6 months after to avoid pregnancy.[37]

Pegylated Interferon

The use of the injectable peg-IFN has diminished profoundly since the approval of the DAAs. The only currently recommended use of peg-IFN is in patients with HCV GT3 as part of a combination therapy with sofosbuvir and ribavirin. The substantial toxicities and side-effect profile of peg-IFN limit its use.

Special Populations

Clinical trials are conducted with a patient population that generally does not reflect the patient spectrum encountered in clinical practice. There are no contraindications to the treatment of PWIDs, prisoners, persons with substance abuse issues, or persons with psychiatric disorders. The sheer number of patients with HCV poses a challenge to access to treatment. Moreover, the costs of the medications are high, resulting in variable access to therapies.

Published recommendations for treatment in various populations are as follows.

Patients with Decompensated Cirrhosis

The presence of cirrhosis poses a substantial challenge in achieving SVR. Furthermore, the level of underlying cirrhosis limits the use of the DAAs. Patients with CTP Class B or C cirrhosis or patients with decompensated cirrhosis are generally recommended to receive care from medical practitioners with expertise managing that level of liver disease. No dose adjustments for hepatic impairment are needed for ledipasvir/sofosbuvir, sofosbuvir, or daclatasvir. In contrast, ombitasvir/paritaprevir /ritonavir with or without dasabuvir is not recommended in CTP Class B cirrhosis and is contraindicated in CTP Class C.

Clinical Controversy…

Although HCV courses of therapy are predetermined, most patients receive medications in 4-week increments. Any delays in receipt of therapy risk the development of HCV resistance. Patients who develop resistance have very limited options for subsequent therapy. The impact of HCV DAA resistance will likely become increasingly important in HCV management. Although pretreatment-resistance testing is not currently recommended for most patients, resistance testing may be indicated for some treatment-experienced patients who failed therapy with DAAs.

Treatment-Experienced Patients

Patients do not have cirrhosis and who failed a previous course of peg-IFN and ribavirin can be retreated similarly to treatment-naïve patients. Patients who are treatment-experienced and have cirrhosis require either an extended duration of therapy or the addition of ribavirin, or both. There are limited data on the retreatment of patients who failed a prior course of therapy with the DAAs; however, the strategy of adding ribavirin and/or extending the treatment duration is recommended.[37] Patients who failed a prior sofosbuvir-regimen may be retreated with ledipasvir/sofosbuvir and ribavirin for 12 weeks if there is no cirrhosis present, and for 24 weeks if cirrhosis is present. Prior to starting HCV therapy, resistance testing is recommended in some patient populations. The role of resistance testing will likely expand.

Acute Exposures

Up to 50% of patients will spontaneously clear an HCV infection and the majority will do so within the first 6 months of exposure.[57] As a result, it is reasonable to defer HCV treatment for 6 months.[37] Once the decision is made to treat, the same regimens used for chronic HCV infections are recommended.[37]

Persons Who Inject Drugs

IDU is not a contraindication to therapy and treatment of PWIDs will be necessary to reduce HCV transmission.[58] Treatment of PWIDs is recommended as part of a comprehensive harm-reduction effort, ideally in a multidisciplinary setting.[37,58] Studies in PWIDs suggest treatment outcomes are comparable to rates in non-IDU and reinfection rates among PWID are low.[59] However, access to

HCV therapies is limited as many insurers refuse coverage of HCV therapies in the setting of active drug use.

Alcoholism

Because continued alcohol use affects disease progression and severity and thus response to therapy, the cessation of alcohol use during therapy is recommended. Moreover, a period of abstinence before initiation of therapy is also recommended.

End-Stage Renal Disease

The pharmacokinetic profile of the DAAs in renal insufficiency is variable; some HCV antivirals can be used in severe renal disease. There are limited data on the treatment of patients on hemodialysis.

HIV Coinfection

Current guidelines do not distinguish separate treatment recommendations for HIV–HCV coinfection; however, potential drug-drug interaction concerns between DAAs and HIV antivirals do merit careful scrutiny and may necessitate antiretroviral drug changes.[37] An important resource for screening of drug-drug interactions with DAAs is the University of Liverpool Web site—www.hep-druginteractions.org. Sofosbuvir has few clinically significant drug-drug interactions. Daclatasvir has potential for some drug-drug interactions; however, the option to adjust the dose of daclatasvir may mitigate the clinical significance of the interactions. Ledipasvir increases tenofovir levels and may increase the risk of tenofovir-associated renal toxicity. The combination of ombitasvir/paritaprevir /ritonavir and dasabuvir includes ritonavir as a pharmacological booster; therefore HIV antivirals which also use ritonavir are not recommended or require dosing without ritonavir. Additional drug-drug interactions exist which may require changes in HIV antivirals. Treatment poses additional problems because of hepatotoxicity issues associated with HAART, hepatic complications from HIV-associated diseases, as well as flares in hepatitis as CD4 counts recover. The prognosis for an SVR is worse than in patients infected with HCV only. In general, treatment is recommended and both HIV and HCV therapies can be coadministered with the exception of didanosine and zidovudine. The combination of ribavirin and didanosine can result in fatal lactic acidosis. Ribavirin causes hemolytic anemia and when combined with zidovudine can result in severe anemia.

Children

Peg-IFN-alfa and ribavirin are approved in children however, due to concerns for use of peg-IFN and ribavirin in this population, and because children with chronic HCV often have mild liver disease, therapy is often deferred. The DAAs are approved in adults 18 and older.

Liver Transplant

Viral eradication prior to transplant is a goal for patients undergoing transplantation as it is associated with improved patient and graft survival. Viral suppression for at least 28 days prior to

transplantation was associated with SVR. Among patients who are treated posttransplant, there are some drug-drug interaction concerns which may require increased monitoring and immunosuppressant dosing adjustments.

Prevention

No vaccine is available for HCV. It is unlikely that a vaccine will be developed in the near future because of the mutagenesis of the virus. Patients infected with HCV should be counseled on not being blood, organ, or semen donors. Although the likelihood of household transmission is small, patients should minimize risks by avoiding possible blood or mucus exposure, such as not sharing razors or toothbrushes and covering open wounds. Patients who continue to use illegal drugs should avoid sharing all drug paraphernalia, as risk of transmission is not limited to needles and syringes.

PERSONALIZED PHARMACOTHERAPY

It is currently not possible to definitively identify patients at risk for disease progression. Several factors may correlate with a decreased risk for chronicity and include host, virus, and environmental factors. Important host factors that minimize the risk of developing chronic infection include being younger than 40 years, female, non-black, not immunosuppressed, and with a symptomatic acute HCV infection. Being older than 20 years at infection triples the risk for chronic HCV. Blacks, especially black men, are more likely to develop chronic infection and have lower treatment responses.[57] Becoming symptomatic and having jaundice is associated with a lower likelihood of chronic infection, perhaps correlating to a stronger immune response to the acute infection. Finally, immunosuppressed patients, such as those with HIV, are more prone to chronic infection, although they are not inherently unable to clear the infection.[57] Similarly, disease progression is associated with increased age, male sex, continued alcohol intake, obesity, and HIV coinfection. Diabetes, as well as steatosis, may also potentiate fibrosis progression.[37]

Variation on a gene encoding for endogenous IFN, interleukin (IL) 28, has been described that is associated with a difference in response to treatment and may explain differences in response between patients of African American and European ancestry.[60] Patients who have the CC GT have higher rates of spontaneous clearance and higher rates of cure than patients who have IL GT CT or TT.[60] The DAA therapies have largely overcome the role of IL28 although this marker continues to be used in clinical studies.

Ribavirin-induced anemia can affect dosing strategies and is likely related to polymorphisms of the *ITPA* gene. The exact mechanism is not fully understood and the clinical relevance is not clear.

The use of IFN-based therapies targeting the host immune system's capacity to eradicate HCV minimized the role of HCV mutations and the potential for HCV resistance. With the approval of the DAAs, the role of resistance in treatment of HCV is likely to play an expanding role. Currently, the presence of the baseline mutation *Q80K* limits the utility of simeprevir-based therapies. As more patients are starting on DAAs, the presence of baseline and developed mutations will provide therapeutic challenge. The impact of mutations is not well understood although combination

therapies will likely be required to overcome various resistance mutations. Moreover, in order to minimize the development of resistance and optimize cure rates, it is imperative for patients to complete their HCV treatment regimens without interruptions.

Chapter 41: Celiac Disease

Priti N. Patel; Robert A. Mangione

INTRODUCTION

KEY CONCEPTS

- 1 Celiac disease is a chronic, small intestinal immune-mediated enteropathy caused by intolerance to gluten found in wheat, barley, rye, and other foods when a genetically predisposed person is exposed to the environmental trigger, gluten.
- 2 The prevalence of celiac disease is 0.7% in America and appears to be increasing in prevalence worldwide.
- 3 The integrity of the tissue junctions of the intestinal epithelium is compromised in patients with celiac disease; this enables gluten to reach the lamina propria. The presence of gluten in the lamina propria and an inherited combination of genes contribute to the heightened immune sensitivity to gluten that is found in patients with celiac disease.
- 4 The classic presenting symptom is diarrhea, which may be accompanied by abdominal pain or discomfort; however, it is noteworthy that during the past decade diarrhea has been reported as the main presenting symptom of celiac disease in less than 50% of cases.
- 5 Dermatitis herpetiformis is a skin manifestation of small intestinal immune-mediated enteropathy caused by exposure to dietary gluten.
- 6 The frequency of diagnosis of patients with celiac disease has increased; however, the majority of patients with this condition remain undiagnosed.
- 7 The confirmation of a diagnosis of celiac disease should be based on a combination of findings from the medical history, physical examination, serology, and duodenal biopsy. The recommended serologic marker that is used for screening patients is serum antitissue transglutaminase antibody.
- 8 Strict, lifelong adherence to a gluten-free diet is the only treatment for celiac disease that is

currently available.

- 9 Clinicians must evaluate the patient with celiac disease for nutritional deficiencies (including folic acid, vitamin B_{12}, fat-soluble vitamins, iron, and calcium) due to malabsorption.

1 Celiac disease is a small intestinal immune-mediated enteropathy caused by intolerance to ingested gluten, a storage protein found in wheat, barley, and rye. Genetic, environmental, and immune factors all play a role in the development of celiac disease. The mainstay of treatment of the disease is strict, lifelong adherence to a gluten-free diet.[1,2]

A disease resembling celiac disease was first described by a Greek physician in the second century AD.[3] In the mid-1900s, the connection between the ingestion of cereals and celiac disease was made. For many years, celiac disease was considered a disease of childhood with primarily GI symptoms. It is now recognized as a disease of all ages with varied presentation.

Celiac disease has also been known as celiac sprue, nontropical sprue, and gluten-sensitive enteropathy; however, these terms are currently not recommended. The non-specific use of celiac disease related terminology may lead to misunderstandings. It is therefore important that accepted terms associated with celiac disease be used, and understood when engaging in patient consultations or discussions with other healthcare providers. The publication of the Oslo Definitions has helped to address this concern.[1]

The disease is characterized by both GI and extraintestinal symptoms. Chronic inflammation caused by exposure to gluten leads to GI discomfort, nutrient malabsorption, and systemic complications. GI symptoms, including diarrhea, cramping, bloating, and flatulence, are the "classic" symptoms; however, a patient with celiac disease may initially present with a variety of extraintestinal symptoms. Patients with subclinical celiac disease have no or minimal symptoms but manifest mucosal damage on biopsy and have positive serologic testing. Patients with celiac disease classified as potential are asymptomatic patients who may show positive serology and have the human leukocyte antigen (HLA)-DQ2 and/or DQ8 haplotype, but have normal mucosa on biopsy.[1,4]

Adherence to a gluten-free diet is essential because it improves symptoms and prevents long-term complications of celiac disease, which include T-cell lymphomas, small bowel adenocarcinoma, and esophageal and oropharyngeal carcinomas.[5]

EPIDEMIOLOGY

2 Originally thought to be a pediatric disease, celiac disease is now being diagnosed in increasing numbers of both adult and pediatric patients due to increased awareness and improved diagnostic techniques.[6] Celiac disease is common in Europe and North America. The prevalence of the disease is 0.71% to 0.79% in the United States, affecting up to 1% of non-Hispanic whites.[7,8] Similar to other autoimmune diseases, the prevalence of celiac disease is higher in females than in males at a rate of 1:2.8.[9] In Finland and the United States, the prevalence of celiac disease has increased fourfold during

the past 50 years.[10] This finding has resulted from a true increase in the prevalence of the disease rather than simply an increase in the number of individuals who are diagnosed. While the reason for this increase is not known, it may be due to environmental factors such as the changing nature of gluten or other factors associated with diet.[11,12]

Celiac disease has been less well studied in other parts of the world. Previously believed to rarely occur in nonwhite populations, improved screening and diagnostic techniques now provide evidence that the prevalence of celiac disease in many non-Western nations is similar to that in Europe and North America.[13] In addition, in Asian countries where rice has traditionally been a staple, meals with rice are increasingly being replaced by a Western-style wheat-based diet. This transition in dietary preferences may lead to an increased prevalence of the disease in those populations.[12,13,14]

ETIOLOGY

Celiac disease is known to occur when a genetically predisposed person ingests gluten. Wheat gluten proteins exist in two fractions: gliadins and glutenins. Storage proteins similar to glutenins, called hordeins and secalins, are found in barley and rye, respectively. **Table 41-1** refers to grains and other foods that do and do not contain gluten and related proteins. Ingestion of any of these proteins will lead to an autoimmune response in celiac disease patients. Wheat, barley, and rye are all derived from the Triticeae tribe of the grass (Gramineae) family. Oats, from the Aveneae tribe, are distantly related and therefore contain fewer disease-activating proteins.[16] One concern with oats is that they may be contaminated with gluten during the manufacturing process.[16]

TABLE 41-1 Grains and Other Foods that Do and Do Not Contain Gluten

Contain Gluten	Do Not Contain Gluten
Wheat	Amaranth
Barley	Buckwheat
Rye	Corn
Bran	Flax
Graham flour	Millet
Spelt	Potato flour
Wheat germ	Quinoa
Triticale	Rice
Oats[a]	Sorghum
	Soybeans
	Tapioca
	Teff

[a]Oats are in a different plant family, but they have also been regarded as problematic, although the ingestion of certified pure gluten-free oats appears to be safe in most patients with celiac disease.[6] Due to the continued difference of opinion regarding the safety of oats, patients are generally

advised to discuss the risks and benefits associated with consuming oats with their healthcare provider before they include oats in their diet.

Genetic factors, in combination with exposure to gluten, are necessary for the development of celiac disease. A concordance rate of 85% in monozygotic twins has been reported, indicating that genetics play a large role in the disease, but other factors also are likely to involved.[17,18]

Virtually all patients with celiac disease have variants of HLA-DQ2 or HLA-DQ8 molecules that are expressed on the surface of antigen-presenting cells.[4,5] Other non-HLA genes may also play a role in enhancing genetic susceptibility to celiac disease.[18]

Certain infectious agents and other compounds may contribute to the development of celiac disease. Both adenovirus and hepatitis C viruses are thought to act as triggers, whereas other agents, including *Campylobacter jejuni*, *Giardia lamblia*, rotavirus, and enterovirus infections, have been described in case reports as associated with celiac disease.[19] Various drugs, such as olmesartan, azathioprine, methotrexate, as well as others, have also been suggested to play a role in the development of sprue-like bowel disease.[3]

In Sweden, increased rates of diagnosis of celiac disease in the mid-1980s corresponded to a change in infant feeding practices where mothers reduced breast-feeding and introduced cereal into babies' diets earlier than had been previously in practice. Based on this finding, prolonged breast-feeding with introduction of gluten-containing grains during breast-feeding was recommended to help avoid the development of celiac disease.[20] However, multinational studies show that the timing of gluten introduction or duration of breastfeeding did not avoid the eventual diagnosis of celiac disease, even at children at higher risk due to the presence of one of the high risk HLA haplotypes.[21,22,23,24]

PATHOPHYSIOLOGY

3 During normal digestion, peptides that remain from gastric or pancreatic digestion are broken down into amino acids, dipeptides, or tripeptides by the small intestinal brush-border membrane enzymes.[25] These GI proteases that are found in the intestinal lumen are one of the body's first defenses against potentially toxic dietary proteins.[15] The intestinal epithelium, with its intact intercellular tight junctions, functions as the primary barrier to the passage of macromolecules into the lamina propria. Gluten is unusually rich in the amino acids glutamine and proline, which enable part of the molecule to withstand the digestive processes. These peptides are kept within the GI tract and are primarily excreted before they can illicit an immune reaction. Small fractions of gluten do cross this important defense barrier in patients without celiac disease; however, the quantity of gluten that passes across the GI lining is generally insufficient to illicit a significant response from a normally functioning immune system.[25,26]

Events likely associated with the pathophysiology of celiac disease have been characterized as an interaction between gluten and immune, genetic, and environmental factors.[25] In celiac disease, the integrity of the tissue junctions of the intestinal epithelium is compromised, enabling gluten to reach

the lamina propria through different routes. The presence of gluten in the lamina propria and an inherited combination of genes contribute to the heightened immune sensitivity to gluten found in patients with celiac disease (**Table 41-2**).[25] The notable immune response to gluten consists of both adaptive and innate immune responses that occur only in individuals who carry the HLA type DQ2 or in some populations DQ8.[25] The precise mechanism by which the immune system leads to damage of the intestinal lining of patients with celiac disease continues to be studied.

TABLE 41-2 Proposed Pathophysiology of Celiac Disease

- Enterocytes release the protein zonulin in response to the presence of indigestible fragments of gluten in the intestine
- Zonulin loosens the intercellular tight junctions
- Abundant quantities of gluten fragments cross the intestinal lining and accumulate under the enterocytes (epithelial cells)
- Gluten induces the enterocytes to secrete interleukin-15 (IL-15)
- IL-15 induces an immune response of intraepithelial lymphocytes against the enterocytes
- The damaged cells release the enzyme tissue transglutaminase (tTG), which modifies the gluten
- Antigen-presenting cells of the immune system join the modified gluten to human leukocyte antigen (HLA) molecules and display the resulting complexes to other immune cells (ie, helper T cells)
- Helper T cells that recognize the complexes secrete molecules that attract other immune cells, which may result in damage to the enterocytes
- Helper T cells spur killer T cells that directly attack the enterocytes
- B cells release antibody molecules that are targeted to gluten and tTG (the role that these antibodies play remains to be further clarified; however, they may cause further damage when they contact their targets on or near the enterocytes)
- Enterocytes are disabled or killed

Data from reference 25.

Clinical Controversy…

Non-celiac gluten sensitivity is a condition in which the ingestion of gluten results in morphological or symptomatic manifestations in the absence of celiac disease.[1] This disorder must therefore be considered in the differential diagnosis of celiac disease. It is noteworthy that symptoms alone cannot reliably differentiate celiac disease from non-celiac gluten sensitivity. Therefore a diagnostic

evaluation including celiac serology and small-intestinal biopsy (while the patient is including gluten in their diet) is needed. If these tests are negative, HLA-DQ typing is required to differentiate between the two disorders. Differentiating between these disorders is very important as it will impact upon the implications of the level of adherence to the gluten-free diet, approach to continued disease-state monitoring and evaluation, and the counseling of family members (as nonceliac disease sensitivity does not appear to have a strong hereditary basis).[5]

The primary toxic components of wheat gluten are a family of closely related proteins called gliadins.[25] The gliadin peptides induce changes in the epithelium through innate immunity and in the lamina propria through adaptive immunity.[25] Protected transport of gliadin peptides occurs in patients with celiac disease via a CD71-mediated transcytosis of immunoglobulin A (IgA)/gliadin peptides immune complexes from the lumen of the intestine to the lamina propria. In patients without celiac disease, the gliadin peptides are entirely degraded by lysosomal acid proteases during intestinal transcytosis. The abnormal expression of the IgA receptor CD71 at the apical side of the enterocytes that is found in celiac disease patients allows a protected retrotransport of serum immunoglobulin A (SIgA) gliadin immune complexes that could play an important role in triggering the immune activation that is characteristic of celiac disease. These researchers note that the normal function of SIgA (ie, the containment of harmful antigens in the intestinal lumen) is deficient in celiac disease. They further state that the fate of the immune complexes once absorbed is unknown; however, the complexes may bind to IgA receptors that are present on local antigen-presenting cells and trigger the activation of local memory CD4 T cells, which will perpetuate the inflammation.[27]

Tissue transglutaminase (tTG), a ubiquitous enzyme that catalyzes posttranslational modification of proteins and is released during inflammation, may play at least two crucial roles in celiac disease by serving as the main target autoantigen for antiendomysial enzymes and as a deaminating enzyme that raises the immunostimulatory effect of gluten. Expression and activity of tTG are raised in the mucosa of patients with celiac disease.[15] This enzyme, by deaminating glutamine to glutamic acid, makes the gliadin peptides become negatively charged and therefore more capable of fitting into pockets of the HLA-DQ2 (or HLA-DQ8) antigen-binding groove on the antigen-presenting cells.[15,28] Gliadin is presented to gliadin-reactive CD4 T cells through a T-cell receptor, which then results in the production of cytokines that cause tissue damage. This then leads to villous atrophy, crypt hyperplasia, and the expansion of antibody-producing B cells found in celiac disease.[28]

CLINICAL PRESENTATION

4 The recognition of celiac disease may be quite challenging due to the wide range of presenting symptoms, which includes patients who are asymptomatic.[15] Clinical manifestations of celiac disease also significantly vary according to age group (**Table 41-3**) in that pediatric patients are more likely to experience classic gastrointestinal symptoms while adults are more likely to have atypical symptoms.[29] Infants and young children generally experience diarrhea, abdominal distention, and failure to thrive. Vomiting, irritability, anorexia, and even constipation are also common in these young patients. Extraintestinal manifestations such as short stature, neurologic findings (eg, peripheral neuropathy, ataxia, seizure, migraine, and dementia), or anemia are often found in older

children and adolescents.[29] The classic presenting symptom in adults is diarrhea, which may be accompanied by abdominal pain or discomfort; however, it is noteworthy that during the past decade diarrhea has been reported as the main presenting symptom of celiac disease in less than 50% of cases. Adults may exhibit iron-deficiency anemia or osteoporosis. Less common but important presentations of celiac disease in adults include abdominal pain, constipation, weight loss, neurologic symptoms, dermatitis herpetiformis, hypoproteinemia, hypocalcemia, and elevated liver enzymes. Some adults may be diagnosed as a result of having an endoscopy performed in response to their complaints of symptoms associated with gastroesophageal reflux.[28] Patients with celiac disease often experience symptoms for a long period of time and may experience multiple hospitalizations and undergo surgical procedures before celiac disease is diagnosed.[28]

TABLE 41-3 Selected Signs and Symptoms of Celiac Disease

Children	Adults
Symptoms • Fatigue • Bloating • Constipation • Abdominal pain • Chronic diarrhea • Irritability • Vomiting	Symptoms • Abdominal pain • Chronic diarrhea • Abdominal distension • Recurrent spontaneous abortion • Peripheral neuropathy • Depression • Fatigue/malaise • Ataxia
Signs • Muscle wasting • Failure to thrive/weight loss • Short stature • Delayed puberty • Osteopenia/osteoporosis • Hepatitis • Dental anomalies • Anemia	Signs • Weight loss • Infertility • Dermatitis herpetiformis • Hepatitis • Anemia • Aphthous ulcers • Alopecia • Malignancy

Children	Adults
	• Seizures • Osteopenia/osteoporosis • Arthritis

Data from reference 23.

5 Dermatitis herpetiformis is a skin manifestation of small intestinal immune-mediated enteropathy caused by the ingestion of gluten (**Figs. 41-1** and **41-2**).[1] It occurs more often in males and in patients 30 to 40 years old.[30] This extremely pruritic, bullous skin rash is generally found on the elbows, knees, buttocks, and scalp but can occur anywhere on the body.[30] Although dermatitis herpetiformis was once considered to be a skin disease that was often found in patients with celiac disease, researchers have also suggested that it is actually a cutaneous manifestation of gluten sensitivity.[30]

6 The diagnosis of celiac disease is based on clinical suspicion and confirmation with laboratory tests and duodenal biopsy.[5] Although the frequency of diagnosis of patients with celiac disease has increased, many patients with this condition remain undiagnosed.[5] This is particularly concerning as undiagnosed celiac disease has been associated with a nearly fourfold increased risk of death compared with subjects without serologic evidence of disease.[10]

Perhaps the most important initial step in making this diagnosis is for healthcare providers to recognize its many and diverse possible symptoms.[37] Only 11% of celiac disease cases are diagnosed in a timely manner, with an average reported period of 5.8 to 11.7 years from the onset of symptoms to the diagnosis.[32] Clinicians can help reduce the time from the onset of symptoms to the diagnosis

of celiac disease by being aware of the common diseases that may also coexist with celiac disease (**Table 41-4**).[32]

TABLE 41-4 Selected Common Misdiagnoses

Irritable bowel syndrome
Viral gastroenteritis
Lactose intolerance
Amoebic/parasitic infection
Inflammatory bowel disease
Psychological dysfunction
Gallbladder disease
Chronic fatigue syndrome
Gastroesophageal reflux disease
Allergies
Ulcers
Cystic fibrosis
Colitis

Data from reference 5.

Clinicians should also note that individuals with certain disorders are more likely to have celiac disease than the general population. Examples include other autoimmune diseases, such as thyroid disease, diabetes mellitus (type 1), multiple sclerosis, myasthenia gravis, Raynaud's disease, rheumatoid arthritis, Addison's disease, chronic active hepatitis, cystic fibrosis, scleroderma, and Sjögren's syndrome; Down's syndrome; neurologic conditions such as ataxia, epilepsy, and cerebral calcifications; and primary biliary cirrhosis. Although patients with these disorders are more frequently found to have celiac disease than the general population, these associated conditions are not believed to cause celiac disease.[15]

Clinical Controversy…

The co-occurrence of celiac disease and type 1 diabetes mellitus is 5 to 7 times more prevalent than celiac disease alone.[33] The most common manifestations of celiac disease in patients with diabetes mellitus are gastrointestinal and diminished or impaired bone demineralization. Although these findings in diabetic patients may lead clinicians to test for celiac disease, testing for celiac disease in asymptomatic diabetes mellitus patients remains controversial.[5] A paucity of data exists clarifying the

implications of celiac disease in adult patients with type 1 diabetes with respect to diabetes-related outcomes including glycemic control, lipids, microvascular complications, quality of life, and the effect of a gluten free diet. It is noteworthy however that researchers have reported that adults with undetected celiac disease and type 1 diabetes were found to have worse glycemic control and a higher prevalence of retinopathy and nephropathy.[34] The impact that effective treatment of celiac disease will have on the overall management of diabetes mellitus also needs to be studied further. Some researchers have suggested that an increase in absorption may lead to the need for increased insulin doses. (2) Careful patient monitoring is therefore always prudent.

7 Diagnostic testing for celiac disease must be performed while the patient continues to consume gluten.[5] A confirmed diagnosis of celiac disease requires both a positive finding on duodenal biopsy and a positive response to a gluten-free diet.[5] The identification of villous atrophy with small bowel endoscopy and biopsy is generally regarded as the diagnostic gold standard (although guidelines from the European Society of Paediatric Gastroenterology, Hepatology, and Nutrition suggest that a small intestinal biopsy may not be required in children with typical symptoms, titers of anti-tTG greater than 10 times the upper normal limit and predisposing HLA genotype).[35] Although villous atrophy is associated with celiac disease, clinicians must consider that this may also be found in other diseases, including giardiasis, autoimmune enteropathy, tuberculosis, Crohn's disease, intolerance to food other than gluten, intestinal lymphoma, and Zollinger-Ellison syndrome.[5]

The Marsh classification system is a standardized approach used by pathologists to describe the histologic changes seen in celiac disease. This classification includes ratings of Marsh I to IV with Marsh III being further subdivided into Marsh IIIa (partial villous atrophy), IIIb (subtotal villous atrophy), and IIIc (total villous atrophy). Most celiac disease patients (50%-60%) are placed in one of the Marsh III categories.[41] Histologic findings lead to a diagnosis that is followed by placing the patient on a gluten-free diet. Dermatitis herpetiformis is diagnosed by skin biopsy.[37]

Serologic test results provide clinicians with a useful noninvasive tool that helps to determine if symptomatic patients, or patients who are at risk for celiac disease, require a biopsy.[5] Available tests include those for antigliadin antibodies, connective tissue antibodies (antireticulum and antiendomysial antibodies), and antibodies against tTG. The most common serologic marker that is used for screening patients is IgA tTG antibodies.[5] Testing for gliadin antibodies is no longer utilized because of its low sensitivity and specificity for celiac disease.[5] Although serology is a good method to identify patients who will benefit from endoscopy and biopsy, negative serology should not preclude a biopsy examination in individuals for whom disease is suspected on clinical grounds.[5]

Genetic testing can be performed as a means of determining which family members of a diagnosed patient may develop the disease (the prevalence of celiac disease has been reported to be 10%-12% in first-degree relatives and is also higher than that found in the general population in second-degree relatives).[5] Patients and their family members can be tested for HLA-DQ2 and HLA-DQ8 as HLA-DQ2 is found in up to 95% of celiac disease patients, with most other patients being HLA-DQ8 positive.[5] Although nearly all celiac disease patients carry one of these alleles, they are also found in 30% to 40% of the general population. Therefore, when these alleles are absent, it is extremely

unlikely that the individual has celiac disease (ie, the test has a high negative predictive value [NPV]).[5] A patient-administered saliva-based test for HLA-DQ2/DQ8 was released for direct sale to consumers but is not recommended for use in the diagnosis of celiac disease.[5]

TREATMENT

Desired Outcomes

Overall goals of treatment include relieving symptoms, healing the intestine, and reversing the consequences of malabsorption while enabling the patient to adhere to a healthy, interesting, and practical gluten-free diet.[27,45]

Nonpharmacologic

Table 41-5 presents a mnemonic that summarizes the major principles of the treatment of celiac disease. Strict lifelong adherence to a gluten-free diet is the only proven treatment for celiac disease.[15] Patients must recognize that adhering to a gluten-free diet includes not ingesting anything that contains gluten or has been contaminated with gluten. Wheat, barley, and rye must be avoided.[4] Although oats are in a different plant family, they have also been regarded to be problematic; however, the ingestion of certified pure gluten-free oats appears to be safe.[15] Due to the continued difference of opinion regarding the safety of oats, they should be added to the diet cautiously and with monitoring.[5] Patients must also commit to avoiding the ingestion of gluten found in nonfood items such as toothpaste, lip balm, lipstick, etc. A list of gluten-free grains can be found in Table 41-1.

Data from reference 37.

Oral prescription drugs, nonprescription drugs, vitamin and mineral supplements, and health and beauty aids and cosmetics that have oral ingestion potential must not be overlooked as sources of gluten due to its presence in their formulation or due to contamination or contact.[38,39] Although clinicians have concluded that as little as 10 to 50 mg/day of gluten is the minimum dose required to produce measurable damage to the small intestinal mucosa, it is difficult to set a universal threshold given the individual variability among patients.[2,4,30]

The FDA determined the tolerable daily intake level for gluten in individuals with celiac disease to be 0.4 mg gluten/day for adverse morphologic effects and 0.015 mg gluten/day for adverse clinical

effects and ruled in 2013 that foods labeled as gluten free must contain less than 20 ppm gluten.[40,41] Although the ruling pertains to food only, the concerns regarding low-level exposure emphasize why healthcare providers must check to determine whether prescription drugs contain gluten in their formulation or have been contaminated with gluten before these drugs are provided to the patient with celiac disease. Lack of reliable information can be confusing and although there are published lists of gluten-free drugs, it is often difficult to obtain information about the gluten content of medications.[42,43] In addition, it is important for clinicians to realize that conflicting data regarding drug absorption in patients with celiac disease requires careful selection and use of drugs in patients with celiac disease.

9 Newly diagnosed patients should be evaluated for nutritional deficiencies associated with vitamin and mineral malabsorption. This assessment should include assuring that the patient does not have deficiencies of folic acid, vitamin B_{12}, fat-soluble vitamins, iron, and calcium.[5] Monitoring for potential nutritional deficiencies should also continue during subsequent followup visits.

Most adults with celiac disease are found to have some degree of bone loss; therefore, all patients must be screened for osteoporosis or osteopenia.[30] Supplementing a calcium-rich gluten-free diet with calcium, magnesium, and vitamin D may arrest or reverse celiac decrease-related bone loss. Although their use has not been extensively studied in patients with celiac disease, bisphosphonates and other drugs have been prescribed for patients with bone disease.[44]

Implementing a gluten-free diet presents some challenges. Consultation with a registered dietician is recommended for dietary evaluation and education.[5] Patients are advised to initiate a complete gluten-free lifestyle immediately after diagnosis. Partial adherence to this diet is not adequate. In order to accomplish this objective, patients must be aware of what foods are gluten-free and when in doubt must know how to confirm whether a food contains gluten. Reading labels is extremely important; however, it may be difficult to identify hidden sources of gluten listed among the ingredients. Patients with celiac disease must also determine whether products were processed on equipment shared with wheat, barley, or rye. It may be necessary to call the manufacturers or check their website to obtain the needed information.[38]

Individuals with celiac disease must also be advised to maintain a gluten-free kitchen. A dedicated toaster, bread maker, waffle iron, and other appliances should be obtained for use in preparing gluten-free meals. Utensils and dishes must be carefully cleaned to avoid gluten contamination. Care must also be taken when dining in restaurants and homes of family and friends. The individuals who prepare and serve the food must be knowledgeable about gluten-free foods and food preparation.[30]

The economic burden associated with maintaining a gluten-free diet may present some challenges.[45,46] The relatively low availability and high cost of these foods contributes to the challenges associated with adhering to the required strict diet and may lead to varying degrees of noncompliance.[45,46] Patients also find that the extra cost associated with the special diet is not reimbursed by healthcare plans, and most policies do not pay for consultations with a dietician.[47] These challenges with compliance are particularly concerning as noncompliance with the gluten-free

diet is associated with an increased mortality rate and compromised quality of life.[46] Patients are also encouraged to investigate their personal circumstances as to whether some of the costs of maintaining a gluten-free diet are eligible for approval as a tax deduction.[47]

Pharmacologic

Dietary avoidance of gluten remains the mainstay of treatment of celiac disease. Novel pharmacologic treatment modalities are under investigation. Most reports related to pharmacotherapy for celiac disease focus on the treatment of refractory disease.

In case reports, corticosteroids, azathioprine, cyclosporine, tacrolimus, infliximab, and alemtuzumab have been reported as effective treatments for refractory celiac disease. Patients characterized to have refractory celiac disease have persistent or recurrent malabsorptive symptoms and signs with villous atrophy despite maintaining a gluten-free diet for more than 12 months.[1] Less than 5% of adult patients are found to have refractory celiac disease.

Based on the pathophysiology of celiac disease, novel targets for the treatment of the disease have been identified: decreasing the antigenic load and modulation of the immune response. Methods of decreasing the antigenic load include blocking the activity of tTG, GI destruction of proline peptides via enzyme therapy, blocking the binding of deaminated proteins to HLA-DQ2 and HLA-DQ8, detoxification of gluten peptides, and decreasing intestinal permeability in patients with celiac disease, in particular through inhibition of zonulin.[3] Investigational tTG inhibitors have been developed; however, their safety is questioned due to the presence of the enzyme throughout the body and its role in many functions necessary for homeostasis.[49] In the area of gluten detoxification, gluten proteins were developed in which the proline residues were replaced by azidoprolines; these azidoproline residues bound to HLA-DQ2 but did not stimulate an autoimmune response.[50] A zonulin inhibitor, larazotide, was well tolerated and effective in a small study of patients with persistent symptoms despite a gluten free diet for 1 year.[51] A vaccine, Nexvax2, that modulates the immune response has passed phase 1b trials.[52]

Evaluation of Therapeutic Outcomes

Clinical improvement will often be observed within days or weeks of instituting the required diet.[28] Although dermatitis herpetiformis is also treated with the prescribed diet, these cutaneous lesions may not completely resolve for months to years after initiating dietary measures.[37]

Healthcare providers must also be mindful of conditions that are related to celiac disease and that are potential complications of the disease, including certain forms of cancer, neurologic manifestations, osteoporosis, depression, diabetes, infertility, as well as other autoimmune and related illnesses. Cancers that are of particular concern include thyroid cancer, adenocarcinoma of the small intestine, lymphoma (predominantly non-Hodgkin's lymphoma of any type), esophageal cancer, melanoma, and malignancies found in childhood.[4] Patients with celiac disease have also been found to have an increased risk of developing certain infectious diseases that include pneumococcal

or staphylococcal sepsis and tuberculosis.[53] The immune system of celiac patients is not compromised as it is actually overactive. The risk of infections due to encapsulated organisms (pneumococcal pneumonia, meningococcal infections) arises from hyposplenism, which is common in active celiac disease. Therefore, patients over 50 years of age are advised to receive pneumococcal vaccine.[30] Annual influenza vaccine is advisable as this will reduce the incidence of secondary bacterial infections.[53] Increased hazard ratios (HRs) for death were found in individuals with biopsy-verified celiac disease, inflammation, and potential celiac disease (the absolute risks were small). Individuals undergoing small-intestinal biopsy in childhood had increased HRs for death. These researchers concluded that the main causes of death in patients they studied were cardiovascular disease and malignancy.[54]

Chapter e42: Evaluation of Kidney Function

Thomas C. Dowling

INTRODUCTION

KEY CONCEPTS

- 1 The stage of chronic kidney disease (CKD) should be determined for all individuals based on the level of kidney function, independent of etiology, in accordance with the Kidney Disease: Improving Global Outcomes (KDIGO) classification system.
- 2 Persistent proteinuria indicates the presence of CKD and is associated with mortality and risk of end-stage renal disease (ESRD).
- 3 Quantitation of urine protein excretion, such as the measurement of a spot urine albumin-to-creatinine ratio, is critical for determining the severity of CKD and monitoring the rate of disease progression.
- 4 The glomerular filtration rate (GFR) is the single best indicator of kidney function.
- 5 Measurement of the GFR is most accurate when performed following the exogenous administration of iohexol, iothalamate, or radioisotopes such as technetium-99m diethylenetriamine pentaacetic acid (^{99m}Tc-DTPA).
- 6 Equations to estimate creatinine clearance (CL_{cr}) or GFR are commonly used in ambulatory and inpatient settings, and incorporate patient laboratory and demographic variables such as serum creatinine concentration (S_{cr}), cystatin C, age, sex, weight, and ethnicity.
- 7 Longitudinal assessment of GFR and albuminuria is important for monitoring the efficacy of therapeutic interventions, such as angiotensin-converting enzyme inhibitors and angiotensin receptor blockers, which are used to slow or halt the progression of kidney disease.
- 8 Assessments of kidney structure and function, such as radiography, computed tomography, magnetic resonance imaging, sonography, and biopsy, are predominantly used for determining the diagnosis of a given condition.

Chronic kidney disease (CKD) is an increasingly alarming worldwide health concern, with nearly 2 million people in the United States estimated to require hemodialysis or kidney transplantation by 2030.[1] In response to this widespread problem, standardized approaches are now used for the identification of individuals with CKD and their subsequent stratification into risk categories for the development of end-stage kidney disease (ESKD or ESRD) (see Chapter 44).[1,2] These efforts have heightened the awareness of the need for early identification of patients with CKD and the importance of monitoring the progression of kidney disease.

Assessment of kidney function using both qualitative and quantitative methods is an important part of the evaluation of patients and an essential characterization of individuals who participate in clinical research investigations. Estimation of creatinine clearance (CL_{cr}) has been considered the clinical standard for assessment of kidney function for nearly 50 years, and continues to be used as the primary method of stratifying kidney function in drug pharmacokinetic studies submitted to the United States Food and Drug Administration (FDA).[3,4] New equations to estimate glomerular filtration rate (GFR) are now used in many clinical settings to identify patients with CKD, and in large epidemiology studies to evaluate risks of mortality and progression to stage 5 CKD, that is, ESKD.[5,6] Other tests, such as urinalysis, radiographic procedures, and biopsy, are also valuable tools in the assessment of kidney disease, and these qualitative assessments are useful for determining the pathology and etiology of kidney disease. Urinalysis, for example, may give clues to the primary location, such as glomerular or tubular, of the renal disease. Follow-up studies, such as imaging procedures or kidney biopsy, may then further differentiate the specific cause, thereby guiding the selection of the optimal therapeutic intervention.

1 Quantitative indices of GFR or CL_{cr} are considered the most useful diagnostic tools for identifying the presence and monitoring the progression of CKD. These measures can also be used to quantify changes in function that may occur as a result of disease progression, therapeutic intervention, or a toxic insult.[7] The measurement or estimation of CL_{cr}, however, remains the most commonly used index for individualizing medication dosage regimens in patients with acute and CKD. Furthermore, CL_{cr} has been the predominant index used to stratify patients in pharmacokinetic studies which serve as the basis for the design of renal dosing algorithms in FDA-approved package inserts and tertiary drug information sources.[4] It is important to note that the term *kidney function* includes the combined processes of glomerular filtration, tubular secretion, and reabsorption, as well as endocrine and metabolic functions. Alterations in any or all of these functions, whether declining or improving, are associated primarily with GFR. This chapter critically evaluates the various methods that can be used for the quantitative assessment of kidney function in individuals with normal kidney function, as well as in those with CKD and acute kidney injury (AKI) (**Table e42-1**). Where appropriate, discussion regarding the qualitative assessment of the kidney function is also presented, including the role of imaging procedures and invasive tests such as kidney biopsy.

EXCRETORY FUNCTION

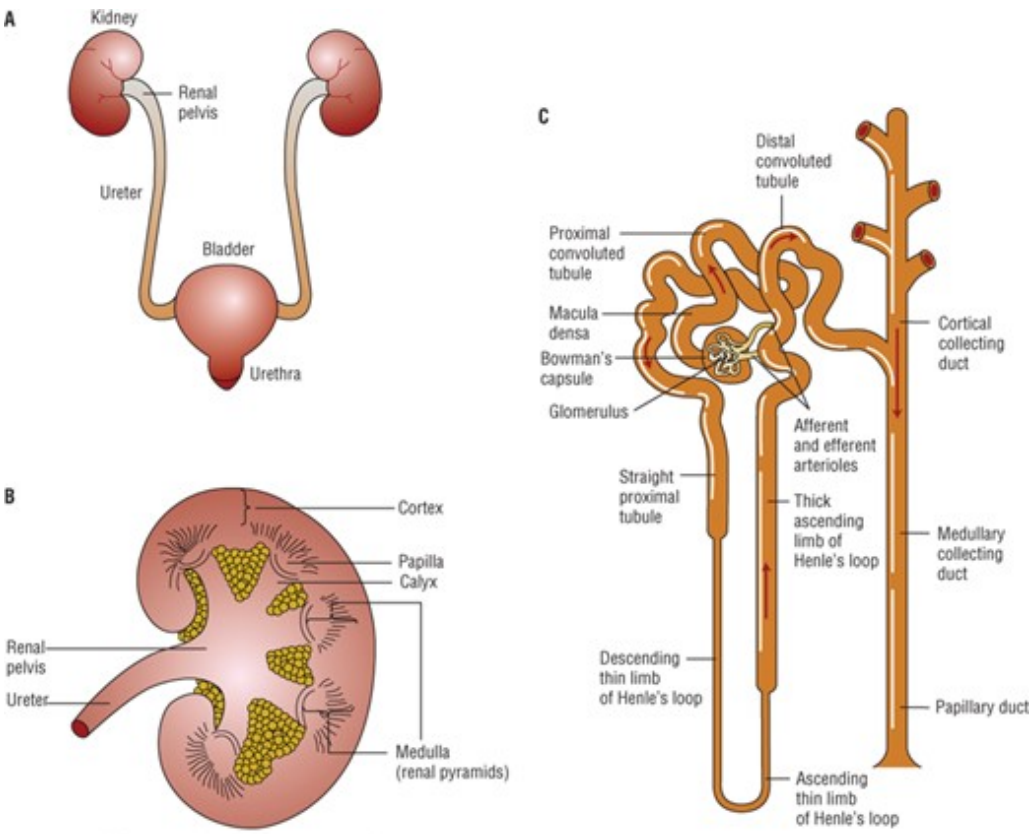
The kidney is largely responsible for the maintenance of body homeostasis via its role in regulating urinary excretion of water, electrolytes, endogenous substances such as urea, medications, and environmental toxins. It accomplishes this through the combined processes of glomerular filtration, tubular secretion, and reabsorption.

Glomerular Filtration

Glomerular filtration is a passive process by which water and small-molecular-weight (less than 5-10 kDa) ions and molecules diffuse across the glomerular–capillary membrane into the Bowman capsule and then enter the proximal tubule (**Fig. e42-1**). Most proteins are too large (greater than 60 kDa) to be substantially filtered, and their filtration is impeded by the electronegative charge on the epithelial surface of the glomerulus. Thus, compounds presented to the glomerulus in the protein-bound state are usually not significantly filtered and remain in the peritubular circulation.

FIGURE e42-1

Structures of the (*A*) urinary system, (*B*) kidney, and (*C*) nephron, the functional unit of the kidney.



Secretion

Secretion is an active process that predominantly takes place in the proximal tubule and facilitates the elimination of compounds from the renal circulation into the tubular lumen. Several highly efficient transport pathways exist for a wide range of endogenous and exogenous substances, resulting in renal clearances of these actively secreted entities that often greatly exceed GFR and in some cases approximate renal blood flow. These transporters are typically found among the solute-linked carrier (SLC) and ATB-binding cassette (ABC) super families. The primary SLC transporters include the organic anion transporting polypeptides (OATPs), organic cation transporters (OCTs), organic anion transporters (OATs), and multidrug and toxin extrusion proteins (MATEs) (**Fig. e42-2**; **Table e42-2**). The key ABC transporters include multidrug resistance protein (MDR1 or

P-glycoprotein [P-GP]), MRP1 and MRP2. Both group of transporters are expressed in a variety of different epithelial membranes throughout the body and play a role in intestinal absorption, blood-brain barrier penetration, and excretion into the bile and urine. Recent research has identified their localized role in drug uptake and efflux in kidney tissues, where the OCT (1-3) and OAT (1-3) are involved in basolateral influx of substrates, and P-GP, MRP, and MATE are apical efflux transporters.[8,9,10,11] Their presence in liver and kidney contributes to the hepatic and renal elimination of many drugs. For example, P-GP, which is located on the apical membrane of the proximal tubule, plays an important role in the renal elimination of a wide range of drugs, such as cimetidine, digoxin, and procainamide. Studies designed to elucidate the mechanisms of drug-induced renal disease have also revealed the important role of drug transporters. For example, cobicisat, a CYP3A inhibitor that is used to enhance the response of several human immunodeficiency virus (HIV) regimens, has been associated with elevations in serum creatinine. The mechanism is attributed to combined inhibition of creatinine uptake (OCT2, OCT3) and efflux (MATE1).[10] The coordination of multiple drug transporters working together can result in a high degree of urinary excretion. For example, pramipexole undergoes OCT2-mediated uptake along with MATE-mediated efflux, resulting in extensive tubular secretion and renal clearance values of 500 to 800 mL/min.[9] Overall, the net process of tubular secretion for drugs is likely a result of multiple secretory pathways acting simultaneously.

FIGURE e42-2

Drug transporters in renal proximal tubule.

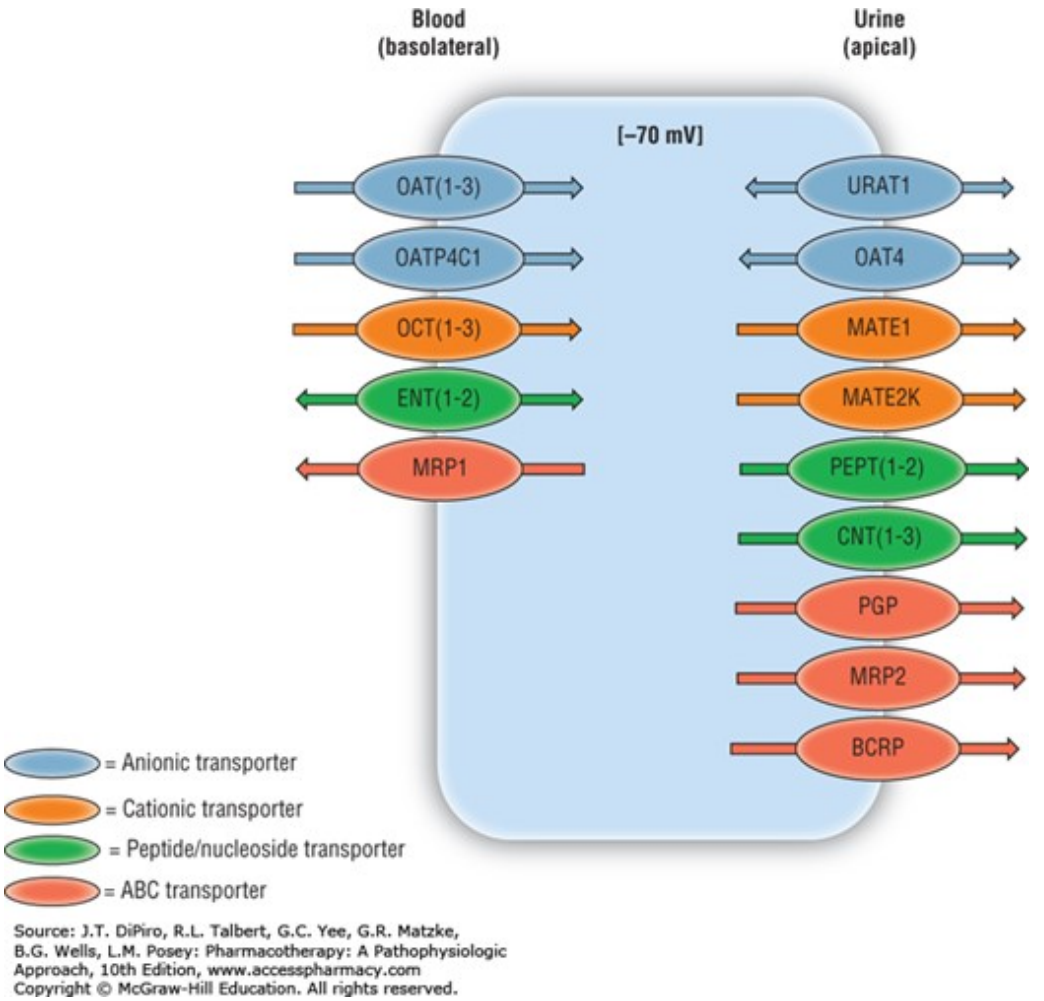


TABLE e42-2 List of Drug Transporting Proteins Present in the Kidney[8,9,10,11]

Class	Name	Gene Location	Expression	Substrates (Endogenous)	Substrates (Drugs/Exogenous)
Anionic transporters	OAT1	SLC22A6	BL (uptake)	Aminohippuric acid, estrone sulfate	PAH, tenofovir, cidofovir, oseltamivir, raltegravir, zidovudine, didanosine (I), stavudine (I), probenecid (I)
	OAT2	SLC22A7	BL (uptake)	Aminohippuric acid, prostaglandin E2, estrone sulfate, creatinine	Paclitaxel, 5-fluorouracil, allopurinol, zidovudine
	OAT3	SLC22A8	BL (uptake)	Aminohippuric acid, estrone sulfate	PAH, zidovudine, tenofovir, didanosine (I), stavudine (I), bendamustine (I)

Class	Name	Gene Location	Expression	Substrates (Endogenous)	Substrates (Drugs/Exogenous)
	OAT4	SLC22A11	AP (bidirectional)	DHEA, estrone sulfate, uric acid	PAH, zidovudine, chlorambucil (I)
	URAT1	SLC22A12	AP (bidirectional)	Uric acid, orotic acid	
	OATP4C1	SLCO4C1	BL (uptake)	Steroid conjugates, thyroid hormones	Digoxin, ouabain, penicillin
	OCT1	SLC22A1	BL (uptake)		Lamivudine (S/I)
	OCT2	SLC22A2	BL (uptake)	Creatinine	Cobicistat (I), cimetidine (I), dolutegravir (I), lamivudine (S/I), metformin
Cationic transporters	OCT3	SLC22A3	BL (uptake)	Creatinine, 5-HT, noradrenaline, dopamine	Cimetidine (I), lamivudine (I), quinidine
	MATE1	SLC47A1	AP (efflux)	Creatinine, thiamine	Cimetidine (I), ritonavir (I), cobicistat (I), metformin, procainamide, cephalexin, cephradine, acyclovir
	MATE2K	SLC47A2	AP (efflux)	Creatinine, thiamine	Oxaliplatin, cimetidine, metformin, acyclovir
	PEPT1	SLC15A1	AP (influx)	Oligopeptides	Cyclacillin, valacyclovir, cefadroxil
	PEPT2	SLC15A2	AP (efflux)	Oligopeptides	Beta-lactams, fosinopril
	CNT1	SLC28A1	AP (efflux)	Nucleosides	Stavudine (S/I), zidovudine (S/I), lamivudine (S/I), ribavirin, gemcitabine, zalcitabine
Peptide/nucleoside transporters	CNT2	SLC28A2	AP (efflux)	Nucleosides	Didanosine, cytidine
	CNT3	SLC28A3	AP (efflux)	Nucleosides	Didanosine, zidovudine, zalcitabine
	ENT1	SLC29A1	BL (bidirectional)	Nucleosides	Didanosine, ribavirin, 2′-3′-dideoxyinosine
	ENT2	SLC29A2	BL (bidirectional)	Nucleosides	Didanosine, zidovudine, 2′-3′-dideoxyinosine

Class	Name	Gene Location	Expression	Substrates (Endogenous)	Substrates (Drugs/Exogenous)
ABC transporters	PGP/MDR1	ABCB1	AP (efflux)	Steroids, lipids, bilirubin, bile acids	Digoxin, dabigatran, doxorubicin, maraviroc, itraconazole (I), cyclosporine (I), tenofovir (S/I), ritonavir (I), stavudine (I), didanosine (I), lamivudine (I), emtricitabine (S/I), efavirenz (I), nevirapine (I), flavonoids, verapamil (I)
	MRP1	ABCC1	BL (efflux)	Prostaglandins, folic acid, bilirubin	Cisplatin, indinavir, lamivudine (I), emtricitabine (S/I), tenofovir (I), efavirenz (I)
	MRP2	ABCC2	AP (efflux)	Bilirubin, estradiol glucuronide, estrone sulfate	Cisplatin, indinavir, tenofovir (I), efavirenz (I)
	BCRP	ABCG2	AP (efflux)	Estrone sulfate, porphyrins	Doxorubicin, lamivudine, tenofovir, efavirenz (I)

AP, apical; BL, basolateral; HT, hydroxytryptamine; I, inhibitor; PAH, para-aminohippuric acid; S/I, substrate and inhibitor.

Reabsorption

Reabsorption of water and solutes occurs throughout the nephron, whereas the reabsorption of most medications occurs predominantly along the distal tubule and collecting duct. Urine flow rate and physicochemical characteristics of the molecule influence these processes: highly ionized compounds are not reabsorbed unless pH changes within the urine increase the fraction unionized, so that reabsorption may be facilitated.

Intact Nephron Hypothesis

The "intact nephron hypothesis" described by Bricker,[12] more than 40 years ago, proposes that "kidney function" of patients with renal disease is the net result of a reduced number of appropriately functioning nephrons. As the number of nephrons is reduced from the initial complement of 2 million, those that are unaffected compensate; that is, they hyperfunction. The cornerstone of this hypothesis is that glomerulotubular balance is maintained, such that those nephrons capable of functioning will continue to perform in an appropriate fashion. Extensive studies have indeed shown that single-nephron GFR increases in the unaffected nephrons; thus, the whole-kidney GFR, which

represents the sum of the single-nephron GFRs of the remaining functional nephrons, may remain close to normal until there is extensive injury. Based on this, one would presume that a measure of one component of nephron function could be used as an estimate of all renal functions. This, indeed, has been and remains our clinical approach. We estimate GFR and assume secretion and reabsorption remain proportionally intact.

Glomerular Filtration Capacity

GFR is dependent on numerous factors, one of which is protein load. Bosch[13] suggested that an appropriate comprehensive evaluation of kidney function should include the measurement of "filtration capacity." Recently, the concept of renal function reserve (RFR) has been defined as the capacity of the kidney to increase GFR in response to physiological or pathologic conditions.[14] This is similar in context to a cardiac stress test. The patient may have no hypoxic symptoms, for example, angina while resting, but it may become quite evident when the patient begins to exercise. Subjects with normal renal function administered an oral or intravenous (IV) protein load prior to measurement of GFR have been noted to increase their GFR by as much as 50%. As renal function declines, the kidneys usually compensate by increasing the single-nephron GFR. The RFR will be reduced in those individuals whose kidneys are already functioning at higher-than-normal levels because of preexisting kidney injury or subclinical loss of kidney mass (**Fig. e42-3**) Thus RFR may be a complementary, insightful index of renal function for many individuals with as yet unidentified CKD.

FIGURE e42-3

Structure-function relationship between GFR and nephron mass. GFR expressed in mL/min is converted to units of mL/s by multiplying by 0.0167. *(Used with permission from Sharma A, Mucino M, J, Ronco C, Renal Functional Reserve and Renal Recovery after Acute Kidney Injury. Nephron* Clin Pract *2014;127:94-100.)*

Quantification of renal function is not only an important component of a diagnostic evaluation, but it also serves as an important parameter for monitoring therapy directed at the etiology of the diminished function itself, thereby allowing for objective measurement of the success of treatment. Measurement of renal function also serves as a useful indicator of the ability of the kidneys to eliminate drugs from the body. Furthermore, alterations of drug distribution and metabolism have been associated with the degree of renal function. A discussion of pharmacokinetic changes in patients with renal disease is extensively reviewed in Chapter 48. Although several indices have been used for the quantification of GFR in the research setting, estimation of CL_{cr} and GFR are the primary approaches used in the clinical arena.

ENDOCRINE FUNCTION

The kidney synthesizes and secretes many hormones involved in maintaining fluid and electrolyte homeostasis. Secretion of renin by the cells of the juxtaglomerular apparatus and production and metabolism of prostaglandins and kinins are among the kidney's endocrine functions.[15] In addition in response to decreased oxygen tension in the blood, which is sensed by the kidney, erythropoietin is produced and secreted by peritubular fibroblasts. Because these functions are related to renal mass, decreased endocrine activity is associated with the loss of viable kidney cells. In patients with stages 3 to 5 CKD and those with moderate-to-severe AKIs, secretion of erythropoietin is impaired leading to reduced red blood cell formation; normocytic anemia and symptoms of reduced oxygen delivery to tissues such as fatigue, dyspnea, and angina (see Chapter 44). Indeed, anemia-induced renal hypoxia results indirectly in erythropoietin gene activation, tubular necrosis, and apoptosis, thereby contributing to further renal cell injury.[16] This cyclic relationship between kidney disease, suppression of erythropoietin secretion, and cardiovascular disease is also referred to as the *cardio-renal anemia syndrome*.[17]

METABOLIC FUNCTION

The kidneys perform a wide variety of metabolic functions, including the activation of vitamin D, gluconeogenesis, and metabolism of endogenous compounds such as insulin, steroids, and xenobiotics. It is common for patients with diabetes and stages 4 to 5 CKD to have reduced requirements for exogenous insulin,[18] and require supplemental therapy with activated vitamin D_3 (calcitriol) or other vitamin D analogs (paricalcitol, doxercalciferol) to avert the bone loss and pain associated with CKD-associated metabolic bone disease.[19] Cytochrome P450 (CYP), *N*-acetyltransferase, glutathione transferase, renal peptidases, and other enzymes responsible for the degradation and activation of selected endogenous and exogenous substances have been identified in the kidney. The CYP enzymes in the kidneys are as active as those in the liver, when corrected for organ mass. In vitro and in vivo studies have shown that CYP-mediated metabolism is impaired in the presence of renal failure or uremia. In clinical studies using CYP3A probes in ESRD patients receiving hemodialysis, hepatic CYP3A activity was reported to be reduced by 28% from values observed in age-matched controls; partial correction was noted following the hemodialysis procedure.[20,21] Impaired nonrenal clearance in the presence of renal failure has been documented for a number of drugs with a fraction eliminated renally unchanged of less than 30%, including those that undergo extensive CYP metabolism by CYP1A2, CYP2D6, CYP3A4, and CYP2C9, such as duloxetine, rosuvastatin, and telithromycin.[22]

Qualitative and Semiquantitative Indices of Kidney Function

Patients who develop CKD remain relatively asymptomatic until they reach stage 4 to 5 and systemic manifestations and/or secondary complications become evident (**Table e42-3**). As renal function declines, patients may develop de novo or experience an exacerbation of hypertension, edema, electrolyte abnormalities, anemia, or other complications (see Chapter 29). The Kidney Disease Outcomes Quality Initiative (KDOQI) workgroup currently recommends that all patients with CKD, and those at increased risk for CKD, undergo at least yearly a comprehensive laboratory assessment that comprises (a) S_{cr} to estimate GFR; (b) albumin-to-creatinine ratio in a spot urine specimen; (c) examination of urine sediment for red blood cell and white blood cell counts; (d) renal ultrasonography; (e) serum electrolytes, including sodium, potassium, chloride, and bicarbonate; (f) urine pH; and (g) urine specific gravity.[23] The role of each of these indices in the identification and monitoring of CKD is discussed in detail below.

TABLE e42-3 Presentation of Chronic Kidney Disease

	Early CKD (Stages 1-2)	Late CKD (Stages 3-4)
General	The patient may not appear in distress.	Patient may have edema.
Symptoms	Not likely present.	The patient may have fatigue, malaise, pruritus, nausea.
Signs	Not likely present.	May present with fluid retention, anemia, dyspnea, reduced urine output.

	Early CKD (Stages 1-2)	Late CKD (Stages 3-4)
Laboratory tests	Microalbuminuria. Mildly elevated serum creatinine and blood urea nitrogen.	Persistent proteinuria. Reduced glomerular filtration rate or creatinine clearance rate. Abnormal urinalysis.
Other diagnostic tests		Renal ultrasound shows reduced kidney mass.

CKD, chronic kidney disease.

Laboratory Procedures to Detect the Presence of Kidney Disease

Urinalysis is an important tool for detecting and differentiating various aspects of kidney disease, which often goes unnoticed as the result of its asymptomatic presentation. Urinalysis can be used to detect and monitor the progression of diseases such as diabetes mellitus, glomerulonephritis, and chronic urinary tract infections.[24] A typical urinalysis provides information about physical and chemical composition, most of which can be completed quickly and inexpensively by visual observation (volume and color) and dipstick testing.

Chemical Analysis of Urine

pH

The normal urine pH typically ranges from 4.5 to 7.8, and an elevation above this may suggest the presence of urea-splitting bacteria. In patients with renal tubular acidosis, urine pH is usually more than 5.5 because of impaired hydrogen ion secretion in the distal tubule or collecting duct.

Glucose

Glucose is usually not present in the urine because the kidney normally completely reabsorbs all the glucose filtered at the glomerulus. When a patient's blood glucose concentration exceeds the maximum threshold for glucose reabsorption (~180 mg/dL [~10.0 mmol/L]), glucosuria will be present. Routine assessment of glucosuria to monitor diabetics has been replaced by newer methods of direct blood glucose measurements. Urine glucose testing is now predominantly used as a screening tool for the detection of diabetes.

Ketones

Acetoacetate and acetone are not normally found in the urine; they are however excreted in patients with diabetic ketoacidosis. They are also present under conditions of fasting or starvation. Typically, values of acetoacetate excretion are reported as small (less than 20 mg/dL [less than 2 mmol/L]), moderate (30-40 mg/dL [3-4 mmol/L]), and large (greater than 80 mg/dL [greater than 8 mmol/L]).

Nitrite

Nitrite is not usually present in urine. The presence of nitrite is most commonly the result of conversion from urinary nitrate by bacteria in the urine. The presence of nitrite thus suggests that the patient has a urinary tract infection, commonly caused by gram-negative rods such as *Escherichia coli*. Although false-positive results are very rare, false-negative results are more common and may be caused by lack of dietary nitrate, reduced urine nitrate concentration as a consequence of diuresis, or infections caused by bacteria such as enterococci and *Acinetobacter*, which do not reduce nitrate, and pseudomonads, which convert nitrate to nitrogen gas.

Leukocyte Esterase

Leukocyte esterase is released from lysed granulocytes in the urine; its presence is suggestive of urinary tract infection. False-positive tests can result from delayed processing of the urine sample, contamination of the sample with vaginal secretions (such as blood or heavy mucus discharge), or by *Trichomonas* infection (such as trichomoniasis). False-negative tests can be produced by the presence of high levels of protein or ascorbic acid.

Heme

The heme test indicates the presence of hemoglobin or myoglobin in the urine. A positive test without the presence of red blood cells suggests either red cell hemolysis or rhabdomyolysis.

Protein or Albumin

2 Evaluation of urinary protein or albumin is now a standard tool to characterize the severity of CKD and to monitor the rate of disease progression or regression.[23] Persistent proteinuria or albuminuria, that is, present on at least three occasions over a period of 3 to 6 months, is now considered a principal marker of kidney damage. Under normal conditions, plasma proteins remain in the glomerular capillaries and thus do not cross the glomerular basement membrane or enter the urinary space. Some of these proteins, such as albumin and globulins are not filtered by the glomerulus as a result of charge and size selectivity (greater than 40 kDa). Smaller proteins (less than 20 kDa) pass across the glomerular basement membrane but are usually readily reabsorbed in the proximal tubule. Most healthy individuals excrete between 30 and 150 mg/day of total protein consisting of approximately 30 mg/day of albumin. The other proteins that may be found in the urine are secreted by the tubules (Tamm-Horsfall, immunoglobulin A, and urokinase) or composed of smaller proteins such as β_2-microglobulin, apoproteins, enzymes, or peptide hormones. Increased renal excretion of these low-molecular-weight proteins is considered a sensitive marker of tubulointerstitial disease.

Historically, the sulfosalicylic acid test was used as a crude measure of proteinuria. This test is performed by adding sulfosalicylic acid to urine and then visually comparing this admixture with a tube of untreated urine; the degree of turbidity is then qualitatively graded (0-4 plus) as the index of the presence of proteinuria. Dipstick tests are now the most common means to determine in a

semiquantitative fashion a patient's urinary protein or albumin excretion. False-positive results can occur in the presence of alkaline urine (pH greater than 7.5), when the dipstick is immersed too long, in those with highly concentrated urine, in the presence of drugs such as penicillin, sulfonamides, or tolbutamide, as well as blood, pus, semen, or vaginal secretions. False-negative results occur with dilute urine (specific gravity less than 1.015) and when proteinuria is caused by nonalbumin or low-molecular-weight proteins such as heavy or light chains or Bence Jones proteins. The results of these dipstick tests are graded as negative (less than 10 mg/dL [less than 100 mg/L]), trace (10-20 mg/dL [100-200 mg/L]), 1+ (30 mg/dL [300 mg/L]), 2+ (100 mg/dL [1,000 mg/L]), 3+ (300 mg/dL [3,000 mg/L]), or 4+ (greater than 1,000 mg/dL [greater than 10,000 mg/L]). Benchtop portable analyzers designed for point-of-care testing, such as the Chemstrip 101 Urine Analyzer (Roche Diagnostics) and Clinitek 50 Urine Chemistry Analyzer (Bayer Corporation) are increasingly used as an alternative to visual urinalysis test-strip evaluation, and provide rapid results for urinary albumin-to-creatinine ratio.[25]

3 Dipstick test strips that are specific for low levels of albuminuria (30-300 mg/day) should be employed when one is screening individuals at risk for CKD. For example, the Microalbumin 2-1 Combo Strip (Teco Diagnostics) is a semiquantitative test for both albumin and creatinine in a spot urine sample. When dipped into a urine sample, colors range from pale green to aqua blue (for albumin) and shades of purple-brown (for creatinine), depending on the amounts present in the sample.[26] The presence of hemoglobin (≥5 mg/dL [≥50 mg/L] or visibly bloody urine) or bilirubin (≥15 mg/dL [≥257 µmol/L] or visibly dark brown color urine) can interfere with test results from these strips, but no interferences have been observed with ascorbic acid. In patients with a positive protein or albumin dipstick test, a 24-hour urine collection with measurement of albumin excretion can be used to quantitate precisely the degree of albuminuria. However, this method requires a high degree of patient compliance and is being replaced by a similarly accurate but less cumbersome technique: calculation of the ratio of protein or albumin (in milligram) to creatinine (in gram [or mmol]) in an untimed (spot) urine specimen. The normal ratio, KDIGO category A1, is less than 30 mg albumin or less than 200 mg protein per gram of creatinine (less than 3.4 mg albumin or less than 22.6 mg protein per mmol of creatinine), with values between 30 and 300 mg of albumin per gram of creatinine (3.4-34.0 mg of albumin per mmol of creatinine) classified as albuminuria that is KDIGO category A2.[23] Positive test results should be repeated, particularly in patients without an underlying cause for CKD, such as diabetes or hypertension. Monitoring of the degree of glomerular injury in CKD patients should use the albumin-to-creatinine ratio, whereas for patients with clinical proteinuria, KDIGO category A3, that is, excretion of more than 500 mg per day or an albumin-to-creatinine ratio more than 300 mg/g (greater than 30mg/nmol), the protein-to-creatinine ratio can be used.

The albumin-to-creatinine ratio has also been incorporated into a new CKD classification system as recommended by a Work Group of the Kidney Disease Improving Global Outcomes (KDIGO).[2] This new standardized "CGA" scoring system requires evaluation of both estimated GFR (G1 to G5) and albuminuria (A1-A3) in a given patient. This approach is expected to provide a more accurate evaluation of a patient's kidney function than reliance on eGFR alone. A detailed description of how to apply this CGA classification system in the monitoring plan for CKD patients is provided in Chapter 44.

Clinical Controversy…

In the past, measurement of urinary protein excretion rate was accomplished using a 24-hour urine collection in patients who were at risk for CKD. However, it is now recommended to use an untimed "spot" urine sample with either an albumin-specific dipstick or point-of-care measurement of the albumin-to-creatinine ratio. The 24-hour measurement of urinary protein is considered for confirmatory testing in most clinical situations.

Specific Gravity

Specific gravity is a measure of urine weight relative to water (1.00) that is performed using a refractometer. Thus, specific gravity is dependent on water intake and urine-concentrating ability. Normal values range from 1.003 to 1.030. Osmolality, which is a measure of the number of solute particles in the urine, is a more accurate measure of the kidney's ability to make a concentrated urine. Generally the two values correlate; however, when large quantities of heavier molecules, such as glucose, are in the urine, the specific gravity may be elevated relative to the osmolality. These tests are used in the assessment of urine-concentrating ability and are most informative when interpreted along with the hydration status of the patient and plasma osmolality.[27]

Microscopic Analysis of Urine

Microscopic examination is a critical aspect of urinalysis. Formed elements that may be detected in the urine include erythrocytes and leukocytes, casts, and crystals. An important consideration in the assessment of hematuria is whether the cells are of renal origin. More than two cells per high-power field is abnormal, and the presence of dysmorphic cells suggest renal parenchymal origin either because they were damaged as they passed through the glomerulus or due to exposure to the varying osmotic environments of the tubular lumen. White blood cells may be present in the urine in association with infection or inflammatory conditions, such as interstitial nephritis. More than one cell per high-power field is usually considered abnormal. Contamination of the sample should also be considered when there are many cells and may be a result of the presence of menses or of inadequate sample collection. Casts are cylindrical forms composed of protein, with or without cells that take the shape of the collecting tubules, where they are formed. Casts without cells are labeled *hyaline casts* and consist of the Tamm-Horsfall mucoprotein, secreted by the renal tubules. They are nonspecific and may appear in concentrated urine. In the presence of red or white blood cells, casts may be formed that include the cells, indicating that the cells were of renal origin. Solubility of the Tamm-Horsfall protein is increased as urine pH rises; therefore, sample collection for casts should occur with the first morning void when the urine is most acidic. Otherwise, casts may dissolve and elude detection.

A variety of crystals may be visualized in the urinary sediment in healthy individuals as well as those with kidney diseases. The most common crystals are those composed of uric acid, calcium oxalate, calcium phosphate, calcium magnesium ammonium pyrophosphate, and cystine. Many of these have a unique crystalline form, which permits them to be identified with microscopy.[28] Images of common types of urinary casts and crystals can be found at publically available Web sites such as

http://www.medical-labs.net/example-of-microscopic-urine-sediment-exam-results-794/.

Serum or Blood Urea Nitrogen

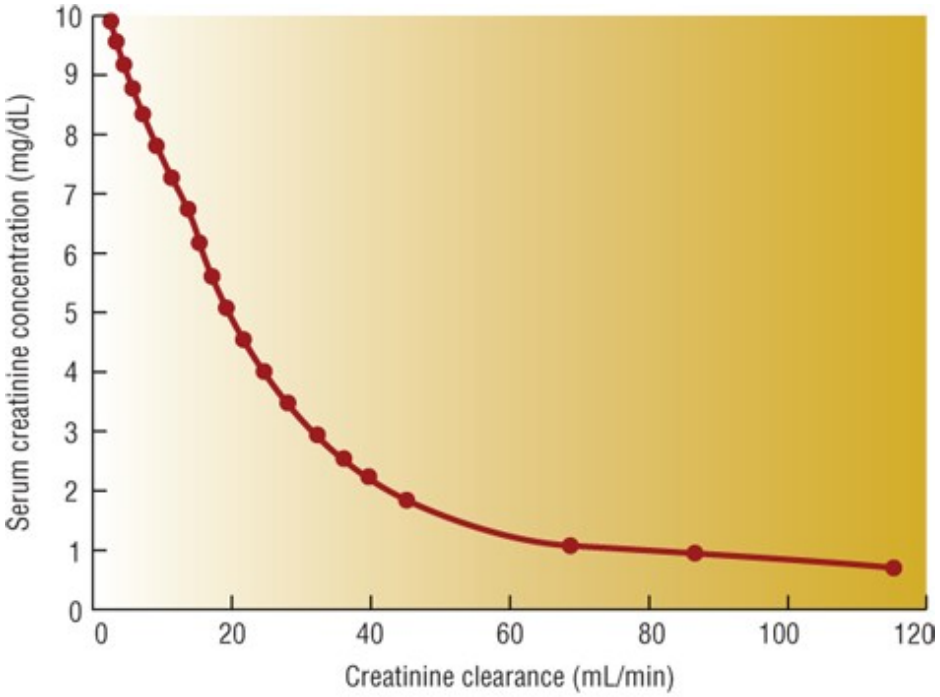
Amino acids metabolized to ammonia are subsequently converted in the liver to urea, the production of which is dependent on protein availability (diet) and hepatic function. Urea undergoes glomerular filtration followed by reabsorption of up to 50% of the filtered load in the proximal tubule. The nitrogen component of urea in serum (SUN) or blood (BUN) is considered normal if it is in the range of 5 to 20 mg/dL (1.8-7.1 mmol/L).[29] The reabsorption rate of urea is predominantly dependent on the reabsorption of water. The excretion of urea may, therefore, be decreased under conditions that necessitate water conservation such as dehydration although the GFR may be normal or only slightly reduced. This condition is evident when a patient exhibits prerenal azotemia, or an increase of the BUN to a greater extent than the S_{cr}. The normal BUN-to-creatinine ratio is 10 to 15:1 using conventional units (or 40-60:1 when both are expressed in identical molar units), and an elevated ratio is suggestive of a decreased effective circulating volume, which stimulates increased water, and hence, urea reabsorption. Creatinine is not reabsorbed to any significant extent by the kidneys. Despite these limitations, the BUN is usually used in combination with the S_{cr} as a simple screening test for the detection of renal dysfunction.

Serum and Urine Creatinine

Creatinine remains the most important endogenous biomarker used for the detection of kidney disease. The concentration of creatinine in serum is a function of creatinine production and renal excretion. Creatinine is a product of creatine metabolism from muscle; therefore, its production is directly dependent on muscle mass. At steady state, the "normal" S_{cr} range is generally reported as 0.5 to 1.5 mg/dL (44-133 µmol/L) for males and females.[29] Creatinine is eliminated primarily by glomerular filtration, and as GFR declines, the S_{cr} rises (**Fig. e42-4**).

FIGURE e42-4

Relationship between serum creatinine and creatinine clearance.



The third National Health and Nutrition Examination Survey (NHANES III) revealed a mean S_{cr} in Caucasian women and men of 0.96 mg/dL (85 µmol/L) and 1.16 mg/dL (103 µmol/L), respectively.[30] Values were lower among Mexican Americans, and higher among African Americans. For all groups, the S_{cr} increased with age. The report also estimated that among US community-dwelling adults, 10.9 million have a S_{cr} greater than 1.5 mg/dL (133 µmol/L); 3.0 million have a S_{cr} greater than 1.7 mg/dL (150 µmol/L); and 0.8 million have a S_{cr} greater than 2.0 mg/dL (177 µmol/L). Although the S_{cr} alone is not an optimal measure of kidney function, it is often used as a marker for referral to a nephrologist. There is presently no accepted single standard for an "abnormal" S_{cr}, as it is dependent on gender, race, age, and lean body mass.

Several methods have been used for the determination of the S_{cr}. The kinetic Jaffe reaction remains the cornerstone of routine quantification of creatinine in most clinical laboratories. This colorimetric method is based on the reaction of creatinine with alkaline picrate. This nonspecific method also reacts with noncreatinine chromogens in the serum, including bilirubin and proteins such as albumin, and hemoglobin, which may result in a falsely increased S_{cr}.[24] The noncreatinine chromogens are not present in the urine in sufficient quantities to interfere with the urinary creatinine measurement, because the concentration of creatinine in urine is several-fold greater than the serum concentration.

This "normal" interference results in an increase in the S_{cr} of approximately 10% and thereby the measured CL_{cr} (mCL_{cr}) would underestimate the true GFR by 10%. In subjects with normal renal function, this tends to counterbalance the effect of the contribution of tubular secretion of creatinine, which increases urine creatinine by nearly 10%. Thus, a mCL_{cr} has been proposed to serve as a good measure of GFR in subjects with normal renal function. However, this false increase in S_{cr} becomes less noticeable as the true creatinine concentration rises, due to the increasing contribution of

tubular secretion to the renal clearance of creatinine.[31] This becomes of major importance when kidney function is reduced to less than 50% of normal.

Diabetic ketoacidosis may produce increased concentrations of acetoacetate, which serves as a chromophore in the Jaffe reaction, thereby increasing the S_{cr}. Other substances that also react with this procedure in the serum include glucose, protein, pyruvate, fructose, uric acid, and ascorbic acid (**Table e42-4**). In addition, some antibiotics are associated with a false increase in the S_{cr}, including cephalothin, cefazolin, cephalexin, cefoxitin, cefaclor, cephradine, and clavulonic acid,[32,33] whereas other agents, such as the fluoroquinolones (ciprofloxacin, fleroxacin, lomefloxacin, ofloxacin, levofloxacin, sparfloxacin, and temafloxacin), do not produce a false elevation in S_{cr}.[34] The degree of interference is dependent on the serum concentration of the antibiotic, so blood samples for creatinine should be obtained when the antibiotic concentration is lowest (at the end of a dosing interval). These interferences are not observed when the S_{cr} is measured using an enzymatic technique employing creatinine iminohydrolase, creatininase, creatinase, or sarcosine oxidase.

TABLE e42-4 Factors That May Alter Creatinine Clearance Determinations

Analytical	Physiologic
Acetoacetate	Age, weight, gender
Ascorbic acid	Diet
Cephalosporins (cephalothin, cefazolin, cephalexin, cefoxitin, cefaclor, cephradine)	Diurnal variation
Clavulanic acid	Cimetidine
Dobutamine	Trimethoprim
Dopamine	Probenecid
5-Flucytosine	Exercise
Fructose	
Glucose	
Protein	
Pyruvate	
Uric acid	

Endogenous and drug interferences continue to plague creatinine measurements for both the Jaffe and enzymatic methods. Recent modifications to the Jaffe method have been employed to address some nonspecific aspects of the assay.[35] For example, the "compensated Jaffe" method is used on the Roche Diagnostics, and Siemens analyzers. Here, a fixed concentration is subtracted from all

results in order to adjust for nonspecific protein influence. The "uncompensated Jaffe" method used by Abbott, Beckman, and Siemens has been reported to be less susceptible to interferences by bilirubin when compared to other Jaffe methods.[36]

Standardized S_{cr} assays are now used in most hospital clinical laboratories.[37,38] The method involves calibration of creatinine values based on standardized reagents that are traceable to an isotope dilution-mass spectrometry (IDMS) method. This approach has significantly reduced interlaboratory variability in S_{cr} values, and has resulted in a downward shift of the "normal range" for S_{cr} values by 0.1 to 0.2 mg/dL (9-18 µmol/L) when compared to noncalibrated ranges. For example, the normal reference range reported by the UNC Hospitals laboratory for healthy males was reduced from 0.8 to 1.4 mg/dL (71-124 µmol/L; pre-IDMS) to 0.7 to 1.3 mg/dL (62-115 µmol/L; post-IDMS).[38] Other recent modifications include reporting S_{cr} values in mg/dL to two decimal places (eg, 0.93 mg/dL), and values in µmol/L to the nearest whole number (eg, 82 µmol/L). This practice is aimed at reducing rounding errors that in the past contributed to bias between creatinine-based GFR or CL_{cr} estimates, but it does not improve GFR estimation in those without CKD.

Despite alterations in creatinine assay methods, many drugs still interfere with these assays resulting in false elevations or reductions in S_{cr} values. The antifungal agent 5-flucytosine cross-reacts with creatinine when measured using the Ektachem enzymatic system, but does not interact with the Jaffe method.[39] Daly et al.[40] reported a false-negative effect of dobutamine and dopamine on the S_{cr} value when measured using the Ektachem system. The interference is concentration-dependent and results in a 10% to 100% decrease of the S_{cr}. The authors hypothesized that both drugs compete with the chromogenic dye for oxidation by hydrogen peroxide in a concentration-dependent manner. The problem is most evident when blood samples are contaminated with residual IV solution containing the interfering drug. Thus, standardization of procedures within the clinic setting and awareness of the creatinine assay method used at the institution are critical to properly interpret each patient's S_{cr} value.

Other compounds are known to truly alter the S_{cr} by inhibition of the active tubular secretion of creatinine. Among these are cimetidine and trimethoprim, which compete for creatinine secretion at the cationic transport system in a dose-dependent fashion. Cimetidine, given as a single 400-mg dose can result in a reduction of the CL_{cr}-to-inulin clearance ratio from 1.30 to 1.03, without a change in inulin clearance. Ranitidine, an H_2-receptor antagonist similar to cimetidine, however, does not have a similar effect on creatinine secretion following single doses of 300 to 1,200 mg.[41] Other drugs known to interfere with the active tubular secretion of creatinine include rilpivirine, dolutegravir, cobicistat, pyrimethamine and amiodarone. These interactions typically result in serum creatinine elevations of 0.1 to 0.4 mg/dL (0.9-35 µmol/L) with apparent reductions in CL_{cr} of up to 30 mL/min/1.73 m^2 (0.29 mL/s/m^2).[42]

The S_{cr} is dependent on the "input" function, or formation rate, and "output" function, or elimination rate. Its formation rate depends on the zero-order production from creatine metabolism, as well as input from other sources, such as dietary intake. Over 95% of creatine stores are found in skeletal muscle, with creatine metabolism being directly proportional to muscle mass. Thus, individuals with

more muscle mass have a higher S_{cr} at any given degree of kidney function than those with less muscle mass. Strenuous exercise is associated with an increase of approximately 10% in the S_{cr}. In contrast, cachectic patients, as the result of minimal muscle mass, will have very low S_{cr}, as do those with spinal cord injuries.[43] Elderly patients and those with poor nutrition may also have low S_{cr} (less than 1.0 mg/dL [88 µmol/L]) secondary to decreased muscle mass.

Creatine or methyl guanidine acetic acid is found in many commonly ingested food sources such as fish and red meat. During the cooking of meat, some creatine is converted to creatinine, which is rapidly absorbed following ingestion. S_{cr} may rise as much as 50% within 2 hours of a meat meal and remain elevated for as long as 8 to 24 hours.[44] Ingestion of creatine as an ergogenic dietary supplement is currently popular, as a means to increase skeletal muscle stores of phosphocreatine leading to adenosine triphosphate (ATP) resynthesis of adenosine diphosphate (ADP). There are conflicting reports as to the effect of creatine ingestion on the S_{cr}. Poortsmans et al.[45] evaluated a short-term regimen of 20 g creatine per day for 5 days in healthy subjects, and reported no significant change in the S_{cr}, creatinine excretion rate, or CL_{cr}. Robinson et al.[46] and Jagim et al.[47] reported a 25% to 40% increase in the S_{cr} after ingestion of 20 g creatine per day for either 5 days or 8 weeks. The renal excretion rate of creatinine was not measured. Spillane et al.[48] reported that creatine ethyl ester intake at a dose of 20 g/day for 6 days had a nearly threefold greater increase in S_{cr} than creatine monohydrate, indicating that different forms of creatine likely have differing effects on S_{cr} values.

The issue of whether, or not, creatine ingestion adversely affects kidney function was studied by Edmonds et al.[49] They noted that creatine supplementation led to an increase in renal disease progression in a rat model for renal cystic disease, suggesting that creatine supplementation may be a risk factor in patients with preexisting renal disease. Thus it is important to question ambulatory patients regarding their dietary intake for the 24 hours preceding the measurement of S_{cr} or CL_{cr}.

Diurnal variation in S_{cr} may also affect the accuracy of the CL_{cr} determination. Although the fluctuation is minimal, the observed peak plasma creatinine concentration generally occurs at approximately 7:00 PM, whereas the nadir is in the morning. The impact of diurnal variation is minimized by using S_{cr} measurements that are drawn at similar times during longitudinal evaluations, or using 24-hour urine collections for CL_{cr} measurements.

Serum and Urine Cystatin C

Cystatin C is a 132-amino-acid (13.3-kDa) cysteine protease inhibitor produced by all nucleated cells of the body that is considered a biomarker of renal function. It is freely filtered at the glomerulus and undergoes both reabsorption and catabolism in the proximal tubule. The renal handling of this biomarker is distinctly different from creatinine and exogenous GFR markers such as inulin, iohexol, and iothalamate. Originally introduced in Europe, it was recommended as a biomarker of kidney function because of findings that serum concentrations significantly correlated with GFR as well as S_{cr}. It was hypothesized that since cystatin C production was not affected by muscle mass, it would provide a more reliable estimate of renal function than S_{cr}. It is known that serum cystatin C (cysC)

concentrations can be altered by many factors other than kidney function, such as age, nutritional status, gender, weight, height, cigarette smoking, serum C-reactive protein levels, steroid therapy, and rheumatoid arthritis.[50,51] Recent studies have reported conflicting results about the sensitivity of serum cysC compared to creatinine in predicting various forms of AKI.[52,53,54,55] cysC concentrations in serum has been shown to perform better than S_{cr} for predicting contrast-induced kidney injury, resulting in a new definition of contrast-induced acute kidney injury (CIAKI), consisting of a more than 10% increase in cysC within 24 hours after exposure to contrast media.[52,53] Serum cysC also detected AKI up to 2 days earlier than serum creatinine in critically ill patients,[54] and cysC concentration was a better predictor of AKI in pediatric cardiac surgery patients.[55] However, three prior studies did not show a clear advantage for serum cysC concentration to predict AKI in cardiopulmonary bypass and cardiothoracic surgery patients.[56,57,58] In a recent multicenter study of 1,150 adults followed after cardiac surgery, cysC was noted to be a less sensitive biomarker than creatinine for detecting AKI in the postoperative period.[58] These differential findings suggest that the role of cysC in assisting with the diagnosis of AKI is yet to be fully determined.

The recent development of automated immunoassay techniques for cysC determination is based on a latex-enhanced immunoturbidimetric assay. cysC in the sample (serum or urine) binds to anti-cysC antibody, which is coated on latex particles, resulting in agglutination. The degree of the turbidity caused by agglutination is measured optically (at 540 nm) and is proportional to the amount of cysC in the sample. The range of serum values is 0.13 mg/L to 8.0 mg/L (10-599 nmol/L), with normal values of 0.55 to 1.18 mg/L (41-88 nmol/L) for women and 0.60 to 1.11 mg/L (45-83 nmol/L) for men based on data from the NHANES study.[59]

The utility of cysC as a quantitative measure of GFR is gaining acceptance in clinical and research settings. In a 4-year longitudinal study in 30 Pima Indians without CKD, the reciprocal cysC index (100/cysC) was shown to be a better predictor of declining measured GFR (mGFR) than estimated GFR (eGFR), or CL_{cr}.[60] However, in patients being treated for malignant disease, Page et al.[61] reported cysC concentrations increased independent of CL_{cr}. cysC concentrations were also noted to be independent of GFR and weakly associated with mCL_{cr}, in pediatric and adult renal transplant recipients, possibly because of the formation of cystatin–immunoglobulin complexes or reduced tubular catabolism.[62,63] Two additional studies have shown a strong association between serum cysC and cardiovascular disease in elderly and non-CKD patients, suggesting that it may provide useful prognostic information in some populations.[64,65] A recent study by Peralta et al. in nearly 25,000 adults enrolled in the REGARDS and NHANES III studies, showed that GFR based on cysC values identified a 14% higher incidence of CKD when compared to creatinine-based eGFR.[66] This suggests that serum cysC may be a more sensitive index of early kidney damage compared to serum creatinine, although further research is needed to identify conditions and patient populations in whom nonrenal factors may influence serum cysC concentrations.

Alternative Methodologies to Identify Kidney Injury

Urinary biomarkers, such as kidney injury molecule-1 (KIM-1), neutrophil gelatinase-associated

lipocalin (NGAL), and cysC have shown promise in detecting AKI[67] (see Chapter 43). Because it is normally reabsorbed and metabolized in the renal proximal tubule, it is hypothesized that tubular damage would lead to increased urinary excretion of cysC. Koyner et al.[68] showed that postop cardiac surgery patients with elevated urinary cysC-to-creatinine ratios had the highest prevalence of developing AKI. S_{cr} did not peak until 48 hours after intensive care unit (ICU) admission, suggesting that urinary biomarkers such as cysC may be beneficial in early diagnosis of AKI. Use of serum cysC as a quantitative measure of GFR requires further evaluation, and may yield useful information for comprehensive evaluations of health and cardiovascular status, including detection of acute and chronic changes in kidney function.

β-Trace protein (BTP) has recently been proposed as a new alternate endogenous marker of GFR.[69,70] Similar to cysC, it is a low-molecular-weight glycoprotein (168 amino acids) that is filtered through the glomerular basement membrane and reabsorbed in the renal proximal tubule. Elevated concentrations of BTP in serum have been reported in patients with CKD,[71] kidney transplant recipients,[72] and children.[73] Equations to estimate GFR that incorporate BTP concentrations in adults and pediatric populations are currently being evaluated.[74] Other markers of early AKI include urinary tissue inhibitor of metalloproteinase 2 (TIMP-2) and urinary insulin-like growth factor binding protein 7 (IGFBP-7). These two biomarkers are important because they are involved in G1 cell cycle arrest of renal tubular cells during the early period of cell injury. Combining these markers into a duplex "TIMP-2 × IGFBP-7" biomarker algorithm in over 500 patients accurately predicted AKI following cardiac surgery in high risk patients.[75,76] These results supported the September 2014 FDA approval of NephroCheck® (Astute Medical, Inc; http://www.astutemedical.com/us/products/nephrocheck-test/) as a urinary diagnostic device indicated for early detection of AKI.

MEASUREMENT OF KIDNEY FUNCTION

The gold standard quantitative index of kidney function is a mGFR. A variety of methods may be used to measure and estimate kidney function in the acute care and ambulatory settings. Measurement of GFR is important for early recognition and monitoring of patients with CKD and as a guide for drug-dose adjustment.

It is important to recognize conditions that may alter renal function independent of underlying renal pathology. For example, protein intake, such as oral protein loading or an infusion of amino acid solution, may increase GFR.[13] As a result, inter- and intrasubject variability must be considered when it is used as a longitudinal marker of renal function. Dietary protein intake has been demonstrated to correlate with GFR in healthy subjects. Brändle et al.[77] evaluated renal function in four groups of healthy volunteers, each ingesting a diet controlled for protein over a 4-month period. The GFR was nonlinearly related to the urine nitrogen excretion, with an observed maximum of 181.7 mL/min (3.03 mL/s) at a urinary nitrogen excretion rate of 20 g/day (1.43 mol/day), or 125 g/day protein intake. Subjects who are vegetarian have a lower GFR because of their reduced dietary protein intake relative to individuals who consume a similar caloric but normal-protein-content diet. When challenged with a protein load, the vegetarian subjects are able to increase their GFR to the "normal" range.[13] Findings from the Nurses' Health Study[78] indicate that longitudinal changes in GFR are independent

of the source of protein (nondairy animal, dairy, or vegetable) in women with normal renal function. However, women with mild renal insufficiency (GFR 71 ± 7 mL/min [1.18 ± 0.12 mL/s]) who consumed the highest amount of protein (93 g/day) had a threefold greater risk of a more than or equal to 5 mL/min (≥0.08 mL/s) decline in GFR compared to the lowest protein group (60 g/day); rates of decline were highest in those consuming nondairy animal protein. The increased GFR following a protein load is the result of renal vasodilation accompanied by an increased renal plasma flow. The exact mechanism of the renal response to protein is unknown, but may be related to extrarenal factors such as glucagon, prostaglandins, and angiotensin II, or intrarenal mechanisms, such as alterations in tubular transport and tubuloglomerular feedback.[79,80] Despite the evidence of a "renal reserve," standardized evaluation techniques have not been developed. Therefore, assessment of a mGFR must consider the dietary protein status of the patient at the time of the study.

Measurement of Glomerular Filtration Rate

4 A mGFR remains the single best index of kidney function. As renal mass declines in the presence of age-related loss of nephrons or disease states such as hypertension or diabetes, there is a progressive decline in GFR. The rate of decline in GFR can be used to predict the time to onset of stage 5 CKD, as well as the risk of complications of CKD. Accurate measurement of GFR in clinical practice is a critical variable for the individualization of the dosage regimens of renally excreted medications so that one can maximize their therapeutic efficacy and avoid potential toxicity.

The GFR is expressed as the volume of plasma filtered across the glomerulus per unit time, based on total renal blood flow and capillary hemodynamics. The normal values for GFR are 127 ± 20 mL/min/1.73 m^2 (1.22 ± 0.19 mL/s/m^2) and 118 ± 20 mL/min/1.73 m^2 (1.14 ± 0.19 mL/s/m^2) in healthy men and women, respectively. These measured values closely approximate what one would predict if the normal renal blood flow were approximately 1.0 L/min/1.73 m^2 (0.01 mL/s/m^2), plasma volume was 60% of blood volume, and filtration fraction across the glomerulus was 20%. In that situation the normal GFR would be expected to be approximately 120 mL/min/1.73 m^2 (1.16 mL/s/m^2).

Optimal clinical measurement of GFR involves determining the renal clearance of a substance that is freely filtered without additional clearance because of tubular secretion or reduction as the result of reabsorption. Additionally, the substance should not be susceptible to metabolism within renal tissues and should not alter renal function. Given these conditions, the mGFR is equivalent to the renal clearance of the solute marker:

$$\text{GFR} = \text{renal CL} = (A_e)/\text{AUC}_{0-t}$$

where renal CL is renal clearance of the marker, A_e is the amount of marker excreted in the urine in a specified period of time, t, and AUC_{0-t} is the area under the plasma-concentration-versus-time curve of the marker.

Under steady-state conditions, for example during a continuous infusion of the marker, the

expression simplifies to

$$\text{GFR} = \text{renal CL} = (A_e)/[(C_{ss}) \times t]$$

where C_{ss} is the steady-state plasma concentration of the marker achieved during continuous infusion. The continuous infusion method can also be employed without urine collection, where plasma clearance is calculated as CL = infusion rate/C_{ss}. This method is dependent on the attainment of steady-state plasma concentrations and accurate measurement of infusate concentrations. Plasma clearance can also be determined following a single-dose IV injection with the collection of multiple blood samples to estimate area under the curve ($AUC_{0-\infty}$). Here, clearance is calculated as CL = dose/AUC. These plasma clearance methods commonly yield clearance values 10% to 15% higher than GFR measured by urine collection methods.[81,82]

5 Several markers have been used for the measurement of GFR and include both exogenous and endogenous compounds. Those administered as exogenous agents, such as inulin, sinistrin, iothalamate, iohexol, and radioisotopes, require specialized administration techniques and detection methods for the quantification of concentrations in serum and urine, but generally provide an accurate measure of GFR. Methods that employ endogenous compounds, such as creatinine or cysC, require less technical expertise, but produce results with greater variability. The GFR marker of choice depends on the purpose and cost of the compound which ranges from $2,000 per vial for radioactive for ^{125}I-iothalamate (Glofil-125, QOL Medical) to $6 per vial for nonradiolabeled iothalamate (Conray-60, Mallincrodt) or iohexol (Omnipaque-300, GE Medical) (**Table e42-5**).

TABLE e42-5 Sensitivity and Clinical Utility of Renal Function Tests

	Accuracy	Clinical Utility	Cost
Inulin clearance	++++	+	$$$$
Radiolabeled markers	+++	+	$$$
Nonisotopic contrast agents	+++	++	$$$
Creatinine clearance	++	+++	$$
Serum cystatin C	+	+++	$$
Serum creatinine	+	++++	$

+, least acceptable; ++, adequate; +++, better; ++++, best.

Inulin and Sinistrin Clearance

Inulin is a large fructose polysaccharide (5,200 Da), obtained from the Jerusalem artichoke, dahlia, and chicory plants. It is not bound to plasma proteins, is freely filtered at the glomerulus, is not secreted or reabsorbed, and is not metabolized by the kidney. The volume of distribution of inulin approximates extracellular volume, or 20% of ideal body weight. Because it is eliminated by glomerular filtration, its elimination half-life is dependent on renal function and is approximately 1.3 hours in subjects with normal renal function. Measurement of plasma and urine inulin concentrations can be performed using high-performance liquid chromatography.[83] Sinistrin, another polyfructosan,

has similar characteristics to inulin; it is filtered at the glomerulus and not secreted or reabsorbed to any significant extent. It is a naturally occurring substance derived from the root of the North African vegetable red squill, *Urginea maritime*, which has a much higher degree of water solubility than inulin. Assay methods for sinistrin have been described using enzymatic procedures, as well as high-performance liquid chromatography with electrochemical detection.[84] Alternatives have been sought for inulin as a marker for GFR because of the problems of availability, high cost, sample preparation, and assay variability.

Iothalamate Clearance

Iothalamate is an iodine-containing radiocontrast agent that is available in both radiolabeled (^{125}I) and nonradiolabeled forms. This agent is handled in a manner similar to that of inulin; it is freely filtered at the glomerulus and does not undergo substantial tubular secretion or reabsorption. The nonradiolabeled form is most widely used to measure GFR in ambulatory and research settings, and can safely be administered by IV bolus, continuous infusion, or subcutaneous injection.[82] Plasma and urine iothalamate concentrations can be measured using high-performance liquid chromatography.[85,86] Plasma clearance methods that do not require urine collections have been shown to be highly correlated with renal clearance, making them particularly well-suited for longitudinal evaluations of renal function.[82,87] These plasma clearance methods require two-compartment modeling approaches because accuracy is dependent on duration of sampling. For example, Agarwal et al.[87] demonstrated that short sampling intervals can overestimate GFR, particularly in patients with severely reduced GFR. In individuals with GFR more than 30 mL/min/1.73 m^2 (greater than 0.29 mL/s/m^2), a 2-hour sampling strategy yielded GFR values that were 54% higher compared with 10-hour sampling, whereas the 5-hour sampling was 17% higher. In individuals with GFR less than 30 mL/min/1.73 m^2 (less than 0.29 mL/s/m^2), the 5-hour GFR was 36% higher and 2-hour GFR was 126% higher than the 10-hour measurement. The authors proposed a 5- to 7-hour sampling time period with eight plasma samples to be the most appropriate and feasible approach for most GFR evaluations.

Iohexol

Iohexol, a nonionic, low osmolar, iodinated contrast agent, has also been used for the determination of GFR. It is eliminated almost entirely by glomerular filtration, and plasma and renal clearance values are similar to observations with other marker agents: Strong correlations of 0.90 or greater and significant relationships with iothalamate have been reported.[88,89,90] These data support iohexol as a suitable alternative marker for the measurement of GFR. A reported advantage of this agent is that a limited number of plasma samples (as few as two collected at 120 and 300 minutes after injection) can be used to quantify iohexol plasma clearance.[91] For patients with a reduced GFR more time must be allotted—more than 24 hours if the eGFR is less than 20 mL/min (0.33 mL/s).

Radiolabeled Markers

The GFR has also been quantified using radiolabeled markers, such as ^{125}I-iothalamate (614 Da,

radioactive half-life of 60 days), ^{99m}Tc-DPTA (393 Da, radioactive half-life of 6.03 hours), and ^{51}Cr-ethylenediaminetetraacetic acid (^{51}Cr-EDTA; 292 Da, radioactive half-life of 27 days).[92] These relatively small molecules are minimally bound to plasma proteins and do not undergo tubular secretion or reabsorption to any significant degree. ^{125}I-iothalamate and ^{99m}Tc-DPTA are used in the United States, whereas ^{51}Cr-EDTA is used extensively in Europe. The use of radiolabeled markers allows one to determine the individual contribution of each kidney to total renal function.[93] Various protocols exist for the administration of these markers and subsequent measurement of GFR using either plasma or renal clearance calculation methods. The nonrenal clearance of these agents appears to be low (3-8 mL/min [0.05-0.13 mL/s]), suggesting that plasma clearance is an acceptable technique except in patients with severe renal insufficiency (GFR less than 30 mL/min [less than 0.50 mL/s]). Indeed, highly significant correlations between renal clearance among radiolabeled markers has been demonstrated.[94] Although total radioactive exposure to patients is usually minimal, use of one of these agents does require compliance with radiation safety committees and appropriate biohazard waste disposal.

Optical Real-Time Glomerular Filtration Rate Markers

A clinically applicable technique to rapidly measure GFR, particularly in critically ill patients with unstable kidney function, is highly desirable. The currently available GFR measurement approaches, as outlined above, are technically demanding, time-consuming, and often cost-prohibitive. Research is underway to develop rapid, accurate, safe, and inexpensive techniques to address this need.[95,96] For example, small, nontoxic, exogenously administered fluorescent tracers are being investigated for "real-time" GFR measurement, and at least two have entered early phase clinical trials. Both methods involve administration of optically active compounds, with continuous detection of the fluorescence signal using fiber optic or photonics technologies. A system involving injection of fluorescent dextran molecules with blood sampling and rapid (bedside) detection over 120 minutes is being developed by FAST BioMedical (Indianapolis, IN), and an NIH-funded clinical trial in healthy volunteers and patients with AKI/CKD was completed in 2014 (NCT01978314, ClinicalTrials.gov). Another method being developed by MediBeacon, LLC (St. Louis, MO), involves injection of a hydrophilic pegylated pyrazine dye (MB-102), with continuous detection using a transdermal photonics system. The results of preclinical safety and early Phase 1 testing indicate that the lead compound (MB-102) yields comparable estimates of GFR to those obtained with iohexol administration in healthy subjects.[97] The current challenge of these approaches will be to translate fluorescent signals into quantitative in vivo measurements of GFR.

Creatinine

Measured Creatinine Clearance

Although the measured (24-hour) CL_{cr} has been used as an approximation of GFR for decades, it has limited clinical utility for a multiplicity of reasons. Short-duration witnessed mCL_{cr} correlates well with mGFR based on iothalamate clearance performed using the single-injection technique. In a multicenter study[98] of 136 patients with type 1 diabetic nephropathy, the correlations of

simultaneous mCL_{cr}, and 24-hour CL_{cr} (compared to $CL_{iothalamate}$) were 0.81 and 0.49, respectively, indicating increased variability with the 24-hour clearance determination. In a selected group of 110 patients, measurement of a 4-hour CL_{cr} during water diuresis provided the best estimate of the GFR as determined by the $CL_{iothalamate}$. Furthermore, the ratio of CL_{cr} to $CL_{iothalamate}$ did not appear to increase as the GFR decreased. These data suggest that a short collection period with a water diuresis may be the best CL_{cr} method for estimation of GFR.

A limitation of using creatinine as a filtration marker is that it undergoes tubular secretion. Tubular secretion augments the filtered creatinine by approximately 10% in subjects with normal kidney function. If the nonspecific Jaffe reaction is used, which overestimates the S_{cr} by approximately 10% because of the noncreatinine chromogens, then the measurement of CL_{cr} is a very good measure of GFR in patients with normal kidney function. Tubular secretion, however, increases to as much as 100% in patients with kidney disease, resulting in mCL_{cr} values that markedly overestimate GFR. For example, Bauer et al.[31] reported that the CL_{cr}-to-CL_{inulin} ratio in subjects with mild impairment was 1.20; for those with moderate impairment, it was 1.87; and in those with severe impairment, it was 2.32. Thus, a mCL_{cr} is a poor indicator of GFR in patients with moderate to severe renal insufficiency, that is, stages 3 to 5 CKD.

Because cimetidine blocks the tubular secretion of creatinine the potential role of several oral cimetidine regimens to improve the accuracy and precision of mCL_{cr} as an indicator of GFR has been evaluated. The CL_{cr}-to-CL_{DPTA} ratio declined from 1.33 with placebo to 1.07 when 400 mg of cimetidine was administered four times a day for 2 days prior to and during the clearance determination.[99] Similar results were observed when a single 800-mg dose of cimetidine was given 1 hour prior to the simultaneous determination of CL_{cr} and $CL_{iothalamate}$; the ratio of CL_{cr} to $CL_{iothalamate}$ was reduced from a mean of 1.53 to 1.12.[100] Thus a single oral dose of 800 mg of cimetidine should provide adequate blockade of creatinine secretion to improve the accuracy of a CL_{cr} measurement as an estimate GFR in patients with stages 3 to 5 CKD.

To minimize the impact of diurnal variations in S_{cr} on CL_{cr}, the test is usually performed over a 24-hour period with the plasma creatinine obtained in the morning, as long as the patient has stable kidney function. Collection of urine remains a limiting factor in the 24-hour CL_{cr} because of incomplete collections, and interconversion between creatinine and creatine that can occur if the urine is not maintained at a pH less than 6.

Estimation of Glomerular Filtration Rate

6 Because of the invasive nature and technical difficulties of directly measuring GFR in clinical settings, many equations for estimating GFR have been proposed over the past 10 years (**Table e42-6**). A series of related GFR estimating equations have been developed for the primary purpose of identifying and classifying CKD in many patient populations.[101,102,103,104,105,106,107,108] The initial equation was derived from multiple regression analysis of data obtained from the 1,628 patients enrolled in the Modification of Diet in Renal Disease Study (MDRD) where GFR was measured using

the renal clearance of ^{125}I-iothalamate methodology. A four-variable version of the original MDRD equation (MDRD4), based on plasma creatinine, age, sex, and race, was shown to provide a similar estimate of GFR results when compared to a six-variable equation predecessor.[102] However, this equation was shown to be inaccurate at GFR more than 60 mL/min/1.73m^2 (less than 0.58 mL/s/m^2), for reasons not associated with standardization of S_{cr} (IDMS) assay results.[103] The MDRD4–IDMS equation is still included in the recommendations of the National Kidney Foundation (NKF) and the National Kidney Disease Education Program (NKDEP) for calculating the eGFR in patients with a history of CKD risk factors and a GFR less than 60 mL/min/1.73 m^2 (less than 0.58 mL/s/m^2). A recent study conducted by the FDA compared the eGFR estimated by the MDRD4 equation to the CL_{cr} estimated by the Cockcroft-Gault (CG) equation in 973 subjects enrolled in pharmacokinetic studies conducted for new chemical entities submitted to the FDA from 1998 to 2010.[107] The MDRD4 eGFR results consistently overestimated the CL_{cr} calculated by the CG method. The FDA investigators concluded that "For patients with advanced age, low weight, and modestly elevated serum creatinine concentration values, further work is needed before the MDRD equations can replace the CG equation for dose adjustment in approved product information labeling."

TABLE e42-6 Equations for the Estimation of Glomerular Filtration Rate in Adults with Stable Renal Function

Levey et al.[102] (MDRD4)	eGFR = 186 × $(S_{cr})^{-1.154}$ × $(age)^{-0.203}$ × (0.742 if patient is female) × (1.210 if patient is black)
Levey et al.[103] (MDRD4-IDMS)	eGFR = 175 × $(S_{cr})^{-1.154}$ × $(age)^{-0.203}$ × (0.742 if patient is female) × (1.210 if patient is black)
Levey et al.[109] (CKD-EPI)	eGFR = 141 × $\min(S_{cr}/\kappa, 1)^{\alpha}$ × $\max(S_{cr/},\kappa, 1)^{-1.209}$ × 0.993^{age} × 1.018 [if female] × 1.159 [if black]
Schaeffner et al.[111] (BIS1)	eGFR = 3736 × $(S_{cr})^{-0.87}$ × $(age)^{-0.95}$ × (0.82 if patient is female)
Schaeffner et al.[111] (BIS2)	eGFR = 767 × $(cysC)^{-0.61}$ × $(S_{cr})^{-0.40}$ × $(age)^{-0.57}$ × (0.87 if patient is female)
Larsson et al.[117]	eGFR = 77.24 × (cysC in mg/L)$^{-1.2623}$
Macdonald et al.[116]	$\text{Log}_{10}\text{eGFR} = 2.222 + \left(-0.802 \times \sqrt{\text{CysC in}\frac{\text{mg}}{\text{L}}}\right) + (0.009876 \times \text{LM})$
CKD-EPI	eGFR = 127.7 × (cysC in mg/L)$^{-1.17}$ × (age in years)$^{-0.13}$ × 0.91 (if female) × 1.06 (if black)
Equation 8[120]	*eGFR = 127.7 × (–0.105 + 1.13 × standardized ScysC)$^{-1.17}$ × age$^{-0.13}$ × (0.91 if female) × (1.06 if black)
CKD-EPI	eGFR (mL/min/1.73 m^2) = 76.7 × (cysC in mg/L)$^{-1.19}$
Equation 9[120]	*eGFR (mL/min/1.73 m^2) = 76.7 × (–0.105 + 1.13 × cysC in mg/L)$^{-1.19}$

CKD-EPI	eGFR (mL/min/1.73 m^2) = 177.6 × (S_{cr} in mg/dL)$^{-0.65}$ × (cysC in mg/L)$^{-0.57}$ × (age in years)$^{-0.20}$ × 0.82 [if female] × 1.11 [if black]
Equation 10[120]	*eGFR (mL/min/1.73 m^2) = 177.6 × (S_{cr} in mg/dL)$^{-0.65}$ × (–0.105 + 1.13 × cysC in mg/L)$^{-0.57}$ × (age in years)$^{-0.20}$ × 0.82 [if female] × 1.11 [if black]

Alb, serum albumin concentration (g/dL); BUN, blood/serum urea nitrogen concentration (mg/dL); CKD, chronic kidney disease; cysC, cystatin C; eGFR, estimated glomerular filtration rate; S_{cr}, serum or plasma creatinine (mg/dL).

κ is 0.7 for females and 0.9 for males, α is –0.329 for females and –0.411 for males, min indicates the minimum of Scr/κ or1, and max indicates the maximum of Scr/κ or 1. (*If S_{Cr} <0.8 mg/dL, use 0.8 for S_{Cr}). For SI conversion purposes serum/plasma creatinine is converted from µmol/L to mg/dL by multiplying by 0.0113; BUN is converted from mmol/L to mg/dL by multiplying by 2.80; Alb is converted from g/L to g/dL by multiplying by 0.1.

Conversion from eGFR conventional units of mL/min/1.73 m^2 to eGFR SI units of mL/s/m^2 requires multiplication by 0.00963; conversion from creatinine clearance or eGFR conventional units of mL/min to SI units of mL/s requires multiplication by 0.0167; Cystatin C in nmol/L can be converted to mg/L by multiplication using 0.01335 as the conversion factor.

The starred equations were developed for use with standardized cysC assays.[120]

Clinical Controversy…

Although widely adopted and incorporated into many EMR systems throughout the United States, the four-variable MDRD study equation has been shown to be inaccurate and inferior to other eGFR equations as well as the CG equation. Replacement of MDRD4 with updated versions, such as the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI), in automated eGFR reporting systems is intended, although the timeline for the transition is not consistent across all clinical settings.

A single eGFR equation may not be best suited for all populations, and choice of equation has been shown to impact CKD prevalence estimates.[108] This has led to a revitalized interest in the development of new equations to estimate GFR. The newest equations to be proposed for the estimation of GFR have been derived from wider CKD populations than the MDRD study, and include the CKD-EPI[109,110] and the Berlin Initiative Study (BIS).[111] The CKD-EPI equation was developed from pooled study data involving 5,500 patients (including the original MDRD population), with mean GFR values of 68 ± 40 mL/min/1.73 m^2 (0.65 ± 0.39 mL/s/m^2) (range 2-190 mL/min/1.73 m^2 [0.02-1.83 mL/s/m^2]). It has been reported that the CKD-EPI equation is less biased (2.5 vs 5.5 mL/min/1.73 m^2 [0.024 vs 0.053 mL/s/m^2]) but similarly imprecise compared to MDRD4.[110]

Chronic Kidney Disease–EPI Equation

The CKD-EPI study equation was compared to the MDRD equation using pooled data from patients

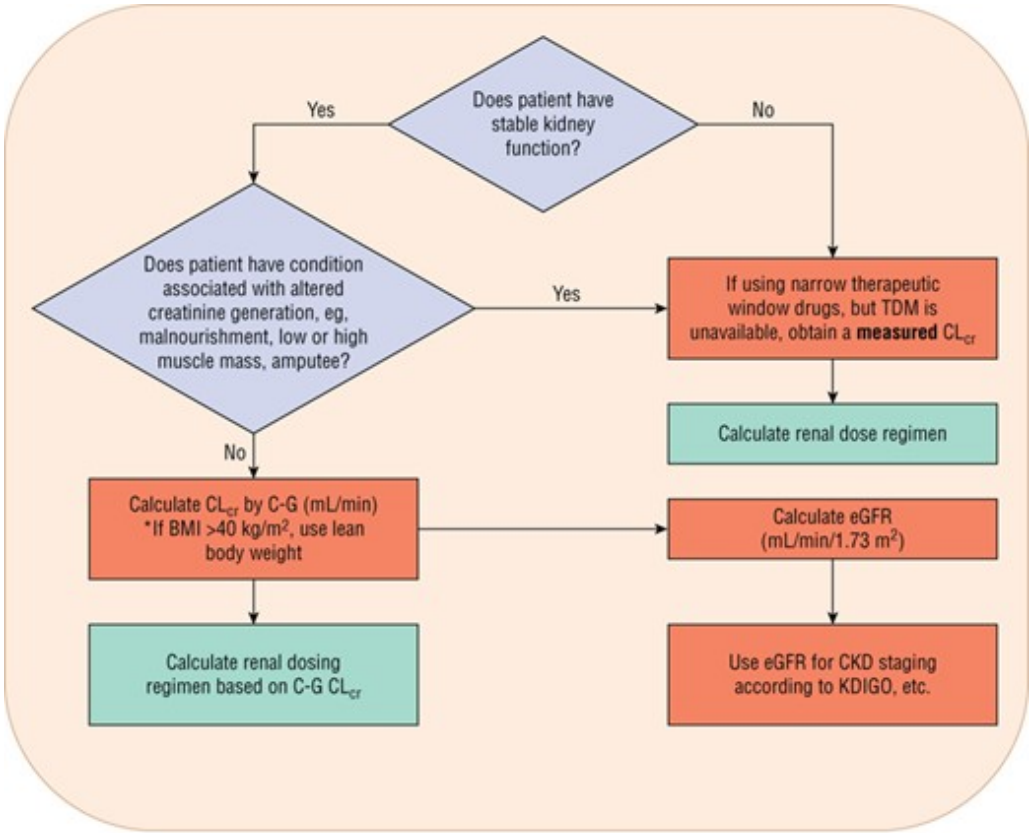
enrolled in research or clinical outcomes studies, where GFR was measured by any exogenous tracer.[110] The results of the study indicated that the bias of CKD-EPI equation was 61% to 75% lower than the MDRD equation for patients with eGFR of 60 to 119 mL/min/1.73 m^2 (0.58-1.15 mL/s/m^2). Based on these findings, the CKD-EPI equation is most appropriate for estimating GFR in individuals with eGFR values more than 60 mL/min/1.73 m^2 (greater than 0.58 mL/s/m^2). Both the KDOQI and the Australasian Creatinine Consensus Working Groups now recommend that clinical laboratories switch from the MDRD4 to CKD-EPI for routine automated reporting.[23,112] If one's clinical lab does not automatically calculate eGFR using the CKD-EPI, it becomes a bit of a challenge since the equation requires a more complex algorithm than the MDRD equation.

Limitations of the pooled analysis approach used to develop the MDRD and CKD-EPI equations include the use of different GFR markers between studies (iothalamate, ^{51}CR-EDTA, ^{99m}Tc-DTPA), different methods of administration of the GFR markers (subcutaneous and IV), and different clearance calculations (renal clearance vs plasma disappearance). These limitations may partly explain the reduced accuracy observed with the MDRD4 equation at GFR values more than 60 mL/min/1.73 m^2 (greater than 0.58 mL/s/m^2). Additionally, a recent inspection of the MDRD GFR study data showed that large intrasubject variability in GFR measures was a likely contributor to the inaccuracy of the gold standard method ([^{125}I] iothalamate urinary clearance) that was used to create the MDRD equation.[113]

Numerous studies have reported that the MDRD4 and CKD-EPI eGFR equation derived values overestimate CG equation values for eCL_{cr}.[114,115] For example, Wargo et al.[114] evaluated 409 patients with CKD admitted to a tertiary care clinic. The CKD-EPI equation values significantly overestimated the CG equation derived eCLcr determinations (39.9 mL/min vs 34.8 mL/min [0.67 mL/s vs 0.58 mL/s], respectively; *p* less than 0.001), with 95% of cases ranging from –5.1 mL/min to +15.3 mL/min (–0.09 mL/s to +0.26 mL/s). In the largest retrospective study comparing the eCLcr by CG and eGFR by MDRD4, Melloni et al.[115] reported that eGFR (expressed in mL/min) resulted in a failure to make manufacturer-recommended dose reductions for enoxaparin and the glycoprotein IIb/IIIa inhibitor (GPI) eptifibatide in up to 50% of their cohort of more than 49,000 patients. The excessive eGFR-derived doses were also correlated with major bleeding episodes (odds ratio 1.57 [95% CI 1.35-1.84]). Thus, the MDRD4 equation for eGFR should not be used in lieu of eCLcr by CG for renal dose adjustments for these drugs. The results of these studies highlight the need to understand that eGFR equations such as MDRD4 and CKD-EPI were developed for the purpose of identifying and stratifying CKD based on large multicenter epidemiologic studies. Extension of their use for individualized drug dosing has not been fully evaluated and automatic substitution of MDRD4 or CKD-EPI in place of estimated or mCL_{cr} for drug dose calculations should be avoided (**Fig. e42-5**).

FIGURE e42-5

Algorithm for estimating kidney function using eGFR and/or eCL_{cr} approaches. Creatinine clearance is converted from mL/min to mL/s by multiplying by 0.0167. (BMI, body mass index; CG, Cockcroft-Gault; CKD, chronic kidney disease; eCL_{cr}, estimated creatinine clearance; eGFR, estimated glomerular filtration rate.)



Cystatin C-Based Equations

Addition of serum cysC as a covariate in equations to estimate GFR has been employed as a means to improve creatinine-based estimations of GFR that historically were limited to the following variables; lean body mass (LM), age, sex, race, and S_{cr}.[116,117,118,119,120,121]

A significant limitation of serum cysC as a renal biomarker is the influence of body mass on serum concentrations. MacDonald et al.[116] and Vupputuri et al.[119] reported that fat-free mass is a significant covariate in GFR determination using cysC. Using GFR measured as plasma inulin clearance, LM accounted for at least 16.3% of the variance in GFR values obtained using serum cysC (*p* less than 0.001). When using a serum cysC-based estimate of GFR, which incorporates the serum cysC, age, race, and sex, a higher prevalence of CKD was reported in obese patients when compared to the MDRD4 equation.[119] In a recent retrospective analysis of over 1,000 elderly individuals (mean age 85 years) enrolled in the Cardiovascular Health Study, GFR was estimated using the CKD-EPI and CKD-EPI-cysC equation, specifically equation 9 in Table e42-6.[121] In this population, all-cause mortality rates were significantly different between equations. The CKD-EPI equation yielded a U-shaped association, whereas the CKD-EPI-cysC equation yielded a linear relationship at eGFR values less than 60 mL/min/1.73 m^2 (less than 0.58 mL/s/m^2), suggesting that cysC does not accurately predict mortality risk in patients with low S_{cr}, reduced muscle mass, and malnutrition. The combined use of serum cysC and creatinine in modified CKD-EPI equations has recently been reported. The CKD-EPI$_{creatinine_cystatin\ C,}$ equation 10 in Table e42-6 is now recommended for use in

patients where unreliable serum creatinine values are anticipated, such as extremes in body mass, diet, or creatinine assay interferences.[120]

The BIS, another eGFR equation includes cysC for CKD classification.[111] An analysis conducted in a cross-sectional cohort of 570 Caucasians average ages 78.5 years and mGFR 60 mL/min/1.73m^2 (range: 17-116 mL/min/1.73m^2 [mGFR 0.58 mL/s/m^2 and range of 0.16-1.12 mL/s/m^2]) by iohexol plasma clearance compared the eGFR calculated by BIS1 (creatinine) and BIS2 (creatinine + cysC), to eCLcr by CG with eGFR by multiple CKD-EPI equations. The BIS2 equation yielded the smallest bias followed by the BIS1 and Cockcroft–Gault equations. The total error rate for misclassification of subjects with GFR less than 60 mL/min/1.73m^2 (less than 0.58 mL/s/m^2) was smallest for the BIS2 equation (11.6%), followed by the CKD-EPI$_{\text{cystatin C}}$ equation (15.1%). Among the creatinine-based equations, BIS1 had the smallest misclassification rate (17.2%), followed by the CKD-EPI (20.4%). Further evaluation of the BIS equations in patients with varying ethnicities, chronic diseases, and GFR values is warranted before its use can be broadly recommended.

Additional research on the utility of these new eGFR equations in diverse ethnic groups has resulted in modifications or "correction factors," such as those for Japanese[124] and Chinese[125] populations. Studies to determine the impact of adding cysC into these equations are yet to be reported.

A variety of online resources provide eGFR calculators such as the NKDEP Web site,[126] which provides eGFR calculators based on the MDRD4–IDMS, CKD-EPI, and CKD-EPIcreatine_cystatin C equations. The NKDEP continues to recommend that laboratories report eGFR values greater than or equal to 60 as "greater than 60 mL/min/1.73 m^2 (greater than 0.58 mL/s/m^2), not as an exact number," due to inaccuracies of eGFR equations at higher levels of GFR. It should be noted that one must verify that a given equation is appropriate for the institutional creatinine reporting method.

Estimation of Creatinine Clearance

7 Many equations describing the mathematical relationships between various patient factors and mCL$_{cr}$, the most widely recognized surrogate for GFR in clinical settings. Most equations incorporate factors such as age, gender, weight, and S$_{cr}$, without the need for urine collection. The most widely used of these estimators is the CG equation,[127] which identified age and body mass as factors, which significantly contribute to the estimate of CL$_{cr}$. This relationship was based on observations from 249 male patients with stable kidney function in whom the creatinine production rates were estimated. Estimated creatinine clearance (eCL$_{cr}$), using the CG equation, is one of the methods endorsed by the FDA for stratifying patients in drug development pharmacokinetic studies, and has been reported most often in FDA-approved package inserts for new drug entities since the 1990s.[4,105]

One of the key considerations with the use of this equation is whether or not a modified weight index should replace actual body weight. Several modified weight indices have been proposed and this remains a controversial issue. For obese individuals, defined as those with a body mass index (BMI) greater than or equal to 30 kg/m^2 but less than 40 kg/m,^{2} it is generally recommended that total or actual body weight be used. This is based on a recent analysis by the FDA indicating that the CG

equation had less than 10% bias in nearly 600 normal weight, overweight, and obese individuals enrolled in drug pharmacokinetic studies.[128] In morbidly obese individuals (BMI ≥40 kg/m,^{2} obesity class III) an alternate measure of body weight such as lean body weight (LBW) was shown to significantly reduce bias in the CG equation, where LBW is calculated as:

$$\text{LBW (kg, males)} \ (9270 \times \text{weight})/(6680 + 216 \times \text{BMI})$$
$$\text{LBW (kg, females)} \ (9270 \times \text{weight})/(8780 + 244 \times \text{BMI})$$

and BMI is calculated as:

$$\text{BMI (kg/m}^2\text{)} = \text{weight (kg)/height (m)}^2$$

Regardless of the approach used to estimate renal function in obese patients, it is imperative that drug therapy outcomes be monitored closely in this population.

Clinical Controversy…

The use of ideal or adjusted body weight for estimating CL_{cr} in obese patients is controversial. Some clinicians recommend using a weight adjustment in patients who are more than 30% above ideal body weight (IBW), where an adjusted body weight is employed. However, recent studies by the FDA indicate that use of IBW or adjusted body weight should be avoided in those with BMI more than 40. Further research evaluating weight-based adjustments and drug pharmacokinetic outcomes is needed.

Luke et al.[129] evaluated the ability of the CG method and four other methods to determine eCL_{cr}, with inulin clearance being considered the standard measure of GFR. The simultaneously determined inulin and measured creatinine clearances correlated best, $r^2 = 0.85$, and the mCL_{cr} overestimated CL_{inulin} by approximately 15% due to tubular secretion of creatinine. Of the five eCL_{cr}, the ones calculated by the CG and Mawer et al. methods[130] correlated the best with GFR. Other methods, such as Jelliffe[131] and Hull et al.[132] consistently underestimated the mCL_{cr} (**Table e42-7**).

TABLE e42-7 Equations for the Estimation of Creatinine Clearance in Adults with Stable Renal Function

Cockroft and Gault[127]	Men: $CL_{cr} = (140 - \text{age})\text{ABW}/(S_{cr} \times 72)$
	Women: $CL_{cr} \times 0.85$
Jelliffe[131]	Men: $CL_{cr} = (100/S_{cr}) - 12$
	Women: $CL_{cr} = (80/S_{cr}) - 7$
Jelliffe[131]	Men: $CL_{cr} = 98 - [0.8\ (\text{age} - 20)]/S_{cr}$
	Women: $CL_{cr} \times 0.9$
Mawer et al.[130]	Men: $\text{ABW}\ [29.3 - (0.203 \times \text{age})]\ [1 - (0.03 \times S_{cr})]/(14.4 \times S_{cr})$
	Women: $\text{ABW}\ [25.3 - (0.175 \times \text{age})]\ [1 - (0.03 \times S_{cr})]/(14.4 \times S_{cr})$

Hull et al.[132]	Men: $CL_{cr} = [(145 - age)/S_{cr}] - 3$ Women: $Cl_{cr} \times 0.85$

ABW, actual body weight (kg); CL_{cr}, creatinine clearance in mL/min; S_{cr}, serum or plasma creatinine (mg/dL).

For SI conversion purposes serum/plasma creatinine is converted from µmol/L to mg/dL by multiplying by 0.0113. Conversion from creatinine clearance conventional units of mL/min to SI units of mL/s requires multiplication by 0.0167.

Patients undergoing screening for participation in the African American Study of Kidney Disease (AASK) were evaluated for kidney function based on eCL_{cr}, simultaneous ^{125}I-iothalamate and measured 24-hour CL_{cr}.[133] The simultaneous mCL_{cr} provided the best estimate of GFR. The CG method was the preferred method for eGFR, based on performance and ease of use. This method was noted to underestimate the GFR by 9%, perhaps because of the increased excretion rate of creatinine by black patients.[134]

Administration of cimetidine has also resulted in improved performance of the CG equation as means to calculate eGFR. Ixkes et al.[135] gave patients three 800-mg doses of cimetidine in 24 hours, and measured creatinine plasma levels from 3 to 7 hours following the final dose. During this 4-hour period, the $CL_{iothalamate}$ was determined as the measure of GFR. The CG calculations were performed with the plasma creatinine measurement 3 hours after the last dose of cimetidine. The ratio of the CG eCL_{cr}-to-$CL_{iothalamate}$ decreased from 1.28 ± 0.21 to 0.98 ± 0.11 in the presence of cimetidine. This cimetidine dosing schedule also improved the accuracy of CG eCL_{cr} relative to GFR in renal transplant patients with GFR values ranging from 20 to 80 mL/min/1.73 m^2 (0.19-0.77 mL/s/m^2).[136,137]

Liver Disease

Evaluation of renal hemodynamics is particularly complicated in patients with liver disease and cirrhosis, where filtration fraction is associated with the degree of ascites, renal artery vasoconstriction, and vascular resistance.[138] The estimation of CL_{cr} or GFR can be problematic in patients with preexisting liver disease and renal impairment. Lower-than-expected S_{cr} values may result from reduced muscle mass, protein-poor diet, diminished hepatic synthesis of creatine (a precursor of creatinine), and fluid overload can lead to significant overestimation of CL_{cr}. Orlando et al.[139] evaluated 10 healthy subjects, 10 patients with mild liver disease, and 10 with severe liver disease, and observed a mCL_{cr}-to-CL_{inulin} ratio of 1.05, 1.03, and 1.04 for each group, respectively. When the CL_{cr} of patients with severe liver disease was estimated using the CG equation, the resultant ratio (eCL_{cr}-to-CL_{inulin}) was 1.23. Lam et al.[140] likewise noted an overestimation by CG of the mCL_{cr} in patients with severe disease, by 40% to 100%.

Studies of renal function in patients with severe hepatic disease confirm the earlier observations of Hull et al.[132] and Caregaro et al.[141] who reported that mCL_{cr} overestimated GFR by up to 50% in

hepatic patients with a GFR of 56 ± 19 mL/min/1.73 m^2 (0.54 ± 0.18 mL/s/m^2) because of increased tubular secretion of creatinine. The effect of cimetidine administration on mCL_{cr} was evaluated in a small study by Sansoe et al.[142] In 12 patients with compensated cirrhosis, S_{cr} values increased from 0.68 ± 0.11 to 0.94 ± 0.14 mg/dL (60 ± 10 µmol/L-83 ± 12 µmol/L) during coadministration of cimetidine (1,000 mg given as 400 mg × 1 then 200 mg every 3 hours) during a 9-hour clearance period. The mCL_{cr} declined from 138 ± 20 prior to cimetidine administration to 89 ± 13 mL/min (2.30 ± 0.33-1.49 ± 0.22 mL/s), with no change in mGFR.

Evaluations of new eGFR equations for use in patients with liver disease have yielded mixed results. In cirrhotic patients being evaluated for liver transplant (mGFR 58 ± 5.1 mL/min/1.73 m^2 [0.56 ± 0.049 mL/s/m^2]) the eGFR by the MDRD4 and the eCL_{cr} by CG significantly overestimated mGFR by 30% to 50%, and both were considered unacceptable methods for kidney function assessment in liver transplant patients.[143,144] Gerhart et al.[145] evaluated the performance of the CKD-EPI and MDRD4–IDMS equations in patients with liver disease following transplantation (group 1, n = 59) and those with cirrhosis (group 2; n = 44). When compared to mGFR, both equations yielded slightly positively biased estimates of GFR (4-9 mL/min/1.73 m^2 [0.04-0.09 mL/s/m^2]) in transplanted patients. However, in patients with hepatic cirrhosis, both equations were significantly positively biased (40-42 mL/min/1.73 m^2 [0.39-0.40 mL/s/m^2]), with low precision (21-26 mL/min/1.73 m^2 [0.20-0.25 mL/s/m^2]) and low accuracy with only 7% of patients having eGFR values within 30% of the mGFR. Incorporation of cysC into eGFR equations has recently shown promise in patients with liver disease. In 72 cirrhotic patients, Mindikoglu et al.[146] reported that the $CKD\text{-}EPI_{creatinine\text{-}cystatin\ C}$ equation was significantly more precise than the CG, CKD-EPI, or $CKD\text{-}EPI_{cystatin\ C}$ when compared to iothalamate-mGFR. The accuracy of the $CKD\text{-}EPI_{creatinine\text{-}cystatin\ C}$ equation, measured as percentage of eGFR that differed by more than 30% with respect to mGFR, was significantly less than mCL_{cr} (p = 0.024), CG (p = 0.0001), MDRD (p = 0.027), and $CKD\text{-}EPI_{creatinine}$ (p = 0.012) equations. In summary, renal function assessment in patients with hepatic disease should be performed by measuring glomerular filtration, and GFR estimation equations that combine creatinine and cysC are preferred.

Other Special Populations

Davis and Chandler[147] confirmed the accuracy of the CG eCL_{cr} method in trauma patients with stable kidney function, and Thakur et al.[43] demonstrated its acceptable performance in 42 paraplegic patients. Kidney transplant recipients are frequently monitored for renal function, as numerous complications may occur during the life of the allograft. Ruiz-Esteban et al.[148] evaluated the bias and precision of the MDRD4 and CKD-EPI relative to CG in 153 postrenal transplant patients. Here, the mean bias for MDRD4 was –10.6 ± 12.7 compared to –9.8 ± 11.3 mL/min/1.73 m^2 (–0.10 ± 0.12 compared to –0.09 ± 0.11 mL/s/m^2) for CKD-EPI (p = 0.006), with the CKD-EPI having a higher percentage of patients within 30% of the CG value than the MDRD equation (86.9% vs 81.7%, p less than 0.001). Huang et al.[149] reported the inability of several CL_{cr} equations to predict renal function in hospitalized patients with advanced HIV disease. All of the prediction methods overestimated the measured 24-hour CL_{cr}. The reasons for the poor predictability of these methods are unclear,

although 24-hour collection methods result in increased variability, often because of inadequate collection of urine. Another recently discovered problem with estimating CL_{cr} in HIV patients relates to drug-creatinine interactions. Nucleoside reverse transcriptase inhibitors (dolutegravir, rilpivirina) and cobicistat can block OCT2 and MATE1-mediated tubular secretion of creatinine, leading to elevations in serum creatinine (0.1-0.2 mg/dL[0.9-1.8 µmol/L]) and reductions in CL_{cr} by up to 5 to 15 mL/min (0.08-0.25 mL/s).[42,150]

Kidney function assessment during pregnancy is usually performed using a 24-hour CL_{cr} determination, and estimation equations have been shown to perform poorly particularly in the preeclampsia population. For example, Alper et al.[151] recently evaluated the CG, MDRD4 and CKD-EPI equations in 543 women, aged 16 to 49 years, with preeclampsia after the 20th week of gestation. When compared to 24-hour mCL_{cr} (mean 133 ± 43 mL/min [2.22 ± 0.72 mL/s]), the CG equation was positively biased (36 ± 2 mL/min [0.60 ± 0.03 mL/s]) whereas both the MDRD4 and CKD-EPI were negatively biased (–20 ± 1.5 mL/min [–0.33 ± 0.025 mL/s]).Thus, kidney function estimating equations should not be used during pregnancy.

Unstable Kidney Function

Patients with unstable kidney function or AKI present a unique situation because S_{cr} values are changing, and steady state cannot be assumed, which is one of the assumptions of all the above-mentioned eCL_{cr} methods. It is now widely accepted that a change in the S_{cr} of more than 50% over a period of 7 days, or an increase in S_{cr} by at least 0.3 mg/dL (≥27 µmol/L) over a 24- to 48-hour period indicates the presence of AKI.[152] Methods to measure GFR in this population, such as ^{125}I-iothalamate clearance, are cumbersome and costly especially in the acute care setting. Although several equations have been proposed the calculate eCL_{cr} in AKI patients or those with rapidly progressive renal disease,[153,154,155] a rigorous evaluation of the accuracy and precision of each of these proposed methods is lacking and none of them is currently recommended for clinical use. Use of semiquantitative approaches is preferred for the purpose of estimating severity of disease using RIFLE or AKIN criteria (see Chapter 43 for more details).

Use of abbreviated CL_{cr} measurements (less than 24 h) may be valuable for detecting early evidence of AKI in critically ill patients. Pickering et al.[156] recently reported that 4-hour CL_{cr} measurements were significantly better at predicting AKI events than S_{cr} alone in 484 patients. However, the lack of true mGFR in these patients prevented assessment of the accuracy and precision of the CL_{cr} values. Hoste et al.[157] used 1-hour CL_{cr} measurements to evaluate the CG and MDRD equations in critically ill patients within 1 week of ICU admission. Both equations were poorly correlated with CL_{cr} and were similarly imprecise with Bland-Altman 95% confidence intervals ranging from –77 to 64 mL/min (–1.29 to 1.07 mL/s) for CG and –77 to 58 mL/min/1.73 m^2 (–0.74 to 0.56 mL/s/m^2) for MDRD.

It is thus, ultimately, most important to recognize that renal function in patients with AKI is generally markedly lower than one would estimate using steady-state methods, and dose adjustments should be made if necessary to avoid drug toxicity (see Chapters 28 and 33).

Kidney Function in Children

Kidney function in the neonate is difficult to assess because of difficulty in urine and blood collection, the frequent presence of a non–steady-state S_{cr}, and apparent disparity between development of glomerular and tubular function. Preterm infants demonstrate significantly reduced GFR prior to 34 weeks, which rapidly increases and becomes similar to term infants within the first week of life.[158] Evaluation of GFR in preterm infants on day 3 of life, using an inulin infusion, failed to identify a relationship between patient weight and GFR. Gestational age, which ranged from 23.4 to 36.9 weeks (mean: 30.2 weeks), however, correlated with both GFR and reciprocal of S_{cr}. The inulin clearance increased from 0.67 to 0.85 mL/min (0.011-0.014 mL/s) in those with gestational age less than 28 weeks versus those of 32 to 37 weeks of age, while S_{cr} decreased from 1.05 to 0.73 mg/dL (93-65 µmol/L), respectively. Creatinine was measured using a specific enzymatic method to avoid interference from bilirubin or drugs.[159] CL_{cr} has also been evaluated in infants younger than 1 week, and values of 17.8 mL/min/1.73 m^2 (0.171 mL/s/m^2) on day 1 increased to 36.4 mL/min/1.73 m^2 (0.351 mL/s/m^2) by day 6.[160] In light of these rapid changes in GFR, estimation of GFR is not recommended for infants younger than 1 week. Kidney function expressed as GFR standardized to body surface area (BSA) increases with age and stabilizes at approximately 1 year. In older children, GFR is best assessed using standard measurement techniques for GFR. Subcutaneous administration of ^{125}I-iothalamate has been effectively used to measure GFR in children ranging in age from 1 to 20 years.[161] The original equation to estimate GFR as described by Schwartz et al.[162] is dependent on the child's age and length:

$$GFR = [\text{length (cm)} \times k]/(S_{cr} \text{ in mg/dL})$$

where *k* is defined by age group: infant (1-52 weeks) = 0.45; child (1-13 years) = 0.55; adolescent male = 0.7; and adolescent female = 0.55. Serum creatinine in µmol/L can be converted to mg/dL by multiplication using 0.0113 as the conversion factor.

A newer version of the Schwartz equation[163] was developed from a population of 349 children (1-19 years) with mild-to-moderate CKD enrolled in the Chronic Kidney Disease in Children (CKiD) study. This simple equation is commonly referred to as the Schwartz "Bedside" formula:

$$GFR = 0.41 * [\text{length (cm)}/S_{cr} \text{ in mg/dL}]$$

Lee et al.[164] recently reported that this new Bedside Schwartz equation performed better than the original Schwartz equation for patients with mild-moderate CKD, but was less accurate in patients with mild CKD. Thus, the appropriate use of the Bedside Schwartz equation and accuracy in subpopulations of CKD is yet to be fully determined.

Equations derived from adult populations have also been evaluated in pediatric patients. Peirrat et al.[165] compared the MDRD, Schwartz, and CG equations in children 3 to 19 years. In children younger than 12 years, the Schwartz and MDRD equations were significantly more biased than CG, and CG provided the best prediction of GFR in children older than 12 years. The results of these investigations suggest that further studies will be needed to clarify the value of any of these

predictive methods in children. Most recently, an equation for GFR based on beta-trace protein was shown to yield similar values of GFR compared to the Schwartz equation in 387 pediatric patients (10.7 ± 7.1 years) who underwent a ^{99m}TC-DTPA GFR scan.[74] The most recent GFR equation evaluated in pediatrics includes use of cysC, BUN, S_{cr} (in mg/dL) and demographic data derived from over 600 pediatric patients enrolled in the CKiD study[166]:

$$\text{eGFR (mL/min/1.73 m}^2) = 39.8 \times [\text{ht(m)}/S_{cr}]^{0.456} \times (1.8/\text{cysC})^{0.418} \times (30/\text{BUN})^{0.079} \times 1.076^{\text{male}} \times [\text{ht(m)}/1.4]^{0.179}$$

This equation had the lowest root-mean square error (0.147), highest R^2 (0.863) and frequency of values within 30% of iohexol-mGFR (91.3%) when compared to seven other GFR equations.

Kidney Function in the Elderly

Cross-sectional studies have historically shown that GFR declines as a function of age.[167,168] The largest prospective study conducted in healthy elderly individuals is the Baltimore Longitudinal Study on Aging (BLSA).[168] In an initial analysis of 254 BLSA participants without kidney disease, it was reported that mCL_{cr} decreases at the rate of approximately 0.75 mL/min/1.73 m^2/y (0.0072 mL/s/m^2/y) beginning at the fourth decade of life. These subjects were then evaluated prospectively for up to 23 years. Interestingly, approximately one-third of the subjects showed no change in renal function from their baseline value, and a small number showed an increased clearance. These changes may be a result of normal physiologic changes or of subclinical insults to the kidneys initiating the events leading to chronic progressive loss of renal function. Fliser et al.[169] studied renal functional reserve in healthy young (23-32 years) and elderly (61-82 years) volunteers using an amino acid infusion technique. mGFR increased by 16% in young and 17% in elderly subjects following the infusion. Renal functional reserve thus appears to be maintained in healthy elderly individuals.

Interpretation of the S_{cr} alone is difficult in the elderly patient primarily because of the decreased muscle mass and resultant lower production rate of creatinine. Thus, the S_{cr} often remains within the normal range despite a reduction in the number of functional nephrons. As renal function declines, the kidneys excrete a larger fraction of creatinine. This perpetuates the “normal” S_{cr}. Recent recommendations such as the adoption of standardized creatinine assays by clinical laboratories and reporting of S_{cr} values to two decimal places will likely improve the accuracy of renal function estimation in the elderly population.[35]

Clinical Controversy…

Estimation of CL_{cr} in elderly with low serum creatinine values is controversial. Some clinicians advocate for replacing serum creatinine with an arbitrary value of 1.0 mg/dL (88 µmol/L) to account for reduced muscle mass. This practice should be avoided, and has been shown to significantly underestimate kidney function in elderly populations. Furthermore, the impact of this practice on GFR estimates such as CKD-EPI and other equations has yet to be evaluated in this population.

The CG formula[127] continues to provide a valid estimate of the CL_{cr} in elderly populations. Smythe et

al.[170] estimated CL_{cr} in 23 patients older than 60 years using seven different methods, and compared the results to a measured 24-hour CL_{cr} determination. Estimations were performed with the actual S_{cr} and also with the S_{cr} corrected, or rounded, up to 1.0 mg/dL (88 µmol/L) if the actual value was less than 1.0 mg/dL (less than 88 µmol/L). Changing the S_{cr} to 1.0 mg/dL (88 µmol/L) resulted in a significantly lower eCL_{cr} (–28.8 mL/min [–0.481 mL/s]) compared to the unadjusted S_{cr} (+2.3 mL/min [+0.038 mL/s]). In patients older than 60 years with S_{cr} less than 1.0 mg/dL (less than 88 µmol/L), rounding the S_{cr} value up to 1.0 mg/dL (88 µmol/L) resulted in dose estimates for gentamicin that were significantly lower (–90 ± 67 mg/day) than doses calculated based on the actual S_{cr} value.[171] In an analysis of the BLSA dataset, Dowling et al.[172] evaluated 269 elderly individuals: age 81 ± 6 (mean + SD) years, S_{cr} 1.1 ± 0.4 mg/dL (97 ± 35 µmol/L), and 24-hour mCL_{cr} of 53 ± 13 mL/min (0.88 ± 0.22 mL/s). The CG equation yielded the least biased estimate of mClcr, whereas the MDRD4 and CKD-EPI equations significantly overestimated the CG and mClcr values by 30% to 47%. Rounding low serum creatinine values up to an arbitrary value of 1.0 mg/dL (88 µmol/L) resulted in CG values that significantly underestimated mClcr (44 vs 56 mL/minute [0.73 vs 0.93 mL/s], *p* less than 0.001) and uncorrected CG (*p* less than 0.001). Taken together, these results strongly suggest that the commonly accepted practice of fixing or rounding S_{cr} to an arbitrary value in elderly patients should be avoided.

An alternative to the estimation of GFR or a 24-hour mCL_{cr} is a 4-hour mCL_{cr} performed during water diuresis. This approach correlated with the inulin clearance as well as with an observed inpatient 24-hour mCL_{cr}.[93] However, one must be aware of the potential risk of hyponatremia in the geriatric patient who is unable to tolerate an oral water load, as well as the need for complete bladder emptying to ensure accurate results. O'Connell et al.[173] assessed the accuracy of 2- and 8-hour urine collections compared with 24-hour CL_{cr} determinations in 45 hospitalized patients older than 65 years with indwelling urethral catheters. The 8-hour timed urine collection for CL_{cr} showed minimal bias (2.2 mL/min [0.037 mL/s]) as compared with the 24-hour value, whereas the 2-hour determination was both positively biased (11 mL/min [0.18 mL/s]) and less precise (25 mL/min [0.42 mL/s]).

Impact on Drug Dosing Recommendations

The automated reporting of eGFR in the clinical setting has led some practitioners to consider substituting eGFR in place of eCL_{cr} for renal dose adjustments as recommended in regulatory agency approved product labelling. The prime concern with this approach, particularly in the elderly, is that substitution of eGFR values in CL_{cr}-based dosage adjustment algorithms may result in dosing errors and toxicity especially for drugs with narrow therapeutic indices since eGFR tends to overestimate eCL_{cr}.[172,174,175,176,177,178,179,180,181]Roberts et al.[174] reported that the MDRD eGFR values overestimated gentamicin clearance by 29% (*p* less than 0.001), whereas the Cockcroft and Gault yielded only 10% overestimation (*p* less than 0.01), and MDRD overestimated renal function more as age increased. Retrospective studies in more than 1,200 patients with renal disease have shown that overestimation of renal function using the MDRD4 with or without IDMS eGFR equation results in up to 30% to 60% higher doses for digoxin, amantadine, and various antimicrobials compared to doses calculated using eCL_{cr}.[176,177,178,179,180,181] In contrast Stevens et al.[182] reported that use of an eGFR

(MDRD4 equation in mL/min based on a calculated BSA), yields dosage regimens for a subset of drugs that are similar to those calculated using mGFR. The authors of this study concluded that the MDRD4 equation could be used for renal dose adjustments. However, this practice was not widely adopted. Modifications to the CKD-EPI equation, including use of cysC, are now being evaluated in drug pharmacokinetic studies, and may be particularly useful for patients with apparently normal renal function. For example, Frazee et al.[183] retrospectively evaluated vancomycin use in critically ill patients (n = 170) and found that the CKD-EPI$_{\text{creatinine-cystatin } C}$ equation (converted to mL/min) yielded a 2.5-fold improvement in achieving target trough values, when compared to eCLcr–. Of note, the predicted trough values were improved among those with normal GFR (greater than 120 mL/min [greater than 2 mL/s]), where under dosing is often problematic. A more detailed discussion of the utilization of kidney function estimates and renal dosing approaches is provided in Chapter 48.

Clinical Controversy…

Drug-dose individualization is often required in patients with CKD. Approved drug labeling typically includes dose-adjustment information based on the patient's CL_{cr} using the CG method. Automated eGFR reporting by many hospital laboratories has now raised the question if any other GFR estimation equations should be used as a guide for drug-dose adjustments.

ASSESSMENT OF PROGRESSION

7 CKD (see Chapter 44) will eventually lead to ESRD, necessitating dialysis (see Chapter 45) or transplantation for survival (see Chapter 90). The rate of progression can be slowed and in some cases halted through dietary modification, strict blood pressure control, initiation of angiotensin-converting enzyme inhibitor or angiotensin receptor blocker therapy to reduce urinary protein excretion, and improved glucose control in patients with diabetes mellitus (see Chapter 44). The efficacy of these interventions is optimally assessed with the sequential measurement of an accurate and sensitive index of mGFR such as iohexol, iothalamate, or radioisotope clearance.[184]

Alternatively, use of newer methods to estimate GFR, based on creatinine, cysC, or a combination of both or traditional methods, such as calculation of the linear decline in the reciprocal of the S_{cr} as a function of time, can be used to evaluate the rate of progression of kidney disease.[1,30]

Clinicians can also use the eGFR or eCL_{cr} plotted as a function of time as a prognostic tool, to predict when dialysis may be needed (eCL_{cr} less than 15 mL/min [less than 0.25 mL/s]) or as a marker for evaluating the success of therapeutic interventions to alter the rate of decline in kidney function. Several factors, such as changes in dietary intake of creatinine and decreased muscle mass, which are associated with a reduction in the production of creatinine, may alter the utility of these relationships. Low levels of albuminuria serve as an early marker of kidney disease in patients with diabetic nephropathy[185] along with numerous other conditions, such as hypertension and obesity.[186,187,188] Albuminuria is a more sensitive marker than total protein for monitoring CKD progression, and it is a modifiable risk factor for kidney disease progression and cardiovascular disease.[1,64,88] Thus patients with low levels of albuminuria (30-300 mg/day) on at least two occasions or overt albuminuria

(greater than 300 mg/day) should begin to receive pharmacotherapy. For children, albuminuria is considered present if albumin excretion exceeds 0.36 mg/kg/day, and overt albuminuria has been defined as an excretion rate that exceeds 4 mg/kg/day. The urinary albumin-to-creatinine ratio is also an accurate predictor of 24-hour albuminuria. Monitoring guidelines suggest that a urine albumin to creatinine ratio of more than 30 mg/g (greater than 3.4 mg/mmol) places the patient at increased risk of developing diabetic nephropathy, mortality, and ESRD and is an indication for the initiation of pharmacotherapeutic intervention.[5,24] Based on the established link between albuminuria and adverse clinical outcomes in more than 1.5 million individuals with varying levels of eGFR, the albumin-to-creatinine ratio is included with eGFR as part of an updated approach for staging CKD recommended by KDIGO.[2]

MEASUREMENT OF RENAL PLASMA AND BLOOD FLOW

Measurement of renal plasma and blood flow is rarely, if ever, determined in the clinical setting; and it is only occasionally used in research settings to evaluate hemodynamic changes related to disease or drug therapy. The kidneys receive approximately 20% of cardiac output and representative values of renal blood flow in men and women of about 1,200 ± 250 and 1,000 ± 180 mL/min/1.73 m^2 (11.6 ± 2.4 and 9.6 ± 1.7 mL/s/m^2) have been reported, respectively.[189] Renal plasma flow (RPF) is estimated to be 60% of blood flow if it is assumed that the average hematocrit (HCT) is 40% and that it can be measured by the use of model compounds that are eliminated from the plasma compartment on a single pass through the kidneys. Because only 20% of the plasma is filtered at the glomerulus, the compound must undergo active tubular secretion and minimal to no reabsorption to be completely eliminated. To accurately reflect RPF, the extraction through the kidney must be nearly 100%. Para-aminohippuric acid (PAH) is an organic anion that has been used extensively for the quantification of RPF. PAH is approximately 17% bound to plasma proteins and is eliminated extensively by active tubular secretion. Because PAH elimination is active, saturation of the transport processes should be anticipated, and concentrations of PAH in plasma should not exceed 10 mg/L. Furthermore, PAH is also metabolized, possibly within the kidney, to *N*-acetyl-PAH, and it is important for the analytical method to differentiate the parent compound from the metabolite.[86,190] The extraction ratio (ER) for PAH is 70% to 90% at plasma concentrations of 10 to 20 mg/L; hence, the term "effective" renal plasma flow (ERPF) has been used when the clearance of PAH is not corrected for the ER or if it is assumed to be 1. Normal values are about 650 ± 160 mL/min (10.9 ± 2.7 mL/s) for men and 600 ± 150 mL/min (10.0 ± 2.5 mL/s) for women.[189] Children will reach normalized adult values by 3 years, and ERPF will begin to decline as a function of age after 30 years, reaching about one-half of its peak value by 90 years. The method for calculation of ERPF is based on the relationship between organ clearance, ER, and flow:

$$\text{ERPF} = \text{renal PAH CL} = \text{RPF} \times \text{ER}$$

Effective renal blood flow (ERBF) can be estimated from ERPF by assuming the extraction ratio is 1 and correcting for the red blood cell volume of the blood (HCT):

$$\text{ERBF} = \text{ERPF}/(1 - \text{HCT})$$

ERPF can also be measured using the radioisotopes[132] I-orthoiodohippurate (^{131}I-OIH) or ^{99m}Tc-mercaptoacetyltriglycine (^{99m}Tc-MAG3).[191] One important advantage of this method is its ability to measure ERPF in total or for each kidney independently, as well as its ability to produce renal images. Russell and Dubovsky,[192] using a single-injection technique, compared clearance methods with and without urine collection and showed similar results with each method.

QUANTITATIVE ASSESSMENT OF TUBULAR FUNCTION

Although GFR is the best overall indicator of renal function, it may not provide an accurate measure of tubular function, either secretory capacity or cellular function, suitable for use in the research environment.[193] Tubular secretory function can be assessed by measuring PAH transport as the prototype marker of the organic anion secretory system. N^1-methylnicotinamide (NMN) and tetraethylammonium are prototype compounds secreted by the cationic transport system and may be used as markers of cationic secretory capacity. Edwards et al.[194] demonstrated delayed recovery of NMN clearance among patients with psoriasis treated with low-dose cyclosporine, as compared with the recovery of GFR and renal blood flow Dowling et al.[190] explored the usefulness of famotidine as a marker for dose-dependent cationic transport, but was unable to demonstrate saturation at doses up to ten times clinically indicated values, likely due to the contribution from other parallel secretory pathways such as MDR1/P-GP.[195]

Furthermore, Karyekar et al.[196] demonstrated that itraconazole, an inhibitor of MDR1, significantly reduced the renal tubular secretion of cimetidine in healthy individuals, suggesting that cimetidine may be used as an in vivo probe of renal P-GP function. It should also be recognized that these transport systems are not necessarily mutually exclusive. Indeed, probenecid, which is secreted by the anionic pathway, inhibits the secretion of cationic compounds. Quantitative measures of tubular transport capacity are currently limited primarily to the research setting.

Other measures of tubular function are less specific and are regarded primarily as indices of damage within the nephron. Low-molecular weight proteins located in the proximal tubule, such as β_2-microglobulin, can be used as urinary biomarkers to detect early tubular toxicity of drugs such as carboplatin, ifosfamide, and etoposide.[197] Other low-molecular-weight proteins used as markers of tubular function include retinol-binding protein (21 kDa), protein HC (also known as α_1-microglobulin, 27 kDa), KIM-1, NGAL, interleukin-18, and fatty-acid binding proteins (FABPs).[67,198,199] These proteins are normally freely filtered at the glomerulus and then completely reabsorbed by the proximal tubule. Increases in their excretion are thus suggestive of tubular dysfunction but are not diagnostic. In each case, the maximal reabsorptive capacity may be exceeded, leading to net excretion of the protein.

Numerous urinary enzymes such as *N*-acetylglucosaminidase, alanine aminopeptidase, alkaline phosphatase, *γ*-glutamyltransferase, pyruvate kinase, glutathione transferase, lysozyme, and pancreatic ribonuclease have been used as diagnostic markers for renal disease. Jung et al.[200] compared the ability of five enzymes (*N*-acetylglucosaminidase, alanine aminopeptidase, alkaline phosphatase, *γ*-glutamyltransferase, and lysozyme) to detect early rejection episodes in kidney

transplant patients. Only *N*-acetylglucosaminidase and alanine aminopeptidase were early predictors of rejection. *N*-acetylglucosaminidase is an enzyme contained within the lysosome of the tubular cell and is released when the lysosome is damaged, whereas alanine aminopeptidase is an enzyme of the brush border. Both markers were increased approximately 2 days earlier than S_{cr} in patients with transplant rejection. Recently, biomarkers associated with fibrosis and collagen degradation in the kidney such as matrix metalloproteinases (ProMMP9), have been shown to be associated with acute allograft rejection, interstitial fibrosis and tubular atrophy.[201]

QUALITATIVE DIAGNOSTIC PROCEDURES

Radiologic Studies

8 The etiology of kidney disease can be evaluated using several qualitative diagnostic techniques, including radiography, ultrasonography, magnetic resonance imaging, and biopsy. The standard radiograph of the kidneys, ureters, and bladder (the KUB) provides a gross estimate of kidney size and identifies the presence of calcifications.[92] Although easy to perform, the value of the information is minimal, and more detailed evaluations are often necessary. The *IV urogram* (formerly known as IV pyelogram) involves the administration of a contrast agent to facilitate visualization of the urinary collecting system. It is primarily used in the assessment of structural changes that may be associated with hematuria, pyuria, or flank pain, resulting from recurrent urinary tract infections, obstruction, or stone formation. For patients with low GFRs, retrograde administration of dye into the ureters may be performed to facilitate visualization of the collecting system. Contrast agents are also employed during renal angiography for the assessment of renovascular disease. The captopril (angiotensin-converting enzyme inhibitor) test is also a useful adjunct. Under conditions of unilateral renal artery stenosis, the affected kidney produces large quantities of angiotensin II, which constricts the efferent arteriole to maintain GFR. The administration of captopril results in reduced uptake of the contrast agent because the efferent arteriole is dilated, thereby decreasing the perfusion pressure of the affected kidney. For patients with bilateral disease, a decrease in uptake is observed in both kidneys.[202] Computed tomography is a cross-sectional anatomic imaging procedure. The procedure is frequently performed with contrast to enhance imaging. Spiral, or helical, computed tomography, a more recent technique, provides for three-dimensional visualization of tissues. Computed tomography is performed as a test for the evaluation of obstructive uropathy, malignancy, and infections of the kidney.

Renal Ultrasonography

Ultrasonography uses sound waves to generate a two-dimensional image. The echogenicity of the kidney is compared with that of an adjacent organ—liver on the right and spleen on the left—with an increased echogenicity indicating an abnormal finding. Ultrasonography can distinguish the renal pyramids, medulla, and cortex, and abnormalities in structure, such as occurs with obstruction. Renal ultrasonography is also used as a guide for site localization during percutaneous kidney biopsy.

Magnetic Resonance Imaging

Magnetic resonance imaging is based on aligning hydrogen nuclei in the body with the use of a powerful magnet and applying radiofrequency pulses. The signals emitted by the hydrogen nuclei during realignment on repeated pulses allows for generation of the tissue image. Realignment times can also be altered with the use of contrast agents (gadolinium, gadopentetate), leading to increased signal intensity and improved imaging. Magnetic resonance imaging is useful for the assessment of obstruction, malignancy, and renovascular lesions. The relative advantages and limitations of these procedures are discussed in more detail in recent reviews.[92,203]

Biopsy

Renal biopsy is used in several conditions to facilitate diagnosis when clinical, laboratory, and imaging findings prove inconclusive. Proteinuria and hematuria are both associated with renal parenchymal disease. When less-invasive studies are unsuccessful in differentiating the cause and the possible causes have different therapeutic approaches, biopsy may be indicated. Functional status of the kidney is not assessed with biopsy, and severity of disease and progression is best measured using quantitative tests discussed above. Contraindications to renal biopsy include a solitary kidney, severe hypertension, bleeding disorder, severe anemia, cystic kidney, and hydronephrosis, among others. Complications resulting from biopsy primarily include hematuria, which may last for several days, and perirenal hematoma.[24]

SUMMARY

Comprehensive approaches to evaluate renal function in CKD patients include the CG equation for estimating CL_{cr} and drug dosing, the creatinine plus cysC CKD-EPI equation for estimation of GFR and staging of CKD, and determination of albumin-to-creatinine ratio as a marker of the integrity of the glomerular basement membrane. Measurement of GFR using exogenous administration of iothalamate, iohexol, or radioisotope techniques such as ^{99m}Tc-DPTA is increasingly being employed to assess progression of disease or acceptability of an individual to be a kidney donor. Other qualitative assessments of kidney function, such as radiography, computed tomography, magnetic resonance imaging, sonography, and biopsy, are most useful to identify the underlying cause of kidney disease.

Chapter 43: Acute Kidney Injury

Jenana Halilovic; William Dager

INTRODUCTION

KEY CONCEPTS

- 1 Three classification systems exist for staging severity of acute kidney injury (AKI): (a) Risk, Injury, Failure, Loss of Kidney Function, and End-Stage Kidney Disease (RIFLE), (b) Acute Kidney Injury Network (AKIN), and (c) Kidney Disease: Improving Global Outcomes (KDIGO) clinical practice guidelines. All three classification systems are based on separate criteria for serum creatinine (S_{cr}) and urine output.

- 2 AKI is a common complication in critically ill patients and is associated with high morbidity and mortality.

- 3 AKI has traditionally been categorized based on three types of injury: (a) prerenal —decreased renal blood flow, (b) intrinsic—structural damage within the kidney, and (c) postrenal—an obstruction within the urine collection system. However, recent advances in early detection of AKI with the availability of novel biomarkers has challenged this traditional classification and instead suggested distinguishing AKI in terms of functional change versus kidney damage.

- 4 Conventional formulas used to estimate glomerular filtration rate (eGFR) and creatinine clearance should not be used to estimate kidney function and adjust medication regimens in AKI patients.

- 5 The most effective prevention strategies for AKI include limiting exposure to nephrotoxic medications and maintaining adequate hydration with isotonic fluids.

- 6 Supportive management remains the primary approach to prevent or reduce complications associated with AKI or comorbid conditions. Supportive therapies include renal replacement therapy (RRT), nutritional support, avoidance of nephrotoxins, and blood pressure and fluid management.

- 7 For patients with prolonged or severe AKI, RRT is the cornerstone of support along with aggressive fluid and electrolyte management.
- 8 Drug dosing for AKI patients receiving continuous renal replacement therapy (CRRT) or sustained low-efficiency dialysis (SLED) is poorly characterized. Dosing requirements of agents primarily eliminated by the kidney may require individualization and require adjustment as renal function declines, and then subsequently increase as AKI resolves. Therapeutic drug monitoring should be utilized whenever possible for any agent with a narrow therapeutic index.
- 9 Diuretic resistance is a common phenomenon in the AKI patient and can be addressed with sodium restriction, combination diuretic therapy, or a continuous infusion of a loop diuretic.

Acute kidney injury (AKI) is a clinical syndrome generally defined by an abrupt reduction in kidney function as evidenced by changes in, serum creatinine (S_{cr}), blood urea nitrogen (BUN), and urine output. The consequences of AKI can be serious, especially in hospitalized patients. Early recognition along with supportive therapy is the focus of management for those with established AKI, as there is no therapy that directly reverses the injury. Individuals at risk, such as those with history of chronic kidney disease (CKD), need to have their hemodynamic status carefully monitored and their exposure to nephrotoxins minimized. A thorough patient assessment including medical and surgical history, medication use, physical examination, and multiple laboratory tests is essential. Management goals include maintenance of blood pressure, fluid, and electrolyte homeostasis, all of which may be dramatically altered in the presence of AKI. Additional therapies designed to eliminate or minimize the insult that precipitated AKI include discontinuation of the offending drug (ie, the nephrotoxin), aggressive hydration, maintenance of renal perfusion, and renal replacement therapy (RRT).

In this chapter, the definition, classification, epidemiology, and common etiologies of AKI are presented. Methods to recognize and assess the extent of kidney function loss are also discussed. Finally, preventive strategies for patients at risk and management approaches for those with established AKI are reviewed.

DEFINITION AND CLASSIFICATION OF ACUTE KIDNEY INJURY

1 Three major classification systems have been developed to define and stage AKI in different patient populations. The *R*isk, *I*njury, *F*ailure, *L*oss of Kidney Function, and *E*nd-Stage Kidney Disease (RIFLE) was published in 2004 and the *A*cute *K*idney *I*njury *N*etwork (AKIN) criteria were developed in 2007.[1,2] **Table 43-1** lists an overview of all classification systems. While generally similar, there are a few noteworthy differences: RIFLE defines AKI as an abrupt (1-7 days) but sustained (more than 24 hours) decrease in renal function from baseline while AKIN designates a 48-hour period for the decrease to occur. Also, AKIN removed RIFLE's last two classification components (Loss of Kidney Function and End-Stage Kidney Disease [ESKD]) from the staging system and instead places all patients receiving RRT automatically into AKIN stage 3. Finally, AKIN removed all estimated glomerular filtration rate (eGFR) criteria from its staging system and lowered the absolute increase in S_{cr} from 0.5 mg/dL (44 µmol/L) designated for the RIFLE-Risk class to 0.3 mg/dL (27 µmol/L) for AKIN

stage 1.[1,2]

TABLE 43-1 RIFLE, AKIN, and KDIGO Classification Schemes for AKI[a]

RIFLE Category	**S_{cr} and GFR[b] Criteria**	**Urine Output Criteria**
Risk	S_{cr} increase to 1.5-fold or GFR decrease >25% from baseline	<0.5 mL/kg/h for ≥6 hours
Injury	S_{cr} increase to twofold or GFR decrease >50% from baseline	<0.5 mL/kg/h for ≥12 hours
Failure	S_{cr} increase to threefold or GFR decrease >75% from baseline, or S_{cr} ≥4 mg/dL (≥354 µmol/L) with an acute increase of at least 0.5 mg/dL (44 µmol/L)	Anuria for ≥12 hours
Loss	Complete loss of function (RRT) for >4 weeks	
ESKD	RRT >3 months	
AKIN Criteria	**S_{cr} Criteria**	**Urine Output Criteria**
Stage 1	S_{cr} increase ≥0.3 mg/dL (≥27 µmol/L) or 1.5- to 2-fold from baseline	<0.5 mL/kg/h for ≥6 hours
Stage 2	S_{cr} increase >2- to 3-fold from baseline	<0.5 mL/kg/h for ≥12 hours
Stage 3	S_{cr} increase >3-fold from baseline, or S_{cr} ≥4 mg/dL (≥354 µmol/L) with an acute increase of at least 0.5 mg/dL (≥44 µmol/L), or need for RRT	<0.3 mL/kg/h for ≥24 hours or anuria for ≥12 hours
KDIGO Criteria	**S_{cr} Criteria**	**Urine Output Criteria**
Stage 1	S_{cr} increase ≥0.3 mg/dL (≥27 µmol/L) or 1.5-1.9 times from baseline	<0.5 mL/kg/h for 6-12 hours
Stage 2	S_{cr} increase 2-2.9 times from baseline	<0.5 mL/kg/h for ≥12 hours
Stage 3	S_{cr} increase three times from baseline, or S_{cr} ≥4 mg/dL (≥354 µmol/L), or need for RRT, or eGFR[c] <35 mL/min/1.73 m^2 (<0.34 mL/s/m^2) in patients <18 years	Anuria for ≥12 hours

AKI, acute kidney injury; AKIN, Acute Kidney Injury Network; ESKD, end-stage kidney disease; eGFR, estimated glomerular filtration rate; h, hours; KDIGO, Kidney Disease: Improving Global Outcomes; RIFLE, Risk, Injury, Failure, Loss of Kidney Function, and End-Stage Kidney Disease; RRT, renal replacement therapy; S_{cr}, serum creatinine.

[a]For all staging systems, the criterion that leads to worst possible diagnosis should be used.

[b]GFR calculated using the Modification of Diet in Renal Disease (MDRD) equation.

[c]GFR calculated using the Schwartz formula.

The Kidney Disease: Improving Global Outcomes (KDIGO) Clinical Practice Guidelines working group in 2012 proposed a staging system that shares many similarities with both RIFLE and AKIN.[3] Their staging system, however, is extended in that it includes pediatric patients (younger than 18 years) in KDIGO Stage 3 for those with an eGFR of less than 35 mL/min/1.73 m^2 (0.34 mL/s/m^2) as determined by the Schwartz formula.[3]

All three staging systems have been validated across different patient populations and their staging correlates closely with hospital mortality, cost, and length of stay. The KDIGO criteria seem to identify more patients with AKI and seem to be slightly more predictive of in-hospital mortality than either RIFLE or AKIN.[4,5,6] However, further studies are needed to definitely determine if one staging system is significantly better than the rest.

Since all three staging systems depend on S_{cr} and urine output as the main diagnostic criteria, they are associated with the same inherent weaknesses. An increase in S_{cr} is usually evident about 1 or 2 days after development of AKI. This lag time in S_{cr} rise may significantly delay diagnosis of AKI and adversely affect patient outcomes. Urine output reduction emerges earlier in AKI but is a very nonspecific marker. In fact, patients with AKI can be anuric (urine output less than 50 mL/day), oliguric (urine output less than 500 mL/day), or nonoliguric (urine output greater than 500 mL/day). Urine output will also vary with volume status, diuretic administration, and presence of obstruction.[7] Further, since all criteria are based on detecting an increase in S_{cr} from its baseline, a patient's renal function prior to the development of AKI needs to be known. If the baseline measure of S_{cr} is not available and the patient has no history of renal dysfunction, the Acute Dialysis Quality Initiative (ADQI), a workgroup composed of experts in nephrology and critical care, has suggested estimating the baseline S_{cr} value by using the four variable Modification of Diet in Renal Disease (MDRD) equation with an assumed normal eGFR of 75 mL/min/1.73 m^2.[1] However, this method needs to be interpreted with caution as it has been found to overestimate the incidence of AKI by as much as 40%.[8,9]

Use of small changes in S_{cr} to diagnose AKI has been associated with additional drawbacks. For example, AKI may be inappropriately diagnosed in patients with low baseline Scr (less than 0.6 mg/dL [53 µmol/L]) when using definitions that incorporate percentage increases from baseline.[4] Also, diagnostic false-positive rates can be as high as because of inherent laboratory and biologic variabilities of creatinine.[10]

EPIDEMIOLOGY

The epidemiology of AKI varies widely depending on the patient population studied and the criteria used to evaluate the patient. While the disorder has a frequency of 2% in hospitalized noncritically ill patients, the prevalence among the critically ill is significantly higher, that is, 60%.[11,12] Common risk factors associated with AKI include the presence of CKD, diabetes, heart or liver disease, albuminuria, major surgery (especially cardiac surgery), acute decompensated heart failure, sepsis, hypotension,

volume depletion (diarrhea, vomiting, or dehydration), medications (exposure to angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers [ARBs], diuretics, aminoglycosides, etc.), advanced age, male gender, and African American race.[3,7,11,13,14,15]

2 Increased mortality and morbidity are two well-recognized complications of AKI. Severity, duration, and frequency of AKI appear to be important predictors of poor patient outcomes. Any degree of AKI is associated with an increased risk of death, and the odds increase with the severity of the insult.[11,13,14] For survivors of AKI, the development of some degree of CKD and need for RRT are other important considerations.[16] In addition, AKI is associated with increased length of hospital stay, cost, readmission, ventilator days, and need for post-hospitalization care.[11,14,17]

ETIOLOGY

3 The etiology of AKI can be divided into three broad categories based on the anatomic location of the injury associated with the precipitating factor(s). The management of patients presenting with this disorder is largely predicated on identification of the specific etiology responsible for the patient's AKI (**Fig. 43-1**). Traditionally, the causes of AKI have been categorized as (a) prerenal, which results from decreased renal perfusion in the setting of undamaged parenchymal tissue, (b) intrinsic, the result of structural damage to the kidney, most commonly the tubule from an ischemic or toxic insult, and (c) postrenal, caused by obstruction of urine flow downstream from the kidney (**Fig. 43-2**).

FIGURE 43-1

Classification of acute kidney injury (AKI) based on etiology. (ACEIs, angiotensin-converting enzyme inhibitors; ARBs, angiotensin receptor blockers; BPH, benign prostatic hyperplasia; HPI, history of present illness; HTN, hypertension; HUS, hemolytic uremic syndrome; NSAIDs, nonsteroidal anti-inflammatory drugs; PMH, past medical history; TTP, thrombotic thrombocytopenic purpura.)

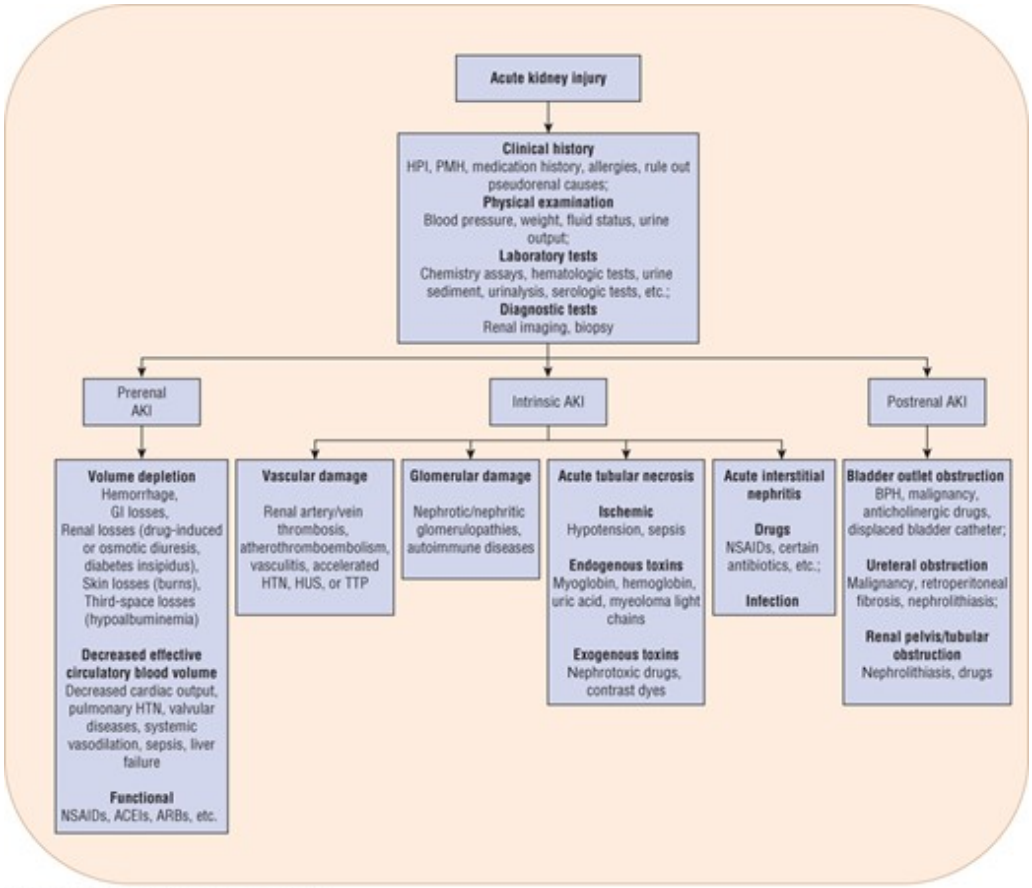

FIGURE 43-2

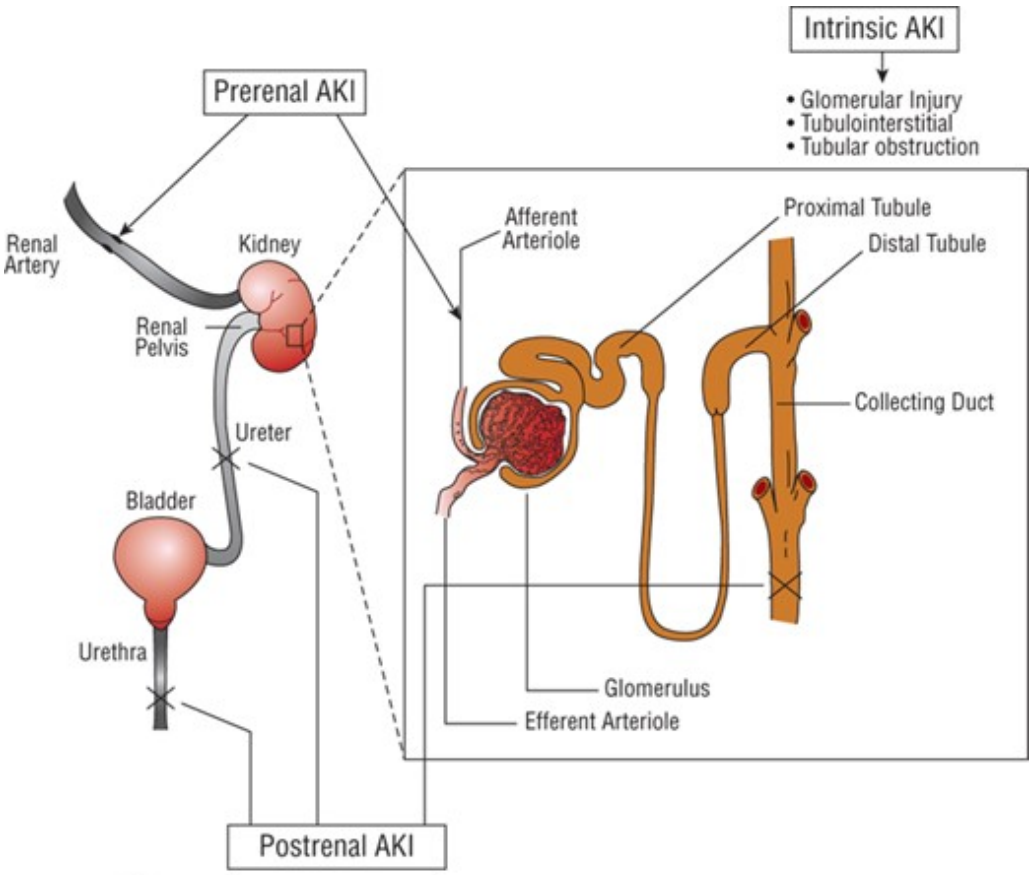
Physiologic classification of acute kidney injury (AKI). Blood flows through the afferent arteriole, to the glomerulus, and exits through the efferent arteriole. A decrease in blood flow and renal perfusion can lead to a prerenal reduction in renal function. Under conditions in which renal blood flow is diminished, the kidney maintains glomerular ultrafiltration by vasodilating the afferent arterioles and vasoconstricting the efferent arterioles. Medications that may interfere with these processes may result in an abrupt decline in glomerular filtration. Damage to the glomerular or tubular regions leads to intrinsic AKI. Obstruction of urine flow in the collecting tubule, ureter, bladder, or urethra is termed postrenal impairment.



The risk of AKI increases substantially with decreasing glomerular filtration rate (GFR) and presence of albuminuria and underlying CKD.[15,18] A history of AKI has also been associated with high risk for developing additional episodes of AKI and subsequent complications such as advanced CKD.[19]

PATHOPHYSIOLOGY

The pathophysiologic processes involved in the development of the three traditional categories of AKI: prerenal AKI, intrinsic AKI, and postrenal AKI are described below. Pseudorenal kidney injury does not represent a true pathophysiologic process since it is associated with an alteration in laboratory measurement accuracy.

Pseudorenal Acute Kidney Injury

Pseudorenal AKI is characterized by a rise in either the BUN or the S_{cr}, which misleadingly may suggest the presence of renal dysfunction, when in fact GFR is not diminished. This could be the result of cross-reactivity of drugs or endogenous substances with the assay used to measure the BUN or S_{cr} or selective inhibition of the secretion of creatinine into the proximal tubular lumen by certain medications (see Chapter 42). A similar problem exists when urine output data are unreliable. Urine output may be either inaccurate (particularly in noncatheterized patients) or not reported at all. Since the urine output criteria for AKI staging are weight-based, some obese individuals may meet the

definition of AKI without truly having any kidney impairment. Thus, clinical judgment should always be applied when interpreting laboratory results.

Prerenal Acute Kidney Injury

Prerenal AKI or prerenal azotemia results from hypoperfusion of the renal parenchyma, with or without systemic arterial hypotension. Renal hypoperfusion with systemic arterial hypotension may be caused by a decline in either the intravascular volume or the effective circulating blood volume. Intravascular volume depletion may result from several conditions, including hemorrhage, excessive gastrointestinal (GI) losses (severe vomiting or diarrhea), dehydration, extensive burns, and diuretic therapy. Effective circulating blood volume may be reduced in conditions associated with a decreased cardiac output and systemic vasodilation. Renal hypoperfusion without systemic hypotension is most commonly associated with bilateral renal artery occlusion or unilateral occlusion in a patient with a single functioning kidney.

Patients with a mild reduction in effective circulating blood volume or volume depletion are generally able to maintain a normal GFR by activating several compensatory mechanisms. Those initial physiologic responses by the body stimulate the sympathetic nervous and the renin–angiotensin–aldosterone system and release antidiuretic hormone if hypotension is present. These responses work together to directly maintain blood pressure via vasoconstriction and stimulation of thirst, which in conscious patients results in increased fluid intake, as well as sodium and water retention. Additionally, GFR may be maintained by afferent arteriole dilation (mediated by intrarenal production of vasodilatory prostaglandins, kallikrein, kinins, and nitric oxide) and efferent arteriole constriction (mainly mediated by angiotensin II). In concert, these homeostatic mechanisms are often able to maintain arterial pressure and renal perfusion, potentially averting the progression to AKI.[20] If, however, the decreased renal perfusion is severe or prolonged, these compensatory mechanisms may be overwhelmed, and prerenal AKI will be clinically evident.

Patients at risk for prerenal AKI are particularly susceptible to changes in the afferent and efferent arteriolar tone, as they may not be able to compensate as readily. Some drugs interfere with these renal adaptive responses, and the resulting reduction in the glomerular hydrostatic pressure precipitates an abrupt decline in GFR and is sometimes referred to as *functional AKI*. A common cause of this syndrome is a decrease in efferent arteriolar resistance as the result of initiation of an ACE inhibitor or ARB (see Chapter 46). For example, individuals with heart failure are often given an ACE inhibitor or ARB to help improve left ventricular function, but if the dose is titrated too rapidly, they may experience a decline in GFR. If the increase in the S_{cr} is less than 30% from baseline and potassium serum levels are within normal range, the medication can generally be continued. Nonsteroidal anti-inflammatory drugs (NSAIDs) may also initiate AKI in susceptible individuals due to their impact on renal prostaglandin production and afferent arteriolar vasodilation, which some patients rely on to maintain GFR.[21,22]

Sepsis is one of the leading clinical conditions associated with AKI. The traditional presumption that decreased renal hypoperfusion was responsible for reduced GFR has recently been questioned as new evidence indicates that there is little association between renal blood flow and GFR in patients

with sepsis-induced AKI.[23] Instead, a complex interplay of different mechanisms may be involved in its pathogenesis; augmented vasoconstriction, capillary occlusion due to endothelial cell swelling, interaction of endothelial cells with leukocytes, and activation of coagulation. Simultaneously occurring renal inflammation and microcirculatory dysfunction further amplify these mechanisms. Recent studies have also found that apoptosis and tubular cell necrosis are rare during sepsis-induced AKI.[24,25,26] Instead, tubular epithelial cells develop adaptive responses, specifically downregulation of the cell function, in order to minimize energy demand and to ensure cell survival. This process also simultaneously results in reduced kidney function.

Intrinsic Acute Kidney Injury

Intrinsic AKI results from direct damage to the kidney and is categorized on the basis of the injured structures within the kidney: vasculature, glomeruli, tubules, and interstitium.

Renal Vasculature Damage

Occlusion of the larger renal vessels resulting in AKI is not common but can occur if large atheroemboli or thromboemboli occlude the bilateral renal arteries or one vessel of the patient with a single kidney. Atheroemboli most commonly develop during vascular procedures that cause atheroma dislodgement, such as angioplasty and aortic manipulations. Thromboemboli may arise from dislodgement of a mural thrombus in the left ventricle of a patient with severe heart failure or from the atria of a patient with atrial fibrillation. Renal artery thrombosis may occur in a similar fashion to coronary thrombosis, in which a thrombus forms in conjunction with an atherosclerotic plaque.

Although smaller vessels can also be obstructed by atheroemboli or thromboemboli, the damage is limited and the development of significant AKI is unlikely. However, these small vessels are susceptible to inflammatory processes that lead to microvascular damage and vessel dysfunction when the renal capillaries are affected. Neutrophils invade the vessel wall, causing damage that can include thrombus formation, tissue infarction, and collagen deposition within the vessel structure. Diffuse renal vasculitis can be severe and promote concomitant ischemic acute tubular necrosis (ATN). Untreated hypertension may also compromise renal microvascular blood flow, causing diffuse renal capillary damage.

Glomerular Damage

Only 5% of the cases of intrinsic AKI are of glomerular origin. The glomerulus is one of two capillary beds in the kidney. It serves to filter fluid and solute into the tubules while retaining proteins and other large blood components in the intravascular space. Because the glomerulus is a capillary system, similar damage in the renal vasculature as described above can occur by the same mechanisms. The pathophysiology and specific therapeutic approaches to glomerulonephritis are described in detail in Chapter 47.

Tubular Damage

Approximately 85% of all cases of intrinsic AKI are caused by ATN, of which 50% are a result of renal ischemia. The remaining 35% are the result of exposure to direct tubule toxins, which can be endogenous (myoglobin, hemoglobin, or uric acid) or exogenous (contrast agents, aminoglycosides, etc.) The tubules located within the medulla of the kidney are particularly at risk for ischemic injury, as this portion of the kidney is metabolically active and thus has high oxygen requirements, yet, as compared with the cortex, receives relatively low oxygen delivery. Thus, ischemic conditions caused by severe hypotension or exposure to vasoconstrictive drugs preferentially affect the tubules more than any other portion of the kidney.

The clinical evolution of ATN is characterized by four distinct phases: initiation, extension, maintenance, and recovery. Renal tubular epithelial cell injury is the hallmark of the initiation phase that results from vasoconstriction and ischemia, and leads to GFR reduction. Contrary to its name, ATN is not only characterized by necrosis and cell death but by a large spectrum of cellular injury that usually involves sublethal damage to the cells. The extent of injury depends not only on the severity and duration of ischemia but also on the sensitivity of renal cells to the insult which may vary based on the cells' metabolic demands, physical location within the kidney, degree of regional blood perfusion, oxygenation status, and membrane permeability. Further, alterations in cytoskeletal structure lead to a loss of epithelial polarity and barrier function. As a result, the glomerular filtrate starts leaking back into the interstitium and is reabsorbed into the systemic circulation. Additionally, urine flow is obstructed by accumulation of sloughed epithelial cells, cellular debris, and formation of casts.[27]

The extension phase is characterized by continued hypoxia following the initial ischemic event and an inflammatory response. Both events are more pronounced in the outer medullary region and the GFR continues to decrease. During the maintenance phase, GFR reaches a nadir during which cellular repair processes are initiated in an attempt to reestablish and maintain cellular and tubular integrity. The surviving cells undergo repair, migration, dedifferentiation, and proliferation. The maintenance phase is eventually followed by a recovery phase, during which new tubule cells are regenerated through redifferentiation and epithelial polarity is reestablished.[27]

Interstitial Damage

Acute interstitial nephritis (AIN) is an idiosyncratic delayed hypersensitivity immune reaction that is most commonly caused by drugs (see Chapter 46) and less commonly by infections, autoimmune diseases, or idiopathic causes. AIN is characterized by tubular and interstitial inflammation, and edema with lesions composed of mononuclear cells, with a predominance of lymphocytes (primarily CD4+ T lymphocytes) and monocytes or macrophages. The specific pathogenic process depends on the cause of AIN. Drug-induced disease is characterized by renal interstitial dendritic and renal tubular epithelial cells recognition of the offending agent as immunogenic and their activation of T lymphocytes which induce proinflammatory molecules. Once acute interstitial inflammation sets in, it can progress very rapidly to a more destructive fibrogenic process marked by increased interstitial matrix, ischemia, tubular atrophy, and interstitial fibrosis.[28] The prognosis of AIN varies widely as it is estimated that anywhere between 30% and 70% of patients may not recover their baseline renal function.[29] Patients who are at higher risk for permanent damage include elderly or those who

develop more severe disease including azotemia, oliguria, or need for dialysis.[30] Delays in discontinuation of the offending drug and in initiating steroid treatment can also adversely affect recovery of kidney function.[31]

Postrenal Acute Kidney Injury

Postrenal AKI accounts for less than 5% of all cases of AKI and may develop as the result of obstruction at any level within the urinary collection system (see Fig. 43-1). However, if the obstructing process is above the bladder, it must involve both kidneys (one kidney in a patient with a single functioning kidney) to cause clinically significant AKI, as one functioning kidney can generally maintain a near-normal GFR. Bladder outlet obstruction, the most common cause of obstructive nephropathy, is often the result of a prostatic process (hypertrophy, cancer, or infection), producing a physical impingement on the urethra and thereby preventing the passage of urine. It may also be the result of an improperly placed urinary catheter. Blockage may also occur at the ureter level secondary to nephrolithiasis, blood clots, sloughed renal papillae, or physical compression by an abdominal process. Crystal deposition within the tubules from oxalate and some medications severe enough to cause AKI is uncommon, but it is possible in patients with severe volume contraction and in those receiving large doses of a drug with relatively low urine solubility (see Chapter 46). In these cases, patients have insufficient urine volume to prevent crystal precipitation in the urine. Extremely elevated uric acid concentrations from chemotherapy-induced tumor lysis syndrome can cause obstruction and direct tubular injury as well.[32] Where ever the location of the obstruction, urine will accumulate in the renal structures above the obstruction and cause increased pressure upstream. The ureters, renal pelvis, and calyces all expand, and the net result is a decline in GFR. If renal vasoconstriction ensues, a further decrement in GFR will be observed.

CLINICAL PRESENTATION

The initiating signs or symptoms of AKI are highly variable and largely dependent on the underlying etiology. It may be a change in urinary character (eg, decreased urine output or urine discoloration), sudden weight gain, or severe abdominal or flank pain. Early recognition and cause identification are critical, as they directly affect the outcome of AKI. One of the first steps in the diagnostic process is to determine if the change in renal function is acute, chronic, or the result of an acute change in a patient with known CKD (also called acute-on-chronic renal failure). Patients should also be promptly evaluated for any changes in their fluid and electrolyte status. Patients presenting with AKI in the outpatient environment may have very nonspecific or seemingly unrelated symptoms so that the time of onset of the injury can be difficult to determine. On the other hand, AKI in hospitalized patients is often detected much earlier in its course due to frequent laboratory studies and daily patient assessment.

Patient Assessment

The assessment of a patient with AKI starts with a thorough review of his or her medical records, with a particular focus on chronic conditions, laboratory studies, procedures, and surgeries. An exhaustive

review of prescription and nonprescription medicines, herbal products, and recreational drugs may help determine if AKI was potentially precipitated by drug ingestion.

During the initial patient evaluation, presumptive signs and symptoms of AKI need to be differentiated from a potential new diagnosis of CKD. A medical history for renal disease–related chronic conditions (eg, poorly controlled hypertension or diabetes mellitus), previous laboratory data documenting the presence of proteinuria or an elevated S_{cr}, and the finding of bilateral small kidneys on renal ultrasonography suggest the presence of CKD rather than AKI. However, it is important to note that patients with CKD may develop episodes of AKI as well. In that case, an abrupt rise in the patient's baseline S_{cr} is one of the most useful indicators of the presence of an acute insult to the kidneys. The staging of AKI should also be assessed including the initial insult and decline in renal function, stabilization of the decline in function, and recovery period.

An acute change in urinary habitus is another common and noticeable symptom associated with AKI. The presence of cola-colored urine is indicative of blood in the urine, a finding commonly associated with acute glomerulonephritis. In hospitalized patients, changes in urine output may be helpful in characterizing the cause of the patient's AKI. Acute anuria is typically caused by either complete urinary obstruction or a catastrophic event (eg, shock or acute cortical necrosis). Oliguria, which often develops over several days, suggests prerenal azotemia, whereas nonoliguric renal failure usually results from acute intrinsic renal failure or incomplete urinary obstruction.

Depending on the underlying cause of AKI, patients may present with a variety of symptoms affecting virtually any organ system of the body. Constitutional symptoms such as nausea, vomiting, fatigue, malaise, and weight gain are common but nonspecific. The onset of flank pain is suggestive of a urinary stone; however, if bilateral, it may suggest swelling of the kidneys secondary to acute glomerulonephritis or AIN. Complaints of severe headaches may suggest the presence of severe hypertension and vascular damage. The presence of fever, rash, and arthralgia may be indicative of drug-induced AIN or lupus nephritis.

A thorough physical examination is an important step in evaluating individuals with AKI, as clues regarding the etiology can be evident from the patient's head (eye examination) to toe (evidence of dependent edema) assessment. Evaluation of the patient's volume and hemodynamic status is critical as well, as it will guide management. For example, patients with prerenal AKI can present with either volume depletion or fluid overload. Volume depletion may be evidenced by the presence of postural hypotension, decreased jugular venous pressure (JVP), and dry mucous membranes. Fluid overload, on the other hand, is often reflected by elevated JVP, pitting edema, ascites, and pulmonary crackles.

Conventional Markers of Kidney Function

4 Commonly available laboratory tests used to evaluate the patient with renal insufficiency are described in Chapter e42. Over the past four decades, S_{cr} has been the most widely used laboratory test for estimating creatinine clearance (eCL_{cr}) and eGFR. However, there are several limitations associated with its use since it is affected by age, gender, muscle mass, diet, and hydration status. For example, patients with reduced creatinine production, such as those with low muscle mass, may have

very low values (less than 0.6 mg/dL [53 µmol/L]); thus, the presence of a gradual rise to normal values (0.8-1.2 mg/dL [71-106 µmol/L]) may actually suggest the presence of AKI. However, in the presence of improved nutrition and a large muscle mass, a S_{cr} of 1.2 mg/dL (106 µmol/L) may be a true representation of a person's current renal status. Instead of using only the most current value to determine renal function, changes in the value from a patient's baseline need to be considered. S_{cr} is normally inversely proportional to GFR. However, rapid changes in GFR disrupt this equilibrium and make S_{cr} a very insensitive marker. In fact, changes in S_{cr} will lag behind the GFR's decline by 1 to 2 days due to slow accumulation, increased tubular secretion, and increased extrarenal clearance.[33,34] This can lead to a significant overestimation of the patient's GFR in the early stages of AKI and consequently a potential delay in the diagnosis of the syndrome.

An example of this phenomenon is illustrated by an acute renal artery thrombus that results in abrupt cessation of GFR in one kidney as a consequence of the complete obstruction of blood flow to that kidney. Although 5 minutes following the event GFR is decreased 50% (assuming the other kidney is functioning and unaffected), the S_{cr} remains unchanged. Assuming a standard daily creatinine production of about 20 mg/kg of lean body weight, one can expect about 1.4 g of creatinine production in a 24-hour period in a 70-kg individual. In pharmacokinetic terms, daily creatinine production is analogous to a continuous infusion, and GFR determines the elimination rate of creatinine. In a patient with normal renal function (GFR of 120 mL/min [2 mL/s]), the half-life of creatinine is 3.5 hours, with 95% of steady state achieved in about 14 hours. If GFR declines to 50%, 25%, or 10% of normal, the half-life of creatinine increases, resulting in prolongation of the time to reach 95% of steady state, specifically taking 1, 2, and 4 days, respectively.

Because S_{cr} steady-state values are assumed when one uses several GFR calculation methods, such as the Cockcroft-Gault, MDRD, and Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equations, they should not be used to estimate GFR in AKI patients with unstable renal function. These equations will typically overestimate GFR when the AKI is worsening and underestimate it when the AKI is resolving. Instead, it may be useful to evaluate changes in S_{cr} values from the patient's baseline and also consider the S_{cr} sequence values to determine if renal function is potentially improving or worsening. The most recent S_{cr} reflects the time-averaged kidney function over the preceding time period. Several mathematical approaches to estimate GFR in patients with unstable S_{cr} that incorporate the principles of creatinine accumulation and elimination have been proposed and are discussed in detail in Chapter e42. However, these methods have not been extensively validated in the setting of AKI, and their value for adjusting medication dosing is questionable. Additionally, these equations are complex and are not commonly used in the clinical setting.

Two other widely available markers of renal function are BUN and urine output. The value of the BUN in AKI is very limited because urea production and renal clearance are heavily influenced by extrarenal factors such as critical illness, volume status, protein intake, and medications. Urine output measured over a specified period of time (eg, 4-24 hours) allows for short-term assessment of kidney function, but its utility is limited to cases in which it is significantly decreased. The presence of anuria suggests complete kidney failure, whereas oliguria indicates some degree of kidney damage. Urine output needs to be interpreted with caution, as it is dependent on several factors, such as hydration

status and medications. As mentioned earlier in the chapter, a patient may have AKI and still maintain a normal urine output; this condition is referred to as *nonoliguric AKI*. Another approach to estimating renal function is to directly measure CL_{cr} over a short period of time, for example, 4 to 12 hours.[35] Although, potentially precise and fairly simple to do, its accuracy is questionable if the urine output is low or the urine collection is incomplete.

In addition to BUN and S_{cr}, selected blood and urine tests, and urinary sediment are routinely evaluated to differentiate the cause of AKI and guide patient management. For example, a complete blood cell count with differential can help rule out infectious causes of AKI. Serum electrolyte values may be abnormal because of the acute decline of the kidney's ability to regulate electrolyte excretion. Particular attention should be paid to serum potassium and phosphorus values, which can be markedly elevated and cause life-threatening complications. In individuals with normal renal function, the ratio between BUN and S_{cr} is usually less than 15:1 using conventional units (~60:1 using SI units). In the presence of prerenal AKI, reabsorption of BUN exceeds that of creatinine; thus, one often sees a ratio greater than 20:1 (greater than 100:1 for urea to creatinine ratio is commonly used when using parameters expressed in identical molar units).

Given the limited usefulness of solely using S_{cr} or BUN concentrations to differentiate the etiology of AKI, urinary electrolytes and osmolality should be determined, and both a microscopic and chemical analysis of the urine should be performed (**Table 43-2**). The finding of a high urinary specific gravity, in the absence of glucosuria or mannitol administration, suggests an intact urinary concentrating mechanism and that the cause of the patient's AKI is likely prerenal azotemia. The presence of urinary protein is often difficult to interpret, especially in the setting of acute or chronic renal failure. A patient with CKD may have a baseline proteinuria, thus clouding the clinical presentation, unless this is known at the time of AKI assessment. Classically, proteinuria is a hallmark of glomerular damage. However, tubular damage can also result in proteinuria, as the tubules are responsible for reabsorbing small proteins that are normally filtered by all glomeruli. The presence of blood also results in a positive urine protein test, so this confounder must always be assessed when a positive urine protein is obtained. Hematuria suggests acute intrinsic AKI secondary to glomerular injury, infection, or a kidney stone. On microscopic examination, the key findings are cells, casts, and crystals, and the presence of one or more of these may suggest specific etiologies of the AKI (**Table 43-3**). The finding of urinary crystals may indicate nephrolithiasis and a postrenal obstruction. If red blood cells or red blood cell casts are present, one should consider the presence of a physical injury to the glomerulus, renal parenchyma, or vascular beds. The finding of white blood cells or white blood cell casts suggests interstitial inflammation (ie, interstitial nephritis), which can be secondary to an allergic, granulomatous, or infectious process.

TABLE 43-2 Diagnostic Parameters for Differentiating Causes of AKI[a]

Laboratory Test	Prerenal AKI	Intrinsic AKI	Postrenal AKI
Urine sediment	Hyaline casts, may be normal	Granular casts, cellular debris	Cellular debris
Urinary RBC	None	2–4+	Variable

Laboratory Test	Prerenal AKI	Intrinsic AKI	Postrenal AKI
Urinary WBC	None	2–4+	1+
Urine Na (mEq/L or mmol/L)	<20	>40	>40
FE_{Na} (%)	<1	>2	Variable
Urine/serum osmolality	>1.5	<1.3	<1.5
Urine/S_{cr}	>40:1	<20:1	<20:1
BUN/S_{cr} (urea/S_{cr}, SI)	>20 (>100)	~15 (~60)	~15 (~60)
Urine specific gravity	>1.018	<1.012	Variable

AKI, acute kidney injury; BUN, blood urea nitrogen; FE_{Na}, fractional excretion of sodium; S_{cr}, serum creatinine; RBC, red blood cell; WBC, white blood cell.

[a]Common laboratory tests are used to classify the cause of AKI. Functional AKI, which is not included in this table, would have laboratory values similar to those seen in prerenal AKI. However, the urine osmolality-to-plasma osmolality ratios may not exceed 1.5, depending on the circulating levels of antidiuretic hormone. The laboratory results listed under intrinsic AKI are those seen in acute tubular necrosis, the most common cause of intrinsic AKI.

TABLE 43-3 Urinary Findings as a Guide to the Etiology of AKI

Type of Urinary Evaluation	Presence of	Suggestive of
Urinalysis	Leukocyte esterases	Pyelonephritis
	Nitrites	Pyelonephritis
	Protein	
	Mild (<0.5 g/day)	Tubular damage
	Moderate (0.5-3 g/day)	Glomerulonephritis, pyelonephritis, tubular damage
	Large (>3 g/day)	Glomerulonephritis, nephrotic syndrome
	Hemoglobin	Glomerulonephritis, pyelonephritis, renal infarction, renal tumors, kidney stones
	Myoglobin	Rhabdomyolysis-associated tubular necrosis
	Urobilinogen	Hemolysis-associated tubular necrosis
Urine sediment	Microorganisms	Pyelonephritis
	Red blood cells	Glomerulonephritis, pyelonephritis, renal infarction, papillary necrosis, renal tumors, kidney stones
Cells	White blood cells	Pyelonephritis, interstitial nephritis
	Eosinophils	Drug-induced interstitial nephritis, renal transplant rejection

Type of Urinary Evaluation	Presence of	Suggestive of
Casts	Epithelial cells	Tubular necrosis
	Granular casts	Tubular necrosis
	Hyaline casts	Prerenal azotemia
	White blood cell casts	Pyelonephritis, interstitial nephritis
	Red blood cell casts	Glomerulonephritis, renal infarct, lupus nephritis, vasculitis
Crystals	Urate	Postrenal obstruction
	Calcium phosphate	Postrenal obstruction

AKI, acute kidney injury.

Simultaneous measurement of urine and serum electrolytes is also helpful in the setting of AKI (see Table 43-2). From these values, a fractional excretion of sodium (FE_{Na}) can be calculated. The equation for the calculation of the FE_{Na} is as follows:

$$FE_{Na} = \frac{\text{Excreted Na}}{\text{Filtered Na}} \times 100 = \frac{U_{vol} \times U_{Na}}{GFR \times S_{Na}} \times 100$$

where

$$GFR = \frac{U_{vol} \times U_{cr}}{S_{cr} \times t}$$

Thus:

$$FE_{Na} = \frac{U_{Na} \times S_{cr} \times 100}{U_{cr} \times S_{Na}}$$

where U_{vol} is urine volume; U_{cr} is urine creatinine concentration; U_{Na} is urine sodium; S_{cr} is serum creatinine concentration; S_{Na} is serum sodium concentration, which usually does not vary much; GFR is the glomerular filtration rate; and *t* is the time period over which the urine is collected.

The FE_{Na} is one of the better diagnostic parameters to differentiate the cause of AKI. A low urinary sodium concentration (less than 20 mEq/L [mmol/L]) and low FE_{Na} (less than 1%) in a patient with oliguria suggest that there is stimulation of the sodium-retentive mechanisms in the kidney and that tubular function is intact. These findings are most characteristic of prerenal azotemia. Unfortunately, diuretic use in the preceding days limits the usefulness of the FE_{Na} calculation by increasing natriuresis, even in hypovolemic patients. The fractional excretion of urea (FE_{Urea}), which can be calculated like FE_{Na}, is sometimes used as an alternative means to assess tubular function. The inability to concentrate urine results in a high FE_{Na} (greater than 2%), suggesting tubular damage as the primary cause of the intrinsic AKI. However, this is also not an absolute finding, as there are some intrinsic causes that can be associated with a low FE_{Na} (eg, contrast nephropathy, myoglobinuria, and interstitial nephritis). Highly concentrated urine (greater than 500 mOsm/kg [500 mmol/kg]) suggests

stimulation of antidiuretic hormone and intact tubular function. These findings are consistent with prerenal azotemia.

Novel Biomarkers of Kidney Damage

A variety of biomarkers have been investigated to detect and predict the clinical outcomes of AKI. While they vary in their origin, function, distribution, and time of release following renal injury, the large majority are molecules that are released as a result of direct kidney cell damage. The performance of most biomarkers is variable and depends on the patient population, cause of AKI, presence of comorbidities, and timing of biomarker measurements. In general, their ability to detect AKI is significantly better within homogenous patient populations where the time of AKI is known than in heterogeneous populations with multiple comorbidities and unknown AKI time or cause such as critically ill patients. Even though some biomarker tests are now commercially available, these tests are not routinely available at most clinical practice sites. Lastly, there is still a barrier for clinical translation since there are little data available on the impact of the biomarker information on clinical decision making.[33,36]

Two of the most promising biomarkers studied in AKI are tissue inhibitor of metalloproteinases 2 (TIMP-2) and insulin-like growth factor binding protein 7 (IGFBP7). Both molecules inhibit specific proteins that result in G1 cell cycle arrest noted to occur during the very early phases of cellular stress or injury. The cell uses cell-cycle arrest as a protective mechanism to avoid cell division when potentially damaged. However, if the cells do not re-initiate the cell cycle and remain arrested, a fibrotic phenotype can develop instead. These findings are of importance as cell cycle arrest activation and deactivation may prove to be potential targets of therapeutic interventions in the future.[37] At this time, TIMP-2 and IGFBP7 have been validated in critically ill patients and noted to outperformed other biomarkers. In 2014, the combination of TIMP-2 and IGFBP7 was approved by the Food and Drug Administration (FDA) as the first point-of-care device to detect early AKI. The test called Nephrocheck® uses a fluorescent immunoassay and reveals test results expressed as an AKI risk score within 20 minutes. Scores over 0.3 $(ng/mL)^2/1,000$ indicate a patient is at greater risk for developing moderate to severe AKI within 12 hours of testing.[37] While TIMP-2 and IGFBP7 appear to be promising biomarkers, the cutoff value of 0.3 has a sensitivity of 92% but a specificity of only 46%.[38] In addition, the test's superior performance in critically ill patients was not reproducible in cardiac surgery patients raising the question of test's utility in various patient settings.[39]

One of the most studied biomarkers is neutrophil gelatinase–associated lipocalin (NGAL), a transporter protein found on cell surfaces of neutrophils and various epithelial cells. It is freely filtered by the glomeruli and reabsorbed by the proximal tubules. As a result, if proximal tubular injury occurs, urinary NGAL levels are expected to rise. Studies indicate that NGAL may be a valuable biomarker of AKI development across a range of clinical settings, including both children and adults, patients with contrast-induced nephropathy (CIN), critically ill, and cardiac surgery patients.[40] Also, the availability of commercial assays for both urine and serum NGAL may facilitate the use of this biomarker in multiple clinical settings. While NGAL has demonstrated promising results for the early recognition of AKI, it does have several limitations. Some comorbidities, especially CKD, may affect its

results since CKD is associated with elevated serum and urinary NGAL levels. Also, NGAL synthesis increases in response to inflammatory triggers irrespective of the presence of AKI. Lastly, it was recently discovered that the total concentration of urinary NGAL represents a mixture of different molecular forms of NGAL with different cellular origins (renal tissue, neutrophils, and extrarenal tissue such as liver and lung), and the current assays are unable to distinguish the NGAL dimer that is specifically produced by the stressed renal tubular cells.[41]

The advances in our knowledge of AKI pathophysiology as well as the advent of biomarkers has prompted ADQI to propose the use of two new terms "functional change" and "kidney damage" instead of the traditional "prerenal, intrinsic, and postrenal" AKI definitions. Functional change refers to changes in glomerular and tubular function and includes markers such as S_{cr}, eGFR, and cystatin C. Kidney damage describes presence of tubular and/or glomerular injury and includes markers such as NGAL, TIMP-2, and IGFBP7. The rationale behind the proposed changes in terminology stems from a relatively new concept of subclinical kidney injury. According to this theory, kidney injury may be detected by changes in the plasma or urinary levels of specific biomarkers before overt changes in renal function (decreased eGFR or increased S_{cr}) have occurred. As a result, a patient may have kidney damage without a change in kidney function. These findings are significant because this patient group is at a greater risk of complications, a longer stay in intensive care unit, and has a higher risk of dying when compared with the group without kidney damage. **Table 43-4** summarizes the relationship between functional change and kidney damage.[42,43]

TABLE 43-4 Newly Proposed Classification of AKI Based on Functional and Kidney Damage Biomarkers

		Kidney Damage	
		No	**Yes**
Functional change	**No**	No functional change or damage; Biomarker negative RIFLE negative	Kidney damage without change in function Biomarker positive RIFLE negative
	Yes	Functional change but no kidney damage RIFLE positive Biomarker negative	Kidney damage with functional change RIFLE positive Biomarker positive

AKI, acute kidney injury; RIFLE, risk, injury failure, loss of function, and end stage renal disease.

Diagnostic Considerations

When the source of renal injury is unclear after a history, physical examination, and assessment of laboratory values, imaging techniques such as abdominal radiography, including the kidneys, ureters, and bladder (KUB), computed tomography (CT), and ultrasonography may be helpful. These may

reveal small, shrunken kidneys indicative of CKD. Postrenal obstruction can often be identified with a renal ultrasonography and/or CT scan. Renal ultrasonography is also useful in detecting obstruction or hydronephrosis. Nephrolithiasis as small as 5 nm or a narrowing of the ureteral tract can be detected by ultrasonography or more sensitive tests, such as KUB and CT.

In cases in which the cause of AKI is not evident, renal biopsies are useful in determining the cause in most patients. Because of the associated risk of bleeding, a renal biopsy is rarely undertaken and should only be performed in those circumstances when a definitive diagnosis is needed to guide therapy, such as the precise etiology of glomerulonephritis (see Chapter 47).

PREVENTION OF ACUTE KIDNEY INJURY

Prevention of AKI is critical since there is no treatment to reverse the insult once it has developed. The risk of AKI can be reduced when the nonpharmacologic and pharmacologic therapies described below are used.

Desired Outcomes

The goals of AKI prevention are to (a) screen and identify patients at risk, (b) monitor high-risk patients until the risk has subsided, and (c) implement prevention strategies when appropriate.

General Approach to Prevention

5 The choice of preventive strategy depends on the cause of the renal insult. Clearly, avoidance of all potential causes of AKI is the most effective preventive method; however, it may not always be possible. Sometimes, the risk of renal injury is predictable, such as decreased perfusion secondary to coronary bypass surgery or secondary to the administration of a radiocontrast dye. In these situations, the potential insult to the kidneys cannot be avoided but may be preventable or minimized with aggressive hydration and avoidance or removal of any additional insults. In the outpatient setting, all healthcare professionals should educate the patient on preventive measures for AKI. Patients should receive counseling regarding their optimal daily fluid intake (~2 L/day) to avoid dehydration, especially if they are to receive a potentially nephrotoxic medication. In the inpatient setting, adequate hydration, standardized hemodynamic support in the critically ill, and avoidance of nephrotoxic medications are commonly recommended strategies for the prevention of AKI. **Table 43-5** summarizes the recommendations published by KDIGO regarding recommended and not recommended therapies for the prevention of AKI.[3]

TABLE 43-5 KDIGO Recommendations for Prevention and Treatment of AKI

Drug	Indication	Recommended for Prevention	Recommended for Treatment	Comments
ANP	AKI	No (2C)	No (2B)	
Diuretics	AKI	No (1B)	No (2C)	Acceptable if managing concurrent fluid overload

Drug	Indication	Recommended for Prevention	Recommended for Treatment	Comments
Dopamine (1-3 μg/kg/min)	AKI	No (1A)	No (1A)	
Fenoldopam	AKI	No (2C)	No (2C)	
	CI-AKI	No (1B)		
Isotonic saline IV	AKI	Yes (2B)	Yes (2B)	For AKI: recommended in the absence of hemorrhagic shock
	CI-AKI	Yes (1A)		
NAC	AKI	No (2D)		For CI-AKI: give in combination with isotonic saline
	CI-AKI	Yes (2D)		
RRT	AKI	No (2C)	Yes (NG)	
	CI-AKI			
Sodium bicarbonate IV	CI-AKI	Yes (1A)		
Theophylline	CI-AKI	No (2C)		
Vasopressors	AKI	Yes (1C)	Yes (1C)	Recommended in combination with fluids in vasomotor shock

AKI, acute kidney injury; ANP, atrial natriuretic peptide; CI-AKI, contrast-induced acute kidney injury; KDIGO, Kidney Disease: Improving Global Outcomes; NAC, *N*-acetylcysteine; RRT, renal replacement therapy.

Strength of recommendation levels: 1, recommended; 2, suggested; NG, not graded.

Quality of supporting evidence: A, high; B, moderate; C, low; D, very low.

Nonpharmacologic Therapy

Hydration is one of the primary interventions that has consistently shown benefit and is routinely used in the prevention of AKI. Fluids have largely been studied in association with hemodynamic instability secondary to intravascular volume depletion as well as contrast administration before a radiologic procedure.

Hemodynamic instability increases the risk of AKI as it can lead to decreased renal perfusion and subsequent renal injury. Both isotonic crystalloids and colloid-containing solutions have been studied as means to replace intravascular volume. Among colloids, synthetic products such as hyperoncotic hydroxyethyl starch have been associated with renal dysfunction and should generally be avoided in patients at risk for AKI.[44] Albumin appears to be safe for the kidneys; however, it is more costly and does not provide better patient outcomes compared with isotonic saline.[45] As a result, KDIGO

guidelines recommend isotonic crystalloids over colloids for intravascular volume expansion in patients at risk for AKI.[3]

Over the past several years, there has been a growing interest in the use of balanced solutions instead of isotonic saline. The main concerns associated with the use of large amounts of saline are hyperchloremic acidosis, interstitial edema, and fluid overload. The chloride content in isotonic saline is 1.5 times that of plasma (154 mEq/L [mmol/L]) which can lead to hyperchloremic metabolic acidosis. Hyperchloremia in turn can decrease renal artery blood flow and renal tissue perfusion. Further, saline infusions cause a greater increase in interstitial fluid volume than balanced solutions and this may result in a relatively greater increase in renal volume and thereby increased intracapsular pressure, decreased microvascular blood flow, and impaired renal function.[46] Balanced solutions (Plasmalyte and Sterofundin) have an electrolyte content that is closer to the plasma concentrations as chloride is partly replaced by bicarbonate precursors such as lactate, acetate, or gluconate. Some studies have demonstrated more favorable outcomes with balanced fluids, including a significantly lower risk of AKI and reduced need for RRT, while others have not.[47,48] Further randomized studies are needed to determine whether balanced solutions should replace isotonic saline as the mainstay of fluid resuscitation in critically ill patients.

CIN is a common cause of ATN in the inpatient setting (see Chapter 46 for a detailed discussion) and is typically characterized by an increase in S_{cr} starting at 12 hours up to 5 days after the radiologic procedure.[3] It is associated with increased mortality especially in individuals with CKD, diabetes, volume depletion, concurrent nephrotoxic drug therapy, or hemodynamic instability. Hydration is thought to counterbalance some of the deleterious effects of radiocontrast dyes by diluting the contrast media, preventing renal vasoconstriction that contributes to hypoxia and ischemia, and minimizing tubular obstruction. Sodium bicarbonate infusion has also been evaluated for the prevention of CIN. The hypothesized mechanism for protection is that sodium bicarbonate may reduce the formation of oxygen-free radicals by alkalinizing renal tubular fluid.[49] There is currently no agreement on which hydration regimen is more effective as some studies indicate lower incidences of CIN with sodium bicarbonate while others show lower CIN rates with isotonic saline.[50,51,52] The KDIGO guidelines currently recommend using either sodium bicarbonate or isotonic saline in high-risk individuals receiving radiocontrast media.[3]

Since there is no consensus on the optimal rate and duration of fluid infusions, CIN hydration protocols may vary. A common sodium bicarbonate regimen is 154 mEq/L (mmol/L) infused at 3 mL/kg/h for 1 hour before the procedure and at 1 mL/kg/h for 6 hours after the procedure.[50,51,52] The rate and duration of normal saline infusion also vary, but one frequently cited regimen is 1 mL/kg/h for 12 hours before and 12 hours after the procedure.[52] The rate of administration may need to be adjusted based on the patient's cardiopulmonary and volume status.

The role of oral hydration (defined as ingestion of a specific amount of water prior and after receiving radiocontrast media) is not as well established as intravenous hydration, however, it has been compared to the intravenous route and found to be as effective in reducing the risk of CIN.[53,54,55] However, this option is best reserved for outpatients, undergoing elective procedures, with either normal renal function or mild renal impairment. For inpatients or individuals who require emergent

coronary angiography or radiological procedures with contrast exposures, IV hydration is still considered first-line treatment for prevention of CIN.[53]

Pharmacologic Therapy

Many pharmacologic therapies have been investigated for the prevention of AKI. Several therapies have shown either no benefit or an unacceptable safety profile.[3] For example, vasodilators such as dopamine and fenoldapam are not recommended due to lack of benefit and risk of hypotension.[57,58] Theophylline has also been studied because of its adenosine receptor antagonist properties, however, its modest benefit does not outweigh potential adverse effects such as tachycardia, tremor, and drug interactions.[3,59,60]

Per KDIGO guidelines, antioxidants (ascorbic acid and *N*-acetylcysteine [NAC]) and glycemic control with insulin may have a role in prevention of AKI for select patient populations and are described below.[3]

Ascorbic Acid

Ascorbic acid has mainly been studied for the prevention of CIN, as its antioxidant properties are thought to alleviate oxidative stress caused by CIN-associated ischemia reperfusion injury. While its excellent safety profile and low cost make it an attractive option, clinical studies have reported inconsistent results.[61,62,63] While the specific dosage regimens and route of administration vary between studies, one of the more frequently studied regimens consists of ascorbic acid 3 g orally before the procedure and 2 g orally twice daily for two doses after the procedure.[63] One meta-analysis demonstrated a small albeit significant reduction in the relative risk of CIN in patients undergoing coronary angiography.[64] While the KDIGO Work Group did not specifically provide recommendations on ascorbic acid, current literature indicates that ascorbic acid may be considered for the prevention of CIN since it is associated with minimal risks and a small protective effect.

N-Acetylcysteine

NAC is another antioxidant that has been widely studied in the prevention of CIN. However, its therapeutic benefit is thought to be quite modest and has not been consistently demonstrated.[51,65,66] A frequently quoted dosing regimen for prevention of CIN is 600 to 1,200 mg orally every 12 hours for 2 to 3 days, with the first two doses administered prior to contrast exposure. Due to its favorable safety profile and potential benefit, the KIDGO guidelines suggest using NAC in combination with IV isotonic saline in patients at risk for CIN.[3]

Glycemic Control

Glycemic control in critically ill patients is important as stress hyperglycemia and insulin resistance are common during critical illness and are associated with increased mortality. The causes of insulin resistance are multifactorial but include impaired glucose homeostasis due to loss of the kidney's

metabolic function, and decreased hepatic and peripheral glucose uptake secondary to uremia. Several studies have found that hyperglycemia increases the risk of acute kidney injury, possibly by triggering oxidative stress within the kidneys via increased production of reactive oxygen species within the mitochondria.[67,68,69]

Critically ill patients with AKI are not only at increased risk for hyperglycemia but also hypoglycemia. Hypoglycemia can develop when insulin protocols are too aggressive and attempt to target normal blood glucose concentrations of 80 to 110 mg/dL (4.4-6.1 mmol/L). Patients with AKI or preexisting kidney disease are particularly susceptible to hypoglycemia as the kidneys are the primary metabolic site of insulin and also contribute significantly to gluconeogenesis.[67] Current KDIGO guidelines suggest using insulin therapy to target plasma glucose of 110 to 149 mg/dL (6.1-8.3 mmol/L).[3] Other guidelines such as the American Diabetes Association and the American Society of Parenteral and Enteral Nutrition have recommended a glycemic target range of 140 to 180 mg/dL (7.8-10.0 mmol/L) in critically ill patients.[70,71]

Clinical Controversy…

Automated, real-time electronic alert systems have the potential to improve recognition and management of AKI. While observational studies suggest that AKI alerts may increase frequency and timeliness of treatment, a recent single-center randomized controlled trial found no difference in clinical outcomes between patient groups who were assigned the electronic alert and those who were not. Further research is needed to determine whether AKI alerts and similar computerized decision-support initiatives are of value to the healthcare provider and if they can significantly improve care.

TREATMENT

6 Since there is no specific treatment that can reverse AKI or hasten its recovery, supportive measures that focus on hemodynamics, fluid balance, acid-base balance, and electrolyte homeostasis are the mainstays of therapy.

Desired Outcomes

Short-term goals of AKI management include minimizing the degree of insult to the kidney, reducing extrarenal complications, and expediting the patient's recovery of renal function. Therapy should focus on maintaining organ functions while sustaining mean arterial pressure. The ultimate goal is to have the patient's renal function restored to pre-AKI baseline. Table 43-5 summarizes the KDIGO clinical practice guidelines regarding recommended and not recommended therapies for the treatment of AKI.[3]

General Approach to Treatment

Identification and management of AKI should be prompt. Prerenal sources of AKI should be managed with hemodynamic support and volume replacement.[72] Postrenal therapy focuses on removing the

cause of the obstruction. It is important to approach the treatment of established AKI with an understanding of the patient's comorbidities and baseline renal function. Loss of kidney function combined with other clinical conditions, such as cardiac and liver failure, is associated with higher mortality.[73] At times, the most efficacious remedy for AKI is management of the comorbid precipitating event. Presence of CKD indicates that the kidneys have less reserve, and there is a greater likelihood that full recovery may not occur. If AKI is severe, RRT may be necessary to maintain fluid, electrolyte, and acid-base balance while removing accumulating waste products or toxins.[72]

Pharmacologic and Nonpharmacologic Therapies

It should be emphasized again that the currently available pharmacologic and nonpharmacologic therapies are only supportive in nature and focus on managing complications such as fluid overload and acid-base/electrolyte imbalances. Maintaining an adequate fluid status is imperative and challenging at the same time. First-line therapies for volume resuscitation consist of crystalloids such as isotonic saline or balanced solutions. On the other hand, fluid overload is treated with loop diuretics or RRT. Patients with severe AKI are more likely to have concomitant acid-base and electrolyte derangements and thus are more likely to receive RRT. However, it is unclear whether RRT or conservative management should be preferred in patients with AKI. Randomized controlled-trials are currently underway to assess whether early initiation of RRT improves patient outcomes and reduces mortality.[74,75]

Hydration

The principal of fluid therapy is to maintain or restore effective intravascular volume to assure adequate tissue perfusion. Similarly to preventative hydration strategies, crystalloids such as isotonic saline or balanced solutions are preferred. At the same time, great care needs to be taken to avoid too liberal fluid administration which can result in interstitial edema, increased intra-abdominal pressure, renal venous congestion, and decreased GFR.[76] These processes have been associated with increased mortality and reduced recovery of renal function further exacerbate AKI and lead to additional fluid retention.[77] Thus, maintaining adequate fluid balance is a major challenge in AKI patients, particularly those who are critically ill. In addition, the patient should be monitored for body weight changes, fluid intake and urine output, pulmonary and peripheral edema, blood pressure (target mean arterial pressure ≥65 mm Hg), and serum electrolytes. Urine output more than or equal to 0.5 mL/kg/h is generally targeted during the initial fluid resuscitation phase.[78]

In patients with anuria or oliguria, slower rehydration, such as 250 mL boluses or 100 mL/h infusions of isotonic saline or a balanced crystalloid solution, should be considered to reduce the risk for pulmonary edema, especially if heart failure or pulmonary insufficiency exists. Isotonic saline has been associated with hyperchloremic metabolic acidosis, especially if the dehydration is accompanied by a severe electrolyte imbalance amenable to large and relatively rapid infusions. For example, if dehydration resulting from severe diarrhea is accompanied by metabolic acidosis as the result of bicarbonate losses, the optimal IV rehydration fluid would be 5% dextrose with 0.45% sodium chloride plus 50 mEq (mmol) of sodium bicarbonate per liter. This fluid will remain mostly in the intravascular space, providing the necessary perfusion pressure to the kidneys, as well as a substantial

amount of bicarbonate to correct the acidosis.

If AKI is a result of blood loss or is complicated by symptomatic anemia, red blood cell transfusion to a hematocrit no higher than 30% (0.30) is the treatment of choice.[78] Although albumin is sometimes used as a resuscitative agent, its use should be limited to individuals with severe hypoalbuminemia (eg, liver disease and nephritic syndrome) who are resistant to crystalloid therapy. These patients have severe hypoalbuminemia-associated third spacing that complicates fluid management, and albumin may be useful in this setting.[79] In critically ill patients with vasomotor shock, vasopressors such as norepinephrine, vasopressin, or dopamine may be used in conjunction with fluids in order to maintain adequate hemodynamics and renal perfusion.[3]

Electrolyte Management

Hypernatremia and fluid retention are frequent complications of AKI. Total daily sodium intake should be monitored since excessive amounts may contribute to diuretic therapy failure. Since several commonly administered IV antibiotics such as metronidazole, ampicillin, piperacillin, and fluconazole contain significant amounts of sodium they can contribute to hypernatremia.

The most common electrolyte disorder encountered in AKI patients is hyperkalemia, as more than 90% of potassium is renally eliminated. Life-threatening cardiac arrhythmias may occur with serum potassium concentrations greater than 6 mEq/L (mmol/L), so frequent monitoring of potassium is essential. Some foods and medications such as oral phosphorous replacement powders (eg, Neutra-Phos and Neutra-Phos-K) and alkalinizers (Polycitra) contain substantial amounts of potassium (see Chapter 51). Some medications may promote potassium retention by the kidneys and should also be avoided or closely monitored (see Chapters 46 and 51).

Other electrolytes that require monitoring are phosphorus and magnesium. Both are eliminated by the kidneys and are not removed efficiently by dialysis. In the early stages of AKI, hyperphosphatemia may be more common than hypophosphatemia. Patients with significant tissue destruction (eg, trauma, rhabdomyolysis, and tumor lysis syndrome) may have substantial amounts of phosphorus released from the destroyed tissue. Calcium-containing antacids should be avoided to prevent precipitation of calcium phosphate in the soft tissues. Typically, the dietary intake of phosphorus and magnesium needs to be restricted. However, patients receiving prolonged RRT can develop deficiency states, particularly pediatric patients as a result of reduced body stores. In contrast to the patient with CKD, AKI patients do not usually develop calcium imbalance secondary to the limited duration of the illness. One exception to this is seen in patients who are receiving CRRT with citrate as the anticoagulant. Citrate binds to serum calcium and is typically infused before the dialyzer/hemofilter. Calcium chloride or calcium gluconate is administered prior to returning the blood to the patient, while the citrate that reaches the systemic circulation is subsequently metabolized by the liver. The goals of citrate anticoagulation are to maintain the circuit ionized calcium between 0.8 and 1.6 mg/dL (0.2 and 0.4 mmol/L), and the patient's systemic ionized calcium between 4.4 and 5.2 mg/dL (1.1-1.3 mmol/L).[3] Since severe hypocalcemia can result in arrhythmias or even death, frequent monitoring of unbound serum calcium concentrations is essential.

Nutritional Considerations in AKI

Nutritional management of critically ill patients with AKI can be extremely complex, as it needs to account for metabolic derangements resulting from both renal dysfunction and underlying disease processes, as well as the effects of RRT on nutrient balance. Stress, inflammation, and injury lead to hypermetabolic/hypercatabolic states and may alter the nutritional requirements. In addition, severe malnutrition found in up to 42% of patients with AKI is a risk factor for increased hospital mortality and length of stay.[78] Thus, patient outcomes can be significantly improved if the nutritional status is optimized.

Loss of the normal physiologic and metabolic functions of the kidney and the hypercatabolic response to stress and injury will have a significant impact on the metabolism of nutrients. Derangements in glucose, lipid, and protein metabolism result in hyperglycemia and insulin resistance, hypertriglyceridemia, protein catabolism, and negative nitrogen balance. The latter, in particular, is problematic to manage, as increased amino acid turnover and skeletal muscle breakdown lead to muscle wasting and malnutrition and do not respond well to increasing exogenous protein supplementation. The KDIGO guidelines currently recommend a caloric intake goal of 20 to 30 kcal/kg/day (84-126 kJ/kg/day); irrespective of the stage of renal impairment and preferentially through the enteral route. In the setting of noncatabolic AKI without need for dialysis, 0.8 to 1 g/kg/day of protein is suggested and 1 to 1.5 g/kg/day if patient is receiving RRT.[3] CRRT is associated with an increased removal of small water-soluble molecules such as amino acids and certain nutrients. As a result, hypercatabolic patients receiving CRRT will typically have higher protein requirements up to a maximum of 1.7 g/kg/day.[3]

Renal Replacement Therapy

RRT is often used to treat fluid overload, electrolyte and acid-base imbalances resulting from severe AKI. Multiple factors influence decisions to initiate dialysis including specific timing and type of modality.[80,81] The choice of continuous versus intermittent RRTs is a matter of considerable debate and usually depends on physician preference and the resources available at the hospital. The most common indications for initiation of RRT are summarized in **Table 43-6**.

TABLE 43-6 Common Indications for RRT

Indication for RRT	Clinical Setting
A: *a*cid-base abnormalities	Metabolic acidosis (especially if pH <7.2)
E: *e*lectrolyte imbalance	Severe hyperkalemia and/or hypermagnesemia
I: *i*ntoxications	Salicylates, lithium, methanol, ethylene glycol, theophylline, phenobarbital
O: fluid *o*verload	Fluid overload (especially pulmonary edema unresponsive to diuretics)
U: *u*remia	Uremia or associated complications (neuropathy, encephalopathy, pericarditis)

RRT, renal replacement therapy.

Intermittent Hemodialysis

Intermittent hemodialysis (IHD) is the most frequently used RRT. IHD machines are readily available in most acute care facilities, and healthcare workers are commonly familiar with their use. Hemodialysis treatments usually last 3 to 4 hours, with blood flow rates to the dialyzer typically ranging from 200 to 400 mL/min. Advantages of IHD include rapid removal of volume and solutes and thereby contribute to correction of most of the electrolyte abnormalities associated with AKI. The primary challenge is hypotension, typically caused by rapid removal of intravascular volume. Venous access for dialysis can be difficult in hypotensive patients and can limit the effectiveness of IHD, leading to ineffective solute clearance, lack of acidosis correction, continued volume overload, and delayed recovery because of further ischemic insults to the kidneys. If hemodialysis is carefully monitored and hypotension avoided, better patient outcomes can be achieved.[82] Patients with CKD stage 5 generally achieve adequate solute and volume control with three times weekly dialysis, but hypercatabolic, fluid-overloaded patients with AKI may require more frequent hemodialysis treatments. Chapter 45 provides a detailed explanation of the principles and processes of IHD.

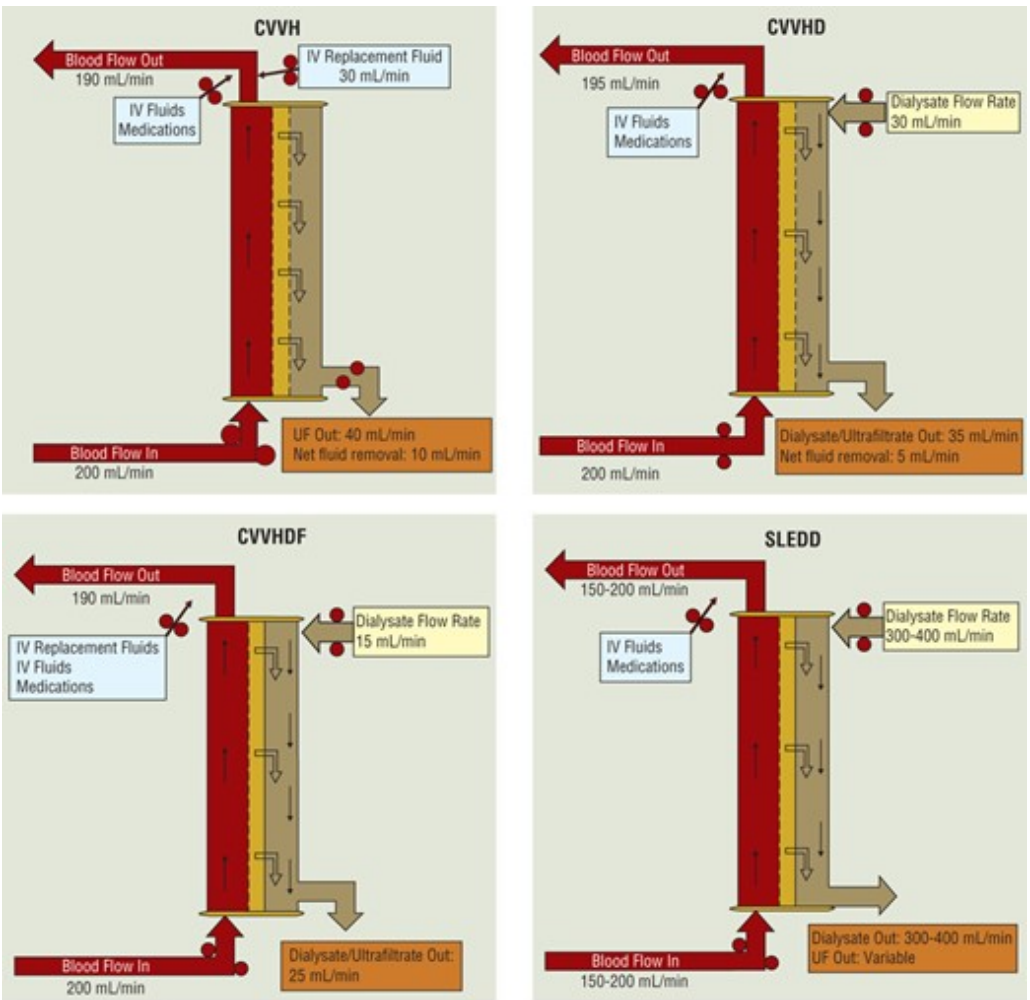
Continuous Renal Replacement Therapy

CRRT is a viable approach to manage hemodynamically unstable patients with AKI. Several CRRT variants have been developed, including continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD), and continuous venovenous hemodiafiltration (CVVHDF). They differ in the degree of solute and fluid clearance that can be clinically achieved as a result of the use of diffusion, convection, or a combination of both. A greater amount of solute removal and higher mean arterial pressures are observed during CCRT compared with IHD in critically ill patients with AKI.[83] In CVVH, solute and fluid clearance is primarily a result of convection, in which fluids containing solutes is removed, while replacement fluids absent of the solutes is replaced (**Fig. 43-3**). CVVHD provides extensive solute removal primarily by diffusion, in which solute molecules at a higher concentration (plasma) pass through the dialysis membrane to an area of lower concentration (dialysate). Also, some fluid is removed as a function of the ultrafiltration coefficient of the dialyzer and the patient's blood pressure. CVVHD potentially has a lower risk of clotting than CVVH because of reduced hemoconcentration, as there is less fluid removal during the process. CVVHDF combines both convection or hemofiltration and hemodialysis, achieving even higher solute and fluid removal rates (Fig. 43-3). The ultrafiltration rate is an important determinant of the effectiveness of all three forms of CRRT. In direct comparisons of ultrafiltration rates of 25 and 40 mL/kg/h or higher, no difference in mortality has been observed, and there was a tendency toward prolonged need for renal replacement in those who received the higher ultrafiltration rate.[84,85] Therefore, current KDIGO guidelines recommend an ultrafiltration rate of no more than 20 to 25 mL/kg/h during CRRT.[3]

FIGURE 43-3

Several renal replacement therapies are commonly used in patients with acute kidney injury (AKI), including one of the three primary continuous renal replacement therapy (CRRT) variants: (a) continuous venovenous hemofiltration (CVVH), (b) continuous venovenous hemodialysis (CVVHD), (c) continuous venovenous hemodiafiltration (CVVHDF), and the hybrid intermittent hemodialysis

therapy (d) sustained low-efficiency dialysis (SLED). The blood circuit in each diagram is represented in red, the hemofilter/dialyzer membrane is yellow, and the ultrafiltration/dialysate compartment is brown. Excess body water and accumulated endogenous waste products are removed solely by convection when CVVH is employed. With CVVHD, waste products are predominantly removed as the result of passive diffusion from the blood, where they are in high concentration to the dialysate. The degree of fluid removal that is accomplished by convection is usually minimal. CVVHDF uses convection to a degree similar to that employed during CVVH as well as diffusion, and thus is often associated with the highest clearance of drugs and waste products. Finally, SLED employs lower blood and dialysate flow rates than intermittent hemodialysis (IHD), but because of its extended duration, it is a gentler means of achieving adequate waste product and fluid removal.



Because of the reduced blood flow rates relative to IHD, CRRT-related thrombosis is a significant concern; thus, some form of anticoagulation is generally necessary for almost all patients. Typical anticoagulation is achieved by the administration of parenteral agents such as regional citrate (preferred if increased risk for bleeding is present), unfractionated heparin, low-molecular-weight heparin in some cases, or a direct thrombin inhibitor when other therapies are contraindicated.[3,86] Replacement fluids can be infused either just before or after the dialyzer/hemofilter. Infusing fluids after the hemofilter can result in hemoconcentration within the filter, a factor associated with an increased risk of thrombosis of the dialyzer. Replacing fluids before the filter reduces thrombosis risk,

but it also reduces solute clearance.

Disadvantages of CRRT may include limited availability of the special equipment necessary to provide these treatments or the need for intensive nursing care, and the need to individualize the IV replacement, dialysate fluids, and drug therapy adjustments. There is also very little known about drug-dosing requirements for patients who are receiving CRRT.[87] CRRT use is most commonly considered for those patients with higher acuity because of their intolerance of IHD-associated hypotension. Current KDIGO guidelines suggest using CRRT over IHD in hemodynamically unstable patients.[3]

Hybrid Dialysis Therapies

8 An alternative to CRRT is extended-duration IHD or hybrid IHD therapies which have a variety of names, with the two most common being sustained low-efficiency dialysis (SLED) and slow, extended, daily dialysis (see Fig. 43-3).[88] These therapies use lower blood (150-200 mL/min) and dialysate (300-400 mL/min) flow rates with extended treatment periods of 6 to 12 hours. For critically ill patients with AKI, SLED appears comparable to CRRT for hemodynamic control.[82] Anticoagulation is still required, but the amount necessary compared with CRRT is lower. Although the use of hybrid hemodialysis therapies is increasing, our knowledge of their impact on drug removal is very limited.[89] Daily delivery of SLED presents challenges to clinicians prescribing drug and nutrition therapy, as most of the dosing guidelines are based on IHD given three times per week in CKD patients. Thus, application of these guidelines in patients with AKI may potentially yield suboptimal outcomes.

Diuretics

Loop diuretics are frequently used for the management of fluid overload in patients at risk for AKI as well as those with established AKI. Early experimental studies proposed that loop diuretics had several theoretical advantages: decreased risk of tubular obstruction secondary to an increased urine flow and flushing out of debris; increased urine output that may be beneficial in itself, as nonoliguric AKI is associated with better outcomes than oliguric AKI; decreased risk of ischemic injury as the result of inhibition of the sodium/potassium chloride cotransporter and thus a reduction in oxygen demand; and enhanced renal blood flow due to increased availability of renal prostaglandins.[90] However, clinical studies have found that even though the loop diuretics increase urine output, they neither reduce the incidence of AKI nor improve patient outcomes, such as mortality, need for RRT, and renal recovery.[90] In fact, they have been associated with a significant increase in the risk of death or nonrecovery of renal function in some studies among critically ill patients.[90,91] One proposed explanation for this lack of benefit is that loop diuretics may actually decrease renal blood flow by reducing effective circulating arterial volume, which, in turn, may stimulate the adrenergic and the renin–angiotensin systems.[92] Therefore, the KDIGO guidelines recommend limiting the use of loop diuretics to the management of fluid overload and avoiding their use for the sole purpose of prevention or treatment of AKI.[3]

9 Diuretic resistance is a relatively common problem in patients with AKI for several reasons.

Excessive sodium intake may override the ability of the diuretics to eliminate sodium. Patients with ATN have a reduced number of functioning nephrons on which the diuretic may exert its action. Other clinical states, such as glomerulonephritis, are associated with heavy proteinuria. Intraluminal loop diuretics cannot exert their effect in the loop of Henle if they are extensively bound to proteins present in the urine. Still other patients may have greatly reduced bioavailability of oral furosemide because of intestinal edema, often associated with high preload states, which further reduces oral furosemide absorption. **Table 43-7** includes possible therapeutic options to counteract each form of diuretic resistance.

TABLE 43-7 Common Causes of Diuretic Resistance in Patients with AKI

Causes of Diuretic Resistance	Potential Therapeutic Solutions
Excessive sodium intake (sources may be dietary, IV fluids, and drugs)	Remove sodium from nutritional sources and medications
Inadequate diuretic dose or inappropriate regimen	Increase dose, use continuous infusion or combination therapy
Reduced oral bioavailability (usually furosemide)	Use parenteral therapy, switch to oral torsemide or bumetanide
Nephrotic syndrome (loop diuretic protein binding in tubule lumen)	Increase dose, switch diuretics, use combination therapy
Reduced renal blood flow	
Drugs (NSAIDs, ACEIs, vasodilators)	Discontinue these drugs if possible
Hypotension	Intravascular volume expansion and/or vasopressors
Intravascular depletion	Intravascular volume expansion
Increased sodium resorption	
Nephron adaptation to chronic diuretic therapy	Combination diuretic therapy, sodium restriction
NSAID use	Discontinue NSAID
Heart failure	Treat heart failure, increase diuretic dose, switch to better-absorbed loop diuretic
Cirrhosis	Paracentesis
Acute tubular necrosis	Increase diuretic dose, diuretic combination therapy

ACEIs, angiotensin-converting enzyme inhibitors; NSAIDs, nonsteroidal anti-inflammatory drugs.

One effective technique to overcome diuretic resistance is to administer loop diuretics via continuous infusion instead of intermittent boluses. Less natriuresis occurs when equal doses of loop diuretics are given as a bolus instead of as a continuous infusion. Furthermore, adverse reactions from loop diuretics (myalgia and hearing loss) occur less frequently in patients receiving continuous infusion compared with those receiving intermittent boluses, ostensibly because higher serum concentrations are avoided. An initial loading dose is recommended prior to the initiation of a continuous infusion of furosemide or its equivalent.[91] Patients with low CL_{cr} may have much lower rates of diuretic secretion into the tubular fluid; consequently, higher doses are generally used in patients with renal

insufficiency.

Combination therapy of loop diuretics plus a diuretic from a different pharmacologic class may be an alternative approach in the setting of AKI.[94,95] Loop diuretics increase the delivery of sodium chloride to the distal convoluted tubule and collecting duct. With time, these areas of the nephron compensate for the activity of the loop diuretic and increase sodium and chloride resorption. Diuretics that work at the distal convoluted tubule (chlorothiazide and metolazone) or the collecting duct (amiloride, triamterene, and spironolactone) may have a synergistic effect when administered with loop diuretics by blocking the compensatory increase in sodium and chloride resorption[95] (see Chapter 49 for more discussion). Of these combinations, oral metolazone is used most frequently because, unlike other thiazides, it produces effective diuresis at a Cr_{Cl} less than 20 mL/min (0.33 mL/s). The combination of metolazone and a loop diuretic has been used successfully in the management of fluid overload in patients with heart failure, cirrhosis, and nephrotic syndrome.

Drug Dosing Considerations in Acute Kidney Injury

Optimization of drug therapy for patients with AKI is often challenging. Many of the recommendations from the KDIGO guidelines are based on limited information and different therapeutic targets depending on the situation and concurrent co-morbid factors present. The multiple variables influencing responses to the drug regimen include the patient's residual drug clearance, fluid accumulation, and delivery of RRT. For renally eliminated drugs, particularly for agents with a narrow therapeutic range, serum drug concentration measurements and assessment of pharmacodynamic responses are likely to be necessary. If hepatic function is intact, choosing an agent eliminated primarily by the liver may be preferred. However, any renally eliminated active metabolites may accumulate to a point where they can elicit an undesired pharmacologic effect. Renal failure can also independently impair nonrenal drug elimination including metabolism.[96] Unfortunately, pharmacokinetic studies in patients with established AKI are fairly limited. Further, the use of dosing guidelines based on data derived from patients with stable CKD may not reflect the clearance and volume of distribution in critically ill AKI patients (see Chapter 48).[87] The inability to adequately dose drugs in critically ill patients with AKI requiring RRT may be one factor contributing to the lack of improving outcomes with newer RRT approaches.

Pharmacotherapy regimen decisions should further take into consideration four distinct phases of AKI described earlier, specifically initiation, extension, maintenance, and recovery phase. The initiation and extension phases occur right after the kidney insult. At this point, decisions on drug therapy should include the specific pharmacokinetics of the drug, the potential for increased risk for an adverse drug event, the goals of therapy, and therapeutic drug monitoring (if available). The severity and timing of the decline in renal function is relatively unpredictable so frequent monitoring and reevaluation of drug dosing is necessary. During the maintenance phase of AKI renal function has stabilized and drug therapy regimens may require less alterations. The third phase is recovery where AKI begins to resolve and there may be a need to increase the drug dose. Following the patient closely and recognizing trends for decreasing or increasing renal function along with adjustments in RRT in advance is important in achieving and maintaining drug therapy management goals.

Edema, which is common in AKI, can significantly increase the volume of distribution of many drugs, particularly water-soluble ones with relatively small volumes of distribution. Increased fluid distribution into the tissues (ie, sepsis and anasarca in heart failure) can also contribute to a larger volume of distribution for many drugs and thereby reduce the proportion of drug in the plasma that is available to be removed by RRT. Because AKI frequently occurs in critically ill patients, multisystem organ failure is often an accompanying problem. In addition to volume overload, reductions in cardiac output or liver function can significantly alter the pharmacokinetic profile of many drugs, such as vancomycin, aminoglycosides, and low-molecular-weight heparins.[87,97,98]

If rapid onset of activity is desired, a loading dose may be necessary to promptly achieve desired serum concentrations because the expanded volume of distribution and the prolonged elimination half-life extend the time (3.5 times the half-life) needed to reach steady-state concentrations. Maintenance dosing regimens should be reassessed frequently and be based on the patient's most current kidney function. A dose that provides the desired serum concentration on one day may be inappropriate a few days later if the patient's fluid status, RRT prescription, or renal function has changed dramatically.

Drug therapy individualization for the AKI patient who is receiving any form of RRT is complicated by the fact that patients with AKI may have a higher residual nonrenal clearance than patients with CKD who have a similar CL_{cr}.[87] Alterations in the activity of some, but not all, cytochrome P450 enzymes have been demonstrated in patients with CKD.[96] The nonrenal clearance of imipenem in patients with AKI (91 mL/min [1.52 mL/s]) is between the values observed in stage 5 CKD patients (50 mL/min [0.83 mL/s]) and those with normal renal function (130 mL/min [2.2 mL/s]).[96] This may be the result of less accumulation of uremic waste products that may alter hepatic function. If a patient with AKI has higher than anticipated nonrenal clearance, this would result in lower than expected, possibly subtherapeutic, serum concentrations. For example, to maintain comparable serum concentrations, the imipenem dose requirement in patients with AKI would be 2,000 mg daily as compared with the recommended dosage for patients with ESRD of 1,000 mg daily.[96] As AKI persists, the nonrenal clearance values appear to approach those observed in patients with CKD.[96] Another challenge is that much of the dosing-related data were acquired in patients with CKD, with initial pharmacokinetic assessments done after single-dose administration. The determination of pharmacokinetic parameters using a single-dose model may result in more rapid initial drug removal estimates secondary to distribution from the plasma to the tissue as well. Thus, application of dosing regimens derived from studies in patients with CKD and ESKD in addition to the use of more aggressive RRT approaches may result in under dosing of certain drugs and thereby contribute to less than optimal clinical outcomes.

Drug Dosing Considerations in Renal Replacement Therapy

There are marked differences between the different types of RRT and drug removal.[88,90,103] During CVVH, drug removal primarily occurs via convection/ultrafiltration (the passive transport of drug molecules at the concentration at which they exist in plasma water into the ultrafiltrate). Convective removal is most efficient for smaller agents, typically less than 15,000 Da (15 kDa) in size, and those

that are primarily unbound in the plasma. The clearance of a drug by either of these methods is thus a function of the membrane permeability for the drug, which is called the sieving coefficient (SC), and the rate of ultrafiltrate formation (UFR). The pore size of the filter and surface charge relative to the molecule being removed may vary between different dialyzers. If diffusion of the drug is not dependent on the filter pore size, then the SC can be calculated as follows:

$$SC = \frac{2 \times C_{UF}}{C_a + C_v}$$

where C_a and C_v are the concentrations of the drug in the plasma going into and returning from the dialyzer/hemofilter, respectively, and C_{UF} is the concentration in the ultrafiltrate. The SC is often approximated by the fraction unbound (f_u) because this information may be more readily available. Thus, the clearance by CVVH can be calculated as

$$Cl_{CVVH} = UFR \times SC$$

or approximated as

$$Cl_{CVVH} = UFR \times f_u$$

In CVVHDF, clearance is a combination of both diffusion and convection. The Cl_{CVVHDF} can be mathematically approximated, providing the blood flow rate is greater than 100 mL/min and the dialysate flow rate (DFR) is between 8 and 33 mL/min, as

$$Cl_{CVVHDF} = (UFR \times f_u) + Cl_{diffusion}$$

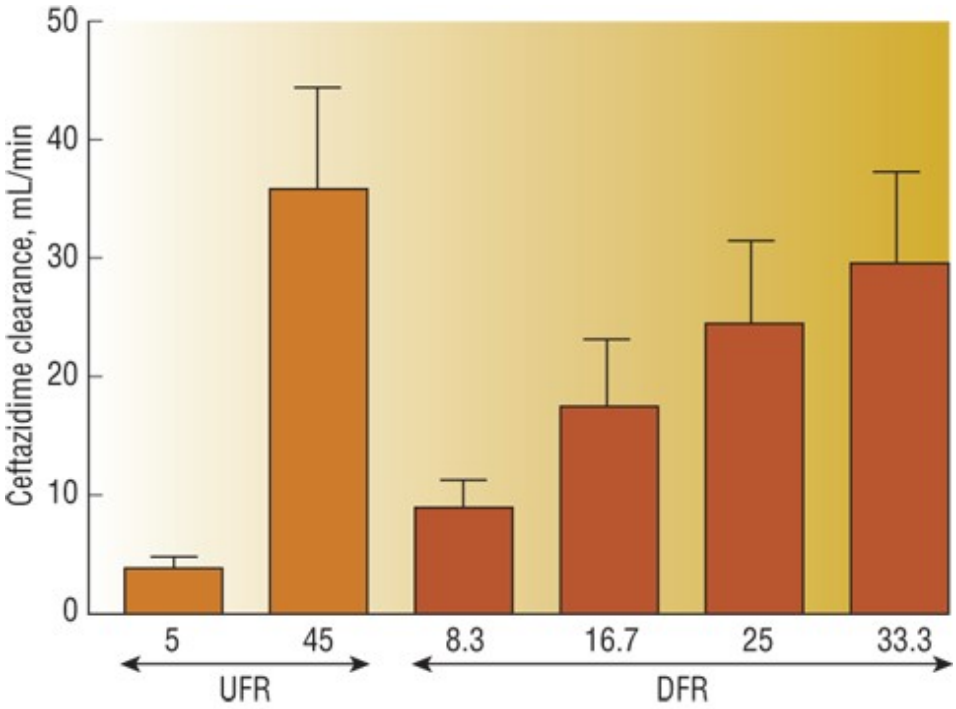
where $Cl_{diffusion}$ is the clearance via diffusion from plasma water to the dialysate. In the clinical setting, it is not possible to separate these two components (UFR and DFR) of Cl_{CVVHDF}. In essence, the Cl_{CVVHDF} is calculated as the product of the combined ultrafiltrate and dialysate volume (V_{df}) and the concentration of the drug in this fluid (C_{df}) divided by the plasma concentration at the midpoint of the V_{df} collection period.

Individualization of therapy for a patient receiving CRRT is dependent on the patient's residual renal function and the clearance of the drug by the mode of CRRT. There are differences in the rate of drug removal, not only between the three primary modes of CRRT but also within each mode.[87,99] This is a result of differences in the filter membrane composition, variable degrees of drug binding to the membrane, and permeability characteristics of the membrane.[99,100] Primary factors that influence drug clearance during CRRT are thus the ultrafiltration rate, blood flow rate, and DFR. For example, clearance in CVVH is directly proportional to the ultrafiltration rate, whereas clearance during CVVHDF, which depends on both the ultrafiltration rate and the DFR, increases as either flow rate increases. An increase in the ultrafiltration flow rate (5-45 mL/min) and DFR (8.3-33.3 mL/min), however, can have dramatic effects on the clearance of agents such as ceftazidime during CVVH and CVVHD, respectively (**Fig. 43-4**).[100] Further, CRRT can rapidly remove excess fluid from edematous patients, thereby changing the volume of distribution (V_D) of drugs with limited distribution (low V_D suggesting a greater proportion in the plasma or extracellular fluid) fairly rapidly.[99] Drug clearances

attained by IHD, CRRTs, and hybrid RRTs all differ from each other and must be added to any endogenous drug clearance that the patient generates.

FIGURE 43-4

The effect of increasing ultrafiltration rate (UFR in milliliters per minute) and dialysate flow rate (DFR in milliliters per minute) on the clearance of ceftazidime. *(Data from reference 95.)*



Limitations of IHD-based dosing charts include variability in the patient's individual pharmacokinetic parameters, differences in the dialysis prescription, such as dialyzer blood flow or duration, and the use of new IHD dialyzers. The approach to hemodialysis may also change on a daily basis, especially in hemodynamically unstable individuals with AKI. This could include, for example, the type of dialyzer/filter used, the duration, the degree of hemofiltration compared with convection, and the blood flow rate. Individualization of a dosing regimen may require daily assessment of the clinical status of the patient and any planned or recently administered hemodialysis.

Overall, there are numerous potential pharmacokinetic and pharmacodynamic alterations to be aware of in the patient with AKI. Unfortunately, there is a dearth of data to quantify these changes, and even less evidence demonstrating that if one incorporates these considerations into patient care, the associated outcomes will be improved.

Clinical Controversy…

Dosing of antimicrobial agents in critically ill patients receiving CRRT or SLED is challenging. Although small pharmacokinetic studies are emerging to provide data to help address this problem, the

variability in results from these studies is significant and makes it difficult for health care professionals to draw conclusions and apply these findings to the care of individual patients.

PERSONALIZED PHARMACOTHERAPY

In the presence of AKI, several processes may exist that can alter drug response such as impaired elimination, RRT-related drug removal, or physiologic alterations in pharmacodynamic response. Guidance from clinical trials on how to appropriately adjust drug regimens is limited. Thus, individualized pharmacotherapeutic regimens and frequent assessment is required to optimize patient outcomes. Changes in the patient's clinical condition including renal replacement regimens may require clinicians to make frequent dosage regimen adjustments. Information from yesterday's medical record review may not reflect what is happening today or will be needed for tomorrow. Patient frequently require more aggressive pharmacotherapy regimens initially because of altered pharmacokinetics that can be subsequently tapered if warranted. Clinicians should keep the overall clinical status of the patient in mind when developing management plans. Key to optimal patient outcomes includes maximizing prevention, early identification of AKI, timely implementation of supportive therapies, and frequent assessments and revisions of the care plan until the AKI has resolved.

EVALUATION OF THERAPEUTIC OUTCOMES

Vigilant monitoring of patients with AKI is essential, particularly in those who are critically ill. **Table 43-8** summarizes the main monitoring parameters for patients with established AKI.

TABLE 43-8 Key Monitoring Parameters for Patients with Established AKI

Parameter	Frequency
Fluid intake & output	Every shift
Patient weight	Daily
Hemodynamics (blood pressure, heart rate, mean arterial pressure, etc.)	Every shift
Blood chemistries	
Sodium, potassium, chloride, bicarbonate, calcium, phosphate, magnesium	Daily
Blood urea nitrogen/serum creatinine	Daily
Drugs and their dosing regimens	Daily
Nutritional regimen	Daily
Blood glucose	Daily (minimum)
Serum concentration data for drugs	After regimen changes and after renal replacement therapy has been instituted
Times of administered doses	Daily

Parameter	Frequency
Doses relative to administration of renal replacement therapy	Daily
Urinalysis	
Calculate measured creatinine clearance	Every time measured urine collection performed
Calculate fractional excretion of sodium	Every time measured urine collection performed
Plans for renal replacement	Daily

Once the laboratory-based tests (eg, urinalysis and FE_{Na} calculations) have been conducted to diagnose the cause of AKI, they usually do not have to be repeated. In established AKI, daily measurements of urine output, fluid intake, and weight should be performed. Vital signs should be monitored at least daily, more often if the acuity of illness warrants. Electrolytes, BUN, serum creatinine, and a complete blood cell count should be considered routine and measured at least daily for hospitalized patients.

Therapeutic drug concentration monitoring should be performed for drugs that have a narrow therapeutic index if results from these serum drug concentrations can be obtained in a timely fashion. The optimal time to measuring serum concentrations is patient-, drug-, and often clinician-specific; consensus is lacking. For patients receiving RRT measuring a serum drug concentration prior to hemodialysis has the advantage of allowing time for the result to be reported and the next dose calculated so that it can be administered shortly after dialysis. This is especially important if the desired pharmacologic effects are lost during or after hemodialysis is complete because the serum concentrations have become subtherapeutic. Knowledge based on previous observations of how a particular agent is removed for a given dialysis approach and a prehemodialysis serum concentration can assist in estimating the amount of the drug removed and predict the need for any postdialysis doses. Serum concentrations drawn after hemodialysis may reflect plasma concentrations that are transiently depressed until the drug can reequilibrate from the tissues (plasma rebound effect). The advantage of collecting a postdialysis sample is the greater accuracy in determining how much drug was removed during hemodialysis. The down side of this strategy is that it delays calculation and administration of the next dose and thus the reestablishment of the target concentration time profile.

CONCLUSION

The unique characteristics of AKI compared with CKD can lead to notable differences in how renal function is measured and how treatment regimens are developed. Most management approaches involve both prevention and support strategies, so as to minimize the potential for additional harm to the kidney. Understanding the constantly changing status inherent to AKI and how to adjust management regimens is a key component to optimizing therapy.

ABBREVIATIONS

Chapter 44: Chronic Kidney Disease

Joanna Q. Hudson; Lori D. Wazny

INTRODUCTION

KEY CONCEPTS

- 1 Chronic kidney disease (CKD) is classified based on the cause of kidney disease, assessment of glomerular filtration rate, and extent of albuminuria.
- 2 The most common causes of category 5 CKD, often called end-stage renal disease (ESRD), are diabetes mellitus and hypertension.
- 3 Anemia of CKD is primarily the result of a deficiency in the production of endogenous erythropoietin by the kidney with iron deficiency as a contributing factor.
- 4 CKD-mineral and bone disorder (CKD-MBD) includes abnormalities in parathyroid hormone (PTH), fibroblast growth factor-23 (FGF-23), phosphorus, calcium, vitamin D, and bone turnover, and contributes to soft-tissue and extravascular calcifications.
- 5 Guidelines from the Kidney Disease: Improving Global Outcomes (KDIGO) provide information to assist healthcare providers in clinical decision making and the design of appropriate therapy to manage CKD progression and the associated complications.
- 6 Patient education plays a critical role in the appropriate management of patients with CKD and its associated complications. An interprofessional team structure is a rational approach to provide this education and effectively design and implement the recommended nonpharmacologic and pharmacologic interventions.
- 7 Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) are key pharmacologic treatments to delay progression of CKD associated with albuminuria because of their effects on renal hemodynamics to reduce intraglomerular pressure and proteinuria.
- 8 Management of anemia includes administration of erythropoiesis-stimulating agents (ESAs)

(eg, epoetin alfa, darbepoetin alfa, methoxy polyethylene glycol-epoetin beta) and regular iron supplementation (oral or IV administration) to maintain hemoglobin concentration and prevent the need for blood transfusions. There is evidence indicating a higher risk of cardiovascular events when hemoglobin is targeted to a value of greater than 11 g/dL (110 g/L; 6.83 mmol/L).

- 9 Management of CKD-MBD includes dietary phosphorus restriction, phosphate-binding agents, vitamin D supplementation, and calcimimetic therapy.

- 10 Initiation of statins for primary prevention of hyperlipidemia in patients receiving dialysis is no longer recommended due to a lack of benefits from recent randomized controlled trials and meta-analyses.

1 Chronic kidney disease (CKD) is defined as abnormalities in kidney structure or function, present for 3 months or longer, with implications for health.[1] For decades kidney disease was primarily considered to be present only when the patient's estimated or measured creatinine clearance (CLcr) was reduced to less than 50 mL/min (0.83 mL/s). In the 2000s a new classification system was proposed that incorporated glomerular filtration rate (GFR) and albuminuria. Documentation of the presence of structural changes in those with what previously would have been classified with normal kidney function (ie, CLcr or GFR >90 mL/min [>1.50 mL/s]) became the most sensitive indicator of CKD and was designated as category 1 CKD based on recommendations from the Kidney Disease: Improving Global Outcomes (KDIGO) guidelines for evaluation and management of CKD.[1] The KDIGO classification system is referred to as *CGA* staging (*C*ause, *G*FR, *A*lbuminuria). **Table 44-1** outlines the KDIGO GFR categories. The KDIGO albuminuria categories are found in Chapter 42 and Table 44-6 in this chapter. A patient is classified with end-stage renal disease (ESRD) when their GFR is below 15 mL/min/1.73 m^2 (0.14 mL/s/m^2) and either chronic dialysis (Chapter 45) or kidney transplantation (Chapter 89) is needed to sustain life. Throughout this chapter CKD categories based on KDIGO classification will be used (eg, CKD 3a or CKD 5). The term CKD 5D indicates a patient with ESRD requiring dialysis as either hemodialysis (CKD 5HD) or peritoneal dialysis (CKD 5PD).

TABLE 44-1 Glomerular Filtration Rate Categories Based on KDIGO Classification

GFR Category[a]	GFR (mL/min/1.73 m^2 [mL/s/m^2])	Terms
1	>90 (>0.87)	Normal or high
2	60–89 (0.58–0.86)	Mildly decreased
3a	45–59 (0.43–0.57)	Mildly to moderately decreased
3b	30–44 (0.29–0.42)	Moderately to severely decreased
4	15–29 (0.14–0.28)	Severely decreased
5	<15 (<0.14)	Kidney failure

CKD, chronic kidney disease; GFR, glomerular filtration rate; KDIGO, Kidney Disease: Improving Global Outcomes.

[a]To meet criteria for CKD there must be a significant reduction in GFR (categories 3a-5) or there must [illegible]categories 1 and 2) for 3 months or greater.

Date from reference 1.

The prognosis of CKD is dependent on the following factors: (a) cause of kidney disease; (b) GFR at time of diagnosis; (c) degree of albuminuria; and (d) presence of other comorbid conditions. Patients with any of the following should be referred to a nephrologist for evaluation and collaborative management: persistent and significant albuminuria, progression of CKD (eg, a marked but nonacute decline in GFR), presence of unexplained urinary red cell casts, hypertension refractory to treatment (eg, ≥4 antihypertensive agents), persistent abnormalities of serum potassium, recurrent or extensive nephrolithiasis, GFR less than 30 mL/min/1.73 m^2 (0.29 mL/s/m^2), or hereditary kidney disease.[1]

Often complications of CKD are unrecognized or are inappropriately managed, and for many patients this contributes to significant morbidity, premature mortality, or a poorer prognosis if and when they develop CKD 5. Frequent complications of advanced CKD include altered sodium and water balance, hyperkalemia, metabolic acidosis, anemia, CKD-related mineral and bone disorder (CKD-MBD), and cardiovascular disease (CVD). This chapter primarily covers the pathophysiology and treatment of progressive CKD, anemia, CKD-MBD, and select cardiovascular (CV) complications. **Table 44-2** lists other complications of advanced CKD not covered in detail in this chapter. The reader is referred to Chapters. 49, 51, and 52 for a more detailed discussion of management and monitoring strategies for CKD patients with sodium and water balance abnormalities, hyperkalemia, and metabolic acidosis.

TABLE 44-2 Other Complications of Chronic Kidney Disease[a]

Organ System or Complication	Clinical Manifestations
Amyloidosis	Accumulation of β_2-microglobulin
	Carpal tunnel syndrome
Blood and immune disorders	Bleeding diathesis
	Impaired cell-mediated immunity
	Lymphopenia
	Platelet dysfunction
Endocrine	Hypoglycemic episodes (result of decreased degradation of insulin by the kidney)
	Nausea, vomiting, anorexia (from uremia)
GI	Delayed gastric emptying
	Gastroesophageal reflux
	GI bleeding
Protein–energy wasting	Malnutrition
Neurologic	Peripheral neuropathies

Organ System or Complication	Clinical Manifestations
	Restless leg syndrome
	Uremic encephalopathy
Uremic pruritus	Generalized itching predominantly of back, face, and extremity used for vascular access, but may affect any area
	May be more severe during or immediately after hemodialysis

[a]Not all inclusive.

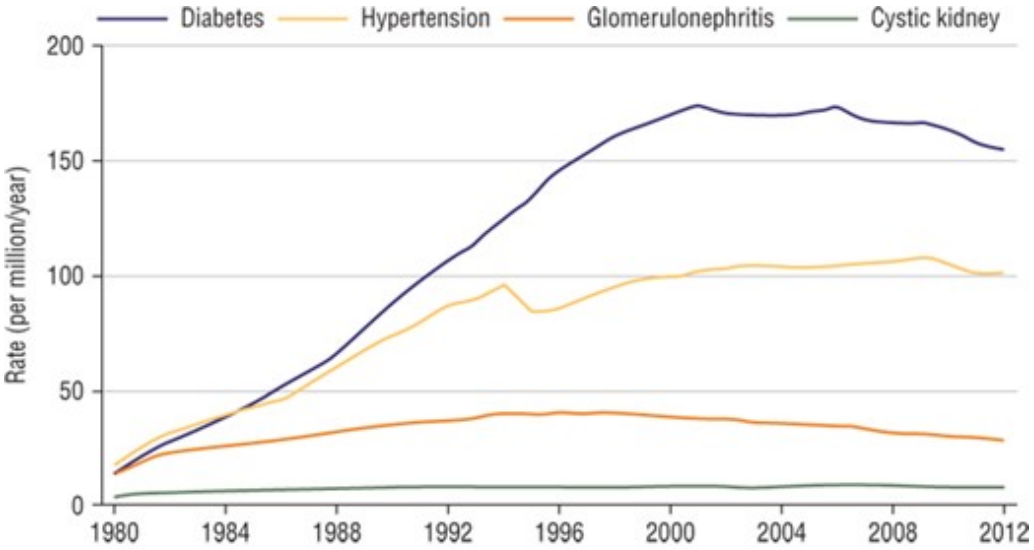
EPIDEMIOLOGY

2 CKD is recognized as a significant global public health problem.[2] People with CKD experience high morbidity and mortality rates with a resulting economic burden to health-care systems due to hospitalizations and the high cost of chronic dialysis and kidney transplantation. From 1990 to 2013 the age-adjusted death rates attributable to CKD increased by 36.9% in 188 countries surveyed and CKD is now the 19th leading cause of life years lost.[3] Worldwide, an estimated 8% to 16% of the general population has CKD and 1.9 million patients are undergoing renal replacement therapy (hemodialysis, peritoneal dialysis, or kidney transplantation).[4,5] As a result, many countries have implemented public health initiatives to reduce the proportion of the population with CKD; increase the proportion of persons with CKD who know they have impaired kidney function; reduce the rate of new cases of ESRD and reduce mortality in persons with CKD.[6,7]

The prevalence of CKD increases with age to about 30% in people older than 70 years.[2] There is, however, some debate as to whether the GFR decline in older individuals as a consequence of the normal physiological aging process in the absence of proteinuria should truly be considered a *disease* necessitating the label of CKD.[8] Diabetes and hypertension are also important risk factors for CKD. A recent evaluation of type 1 diabetics in the Diabetes Control and Complications Trial (DCCT) and the Epidemiology of Diabetes Interventions and Complications (EDIC) studies reported that 17% to 25% of the participants developed diabetic chronic kidney disease (DCKD) after 30 years.[9] In patients with type 2 diabetes, a recent study from Spain noted a prevalence of 27%.[10] In the United States and other first-world countries, the leading cause of new ESRD cases is diabetes mellitus followed by hypertension (**Fig. 44-1**).[11]

FIGURE 44-1

Incident rates of end-stage renal disease (ESRD) by primary diagnosis (1980-2012).[11]



Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

Racial and socioeconomic disparities also exist. In the United States the rate of incident ESRD is 3.3 times greater for Blacks/African Americans and 1.5 times greater for Native Americans and Hispanics than for Whites.[11] The disparities are more striking among diabetics, with incidence rates of ESRD being approximately threefold higher in Blacks/African Americans and twofold higher in Hispanics. The rates of ESRD due to hypertension are also significantly higher among Blacks/African Americans than all other racial groups.[11] A survey in England found that high albuminuria was associated with low socioeconomic status even after adjustment for ethnicity, lifestyle, and clinical variables such as obesity, diabetes, hypertension, and smoking.[12] Greater prevalence of obesity, uncontrolled hypertension, and diabetes among nonwhite individuals are the most common reasons suggested for racial differences in albuminuria.[13] However, a study from Brazil found that the higher prevalence of CKD in individuals with lower educational status and in nonwhites could not be explained by differences in health-related factors.[14]

ETIOLOGY

Susceptibility and Initiation Risk Factors

Clinical and sociodemographic risk factors for susceptibility to and initiation of CKD are listed in **Table 44-3** and are useful for identifying individuals at high risk of developing CKD.[15]

TABLE 44-3 Risk Factors for Susceptibility to and Initiation of Chronic Kidney Disease

Clinical Factors
Diabetes
Hypertension
Obesity

Autoimmune diseases

Systemic infections

Urinary tract infections

Urinary stones

Lower urinary tract obstruction

Neoplasia

Family history of CKD

Recovery from acute kidney injury

Reduction in kidney mass

Exposure to certain drugs

Low birth weight

Sociodemographic Factors

Older age

US ethnic minority status: African American, American Indian, Hispanic, Asian or Pacific Islander

Exposure to certain chemical and environmental conditions

Low income/education

Used with permission from Inker LA, Astor BC, Fox CH, et al. KDOQI US commentary on the 2012 KDIGO clinical practice guideline for the evaluation and management of CKD. *Am J Kidney Dis* 2014;63:713-735.

Progression Risk Factors

Progression risk factors are those associated with further decline in kidney function. Persistence of the underlying initiation factors (eg, diabetes mellitus, hypertension, glomerulonephritis) appears to be the most important predictor of progressive CKD. Other factors associated with progression include those that may be consequent to the underlying kidney disease (eg, hypertension, proteinuria) or independent of underlying kidney disease (eg, smoking, obesity).

Diabetes Mellitus

Achieving a hemoglobin A_{1C} (HbA1c) target of approximately 7% has been shown to prevent the surrogate endpoints of microalbuminuria and macroalbuminuria associated with diabetic chronic

kidney disease (DCKD).[16,17] The original evidence to support this recommendation came from the type 1 diabetes DCCT trial and the long-term follow-up of these participants in the EDIC trial.[9] The evidence for individuals with type 2 diabetes comes from the United Kingdom Prospective Diabetes Study (UKPDS) and the Veterans Affairs Cooperative Study on Glycemic Control and Complications in Type 2 Diabetes Trial.[16] More recent trials in individuals with type 2 diabetes have also demonstrated reductions in new onset microalbuminuria or the development of macroalbuminuria with achievement of HbA1c less than 7% (0.07; 53 mmol/mol Hb).[18,19,20]

Hypertension

Data from the Prevention of Renal and Vascular End-stage Disease (PREVEND) study, a prospective, population-based cohort study in 6,894 people over a 4-year period, noted that the rate of eGFR decline was approximately 1.5 times higher in participants with hypertension.[21] The KDIGO guidelines for the management of blood pressure in CKD recommend the goal is to control blood pressure at all categories of CKD regardless of the underlying cause since early treatment of hypertension and achievement of target blood pressure have been demonstrated to slow the rate of progression of CKD.[22]

Proteinuria

Proteinuria, like hypertension, is an independent predictor of accelerated progression of CKD.[1] Proteinuria is also a risk factor for CV mortality and morbidity although there is some debate regarding the utility of proteinuria as a surrogate for more specific outcomes.[23,24,25]

Clinical Controversy...

Although proteinuria is associated with a faster rate of decline in kidney function, there is considerable controversy as to whether it is an appropriate surrogate endpoint for trials investigating therapies which slow progression of CKD. Critics of the use of proteinuria as a surrogate marker state that studies of ACEI or ARBs, which lower proteinuria, showed decreased risk of progression of CKD, but were not designed to test whether proteinuria itself was an appropriate target.[24] A recent meta-analysis of proteinuria as a surrogate marker suggested that data are limited and further assessment in prospective randomized controlled trials is needed.[25]

Smoking

Smoking is associated with an acute reduction in GFR and an increase in urinary albumin excretion, heart rate, and blood pressure, likely secondary to nicotine exposure.[26] Smoking is associated with kidney damage in the general population as well as in patients with diabetes and hypertension.[27] Smoking is also associated with an increase in CV events in people with CKD.[1]

Obesity

Population data from Kaiser Permanente revealed an increased risk of CKD 5 in overweight and obese subjects.[28] The risk of CKD 5 was directly related to the magnitude of obesity and remained even after adjustment for diabetes and hypertension. Another study showed that a body mass index (BMI) greater than or equal to 25 kg/m^2 at age 20 is associated with a threefold increase in risk of CKD compared with a BMI lower than 25 kg/m^2. Obesity (BMI ≥30 kg/m^2) among men and morbid obesity (BMI ≥35 kg/m^2) among women were associated with three- to fourfold increases in risk.[29] This finding has been supported by the results of a meta-analysis where the presence of kidney disease was associated with higher BMI and obesity led to more progressive loss of kidney function.[30]

Observational studies have shown obesity to be an independent risk factor for onset of CKD and a factor associated with the development of CKD secondary to focal and segmental glomerulosclerosis.[1,30,31,32] However, as evidenced by a meta-analysis, intentional weight loss in individuals with CKD was associated with decreases in proteinuria, systolic blood pressure, and stabilization in GFR during a mean follow-up of 7.4 months.[33] These data suggest that weight reduction be included as part of the treatment of CKD.

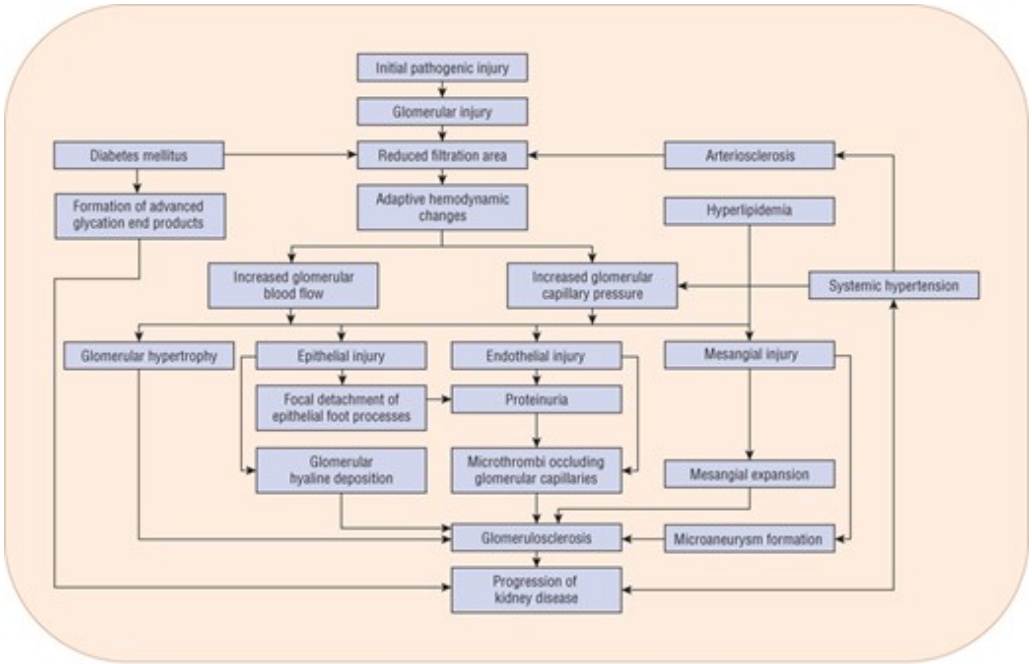
PATHOPHYSIOLOGY

Chronic Kidney Disease

Progression of CKD from category 1 to 5 occurs over decades in the majority of people, with the precise mechanism of kidney damage dependent on the etiology of the disease. As evidenced by the variety of initiation and progression factors, kidney damage can result from an array of heterogeneous causes. Diabetic CKD is characterized by glomerular mesangial expansion while with hypertensive nephrosclerosis, the kidney's arterioles have arteriolar hyalinosis. Polycystic kidney disease is characterized by the development and expansion of renal cysts.[34] While the initial structural damage depends on the primary disease affecting the kidney, the key elements of the pathway to ESRD are (a) loss of nephron mass, (b) glomerular capillary hypertension, and (c) proteinuria (**Fig. 44-2**).

FIGURE 44-2

Proposed mechanisms of progression of kidney disease.



Exposure to any of the initiation risk factors can result in loss of nephron mass. In response to the decrease in nephron function, the remaining nephrons compensate through the process of autoregulation. With nephron loss and the resulting reduction in perfusion pressure and GFR, renin release from the juxtaglomular apparatus increases and converts angiotensinogen to angiotensin I, which is then converted to angiotensin II (ATII). ATII is a potent vasoconstrictor of both afferent and efferent arterioles, but it preferentially affects the efferent arterioles, leading to increased pressure within the glomerular capillaries and consequent increased filtration fraction. Initially, this compensatory action may be adaptive and beneficial; however, over time it can lead to the development of intraglomerular hypertension and hypertrophy and a further decline in the number of functioning nephrons.[35] High intraglomerular capillary pressure impairs the size-selective function of the glomerular permeability barrier, resulting in increased urinary excretion of albumin and proteinuria. The development of intraglomerular hypertension usually parallels the development of systemic hypertension. ATII as well as aldosterone, may also mediate CKD progression through nonhemodynamic effects by increasing growth factors (eg, transforming growth factor beta [TGF-β]) and causing cellular proliferation and hypertrophy of the glomerular endothelial cells, epithelial cells, and fibroblasts ultimately resulting in further inflammation and fibrosis.[36]

Proteinuria alone may promote progressive loss of nephrons as a result of direct cellular damage. Filtered proteins such as albumin, transferrin, complement factors, immunoglobulins, cytokines, and ATII are toxic to kidney tubular cells. Numerous studies have demonstrated that the presence of these proteins in the renal tubule leads to increased production of inflammatory and vasoactive cytokines such as endothelin and monocyte chemoattractant protein-1 (MCP-1).[37] Proteinuria is also associated with the activation of complement components on the apical membrane of proximal tubules. Intratubular complement activation may be the key mechanism of damage in the progressive proteinuric nephropathies.[37] Furthermore, these events ultimately lead to scarring of the interstitium, progressive loss of structural nephron units, and a reduction in GFR.

Anemia of Chronic Kidney Disease

3 The primary cause of anemia of CKD is a decrease in production of erythropoietin, the glycoprotein hormone necessary for erythropoiesis (red blood cell production), by interstitial fibroblasts in the renal cortex of the kidney where approximately 90% of production occurs. In individuals with normal kidney function, plasma concentrations of erythropoietin increase exponentially in response to hypoxia; however, this response is lost as kidney disease progresses to CKD 3 and higher. The result is a normochromic (normal colored red cell), normocytic (normal size red cell) anemia (see Chapter 100).[38]

Iron deficiency is common in individuals with advanced kidney disease (ie, CKD 4 and 5) due to decreased gastrointestinal (GI) absorption of iron, inflammation, frequent blood testing, blood loss from hemodialysis (HD), and increased iron demands from erythropoiesis stimulating agent (ESA) therapy. It is the leading cause of resistance to ESAs and the reason frequent iron supplementation is necessary.[39] Hepcidin, a hormone produced by the liver directly inhibits the protein ferroportin that transports iron out of storage cells. When iron stores are high, hepcidin production is increased and results in a decrease in intestinal iron absorption, impairment of iron recycling from macrophages, and decreased mobilization of stored iron from hepatocytes. Hepcidin production is also induced by inflammation or infection. As a result, the increase in hepcidin in inflammatory conditions may lead to a sequestering of iron and ineffective red blood cell production. Conversely, hepcidin production is decreased when iron stores are low. The fact that hepcidin plays such a role in iron regulation has prompted the development of hepcidin antagonists to potentially alter iron transport.[40] At this time there are no commercially available agents.

Additional factors contributing to the development of anemia of CKD are the decreased red cell life span (from the normal of 120 days to approximately 60 days in individuals with CKD 5D), the effects of accumulation of uremic toxins and inflammatory cytokines, and vitamin B_{12} and folate deficiencies.[41]

Chronic Kidney Disease-Related Mineral and Bone Disorder

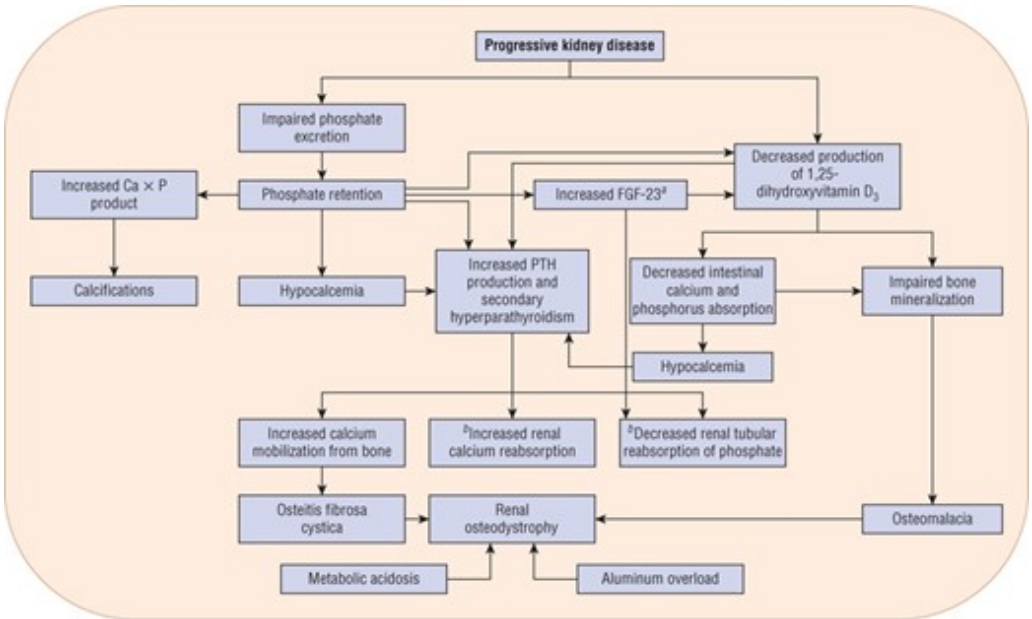
4 Disorders of mineral and bone metabolism are common in the CKD population and include abnormalities in PTH, calcium, phosphorus, vitamin D, fibroblast growth factor-23 (FGF-23), bone turnover, as well as soft-tissue calcifications. Historically these abnormalities have been described as characteristics of secondary hyperparathyroidism (sHPT) and renal osteodystrophy (ROD). The term CKD-MBD encompasses both of these abnormalities in mineral and bone metabolism as well as associated calcifications.[42]

The pathophysiology of CKD-MBD is complex (**Fig. 44-3**). Calcium and phosphorus homeostasis is mediated through the effects of PTH, 1,25-dihydroxyvitamin D_3 (calcitriol), and FGF-23 on bone, the GI tract, kidney, and the parathyroid gland. As kidney function declines, there is a decrease in phosphate elimination, which results in hyperphosphatemia and a decrease in serum calcium concentration. Hypocalcemia is the primary stimulus for secretion of PTH by the parathyroid glands.

Hyperphosphatemia also increases PTH synthesis and release through its direct effects on the parathyroid gland and production of prepro-PTH messenger RNA.[43] In an attempt to normalize ionized calcium, PTH increases calcium reabsorption by the distal tubules and decreases phosphate reabsorption in the proximal tubules of the kidney (at least until the GFR falls to approximately 30 mL/min/1.73 m^2 [0.29 mL/s/m^2]) and also increases calcium mobilization from bone. FGF-23 production in bone also increases in response to high phosphate levels and promotes phosphate excretion by the kidney. The result is a relative normalization of calcium and phosphorus, at least in the early stages of CKD; however, this occurs at the expense of an elevated PTH and FGF-23 ("the trade-off hypothesis").[44] The increase in PTH is most notable when GFR is less than 60 mL/min/1.73 m^2 (0.58 mL/s/m^2) (CKD 3a and higher) and worsens as kidney function further declines.[43] With advanced kidney disease, the kidney fails to respond to PTH or to FGF-23 and abnormalities in calcium and phosphorus worsen. Over time the negative effects of sustained hyperparathyroidism on bone are realized as calcium resorption from bone persists.

FIGURE 44-3

Pathophysiology of CKD-MBD. (Ca, calcium; FGF-23, fibroblast growth factor-23; PTH, parathyroid hormone.) [a]FGF-23 also increases in response to 1,25-dihydroxyvitamin D_3. [b]These adaptations are lost as kidney disease progresses.



[a]FGF-23 also increases in response to 1,25-dihydroxyvitamin D_3.

[b]These adaptations are lost as kidney disease progresses.

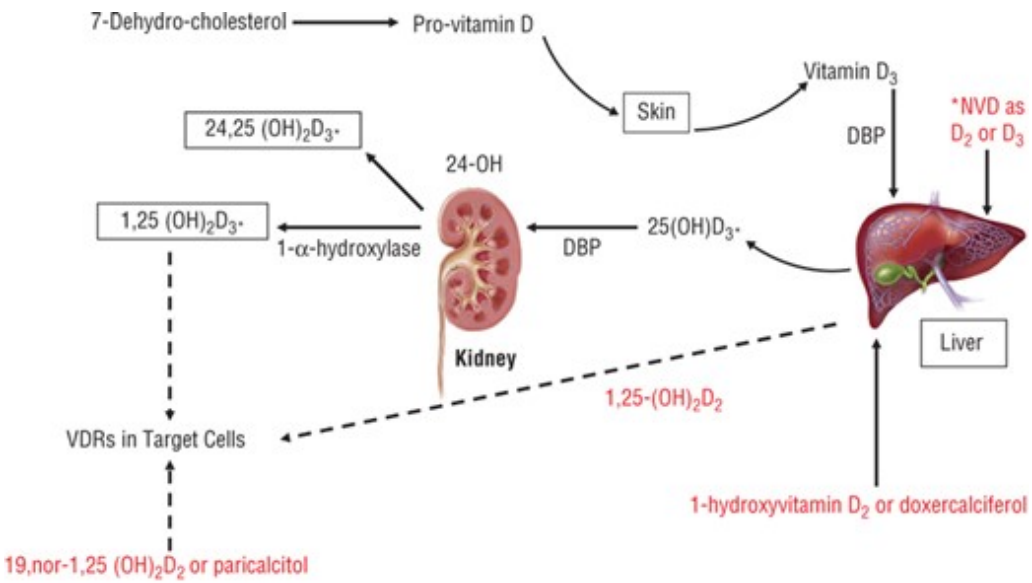
1,25-dihydroxyvitamin D_3 or calcitriol promotes increased intestinal absorption of calcium and phosphorus, which helps normalize ionized calcium. Calcitriol also works directly on the parathyroid gland to suppress PTH production. The enzyme 1-α-hydroxylase is responsible for the final hydroxylation and conversion of the vitamin D precursor, 25-hydroxyvitamin D or 25(OH)D, to calcitriol in the kidney (**Fig. 44-4**). As kidney disease progresses, the concentrations of calcitriol

e activity. The resultant vitamin D deficiency leads to reduced

intestinal calcium and phosphorus absorption and worsening hyperparathyroidism. Increases in FGF-23 also promote calcitriol deficiency.[45] Calcitriol deficiency is more prevalent in individuals with CKD 4-5.[46] Deficiency in 25(OH)D (levels of <30 ng/mL [<75 nmol/L]) is also common in individuals with CKD due to decreased dermal synthesis of vitamin D, decreased exposure to sunlight, and reduced dietary intake of vitamin D.[46]

FIGURE 44-4

Vitamin D metabolism. (DBP, vitamin D binding protein; NVD, nutritional vitamin D; VDRs, vitamin D receptors.) Production of active vitamin D requires conversion of 7-dehydrocholesterol to cholecalciferol (vitamin D_3) by sunlight, followed by the first hydroxylation step in the liver to form 25-hydroxyvitamin D_3 or 25(OH)D_3, and the final conversion step in the kidney to form 1,25-dihydroxyvitamin D_3 or calcitriol. Within the kidney vitamin D may also be converted to an inactive form 24,25(OH)D_3. *If NVD is administered the resulting compound will be either a D_2 compound (as with ergocalciferol) or a D_3 compound (as with cholecalciferol). Paricalcitol and doxercalciferol are vitamin D analogs.



The abnormalities of CKD-MBD lead to alterations in structural integrity of bone and other associated consequences. The continuous high rate of production of PTH by the parathyroid glands promotes parathyroid hyperplasia. Nodular tissue demonstrates more rapid growth potential and appears to be associated with fewer vitamin D and calcium-sensing receptors, resulting in resistance to exogenous calcitriol therapy.[43] Bone abnormalities are almost universal in dialysis patients and observed in the majority of those with CKD 3-5.[42] The bone abnormalities include osteitis fibrosa cystica (high bone turnover disease), osteomalacia (low bone turnover disease), and adynamic bone disease. Osteitis fibrosa cystica is most common and is characterized by areas of peritrabecular fibrosis. Bone marrow fibrosis and decreased erythropoiesis are also consequences of severe osteitis fibrosa cystica. Osteomalacia was historically noted in HD patients with aluminum toxicity, a finding less common

today due to the decreased use of aluminum-containing phosphate binders and changes in the processing of dialysate solutions to decrease aluminum content. Adynamic lesions are characterized by low amounts of fibrosis or osteoid tissue and low bone formation rates. Multiple risk factors for the development of this bone disease include high concentrations of dialysate calcium along with high doses of calcium-containing phosphate binders, aggressive management with vitamin D therapy, diabetes, and aluminum toxicity.[42]

The morbidity and mortality of CKD patients is increased in individuals with both severe hypo- and hyperparathyroidism (ie, less than two or greater than nine times the upper normal limit for the PTH assay, respectively).[42] Elevations of serum phosphorus, even within the upper limits of the normal range, have been associated with increased risk of CV events and/or mortality (all-cause or CV mortality) in patients with CKD 3-5.[47] The incidence of calciphylaxis, or rapid calcification of subcutaneous tissue, in patients with advanced kidney disease has increased over the past decade and has been associated with CKD-MBD, an elevated calcium times phosphorus product, and warfarin use.[42,48] Intake of calcium from calcium-based binders may also contribute to coronary artery calcification. These data underscore the need to consider all the consequences of elevated PTH, calcium, and phosphorus, not just their effects on bone.

CLINICAL PRESENTATION OF CHRONIC KIDNEY DISEASE

CKD is often asymptomatic, which is a reason many patients are not diagnosed with the disease until they reach CKD 4 or 5 and are at or near the point of requiring renal replacement therapy. This problem has prompted automated reporting by clinical laboratories of the eGFR as determined by the Modification of Diet in Renal Disease (MDRD) equation or Chronic Kidney Disease Epidemiology Collaboration equation (CKD-EPI equation) for the purpose of identifying individuals with CKD earlier (see Chapter 42). Clinicians must understand how to interpret the eGFR and values for urine albumin excretion to appropriately stage individuals with CKD. Chapter 42 provides a detailed discussion of the methods available for detection of urinary albumin and protein.

CLINICAL PRESENTATION Stage 4 or 5 Chronic Kidney Disease Symptoms

- Fatigue, weakness, shortness of breath, mental confusion, nausea and vomiting, bleeding, and loss of appetite, itching, cold intolerance, and peripheral neuropathies are common.

Signs

- Edema, weight gain (from accumulation of fluid), changes in urine output (volume and consistency), “foaming” of urine (indicative of proteinuria), and abdominal distension.

Laboratory Tests

- *Decreased*: eGFR, bicarbonate (metabolic acidosis), Hb/hematocrit (Hct) (anemia), transferrin saturation (TSat) and/or ferritin (iron deficiency; note: ferritin may be increased due to inflammatory conditions), vitamin D levels, albumin (malnutrition), glucose (may result from n with impaired kidney function or poor oral intake), and

calcium (in early stages of CKD).

- *Increased*: Serum creatinine, blood urea nitrogen, potassium, phosphorus, PTH, FGF-23, ACR, PCR blood pressure (hypertension is a common cause and result of CKD), glucose (uncontrolled diabetes is a cause of CKD), low-density lipoprotein (LDL) and triglycerides, and calcium (more likely in CKD 5).

- *Other*: May be hemoccult-positive if GI bleeding occurs secondary to uremia.

Other Diagnostic Tests

- Urine sediment abnormalities (hematuria, red blood cell and white blood cell casts, renal tubular epithelial cells)

- Pathologic abnormalities indicating glomerular, vascular, tubulointerstitial disease, or cystic and congenital diseases

- Structural abnormalities such as polycystic kidneys, renal masses, renal artery stenosis, cortical scarring due to infarcts and pyelonephritis, or small kidneys (common in more severe CKD) detected by imaging studies (eg, ultrasound, computed tomography, magnetic resonance imaging, angiography)

Diagnostic Considerations for Anemia of Chronic Kidney Disease

Signs and symptoms of anemia of CKD include fatigue, shortness of breath, cold intolerance, chest pain, tingling in the extremities, tachycardia, headaches, and general malaise. Since individuals with anemia of CKD may be asymptomatic, laboratory evaluation is commonly the initial approach to diagnosing anemia of CKD. According to the KDIGO guidelines Hb concentrations should be measured annually in CKD 3, biannually in CKD 4-5, and at least every 3 months in CKD 5D patients.[39] The diagnosis of anemia is made and further workup of anemia is required when the Hb is less than 13 g/dL (130 g/L; 8.07 mmol/L) for adult males and less than 12 g/dL (120 g/L; 7.45 mmol/L) for adult females.[39] As iron deficiency is the primary cause of resistance to treatment of anemia with ESAs, assessment of the iron status is necessary. The TSat provides information on iron immediately available for use in the bone marrow for red blood cell production and the serum ferritin is in indirect measure of storage iron. The TSat is calculated as follows: (serum iron/total iron-binding capacity [TIBC]) × 100. Transferrin is the carrier protein for iron and may be affected by nutritional status. Serum ferritin is an indirect measure of storage iron and an acute-phase reactant, meaning it may be elevated under certain inflammatory conditions and give a false indication of storage iron. Patients may be diagnosed with *absolute iron deficiency* when whole-body iron stores are low (low TSat and ferritin), or with *functional iron deficiency* when the TSat is low, but the serum ferritin is at or above goal. In this situation iron is not released rapidly enough to satisfy the demands for erythropoiesis and further evaluation is warranted. If the TSat and serum ferritin values are below the desired thresholds iron supplementation is warranted.

Additional workup should be done to evaluate other causes of anemia such as blood loss,

deficiencies in vitamin B_{12} or folate, or other disease states that contribute to anemia, including human immunodeficiency virus infection and malignancies (see Chapter 100). Red blood cell indices (mean corpuscular volume, mean corpuscular Hb concentration), white blood cell count, differential and platelet count, and absolute reticulocyte count should also be assessed. A stool guaiac test should be performed to rule out GI bleeding. Measurement of serum erythropoietin concentrations is not generally useful since levels may fall into what is considered a "normal" range, but are insufficient relative to the degree of decline in Hb.

Diagnostic Considerations for Chronic Kidney Disease-Related Mineral and Bone Disorder

Symptoms of CKD-MBD are often not evident until significant skeletal damage has developed; consequently, prevention is the key to minimize the risk of long-term complications. When signs and symptoms such as bone pain and skeletal fractures are evident, the disease is not easily amenable to treatment. Thus the identification of biochemical or imaging abnormalities which typically precede clinical manifestations is an essential component of patient evaluation. The biochemical abnormalities of CKD-MBD that are commonly present in patients with CKD include alterations in serum phosphorus, calcium, PTH, and 25(OH)D. Because deficiency in the vitamin D precursor, 25(OH)D is common and has been associated with negative outcomes in the CKD population, measurement of 25(OH)D levels in patients with CKD 3-5D is suggested.[42] It should be noted, however, that the assay methods for 25(OH)D are not standardized, which creates a challenge regarding the clinical implications of abnormal values and limits its value as an indicator of therapeutic response.[49] The Vitamin D Standardization Program may help apply uniform laboratory measurement processes among manufacturers of assays and clinical and research laboratories. Current monitoring recommendations and goals of therapy are covered in the section on "Treatment of CKD-MBD."[50]

In addition to evaluating biochemical indices that define CKD-MBD, evaluation of bone architecture may be desirable. The gold standard test for diagnosing bone manifestations of CKD-MBD is a bone biopsy for histologic analysis; however, this is a very invasive test that is not easily performed. KDIGO guidelines recommend bone biopsy only in patients in whom the etiology is not clear or in those with a nontraditional biochemical presentation.[42] This includes patients experiencing unexplained fractures, persistent hypercalcemia, and possible aluminum toxicity. If aluminum concentrations are elevated (60-200 µg/L [2.2-7.4 µmol/L]), a deferoxamine test should be done. KDIGO also suggests a bone biopsy be considered in CKD patients prior to beginning treatment with bisphosphonates since adynamic bone disease is a contraindication to the use of these agents. Bone biopsy findings are described on the basis of turnover rate, mineralization, and volume. Routine bone mineral density testing is not recommended in patients with CKD 3-5D since this test has not been shown to predict fracture risk and does not indicate the type of bone abnormality. CKD-MBD is also highly associated with vascular and soft-tissue calcifications, known risk factors for mortality; therefore, diagnostic testing for calcifications should be considered in the evaluation for CKD-MBD.[42]

TREATMENT of CKD

General Approach to Patient Care for Chronic Kidney Disease

Individuals with CKD should be evaluated frequently to assess the rate of progression of CKD, to identify the presence and causes of secondary complications and comorbid conditions, and to receive treatment for these complications prior to development of CKD 5D. Many nonpharmacologic and pharmacologic recommendations can be broadly applied as part of the general approach to care for all CKD patients **Table 44-4**.[1,22,51]

TABLE 44-4 Recommendations for Individuals with Chronic Kidney Disease

Nonpharmacologic

Exercise 30 minutes five times per week [1D]

Weight loss if BMI >25 kg/m^2 [1D]

Smoking cessation [1D]

Alcohol: Two standard drinks per day for men and one standard drink per day for women[a] [2D]

If hypertension: Low-sodium diet (<2 g/day, <90 mmol/day) [1C]

Pharmacologic

Adjust medication doses for kidney function [1A]

Seek pharmacist or medical advice before using over-the-counter medicines or nutritional protein supplements [1B]

Herbal medicines are not recommended [1B]

Temporarily discontinue potentially nephrotoxic/renally excreted drugs if eGFR <60 mL/min/1.73 m^2 in patients who are acutely unwell or hypovolemic (eg, metformin, RAAS blockers, diuretics, NSAIDs/COX II inhibitors, lithium, digoxin) [1C]

Vaccines:

- Influenza yearly [1B]
- Pneumococcal vaccine if eGFR <30 mL/min/1.73 m^2, nephrotic syndrome, diabetes, or receiving immunosuppression. Single booster dose at year 5 [1B]
- Hepatitis B vaccine if eGFR <30 mL/min/1.73 m^2 and risk of progression of CKD [1B]

ASA suggested for patients at risk for atherosclerotic events unless there is an increased bleeding risk [2B]

Avoid oral phosphate-containing bowel preparations in people with a GFR <60 mL/min/1.73 m^2 (<0.58 mL/s/m^2) or in those known to be at risk of phosphate nephropathy [1A]

BMI, kidney disease; COX; cyclooxygenase; eGFR, estimated

glomerular filtration rate; NSAIDs, nonsteroidal anti-inflammatory drugs; RAAS, renin–angiotensin–aldosterone system.

See Table 44-5 for definitions of evidence grading in brackets.

[a]Standard drink: 30 mL spirits, 100 mL wine, 285 mL full-strength beer, and 425 mL light beer.

From references 1, 22, and 51.

5 Management of CKD should be based on the most current consensus guidelines and the best clinical practices such as those developed by KDIGO, which are based on evidence, when available, and expert recommendations. These recommendations should not replace clinical judgment, but rather provide a basis on which treatment decisions can be made in the context of both evidence and opinion. The secondary complications of CKD that are addressed in the currently available KDIGO clinical practice guidelines address evaluation and management of CKD, blood pressure, CKD-MBD, anemia, lipid management, hepatitis C in CKD, and glomerulonephritis. **Table 44-5** provides a guide to the grading and strength of recommendations used in these guidelines. Where appropriate, comparisons with the Kidney Disease Outcome Quality Initiative (KDOQI) Guidelines will be made in this chapter.

TABLE 44-5 KDIGO Guidelines: Grading and Strength of Recommendations

Grade	Description	Implications for Clinicians
Level 1	"We recommend"	Most patients should receive the recommended course of action.
Level 2	"We suggest"	Different choices will be appropriate for different patients. Each patient needs help arrive at a management decision consistent with her or his values and preferences.
Grade	**Quality of Evidence**	**Meaning**
A	High	We are confident that the true effect lies close to that of the estimate of the effect.
B	Moderate	The true effect is likely to be close to the estimate of the effect, but there is a possibility that it is substantially different.
C	Low	The true effect may be substantially different from the estimate of the effect.
D	Very low	The estimate of effect is very uncertain, and often will be far from the truth.

The strength of recommendation is indicated as Level 1, Level 2, or Not Graded. The quality of the supporting evidence is shown as A, B, C, or D.

Date from reference 1.

6 Appropriate management of CKD ideally involves an interprofessional approach to address the nonpharmacologic and pharmacologic interventions, dietary education, and social/financial concerns. cial barriers, low health literacy, and psychosocial concerns are

just a few of the unique challenges that necessitate comprehensive services. Furthermore, CKD 5D patients are prescribed an average of 10 to 12 medications, which increases the potential for medication-related problems (MRPs; eg, inappropriate dose or indication for a medication, adverse drug reactions).[52] The typical team in outpatient dialysis facilities includes physicians (nephrologists), nurses, dietitians, and social workers as mandated by the United States government. Although not mandated to be part of the care team, nephrology-trained pharmacists are active members of the care team in some CKD and especially dialysis settings in the United States and their inclusion has resulted in a reduction of MRPs.[52,53] In Canada, pharmacists' involvement is more standardized and pharmacists have a more clearly delineated role in the care of the CKD population.[54]

Pharmacists can provide comprehensive medication management (CMM) services and collaborate with community care coordinators and pharmacists. It is estimated that over 70% of MRPs could be prevented with integrated pharmacy services that include CMM.[55] Drug-dosing guidelines based on the degree of kidney function should be followed, and a complete medication history of prescription and nonprescription medications, as well as herbals and nutritional supplements, should be obtained and routinely updated. General recommendations for drug dosing in CKD patients were developed at a 2011 KDIGO conference and are presented in detail for CKD and dialysis patients in Chapter 48.[56] Appropriate measures should also be taken for patients with CKD to decrease the risk of nephrotoxicity from radiocontrast agents, antibiotics such as aminoglycosides, as well as from nonsteroidal anti-inflammatory drugs and ACEIs (Chapter 46).

Desired Outcome of CKD Treatment

The overall goal of therapy in CKD patients is to delay or prevent progression of the disease while minimizing the development or severity of associated complications. During CKD 4 planning for renal replacement therapy (HD or PD) should begin, including patient education about dialysis modalities and options for transplantation (Chapter 45). With CKD 5D the primary goal is to sustain and improve, if possible, the patient's quality of life and prevent adverse outcomes by aggressively managing complications of CKD.

Nonpharmacologic Therapy for CKD

Nonpharmacologic therapies for CKD include diet and lifestyle interventions targeted at reducing the risk factors for CKD progression.

Diet

There is no convincing or conclusive evidence that long-term protein restriction delays the progression of CKD.[1] Protein restriction to 0.8 g/kg/day is recommended only in patients with an eGFR less than 30 mL/min/1.73 m^2 (ie, CKD 4) with appropriate monitoring by a dietitian to avoid malnutrition.[1] High sodium intake can increase blood pressure and proteinuria, blunt the response to renin–angiotensin system blockade, and induce glomerular hyperfiltration; therefore, decreasing sodium intake to less than 2 g or 90 mEq (mmol) per day (corresponding to 5 g sodium chloride) is

recommended, particularly in patients with preexisting hypertension or proteinuria (Table 44-4).[1]

Smoking Cessation, Exercise, and Weight Loss

Smoking cessation is encouraged to slow progression of CKD and to reduce the risk of CVD (Table 44-4). Clinicians should educate patients regarding the risks of smoking and institute appropriate therapeutic options, both nonpharmacologic and pharmacologic, for smoking cessation. These options are discussed in detail in Chapter 66. All individuals with CKD are encouraged to exercise at least 30 minutes five times per week and to achieve a BMI of 20 to 25 kg/m^2 if needed (see Chapter 144).[1]

Pharmacologic Therapy for CKD

Pharmacologic therapies used in slowing the progression of CKD include ACEIs and ARBs in patients with proteinuria as well as other antihypertensives used for achieving blood pressure targets. Glycemic control with oral hypoglycemic agents or insulin is also important for patients with diabetes mellitus.

Proteinuria

The antiproteinuric effect of ACEIs and ARBs is a class effect and not specific to any one agent.[22] For patients with hypertension, the primary goal is to achieve the target blood pressure while a secondary goal is to control proteinuria. For patients with DCKD, an ACEI or an ARB should be used as first-line therapy if the patient's urine albumin excretion is in category A2 or greater (ACR between 30-300 mg/g).

Specific dosing recommendations for ACEIs and ARBs for the treatment of proteinuria have not been established; consequently, the lowest recommended dose should be initiated. The dose is usually increased until albuminuria is reduced by 30% to 50% or side effects such as a greater than 30% decrease in eGFR or elevation in serum potassium occur (see Chapter 13). If patients exhibit a cough with an ACEI, a switch to an ARB is appropriate.

7 Evidence from clinical trials has confirmed the beneficial effects of ACEIs and ARBs on kidney function for DCKD. A meta-analysis has shown that the effects of ACEIs or ARBs on key CKD outcomes such as doubling of creatinine and prevention of progression of micro- to macroalbuminuria are equivalent and, thus, they can be used interchangeably.[57] A thorough discussion of dose, dose titration, monitoring, and adverse effects of ACEIs and ARBs is presented in Chapter 13.

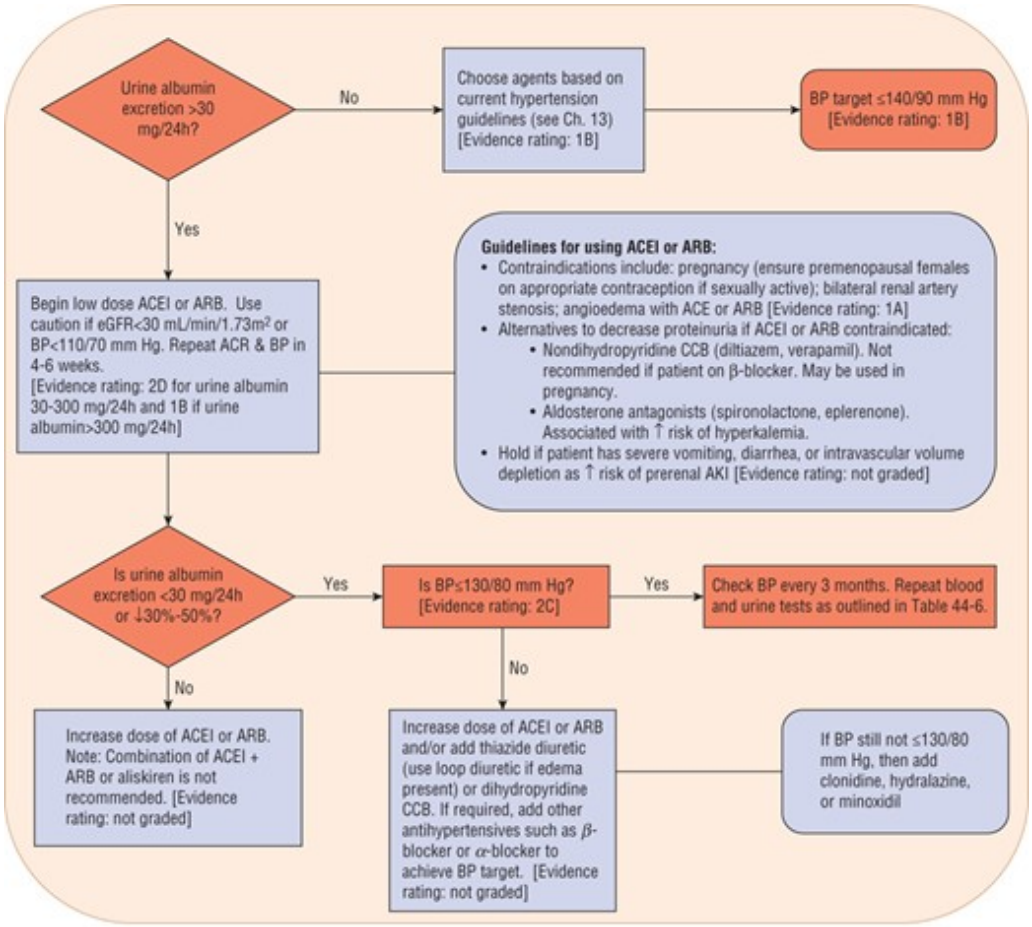
The lack of response of some patients to ACEI or ARB therapy may be due to aldosterone escape from renin–angiotensin–aldosterone system (RAAS) blockade. Combination therapy with an ACEI plus an ARB produces a more complete blockade of the RAAS and results in a greater reduction in macroalbuminuria.[58] As a result, it was postulated that dual therapy would slow progression of CKD [illegible] ready receiving the maximum dose of an ACEI or an ARB alone,

but who still had macroalbuminuria.[59] The ONTARGET study first raised concerns with the use of an ACEI plus an ARB.[60] This study randomized 25,620 patients with established atherosclerotic vascular disease or diabetes with end-organ damage to telmisartan, ramipril, or a combination of the two drugs. The composite outcome of dialysis, renal transplantation, doubling of serum creatinine, or death occurred more frequently in patients receiving combination treatment than in either of the two other groups, despite a lower degree of albuminuria and less progression to microalbuminuria or macroalbuminuria. These findings led some to advise against the combination of these two agents; however, critics of the study argued that these findings cannot be extrapolated to individuals with proteinuric kidney disease as only 4% of patients in the study had overt proteinuria.[61] Combination therapy with an ACEI and an ARB in diabetic patients with CKD and macroalbuminuria in the VA NEPHRON D study revealed that ACEI plus ARB therapy increased the risk of acute kidney injury (12.2 vs 6.7 events per 100 person-years, p <0.001) and hyperkalemia (6.3 vs 2.6 events per 100 person-years, p <0.001) with no reduction in mortality.[62] Two other randomized controlled trials (ALTITUDE and a subgroup analysis of ORIENT) which employed various combinations of ACEI and ARB or aliskiren, a direct renin inhibitor, failed to show that dual blockade of the RAAS either slowed progression of CKD or decreased CV events.[63,64] Combination therapy in these trials was also associated with increased risks of hyperkalemia and acute kidney injury. Thus, the combination of an ACEI plus an ARB or aliskiren for the treatment of DCKD, even in patients with macroalbuminuria, is no longer recommended.

The concept of aldosterone escape has led to the search for other drug combinations to further suppress the RAAS in an effort to improve kidney outcomes. A Cochrane systematic review examined the addition of an aldosterone antagonist (spironolactone) to an ACEI or ARB (or both) in patients with CKD1-4.[65] Aldosterone antagonists significantly reduced proteinuria and blood pressure, but doubled the risk of hyperkalemia and significantly increased the risk of gynecomastia. However, it is unknown whether adding spironolactone to ACEI or ARB (or both) will reduce the risk of major CV events or ESRD. Another meta-analysis of spironolactone in DCKD reported similar results.[66] Dihydropyridine calcium channel blockers (CCBs) do not appear to have any beneficial effects beyond those attributable to reducing blood pressure. Nondihydropyridine agents (diltiazem and verapamil), however, have yielded beneficial effects on proteinuria, although not as profoundly as ACEIs.[67] The postulated mechanisms for this decrease in kidney injury include suppression of glomerular hypertrophy, inhibition of platelet aggregation, and a decrease in salt accumulation. These agents have been used to reduce proteinuria in combination with an ACEI or ARB despite the fact that there are limited data to support this strategy. In general, nondihydropyridine CCBs should be considered second-line antiproteinuric drugs when an ACEI or ARB is contraindicated or not tolerated (Figure 44-5).[68]

FIGURE 44-5

Treatment of hypertension in chronic kidney disease.[22] (ACEI, angiotensin-converting enzyme inhibitor; ACR, albumin-to-creatinine ratio; AKI, acute kidney injury; ARB, angiotensin receptor blocker; BP, blood pressure; CCB, calcium channel blocker; eGFR, estimated glomerular filtration rate.)



Endothelin-1 is present in the renal microvasculature, glomerular cells, and in the tubules, and exerts its actions via the endothelin A and B receptors. In type 2 diabetics a trial of the endothelin antagonist, avosentan was terminated early because of increased edema and heart failure.[69] The impact of atrasentan, another endothelin antagonist, on CKD progression when added to RAAS inhibitor therapy in patients with type 2 diabetes and CKD revealed that it significantly reduced albuminuria, blood pressure, LDL cholesterol, and triglycerides.[70] A longer trial examining the efficacy of atrasentan on preventing progression of DCKD is now underway, the Study of Diabetic Nephropathy with Atrasentan (SONAR), with results expected in 2018.[71]

Glomerulonephritis is the third leading cause of CKD and almost all of the many variants are associated with significant proteinuria. A thorough review of the epidemiology, pathophysiology, and treatment strategies is provided in Chapter 47.

Hypertension

Figure 44-5 provides an algorithm for the recommended blood pressure goals based on the degree of albuminuria present and the choice of antihypertensive agent. Previous guidelines suggested a target blood pressure of less than 130/80 mm Hg for all patients with CKD. A meta-analysis of 2,272 subjects with nondiabetic kidney disease concluded that no benefits in kidney, CV outcomes, or mortality were achieved in patients treated to a goal blood pressure of 125 to 130/75 to 80 mm Hg

as compared with 140/90 mm Hg.[72] Subjects with proteinuria greater than 300 mg/day did benefit from the lower blood pressure target. The Systolic Blood Pressure Intervention Trial (SPRINT) assessed whether a lower systolic blood pressure goal of less than 120 mm Hg versus a target of less than 140 mm Hg was desirable.[73] Patients aged 50 years or older with a systolic blood pressure of 130 to 180 mm Hg and an increased risk of CV events were included. CKD 3a to 4 patients (eGFR of 20-59 mL/min/1.73 m^2) were enrolled into this trial as they were considered to be at high CV risk (see chapter 13 for a discussion of non-CKD results). It is important to note that patients with a history of diabetes, category A3 proteinuria defined as greater than or equal to 1 g/24 hours of protein or albuminuria greater than or equal to 600 mg/24 hours, polycystic kidney disease, or a history of stroke were excluded. In the 2,646 participants with CKD, the composite renal outcome of a decrease in eGFR of 50% or more or the need for chronic dialysis or kidney transplantation was not significant over the 3.3 years duration of this trial. There were also potential harms to all participants (with and without CKD) in the intensive systolic blood pressure group that included significantly increased risks of syncope, hypotension, electrolyte abnormalities, AKI and CKD progression.[72] The current KDIGO Blood Pressure guidelines recommend a target blood pressure of less than or equal to 140/90 mm Hg for those with category A1 albuminuria.[22] In patients with category A2 and higher albuminuria, the target blood pressure is less than or equal to 130/80 mm Hg and first-line therapy with an ACEI or ARB is recommended.[22] If this regimen fails to achieve the target blood pressure, then the addition of a thiazide diuretic may be warranted.[74,75] KDIGO has started the process to review the SPRINT trial and other new data to determine if revisions to its blood pressure guideline are warranted.[22]

Clinical Controversy…

It has been widely quoted that thiazide diuretics are not effective for blood pressure control for CKD 4 and 5, but there is limited evidence to support this statement.[155] While salt and water excretion may initially account for their antihypertensive effect, long-term lowering of blood pressure appears to involve direct vasodilation that is not affected by kidney function. A number of small trials have demonstrated significant blood pressure lowering with systolic blood pressure reductions of 12 to 15 mm Hg in patients with CKD 4 and 5.[76] Various thiazide diuretics have been used including hydrochlorothiazide 25 mg daily, indapamide 1.5 to 5 mg daily, and chlorthalidone 25 mg daily. In addition, thiazides have also been combined with loop diuretics, such as furosemide 40 to 80 mg daily, with reductions in systolic blood pressure of 15 to 22 mm Hg so this combination may also have benefits.[76] A larger randomized controlled trial of the safety and efficacy of thiazides added to existing antihypertensives in individuals with CKD 4 and 5 is needed.

The choice of additional antihypertensive agents should be based on concomitant disease states and other compelling indications as discussed in Chapter 13. Patients and clinicians should be aware that targeting a blood pressure of less than 130/80 mm Hg will often require three or more drugs.

Diabetes

Patients with diabetes should be screened annually for CKD starting at the time of diagnosis of type 2

diabetes and 5 years after the diagnosis of type 1 diabetes by ordering a serum creatinine, eGFR, and a urine albumin-to-creatinine ratio (ACR).[51]

The management of diabetes in patients with CKD includes reduction of proteinuria and achievement of desired blood pressure and HbA1c (Chapter 74). The HbA1c target in this patient population should be 7% (0.07; 53 mmol/mol Hb); however, clinicians may consider a target greater than 7% (0.07; 53 mmol/mol Hb) if there is a risk of hypoglycemia or limited life expectancy (Evidence rating: 1A).[51] It should be noted that HbA1C measurements are based on an assumed red blood cell life span of 90 days. In CKD, the red blood cell life span is decreased, so HbA1c values may be falsely low.[51] Hence, in patients with CKD, the HbA1c should be interpreted along with the patient's home blood glucose readings before making a determination of diabetic control. It is also important to note that patients with CKD 3 and 4 are at higher risk of developing hypoglycemia because of the reduction in metabolism of insulin by the kidney as GFR declines. As a result, these patients may require reduced doses of oral or injectable hypoglycemic agents. Metformin can be continued in people with eGFR greater than or equal to 45 mL/min/1.73 m^2; reviewed in those with an eGFR 30 to 44 mL/min/1.73 m^2, and discontinued in individuals with an eGFR less than 30 mL/min/1.73 m^2 (Evidence level: not graded).[51] Dose adjustments or avoidance of other renally eliminated hypoglycemic agents may be necessary; the dosing, monitoring, and goals of therapies to treat diabetes mellitus is provided in Chapter 74 and an evidence-based approach to drug therapy individualization is presented in Chapter 48.

Personalized Pharmacotherapy

The clearance of all ACEIs (with the exception of fosinopril) is reduced in CKD; therefore, it is necessary to initiate therapy at lower initial doses and subsequently titrate the dose to achieve the optimal therapeutic effects such as decreased proteinuria and blood pressure. The antiproteinuric effects of ACEIs/ARBs are not necessarily attained at the same doses as the antihypertensive effects. Thus, individualization of therapy is required for patients who have reached their blood pressure goals yet require further reductions in urinary protein excretion.

Evaluation of Therapeutic Outcomes

Frequency of laboratory and urine testing based on CKD category and degree of albuminuria as defined by KDIGO is shown in **Table 44-6**. The monitoring necessary for patients with hypertension and diabetes is the same in the CKD population as it is in the non-CKD population, and readers should refer to the appropriate chapters in this textbook for further information.

TABLE 44-6 Recommended Monitoring Intervals for Outcome Measure in Patients with Chronic Kidney Disease (Evidence Rating: Not Graded)

		Albuminuria Stage (based on ACR in mg/g)		
KDIGO GFR Category	**eGFR (mL/min/1.73 m^2)**	**A1: <30 mg/g (<3 mg/mmol)**	**A2: 30-300 mg/g (3-30 mg/mmol)**	**A3: >300 mg/g (>30 mg/mmol)**
1	>90	12 months	12 months	6 months

		Albuminuria Stage (based on ACR in mg/g)		
KDIGO GFR Category	**eGFR (mL/min/1.73 m^2)**	**A1: <30 mg/g (<3 mg/mmol)**	**A2: 30-300 mg/g (3-30 mg/mmol)**	**A3: >300 mg/g (>30 mg/mmol)**
2	60-89	12 months	12 months	6 months
3a	45-59	12 months	6 months	4 months
3b	30-44	6 months	4 months	4 months
4	15-29	4 months	4 months	2-3 months
5	<15	1-3 months	1-3 months	1-3 months

Blood tests to monitor: CBC, Na, K, Cl, bicarbonate, urea, creatinine, and eGFR. If DKD, add HbA1C. Fasting lipid profile at least yearly. At CKD category 3b or later: also add albumin, calcium, phosphorus, parathyroid hormone, serum iron, TIBC, and ferritin.

Urine tests to monitor: ACR (or PCR if indicated), standard urinalysis, and urine culture and sensitivity only if symptoms suggestive of urinary tract infection.

Anemia, CKD-MBD, and CVD

Treatment of CKD Complications

Treatment of anemia often requires a combination of iron supplementation and ESA therapy to promote and maintain erythropoiesis and to achieve the individual patient goals.

Desired Outcome

The desired outcomes of anemia management are to increase oxygen-carrying capacity, decrease signs and symptoms of anemia, and decrease the need for blood transfusions. Hb is the preferred monitoring parameter for red blood cell production because, unlike Hct, its concentration is not affected by blood storage conditions and instrumentation used for analysis. Initiation of iron or ESA therapy is guided by the patient's Hb, TSat, and ferritin (**Table 44-7**).[39] The risk of mortality and CV events is higher in CKD patients treated to higher Hb target values with an ESA. There are discrepancies, however, in the FDA-approved labeling for ESAs and the KDIGO and KDOQI anemia guidelines in terms of when to initiate therapy and the target Hb.[39,77,78] Notably the KDOQI guidelines suggest a Hb range of 11 to 12 g/dL (110-120 g/L; 6.83-7.45 mmol/L) for all CKD patients, a target TSat of greater than 20% (>0.20), and a serum ferritin of greater than 100 ng/mL (µg/L; >225 pmol/L) for CKD patients not requiring HD and greater than 200 ng/mL (µg/L; >450 pmol/L) for CKD 5HD patients.

TABLE 44-7 KDIGO Recommendations for Initiation of Erythropoiesis Stimulating Agents and Iron in Anemia of Chronic Kidney Disease[a]

	ND-CKD	CKD 5HD and CKD 5PD	Pediatric CKD

	ND-CKD	CKD 5HD and CKD 5PD	Pediatric CKD
ESA initiation	If Hb <10 g/dL (<100 g/L; <6.21 mmol/L). Consider rate of fall of Hb, prior response to iron, risk of needing a transfusion, risk of ESA therapy, and presence of anemia symptoms before initiating an ESA. [2C] Do not initiate if Hb ≥10 g/dL (≥100 g/L; ≥6.21 mmol/L). [2D]	Use ESAs to avoid drop in Hb to <9 g/dL (<90 g/L; <5.59 mmol/L) by starting an ESA when Hb is between 9 and 10 g/dL (90 and 100 g/L; 5.59 and 6.21 mmol/L). [2B]	Selection of Hb concentration at which to initiate ESA therapy should include consideration of potential benefits (eg, improvement in QOL, school attendance, avoidance of blood transfusions) and potential harms. [2D]
Hb level	Do not use ESAs to *intentionally* increase Hb above 13 g/dL (130 g/L, 8.07 mmol/L). [1A] Do not use ESAs to maintain Hb above 11.5 g/dL (115 g/L; 7.14 mmol/L). [2C]	Do not use ESAs to *intentionally* increase Hb above 13 g/dL (130 g/L, 8.07 mmol/L). [1A] Do not use ESAs to maintain Hb above 11.5 g/dL (115 g/L; 7.14 mmol/L). [2C]	Suggest Hb range of 11-12 g/dL (110-120 g/L, 6.83-7.45 mmol/L). [2D]
Iron initiation[b]	If TSat is ≤30% (≤0.30) and ferritin is ≤500 ng/mL (µg/L; ≤1,120 pmol/L). [2C]	If TSat is ≤30% (≤0.30) and ferritin is ≤500 ng/mL (µg/L; ≤1,120 pmol/L). [2C]	If TSat is ≤20% (≤0.20) and ferritin is ≤100 ng/mL (µg/L; ≤225 pmol/L). [1D]

CKD, chronic kidney disease; ESA, erythropoiesis stimulating agent; Hb, hemoglobin; ND-CKD, nondialysis CKD patients; QOL, quality of life; TSat, transferrin saturation.

See Table 44-5 for definitions of evidence grading in brackets.

[a]The Kidney Disease Outcome Quality Initiative (KDOQI) Anemia Guidelines are discussed in the text.

[b]If TSat and serum ferritin are below suggested levels, consider iron supplementation if goal is to increase Hb and/or decrease ESA dose. *Note*: Serum ferritin is an acute-phase reactant-use clinical judgment when above 500 ng/mL (µg/L; 1120 pmol/L).

Date from reference 39.

Despite associations of development of left ventricular hypertrophy (LVH) with worsening anemia, there are no prospective studies demonstrating that early and aggressive treatment improves CV end points or reduces LVH in CKD patients. Improvements in quality of life have been observed with increases in Hb in select populations, but such improvements must be weighed against reported risks e near-normal Hb levels in the CKD population.[79]

Target Hemoglobin and Use of Erythropoiesis Stimulating Agents

The target range for Hb in the CKD population has been a topic of much debate. Although the benefits of achieving a normal or near normal Hb seemed rational when ESAs became available in the late 1980s, the Normal Hematocrit Cardiac Trial (NHCT),[80,81] the Correction of Hb and Outcomes in Renal Insufficiency (CHOIR),[82] and the Cardiovascular Risk Reduction by Early Anemia Treatment with Epoetin Beta (CREATE)[83] trials later proved otherwise, and the suggested target Hb at the time of those trials of 11 to 12 g/dL (110-120 g/L; 6.83-7.45 mmol/L) was subsequently lowered. Several FDA advisories were released and changes were made to the precautions, black box warning, and dosing sections of ESA product labeling promoting more conservative use of ESAs.[84] The current labeling for all ESAs warns that dosing ESAs to target Hb levels greater than 11 g/dL (110 g/L; 6.83 mmol/L) for CKD patients increases the risk for death, serious CV reactions, and stroke. Practitioners are advised to consider ESAs in patients with CKD only when the Hb is below 10 g/dL (100 g/L; 6.21 mmol/L) and to individualize therapy to use the lowest ESA dose necessary to decrease the need for red blood cell transfusions.

Of concern is the fact that CHOIR demonstrated that targeting Hb levels above 11 g/dL (110 g/L; 6.83 mmol/L) with ESA therapy in individuals with CKD not requiring dialysis resulted in increased risk of mortality and CV events compared with patients maintained in a lower Hb range (trial was terminated early).[82] CREATE demonstrated no benefit of targeting a higher Hb target (13-15 g/dL [130-150 g/L; 8.07-9.31 mmol/L]) to reduce CV events in the non-dialysis CKD patients.[83] An increased risk of all-cause mortality with ESA treatment was also reported in a meta-analysis of nine randomized controlled trials that included over 5,100 CKD patients treated to Hb targets in the range of 12 to 16 g/dL (120-160 g/L; 7.45-9.93 mmol/L).[85] There was also a higher risk of dialysis access thrombosis and uncontrolled blood pressure in the higher Hb groups. Results from the Trial to Reduce Cardiovascular Events with Aranesp Therapy (TREAT) also failed to support a higher Hb.[86] In addition, there was also an almost twofold increase in the risk of stroke (5% in the treatment group vs 2.6% in the placebo group), a finding that was not associated with baseline characteristics of the patients or other potential risk factors.[87] Those patients with a history of cancer in the higher Hb group also had a higher risk of death, a finding that requires additional investigation.

The overall negative CV outcomes observed with higher Hb targets in the randomized trials have prompted much discussion about the potential causes, including not only ESA dose and Hb target, but also the rate of rise in Hb and the variability in Hb over time (eg, degree of fluctuation in Hb).[88] Subsequent analysis of the CHOIR study showed that high-dose ESA use was associated with greater risk of death.[89] Those individuals able to achieve the target Hb in the CHOIR study did not have worse outcomes. Further analysis of the NHCT data also showed a reduction in mortality by 60% for those individuals who responded to epoetin therapy compared with nonresponders.[90] Such findings have led to discussion of whether hyporesponsiveness to ESAs due to other conditions such as inflammation may explain the higher event rates in this group of individuals.

Clinical Controversy...

Recommendations in the product labeling for ESAs differ from KDIGO and KDOQI guidelines with regard to the "target" Hb. The KDIGO expert panel considered the quality of the evidence regarding target Hb to be *low* or *very* low (2C or 2D grade recommendations). Clinicians should always take into account trends in Hb when adjusting ESA doses. Before making treatment decisions, the risks of ESA use and targeting Hb values greater than 11 g/dL (110 g/L; 6.83 mmol/L) must be weighed against the benefit of fewer blood transfusions.

Nonpharmacologic Therapy

Nonpharmacologic therapy for anemia of CKD includes maintaining adequate dietary intake of iron as well as folate and B_{12}. A relatively small amount of dietary iron, approximately 1 to 2 mg, is absorbed each day, primarily in the duodenum (see Chapter 101). Although there is some debate as to whether GI absorption of iron is significantly altered in patients with severe CKD, it is clear that oral intake from dietary sources alone is insufficient to meet the increased iron requirements from initiation of ESA therapy.

Pharmacologic Therapy

8 Pharmacologic therapy for anemia of CKD includes iron supplementation to prevent and correct iron deficiency and ESA therapy to correct erythropoietin deficiency. Iron supplementation is first-line therapy for anemia of CKD if iron deficiency is present, and for some patients the target Hb may be achieved without concomitant ESA therapy. For most individuals with advanced CKD, however, combined therapy with iron and an ESA will be necessary to achieve the target Hb.

Iron Supplementation

Iron supplements provide the elemental iron required for production of Hb and its subsequent incorporation in red blood cells, the net result of which is an increase in the transportation of oxygen to tissues. Iron supplementation is required for *absolute iron deficiency*, but may also be warranted in individuals with a TSat less than 30% (<0.30) and a ferritin less than 500 ng/mL (µg/L; <1120 pmol/L) in whom an increase in Hb or a decrease in ESA dose is desired.[39]

Therapeutic Options

Multiple oral and IV products are marketed in the United States as well as a newly approved dialysate iron formulation. Oral iron preparations include ferrous salts (ferrous sulfate, ferrous fumarate, and ferrous gluconate), polysaccharide iron complex, and carbonyl iron. These forms of iron differ in terms of the amount of elemental iron: ferrous sulfate (20%), ferrous gluconate (12%), ferrous fumarate (33%), iron polysaccharide (100%), and carbonyl iron (100%). A heme iron polypeptide formulation is also available and contains 12 mg of elemental iron. Numerous nonprescription as well as prescription products that contain these iron formulations are available (see Table 101-2). Approximately 10% of orally administered iron is absorbed in the duodenum and upper jejunum. Absorption of iron is decreased by food and achlorhydria. Some oral iron formulations also include

tion.

Soluble ferric pyrophosphate citrate (Triferic) was approved in the United States in January 2015.[90] This iron compound is designed to be added to the dialysate used for HD and crosses from the dialysate to the blood side of the dialyzer by diffusion to allow for continuous iron administration during the procedure. Once in the systemic circulation ferric pyrophosphate binds directly to transferrin, bypassing the reticuloendothelial system, and is delivered to the bone marrow for use in red blood cell production. Studies performed to date have shown an increase in Hb concentration and a reduction in ESA dose and IV iron requirements, but no significant increase in ferritin or in nontransferrin bound iron.[91,92] These findings are important when considering the potential adverse effects associated with iron accumulation and free (unbound) iron. The role of this agent in treating anemia of CKD is yet to be determined as this agent is introduced in the clinical setting.

IV iron preparations are colloids that consist of an iron-containing core that is surrounded by a carbohydrate shell to stabilize the iron complex. Available agents differ in the size of the core and the composition of the surrounding carbohydrate. Such differences affect the rate of dissociation of iron from the complex, the rate of distribution, and the maximum tolerated dose and rate of infusion. Six IV iron products are currently available in the United States. (**Table 44-8**).

TABLE 44-8 IV Iron Preparations

Iron Compounds	Brand Names	Half-Life (Hours)	Molecular Weight (Daltons)	FDA-Approved Indications	FDA-Approved Dosing[a]	Dose Ranges (mg)[b]
Ferric carboxymaltose	Injectafer	7-12	150,000	Adult patients with intolerance to oral iron or who have had an unsatisfactory response to oral iron and in adult patients with CKD not on dialysis	Give 2 doses separated by at least 7 days of 750 mg per dose (if body weight is ≥50 kg) or 15 mg/kg per dose (if body weight is <50 kg) not to exceed 1,500 mg per course. Give either IV push (100 mg per min) or diluted in not more than 250 mL of 0.9 NaCl as an infusion over at least 15 minutes	750
Ferumoxytol	Feraheme	15	750,000	Adult patients with iron-deficiency anemia associated with chronic kidney disease	510 mg (17 mL) as a single dose, followed by a second 510 mg dose 3-8 days after the initial dose. Dilute in 50-200 mL	510

Iron Compounds	Brand Names	Half-Life (Hours)	Molecular Weight (Daltons)	FDA-Approved Indications	FDA-Approved Dosing[a]	Dose Ranges (mg)[b]
					of 0.9% NaCl or 5% dextrose and administer as an IV infusion over 15 minutes	
Iron dextran	INFeD Dexferrum	40-60	96,000 265,000	Patients with iron deficiency in whom oral iron is unsatisfactory or impossible	100 mg over 2 minutes (25-mg test dose required) Note: Equation provided by manufacturer to calculate dose based on desired Hb	25-1,000
Iron sucrose	Venofer	6	43,000	Adult and pediatric CKD 5HD patients aged 2 years and older	Adult: 100 mg over 2-5 minutes or 100 mg in maximum of 100 mL of 0.9% NaCl over 15 minutes per consecutive HD session Pediatric: 0.5 mg/kg not to exceed 100 mg per dose over 5 minutes or diluted in 25 mL of 0.9% NaCl administered over 5-60 minutes (give dose every 2 weeks for 12 weeks)	25-1,000
				Adult and pediatric ND-CKD patients aged 2 years and older	Adult: 200 mg over 2–5 minutes on five different occasions within 14-day period. There is limited experience with administration of 500 mg diluted in a maximum of 250 mL	

Iron Compounds	Brand Names	Half-Life (Hours)	Molecular Weight (Daltons)	FDA-Approved Indications	FDA-Approved Dosing[a]	Dose Ranges (mg)[b]
					of 0.9% NaCl over 3.5 to 4 hours on day 1 and day 14 Pediatric: see pediatric dosing for CKD 5HD (give dose every 4 weeks for 12 weeks)	
				Adult and pediatric CKD 5PD patients aged 2 years and older	Adult: Give 3 divided doses within 28 days as 2 infusions of 300 mg over 1.5 hours 14 days apart followed by one 400 mg infusion over 2.5 hours 14 days later. Dilute in a maximum of 250 mL of 0.9% NaCl Pediatric: see pediatric dosing for CKD 5HD (give dose every 4 weeks for 12 weeks)	
Sodium ferric gluconate	Ferrlecit	1	350,000	Adult and pediatric CKD 5HD patients aged 6 years and older receiving ESA therapy	Adult: 125 mg over 10 minutes or 125 mg in 100 mL of 0.9% NaCl over 60 minutes Pediatric: 1.5 mg/kg in 25 mL of 0.9% NaCl over 60 minutes; maximum dose 125 mg per dose	62.5-1,000

CKD, chronic kidney disease; ESA, erythropoiesis stimulating agent; ND-CKD, non-dialysis CKD

[a]Monitor for 30 minutes following an infusion; KDIGO guidelines recommend monitoring for 60 minutes (1B recommendation for iron dextran, 2C recommendation for non-dextran products).

[b]With the exception of ferric carboxymaltose and ferumoxytol, small doses (eg, 25-150 mg/wk) are generally used for maintenance regimens. Larger doses (eg, 1 g) should be administered in divided doses.

Either oral or IV administration of iron is recommended in non-HD patients (eg, CKD category 3 or higher and PD patients). Oral iron supplementation is more convenient since these patients do not have regular IV access; however, at some point they are likely to require IV iron supplementation to correct absolute iron deficiency, especially if they are receiving an ESA. The route of administration should be based on the severity of iron deficiency, availability of IV access, response to prior oral iron therapy, side effects, patient adherence to therapy, and cost. If oral therapy is initiated a 1- to 3-month trial is recommended to assess response. In patients with CKD 5HD GI absorption of iron is often inadequate to meet the increase in iron demand from ESA therapy and chronic blood loss. Thus the IV route is preferred for almost all HD patients.[39,78] IV administration is also recommended in the PD population, although the desire to preserve potential future venous access sites for HD (if needed) must be considered. Parenteral iron improves the responsiveness to ESA therapy and, thus, lower doses can be used to maintain the target Hb in HD patients.[39] Iron administration in patients with functional iron deficiency (ie, low TSat, high serum ferritin) is questionable. A trial of IV iron therapy may be warranted if the Hb is less than desired despite high dose ESA therapy.

Adverse Effects

Adverse effects of oral iron are primarily GI in nature and include constipation, nausea, and abdominal cramping (see Chapter 100). These adverse effects are more likely as the dose is escalated and may be present in more than 50% of patients receiving 200 mg of elemental iron per day. These unfavorable effects often discourage patients from taking these medications on a chronic basis. Some of these GI side effects can be minimized if oral iron products are taken with food; however, food may decrease absorption of oral iron.

Adverse effects of IV iron include allergic reactions, hypotension, dizziness, dyspnea, headaches, lower back pain, arthralgia, syncope, and arthritis. Some of these reactions, in particular hypotension, can be minimized by decreasing the dose or rate of infusion of iron. The most concerning potential consequence of IV iron administration is anaphylaxis. Serious reactions to iron dextran including respiratory complications and CV collapse have been reported in approximately 0.6% to 0.7% of patients.[39] Such reactions are believed to be partly a response to antibody formation to the dextran component. Adverse reactions have been reported more frequently in those receiving Dexferrum compared with INFeD and it should be noted that these iron dextrans products are not interchangeable.[39] Iron dextran products carry a black box warning of the risk of anaphylactic-type reactions, including fatalities, and a 25-mg test dose is required. A recent analysis of anaphylaxis risk in patients newly exposed to IV iron products (including dextran, gluconate, sucrose, or ferumoxytol) reported the highest risk for iron dextran with the lowest risk with iron sucrose.[93]

The non-dextran IV iron formulations have a better safety record than either of the iron dextran products. The labeling for these formulations also includes a warning of the risk of hypersensitivity reactions. Since the approval of ferumoxytol in 2009, there have been 79 cases of anaphylactic reactions, of which 18 were fatal.[94] Almost half of the cases occurred with the first dose and approximately 75% occurred during the infusion or within 5 minutes of completion. In July 2014, a warning was issued by Health Canada that ferumoxytol should not be used in patients allergic to other iron products given by injection or infusion, or in patents with multiple drug allergies. In November 2014, the Canadian product monograph for ferumoyxtol was also changed to indicate that this agent only be administered as an IV infusion over a minimum of 15 minutes and that administration by direct IV injection of the undiluted product is no longer recommended. In March 2015, the FDA required a black box warning for ferumoxytol stating that "fatal and serious hypersensitivity reactions including anaphylaxis have occurred" in patients receiving this agent.[95] It is also recommended that ferumoxytol not be administered IV push (as previously recommended), but should be diluted and administered as an IV infusion (see Table 44-8), and that the risks and benefits should be considered in patients with a history of multiple drug allergies. As a superparamagnetic oxide, ferumoxytol may alter the diagnostic ability of magnetic resonance imaging studies for up to 3 months after administration; therefore, they should be done prior to administration of ferumoxytol whenever possible.[95]

Long-term administration of IV iron also introduces a risk of iron overload. Deposition of excess iron may affect several organ systems, leading to hepatic, pancreatic, and cardiac dysfunction. Bone marrow biopsy provides the most definitive diagnosis of iron overload, but because it is an extremely invasive procedure, it is not widely employed in most clinical settings. Maintaining target serum ferritin and TSat values is the most reasonable approach to minimize the risk of iron toxicity. The challenge is in defining what should be the upper limit, particularly for serum ferritin, which may be elevated in inflammatory conditions and not reflective of true iron stores in such situations. If symptomatic overload does occur, iron chelating agents such as deferoxamine (Desferal), deferiprone (Ferriprox), deferasirox (Exjade), or phlebotomy may be necessary.[96]

Safety concerns and recent labeling changes for ESAs have led to increased use of IV iron in HD patients to maintain target Hb, TSat, and ferritin values while minimizing ESA use.[97] Furthermore, the bundled payment system adopted by the US Centers for Medicare and Medicaid Services (CMS) has contributed to higher IV iron use. This increase in iron utilization resulted in an upward shift in mean ferritin levels, from approximately 600 ng/mL (µg/L; 1,350 pmol/L) in 2007 to 800 ng/mL (µg/L; 1,800 pmol/L) in 2013.[96] The potential detrimental effect of increased iron exposure on patient outcomes is of concern even though there are no data confirming unequivocally that aggressive use of IV iron in CKD patients treated with ESA therapy increases patient morbidity or mortality.[98,99,100,101,102] Data from an observational study to assess the association between cumulative IV iron dose in a given time frame and mortality in 14,000 HD patients indicated that administration of cumulative IV iron doses below 1,050 mg or 2,100 mg within a relatively short time period (3-6 months) were not associated with a significant increase in all-cause, CV, or infection-related mortality.[98] Some studies found that IV iron contributed to infection,[99,100] whereas others refuted this assertion although they did indicate a link to increased oxidative stress.[101,102]

Clinical Controversy...

Although there are conflicting reports, some clinicians believe that exposure to iron may contribute to the risk of bacterial infection because iron is used by microorganisms for metabolic functions. KDIGO guidelines suggest that IV iron be avoided in patients with active systemic infections.[39] Healthcare providers should be aware of this controversy when deciding whether to initiate IV iron in patients with active infection.

Drug Interactions

Drug interactions with oral iron are common. Iron absorption is decreased by other elements (eg, calcium in calcium-containing phosphate binders), medications that increase the pH of the GI tract such as proton pump inhibitors and H_2-antagonists, and antibiotics including doxycycline and tetracycline. Iron also decreases absorption of other drugs such as antibiotics (fluoroquinolones, doxycycline) (see Chapter 100).

Dosing and Administration

If oral therapy is initiated, the recommended dose is 200 mg of elemental iron per day. With numerous oral agents to choose from, the best option is one that provides adequate elemental iron with the fewest number of dosage units required per day and the lowest incidence of adverse effects. KDIGO guidelines suggest a 1- to 3-month trial of oral therapy in the non-HD CKD population prior to initiating IV therapy.[39] For the HD population, IV therapy is preferred with administration of a 1-g course of IV iron (in divided doses) recommended to initially replete patients with an absolute iron deficiency. The amount per dose and rate at which to administer IV iron depends on the product (see Table 44-8). Typical repletion dosing regimens for IV iron are 100 mg as iron sucrose over 10 dialysis sessions or 125 mg of sodium ferric gluconate over 8 dialysis sessions. The 1-g course of IV iron may be repeated as needed with close monitoring of Hb and iron indices. Iron indices should not be measured within 1 week of receiving an IV iron dose. Without ongoing iron supplementation, many patients quickly become iron-deficient. To prevent iron deficiency, maintenance doses of IV iron can be administered in HD patients (eg, iron sucrose 25-100 mg/wk; sodium ferric gluconate 62.5-125 mg/wk).[39,78] As a general practice, if IV iron doses higher than those currently approved are needed, they should be infused over a longer period of time (eg, at least 2-4 hours) due to the risk of hypersensitivity reactions, hypotension, dizziness, and nausea. The newer agents, ferumoxytol and ferric carboxymaltose, differ in terms of how rapidly iron is released from the compound, which allows for higher single doses to be administered.

Administration of a 25-mg test dose is required for all iron dextran products. This test dose should be administered over at least 30 seconds for InFeD and 5 minutes for Dexferrum. It is recommended that patients be observed for at least 1 hour before administering the remainder of the dose. For this reason the non-dextran agents are more commonly used in the CKD population. Regardless of which IV iron agent is used all patients should be monitored for signs and symptoms of hypersensitivity for at least 30 minutes following completion of a dose. KDIGO clinical practice guidelines suggest [redacted] minutes following administration of IV iron; a 1B recommendation

for iron dextran products and a 2C recommendation for non-dextran forumulations.[39] These agents should only be administered when personnel and therapies are immediately available for the treatment of anaphylaxis and other hypersensitivity reactions.

Erythropoiesis-Stimulating Agent Therapy

Since FDA approval of epoetin alfa in 1989, ESA therapy has become an integral part of the care for patients with CKD. ESAs available in the United States are listed in **Table 44-9**. Methoxy polyethylene glycol (PEG)-epoetin beta was approved for treatment of anemia in CKD patients (including dialysis patients) in 2007. It was not marketed in the United States, however, until recently due to an injunction for patent infringement. It has been used in Europe since its approval in 2007.

TABLE 44-9 Erythropoiesis-Stimulating Agents in Chronic Kidney Disease

Drug Name	Brand Name(s)	Starting Dose	Route of Administration	Half-Life (Hours)
Epoetin alfa	Epogen, Procrit	Adults: 50-100 units/kg three times per week Pediatrics: 50 units/kg three times per week	IV or SubQ	8.5 (IV) 24 (SubQ)
Darbepoetin alfa	Aranesp	Adults: ND-CKD: 0.45 µg/kg once every 4 weeks CKD 5HD or CKD 5PD: 0.45 µg/kg once per week or 0.75 µg/kg every 2 weeks Pediatrics: 0.45 µg/kg once weekly; may give 0.75 µg/kg once every 2 weeks in ND-CKD patients	IV or SubQ	25 (IV) 48 (SubQ)
Methoxy PEG-epoetin beta	Mircera	All adult CKD patients: 0.6 µg/kg every 2 weeks; Once Hb stabilizes, double the dose and administer monthly (eg, if administering 0.6 µg/kg every 2 weeks, give 1.2 µg/kg every month)	IV or SubQ	134 (IV) 139 (SubQ)

CKD, chronic kidney disease; ND-CKD, non-dialysis CKD patients; PEG, Polyethylene glycol; SubQ, subcutaneous.

Biosimilar ESAs are also expected in the US market in the near future. Biosimilars are nonbrand name products that are essentially replicas of the biologic drug. Biosimilar epoetin became available in Europe in 2007 after the expiration of patent protection for epoetin alfa in 2004.[103] The approval of biosimilars in the United States is expected since the patent for recombinant human erythropoietin expired in 2014.

Pharmacology and Mechanism of Action

Epoetin alfa is a glycoprotein manufactured by recombinant DNA technology that has the same amino acid sequence as endogenous erythropoietin. Darbepoetin alfa has two additional *N*-linked carbohydrate chains that decrease the affinity for the erythropoietin receptor, but yield a longer duration of activity compared with erythropoietin. Methoxy PEG-epoetin beta was created by the addition of an amide bond between the N-terminal or ε-amino group of epoetin beta and methoxy polyethylene glycol butanoic acid. The compound, which is referred to as a continuous erythropoietin receptor activator (CERA), has a much longer half-life than the other ESAs. All ESAs have the same biologic activity as endogenous erythropoietin in that they bind to and activate the erythropoietin receptor to stimulate erythropoiesis.

Pharmacokinetics and Pharmacodynamics

All available ESAs may be administered by either the IV or the subcutaneous (SubQ) route. Although bioavailability is less with SubQ than with IV administration, the prolonged absorption phase leads to an extended half-life (see Table 44-9). Thus the same target Hb can be achieved and maintained at SubQ epoetin doses 15% to 30% lower than IV doses.[39] The prolonged half-lives of darbepoetin alfa and methoxy PEG-epoetin beta offer the advantage of less-frequent dosing. This is of particular benefit for individuals with CKD who are not yet receiving dialysis and those receiving PD since these patients are not in a clinical setting as frequently as HD patients and do not have regular IV access.

The pharmacodynamic effect of ESAs is important to consider when evaluating response to therapy. With initiation of ESA therapy or a change in dose, the Hb may begin to rise as the result of demargination of reticulocytes; however, it takes approximately 10 days before erythrocyte progenitor cells mature and are released into the circulation. The Hb continues to increase until the life span of the cells stimulated by ESA therapy is reached (mean 2 months; range 1-4 months in patients with ESRD). At this point a new steady state is achieved (ie, the rate at which red blood cells are being produced equals the rate at which they are leaving the circulation). For this reason it is important to evaluate the Hb response over several weeks and not make dosing changes too soon.

Efficacy

Patients will generally respond to ESA therapy in a dose-related fashion. The most common causes of resistance are iron deficiency, acute illness, inflammation, infection, chronic bleeding, aluminum toxicity, malnutrition, hyperparathyroidism, cancer, and chemotherapy.[39] Deficiencies in folate and vitamin B_{12} should also be considered as potential causes of resistance to ESA therapy, as both are essential for optimal erythropoiesis. Use of ACEIs and ARBs has also been associated with hyporesponsiveness to ESA therapy.[39]

Adverse Effects

Hypertension is the most common adverse event reported with ESAs and may be associated with the

ephalopathy has also been observed. According to

FDA-approved product labeling, ESAs should not be used in those with uncontrolled blood pressure. Protocols established in some clinical settings recommend withholding ESA therapy if blood pressure is above a defined threshold; however, others advocate more judicious use of antihypertensive agents and dialysis to control blood pressure. Seizures have occurred in patients treated with ESAs, particularly within the first 90 days of starting therapy. Thrombosis of the HD vascular access site and other thromboembolic events were reported when ESAs were used to target Hb greater than 13 g/dL (130 g/L; 8.07 mmol/L).[104,105,106] The potential for these adverse effects calls for close monitoring of the rate of rise in Hb, changes in blood pressure, and neurologic symptoms following initiation of therapy or a change in ESA dose.

Antibody-associated pure red cell aplasia (PRCA), caused by induction of antibodies directed against the ESA molecule, was reported in the late 1990s and early in 2000 and was primarily associated with subcutaneous administration of Eprex, an epoetin alfa formulation manufactured outside the United States.[107] This reaction was potentially a result of organic compounds being formed when the stabilizing agent polysorbate was used in combination with uncoated rubber stoppers in the prefilled syringes. There have been very few cases since changes in the packaging of this product were made; however, the cause of PRCA with this formulation has been disputed.[108] Of note, there have been reports of PRCA with methoxy PEG-epoetin beta.[102] This is important to consider since this agent has only recently been introduced to the US market. An evaluation for PRCA should be considered for patients receiving ESA therapy for more than 8 weeks who develop either a rapid decrease in Hb level (rate of 0.5-1 g/dL/wk [5-10 g/L/wk; 0.31-0.62 mmol/L/wk]) or require one to two blood transfusions per week, and have an absolute reticulocyte count of less than 10,000/µL (10×10^9/L) with a normal platelet and white blood cell count.[39] Discontinuation of ESA therapy is recommended if antibody-mediated PRCA develops because antibodies are cross-reactive and continued exposure may lead to anaphylactic reactions (a grade 1A recommendation).

ESAs have also been associated with a reduction in overall survival and increased risk of progression of certain tumor types among CKD patients (eg, head and neck). ESAs are not indicated in patients receiving myelosuppressive chemotherapy when the anticipated outcome is cure. These are important effects to consider when managing a CKD patients with an oncologic disorder.[109]

In 2010, the FDA required all ESAs to be prescribed and used under a risk management program, known as a risk evaluation and mitigation strategy (REMS). As part of the REMS, a Medication Guide explaining the risks and benefits of ESAs must be provided to all patients receiving ESAs.

Drug–Drug Interactions

No significant drug interactions have been reported with the available ESAs.

Dosing and Administration

Recommended starting doses of ESA are listed in Table 44-9. Less frequent dosing of epoetin alfa (eg, every 1-2 weeks) is effective and may be preferred for ND-CKD patients since these individuals are on a relatively infrequent basis.[110] Subcutaneous dosing is also

more convenient in this population and in PD patients who do not have regular IV access. Conversion tables for patients who are to be switched from epoetin alfa (units per week) to darbepoetin alfa (micrograms per week) are available in the labeling information for darbepoetin.[106] There is also a conversion chart for patients being converted from epoetin alfa or darbepoetin alfa to methoxy PEG-epoetin beta.[104]

When starting an ESA, Hb levels should be monitored at least monthly (weekly may be preferred) until stable and then monthly thereafter. Dose adjustments should be made based on Hb response with a goal of avoiding an excessively quick rise or the achievement of values above the recommend target values. An acceptable rate of increase in Hb is 1 to 2 g/dL (10-20 g/L; 0.62-1.24 mmol/L) per month. As a general rule, ESA doses should not be increased more frequently than every 4 weeks, although decreases in dose may occur more frequently in response to a rapid rate of rise in Hb. The dose should be reduced by at least 25% if the Hb increases by more than 1 g/dL (10 g/L; 0.62 mmol/L) in a 2-week period.[104,105,106] The dose should be reduced or temporarily discontinued if the Hb level approaches or exceeds 11 g/dL (110 g/L; 6.83 mmol/L) in dialysis patients or 10 g/dL (100 g/L; 6.21 mmol/L) in patients with CKD not requiring dialysis. KDIGO recommendations advocate a decrease in dose as opposed to withholding the ESA when a decrease in Hb concentration is desired (2C grade recommendatio)[39] A 25% increase in dose may be considered if the Hb has not increased by 1 g/dL (10 g/L; 0.62 mmol/L) after 4 weeks of ESA treatment and if no causes of hyporesponsiveness to the ESA have been identified. For patients who do not respond adequately over a 12-week escalation period, an increase in ESA dose is unlikely to improve response and may increase risks. Initial hyporesponsiveness to ESAs should be considered when there is no increase in Hb from baseline after the first month of appropriate weight-based dosing. In this situation escalations in ESA dose beyond double the initial weight-based dose should be avoided (a grade 2D recommendation). Acquired ESA hyporesponsiveness may be suspected when patients previously on a stable ESA dose require two increases in ESA doses up to 50% beyond the previously utilized stable dose.[39] In this situation repeat escalations in ESA dose beyond double the dose at which they had been stable should be avoided (a grade 2D recommendation). The lowest dose of ESA should be used to maintain an Hb level sufficient to reduce the need for red blood cell transfusions. **Figure 44-6** provides an approach to management of anemia using ESAs and iron therapy in patients with CKD.

FIGURE 44-6

Algorithm for management of anemia of CKD in adults.[39,104] (CKD, chronic kidney disease; ESA, erythropoiesis-stimulating agent; Hb, hemoglobin; ND-CKD, non-dialysis CKD patients; TSat, transferrin saturation.) See Table 44-5 for definitions of evidence grading in brackets. [a]See Table 44-7 and text for discussion of Hb levels. [b] Clinical judgement should be used to determine if iron supplementation should be continued when ferritin >500 ng/mL (µg/L; >1,120 pmol/L). [c]Weekly monitoring of Hb may be warranted. Wait at least 1 week after an IV dose of iron to measure TSat and ferritin.

Transfusions and Adjunct Therapies

Red blood cell transfusions carry many risks and therefore should only be used in select situations, such as acute management of symptomatic anemia, following significant acute blood loss, and prior to surgical procedures that carry a high risk of blood loss, with the goal of preventing inadequate tissue oxygenation or cardiac failure. L-carnitine supplementation and vitamin C were previously suggested as adjunctive treatments of CKD anemia, but are not recommended because of the lack of evidence supporting improved anemia management with these therapies.[39]

Evaluation of Therapeutic Outcomes

Important therapeutic outcomes to monitor in patients with anemia of CKD include Hb, iron status, as well as the need for blood transfusions. Iron status should be assessed at least every 3 months in patients receiving a stable ESA regimen.[39] Iron status should be monitored more frequently (eg, every month) when initiating or increasing the ESA dose, following a course of IV iron, or when other factors put the patient at risk for iron loss (eg, bleeding). Hb levels should be monitored at least every 3 months in patients with CKD not on dialysis or CKD 5PD and at least monthly in CKD 5HD patients.[39] Hb should be monitored at least monthly in patients started on ESA therapy until the Hb is stable. Of note, FDA labelling for ESAs recommends weekly monitoring of Hb with initiation of therapy or a change in dose until the Hb is stable.[104,105,106]

Chronic Kidney Disease-Related Mineral and Bone Disorder

Management of PTH, phosphorus, and calcium is important in preventing CKD-MBD and CV and extravascular calcifications. Patients with CKD-MBD usually require a combination of dietary intervention, phosphate-binding medications, vitamin D, and calcimimetic therapy (for ESRD patients) to achieve these goals.

Desired Outcome

9 The desired outcomes for management of CKD-MBD are to "normalize" the biochemical parameters and prevent bone manifestations, CV and extravascular calcifications, and the associated morbidity and mortality with both nonpharmacologic and pharmacologic interventions. At present there are two guidance documents—KDOQI and KDIGO—that clinicians can use in their patient care decision-making process.[42,111] It should be noted that many of the recommendations in both documents are based on opinion or limited evidence given the lack of randomized controlled studies to evaluate treatment outcomes. The 2009 KDIGO clinical practice guidelines for CKD-MBD will be emphasized in this chapter with some comparisons made to KDOQI.

The KDIGO-recommended targets for calcium, phosphorus, and PTH and frequency of monitoring based on the CKD category are shown in **Table 44-10**. There are minor differences between KDIGO and KDOQI and with regard to recommendations for serum calcium (corrected for serum albumin): KDOQI recommends a more conservative calcium range (8.4-9.5 mg/dL, [2.10-2.38 mmol/L]) in ESRD patients based on an increased risk of soft-tissue and vascular calcifications.[111] The most appropriate strategy is to evaluate trends in corrected calcium to predict if hypercalcemia is a concern that warrants changes in therapy. The adoption by CMS of an *uncorrected* calcium value greater than 10.2 mg/dL (>2.55 mmol/L) as a quality measure starting in 2016 may influence patient care decisions and thereby reduce the prevalence of elevated calcium values.[111] Monitoring of alkaline phosphatase activity is also recommended in patients with CKD 4, 5, and ESRD as this test may serve as a gauge of a patient's response to therapy and/or bone turnover status. Avoiding the development of calciphylaxis is also important as treatment options for this complication once it develops are extremely limited.

TABLE 44-10 KDIGO Monitoring and Goals for Calcium, Phosphorus, and Parathyroid Hormone

	Chronic Kidney Disease Category[a]			
Parameter	**3**	**4**	**5**	**ESRD**

Evaluation of Parathyroid Hormone

Clinicians involved in the care of patients with CKD should know which PTH assays are available in their facilities. PTH is secreted from the parathyroid gland as intact PTH, an 84-amino-acid peptide chain (1-84 PTH) that is biologically active, and as smaller carboxy-terminal PTH fragments.[113] Circulating levels of these fragments (eg, 7-84 PTH) may increase substantially in patients with CKD and actively antagonize the effects of 1 to 84 PTH. The available immunoradiometric assays measure not only the intact PTH molecule but also fragments, which may lead to overestimation of biologically active PTH. While correction factors have been proposed, they cannot be uniformly applied to all commercially available assays and thus inconsistent results are common. Because of the variability in PTH measurement and lack of evidence to support a specific target, it is not surprising that KDOQI and KDIGO both recommend monitoring trends in serum PTH to guide treatment decisions but have established different target ranges. KDIGO recommends that PTH values for ESRD patients be within two to nine times the upper limit of the normal range, which corresponds to a PTH of approximately 130 to 600 pg/mL [ng/L; 14-64 pmol/L]).[42] PTH values above 600 pg/mL (ng/L; 64 pmol/L) have been associated with higher CV mortality and hospitalizations.[114] In contrast, KDOQI

be between 150 and 300 pg/mL (ng/L; 16-32 pmol/L).[110]

Nonpharmacologic Therapy

Dietary Phosphorus Restriction

Dietary phosphorus restriction is a first-line intervention for management of hyperphosphatemia and should be initiated for most patients with CKD 3-5.[42,111,115] The KDOQI guidelines recommend phosphorus restriction to 800 to 1,000 mg/day when the upper levels of serum phosphorus are reached (opinion-based recommendation in CKD 3-5, evidence-based recommendation in ESRD).[111] This recommendation also applies to patients with PTH levels above the recommended range given the evidence that lowering phosphorus ingestion directly decreases PTH synthesis and secretion.[116] The challenge with dietary restriction of phosphorus is providing enough protein to prevent malnutrition, a common problem in the ESRD population because dialysis patients require a higher protein intake (1.2-1.3 g/kg/day) and foods high in phosphorus are generally high in protein. An additional consideration is the source of phosphorus, organic versus inorganic. Inorganic sources such as from frozen meals and processed foods include preservatives or additives used during food processing, whereas organic sources such as from meat and plant sources typically do not and may be a better option. One of the most common obstacles to dietary phosphorus restriction is patient nonadherence because of the poor palatability of the allowed foods. Regular counseling by a dietitian is necessary to design a realistic diet that works with the patient's lifestyle and considers nutritional goals.

Dialysis

HD and PD lower serum phosphorus and calcium, the extent of which is dependent on the concentration of each in the dialysate and the duration of dialysis. It is recommended that the dialysate calcium concentration be between 2.5 and 3 mEq/L (1.25 and 1.5 mmol/L) (a grade 2D recommendation).[42,110] Removal of phosphorus does occur with dialysis (approximately 2.5-3.5 g/wk, dependent on the dialysis prescription); however, dialysis alone does not usually control hyperphosphatemia.[116] Patients on daily HD or nocturnal HD who typically have longer and/or more frequent dialysis sessions may have better phosphorus control and require fewer phosphate-binding agents.

Parathyroidectomy

Parathyroidectomy is a therapeutic option for those patients with persistently elevated PTH associated with hypercalcemia and/or hyperphosphatemia who are refractory to medical therapy (a grade 2B recommendation).[42] KDOQI suggests considering a parathyroidectomy when the PTH level is persistently above (PTH >800 pg/mL [ng/L; >86 pmol/L], an opinion-based recommendation.[111] Surgical approaches include either subtotal parathyroidectomy or total parathyroidectomy with autotransplantation of parathyroid tissue to an accessible site, such as the forearm. Postoperative hypocalcemia, hypophosphatemia, and hypomagnesemia may occur because of a marked increase in bone production in relation to bone absorption ("hungry bone syndrome"). Following surgery frequent monitoring of calcium and phosphorus is necessary. Treatment with supplemental calcium

and vitamin D may be required for weeks or months.

While a parathyroidectomy is indicated for refractory patients, these patients may experience significant morbidity following the procedure. In a study of over 4,400 ESRD patients who underwent a parathyroidectomy from 2007 to 2009, there was an increase in hospitalizations (particularly for acute myocardial infarction and dysrhythmia) and emergency room visits for treatment of hypocalcemia in the year following the procedure.[118] For some patients a parathyroidectomy may be ineffective and there is also the risk of oversuppression of PTH and prolonged hypocalcemia.[119]

Pharmacologic Therapy

Patients with CKD-MBD usually require a combination of dietary intervention, phosphate-binding medications, vitamin D, and calcimimetic therapy (for ESRD patients) to achieve goals.

Phosphate-Binding Agents

Patients with CKD, especially those with ESRD, typically require phosphate-binding agents in addition to dietary interventions to limit GI absorption and thereby control serum phosphorus. For many patients the pill burden with phosphate-binding agents affects nonadherence and efforts should be made to simplify their regimen when possible.

Pharmacology and Mechanism of Action

Drugs that bind dietary phosphorous in the GI tract form insoluble phosphate compounds that are excreted in feces, thus reducing dietary phosphorus absorption. A variety of phosphate-binding agents are available including elemental calcium, iron, and lanthanum-containing compounds, and the nonelemental agent sevelamer (**Table 44-11**). Binding affinity varies depending on the binding agent (eg, calcium, iron, etc). Patients must be instructed to take these agents with meals to maximize the binding of phosphorus from dietary sources.

TABLE 44-11 Phosphate-Binding Agents for Treatment of Hyperphosphatemia in Chronic Kidney Disease Patients

Category	Drug	Brand Name	Compound Content	Starting Doses	Dose Titration[a]	Comments[b]
Calcium-based binders	Calcium acetate (25% elemental calcium)	PhosLo	25% elemental calcium (169 mg elemental calcium per 667 mg capsule)	1,334 mg three times a day with meals	Increase or decrease by 667 mg per meal (169 mg elemental calcium)	Comparable efficacy to calcium carbonate with lower dose of elemental calcium Approximately 45 mg phosphorus bound per 1 g calcium acetate

Category	Drug	Brand Name	Compound Content	Starting Doses	Dose Titration[a]	Comments[b]
						Evaluate for drug interactions with calcium
		Phoslyra	667 mg calcium acetate per 5 mL			
	Calcium carbonate[c]	Tums, Os-Cal, Caltrate	40% elemental calcium	0.5-1 g (elemental calcium) three times a day with meals	Increase or decrease by 500 mg per meal (200 mg elemental calcium)	Dissolution characteristics and phosphate binding may vary from product to product Approximately 39 mg phosphorus bound per 1 g calcium carbonate
						Evaluate for drug interactions with calcium
Iron-based binders	Ferric citrate	Auryxia	210 mg tablets (= 1 g ferric citrate)	420 mg ferric iron three times daily with meals	Increase or decrease dose by 1 or 2 tablets per meal	May increase serum iron, ferritin, and TSat May cause discolored (dark) stools
						Evaluate for drug interactions with iron
	Sucroferric oxyhydroxide	Velphoro	500 mg chewable tablets	500 mg three times daily with meals	Increase or decrease by 500 mg per day	May cause discolored (dark) stools Evaluate for drug interactions with iron
Resin binders	Sevelamer carbonate	Renvela	800 mg tablet 0.8 and 2.4 g powder	800-1,600 mg three times a day with meals (once-daily	Increase or decrease by 800 mg per meal	Also lowers low-density lipoprotein cholesterol

Category	Drug	Brand Name	Compound Content	Starting Doses	Dose Titration[a]	Comments[b]
						Consider in patients at risk for extraskeletal calcification Risk of metabolic acidosis with sevelamer hydrochloride (less risk with carbonate formulation) May interact with cipro and mycophenolate mofetil
	Sevelamer hydrochloride	Renagel	400 & 800 mg caplets	800-1,600 mg three times a day with meals	Increase or decrease by 800 mg per meal	
Other elemental binders	Lanthanum carbonate	Fosrenol	500, 750, and 1,000 mg chewable tablets 750 and 1,000 mg oral powder	1,500 mg daily in divided doses with meals	Increase or decrease by 750 mg/day	Potential for accumulation of lanthanum due to GI absorption (long-term consequences unknown) Evaluate for drug interactions (eg, cationic antacids, quinolone antibiotics)
	Aluminum hydroxide	AlternaGel	Content varies (range 100-600 mg/unit)	300-600 mg three times a day with meals	Not for long-term use requiring titration	Not a first-line agent; risk of aluminum toxicity; do not use concurrently with citrate-containing products
						Reserve for

Category	Drug	Brand Name	Compound Content	Starting Doses	Dose Titration[a]	Comments[b]
						short-term use (4 weeks) in patients with hyperphosphatemia not responding to other binders Evaluate for drug interactions

TSat, transferrin saturation.

[a]Based on phosphorus levels, titrate every 2 to 3 weeks until phosphorus goal reached.

[b]GI side effects are possible with all agents (eg, nausea, vomiting, abdominal pain, diarrhea, or constipation).

[c]Multiple preparations available that are not listed.

Efficacy

Oral calcium compounds are well established as first-line agents for control of serum phosphorus. Calcium carbonate and calcium acetate are the primary preparations used. Calcium citrate is also available but is used less frequently since the citrate component increases aluminum absorption and may cause more GI side effects. Calcium carbonate is marketed in a variety of dosage forms and is relatively inexpensive. Unfortunately, many calcium carbonate products are considered food supplements and thus do not meet US Pharmacopeia (USP) disintegration and dissolution requirements. In general, nationally advertised brands do meet these requirements, but it is difficult to determine whether private labels or house brands conform to these standards. Variability in gastric pH may also affect disintegration or dissolution, and thus phosphate-binding efficacy. Calcium carbonate is more soluble in an acidic medium and should be administered prior to meals when stomach acidity is highest. In addition, acid-suppressing agents such as ranitidine and proton pump inhibitors may reduce the phosphate-binding activity of calcium carbonate by increasing gastric pH. Calcium acetate binds approximately twice as much phosphorus as calcium carbonate at comparable doses of elemental calcium.[111] Increased binding potency limits GI calcium absorption; however, calcium acetate is more soluble and therefore better absorbed than calcium carbonate in an alkaline pH. There is some evidence that calcium acetate may be less likely to cause hypercalcemia compared to carbonate.[111] For patients with hypocalcemia, calcium carbonate or calcium acetate may also be given as a calcium supplement taken between meals to promote calcium absorption. This is a common scenario for patients following a parathyroidectomy.

Hyperphosphatemia and vascular calcifications are associated with higher mortality.[42] There is

evidence that chronic use of calcium-containing phosphate binders promotes progression of vascular calcification; however, not all studies support this finding and recent evidence suggests this effect may occur with non–calcium-containing binders as well. The effect of binder choice on mortality is also controversial. KDOQI guidelines suggest using a non–calcium-containing binder in dialysis patients with severe vascular or soft-tissue calcifications and that the total dose of elemental calcium provided by binders should not exceed 1,500 mg/day and the total daily intake of elemental calcium from all sources should not exceed 2,000 mg (opinion-based recommendations).[111] In general, KDIGO recommends that binder choice be made considering the CKD category and the risk of calcifications, and that calcium-based phosphate binders be restricted in patients with vascular calcifications and/or adynamic bone disease (a grade 2C recommendation).[42]

Sevelamer is a nonabsorbable, nonelemental hydrogel phosphate-binding agent approved for ESRD patients that effectively lowers phosphorus and has also been shown to lower LDL and increase HDL cholesterol. Sevelamer hydrochloride carries the risk of metabolic acidosis, a problem that has been overcome with development of the carbonate formulation. Sevelamer carbonate also comes in a powder formulation which is a good option for many patients unable to swallow tablets. Once-daily dosing of sevelamer carbonate powder has also been shown to significantly decrease phosphorus levels, although this regimen was not as effective as three times daily dosing.[119]

Lanthanum carbonate is a phosphate binder approved for patients with ESRD and has demonstrated efficacy in controlling phosphorus and maintaining PTH in the target range with less risk of hypercalcemia than calcium-containing binders.[42] The initial daily dose of 1,500 mg (administered in divided doses with meals) is often titrated to a range of 1,500 to 3,000 mg to maintain target phosphorus. The poor GI absorption, which limits systemic effects, and high binding capacity with phosphorus make this an attractive phosphate-binding agent, particularly when calcium-containing binders are not recommended due to hypercalcemia. Lanthanum is available as a chewable tablet, which may be appealing for some patients.

Ferric citrate and sucroferric oxyhydroxide are the newest iron-based phosphate-binding agents approved for ESRD patients. Sucroferric oxyhydroxide effectively lowers phosphorus over a long term (1-year) period and may have a lower pill burden compared to other agents.[121] It is also available as a chewable tablet. Ferric citrate effectively lowers phosphorus and also offers the potential advantage of increasing iron indices (TSat and ferritin) while lowering IV iron and ESA use.[122]

Aluminum salts were widely used in the 1980s as phosphate-binding agents because of their high binding potency. They should no longer be used as first-line agents, but rather reserved for acute treatment of severe hyperphosphatemia or used at low doses in combination with other binders in cases of hyperphosphatemia that is not responding to therapy with a single agent. According to KDOQI guidelines, the duration of aluminum therapy should be limited to 4 weeks if these agents are used at all.[111] Magnesium-containing antacids are also effective phosphate binders and may decrease the amount of calcium-containing binders necessary for control of phosphorus; however, their use is limited by the frequent occurrence of GI side effects (ie, diarrhea) and the potential for magnesium accumulation.

Adverse Effects

Adverse effects of all available phosphate binders are generally limited to constipation, diarrhea, nausea, vomiting, and abdominal pain. The risk of hypercalcemia may necessitate restriction of calcium-containing binder use and/or a reduction in dietary intake. Aluminum binders have been associated with CNS toxicity and the worsening of anemia, whereas magnesium binder use may lead to hypermagnesemia and hyperkalemia (see Chapter 51); therefore, aluminum and magnesium are not recommended for regular use in patients with kidney disease. There has been a report of lanthanum tablets accumulating in the GI tract and causing severe complications in a patient who swallowed these tablets whole; therefore, it is important to counsel patients to chew these tablets.[121] The same counseling point applies for sucroferric oxyhydroxide.

Drug–Drug and Drug–Food Interactions

Calcium-containing phosphate-binding agents interfere with the absorption of several oral medications that are commonly prescribed for CKD patients, including iron, zinc, and quinolone antibiotics. Coadministration of sevelamer with ciprofloxacin and mycophenolate did result in a reduction in bioavailability of these agents and they should be taken at least 2 hours before sevelamer. Coadministration of lanthanum with tetracyclines, fluoroquinolones, levothyroxine, or drugs known to bind with cationic antacids may result in decreased bioavailability of these agents. The iron containing products ferric citrate and sucroferric oxyhydroxide also have the potential for drug interactions due to the iron component. In general, it is rational to separate the administration time of oral medications for which a reduction in bioavailability has a clinically significant effect (eg, quinolones) from phosphate binders by at least 1 hour before or 3 hours after administration of the phosphate binder. Many phosphate binders are marketed as antacids or calcium supplements, and often CKD patients do not know why they have been prescribed these agents. Regular patient counseling is essential to improve adherence and minimize the potential for drug interactions.

Dosing and Administration

Initial dosing regimens for phosphate-binding agents and suggested dose titration schemes are shown in Table 44-11. Doses should be titrated to achieve the recommended serum phosphorus concentrations in conjunction with dietary intervention and dialysis (for ESRD patients).

Vitamin D Therapy

Vitamin D compounds available in the United States include nutritional vitamin D [ergocalciferol (D_2) and cholecalciferol (D_3)], active vitamin D [calcitriol (D_3)], and vitamin D analogs [paricalcitol and doxercalciferol (both D_2)] (**Table 44-12**). Nutritional vitamin D (NVD) is derived from dietary plant (D_2) and animal (D_3) sources, or from supplements. While this chapter focuses on the role of NVD and FDA-approved vitamin D formulations for the management of mineral homeostasis, there are several other therapeutic uses for vitamin D (eg, for CV and immune-related effects) and other analogs available outside the United States which are not discussed (eg, alfacalcidol).

Pharmacology and Mechanism of Action

Vitamin D is a cholesterol derivative and is transported in the circulation by vitamin D binding protein. The process of vitamin D metabolism is shown in Fig. 44-4. Both endogenously synthesized D_3 and NVD compounds (as D_2 or D_3) are converted in the liver to 25(OH)D, by the 25-hydroxylase enzyme. The 25(OH)D form is subsequently converted to the biologically active form 1,25-dihydroxyvitamin D (either D_2 or D_3 depending on the parent compound) by the 1-α-hydroxylase enzyme. This conversion occurs primarily in the kidney, but this enzyme is also present in extrarenal tissues. It is not clear whether active vitamin D produced in extrarenal tissue exerts its effects only locally or contributes to the systemic endocrine functions. It is the concentration of 25(OH)D that is most commonly measured clinically to diagnose vitamin D deficiency.

Calcitriol and the vitamin D analogs bind to the vitamin D receptors (VDRs), which are located in many organ systems including the parathyroid glands, intestine, bone, kidney, heart, nervous, and immune systems. When vitamin D binds to the VDR there is a conformational change in the VDR that allows for interaction of the receptor with the retinoid X receptor (RXR), a transcriptional factor.[124] The VDR-RXR complex binds to DNA sequences in target genes to either promote or inhibit transcription depending on the organ system. Vitamin D inhibits or suppresses PTH synthesis and also stimulates absorption of serum calcium by intestinal cells. As a result, the serum calcium concentration is raised, which decreases PTH secretion by the parathyroid glands. The set point for calcium (ie, the calcium concentration at which PTH secretion is decreased by 50%), which is generally raised in those with CKD-MBD, is lowered when active vitamin D therapy is initiated. This results in a lower ionized calcium concentration becoming effective at suppressing secretion of PTH. Unfortunately, the enhanced GI absorption of calcium and phosphorus associated with calcitriol therapy may lead to hypercalcemia and hyperphosphatemia, which are associated with soft-tissue and vascular calcifications.

The unique interactions of vitamin D with the VDRs have led to the development of vitamin D analogs that vary in their affinity for the VDRs. Paricalcitol and doxercalciferol retain activity with vitamin D receptors on the parathyroid gland to effectively lower PTH, but have less risk of hypercalcemia and hyperphosphatemia due to their lower intestinal activity. Paricalcitol differs from calcitriol by the absence of the exocyclic carbon 19 and the fact that it is a vitamin D_2 derivative (19-nor-1,25-dihydroxyvitamin D_2). This compound is active as given. Doxercalciferol, however, is a prohormone that does require activation by CYP27 in the liver to form the major active D_2 metabolite 1,25-dihydroxyvitamin D_2 (see Fig. 44-4).

Pharmacokinetics

Oral absorption of calcitriol occurs rapidly; therefore, both oral and IV therapies are reasonable options for treatment of CKD-MBD. The half-life of active calcitriol ranges from 15 to 38 hours in patients with ESRD.[125] The half-lives of paricalcitol and doxercalciferol are approximately 15 hours and 32 to 37 hours, respectively.[126,127] These agents are extensively bound to plasma proteins and

Efficacy

Calcitriol, paricalcitol, and doxercalciferol are all effective in lowering PTH in patients with CKD; however, the trade-off is the undesired effect of raising calcium and phosphorus concentrations due to increased intestinal absorption. Although these effects are less likely with paricalcitol and doxercalciferol, elevated calcium concentrations have been observed. An all-cause and CV survival benefit has also been reported with these agents in both CKD and ESRD patients.[128] It must be noted that these are observational studies and that prospective, randomized controlled trials are required to verify these survival benefits. When the effect of paricalcitol on left ventricular mass was evaluated in patients with CKD and mild to moderate LVH, no reduction in left ventricular mass was noted after 48 weeks of therapy.[129] A significant reduction in the urinary ACR was observed in CKD patients with type 2 diabetes receiving 2 µg of oral paricalcitol daily compared with placebo.[130] These findings suggest potential new roles for vitamin D beyond suppression of PTH.

A review and meta-analysis in CKD patients (including ESRD patients) revealed that NVD supplementation was associated with an improvement in 25(OH)D levels and decreased PTH without significant hypercalcemia or hyperphosphatemia.[131] Suppression of secondary hyperparathyroidsim with NVD is most effective in patients with CKD 3. In ESRD patients, NVD has resulted in increased levels of 25(OH)D and a decrease in PTH, which suggests a potential role of extrarenal pathways of vitamin D activation; however, these patients typically also require active vitamin D or analog therapy. The survival benefit of correcting vitamin D deficiency with NVD in the CKD population is unknown.

Adverse Effects

Although all agents are effective in suppressing PTH, they may cause hypercalcemia and hyperphosphatemia, an effect that is most likely with calcitriol. Oversuppression of PTH and inducement of adynamic bone disease are also distinct possibilities.

Drug–Drug and Drug–Food Interactions

Cholestyramine may reduce the absorption of orally administered calcitriol and doxercalciferol. In vitro data suggest that paricalcitol is metabolized by the hepatic enzyme CYP3A4 and thus it has the potential to interact with other agents that are metabolized by this enzyme. Caution is also advised when CYP3A4 inhibitors are given to those receiving doxercalciferol since hydroxylation of this precursor agent may be inhibited.

Dosing and Administration

Despite the lack of evidence, KDIGO guidelines support administering NVD to patients with CKD 3-5 and ESRD with vitamin D deficiency or insufficiency (a grade 2C recommendation).[42] KDOQI specifies that supplementation is warranted if the 25(OH)D level is less than 30 ng/mL (75 nmol/L).[111] The dose and duration of treatment are dependent on the severity of the deficiency: oral ergocalciferol 50,000 IU per week for 12 weeks, then monthly for 6 months for severe deficiency [25(OH)D levels <5

onthly for 6 months for insufficiency [25(OH)D less than 30

ng/mL, 75 nmol/L]. Calcitriol, doxercalciferol, or paricalcitol should be administered when PTH remains elevated despite the achievement of adequate 25(OH)D levels.

Administration of calcitriol by either the oral or the IV route may utilize a daily (usually 0.25-1 µg/day) or pulse dosing (0.5-2 µg two to three times per week) approach. Logistically, IV dosing with doses administered three times per week is usually optimal in HD patients since this correlates with their in-center dialysis treatment schedule and IV therapy is covered in the bundled payment for dialysis (see the "Pharmacoeconomic Considerations" section). Oral therapy is more practical for non-dialysis CKD and PD patients. Recommended doses of calcitriol, doxercalciferol, and paricalcitol and suggested dose titration schemes are shown in **Table 44-12**. Prior to starting therapy, the serum calcium and phosphorus should be within the normal range. This does not mean that vitamin D therapy should be withheld or discontinued in all patients with elevated calcium and phosphorus values, but rather that use of agents with a lower risk of hypercalcemia and hyperphosphatemia and more prudent use of phosphate binders to lower calcium and phosphorus may be necessary in such patients. Dose adjustments of vitamin D should be made every 2 to 4 weeks based on PTH concentrations and trends in calcium and phosphorus.

TABLE 44-12 Vitamin D Agents

Generic Name	Brand Name	Form of Vitamin D	Dosage Forms	Initial Dose[a]	Dosage Range	Frequency of Dosing
Nutritional Vitamin D						
Ergocalciferol	Drisdol	D_2	po	Varies based on 25(OH) D levels	400-50,000 international units	Daily (doses of 400-2,000 international units)
Cholecalciferol[b]	Generic	D_3	po			Weekly or monthly for higher doses (50,000 international units)
Vitamin D and Analogs						
Generic Name	**Brand Name**	**Form of Vitamin D**	**Dosage Forms**	**Initial Dose[a,c]**	**Dosage Range**	**Dose Titration[d]**
Calcitriol	Rocaltrol	D_3	po	0.25 µg daily	0.25-5 µg	Increase by 0.25 µg/day at 4-8 week intervals
	Calcijex		IV	1-2 µg three times per week	0.5-5 µg	Increase by 0.5-1 µg at 2 to 4 week intervals
Doxercalciferol[e]	Hectorol	D_2	po	ND-CKD: 1 µg daily ESRD: 10 µg three times per week	5-20 µg	Increase by 0.5 µg at 2-week intervals for daily dosing or by 2.5 µg at 8-week

Generic Name	Brand Name	Form of Vitamin D	Dosage Forms	Initial Dose[a]	Dosage Range	Frequency of Dosing
						intervals for three times per week dosing
			IV	ESRD: 4 µg three times per week	2–8 µg	Increase by 1-2 µg at 8-week intervals
Paricalcitol	Zemplar	D_2	po	ND-CKD: 1 µg daily or 2 µg three times per week if PTH ≤500 pg/mL (ng/L; ≤54 pmol/L); 2 µg daily or 4 µg three times per week if PTH >500 pg/mL (ng/L; >54 pmol/L)	1-4 µg	Increase by 1 µg (for daily dosing) or 2 µg (for three times per week dosing) at 2-4 week intervals
			IV	ESRD: 0.04-1 µg three times per week	2.5-15 µg	Increase by 2-4 µg at 2-4 week intervals

ESRD, end-stage renal disease; ND-CKD, non-dialysis chronic kidney disease; PTH, parathyroid hormone.

[a]Dose ratios are as follows: 1:1 for IV paricalcitol to oral doxercalciferol, 1.5:1 for IV paricalcitol to IV doxercalciferol, and 1:1 for IV to oral calcitriol.

[b]Multiple preparations are available that are not listed.

[c]Daily orally dosing most common for non-hemodialysis CKD patients, IV dosing three times per week more often used in the hemodialysis population.

[d]Based on PTH, calcium and phosphorus levels. Decreases in dose are necessary if PTH is oversuppressed and/or if calcium and phosphorus are elevated.

[e]Prodrug that requires activation by the liver.

Calcimimetics

Cinacalcet hydrochloride (Sensipar) is currently the only calcimimetic agent approved for treatment of secondary hyperparathyroidsim in CKD patients on dialysis.

Pharmacology and Mechanism of Action

Cinacalcet acts by increasing the sensitivity of the calcium-sensing receptor located on the surface of the chief cells of the parathyroid gland to extracellular calcium, subsequently reducing PTH secretion. Cinacalcet does not increase intestinal calcium and phosphorus absorption. In fact, the reduction in PTH with cinacalcet is associated with a decrease in serum calcium.

Pharmacokinetics

Cinacalcet peak concentrations are observed 2 to 6 hours following oral administration and its elimination half-life is approximately 30 to 40 hours. It has a large volume of distribution (approximately 1,000 L) and is 93% to 97% bound to plasma proteins, and thus removal by dialysis is likely negligible. It is metabolized by the liver, specifically by the cytochrome P450 isoenzymes CYP3A4, CYP2D6, and CYP1A2.[132]

Efficacy

In clinical trials conducted predominantly in dialysis patients, cinacalcet significantly decreased PTH, calcium, and phosphorus, regardless of the severity of secondary hyperparathyroidsim.[42] In non-dialysis CKD patients it reduced PTH, but was associated with a high incidence of hypocalcemia and hyperphosphatemia; thus, this agent is not approved for use in non-dialysis CKD patients. Cinacalcet may be used as a single agent to control hyperparathyroidism in ESRD patients; however, combined therapy with vitamin D is often necessary to achieve target PTH, calcium, and phosphorus values. Cinacalcet plus low-dose active vitamin D increased coronary artery calcification scores but to a lesser degree than its comparator calcitriol alone.[133] A decrease in all-cause and CV mortality was also suggested by results of an observational study in HD patients prescribed cinacalcet in addition to vitamin D compared with those on vitamin D alone.[134] While these findings were promising, they were not supported by the EVOLVE trial (the Evaluation of Cinacalcet Therapy to Lower CV Events), a prospective study which revealed that cinacalcet did not significantly reduce the risk of all-cause mortality or major CV events in patients with CKD 5HD.[135]

Adverse Effects

The most frequent adverse events associated with cinacalcet are nausea and vomiting. Since cinacalcet lowers serum calcium it should not be started if the serum calcium is less than the lower limit of normal, approximately 8.4 mg/dL (2.10 mmol/L). Serum calcium should be measured within 1 week after initiation or following a dose adjustment. Once the maintenance dose is established, serum calcium should be measured monthly. Potential manifestations of hypocalcemia include paresthesia, myalgia, cramping, tetany, and convulsions. Hypocalcemia may also lead to Q-T interval prolongation and ventricular arrhythmias, which further emphasizes the importance of regular calcium monitoring.[131]

Drug–Drug and Drug–Food Interactions

Because cinacalcet is partially metabolized by cytochrome P450 CYP3A4, there is potential for drug

interactions with agents that inhibit this pathway. Coadministration of cinacalcet and ketoconazole, a strong inhibitor of CYP3A4, resulted in a twofold increase in the area under the curve and maximum concentration. Cinacalcet is also a potent inhibitor of the enzyme CYP2D6. As a result, dose adjustments of concomitant medications that are predominantly metabolized by this enzyme and have a narrow therapeutic index, such as flecainide, thioridazine, vinblastine, and most tricyclic antidepressants (eg, amitriptyline), may be necessary.[132] Concurrent administration of cinacalcet with amitriptyline increased amitriptyline and nortriptyline (active metabolite) exposure by approximately 20% in CYP2D6-extensive metabolizers.

Food has been shown to increase absorption of cinacalcet by up to 82% compared with fasting; therefore, this medication should be taken with meals to achieve the maximal effect.[131]

Dosing and Administration

The recommended starting dose of cinacalcet is 30 mg once daily. Calcium and phosphorus should be measured within 1 week and PTH should be measured within 1 to 4 weeks after starting cinacalcet or adjusting the dose. The dose should be titrated every 2 to 4 weeks to a maximum dose of 180 mg once daily until the desired PTH values are achieved and to maintain goal serum calcium concentrations. Patients with hepatic disease may require lower doses, since the cinacalcet half-life is approximately doubled in those with severe liver disease.[132] Cinacalcet is available as film-coated tablets containing 30, 60, or 90 mg.

Evaluation of Therapeutic Outcomes

The parameters listed in Table 44-10 should be evaluated to assess response to therapy. Of note, the shift in the treatment approach from the more conservative KDOQI guidelines to the KDIGO recommendations have led to changes in observed trends in these parameters. For example, PTH values have increased in most countries as a result of the higher range for PTH recommended by the more globally accepted KDIGO guidelines.[114] More definitive data on the effect of treatment approaches and achievement of target calcium, phosphorus, and PTH values on therapeutic outcomes are needed.

Pharmacoeconomic Considerations for Anemia and Chronic Kidney Disease-Related Mineral and Bone Disorder

The cost of medications to treat anemia and CKD-MBD is substantial.[11,136] In the United States insurance requirements for coverage of agents including ESAs, IV iron, and vitamin D analogs can be a major limitation to treatment of the CKD patient with anemia or MBD. The high cost of ESAs is a reason that legislation led to a *bundled* payment system for dialysis patients. The Medicare Modernization Act became effective in 2006 and provided for separately billable drugs such as ESAs, IV iron, IV vitamin D to be reimbursed based on the average sales price. The results of CHOIR and perceived overuse of ESAs later prompted Congress to reevaluate the reimbursement system, and in 2009 the bundled reimbursement system for dialysis was established (implemented in 2011), which

s and injectable drugs and oral equivalents. The primary goal of

the bundled payment system was to decrease incentives for the overuse of previously separately reimbursable drugs, primarily ESAs because they were the most expensive and due to safety concerns with these agents.

Healthcare providers must consider the reimbursement structure with regard to ESA use and weigh the risks and benefits of ESA and IV iron treatment in individual patients when making decisions about anemia management. Since the introduction of erythropoietin in the late 1980s, the mean Hb rose from an average of 9.7 g/dL (97 g/dL, 6.02 mmol/L) in 1991 to a maximum of 12 g/dL (120 g/L, 7.45 mmol/L) in 2005 as weekly ESA doses increased from an average of approximately 7,300 units to over 19,000 units per week.[11,137] While doses have decreased since that time (to approximately 9,450 units per week in 2013) due to safety concerns, over 90% of US dialysis patients still receive an ESA.[11,138] On an international level (according to the Dialysis Outcomes and Practice Patterns Study Program) over 85% of CKD 5D patients use ESAs and 72% use IV iron.[138] Some observational studies also showed improved quality of life with Hb levels above 11 g/dL (110 g/L; 6.83 mmol/L).[79] It is clear now, however, that targeting Hb levels above 11 g/dL (110 g/L; 6.83 mmol/L) with ESA therapy increases risk of mortality and CV events and is associated with higher cost per quality-adjusted live-year (QALY) gained compared with patients maintained in a lower Hb range.[139] Patients may decide that risk of ESA therapy outweighs the benefits and is one reason a discussion with the patient (ie, as with the REMS program) is necessary. With the availability of biosimilars the cost of therapy is expected to decrease, although this will depend on the how these agents are accepted and adopted in clinical practice.[103]

The US payment system does affect treatment approaches for CKD-MBD. Oral ESRD drugs that do not have an IV equivalent, such as phosphate binders and cinacalcet, are outside the bundle and are reimbursable through Medicare part D, Medicaid or commercial prescription drug plans. These agents were to be included in the bundle in 2014, but their inclusion has been postponed until 2024. Since Medicare part D plans are administered through various insurance contractors with varying formularies and drug pricing tiers, the covered phosphate binder may be different depending upon the plan. From an international perspective approximately 80% of CKD 5D patients are prescribed phosphate binders, 70% vitamin D, and 17% cinacalcet.[138] The cost-effectiveness of phosphate binders, vitamin D, and cinacalcet on an international level have been evaluated; however, it is difficult to make conclusions about the value of such medications when data on hard outcomes such as mortality are limited.[140]

CARDIOVASCULAR COMPLICATIONS OF CHRONIC KIDNEY DISEASE

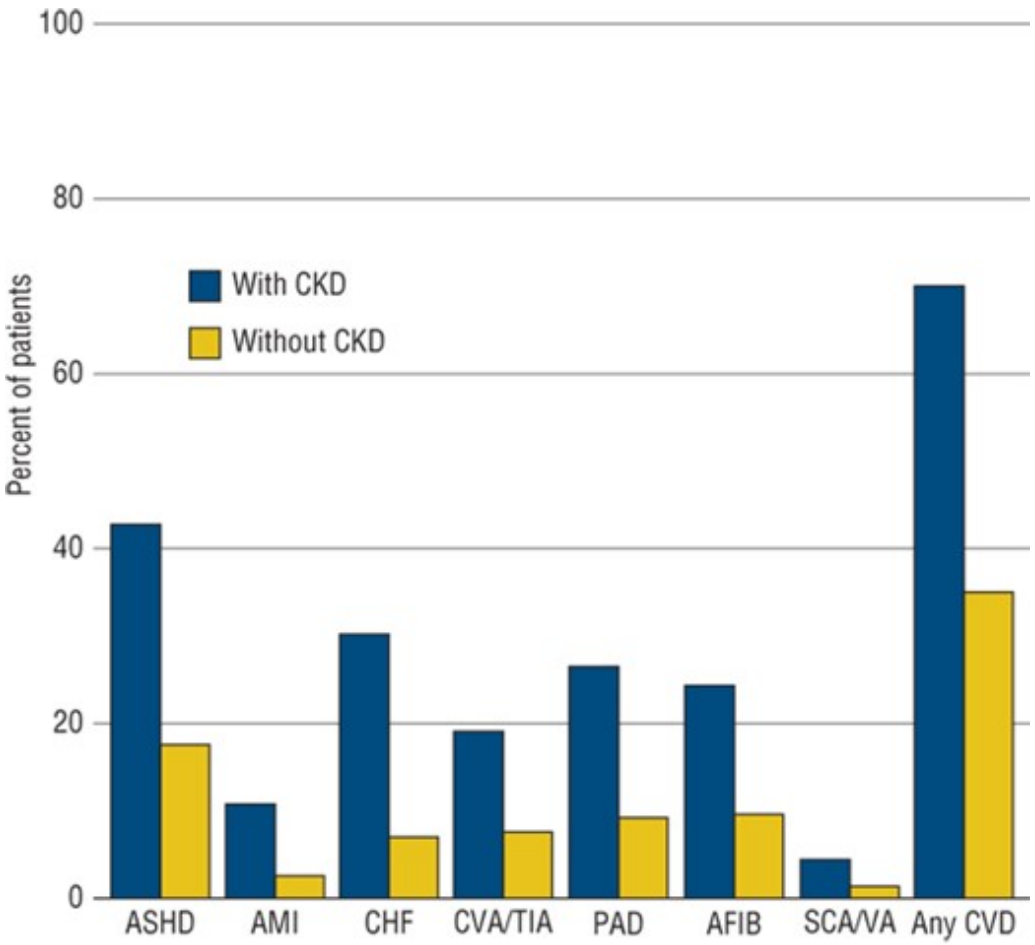
Cardiovascular Disease

Patients with CKD are at increased risk of CVD, independent of the etiology of their kidney disease. This greater burden of CVD in patients with CKD is illustrated in **Fig. 44-7**. The prevalence of any form of CVD is double in CKD patients compared to patients without CKD (70% vs 35%).[141] Thirty

percent of CKD patients had heart failure and 11% had a history of acute myocardial infarction. In contrast, the rates in non-CKD patients were 7% and 2%, respectively. This burden of CVD is associated with much higher mortality rates. For ESRD, adjusted rates of all-cause mortality are six to eight times greater than for individuals in the general population. In particular, cardiac death due to arrhythmia is the leading cause of death in this population.[141]Higher mortality and risk of CV events has also been observed in individuals with CKD 3 to 5.[142]

FIGURE 44-7

Cardiovascular disease in patients with or without CKD.[140] (AFIB, atrial fibrillation; AMI, acute myocardial infarction; ASHD, atherosclerotic heart disease; CHF, congestive heart failure; CKD, chronic kidney disease; CVA/TIA, cerebrovascular accident/transient ischemic attack; CVD, cardiovascular disease; PAD, peripheral arterial disease; SCA/VA, sudden cardiac arrest and ventricular arrhythmias.) Data Source: Medicare 5 percent sample. Patients aged 66 and older, alive, without end-stage renal disease, and residing in the U.S. on 12/31/2012 with fee-for-service coverage for the entire calendar year.



Traditional CVD risk factors present in patients with CKD include diabetes mellitus, dyslipidemia, sity. Nontraditional risk factors include proteinuria,

hyperhomocysteinemia, anemia, inflammation, and abnormal calcium and phosphate metabolism resulting in vascular calcification oxidative stress.[142] Unfortunately, the lack of randomized trials treating CVD in patients with CKD often leads to treatment decisions that are based on extrapolation from trials in non-CKD populations and from observational data in CKD.[143] However, the level of care for ischemic heart disease offered to people with CKD should not differ from people without CKD (grade 1A recommendation) as there is evidence indicating that treatment of traditional risk factors in CKD patients is of benefit.[1] These patients should also receive the standard assessments and treatments such as statins for CKD 1-5 (nondialysis), beta-blockers, ACEIs/ARBs, and antiplatelet agents (see Chapter 16). Clinicians should note that in the diagnosis of acute coronary syndrome, elevated serum troponins should be interpreted with caution in individuals with a GFR less than 60 mL/min/1.73 m^2 (<0.58 mL/s/m^2) because these markers are often elevated as a result of reduced renal excretion (a grade 1B recommendation).[1]

Patients with CKD should receive standard heart failure therapies (Chapter 14); however, clinicians should be aware that RAAS blockade (eg, ACEI, ARB, spironolactone, eplerenone) and diuretic therapy (eg, furosemide, metolazone) may lead to significant changes in GFR and serum potassium concentrations. Such therapy should not be avoided, but closely monitored and put into the context of individual risks and benefits. With regard to the cardiac biomarkers of B-type natriuretic peptide (BNP) and N-terminal pro-BNP (NT-pro-BNP) in individuals with a GFR less than 60 mL/min/1.73 m^2 (<0.58 mL/s/m^2) (CKD 3a-5), it is recommended that serum concentrations be interpreted with caution with respect to diagnosis of heart failure and assessment of volume status (a grade 1B recommendation).[1]

Aspirin is recommended for secondary prevention in all patients with CKD based on decreased mortality in observational studies.[144,145] There is, however, controversy over the use of aspirin (ASA) for primary prevention in patients with CKD.[146,147,148]

Clinical Controversy…

The KDIGO guidelines state in one section that ASA is not recommended for primary prevention.[1] However, later in the guidelines it is stated that "adults with CKD at risk for atherosclerotic events be offered treatment with antiplatelet agents unless there is an increased bleeding risk that needs to be balanced against the possible CV benefits."[1] This position statement is derived from a post-hoc analysis of the Hypertension Optimal Treatment (HOT) trial which concluded that the increased risk of major bleeding appears to be outweighed by the substantial benefits of aspirin in individuals with CKD and hypertension.[146,147] As post-hoc analyses are hypothesis generating and should always be interpreted with caution, an editorial on the HOT trial CKD subgroup analysis made the following recommendations: (1) This study should not be taken as robust evidence in favor of aspirin therapy for primary prevention in CKD; (2)There is an urgent need for a prospective randomized controlled trial that includes patients with all categories of CKD and; (3) The risk of major bleeding as well as paradoxical thrombosis is a genuine concern when using aspirin for primary prevention in patients with CKD.[148]

Hyperlipidemia

CKD with or without nephrotic syndrome is frequently accompanied by abnormalities in lipoprotein metabolism (see Chapter 47). A clear association between hypercholesterolemia, hypertriglyceridemia, and other lipoprotein changes in patients with CKD and CVD has not been demonstrated in large prospective studies because individuals with kidney disease are usually excluded from these trials. A low or declining serum cholesterol in patients with ESRD is associated with higher mortality, a paradoxical effect.[149] These findings beg the question of whether aggressive lipid lowering is warranted in this population.

Although the concentrations of LDL are not uniformly increased in patients with kidney disease, these patients appear to produce small, dense LDL particles that are more susceptible to oxidation and more atherogenic than larger LDL subfractions. Other lipid abnormalities include low HDL and increased triglycerides.[149] In patients with nephrotic syndrome, the major lipid abnormalities are elevation of plasma total and LDL cholesterol, with or without low HDL cholesterol, and elevated triglycerides. See Chapter 47 for a detailed discussion of the management of proteinuria in patients with glomerulonephritis.

The KDIGO Lipid Guidelines recommend that a complete fasting lipid profile be performed in all adults with newly identified CKD (a grade 1C recommendation).[150] Follow-up lipid levels are not recommended unless the information may alter management (eg, assessing adherence to therapy or assessing CV risk in a patient <50 years and not currently on a statin). Reduction in the risk of CV events in patients with CKD has only been demonstrated with statins or a statin plus ezetimibe combination.[150]

Statins in Chronic Kidney Disease

Statins have been shown to decrease mortality and CV events in CKD 1-5 patients, however, data are not as compelling in the ESRD population.[151] Although observational studies in HD patients receiving statins indicated a significant benefit, findings from prospective studies have not been encouraging. The 4D Trial, a 4-year study evaluating the effect of atorvastatin therapy on cardiac mortality in more than 1,200 HD patients with type 2 diabetes, showed no significant benefit in the composite end point compared with the placebo group.[152] In fact, there was a significantly greater relative risk (RR) of fatal stroke in the atorvastatin-treated patients. These findings do not support initiation of statin therapy in ESRD patients, especially those with type 2 diabetes. The findings with rosuvastatin were similar: despite a 43% reduction in cholesterol there was no significant change in the primary end points of death from CV causes, nonfatal MI, or nonfatal stroke.[153] The Study of Heart and Renal Protection (SHARP) trial was a primary prevention trial that evaluated the effects of combined simvastatin (20 mg) and ezetimibe (10 mg) compared with placebo on time to first major vascular event (nonfatal MI or cardiac death, any stroke, or revascularization) in patients with no history of MI or coronary revascularization and included patients with CKD (6,247) and ESRD (3,023).[154] In all patients receiving combined therapy during the 4.9-year follow up period, there was a significant 17% reduction in the RR of major vascular events and a 32% reduction in LDL in the patients who

apy (two-thirds were compliant). While overall these results are

positive, the study was not powered to evaluate whether the observed effect was significant in ESRD patients as a separate group. A subgroup analysis comparing dialysis versus non-dialysis and diabetic versus non-diabetic patients showed no differences in the RR of CV events even after adjustment for the reduction in LDL.

A recent meta-analysis of statins in dialysis patients indicated that they had no significant beneficial effect on major CV events, all-cause mortality, CV death, or myocardial infarction, and a trend toward increased strokes despite clinically relevant reductions in LDL cholesterol.[155] In contrast, a meta-analysis of statins in non-dialysis CKD showed significant reductions in major CV events, CV death, all-cause mortality; myocardial infarction but uncertain effects on stroke.[156]

BOTTOM LINE

The incidence of CKD has recently declined but the prevalence continues to increase. Although efforts to delay progression of CKD including prudent use of ACEIs and ARBs are paramount, measures to diagnose and manage the associated secondary complications and comorbid conditions early in the course of the disease are also essential. Common complications of CKD 4 and 5 include anemia and CKD-MBD. CV complications are also prevalent in the population with CKD, and are the leading cause of mortality in patients with ESRD.

A multidisciplinary team structure is a rational approach to effectively design and implement individual patient care plans often required in the CKD population given the extensive nonpharmacologic and pharmacologic interventions. Thus pharmacists are well positioned to actively participate in the chronic disease and medication management of ambulatory CKD and dialysis patients as well as those who are hospitalized.

Chapter 45: Hemodialysis and Peritoneal Dialysis

Kevin M. Sowinski; Mariann D. Churchwell; Brian S. Decker

INTRODUCTION

KEY CONCEPTS

- 1 Hemodialysis (HD) involves the perfusion of blood and dialysate on opposite sides of a semipermeable membrane. Solutes are removed from the blood by diffusion and convection. Excess plasma water is removed by ultrafiltration.
- 2 Native arteriovenous (AV) fistulas are the preferred access for HD because of fewer complications and a longer survival rate. Venous catheters are plagued by complications such as infection and thrombosis and often deliver low blood flow rates.
- 3 Adequacy of HD can be assessed by the *Kt/V* and urea reduction ratio (URR). The National Kidney Foundation's Kidney Disease Outcomes Quality Initiative minimum goal *Kt/V* is greater than 1.2 per treatment and the URR is greater than 65%.
- 4 During HD, patients commonly experience hypotension and cramps. Other more serious complications include infection and thrombosis of the vascular access.
- 5 Peritoneal dialysis (PD) involves the instillation of dialysate into the peritoneal cavity via a permanent peritoneal catheter. The peritoneal membrane lines the highly vascularized abdominal viscera and acts as the semipermeable membrane. Solutes are removed from the blood across the peritoneum via diffusion and ultrafiltration. Excess plasma water is removed via ultrafiltration created by osmotic pressure generated by various dextrose or icodextrin concentrations.
- 6 Patients on PD are required to instill and drain, manually or via automated systems, several liters of fresh dialysate each day. The more exchanges completed each day results in greater solute removal.

- 7 Peritonitis is a common complication of PD. Initial empiric therapy for peritonitis should include intraperitoneal antibiotics that are effective against both gram-positive and gram-negative organisms.

- 8 Nasal carriage of *Staphylococcus aureus* is associated with an increased risk of catheter-related infections and peritonitis. Prophylaxis with intranasal mupirocin (twice a day for 5 days every month) or mupirocin (daily) at the exit site can effectively reduce *S. aureus* infections.

The three primary treatment options for patients with end-stage renal disease (ESRD) are hemodialysis (HD), peritoneal dialysis (PD), and kidney transplantation. The United States Renal Data System (USRDS) is the national system that "collects, analyzes, and distributes" data relating to patients with ESRD or Stage 5 chronic kidney disease (CKD) in the United States and releases these data yearly.[1] According to the 2014 USRDS, at the end of 2012, there were 636,905 patients in the United States with ESRD. Of these, greater than 475,000 patients were being treated with HD or PD, and 186,303 had a functioning kidney transplant. In 2012, 114,813 new patients started therapy for ESRD (dialysis or transplantation) and more than 88,000 patients died. Greater than 90 percent of new dialysis patients are treated with HD. The number of patients treated with PD has decreased steadily since 2000.[1]

Since 1972, the cost of treating ESRD (both dialysis and kidney transplantation) has been covered by Medicare. The total cost of ESRD in 2012 was $42.5 million. This includes Medicare costs ($28.6 billion) and Medicare patient obligation costs, which together make up approximately 75% of all costs. Non-Medicare costs make up the remainder of the total disease costs. Total Medicare spending for ESRD rose by 3.5 percent in 2012. Medicare spending for ESRD does not include Part D expenditures, which were $2.16 billion in 2011. ESRD consumes a vastly disproportionate amount of resources. Approximately 1% of the patients in the Medicare program have ESRD, yet the ESRD program consumes nearly 6% of the Medicare budget. Although total spending for ESRD treatment continues to climb, per-patient spending (after adjusting for inflation) was nearly unchanged from 2011 to 2012.[1]

There are some positive signs as it relates to public health and ESRD. Although the total number of dialysis patients is increasing in the United States, the number of new dialysis patients per total population has stabilized or slightly decreased from the highest value observed in 1997. The prevalence of ESRD continues to climb, reflective of reduced mortality and enhanced patient care. The two primary diagnoses and underlying etiologies of kidney disease for new patients with ESRD are diabetes and hypertension.[1] Chapter 44 provides a thorough discussion on the epidemiology of chronic kidney disease.

This chapter serves as a primer on the principles and practice of dialysis and the complications associated with the delivery of dialysis treatments. The chapter focuses on HD and PD as the modalities most commonly employed for the management of ESRD (see Chapter 43 for a discussion of the role of renal replacement therapies in the management of acute kidney injury). The pertinent factors that should be considered before the initiation of dialysis are described. The morbidity and mortality associated with HD and PD are compared, as these considerations may influence the

dialysis method chosen by patients and clinicians. The variants of HD and PD are detailed, and multiple types of vascular and peritoneal access used with each (ie, catheters and surgical techniques) are illustrated. The concept of dialysis adequacy for each modality is briefly reviewed. Finally, the clinical presentation of common complications of both dialytic therapies is presented, along with pertinent nonpharmacologic and pharmacologic therapeutic approaches. Information resources that describe the influence of CKD on patient's quality of life, as well as the patient perspective on dialysis and dialysis related therapies are presented to highlight the human consequences of chronic disease.

Morbidity and Mortality in Dialysis

Morbidity in patients receiving dialysis can be assessed in a number of different ways including tabulation of the number of hospitalizations per patient-year, the number of days hospitalized per patient per year, or the incidence of certain complications. The number of all-cause hospital admissions, 1.73 hospitalizations/patient year, has fallen in recent years. Trends in hospitalization demonstrate an increase in hospitalization as a consequence of infection and cardiovascular disease and a decrease in hospitalizations as a consequence of vascular access problems. Patients with a functioning kidney transplant have a lower rate of hospitalization and shorter length of stay. Hospitalizations are more frequent for whites than for blacks, and the frequency and duration increase with age in both dialysis modality groups.[1]

The life expectancy of U.S. dialysis patients is markedly lower than that of healthy subjects of the same age and sex. In those older than 65 years, the risk of dying is 2 to 3 fold higher in dialysis patients compared to those with diabetes, cancer, heart failure, or cardiovascular disease but not receiving dialysis.[1] Adjusted all-cause mortality is 6 to 8 fold greater for dialysis patients compared with age-matched individuals. Approximately 50% of deaths in dialysis patients are cardiovascular related. In fact, those with CKD are more likely to die from cardiovascular disease before they reach ESRD. Infections, usually related to the dialysis access, are the second most common cause of death in dialysis patients. Although mortality remains high in this patient population, the overall patient mortality rate has fallen among dialysis patients since 1991. Since that time, mortality has declined by 9% (1991-2002) and 26% (2003-2012). The reductions are dependent on treatment type, and are smallest for HD and greatest for transplantation. The changes in mortality rates are more impressive when the duration of a patient's time receiving dialysis is considered. For the first several months of dialysis therapy there is marked increase in mortality, followed by a reduction over the first 12 months. Mortality rates ultimately increase with time. In the United States, only 54% of HD patients and 65% of PD patients are alive 3 years after ESRD diagnosis and initiation of dialysis treatment.[1]

In addition to high morbidity and mortality, a dialysis patient's quality of life is generally poor. For example, restrictions caused by thrice weekly HD and/or associated treatments have been shown to impact many areas of a patient's life. These include but are not limited to, physical endurance, sex, employment, social life, and diet. Patients often complain of fatigue and fear of the unknown related to their disease and its progression. The PD patient or the home HD patient may have some freedom from these restrictions, but this freedom comes with its own constraints.

Indications for Dialysis

Since first published in 2002, The National Kidney Foundation's Kidney Disease Outcome Quality Initiative (KDOQI) has been the primary treatment guideline for CKD. Although the Kidney Diseases: Improving Global Outcomes (KDIGO) guidelines[2] published in 2013 now serve as a general update to the KDOQI guidelines, the 2006 version of the KDOQI guidelines established recommendations related to dialysis initiation. Planning for dialysis initiation when a patient's kidney function declines to CKD stage 4 (estimated glomerular filtration rate [eGFR] below 30 mL/min/1.73 m^2).[3] Beginning the preparation process at this point allows adequate time for proper education of the patient and family and for the creation of a suitable vascular or peritoneal access. For patients choosing HD, a permanent arteriovenous (AV) access (preferably a fistula) should be surgically created when eGFR falls below 25 mL/min/1.73 m^2, serum creatinine is greater than 4 mg/dL (354 µmol/L) or 1 year prior to the anticipated need for dialysis.[4] The KDIGO guidelines provide recommendations for referral to a specialist in kidney care services and for planning for RRT. The recommendation for timely referral is for patients with progressive CKD in whom the risk of kidney failure within 1 year is greater than 10% based upon validated risk prediction tools.[2]

Clinical Controversy…

There is debate over which dialysis treatment modality, HD or PD, is most desirable in terms of morbidity and mortality. There is further debate over which type of HD is more beneficial, standard in-center HD or intensive HD. Although most U.S. patients are treated with in-center HD, other therapies may provide more benefit.

The KDIGO guidelines and commentaries addressing them agree that the primary criterion for initiation of dialysis is the patient's clinical status, rather than a specific level of kidney function.[2,5] Namely, dialysis should be initiated when one or more of the following are present: signs or symptoms of kidney failure (eg, serositis, acid-base or electrolyte abnormalities, pruritis); inability to control volume status or blood pressure; a progressive deterioration in nutritional status or cognitive impairment. The guidelines suggest that these signs and symptoms tend to be evident once the patient's eGFR is in the range of 5 to 10 mL/min/1.73 m^2. The guidelines specifically indicate that RRT should be initiated to manage signs and symptoms and not to treat an arbitrary kidney function measurement.[2] The advantages and disadvantages of HD and PD are depicted in **Tables 45-1** and **45-2**, respectively. These factors, along with the patients' concomitant diseases, personal preferences, and support environments, are the principal determinants of the dialysis mode they will receive.[6] The timing of dialysis initiation is a compromise between maximizing patient quality of life by extending the dialysis-free period while avoiding complications that will decrease the length and quality of dialysis-assisted life.[3]

TABLE 45-1 Advantages and Disadvantages of Hemodialysis

Advantages

1. Higher solute clearance allows intermittent treatment.
2. Parameters of adequacy of dialysis are better defined and therefore underdialysis can be detected early.

3. Technique failure rate is low.
4. Even though intermittent heparinization is required, hemostasis parameters are better corrected with hemodialysis than peritoneal dialysis.
5. In-center hemodialysis enables closer monitoring of the patient.

Disadvantages

1. Requires multiple visits each week to the hemodialysis center, which translates into loss of patient independence.
2. Disequilibrium, dialysis induced hypotension, and muscle cramps are common. May require months before the patient adjusts to hemodialysis.
3. Infections in hemodialysis patients may be related to the choice of membranes, the complement-activating membranes being more deleterious.
4. Vascular access is frequently associated with infection and thrombosis.
5. Decline of residual renal function is more rapid compared to peritoneal dialysis.

TABLE 45-2 Advantages and Disadvantages of Peritoneal Dialysis

Advantages

1. Hemodynamic stability due to slow ultrafiltration rate.
2. Higher clearance of larger solutes, which may explain good clinical status in spite of lower urea clearance.
3. Better preservation of residual renal function.
4. Convenient intraperitoneal route for administration of drugs such as antibiotics and insulin.
5. Suitable for elderly and very young patients who may not tolerate hemodialysis well.
6. Freedom from the “machine” gives the patient a sense of independence (for continuous ambulatory peritoneal dialysis).
7. Less blood loss and iron deficiency, resulting in easier management of anemia or reduced requirements for erythropoietin and parenteral iron.
8. No systemic heparinization required.
9. Subcutaneous vs intravenous erythropoietin or darbepoetin may reduce overall doses and be more physiologic.

Disadvantages

1. Protein and amino acid losses through peritoneum and reduced appetite from continuous glucose load and sense of abdominal fullness predispose patients to malnutrition.
2. Risk of peritonitis.
3. Catheter malfunction, exit site, and tunnel infection.
4. Inadequate ultrafiltration and solute clearance in patients with a large body size, unless large volumes and frequent exchanges are employed.
5. Patient burnout and high rate of technique failure.
6. Risk of obesity with excessive glucose absorption.
7. Mechanical problems such as hernias, dialysate leaks, hemorrhoids, or back pain are more common than HD.
8. Extensive abdominal surgery may preclude peritoneal dialysis.
9. No convenient access for intravenous iron administration.

While the intent of this chapter is not to exhaustively compare and contrast HD and PD and the relative benefits of each, there is considerable debate in the literature regarding the mortality differences between HD and PD.[7] Most observational trials suggest that PD is associated with a survival advantage early in therapy, which wanes with increased treatment time. Prospective trials have reported conflicting results relative to efficacy of one modality over another. If there is a survival advantage for PD, the consensus is that the advantage is early in therapy and not with continued therapy. Well-designed studies are extremely difficult to conduct in this population and thus the question of superiority of one modality over the other is controversial. Differences in outcomes may be related to a wide array of confounding factors, such as the dose of dialysis, baseline patient health status, physician bias in modality selection, patient compliance with dialysis and medication therapy, or other unknown factors. For example, healthier patients tend to be directed toward PD and factors such as age, duration of dialysis, and comorbidities play an important role in the complex relationship between patient outcomes and mortality.[8] Without clear distinction between modalities in terms of many important outcomes, the selection of the optimal therapy for a given patient is challenging. The selection of one modality over the other should be based upon patient motivation, desire, geographic distance from a HD unit, health care team preference, and patient education rather than survival advantages alone.

HEMODIALYSIS

Although HD was first successfully used in 1940, the procedure was not used widely until the Korean War in 1952. Permanent dialysis access was developed in the 1960s,[9] which allowed routine use of

HD in patients with ESRD. Subsequent decades brought advances in dialysis technology, including the introduction of more efficient and biocompatible dialyzer membranes and safer techniques. HD is now the most common type of renal replacement therapy for patients with ESRD.

Principles of Hemodialysis

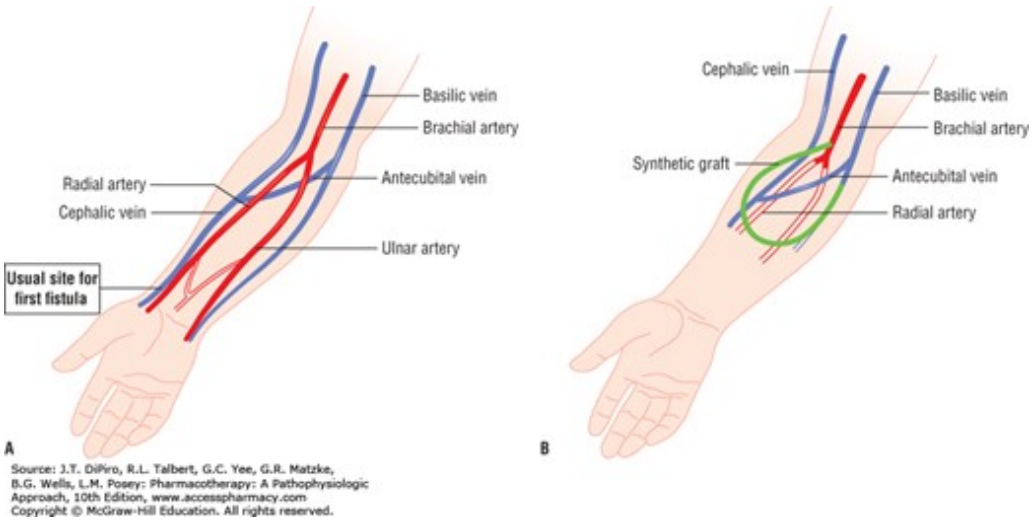
1 Hemodialysis consists of the perfusion of blood and a physiologic solution on opposite sides of a semipermeable membrane. Multiple substances, such as water, urea, creatinine, potassium, uremic toxins, and drugs, move from the blood into the dialysate, by either passive diffusion or convection as the result of ultrafiltration. Diffusion is the movement of substances down a concentration gradient. The rate of diffusion depends on the difference between the concentration of the solute in blood and dialysate, solute characteristics, ie, size, water solubility, and charge, the dialyzer membrane composition, and blood and dialysate flow rates. Diffusive transport is rapid for small solutes, but decreases with increasing molecular size. Other important diffusive solute transport factors include the membrane thickness, porosity and the steric hindrance between the membrane pores and solute. Ultrafiltration is the movement of water across the dialyzer membrane as a consequence of hydrostatic or osmotic pressure and is the primary means for removal of excess fluid. Convection occurs when dissolved solutes are "dragged" across a membrane with water transport. This occurs only if the pores in the dialyzer are large enough to allow them to pass along with water. Convection can be maximized by increasing the hydrostatic pressure gradient across the dialysis membrane, or by changing to a dialyzer that is more permeable to water transport. Diffusion and convection can be controlled independently, and thus a patient's HD prescription can be individualized to attain the desired degree of solute and fluid removal.

Hemodialysis Access

2 Obtaining and maintaining access to the circulation has been a challenge for long-term use and success of HD. Permanent access to the circulation may be accomplished by several techniques, including the creation of an AV fistula, an AV graft, or by the use of venous catheters (**Fig. 45-1**).[10] The native AV fistula is created by the anastomosis of a vein and artery (ie, the radial artery to the cephalic vein or the brachial artery to the cephalic vein). The native AV fistula has many advantages including providing the longest survival time of all blood-access devices and the lowest rate of complications such as infection and thrombosis. Patients with fistulas have increased survival and lower hospitalization rates compared to other HD patients. Finally, AV fistulas are the most cost-effective in terms of placement and long-term maintenance. Ideally, the most distal site (the wrist) is used to construct the first fistula; it is the easiest to create, and in the case of access failure, more proximal sites on the arm are preserved for later use. Unfortunately, fistulas require at least 1 to 2 months to mature before they can be routinely utilized for dialysis. Creation of an AV fistula however may be difficult in elderly patients and in patients with peripheral vascular disease, which is a particularly common comorbidity in patients with diabetes.

FIGURE 45-1

The predominant types of vascular access for chronic dialysis patients are (*A*) the arteriovenous fistula and (*B*) the synthetic arteriovenous forearm graft. The first primary arteriovenous fistula is usually created by the surgical anastomosis of the cephalic vein with the radial artery. The flow of blood from the higher-pressure arterial system results in hypertrophy of the vein. The most common AV graft (depicted in green) is between the brachial artery and the basilic or cephalic vein. The flow of blood may be diminished in the radial and ulnar arteries since it preferentially flows into the low pressure graft.



Synthetic AV grafts, usually made of polytetrafluoroethylene, are another permanent AV access option. These grafts require only 2 to 3 weeks before they can be routinely used. Their primary disadvantages are shorter survival of the graft, and higher rates of infection and thrombosis. The least-desirable and least permanent HD access option involves the placement of a central venous catheter. Venous catheters can be placed in the femoral, subclavian, or internal jugular veins. Their main advantage is that they can be used immediately and they are often used in small children, diabetic patients with severe vascular disease, the morbidly obese, and patients who have no viable sites for permanent AV access. Late referrals to a nephrology specialist and delayed placement of a more appropriate long-term access contribute to the use of venous catheters in chronic HD patients. The major problem with all venous catheters is they have a short life span and are more prone to infection and thrombosis than either AV grafts or fistulas. Furthermore, some catheters are not able to provide adequate blood flow rates, which can limit the deliverable dose of dialysis.[10,11,12] Regardless, tunneled dialysis catheters are used frequently because of the ease of insertion, pain-free dialysis needle placement and availability for immediate use. They are however associated with increased morbidity, mortality and cost.[13]

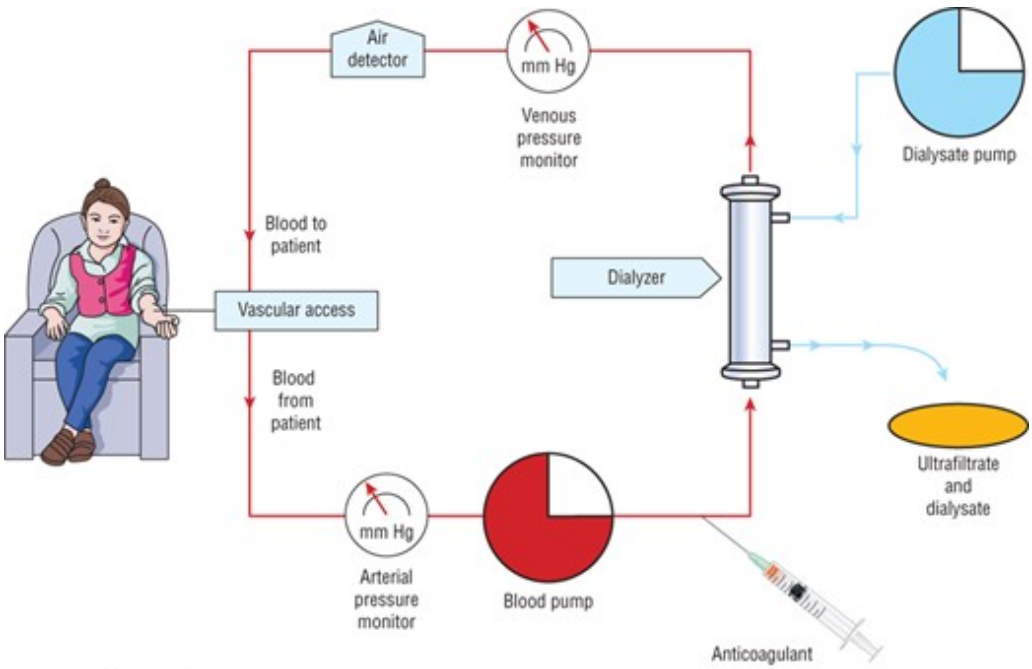
Hemodialysis Procedures

The HD system consists of an external vascular circuit through which the patient's blood is transferred in sterile polyethylene tubing to the dialyzer via a mechanical pump (**Fig. 45-2**).[14] The patient's blood then passes through the dialyzer on one side of the semipermeable membrane and is returned to the patient. The dialysate solution, which consists of purified water and electrolytes, is pumped through the dialyzer countercurrent to the flow of blood on the opposite side of the semipermeable

membrane. In most cases, systemic anticoagulation (with heparin) is used to prevent blood clotting in the HD circuit tubing. The process of dialysis results in the removal of metabolic waste products, medications, and water and replenishment of body buffers, such as acetate and bicarbonate.

FIGURE 45-2

In hemodialysis, the patient's blood is pumped to the dialyzer at a rate of 300 to 600 mL/min. An anticoagulant (usually heparin) is administered to prevent clotting in the dialyzer. The dialysate is pumped at a rate of 500 to 1,000 mL/min through the dialyzer countercurrent to the flow of blood. The rate of fluid removal from the patient is controlled by adjusting the pressure in the dialysate compartment.



Hemodialfiltration (HDF) another variant of traditional HD enhances convective solute and water transport in addition to diffusive clearance to a much greater extent than high-flux HD.[15,16,17] When fluid losses exceed those desired for the patient, an IV infusion referred to as replacement fluid may be administered. HDF may improve outcomes due to its ability to remove middle molecular weight uremic solutes more efficiently than the other HD variants. Recent evidence suggests that HDF improves survival compared to conventional HD.[16,18] Preliminary information suggests that HDF enhances clearance of phosphate, beta-2 microglobulin and pro-inflammatory solutes. Currently, this procedure is not used extensively in the United States. Barriers to its use are the high cost and logistic issues associated with providing the fluid replacement needs.

Three categories of dialysis membranes have historically been utilized: low flux, high efficiency, and high flux. Low-flux and high-efficiency dialyzers, have small pores that limit clearance to relatively small molecules (size less than or equal to 500 daltons) such as urea and creatinine and are currently utilized for less than 20% of chronic HD procedures.[14] High-flux dialyzers are now used in the vast majority of patients because they are capable of removing high-molecular-weight endogenous

substances, such as β_2-microglobulin, and medications such as vancomycin.[14,19] The primary reason to use high-flux membranes is that clearance of water as well as low- and high-molecular-weight substances is much greater allowing for shorter treatment times. To maximize the clearance capacity of high flux dialyzers the blood flow rates should be 400 to 600 mL/min, dialysate flow rates greater than 500 mL/min, which necessitates strict controls and active monitoring of the rate of fluid removal. Typically these dialyzers are composed of polysulfone, polymethylmethacrylate, polyamide, cellulose triacetate, and polyacrylonitrile.[14]

Hemodialysis is usually prescribed as three sessions weekly for 3 to 5 hours per session. These sessions are usually performed in "in-center" dialysis units. This is a large time commitment for any patient undergoing HD and results in substantial loss of control over their life. Several variants of HD have been explored in an effort to balance dialysis adequacy with patient outcomes and quality of life, including "intensive dialysis" procedures that increase dialysis frequency, enhance dialysis duration, or both.[20,21,22] Examples of these procedures include: 1) frequent HD (5-7 sessions/week), which can be frequent short (1.5-3 hours/session), frequent standard (3-5 hours/session), or frequent long sessions (longer than 5 hours/session); 2) long-session length regimens (more than 5 hours/session given 3 times/week or every other day; 3) short and standard frequent HD (also called daily HD); and 4) long frequent HD (or Nocturnal HD), typically performed at night. Many of these procedures that increase the frequency or duration of dialysis maybe associated with improved survival.[20,21,22] For example, in-center, thrice weekly HD was associated with a higher risk of the composite outcome of death, left-ventricular mass and change in health composite score than in-center six-times per week HD.[23] Intensive dialysis has been associated with reductions in left-ventricular mass and improved blood pressure control, both surrogates for improved cardiovascular outcomes, and improved phosphate removal. Lastly, and perhaps most importantly, these procedures are associated with a reduction in dialysis related symptoms and improved quality of life.[20,21,22] Despite the perceived advantages and more frequent use in other countries such as New Zealand and Canada, the use of home HD is uncommon in the United States, with less than 1% of dialysis patients receiving HD care at home.[1] Potential obstacles to home HD include patient factors (eg, lack of self-efficacy, fear of self-cannulation, fear of catastrophic event, and fear of lack of quality care), and a lack of awareness of the availability of this type of dialysis.[24,25] Finally, there are suggestions that patients receiving intensive dialysis may be at higher risk of access infections and need for vascular access procedures. Further clinical trials are needed to elucidate the role of these types of dialysis therapy.

Adequacy of Hemodialysis

The optimal dose of HD, the patient's dialysis prescription, is that amount of therapy above which there is no cost-effective increment in the patient's quality-adjusted life expectancy. The two primary goals of the dialysis prescription are to achieve the patient's dry weight and the adequate removal of endogenous waste products such as urea. Dry weight is the target postdialysis weight at which the patient is normotensive and free of edema. Measurement of urea removal, while imperfect, is the typical method used to quantify dialysis adequacy. Urea removal reflects the "delivered dose" of dialysis and is utilized as the surrogate for removal of other toxins.

The delivered or desired dose of dialysis in terms of solute removal can be expressed as the urea reduction ratio (URR) or the *Kt/V* (pronounced "K-T-over-V"). The URR is a simple concept and is easily calculated as:

$$\text{URR} = \frac{\text{Predialysis BUN} - \text{Postdialysis BUN}}{\text{Predialysis BUN}} \times 100$$

The URR is frequently used to measure the delivered dialysis dose, however, it does not account for the contribution of convective removal of urea. The *Kt/V* is a unitless index based on the dialyzer clearance of urea (*K*) in L/h multiplied by the duration of dialysis (*t*) in hours, divided by the urea distribution volume of the patient (*V*) in liters.[26] *Kt/V* is thus the fraction of the patient's total body water that is cleared of urea during a dialysis session. Urea kinetic modeling, using computer software, is the optimal means to calculate the *Kt/V*.[27] An in-depth discussion of the pros and cons of various methods of calculating and interpreting *Kt/V* is beyond the scope of this chapter. The reader is referred to other sources for more in-depth information.[26,27]

3 The KDOQI recommends that the minimally adequate delivered dose of dialysis is a *Kt/V* of 1.2 (equivalent to an average URR of 65%).[3] To achieve this goal, the recommended target prescribed *Kt/V* is 1.4 (equivalent to an average URR of 70%).[3] Lower doses of dialysis treatment are thought to be associated with increased morbidity and mortality. Many nephrologists believe that even greater doses of dialysis would have positive outcomes in dialysis patients, and so the average dose of dialysis has been increasing in the United States. In 2004, the mean delivered *Kt/V* as reported by the CPM was 1.55.[28] The results of HEMO study a prospective, randomized trial that assigned patients to either standard (*Kt/V* = 1.25) or high-dose (*Kt/V* = 1.65) dialysis with high-flux or low-flux membranes revealed that the risk of death was similar in both the standard and high-dose therapy and the low- and high-flux groups. Thus there does not appear to be any benefit in increasing the dose of dialysis above the current recommendations. The HEMO study only enrolled patients who were on traditional thrice-weekly dialysis, so the applicability of these findings to patients on more intensive regimens such as daily or nocturnal HD regimens remain to be determined.[29] However, intensive HD regimens may result in better blood pressure, anemia, and phosphate control.[29] In those relatively few patients who are below the adequacy goal, the deficiency may be related to patient compliance with the dialysis prescription (ie, ending dialysis early) or low blood flow rates caused by access stenosis or thrombosis, or due to the use of catheters. Adequate dialysis may not be achieved in some patients despite compliance and sufficient blood flow. For these patients there are two options to increase urea clearance: use a larger membrane or increase the treatment time.

Complications of Hemodialysis

4 Complications associated with HD therapy are significant and can limit therapy efficacy. These complications that occur during the actual therapy (intradialytic), as well as those associated with vascular access are discussed in this chapter.[30,31]

Hemodialysis Procedure Complications

The most common complications that occur during the HD procedure include hypotension, hypertension, cramps, nausea and vomiting, headache, chest pain, back pain, and fever or chills.[30,31] **Table 45-3** lists these complications and their etiology and predisposing factors.

TABLE 45-3 Common Complications during Hemodialysis[37]

	Incidence (%)	Etiology/Predisposing Factors
Hypotension	20-30	Hypovolemia and excessive ultrafiltration Antihypertensive medications prior to dialysis Target dry weight too low Diastolic dysfunction Autonomic dysfunction Low calcium and sodium in dialysate High dialysate temperature Meal ingestion prior to or during dialysis
Hypertension	5-15	Plasma sodium concentration Intravascular volume Dialytic removal of antihypertensive medications Activation of the Renin Angiotensin Aldosterone system
Cramps	5-20	Muscle hypoperfusion due to ultrafiltration and hypovolemia Hypotension Electrolyte imbalance Acid-base imbalance
Nausea and vomiting	5-15	Hypotension Dialyzer reaction Disequilibrium syndrome Caffeine withdrawal due to dialysis removal
Headache	5	Unknown
Chest and back pain	2-5	Inadequate dialysis Skin dryness Secondary hyperparathyroidism Abnormal skin concentrations of electrolytes Histamine release Mast cell proliferation
Pruritus	5	Endotoxin release; Infection of dialysis catheter
Fever and chills	<1	

A decrease in blood pressure is often noted during HD, but a symptomatic decline in blood pressure that requires nursing or medical intervention can lead to a decrease in the effectiveness of this treatment.[31] Intradialytic hypotension (IDH) is primarily related to the rate and amount of fluid removed during[30,31] typical treatments, although other causes, as listed in **Table 45-4**, may also play

a role.[30,31] Other symptoms such as nausea and cramping are often present during acute hypotensive episodes. The replacement of acetate with bicarbonate as the dialysate buffer, the use of volumetric ultrafiltration controllers, as well as individualized or modeled dialysate sodium concentrations have helped reduce the incidence of IDH. Sodium modeling uses a higher initial dialysate sodium concentration (145-155 mM) and tapers the sodium concentration down (135-140 mM) over the dialytic session. Dialytic treatment modifications such as sodium individualizing or modeling may decrease intradialytic weight gain and post-HD thirst decreasing hypotension related to aggressive dialytic fluid removal.[32,33,34]

TABLE 45-4 Management of Hypotension

Acute treatment	Place patient in Trendelenburg position
	Decrease ultrafiltration rate
	Give 100-200 mL bolus of normal saline intravenous
	Give 10-20 mL of hypertonic saline (23.4%) intravenous over 3-5 minutes
	Give 12.5 g mannitol
Prevention	
Nonpharmacologic	Accurately set "dry weight"
	Use steady constant ultrafiltration rate
	Keep dialysate sodium >serum sodium
	Lower dialysate temperatures
	Bicarbonate dialysate
	Avoid food before or during hemodialysis
Pharmacologic	Midodrine 2.5-10 mg orally 30 minutes before hemodialysis (start at 2.5 mg and titrate)
	Other options (limited evidence):
	Levocarnitine 20 mg/kg IV after hemodialysis
	Sertraline 50-100 mg daily
	Fludrocortisone 0.1 mg before hemodialysis
	DDAVP 1-2 intranasal sprays (150 mcg per spray)

Intradialytic or post-HD hypertension can occur in 5% to 15% of HD patients and may increase the risk of cardiovascular and all-cause mortality.[35] Underlying causes can include, not achieving postHD dry weight goal, over-estimation of dry weight, dialytic removal of antihypertensive medications or the activation of the renin-angiotensin system secondary to abrupt hypovolemia.[36]

Skeletal muscle cramps complicate 5% to 20% of HD treatments. Although the pathogenesis of cramps is multifactorial, plasma volume contraction and decreased muscle perfusion caused by excessive ultrafiltration are frequently the initiating events.[37] Pruritus, another complication that may appear to increase in severity during the HD treatment, is actually a complication of CKD and the management of this condition is discussed in Chapter 44.

Vascular Access Complications

The maintenance of vascular access patency is critical for HD patients. Aneurysm and stenosis are associated with AV fistulas and grafts, and these are resolved primarily by surgical intervention. Thrombosis and infection are the most common vascular access complications with the highest occurrence found in patients with a catheter compared with those with an AV graft or AV fistula.[31,38,39]

Vascular access dysfunction is usually identified by a decrease in blood flow through the access (blood flow less than 300 mL/min) over a period of days to weeks. Ultrasound, venography, or computed tomography scans can provide a definitive diagnosis.[39,40] Catheter thrombosis can form either inside (intrinsic) or outside (extrinsic) the catheter. The occlusion can form within the lumen at the tip or develop a fibrin sleeve around the catheter where this fibrin sleeve can serve as a nidus for infection and ultimately require catheter removal.[41,42]

Infection is a leading cause of mortality in HD patients.[1] The risk of sepsis-related death is 100 times greater in dialysis patients than the general population and those with an indwelling catheter have the highest risk.[42] Frequently, *Staphylococcus aureus* and coagulase-negative staphylococcus are the source of infection, but gram-negative bacterial and fungal causes must also be considered. Catheter-related infections develop at the insertion site, hub, or both. The infection source for long-term catheters such as a tunneled cuffed catheter is usually the hub where bacteria can enter the blood leading to a bloodstream infection.[39,42] Overall, HD access with a catheter is associated with higher rates of bacteremia, osteomyelitis, septic arthritis, endocarditis, thrombus and death, as well as increased treatment costs compared with an AV fistula or AV graft.[38,43]

Complications of CKD

HD patients are likely to have at least one additional co-morbid disease such as diabetes, hypertension, cardiovascular disease, or obesity (BMI greater than or equal to 30 kg/m^2 and older age, greater than or equal to 60). The pharmacotherapy management of most CKD complications and the multitude of co-morbid diseases that persist in HD patients are described in Chapter 44. The daily medication burden for HD patients is one of the highest for any chronic disease state, on average 11 medications (9 oral and 2 parenteral), which based on the oral medications alone results in a total burden of about 19 dosages per day. This burden is associated with a lower quality of life in HD patients.[44]

Management of Hemodialysis Complications

The management of HD complications are discussed in this section. The most common causes of HD complications and appropriate management are reviewed.

Hypotension

Acute management of (IDH) includes placing the patient in the Trendelenburg position, decreasing

the ultrafiltration rate, lowering the dialysate temperature, modifying dialysate electrolyte concentrations, and/or administering normal or hypertonic saline.[30,33,34,37,45] IDH may not occur during each HD session and a patient's response to therapeutic modifications can be variable, which could necessitate modification of their HD prescription. Antihypertensive medications administered prior to HD therapy may contribute to IDH; therefore, a careful review of all medications including antihypertensive therapies is warranted. Patients with IDH should be counseled to take their blood pressure medications after HD.

Intradialytic hypotension is often due to an insufficient cardiac response to reduced circulating blood volume; therefore, most treatments are directed toward restoring or maintaining adequate blood vessel perfusion in these patients. For example, decreasing the dialysate temperature to 36.5°C (97.7°F) may help reduce core body temperature, which can decrease vasodilation.[40,45,46] If nonpharmacologic interventions are not adequate to prevent or reduce the incidence of symptomatic IDH, then pharmacologic interventions should be considered (see Table 45-4).

Oral midodrine (5 mg) given 2 to 3 times daily can increase blood pressure in HD patients with chronic hypotension on nondialysis days. It is important to note that the effects of midodrine are probably best in patients with hypotension related to autonomic dysfunction. Patients with peripheral vascular disease should be monitored for digital or lower limb ischemia.[47]

Other potential therapeutic agents for IDH include levocarnitine, sertraline and intra-nasal desmopressin acetate (DDAVP). Administration of levocarnitine (20 mg/kg IV at the end of each dialysis session) may reduce hypotensive episodes, particularly with carnitine deficiency.[48] High cost and limited efficacy precludes a strong recommendation for routine levocarnitine use. The administration of sertraline 50 mg daily titrated to 100 mg daily after 1 week improved systolic and diastolic blood pressure in a small trial.[49] An earlier study administered sertraline 50 mg daily and did not report an increase in post-HD blood pressure.[50] The mixed results do not support routine sertraline administration for hypotension. Overall, the use of DDAVP increased post-HD blood pressure and decreased the incidence of IDH.[51] In addition, fludrocortisone has been suggested as a potential agent for symptomatic hypotension. These medications have limited clinical evidence and should be used with caution in HD patients with IDH.

Hypertension

An increase in blood pressure either during or postHD may require a change in the delivery of a HD session, as well as changes in antihypertensive medications or adjustments to the timing of medication administration.[36] Carvedilol initiated at 6.25 mg twice daily and titrated up to 50 mg twice daily as tolerated significantly improved intradialytic hypertension in patients receiving HD. During HD sessions patients receiving carvedilol need to be monitored for bradycardia and hypotension. Although this small trial provides a possible treatment option for intradialytic hypertension initiation of carvedilol in HD patients requires careful titration and monitoring.

Muscle Cramps

Nonpharmacologic interventions related to dialytic therapy may help alleviate muscle cramps. These measures include adjusting the ultrafiltration rate to avoid hypotension, volume contraction or hypoosmolality. Other methods to reduce muscle cramps, including compression devices, moist heat, massage, exercise, stretching or muscle flexing should be considered first to minimize adverse consequences (**Table 45-5**).[30,31]

TABLE 45-5 Management of Cramps

Acute treatment	Give 100-200 mL bolus of intravenous normal saline
	Give 10-20 mL of intravenous hypertonic saline (23.4%) over 3-5 minutes
	Give 50 mL of 50% intravenous glucose (nondiabetic patients)
Prevention	
Nonpharmacologic	Accurately set "dry weight"
	Keep dialysate sodium >serum sodium
	Stretching exercises, massage, flexing or compression devices
Pharmacologic	Vitamin E 400 international units at bedtime.
	Quinine 324 mg daily (second-line therapy)

Both vitamin E and quinine can significantly reduce the incidence of muscle cramps.[52,53] Quinine is well tolerated, but rarely may cause temporary sight and hearing disturbances, thrombocytopenia, or gastrointestinal distress. Although, quinine sulfate is available as 324 mg capsule (Qualaquin, URL Pharma, Philadelphia, PA) it is only FDA approved for malaria. The FDA has warned against the off-label use of quinine for muscle cramps.[54] The dosage for HD-related muscle cramps is one capsule (324 mg) either at bedtime or 1 to 2 hours prior to HD.

Both vitamin E (400 mg) and vitamin C (250 mg) reduce the frequency of cramps in dialysis patients.[55] The combination of these two drugs had an additive effect. Although these data further strengthen the case for vitamin E, it is unclear what role oral vitamin C would play since many patients are on a renal multiple vitamin containing vitamin C. Furthermore, both vitamin C and vitamin E as long-term therapy must be used with caution since doses of vitamin E greater than 400 units per day have been reported to increase mortality and there is a risk of systemic oxalosis with the accumulation of a vitamin C metabolite, oxalate in HD patients. Pharmacologic interventions to diminish muscle cramps are limited and currently vitamin E has the strongest evidence-based efficacy and safety profile.

Vascular Access Thrombosis

Prevention of vascular access thrombus formation is a key to maintaining this lifeline for HD patients. Multiple oral and intravenous anticoagulant and antiplatelet agents and intravenous thrombolytic agents have been studied to ascertain their clinical value.

Clinical Controversy…

The use of oral anticoagulant or antiplatelet agents to maintain vascular access patency is

controversial since the risk may be greater than the benefit. Studies have reported conflicting results and serious adverse reactions in HD patients that may increase morbidity and mortality.

Oral antiplatelet agents role in the prevention of vascular access thrombosis has been controversial since efficacy is not well-established and there is an increased risk of bleeding.[40,56,57] A trend toward maintaining primary AV graft patency has been shown with daily aspirin use.[56] Daily aspirin use also is associated with a lower rate of AV fistula failure and no increase in new GI bleeding.[58] The use of warfarin to maintain vascular access patency is controversial with some trials suggesting an increase in morbidity and mortality with the use of warfarin.[59,60,61] HD patients generally require a lower dose and are at a much higher risk of a major hemorrhagic event.[59,61]

The effect of fish oil supplementation, a combination of eicosapentaenoic acid (EPA) 400 mg and docosahexaenoic acid (DHA) 200 mg, on AV graft patency for 12 months after graft placement revealed that the loss of patency was lower in the fish oil (48%) than the placebo (62%). Fish oil thus may benefit some patients with an AV graft since time to thrombus was longer and thrombus rates were about half that of placebo.[62]

Catheter locking solutions with unfractionated heparin (UFH), recombinant tissue plasminogen activator (rt-PA), or sodium citrate instilled in each HD catheter lumen between HD sessions has been associated with a reduction in catheter thrombosis. Sodium citrate 4% is as effective as UFH but may offer a better safety profile at a reduced cost.[63] A systematic review and meta-analysis of randomized control trials of HD lock solutions containing UFH and citrate was associated with significantly fewer bleeding episodes.[64] UFH 5,000 units/mL twice weekly and recombinant tissue plasminogen activator (rt-PA) 1 mg per catheter lumen once weekly were instilled in patients receiving HD with a CVC. Alternating the catheter lock solution regimen with rt-PA significantly decreased catheter malfunction compared to the patients receiving UFH only for catheter patency. The cost of catheter replacement and hospitalization may offset the cost of once weekly administration of rt-PA.

The therapeutic alternatives for the management of venous catheter thrombosis are listed in **Table 45-6**. If a catheter-related thrombus is suspected, a forced saline flush should be used to clear the catheter, followed by installation of a thrombolytic. A number of studies have been published using alteplase and reteplase and initial reperfusion rates for both were approximately 90%, respectively.[65] The efficacy, safety, and cost of alteplase, reteplase, and tenecteplase were compared and venous catheter clearance rates, were similar with reteplase (88 ± 4%) and alteplase (81 ± 37%), but markedly lower with tenecteplase (41 ± 5%).[65] The cost analysis favored the use of reteplase; however, to attain these savings reteplase must be batch prepared and the fact that it is not currently FDA approved for this indication likely limits its use.[65]

TABLE 45-6 Management of Hemodialysis Catheter Thrombosis

Nonpharmacologic therapy
Forced saline flush
Referral to vascular surgeon
Pharmacologic therapy

Alteplase: instill 2 mg/2 mL per catheter lumen port; attempt to aspirate after 30 minutes; may repeat dose if catheter function is not restored in 120 minutes; longer durations of instillation have been used.

Reteplase: instill 0.4 units/0.4 mL in each lumen, attempt to aspirate after 20-30 minutes, may repeat if necessary.

Alteplase is available commercially and the only agent FDA approved, for venous catheter clearance and can be administered as a short dwell for 30 to 60 minutes, as a long dwell or left in the catheter between treatments. No difference in patency rates between the short or long dwells has been demonstrated. Alteplase has also been given as a short infusion 2 mg/h over 4 hours for a blocked catheter and 1 mg/h over 4 hours for sluggish blood flow. Infusions may theoretically be more efficacious than the dwell technique because the thrombus is only exposed to the thrombolytic at the very tip of the catheter. Another consideration is dwell versus push techniques for thrombolytic therapy, with recent data indicating a push protocol with alteplase is as effective and safe for managing HD catheter dysfunction and might be more practical than a dwell technique.[66]

Infection

HD patients who develop a fever during dialysis should immediately be evaluated for infection; blood cultures should be collected prior to the administration of any antibiotics. When an AV fistula infection is suspected, empiric broad-spectrum antibiotic therapy must be initiated usually with vancomycin plus an aminoglycoside. Antibiotic therapy, if the infection is confirmed, should continue for a total of 6 weeks and should be tailored to culture sensitivities. Unfortunately, a suspected infection in an AVG may require more than antibiotic therapy alone, and a surgical procedure to remove the infected graft material may be needed. A suspected infection in a temporary catheter may warrant catheter removal and a culture of the catheter tip should, if possible, be obtained.[41,67] Since catheter-related infections are more common than infections of an AV fistula or AVG, preventative care approaches are paramount. Preventative care includes minimizing the use and duration of catheters, proper disinfection and sterile technique, and the use of an antimicrobial ointment at the exit site (mupirocin 2%, povidone-iodine). Dialysis unit protocols that employ universal precautions, limit the manipulation of the catheter, utilize an antiseptic wash (tincture of iodine, chlorhexidine, etc.) for skin preparation, and the use of face masks by the patient and caregiver, can significantly reduce the incidence of catheter-related bacteremia.[41,67,68] Topical application of 2% mupirocin ointment to a tunneled HD catheter exit site after each HD session can increase infection-free days. However, there are concerns that the use of mupirocin prophylaxis may lead to the development of methicillin-resistant *S. aureus* (MRSA). A 6-year study that prospectively monitored HD patient catheter infection rates with a once-a-week application of a topical polysporin triple ointment (bacitracin/gramicidin/polymyxin B) to CVC exit sites did not reveal an increase in *S. aureus* resistance.[69] Alternative topical preparations to mupirocin to combat potential MRSA resistance are emerging and include octenidine dihydrochloride body wash, polyhexanide gel, and ethanol 70% combined with natural oil emollients.[70]

The Infectious Disease Society of America (IDSA) comprehensive guidelines regarding catheter care

and the diagnosis and management of catheter-related infections[41,68] differ some from the KDOQI guidelines, which also provide an outline for patient care. Peripheral blood draws are often avoided in HD patients as an effort to protect potential or future HD vascular access sites. Thus blood cultures are generally obtained from the blood tubing connecting the catheter to the HD machine. A full-course of antimicrobial treatment is warranted if these blood cultures are found to be positive.[41,68] Empiric therapy with coverage for both gram-positive and gram-negative bacteria should be initiated after the blood cultures are obtained. The incidence of MRSA bacteremia is high enough to warrant initial treatment with vancomycin for gram-positive coverage and either an aminoglycoside or third-generation cephalosporin for gram-negative coverage.[41,68] Therapy should be adjusted once blood cultures identify an organism. For example, if the isolated organism is methicillin-sensitive *S. aureus*, therapy IV cefazolin (20 mg/kg, rounded to the nearest 500 mg) after each dialysis session is recommended.[67,71] Antibiotic selection should be based on bacterial coverage and the ability to optimize pharmacokinetics by administering a dose after a HD treatment session without requiring additional dosages between HD sessions. Examples of antimicrobial agents that meet these objectives are vancomycin, cefazolin, ceftazidime, daptomycin, and aminoglycosides.[68,71]

The IDSA guidelines recommend that the infected catheter be removed if *S. aureus*, *Pseudomonas* species, or *Candida* species are identified as the infectious cause. Although removal of the catheter is warranted since up to 75% of patients have a recurrence of bacteremia after completing a course of antibiotics, this is not always possible and other options may need to be considered. Options such as replacing the catheter over a guidewire or using a catheter lock solution in conjunction with IV antibiotics have been suggested as an alternative.[41,68] Between 62% and 70% of catheters can be salvaged using catheter lock solutions in addition to systemic antibiotics.[41,68] The IDSA guidelines recommend the use of catheter lock solutions as adjunctive therapy after each dialysis session for 10 to 14 days in a patient whose catheter was not removed and bacteremia symptoms resolved in 2 to 3 days. The IDSA recommendations for antibiotic therapy are listed in **Table 45-7**.[41,68]

TABLE 45-7 Management of Hemodialysis Access Infection[41,68]

I. Primary arteriovenous fistula

A. Treat as subacute bacterial endocarditis for 6 weeks.

B. Initial antibiotic choice should always cover gram-positive organisms, (eg, vancomycin 20 mg/kg IV with serum concentration monitoring or cefazolin 20 mg/kg IV 3 times per week or after each dialysis session).

C. Gram-negative coverage is indicated for patients with diabetes, human immunodeficiency virus infection, prosthetic valves, or those receiving immunosuppressive agents, gentamicin 2 mg/kg IV with serum concentration monitoring.

II. Synthetic arteriovenous grafts

A. Local infection—empiric antibiotic coverage for gram-positive, gram-negative, and *Enterococcus* (eg, gentamicin plus vancomycin then individualized after culture results available). Continue for 2 to 4 weeks.

B. Extensive infection—antibiotics as above plus total resection.

C. If access is less than 1 month old, antibiotics as above plus remove the graft.

III. Tunneled cuffed catheters (internal jugular, subclavian)

A. Infection localized to catheter exit site.

1. No drainage—topical antibiotics, (eg, mupirocin ointment).

2. Drainage present—gram-positive antibiotic coverage, vancomycin 20 mg/kg IV with serum concentration monitoring or cefazolin 20 mg/kg IV three times per week.

B. Bacteremia with or without systemic signs or symptoms.

1. Gram-positive antibiotic coverage as in III.A.2.

2. If symptomatic at 36 hours, remove the catheter.

3. If stable and asymptomatic, change catheter and provide culture-specific antibiotic coverage for a minimum of 3 weeks.

Microbial colonization of a catheter could affect patency and a patient's access to dialytic treatment. An examination of the catheter lock solutions, UFH 5,000 units/mL and tetra sodium EDTA, found an increased rate of microbial colonization with UFH but the tetra sodium EDTA solution had an increase rate of thrombosis.[72] An alternative to UFH and tetra sodium EDTA may be 4% sodium citrate to maintain catheter patency.[63,64,73]

Catheter locking has also been utilized to prevent infection and thrombosis in HD catheters.[73] A meta-analysis of randomized control trials of catheter-related bacteremia and antimicrobial lock solutions identified eight studies with 829 patients and more than 90,100 catheter days. Overall analysis found that the use of an antimicrobial lock solution significantly reduced the risk of a catheter-related infection (relative risk [RR] 0.32; 95% confidence interval [CI] 0.10-0.42).[73] A comparison of UFH 1,000 units/mL to the combination solution of 4% sodium citrate with gentamicin 320 mcg/mL (mg/L; 669 µmol/L) as a catheter lock solution significantly reduced the incidence of catheter related bloodstream infections.[74] The value of catheter lock solutions for treatment and prevention of catheter-related infections is increasingly becoming evident, but the possibility of antibiotic resistance with the wide use of antibiotics in catheter locks remains a concern. Currently, NKF-KDOQI does not recommend routine locking of catheters with antibiotics.

Clinical Controversy…

The use of a catheter lock solution containing an antimicrobial agent (ie, gentamicin) with citrate to prevent catheter related bloodstream infections is controversial since the risk of antimicrobial resistance may be greater than the benefit.

PERITONEAL DIALYSIS

Although the concept of peritoneal lavage has been described as far back as the 1700s, it wasn't until the 1920s that PD was first employed as an acute treatment for uremia. It was used infrequently during subsequent years until the concept of PD as a chronic therapy for ESRD was proposed in the 1960s. Over the ensuing years the number of patients receiving PD increased slowly until the early 1980s. At that time, several innovations in PD delivery systems were introduced, such as improved catheters and dialysate bags. These innovations led to improved outcomes, decreased morbidity, mortality and a corresponding increase in the use of PD as a viable alternative to HD for the treatment of ESRD. However, the worldwide use of PD has declined over the past decade.[6] Some patients, such as those with more hemodynamic instability (eg, hypotension) or significant residual renal function (RRF), and perhaps patients who desire to maintain a significant degree of self-care may be better suited to PD than to HD. Table 45-2 shows the advantages and disadvantages of PD.

Principles of Peritoneal Dialysis

5 The three basic components of HD—namely, a blood-filled compartment separated from a dialysate-filled compartment by a semipermeable membrane—are also present in PD.[75] In PD, the dialysate-filled compartment is the peritoneal cavity, into which dialysate is instilled via a peritoneal catheter that traverses the abdominal wall. The contiguous peritoneal membrane surrounds the peritoneal cavity. The cavity, which normally contains about 100 mL of lipid-rich lubricating fluid, can expand to a capacity of several liters. The peritoneal membrane that lines the cavity functions as the semipermeable membrane, across which diffusion and ultrafiltration occur. The peritoneal dialyzing membrane is comprised of a monocellular layer of peritoneal mesothelial cells, the basement membrane, and underlying connective and interstitial tissue. The peritoneal membrane has a total area that approximates body surface area (approximately 1-2 m^2). Blood vessels supplying and draining the abdominal viscera, musculature, and mesentery constitute the blood-filled compartment.

Unlike HD, the crucial components of PD cannot be manipulated to maximize solute and fluid removal. Because the blood is not in intimate contact with the dialysis membrane as it is in HD, metabolic waste products must travel a considerable distance to the dialysate-filled compartment. In addition, unlike HD, there is no easy method to regulate blood flow to the surface of the peritoneal membrane, nor is there a countercurrent flow of blood and dialysate to increase diffusion and ultrafiltration via changes in hydrostatic pressure. Similarly there is no easy means available to manipulate the peritoneal membrane. Thus, the available means to enhance PD clearance involve alterations in dialysate volume, dwell time, and the number of exchanges per day. For these reasons, PD is a much-less-efficient process per unit time as compared with HD, and must, therefore, be a virtually continuous procedure to achieve acceptable goals for clearance of metabolic waste

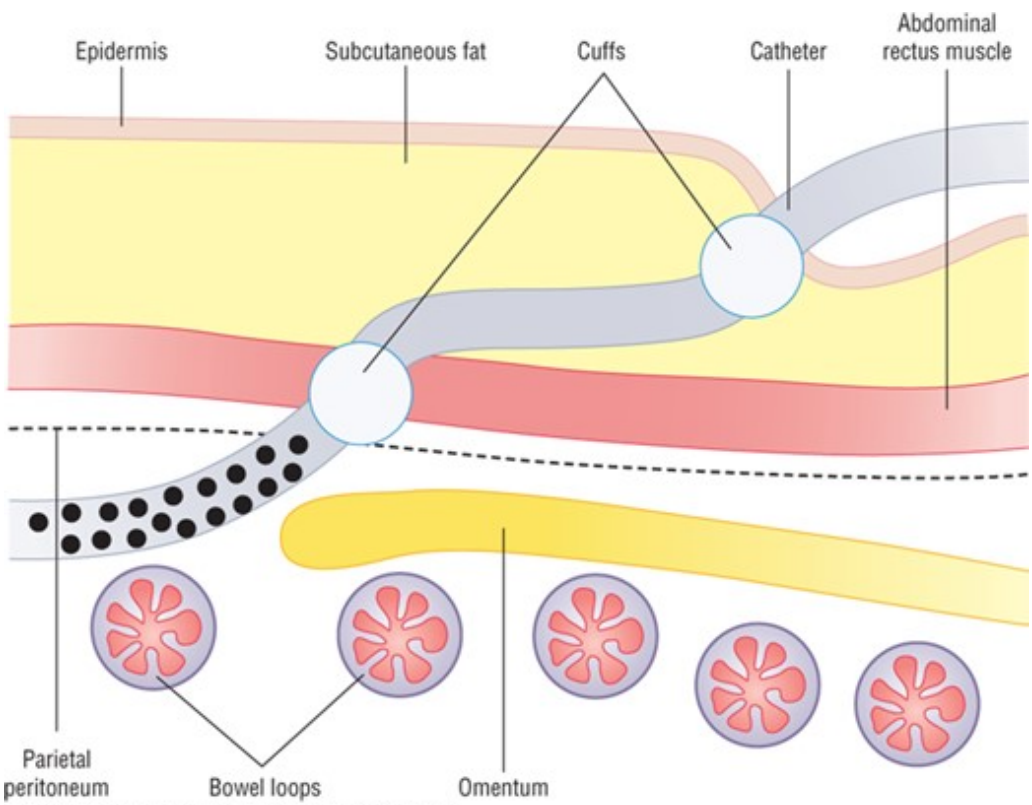
products.

Peritoneal Dialysis Access

Access to the peritoneal cavity is via the placement of an indwelling catheter. Many types are available and **Fig. 45-3** shows an example.[75] Most catheters are manufactured from silastic, which is soft, flexible, and biocompatible. A typical adult catheter is 40 to 45 cm long, 20 to 22 cm of which is inside the peritoneal cavity. Placement of the catheter is such that the distal end lies low in a pelvic gutter. The center section of the catheter has one or two cuffs made of a porous material that is tunneled inside the anterior abdominal wall so that the cuffs provide mechanical support and stability to the catheter, serves as a mechanical barrier to skin organisms, and prevents their migration along the catheter into the peritoneal cavity. The cuffs are placed at different sites surrounding the abdominal rectus muscle. The remainder of the central section of the catheter is tunneled subcutaneously before exiting the abdominal surface, usually a few centimeters below and to one side of the umbilicus.

FIGURE 45-3

Diagram of the peritoneal dialysis catheter placement through the abdominal wall into the peritoneal cavity. *Data From Reference 37*.



The placement of the catheter exit site is one of the factors related to the development or prevention of exit-site infections and peritonitis. The external section of most peritoneal catheters ends with a

Luer-Lok connector, which can be connected to a variety of administration sets. These catheters can be used immediately if necessary, provided small initial volumes are instilled; however, a maturation period of 2 to 6 weeks is preferred.

Peritoneal Dialysis Procedures

6 Several variants of PD are clinically utilized in the United States. All variants of PD require the placement of a dialysis solution to dwell in the peritoneal cavity for some period, removing the spent dialysate, and then repeating the process. The prescribed dose of PD may be altered by changing the number of exchanges per day, by altering the volume of each exchange, or by altering the strength of dextrose or other osmotic agent in the dialysate for some or all exchanges. Increasing any one of these variables increases the effective osmotic gradient across the peritoneum, leading to increased ultrafiltration and diffusion (solute removal). If the dwell time is extended, equilibrium may be reached, after which time there will be no further water or solute removal. In fact, after a critical period, reverse water movement may occur.[75] In a basic continuous ambulatory peritoneal dialysis (CAPD) system, the patient or caregiver is manually responsible for performing the prescribed number of dialysate exchanges. The patient is connected to a bag of prewarmed peritoneal dialysate via the PD catheter, by a length of tubing called a transfer set. The most common transfer set used is the Y transfer set which consists of a Y-shaped piece of tubing that is attached at its stem to the patient's catheter, leaving the remaining two limbs of the Y attached to dialysate bags, one filled with fresh dialysate and the other empty. The spent dialysate from the previous dwell is drained into the empty bag, and the peritoneum is subsequently refilled from the bag containing fresh dialysate. The Y set is then disconnected and the bag containing the spent fluid and the empty bag that had contained fresh dialysate are detached and discarded. Typically a patient instills 2 to 3 L of dialysate three times during the day with each exchange lasting 4 to 6 hours, and then a single dialysate exchange overnight lasting 8 to 12 hours. At the end of the prescribed dwell period a new Y set is attached and the process is repeated. The process of outflow, aseptic manipulation of the administration set and catheter, and inflow requires a total time of approximately 30 minutes.

Continuous ambulatory peritoneal dialysis involves performing the dialysate exchanges manually, whereas automated systems collectively termed automated peritoneal dialysis (APD) performs the exchanges with a device referred to as a cycler. APD systems are designed for patients who are unable or unwilling to perform the necessary aseptic manipulations, and for those who require more dialysis. The device is set up in the evening, and the patient attaches the peritoneal catheter to it at bedtime. The machine performs several short-dwell exchanges (usually 1-2 hours) during the night. This permits a long cycle-free daytime dwell of up to 12 to 14 hours. Typical APD regimens involve total 24-hour exchanges of approximately 12 L, which include one or more daytime instillations and dwell periods.[76] This type of regimen is referred to as APD with a "wet" day. The APD variant, nightly intermittent PD, has a similar theme, except that the peritoneal cavity tends to be dialysate free during the day. This type of regimen is frequently referred to as APD with a "dry" day. A number of variants exist and depend largely on equipment availability, patient and prescriber preference, and whether the patient retains any RRF, which influences the quantity of dialysis prescribed.

The APD systems include continuous cycling PD, tidal PD, and nightly intermittent PD. The prototypic

form of APD is usually a hybrid between CAPD and continuous cycling PD, in which some of the daily exchanges (usually the overnight exchanges) are completed using an automated device. Recent advances in PD procedures involve using continuous flow peritoneal dialysate.[77] This technique maintains a fixed intraperitoneal volume and rapid, continuous movement of dialysate into and out of the peritoneal cavity. To accomplish this, two PD catheters (an inlet and outlet catheter) and a means of generating a large volume of sterile dialysate are required. Dialysate is generated via conventional HD equipment or sorbent technology. In continuous flow peritoneal dialysate, clearance of small solutes is three to eight times greater than with APD, and approximates daily HD. Potential applications of continuous flow peritoneal dialysate include daily home dialysis, treatment of acute kidney injury in the intensive care unit, and ultrafiltration of ascites.

Peritoneal Dialysis Solutions

All forms of PD use dialysate solutions, which are commercially available in volumes of 1 to 3 L in flexible polyvinyl chloride plastic bags. It is beyond the scope of this chapter to exhaustively review all the options, but the most commonly used solutions which are commercially available contain glucose or icodextrin with varying concentrations of electrolytes, such as sodium (132 mEq/L [mmol/L]), chloride (96 mEq/L [mmol/L]), calcium (2.5-3.5 mEq/L [1.25-1.75 mmol/L]), magnesium (0.5 mEq/L [0.25 mmol/L]), and lactate (40 mEq/L [mmol/L]). These solutions may contain dextrose (1.5%, 2.5%, 3.86%, or 4.25%) or icodextrin (a glucose polymer) at a concentration of 7.5%. The dextrose solutions are hyperosmolar (osmolarity ranges from 345 to 484 mOsm/L) and induce ultrafiltration (removal of free water) by crystalline osmosis. Dextrose is not the ideal osmotic agent for peritoneal dialysate because these solutions are not biocompatible with peritoneal mesothelial cells or with peritoneal leukocytes. The cytotoxic effects on these cells are mediated by the osmolar load and the low pH of the solutions, as well as the presence of glucose degradation products formed during heat sterilization of these products. Icodextrin PD solution contains icodextrin, a starch-derived glucose polymer. It has an osmolality of 282 to 286 mOsm/L, which is isoosmolar with serum. Icodextrin produces prolonged ultrafiltration by a mechanism resembling colloid osmosis resulting in ultrafiltration volumes similar to those with 4.25% dextrose. Icodextrin may have fewer of the metabolic effects associated with dextrose, such as hyperglycemia and weight gain. It is indicated for use during the long (8-16 hours) dwell of a single daily exchange in CAPD and APD patients. Lower glucose degradation product dialysate solutions are also available with similar solute concentrations, but with pH of 7.3.[75,78] These newer, biocompatible dialysate solutions are described as less harmful to the peritoneal membrane and preserve RRF to a greater extent than currently available standard solutions.[79,80] Preservation of RRF in PD and HD patients is important as it has been shown to decrease mortality and increase the time to the first episode of peritonitis. However, the putative benefits of the biocompatible dialysate solutions have not been completely borne out: their use has not consistently slowed the rate of decline in glomerular filtration rate as compared to standard solutions, although the incidence of peritonitis has been lower.[81]

Adequacy of Peritoneal Dialysis

The adequacy of PD is determined by clinical assessment, solute clearance determination and fluid removal. As in HD, the clearance of urea can be quantified by calculating *Kt/V*. The calculations

determine a daily *Kt/V*, which is then converted to a weekly value that is relevant to PD patients.

PD adequacy is a major issue that has received considerable attention. The most recent KDOQI guidelines recommend that patients on PD have a total *Kt/V* of at least 1.7 per week.[82] It is important to note that RRF may provide a significant component of the total *Kt/V*. Patients may commence PD with a residual CL_{cr} of approximately 9 to 12 mL/min (0.15-0.200 mL/s), which contributes a renal *Kt/V* of 0.2 to 0.4. Over a period of 1 to 2 years, if RRF progressively deteriorates the total *Kt/V* will progressively diminish unless PD *Kt/V* is increased (by increasing the prescribed dose of PD) to compensate for the reduced renal *Kt/V*.

For patients producing less than 100 mL urine per day, the weekly *Kt/V* dose of 1.7 must be provided entirely by peritoneal clearance. For patients producing greater than 100 mL urine per day, combined renal and peritoneal urea clearances must exceed the weekly *Kt/V* dose of 1.7.[82] The weekly *Kt/V* dose should be measured within the first month of PD initiation and at least once every 4 months thereafter. It is imperative to detect subtle decreases in RRF along with poor adherence to make necessary alterations to the prescribed PD dose to attain adequate clearance of waste products.

The KDOQI guidelines also stress the importance of preserving RRF in PD patients because it is associated with decreased mortality. Typical measures to preserve RRF include preferential use of angiotensin-converting enzyme inhibitors or angiotensin receptor blockers, regardless of blood pressure, and avoidance of medications or procedures that are associated with insults to the kidney (eg, nonsteroidal anti-inflammatory drugs, cyclooxygenase-2 inhibitors, aminoglycosides, intravenous iodinated radiocontrast dyes, withdrawal of immunosuppressant therapies from a transplanted kidney, hypovolemia, urinary tract obstruction, and hypercalcemia).[82]

Complications of Peritoneal Dialysis

Mechanical, medical, and infectious problems complicate PD therapy. Mechanical complications include kinking of the catheter and inflow and outflow obstruction; excessive catheter motion at the exit site, leading to induration and possible infection and aggravation of tissues; pain from impingement of the catheter tip on the viscera; or inflow pain resulting from a jet effect of too rapid dialysate inflow.

Table 45-8 lists the numerous medical complications of PD. An average PD patient absorbs up to 60% of the dextrose in each exchange. This continuous supply of calories leads to increased adipose tissue deposition, decreased appetite, malnutrition, and altered requirements for insulin in diabetic patients. Fibrin formation in dialysate is common and can lead to obstruction of catheter outflow. Infectious complications of PD are a major cause of morbidity and mortality and are the leading cause of technique failure and transfer from PD to HD. The two predominant infectious complications are peritonitis and catheter-related infections, which include both exit-site and tunnel infections.

TABLE 45-8 Medical Complications of Peritoneal Dialysis

Cause	Complication	Treatment
Glucose load	Exacerbation of diabetes	IP insulin

Cause	Complication	Treatment
	mellitus	
	Exacerbation of heart failure	Increase ultrafiltration
Fluid overload	Edema	Diuretics, if the patient has residual renal function
	Pulmonary congestion	
Electrolyte abnormalities	Hypercalcemia/Hypocalcemia	Alter dialysate calcium content
PD additives	Chemical peritonitis	Discontinue PD additives
Malnutrition	Albumin loss	Dietary changes
	Loss of amino acids	Parenteral nutrition
	Muscle wasting	Discontinue PD
	Increased adipose tissue	
Unknown	Fibrin formation in dialysate	IP heparin

IP, intraperitoneal; PD, peritoneal dialysis.

Peritonitis

7 The incidence of peritonitis is influenced by connector technology, by the composition of patient populations, and by the use of APD versus CAPD. The incidence of peritonitis reported by most dialysis centers in the United States is about 1 episode every 24 patient-months, although it may be as low as 1 episode every 60 patient-months.[83] Within 1 year of starting CAPD, 40% to 60% of patients develop their first episode of peritonitis (although the incidence is significantly lower in APD patients).

Peritonitis is a major cause of catheter loss in PD patients. The clinical presentation and diagnosis is shown in **Table 45-9**. A statistically significant correlation between infectious complications and death rates has been reported: patients who had more than 1 peritonitis episode per year, 0.5 to 1 episode per year, or less than 0.5 episode per year, 50% died after 3, 4, and 5 years of therapy, respectively. It is important to note that these relationships are not necessarily cause and effect, as many of these patients succumb to cardiovascular events.[84]

TABLE 45-9 Clinical Presentation and Diagnosis of Peritoneal Dialysis-Related Peritonitis

General

- Patients generally present with abdominal pain and cloudy effluent

Symptoms

- The patient may complain of abdominal tenderness, abdominal pain, fever, nausea and

vomiting, and chills

Signs

- Cloudy dialysate effluent may be observed
- Temperature may or may not be elevated

Laboratory Tests

- Dialysate white blood cell count >100/mm^3 (>0.1×10^9/L), of which at least 50% are polymorphonuclear neutrophils
- Ram stain of a centrifuged dialysate specimen

Other Diagnostic Tests

- Culture and sensitivity of dialysate should be obtained

Peritonitis has several imprecise definitions, but guidelines suggest that an elevated dialysate white blood cell count of greater than 100 per microliter (0.1×10^9/L) with at least 50% polymorphonuclear neutrophils indicates the presence of inflammation, of which peritonitis is the most likely cause.[85] A patient who presents with abdominal pain and a cloudy effluent is usually given a provisional diagnosis of peritonitis. Inherent in this definition is a number of false-positive and false-negative diagnoses, because a small percentage of patients with culture-proven peritonitis will have clear dialysate, and some patients, such as menstruating females, may have cloudy PD effluent without clinical infection. Sterile culture peritonitis remains problematic; it is defined as an episode in which there is clinical suspicion of peritonitis, but for which the culture of the dialysate reveals no organism. There are several postulates for the high incidence (up to 20% of episodes) of culture-negative peritonitis. Many peritonitis-producing organisms are slime producers and may adhere to the peritoneal membrane or to the catheter surface and may be protected from exogenous antibiotics. Sufficient numbers of these bacteria may proliferate to cause peritoneal membrane inflammation and clinical peritonitis, but an inadequate number may seed into the peritoneal cavity to be recovered by conventional microbiologic techniques. In addition, free-floating planktonic bacteria may be rapidly phagocytosed by peritoneal white blood cells, thereby rendering them unavailable for culture.[86]

Contemporary methods have increased the recovery rate of organisms and decreased the culture-negative rate. Centrifugation is currently recommended as the optimum culture method. Centrifugation of a large volume of dialysate (50 mL), resuspension of the sediment in 3 to 5 mL of sterile saline, and subsequent inoculation in culture media produce a culture-negative rate less than 5%. If centrifuge equipment is not available, blood culture bottles can be directly injected with 5 to 10 mL of dialysate effluent. However, this method results in a culture-negative rate of up to 20%.[85]

The majority of infections are caused by gram-positive bacteria, of which *Staphylococcus epidermidis* is the predominant organism. There is no single predominant gram-negative organism. Together,

gram-positive and gram-negative organisms account for 80% to 90% of all episodes of peritonitis, and constitute the spectrum against which initial empiric therapy is directed.[87]

Catheter-Related Infections

PD patients experience an exit-site infection approximately once every 24 to 48 months. Patients with previous infections tend to have a higher subsequent incidence. The majority of exit-site infections are caused by *S. aureus*. In contrast to peritonitis, *S. epidermidis* accounts for less than 20% of exit-site infections. Although gram-negative organisms, such as *Pseudomonas*, are less common, they can result in significant morbidity. The diagnostic characteristics of these infections are somewhat vague but generally include the presence of purulent drainage, with or without erythema at the catheter exit site. The risk of exit-site infections is increased several-fold in patients who are nasal carriers of *S. aureus*.[88]

Management

The management of PD related complications are discussed in this section.

Peritonitis

The International Society of Peritoneal Dialysis (ISPD) updated the Peritoneal Dialysis-Related Infections recommendations in 2010, which provide guidelines for treatments for peritonitis, tunneled and exit-site infections.[85] These PD related infections are associated with dialysis modality treatment failures and substantial morbidity and mortality; therefore appropriate pharmacotherapy treatment is essential (**Fig. 45-4**). The ISPD guidelines specifically address the importance of dialysis center antibiotic selection, the effect of RRF on antibiotic pharmacokinetics, and updated recommendations regarding the use of aminoglycosides and vancomycin in PD patients.[85] In 2011, ISPD published a position statement on reducing the risks of PD related infections that includes updates to the prevention of exit-site infections and routine care for PD patients.[89] There are also many institution specific guidelines, which may impact individual clinicians recommended treatment strategies.

FIGURE 45-4

Pharmacotherapy recommendations for the treatment of bacterial peritonitis in peritoneal dialysis patients. [a]Choice of empiric treatment should be made based on the dialysis center's and the patient's history of infecting organisms and their sensitivities. [b]Final choice of therapy should always be guided by culture and sensitivity results. (MRSA, methicillin-resistant *Staphylococcus aureus;* MRSE, *methicillin-resistant Staphylococcus epidermidis; S. aureus, Staphylococcus aureus; S. epidermidis, Staphylococcus epidermidis;* VRE, vancomycin-resistant enterococci; WBC, white blood cell.)

Intraperitoneal (IP) administration of antibiotics remains the preferred delivery route over IV therapy. Antimicrobial dosing recommendations provided in the ISPD guidelines distinguish between dosing for intermittent (one exchange per day) and continuous therapy (all exchanges). In addition, dosing recommendations are modified on the basis of the patient's PD modality (CAPD or APD) and whether the patient has RRF (urine output) greater than 100 mL/day.[85,89]

Following a single IP antibiotic dose the drug concentrations achieved in dialysate and serum differ between intermittent and continuous methods. Intermittent IP therapy necessitates that a sufficient amount of drug transfers from the peritoneal cavity to the systemic circulation, thus allowing drug to diffuse back into the peritoneum during drug-free dialysate dwell time(s). Therefore, once daily dosing requires drug(s) be added to the exchange with the longest dwell time to ensure maximum systemic exposure.

Continuous dosing recommendations may require a loading dose with the very first IP dose and a maintenance dose for each subsequent exchange. Vancomycin, aminoglycosides, and cephalosporins generally can be administered by either dosing method. It is recommended that a continuous dosing method be used for penicillins and fluoroquinolones. No matter which CAPD drug dosing method is used, the goal is to deliver and maintain adequate peritoneum drug concentrations. Intermittent or continuous dosing is effective for CAPD patients but IP dosing for APD patients may require a different dosing schedule. The rapid overnight dialysate exchanges with APD will increase solute clearance over a short time period. This appears to be particularly important for first generation cephalosporin agents. The ISPD guidelines recommend continuous dosing of a first-generation cephalosporin because of concerns over inadequate IP drug concentration during the shorter APD

dialysate dwells. Another consideration would be to switch a patient to a CAPD regimen until treatment for peritonitis is completed. With regard to RRF, in patients with daily urine output greater than 100 mL, the dose of drugs that are renally eliminated should be empirically increased by 25%. The ISPD dosing recommendations for IP antibiotics in CAPD and APD patients are shown in **Tables 45-10** and **45-11**, respectively.[85]

TABLE 45-10 Intraperitoneal Antibiotic Dosing Recommendations for Continuous Ambulatory Peritoneal Dialysis Patients[85]

Drug	Intermittent (per exchange, once daily)	Continuous (mg/L, all exchanges)
Aminoglycosides		
Amikacin[a]	2 mg/kg	LD 25, MD 12
Gentamicin[a]	0.6 mg/kg	LD 8, MD 4
Netilmicin[a]	0.6 mg/kg	LD 8, MD 4
Tobramycin[a]	0.6 mg/kg	LD 8, MD 4
Cephalosporins		
Cefazolin[a]	15 mg/kg	LD 500, MD 125
Cefepime[a]	1,000 mg	LD 500, MD 125
Cephalothin[a]	15 mg/kg	LD 500, MD 125
Cephradine[a]	15 mg/kg	LD 500, MD 125
Ceftazidime[a]	1,000-1,500 mg	LD 500, MD 125
Ceftizoxime[a]	1,000 mg	LD 250, MD 125
Penicillins		
Azlocillin[a]	ND	LD 500, MD 250
Ampicillin[a]	ND	MD 125
Oxacillin[a]	ND	MD 125
Nafcillin[a]	ND	MD 125
Amoxicillin[a]	ND	LD 250-500, MD 50
Penicillin G[a]	ND	LD 50,000 units, MD 25,000 units
Quinolones		
Ciprofloxacin[a]	ND	LD 50, MD 25
Others		
Vancomycin[a]	15-30 mg/kg Q5-7d	LD 1,000, MD 25
Daptomycin	ND	LD 100, MD 20
Aztreonam[a]	ND	LD 1,000, MD 250

Drug	Intermittent (per exchange, once daily)	Continuous (mg/L, all exchanges)
Teicoplanin Linezolid	15 mg/kg	LD 400, MD 20 Oral 200-300 mg q.d.
Antifungals		
Amphotericin B	NA	MD 1.5
Fluconazole	200 mg IP every 24-48 hours	
Combinations		
Ampicillin/sulbactam[a]	2 g q 12 h	LD 1,000, MD 100
Imipenem/cilastatin[a]	1 g twice daily	LD 500, MD 200
Quinupristin/dalfopristin[b]	25 mg/L in alternate bags	

LD, loading dose in mg; MD, maintenance dose in mg; NA, not applicable; ND, no data.

[a]Dosing of these drugs in patients with residual renal function (defined as more than 100 mL/day urine output) dose should be empirically increased by 25%.

[b]Given in conjunction with 500 mg IV twice daily.

TABLE 45-11 Intermittent Intraperitoneal Antibiotic Dosing Recommendations for Automated Peritoneal Dialysis Patients[85]

Drug	Intraperitoneal Dose
Vancomycin	LD: 30 mg/kg IP in longest dwell, repeat dosing 15 mg/kg IP in longest dwell every 3-5 days, (aim to keep serum trough concentrations above 15 mcg/mL [mg/L; 10 µmol/L])
Tobramycin	LD: 1.5 mg/kg IP in longest dwell, then 0.5 mg/kg IP each day in longest day dwell
Fluconazole	200 mg IP in one exchange per day every 24-48 hours
Cefepime	1 g IP in longest dwell
Cefazolin	20 mg/kg IP every day, in longest dwell

IP, Intraperitoneal; LD, loading dose in mg; MD, maintenance dose in mg.

The compatibility and stability of antibiotics added to peritoneal dialysate is another important consideration. In dextrose solutions, most antibiotic additives appear to be stable (usually defined as retaining at least 90% of initial activity) for about 1 week if refrigerated, or 1 to 2 days if left at room temperature. Recent data suggests that cefazolin, ceftazidime, cefepime, vancomycin, gentamicin, tobramycin, netilmicin, and heparin are stable in icodextrin.[90] A concern with some compatibility and stability studies is that an assay of total drug concentration may include parent drug-degradation products in addition to active drug. Therefore, the solution may not retain sufficient pharmacologic activity. The systemic toxicities of IP regimens remain unclear, but are likely similar to those associated with IV and oral antibiotic administration. Intermittent (once-daily) IP dosing of drugs, such as aminoglycosides, may reduce the risk of systemic toxicity (ototoxicity and nephrotoxicity).[85] Due to controversial and conflicting clinical trial data the current ISPD guidelines state that there is

no convincing evidence that short courses of aminoglycosides lead to loss of RRF. Also, that prolonged or repeated courses are probably inadvisable if an alternative approach is available.[85] This latter controversial recommendation was based on the opinion of the committee and restated in a recent KDOQI document. Since the preservation of RRF is very important for PD patients, routine use of aminoglycosides should be avoided in patients with significant RRF (producing greater than 100 mL urine per day) if other antibiotic choices are available.[85]

Clinical Controversy…

The ISPD guidelines for peritonitis treatment state that patients with significant RRF should not receive aminoglycosides if other antibiotic choices are available. Aminoglycosides were found to increase the rate of decline in RRF in one study. However, another study refuted this claim.

Initial empiric therapy for peritonitis, regardless of whether a Gram stain was performed or organisms were identified, should include agents effective against both gram-positive and gram-negative organisms. Antibiotic selection should be based on a dialysis center's antibiogram or resistance patterns, a history of the patient's infections and the organism's antibiotic sensitivity profile. In many cases, a first-generation cephalosporin such as cefazolin in combination with a second drug that provides broader gram-negative coverage, such as ceftazidime, cefepime, or an aminoglycoside, will prove suitable. Patients with documented allergy to cephalosporin antibiotics can be treated with vancomycin and an aminoglycoside. High rates of methicillin resistance have been reported by many dialysis centers and vancomycin should be used as first-line therapy against gram-positive organisms for patients treated at these centers. Monotherapy with agents providing both gram-positive and gram-negative coverage is an alternative option. Both imipenem-cilastin and cefepime are effective in treating CAPD-related peritonitis.[91]

After culture and sensitivity results are obtained, antibiotic therapy should be adjusted appropriately (see Fig. 45-4). Tables 45-10 and 45-11 list doses for antibiotics. Treatment should be continued for 14 to 21 days. If the patient does not show signs of clinical improvement within 72 hours after antibiotic treatment is initiated, the culture should be repeated and the patient reevaluated. If the peritoneal dialysate white blood cell count remains high after 4 days of appropriate antibiotic therapy, clinicians should consider removing the peritoneal catheter, starting IV antibiotics and initiating HD for dialytic maintenance therapy.

Fungal peritonitis is associated with a poor prognosis and high morbidity and mortality. One problem with prospective assessment of antifungal regimens is the infrequency with which these infections occur. This makes it difficult to design and implement comparative studies. Most literature about antifungal treatment is therefore retrospective or limited to reports of local experience. As a result, the ISPD recommendations for treatment of fungal peritonitis are somewhat vague and treatment should be based on culture and sensitivity results. However, one area that has been clarified is the question as to whether the PD catheter should be removed. The ISPD recommendations are to remove the catheter immediately after identifying fungi. If the Gram stain indicates the presence of yeast, treatment may be initiated with amphotericin B and oral flucytosine. Once culture and sensitivity results are available, fluconazole, caspofungin, or voriconazole may replace amphotericin B. Treatment with these agents should be continued orally for an additional 10 days after catheter

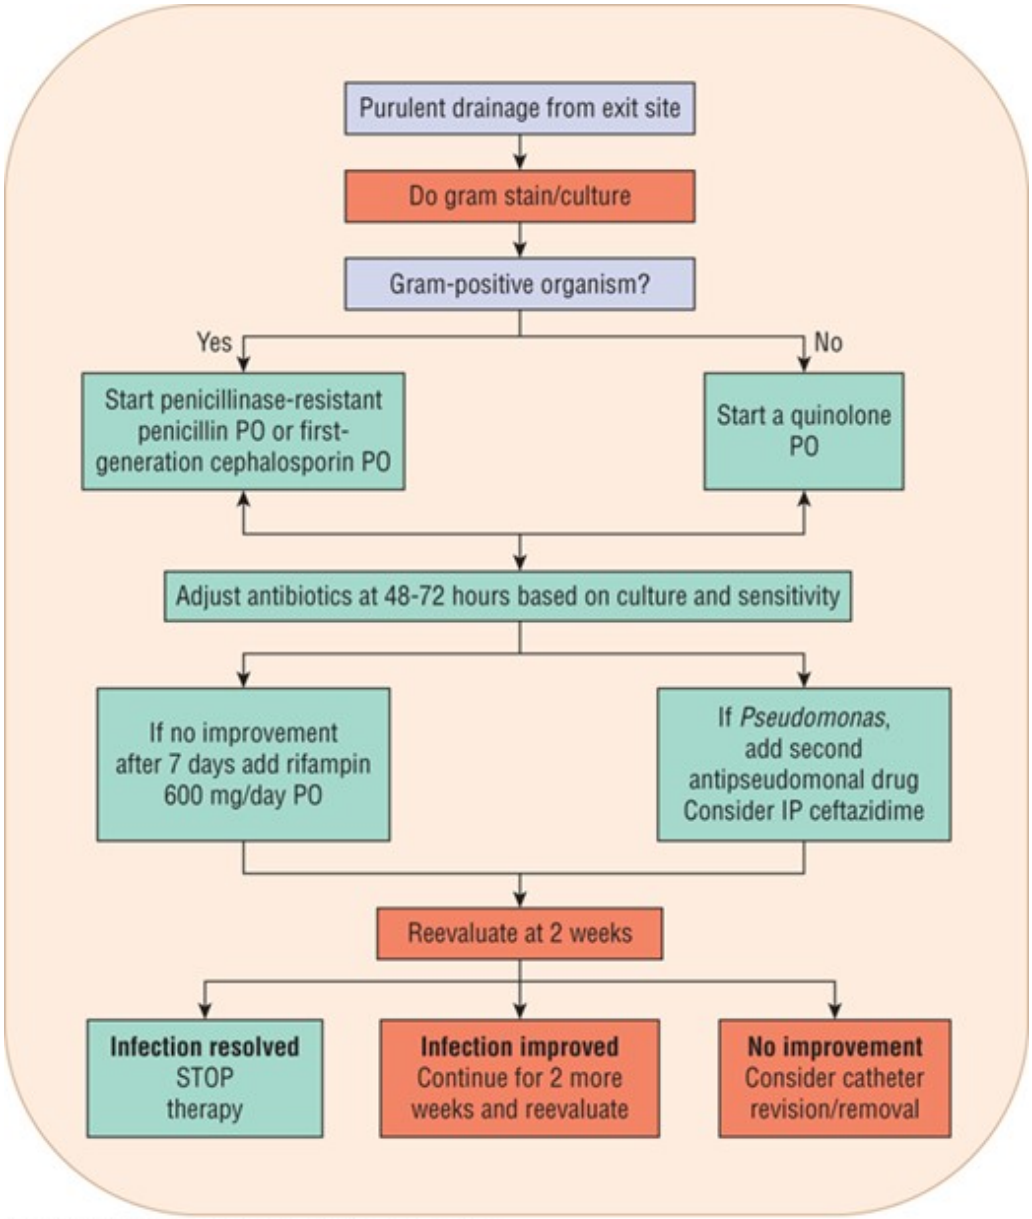
removal. It remains unclear whether there is any benefit from fungal prophylaxis. Recommendations are also provided for the treatment of mycobacterial, or tuberculous, peritonitis. Although this infection is a rare complication, it can be difficult to diagnose, and treatment requires multiple drugs.

Catheter-site Infections

Topical antibiotics and disinfectants appear to be effective agents for the prevention of exit-site infections.[92] Gram-positive organisms should be treated with oral penicillinase-resistant penicillin or a first-generation cephalosporin such as cephalexin (**Fig. 45-5**). Rifampin may be added if necessary, in slowly resolving or particularly severe *S. aureus* infections. Vancomycin should be avoided in routine or empiric treatment of gram-positive catheter-related infections, but will be necessary for methicillin-resistant *S. aureus*. Gram-negative organisms should be treated with oral quinolones. The effectiveness of oral quinolones may be diminished owing to the chelation drug interactions with divalent and trivalent metal ions, which are commonly taken by dialysis patients. Administration of quinolones should occur at least 2 hours prior to these drugs. In cases where *Pseudomonas aeruginosa* is the pathogen, a quinolone should not be used as monotherapy. Options for a second antipseudomonal drug include the IP administration of aminoglycoside, ceftazidime, cefepime, piperacillin, imipenem-cilastatin or meropenem. In all cases antibiotics should be continued until the exit site appears normal; 2 to 3 weeks of therapy may be necessary. A patient with a catheter-related infection that progresses to peritonitis will usually require catheter removal.[85,89]

FIGURE 45-5

Management strategy of exit-site infections for peritoneal dialysis patients.[87] (IP, intraperitoneal; PO, orally.) *Data from reference 87*.



Prevention of Peritonitis and Catheter Exit-site Infections

8 Attempts to prevent peritonitis and catheter-related infections have included refinement of connector system technology (Luer-lok connectors), enhanced patient training techniques, and the use of prophylactic antibiotic regimens and vaccines. Several studies have examined the impact of antibacterial agents as prophylaxis against both peritonitis and tunnel-related infections. Intermittent rifampin 300 mg orally twice a day for 5 days, repeated every 3 months, appears to decrease the number of catheter-related infections, but not the incidence of peritonitis. The efficacy of other antibiotic prophylaxis for peritonitis and catheter-related infections is limited. Long-term, extended-duration prophylaxis with penicillins or cephalosporins is not effective.[85,89]

Clinical Controversy...

Alternative topical agents have been studied to decrease PD exit-site infections but these topical agents have not been shown to be superior to mupirocin or gentamicin. Additionally, the clinician needs to assess the risk versus benefit based on the side effect profile of these agents.

Nasal carriage of *S. aureus* is associated with an increased risk of catheter-related infections and peritonitis.[85,89] In addition, diabetic patients and those on immunosuppressive therapy are at increased risk for *S. aureus* catheter infections. Prophylaxis with intranasal mupirocin (twice daily for 5-7 days every month), mupirocin (daily) at the exit site, or oral rifampin can effectively reduce *S. aureus* exit-site infections. Because of the minimal toxicity of mupirocin and the risk of rifampin resistance, mupirocin regimens are preferred.[85,89] However, it is important to note that *S. aureus* isolates with a high degree of resistance to mupirocin have been isolated from PD patients using prophylactic mupirocin at the peritoneal catheter exit site. A recent study did not observe resistance patterns with the use of mupirocin. Patients in this study applied mupirocin to the exit-site either once or thrice weekly. After 3 years exit-site infections and peritonitis rates were significantly lower in the thrice-weekly application group.[93] In addition, gentamicin cream applied daily to the exit site has been found to effectively reduce both *S. aureus* and *P. aeruginosa* exit-site infection.[85,89] However, a comparison of mupirocin 2% and gentamicin 0.1% creams for exit-site prophylaxis noted a decrease in gentamicin susceptibility patterns for *Enterobacteriaceace* (12%) and *Pseudomonas* (14%).[94]

A double-blinded, randomized controlled trial compared the use of the topical ointments mupirocin to polysporin triple (P^3; bacitracin, gramicidin and polymixin B) in PD patients (n = 201) for the prevention of PD-related infections. Patients applied the ointment to the exit-site with each dressing change and were followed for up to 18 months. No significant difference was found between groups for time to first PD-related infections (P = 0.41) for either agent but a significant increase in fungal infections was observed in the P^3 versus mupirocin group (7 vs 0; P = 0.01). The authors concluded that the use of P^3 for PD-related infection prophylaxis was not superior to mupirocin and may increase the risk of fungal infections.[95]

The use of polyhexanide was compared to povidone-iodine to prevent exit-site infections in PD patients in a single center prospective open label study (n = 46). After 12 months, there was a lower rate of overall infections (P = 0.037) and exit site infections (P = 0.032) with use of polyhexanide compared to povidine-iodine. The infection source in the polyhexanide group was identified as *P. aeruginosa* (n = 3) but in the povidine-iodine group (n = 9) three sources were identified as *S. aureus* (n = *6*), *Corynebacterium jeikeium* (n = 2), *P. aeruginosa* (n = 1). During the study no infected catheters required removal.[96]

A multi-center open label trial to assess daily application at the exit site of antibacterial honey compared to standard care in **PD** patients (n = 371). Time to first peritonitis (P = 0.97) and time to first exit site infection (P = 0.24) were not different between groups but the honey group reported a higher rate of infection in patients with diabetes (*HR* 1.85 [1.05-3.24]; P = 0.03). Also, there was a higher rate of study withdrawal and skin rash in the honey group. The authors concluded that topical use of honey could not be recommended as routine therapy in PD patients.[97] These findings differ from previous smaller studies that examine the use of topical honey to prevent catheter related infections, which found medical-grade *Leptospermum* honey to be as effective as mupirocin in

reducing catheter infections.[98]

CONCLUSION

Because of the limitation of available kidneys for transplantation, HD and PD remain the most widely available and commonly used ESRD treatments. Despite continual advances in dialysis and transplantation, kidney disease is associated with significant morbidity and mortality. Given the lack of a true cure for kidney disease, emphasis has been placed on the prevention and early detection of kidney disease. Goals set by the KDOQI, the Healthy People 2020 initiative, and the Centers for Medicare and Medicaid Services' CPM Project provide guidance and direction for all healthcare practitioners. In fact, there have been significant reductions in the incidence rate of ESRD, enhanced timing and selection of the preferred access placement, and mortality and morbidity.[99,100] For patients with ESRD, a focus on quality of life and rehabilitation is now a valuable and viable goal toward which the nephrology community should direct its research resources. Several links to patient related videos that discuss CKD patient experiences are presented in **Table 45-12**. Although prevention of ESRD is the primary goal for clinicians and adequate access to renal transplantation is secondary, dialysis will likely be a part of the treatment paradigm for ESRD for many years to come.

Chapter 46: Drug-Induced Kidney Disease

Thomas D. Nolin

INTRODUCTION

KEY CONCEPTS

- 1 The initial diagnosis of drug-induced kidney disease (DIKD) typically involves detection of elevated serum creatinine (S_{cr}) and blood urea nitrogen, for which there is a temporal relationship between the toxicity and use of a potentially nephrotoxic drug.
- 2 Drug-induced kidney disease is best prevented by avoiding the use of potentially nephrotoxic agents for patients at increased risk for toxicity. However, when exposure to these drugs cannot be avoided, recognition of risk factors and specific techniques, such as hydration, may be used to reduce potential nephrotoxicity.
- 3 Acute tubular necrosis (ATN) is the most common presentation of DIKD in hospitalized patients. The primary agents implicated are aminoglycosides, radiocontrast media, cisplatin, amphotericin B, and osmotically active agents.
- 4 Angiotensin-converting enzyme inhibitors (ACEIs) and nonsteroidal antiinflammatory drugs (NSAIDs) are associated with hemodynamically mediated kidney injury, the pathogenesis of which is a decrease in glomerular capillary hydrostatic pressure.
- 5 Acute allergic interstitial nephritis (AIN) is observed in up to 27% of kidney biopsies performed for hospitalized patients with unexplained acute kidney injury (AKI). Clinical manifestations of AIN typically present approximately 14 days after initiation of therapy and include fever, maculopapular rash, eosinophilia, arthralgia, often with pyuria, hematuria, proteinuria, and oliguria.

Numerous diagnostic and therapeutic agents have been associated with the development of drug-induced kidney disease (DIKD) or nephrotoxicity. It is a relatively common complication with variable presentations depending on the drug and clinical setting, inpatient or outpatient. Manifestations of DIKD may include acid–base abnormalities, electrolyte imbalances, urine sediment abnormalities, proteinuria, pyuria, and/or hematuria.[1] However, the most common manifestation of

nephrotoxicity is a decline in the glomerular filtration rate (GFR) and a corresponding rise in serum creatinine (S_{cr}) concentrations. Initial diagnosis of nephrotoxicity is often delayed because it typically is based on the detection of elevated S_{cr}, for which there is a temporal relationship between the kidney injury (evidenced by the rise in S_{cr}) and exposure to the potentially nephrotoxic drug. This is consistent with contemporary definitions of acute kidney injury (AKI), which rely on either an abrupt increase in S_{cr} or an abrupt decline in urine output (see Chapters e42 and 43).[2]

Nephrotoxicity is often reversible if one discontinues the use of the offending agent, but in some cases it may evolve into AKI and may even progress to stage 5 chronic kidney disease (CKD). Currently, many different mechanisms are responsible for the pathogenesis of DIKD, and the introduction of new drugs with novel mechanisms of action provides the potential for the identification of new presentations of AKI and CKD. This chapter reviews the epidemiology, pathophysiology, risk factors, and basic principles of prevention of DIKD. Detailed discussions of these issues plus management strategies are presented for the most commonly used agents that have been associated with a moderate to high likelihood of DIKD.

EPIDEMIOLOGY

The incidence and characteristics of outpatient or community-acquired DIKD are not well understood since mild toxicity is often unrecognized in this setting. However, the acquisition of data regarding the pharmacoepidemiology of these effects has become more important as care increasingly shifts to the outpatient setting. The incidence of community-based AKI requiring dialysis is as high as 29.5 per 100,000 person years and 522.4 per 100,000 person years for patients not requiring dialysis.[3] Although the incidence of drug-induced AKI was not specifically reported, up to 20% of hospital admissions due to AKI have been attributed to nephrotoxicity acquired in the community setting.[4] The incidence of AKI is even higher in hospitalized patients and appears to be increasing over time.[3,5] As many as 22% of adults and 34% of children worldwide experience AKI during a hospital admission.[6] While up to 30% of critically ill patients experience AKI during their hospitalization, and 1 in 4 cases is associated with nephrotoxic medication exposure.[7] Indeed, drugs have been implicated in 26% of all cases of in-hospital AKI and as such are a recognized source of significant morbidity and mortality.[1]

1 Because the most common manifestation of DIKD is a decline in GFR leading to a rise in S_{cr} and BUN, the onset of toxicity in hospitalized, acutely ill patients is most often recognized by routine laboratory monitoring. Decreased urine output may also be an early sign of toxicity, particularly with radiographic contrast media, nonsteroidal antiinflammatory drugs (NSAIDs), and ACEIs. In the outpatient setting, nephrotoxicity is often recognized by the development of symptoms such as malaise, anorexia, vomiting, volume overload (shortness of breath or edema), and hypertension. S_{cr} or BUN concentrations and urine collection for creatinine clearance may subsequently be measured to quantify the degree of decline in GFR. Marked intrasubject between-day variability of S_{cr} values have been noted (±20% for values within the normal range; see Chapter e42). Furthermore, they may be altered as the result of dietary changes and initiation of drug therapy, which may interfere with

the assay procedure. Nevertheless, changes in S_{cr} or urine output consistent with the diagnostic criteria for AKI (see Chapter 43), when correlated temporally with the initiation of drug therapy, are a common threshold for the identification of DIKD.[1]

CLINICAL PRESENTATION Drug-Induced Kidney Disease General

- The most common manifestation is a decline in GFR leading to a rise in S_{cr} and BUN.
- Alterations in renal tubular function without loss of glomerular filtration may be evident.

Symptoms

- Patients may complain of malaise, anorexia, vomiting, shortness of breath, or edema, particularly in the outpatient setting.

Signs

- Decreased urine output may be an early sign of toxicity, particularly with radiographic contrast media, NSAIDs, and ACEIs, with progression to volume overload and hypertension.
- Proximal tubular injury: Metabolic acidosis with bicarbonaturia; glycosuria in the absence of hyperglycemia; and reductions in serum phosphate, uric acid, potassium, and magnesium due to increased urinary losses.
- Distal tubular injury: Polyuria from failure to maximally concentrate urine, metabolic acidosis from impaired urinary acidification, and hyperkalemia from impaired potassium excretion.

Laboratory Tests

- An abrupt (within 48 hours) reduction in kidney function defined as an absolute increase in S_{cr} of greater than or equal to 0.3 mg/dL (greater than or equal to 27 μmol/L), a percentage increase in S_{cr} of greater than or equal to 50% (1.5-fold from baseline) within 7 days, or a reduction in urine output (documented oliguria of less than 0.5 mL/kg/h for more than 6 hours), when correlated temporally with the initiation of drug therapy may indicate drug-induced AKI.[1]

Other Diagnostic Tests

- Urinary excretion of *N*-acetyl-*β*-d-glucosaminidase, *γ*-glutamyl transpeptidase, glutathione *S*-transferase, and interleukin (IL)-18 are markers of proximal tubular injury and have been used for the early detection of AKI in critically ill patients.
- Kidney injury molecule-1 (KIM-1) is expressed in the proximal tubule and is upregulated for patients with ischemic acute tubular necrosis (ATN), appearing in the urine within 12 hours after the ischemic insult.
- Neutrophil gelatinase-associated lipocalin (NGAL) protein may be detected in the urine within 3

hours of ischemic injury.

Nephrotoxicity may also be evidenced by primary alterations in renal tubular function without a corresponding loss of glomerular filtration. In this setting, urinary enzymes and low-molecular-weight proteins may be used as earlier and more specific biomarkers of nephrotoxicity compared with S_{cr} and BUN, which are relatively insensitive markers of kidney injury.[8,9] S_{cr} and BUN are used as surrogates of kidney function, not injury per se, and typically significant kidney injury must have occurred days before a rise in either is evident. The emergence of novel biomarkers of kidney injury represents an important opportunity for earlier detection of DIKD. Urinary excretion of KIM-1, *N*-acetyl-*β*-glucosaminidase, *γ*-glutamyl transpeptidase, glutathione *S*-transferase, NGAL, and interleukin-18 markers of proximal tubular injury have been used for the early detection of acute kidney damage in several patient populations.[8,9,10] For example, the transmembrane protein KIM-1 is upregulated for patients with ischemic ATN, appearing in the urine within 12 hours after the ischemic insult. Urinary *N*-acetylglucosamine (NAG) concentrations are a highly sensitive indicator of AKI and have been shown to detect AKI in critically ill patients up to 4 days prior to a rise in S_{cr} was observed. Similarly, urinary NGAL is an early marker of AKI, preceding a rise in S_{cr} by up to 3 days.[11]

Recently, the urinary cell-cycle arrest biomarkers insulin-like growth factor-binding protein 7 (IGFBP7) and tissue inhibitor of metalloproteinase 2 (TIMP-2) were shown to predict AKI in high-risk surgical patients,[12] and clinical outcomes (death and the need for dialysis) in critically ill adults.[13] To date, no clinical studies demonstrating the utility of IGFBP7 and TIMP-2 in detecting and/or minimizing DIKD have been reported, but several pre-clinical studies provide proof of principle for the potential clinical role and utility of monitoring TIMP or IGFBP for this purpose. For example, TIMP-1 is an effective biomarker of cisplatin-induced nephrotoxicity in human kidney cells,[14] and is useful in predicting aristolochic acid–induced kidney injury in rats.[15] In the future, urinary biomarkers may facilitate the earlier detection of kidney injury and diagnosis of nephrotoxicity and minimize the long-term consequences of this common drug-induced disorder.

PRINCIPLES FOR PREVENTION OF DRUG-INDUCED NEPHROPATHY

2 The primary principle for prevention of DIKD is to avoid the use of nephrotoxic agents for patients at increased risk for toxicity. Therefore, an awareness of potentially nephrotoxic drugs and knowledge of risk factors that increase renal vulnerability is essential.[16] Exposure to these drugs often cannot be avoided, so several interventions have been proposed to reduce the potential for the development of nephrotoxicity, for example, adjustment of medication dosage regimens based on accurate estimates of kidney function, and careful and adequate hydration to establish high urine flow rates.[17] Other preventative strategies are still theoretical and/or investigational and relate directly to the specific nephrotoxic mechanisms of a given drug.

The several specific drug-induced renal structural–functional alterations that are responsible for the vast majority of cases of DIKD are listed in **Table 46-1**. This chapter discusses the pathophysiologic

mechanisms responsible for the development of DIKD with these agents in detail, along with clinical presentation, prevention strategies, therapeutic management approaches, and relevant monitoring plans.

TABLE 46-1 Drug-Induced Kidney Structural–Functional Alterations

Tubular epithelial cell damage

Acute tubular necrosis

- Aminoglycoside antibiotics
- Radiographic contrast media
- Cisplatin, carboplatin
- Amphotericin B
- Cyclosporine, tacrolimus
- Adefovir, cidofovir, tenofovir
- Pentamidine
- Foscarnet
- Zoledronate

Osmotic nephrosis

- Mannitol
- Dextran
- IV immunoglobulin

Hemodynamically mediated kidney injury

- Angiotensin-converting enzyme inhibitors
- Angiotensin II receptor blockers
- Nonsteroidal antiinflammatory drugs (NSAIDs)
- Cyclosporine, tacrolimus
- OKT3

Obstructive nephropathy

Crystal nephropathy

- Acyclovir
- Sulfonamides
- Indinavir
- Foscarnet
- Methotrexate

Nephrolithiasis

- Sulfonamides
- Triamterene
- Indinavir

Nephrocalcinosis

- Oral sodium phosphate solution

Glomerular disease

Minimal Change Disease

- NSAIDs, COX-2 inhibitors
- Lithium

Focal Segmental Glomerulosclerosis

- Pamidronate
- Interferon-α and -β

- Pamidronate
- Interferon-α and -β

Membranous Disease

- NSAIDs
- Penicillamine
- Captopril
- Lithium
- Sirolimus
- Anabolic steroids

Tubulointerstitial disease

Acute allergic interstitial nephritis

- Penicillins
- Ciprofloxacin
- NSAIDs, cyclooxygenase-2 inhibitors
- Proton pump inhibitors
- Loop diuretics

Chronic interstitial nephritis

- Cyclosporine
- Lithium
- Aristolochic acid

Papillary necrosis

- NSAIDs, combined phenacetin, aspirin, and caffeine analgesics

Renal vasculitis, thrombosis, and cholesterol emboli

Vasculitis and thrombosis

- Hydralazine
- Propylthiouracil
- Allopurinol
- Penicillamine
- Gemcitabine
- Mitomycin C

Methamphetamines

- Cyclosporine, tacrolimus
- Adalimumab
- Bevacizumab

Cholesterol emboli

- Warfarin
- Thrombolytic agents

TUBULAR EPITHELIAL CELL DAMAGE

3 Drugs that lead to renal tubular epithelial cell (RTEC) damage typically do so via direct cellular toxicity or ischemia. Damage is most often localized in the proximal and distal tubular epithelia and is termed ATN when cellular degeneration and sloughing from proximal and distal tubular basement

membranes are observed. This classically manifests as cellular debris-filled, RTECs and RTEC casts and/or muddy brown granular casts in the urinary sediment.[18] Specific indicators of proximal tubular injury include metabolic acidosis with bicarbonaturia; glycosuria in the absence of hyperglycemia; and reductions in serum phosphate, uric acid, potassium, and magnesium as a result of increased urinary losses.[19] Indicators of distal tubular injury include polyuria from failure to maximally concentrate urine (ie, nephrogenic diabetes insipidus), metabolic acidosis from impaired urinary acidification, and hyperkalemia from impaired potassium excretion.[20]

Acute Tubular Necrosis

Acute tubular necrosis is the most common presentation of DIKD in the inpatient setting. The primary agents associated with this type of injury are aminoglycosides, radiocontrast media, cisplatin, amphotericin B, foscarnet, and osmotically active agents such as immunoglobulins, dextrans, and mannitol.[21]

Aminoglycoside Nephrotoxicity

Incidence

Aminoglycoside antibiotic-associated nephrotoxicity has been reported to occur in between 10% and 25% of patients receiving a therapeutic course.[22,23] Critically ill patients appear to have a higher risk for nephrotoxicity with reported rates as high as 58%.[24] The large variance is in part a result of the use of different definitions of toxicity, variability between agents in the class, and the risk factors present in the study population.

Clinical Presentation

Clinical evidence of aminoglycoside-associated nephrotoxicity is typically seen within 5 to 7 days after initiation of therapy and manifests as a gradual progressive rise in S_{cr} and BUN and decrease in creatinine clearance.[23] Patients usually present with nonoliguria, that is, they maintain urine volumes greater than 500 mL/day and sometimes have microscopic hematuria and proteinuria.[21] Although renal magnesium wasting can occur (ie, daily excretion of more than 10-30 mg), the risk of symptomatic hypomagnesemia is generally low. Full recovery of kidney function is common if aminoglycoside therapy is discontinued immediately upon discovering signs of toxicity. However, severe AKI may develop occasionally, and for these individuals renal replacement therapy may be required (see Chapter 43). The diagnosis of aminoglycoside-associated nephrotoxicity is often difficult, particularly in critically ill patients with multiple comorbidities and is confounded by other factors that are independently associated with the development of AKI.[24] For instance, concurrent dehydration, sepsis, hypotension, ischemia, and use of other nephrotoxic drugs frequently contribute to AKI in patients who are receiving aminoglycosides.

Pathogenesis

Aminoglycoside-associated ATN is primarily due to accumulation of high drug concentrations within proximal tubular epithelial cells, and subsequent generation of reactive oxygen species that produce mitochondrial injury, which leads to cellular apoptosis and necrosis.[22] This results in cell sloughing from proximal tubular basement membranes into the tubular lumen, which can result in tubular obstruction and back leakage of the glomerular filtrate across the damaged tubular epithelium. Toxicity is related to cationic charge of the drugs in this class, which facilitates their binding to negatively charged renal tubular epithelial membrane phospholipids in the proximal tubules, followed by intracellular transport and concentration in lysosomes. The number of cationic groups on the drug molecule appears to correlate with the degree of nephrotoxicity, which is consistent with the observation of higher rates of toxicity with neomycin versus gentamicin, followed by tobramycin, then amikacin.[23]

Risk Factors

Multiple risk factors for aminoglycoside-associated nephrotoxicity have been identified: the aggressiveness of aminoglycoside dosing, synergistic toxicity as the result of combination drug therapy, and preexisting clinical conditions of the patient (**Table 46-2**).[22,24]

TABLE 46-2 Potential Risk Factors for Aminoglycoside Nephrotoxicity

(A) Related to aminoglycoside dosing:
Large total cumulative dose
Prolonged therapy
Trough concentration exceeding 2 mg/L[a]
Recent previous aminoglycoside therapy
(B) Related to synergistic nephrotoxicity. Aminoglycosides in combination with
Cyclosporine
Amphotericin B
Vancomycin
Diuretics
Iodinated radiographic contrast agents
Cisplatin
NSAIDs
(C) Related to predisposing conditions in the patient
Preexisting kidney disease

Diabetes

Increased age

Poor nutrition

Shock

Gram-negative bacteremia

Liver disease

Hypoalbuminemia

Obstructive jaundice

Dehydration

Hypotension

Potassium or magnesium deficiencies

[a]The equivalent concentration in SI molar units are 4.3 µmol/L for tobramycin and 4.2 µmol/L for gentamicin.

Prevention

Aminoglycoside-associated ATN may be prevented by careful and cautious selection of patients and the use of alternative antibiotics whenever possible and as soon as microbial sensitivities are known. Commonly used alternatives include fluoroquinolones (eg, ciprofloxacin or levofloxacin) and third- or fourth-generation cephalosporins (eg, ceftazidime or cefepime). When aminoglycosides are necessary, gentamicin, tobramycin, and amikacin are most commonly used, but therapy should be selected to optimize antimicrobial efficacy. Furthermore, it is imperative to avoid volume depletion, limit the total aminoglycoside dose administered, and avoid concomitant therapy with other nephrotoxic drugs.[22] Future therapeutic alternatives may include new aminoglycoside congeners that retain the desired bactericidal activity and yet are devoid of nephrotoxicity, and may also include concurrent use of antioxidant compounds such as alpha-lipoic acid, vitamin E and *N*-acetylcysteine.[25,26]

Prospective, individualized pharmacokinetic monitoring has been associated with a decrease in the incidence of aminoglycoside-associated nephrotoxicity.[27] These studies, however, were often small and statistically underpowered. High-dose intermittent dosing of aminoglycosides, termed once daily dosing, used in combination with other antibiotics, has been intensively investigated as a practical cost-effective method to maintain antimicrobial efficacy while reducing the risk of AKI.[27,28] The reduction in incidence may be the result of limited proximal tubular aminoglycoside uptake during the transient, high-peak serum concentrations, and because of the presence of low aminoglycoside

concentrations for a greater proportion of the dosing interval, which facilitates excretion of the aminoglycoside.[22] Although greater clinical efficacy and reduced nephrotoxicity may be realized with once daily compared with standard dosing, seriously ill, immunocompromised, and elderly patients, as well as those with preexisting kidney disease, are not ideal candidates for this approach.

Management

Aminoglycoside use should be discontinued or the dosage regimen revised if AKI is evident (ie, there is an S_{cr} increase of 0.5 mg/dL [44 µmol/L] or more that is not attributable to another cause). Other nephrotoxic drugs should be discontinued if possible, and the patient should be maintained adequately hydrated and hemodynamically stable.[28] Short-term renal replacement therapy may be necessary, but ESRD is rarely the result of aminoglycoside toxicity alone.

Radiographic Contrast Media Nephrotoxicity

Incidence

Radiographic contrast media-induced nephrotoxicity (CIN) is the third leading cause of hospital-acquired AKI, accounting for 10% to 13% of cases.[29] The incidence varies depending on the population studied and presence of risk factors; rising from less than 2% for patients with normal kidney function, to 17% in patients with impaired kidney function, and 23% to 50% of critically ill patients.[21,30,31] As the number of risk factors associated with CIN increases, there is a corresponding increase in the incidence of nephrotoxicity and mortality rates. A nearly 5-fold increased risk of death has been reported for patients who develop CIN compared with those who do not, with the highest mortality rates observed for patients who developed AKI and required renal replacement therapy. Specifically, in-hospital mortality for patients who developed CIN was 34% versus only 7% of patients who received contrast but did not develop AKI.[29] Moreover, a 2-year mortality rate of 81% has been observed for patients who developed CIN and required dialysis.[29]

Clinical Presentation

Contrast media-induced nephrotoxicity is usually transient in nature, presenting most commonly as nonoliguria with kidney injury apparent within the first 24 to 48 hours after the administration of contrast. The S_{cr} concentration usually peaks between 3 and 4 days after exposure, with recovery after 7 to 10 days.[23] However, irreversible oliguric (urine volume less than 500 mL/day) AKI requiring dialysis has been reported in high-risk patients.[32] Urinalysis typically reveals tubular enzymuria with hyaline and granular casts but may also be completely void of casts. The urine sodium concentration and fractional excretion of sodium are frequently low, with the latter typically less than 1% (less than 0.01).

Pathogenesis

The primary mechanisms by which contrast media induces nephrotoxicity are renal ischemia and

direct cellular toxicity.[33] Renal ischemia likely results from systemic hypotension and simultaneous acute vasoconstriction caused by disruption of normal prostaglandin synthesis and the release of adenosine, endothelin, and other renal vasoconstrictors. Subsequently, a sustained reduction in renal blood flow of up to 25% that lasts for several hours immediately following contrast administration may be evident.[33] This reduced renal blood flow leads to a 50% reduction in oxygen partial pressure and renal ischemia, along with increased concentrations of contrast in the renal tubules, which exacerbates the direct cytotoxicity.[33,34] The extent of cellular toxicity is directly related to the duration of tubular cell exposure to contrast. Thus, preservation of high urinary flow rates with adequate hydration before, during, and after contrast administration is vital to keep renal blood flow as high as reasonably possible to minimize tubular cell exposure to the contrast agent.[34] In humans, plasma osmolality is normally between 275 and 290 mOsm/kg (mmol/kg). Since low- and high-osmolar contrast agents are hyperosmolar to plasma (ie, 600-800 mOsm/kg [mmol/kg] and ~2,000 mOsm/kg [mmol/kg], respectively), their use may result in osmotic diuresis, dehydration, renal ischemia, and increased blood viscosity caused by red blood cell aggregation.[35] Oxidative stress has also been implicated in the development of ATN after contrast administration, which may explain the possible benefit of the antioxidants *N*-acetylcysteine and ascorbic acid.[36]

Risk Factors

Decreased renal blood flow exacerbates the ischemic and direct cytotoxic effects of contrast media on the renal tubules. Therefore, preexisting kidney disease, particularly in those with estimated GFR less than 60 mL/min/1.73 m^2 (less than 0.58 mL/s/m^2), is the most important risk factor, since lower GFR is associated with increasing levels of risk.[31] Other patient-specific risk factors include conditions associated with decreased renal blood flow (ie, congestive heart failure, dehydration/volume depletion, and hypotension), and patients with atherosclerosis and reduced effective circulating arterial blood volume appear to also have an elevated risk.[37,38] Diabetes is also a significant risk factor, likely due to coexisting kidney disease (diabetic nephropathy). The presence of multiple myeloma has traditionally been considered a relative contraindication for contrast use, but the risk appears to be associated with concomitant dehydration, kidney disease, or hypercalcemia rather than the diagnosis itself. Larger volumes or doses of contrast and the use of low- as well as high-osmolar contrast agents are also independent predictors of CIN.[37,38] Intraarterial administration of contrast confers greater risk than IV administration.[31] Lastly, concurrent use of nephrotoxins and drugs that alter renal hemodynamics such as NSAIDs and ACEIs also increases risk. Risk factors are additive, and there is a proportional increase in the incidence of CIN and associated mortality as the number of risk factors increases.[38]

Prevention

Contrast media-induced nephrotoxicity can be anticipated in the majority of patients who are at risk; so the use of preventative procedures is justified for virtually all patients. **Table 46-3** lists the recommended interventions for prevention of contrast nephrotoxicity. All patients scheduled to receive contrast media should be assessed for risk factors, and the risk-to-benefit ratio should be

considered.[29,37,38] High-risk patients can be identified by evaluating medical history and indication for the contrast study, along with their most recent S_{cr} concentrations. Nephrotoxicity is best prevented in high-risk patients by using alternative imaging procedures (eg, ultrasound, noncontrast magnetic resonance imaging, and nuclear medicine scans). However, if contrast media must be used, the smallest adequate volume should be administered.[29] If the ratio of the volume of contrast to be infused relative to the patient's creatinine clearance is greater than or equal to 3.7 (greater than or equal to 222 if creatinine clearance is expressed in units of milliliters per second), the likelihood of nephrotoxicity is markedly increased.[38] Therefore, in general, the volume of contrast administered should not be greater than twice the baseline estimated creatinine clearance.

TABLE 46-3 Recommended Interventions for Prevention of Contrast Nephrotoxicity[36,37,38,39]

Intervention	Recommendation	Recommendation Grade[a]
Contrast	• Minimize contrast volume/dose	A-1
	• Use noniodinated contrast studies	A-2
	• Use low- or iso-osmolar contrast agents	A-2
Medications	• Avoid concurrent use of potentially nephrotoxic drugs, eg, NSAIDs, aminoglycosides	A-2
Isotonic sodium chloride (0.9%)	• Initiate infusion 3-12 hours prior to contrast exposure and continue 6-24 hours postexposure • Infuse at 1-1.5 mL/kg/h adjusting postexposure as needed to maintain a urine flow rate of 150 mL/h • Alternatively, in urgent cases, initiate infusion at 3 mL/kg/h, beginning 1 hour prior to contrast exposure, then continue at 1 mL/kg/h for 6 hours postexposure	A-1
N-acetylcysteine	• Administer 600-1,200 mg by mouth (PO) every 12 hours, 4 doses beginning prior to contrast exposure (ie, 1 dose prior to exposure and 3 doses postexposure)	B-1

[a]*Strength of recommendations*: A, B, and C are good, moderate, and poor evidence to support recommendation, respectively. *Quality of evidence*: 1, evidence from more than 1 properly randomized, controlled trial; 2, evidence from more than 1 well-designed clinical trial with

randomization, from cohort or case-controlled analytic studies or multiple time series, or dramatic results from uncontrolled experiments; 3, evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

Low-osmolar (600-800 mOsm/kg [mmol/kg]) nonionic (iohexol and iopamidol) and ionic (ioxaglate) contrast agents may be used to minimize the incidence of n ephrotoxicity. Standard hyperosmolar contrast media (eg, low- and high-osmolar agent) are not reabsorbed in the kidney and cause osmotic diuresis, which contributes to the renal toxicity observed with these agents. Low-osmolar contrast agents have less than half the osmolality of high-osmolar (~2,000 mOsm/kg [mmol/kg]) agents and are associated with less toxicity, especially when used for patients with preexisting kidney disease.[35] However, use of low-osmolar agents does not preclude the development of nephrotoxicity. Even low-osmolar agents are hyperosmolar relative to plasma, which is likely the reason they have been associated with greater nephrotoxicity than the iso-osmolar nonionic contrast agent iodixanol. Currently, the relative differences in nephrotoxicity between the class of low-osmolar agents and iodixanol are unclear.[38,39]

Clinical Controversy…

Some clinicians believe that low- or iso-osmolar contrast media should be used for virtually all patients at risk for toxicity. Others believe that the cost-to-benefit ratio of using low-osmolar contrast agents to prevent nephrotoxicity is questionable except for patients at high risk.

Volume expansion and correction of dehydration prior to contrast administration is a mainstay of preventive therapy.[34] Parenteral hydration with isotonic saline before and after contrast administration reduces the incidence of toxicity, particularly in high-risk patients, and is currently the most widely accepted preventative intervention.[38] Volume expansion may exert its beneficial effects through dilution of contrast media, prevention of renal vasoconstriction, preservation of high urine flow rates, decreased tubular cell exposure to contrast, and avoidance of tubular obstruction. Numerous clinical trials have compared the efficacy of hydration with isotonic saline to isotonic sodium bicarbonate for CIN prevention. Contradictory findings have been observed, and to date, there is no strong evidence of a benefit of sodium bicarbonate over saline. Thus, current guidelines recommend hydration with isotonic saline for CIN prevention.[38,39] The use of oral hydration is not currently recommended in lieu of parenteral hydration.[38,39]

N-acetylcysteine is a thiol-containing antioxidant that may effectively reduce the risk of developing CIN for patients with preexisting kidney disease. Despite the publication of dozens of clinical trials and meta-analyses, a therapeutic benefit of NAC has not been consistently demonstrated, and its therapeutic role remains controversial.[36] Although it is no longer recommended in CIN prevention guidelines,[38,39] it is still widely used, particularly in patients who are at high risk of toxicity.[23] The typical *N*-acetylcysteine dosing regimen for prevention of CIN is to give four doses of 600 mg to 1,200 mg orally every 12 hours, with the first dose administered prior to contrast exposure (see Table 46-3).[36] Finally, other nephrotoxic drugs should be discontinued if possible, and subsequent contrast studies appropriately timed to minimize cumulative toxicity.

Clinical Controversy…

Some clinicians believe that insufficient evidence exists to justify use of *N*-acetylcysteine for the prevention of contrast-induced nephrotoxicity, while others feel that its safety profile, ease of use, low cost, and potential for benefit are adequate justification for use for all patients.

Renal replacement therapy, including intermittent hemodialysis and continuous modalities, for example, continuous venovenous hemofiltration (CVVH), effectively removes iodinated contrast, and was considered by some to be a therapeutic option for the prevention of CIN. However, because of the logistical issues (eg, technical difficulty), potential infectious and noninfectious risks, high cost of renal replacement therapy, and lack of consistent clinical efficacy data, renal replacement therapy is not recommended.[31,39]

Management

Currently there is no specific therapy available for managing established CIN. Care is supportive as described in Chapter 43. Kidney function (eg, S_{cr} and urine output), electrolytes (eg, sodium and potassium), and volume status should be closely monitored.

Cisplatin Nephrotoxicity

Incidence

Cisplatin is one of the most important and widely used antineoplastic drugs for the treatment of solid tumors, often demonstrating exceptional efficacy (ie, cure rates over 90% in testicular cancers).[40] Unfortunately, the primary dose-limiting toxicity of platin-containing compounds is nephrotoxicity. Cisplatin nephrotoxicity occurs in up to one third of patients receiving the drug and is a significant cause of morbidity.[40,41] Carboplatin, a second-generation platinum analog, is associated with a lower incidence of nephrotoxicity than cisplatin and thus is the preferred agent in high-risk patients.[42]

Clinical Presentation

Cisplatin administration results in impaired tubular reabsorption and decreased urinary concentration ability, leading to increased excretion of salt and water (ie, polyuria) within 24 hours of treatment. Polyuria persists, and a decrease in GFR evidenced by a rise in S_{cr} concentration may be seen within 72 to 96 hours after cisplatin administration.[43] S_{cr} peaks approximately 10 to 14 days after initiation of therapy, with recovery by 21 days.[44] As many as 25% of patients may have reversible elevations in S_{cr} and BUN for 2 weeks after cisplatin treatment. However, kidney damage is dose related and cumulative with subsequent cycles of therapy, so the S_{cr} concentration may continue to rise, and irreversible kidney injury may result.[42] Hypomagnesemia is a hallmark finding of cisplatin nephrotoxicity, due to impaired magnesium reabsorption and thus increased urinary losses.[45] Hypomagnesemia is often accompanied by hypocalcemia and hypokalemia and may be severe, leading to seizures, neuromuscular irritability, or personality changes. Urinalysis typically reveals

leukocytes, RTECs, and granular casts.

Pathogenesis

The pathogenesis of cisplatin nephrotoxicity is multifactorial in nature and likely begins with cellular uptake and accumulation of the drug in proximal tubular epithelial cells to concentrations that may reach five times the serum concentration.[46] Tubular cell exposure to cisplatin then activates a series of cell signaling pathways, including the mitogen-activated protein kinase (MAPK) pathway, p53, caspase, and the generation of reactive oxygen species, that collectively promote tubular cell injury and death via necrosis and/or apoptosis.[40,41] Simultaneous production of proinflammatory cytokines such as tumor necrosis factor-α (TNF-α) within tubular cells activates an inflammatory response, which may worsen the renal insult. Although tubular damage is evident in both the proximal and distal segments, the majority occurs in the proximal tubules and is followed by a progressive loss of glomerular filtration capacity and impaired distal tubular function. Renal biopsies generally reveal necrosis-apoptosis of proximal and distal tubules and collecting ducts, with no obvious morphological changes to the glomeruli.[44]

Risk Factors

Risk factors include age more than 65 years, dehydration, preexisting kidney disease, renal irradiation, concurrent use of nephrotoxic drugs, large cumulative doses, and alcohol abuse.[47]

Prevention

The best renoprotective strategy is a combination of interventions, including prospective dose reduction and decreased frequency of administration, which usually requires using the platin compounds in combination with other chemotherapeutic agents, avoiding concurrent use of other nephrotoxic drugs, and ensuring patients are euvolemic or somewhat hypervolemic prior to initiating treatment.[47,48] Vigorous hydration with isotonic saline should be used for all patients with a goal of maintaining at least 100 to 150 mL/h of urine output during and after cisplatin treatment. Hydration should be initiated 12 to 24 hours prior to and continued for 2 to 3 days after cisplatin administration at rates of 100 to 250 mL/h, as tolerated, to maintain a urine flow of 3 to 4 L/day.[43]

Amifostine, an organic thiophosphate that is converted to an active metabolite, chelates cisplatin in normal cells and reduces the nephrotoxicity, neurotoxicity, ototoxicity, and myelosuppression associated with cisplatin and carboplatin therapy. It is also thought to serve as a thiol donor, thereby reducing intracellular reactive oxygen species and corresponding oxidative stress that plays a critical role in the development of cellular injury.[41] Amifostine is FDA approved to reduce nephrotoxicity associated with repeated cisplatin treatment in patients with advanced ovarian cancer. Pretreatment with amifostine should be considered for patients who are at high risk for kidney injury, particularly patients who are elderly, volume depleted, have CKD, or are receiving other nephrotoxic drugs concurrently. The current recommended dose of amifostine is 910 mg/m^2 administered IV over 15 minutes, beginning 30 minutes prior to cisplatin administration. Common toxicities include acute

hypotension, nausea, and fatigue.

Other renoprotective strategies include the use of hypertonic saline (eg, administration of each dose in 250 mL of 3% saline) to reduce tubular cisplatin uptake. Classic antioxidants such as ascorbic acid, thiol-based antioxidants such as *α*-lipoic acid and *N*-acetylcysteine, which reduce oxidative damage by acting as a sulfhydryl donor, and the disulfiram metabolite diethyldithiocarbamate to reduce cytochrome P450 2E1-mediated generation of hydroxyl radicals have also been evaluated.[46,49] Finally, reduced renal exposure can be achieved with the use of localized intraperitoneal administration in conjunction with systemic administration of sodium thiosulfate for those with peritoneal tumors.[43]

Management

AKI caused by cisplatin therapy is usually partially reversible with time and supportive care, including dialysis. Kidney function indices should be closely followed, with S_{cr} and BUN concentrations checked daily. Serum magnesium, potassium, and calcium concentrations should be monitored daily and corrected as needed.[42] Hypocalcemia and hypokalemia may be difficult to reverse until hypomagnesemia is corrected. Progressive kidney disease caused by cumulative nephrotoxicity may be irreversible and in some cases may lead to ESRD and require chronic dialysis support.[42]

Amphotericin B Nephrotoxicity

Incidence

Variable rates of amphotericin B nephrotoxicity have been reported that correspond in large part to the cumulative dose administered. Nephrotoxicity may be seen in nearly 30% of patients receiving median cumulative doses as low as 240 mg and reaches an incidence of greater than 80% when cumulative doses approach 5 g.[50,51,52] Although numerous studies demonstrate lower rates of nephrotoxicity with liposomal formulations compared with conventional amphotericin B, it is difficult to compare rates of toxicity between products and studies because of the variability in the study populations, doses administered, and inconsistent definitions of nephrotoxicity and methods of assessment.[50,51,53]

Clinical Presentation

Dose-dependent nephrotoxicity is often evident after administration of cumulative doses of 2 to 3 g as nonoliguria, renal tubular potassium, sodium, and magnesium wasting, impaired urinary concentrating ability, and distal renal tubular acidosis.[23,53] Although the cumulative dose is a significant risk factor, the time to onset of kidney injury varies considerably, ranging from a few days to weeks. Tubular dysfunction usually manifests 1 to 2 weeks after treatment is begun, and potassium and magnesium replacement may be necessary.[50] This is typically followed by a decrease in GFR and a rise in S_{cr} and BUN concentrations. Consequently, kidney function indices should be closely followed, with S_{cr} and BUN concentrations checked daily, and serum magnesium, potassium, and

calcium concentrations monitored every other day and corrected as needed.

Pathogenesis

Amphotericin B nephrotoxicity occurs predominantly via two mechanisms. The first is direct tubular epithelial cell toxicity resulting from interaction of amphotericin B with ergosterol in the cell membrane, leading to increased tubular cell membrane permeability, lipid peroxidation, and eventual necrosis of proximal tubular cells.[53] The second mechanism is afferent arteriolar vasoconstriction leading to a reduction in renal blood flow and GFR, and ischemic tubular injury.[23,53]

Risk Factors

Risk factors that impact the likelihood of developing amphotericin B nephrotoxicity include preexisting kidney disease, large individual and cumulative doses, short infusion times, volume depletion, hypokalemia, increased age, and concomitant administration of diuretics and other nephrotoxins, including vancomycin and cyclosporine.[50,53]

Prevention

Permanent decrements in GFR are best prevented by incorporating a low threshold (ie, if S_{cr} reaches 2 mg/dL [177 µmol/L] on 2 consecutive days) for stopping amphotericin B or switching to a liposomal formulation. Several lipid formulations of amphotericin B (eg, amphotericin B lipid complex, liposomal amphotericin B) are available and should be used in most high-risk patients as they reduce nephrotoxicity by enhancing drug delivery to sites of infection and reducing interaction with tubular epithelial cell membranes.[51,53] Nephrotoxicity can also be minimized by limiting the cumulative dose, increasing the infusion time, ensuring the patient is well hydrated, and avoiding concomitant administration of other nephrotoxins.[53] Administration of 1 L IV 0.9% sodium chloride daily during the course of therapy appears to reduce toxicity and a single infusion of saline 10 to 15 mL/kg prior to administration of each dose of amphotericin B are generally recommended.[53] A number of other antifungal agents such as itraconazole, voriconazole, and caspofungin are viable alternatives and are now routinely used in lieu of amphotericin B for patients at high risk of developing nephrotoxicity. Administration of the antioxidant *N*-acetylcysteine (600 mg orally twice daily in adults) during amphotericin treatment may be nephroprotective.[54]

Clinical Controversy…

Although liposomal formulations of amphotericin B are up to 200 times more expensive than conventional amphotericin B (ie, up to $1,000 per day vs $5 per day),[53] many clinicians recommend using liposomal formulations for all patients with CKD and those at risk for developing nephrotoxicity. Others maintain that the safety and efficacy of liposomal formulations are not yet established enough to warrant their use for all patients.

Management

Amphotericin B nephrotoxicity is best treated by discontinuation of therapy and substitution of alternative antifungal therapy, if possible. Renal tubular dysfunction and glomerular filtration will improve gradually to some degree in most patients, but damage may be irreversible. Kidney function indices should be closely followed, with S_{cr} and BUN concentrations checked daily, and serum magnesium, potassium, and calcium concentrations should be monitored daily and corrected as needed.

Osmotic Nephrosis

Several drugs, including mannitol, low-molecular-weight dextran, hydroxyethyl starch, and radiographic contrast media, or drug vehicles, such as sucrose, maltose, and propylene glycol, are associated with osmotic nephrosis, which may rarely lead to ATN and AKI.[55] Since osmotic nephrosis does not necessarily negatively affect proximal tubular function, its presence may often go undetected in patients without overt signs of ATN. This likely contributes to the extremely low incidence of osmotic nephrosis reported for causative agents. IV immunoglobulin solutions containing hyperosmolar sucrose may cause osmotic nephrosis and AKI in 1% to 10% of cases, which is usually reversible shortly after discontinuing therapy.[56,57] Maltose-based IV immunoglobulin solutions have also been implicated in the development of osmotic nephrosis. Although IV immunoglobulin-induced AKI is the modern prototype for osmotic nephrosis, it is understood that the vehicle (ie, sucrose or maltose) is the culprit and not the immunoglobulins themselves.[57]

Clinical Presentation and Pathogenesis

The clinical presentation of osmotic nephrosis is often subtle. While tubular proteinuria or vacuolated tubular cells may be observed on urinalysis for patients with AKI, the definitive diagnosis of osmotic nephrosis is only made via a kidney biopsy.[56] IV immunoglobulin-induced AKI typically presents as oliguria after 2 to 4 days of treatment and may persist for up to 2 weeks. Kidney injury occurs via uptake of the offending agent through pinocytosis into proximal tubular epithelial cells, subsequent formation of vacuoles, and accumulation of lysosomes, which collectively results in an oncotic gradient and thus cellular swelling, tubular luminal occlusion, and compromised cellular integrity.[58] Renal replacement therapy may be necessary for up to 40% of patients developing osmotic nephrosis-associated AKI.[56] However, it is usually reversible, with nearly all patients recovering normal kidney function following withdrawal of the offending drug.

Risk Factors

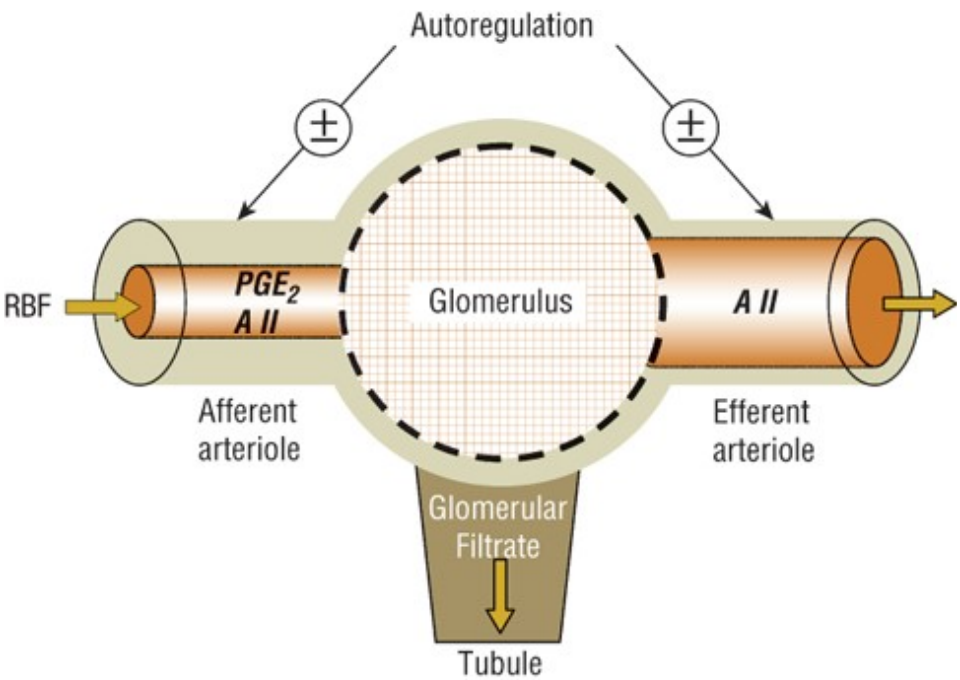
Risk factors for osmotic nephrosis include excessive doses of offending agents, preexisting kidney disease, ischemia, older age (greater than 65 years), and concomitant use of other nephrotoxins. Nephrotoxicity may be prevented by limiting the dose, reducing the rate of infusion, and avoiding dehydration and concomitant nephrotoxins.[57,58]

HEMODYNAMICALLY MEDIATED KIDNEY INJURY

4 Hemodynamically mediated kidney injury generally refers to any cause of AKI resulting from an acute decrease in intraglomerular pressure, including "prerenal" states leading to reduced effective renal blood flow (eg, hypovolemia and congestive heart failure) and medications that affect the renin–angiotensin system.[23,59] The kidneys receive approximately 25% of resting cardiac output, which renders them particularly susceptible to alterations in renal blood flow and enhances their exposure to circulating drugs.[16,60] Within each nephron, blood flow and pressure are regulated by glomerular afferent and efferent arterioles to maintain intraglomerular capillary hydrostatic pressure, glomerular filtration, and urine output. Afferent and efferent arteriolar vasoconstrictions are primarily mediated by angiotensin II, whereas afferent vasodilation is primarily mediated by prostaglandins (**Fig. 46-1**). This specialized blood flow is precisely regulated by interrelations between arachidonic acid metabolites, natriuretic factors, nitric oxide, the sympathetic nervous system, the renin–angiotensin system, and the macula densa response to distal tubular solute delivery.[60] Drug-induced causes of hemodynamic kidney injury typically stem from constriction of glomerular afferent arterioles and/or dilation of glomerular efferent arterioles. ACEIs, angiotensin II receptor blockers (ARBs), and NSAIDs are the agents that have been most commonly implicated.[23,61]

FIGURE 46-1

Normal glomerular autoregulation serves to maintain intraglomerular capillary hydrostatic pressure, glomerular filtration rate (GFR), and, ultimately, urine output. (A II, angiotensin II; PGE_2, prostaglandin E_2; RBF, renal blood flow.)



Angiotensin-Converting Enzyme Inhibitors and Angiotensin II Receptor Blockers

Angiotensin-converting enzyme inhibitors (ACEIs) and ARBs are extensively utilized for the management of hypertension and prevention of the progression of CKD even though they have been associated with the development of AKI.

Incidence

Patients with renal artery stenosis, volume depletion, and congestive heart failure and those with preexisting kidney disease, including diabetic nephropathy, are most likely to experience a significant decline in kidney function when therapy with one of these agents is initiated.[23] For example, up to 25% of hospitalized patients with congestive heart failure develop AKI within weeks after beginning treatment with ACEIs.[62] Moreover, ACEIs and ARBs are among the most commonly implicated medications in emergency hospitalizations, contributing to nearly 3% of emergency room visits for adverse drug events.[63]

Clinical Presentation

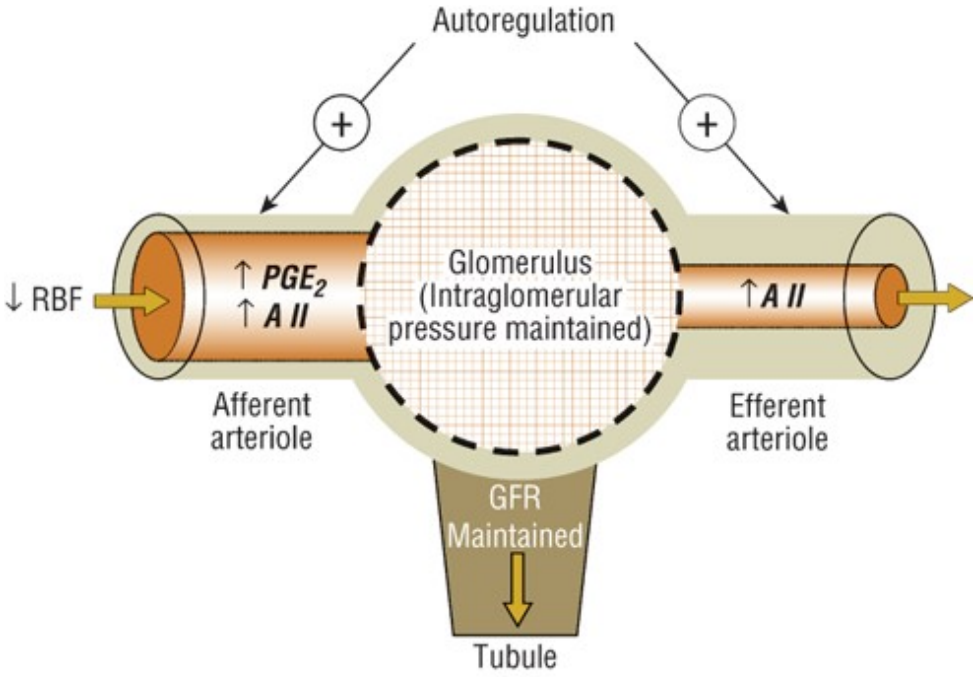
Therapy with ACEIs and ARBs will acutely reduce GFR; so a moderate rise in S_{cr} after initiation of therapy should be anticipated.[64] Importantly, a distinction must be made between a potentially detrimental reduction in GFR and a normal, predictable rise in S_{cr}. An increase in S_{cr} of up to 30% is commonly observed within 3 to 5 days of initiating therapy and is an indication that the drug has begun to exert its desired pharmacologic effect.[64] The increase in S_{cr} typically stabilizes within 1 to 2 weeks and is usually reversible upon stopping the drug. Furthermore, an association exists between acute increases in S_{cr} of less than or equal to 30% from baseline that stabilize within the first 2 months of initiating therapy and preservation of kidney function. The S_{cr} threshold for discontinuation of ACEI or ARB therapy is unclear. However, an increase in S_{cr} of more than 30% above baseline in the course of 1 to 2 weeks may necessitate discontinuation of the offending drug.[64]

Pathogenesis

Angiotensin-converting enzyme inhibitors—or ARB-mediated kidney injury is primarily the result of disruption of normal autoregulation of intraglomerular capillary hydrostatic pressure.[23] Normally, the kidney attempts to maintain GFR by dilating the afferent arteriole and constricting the efferent arteriole in response to a decrease in renal blood flow. During states of reduced blood flow, the juxtaglomerular apparatus increases renin secretion. Plasma renin converts angiotensinogen to angiotensin I, and ultimately angiotensin II by angiotensin-converting enzyme. Angiotensin II constricts the afferent and efferent arterioles, but has a greater effect on the efferent arterioles, resulting in a net increase in intraglomerular pressure.[60] Additionally, renal prostaglandins, prostaglandin E_2 in particular, are released and induce a net dilation of the afferent arteriole, thereby improving blood flow into the glomerulus. Together these processes maintain GFR and urine output (**Fig. 46-2**).

FIGURE 46-2

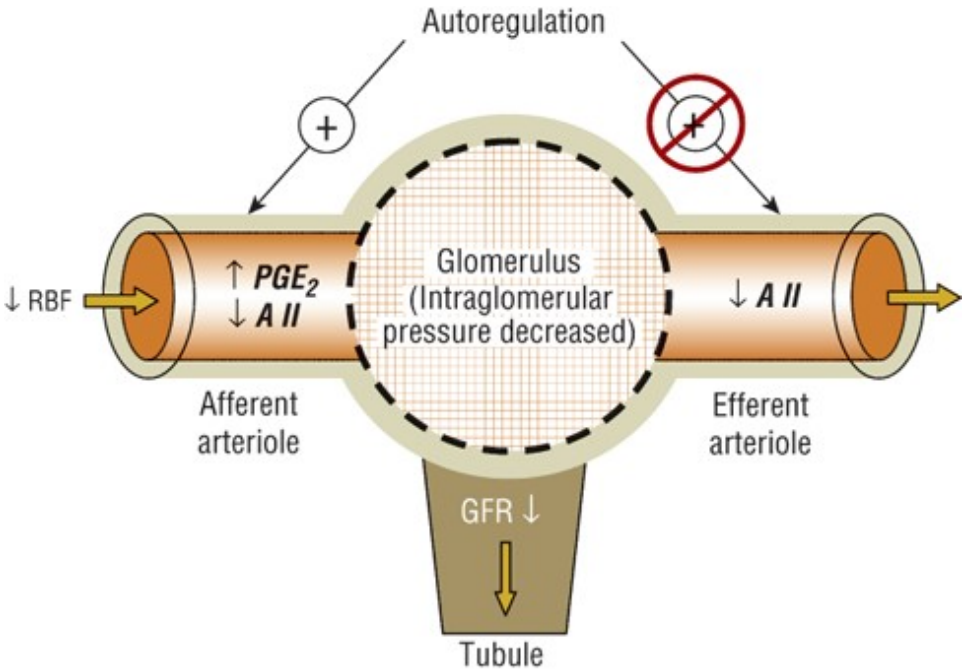
Glomerular autoregulation during “prerenal” states (ie, reduced blood flow). (A II, angiotensin II; GFR, glomerular filtration rate; PGE_2, prostaglandin E_2; RBF, renal blood flow.)



When ACEI therapy (eg, enalapril or ramipril) is initiated, the synthesis of angiotensin II is decreased, thereby preferentially dilating the efferent arteriole. This reduces outflow resistance from the glomerulus and decreases hydrostatic pressure in the glomerular capillaries, which alters Starling forces across the glomerular capillaries to decrease intraglomerular pressure and GFR. This in turn often leads to nephrotoxicity, particularly in the setting of reduced renal blood flow or effective arterial blood volume (**Fig. 46-3**), that is, prerenal settings (eg, congestive heart failure) in which glomerular afferent arteriolar blood flow is reduced and the efferent arteriole is vasoconstricted to maintain sufficient glomerular capillary hydrostatic pressure for ultrafiltration.[23]

FIGURE 46-3

Pathogenesis of angiotensin-converting enzyme inhibitor (ACEI) nephropathy. (A II, angiotensin II; GFR, glomerular filtration rate; PGE_2, prostaglandin E_2; RBF, renal blood flow.)



Risk Factors

Patients at greatest risk are those dependent on angiotensin II and renal efferent arteriolar constriction to maintain blood pressure and GFR. These include patients with bilateral renal artery stenosis or stenosis in a single kidney (ie, renal transplant); patients with decreased effective arterial blood volume (ie, prerenal states), especially those with decompensated congestive heart failure, volume depletion from excess diuresis or GI fluid loss, hepatic cirrhosis with ascites, and nephrotic syndrome; patients with preexisting kidney disease; and patients receiving concurrent nephrotoxic drugs, particularly other drugs that affect intraglomerular autoregulation such as NSAIDs.[23,61,65]

Prevention

Hemodynamically mediated AKI caused by ACEIs or ARBs is frequently preventable by recognizing the presence of preexisting kidney disease or decreased effective renal blood flow as a result of volume depletion, heart failure, or liver disease. A common strategy for at-risk patients is to initiate therapy with very low doses of a short-acting ACEI (eg, captopril 6.25 mg-12.5 mg), then gradually titrate the dose upward and convert to a longer-acting agent after patient tolerance has been demonstrated. Outpatients may be started on low doses of long-acting ACEIs (eg, enalapril 2.5 mg) with gradual dose titration every 2 to 4 weeks until the maximum dose or desired response is achieved.[64] Kidney function indices and serum potassium concentrations must be monitored carefully, daily for hospitalized patients and every 2 to 3 days for outpatients. Monitoring may need to be more frequent during outpatient initiation of ACEI or ARB therapy for patients with preexisting kidney disease, congestive heart failure, or suspected renovascular disease. Use of concurrent hypotensive agents and other drugs that affect renal hemodynamics (eg, NSAIDs, diuretics) should be discouraged and dehydration avoided.[64]

Management

Acute decreases in kidney function and the development of hyperkalemia usually resolve over several days after ACEI or ARB therapy is discontinued. Occasionally patients will require management of severe hyperkalemia, as described in detail in Chapter 51.

Angiotensin-converting enzyme inhibitors or ARB therapy may frequently be reinitiated, particularly for patients with congestive heart failure, after intravascular volume depletion has been corrected or diuretic doses reduced. Slight reductions in kidney function (maintenance of a S_{cr} concentration of 2-3 mg/dL [177-265 µmol/L]) may be an acceptable trade-off for hemodynamic improvement in certain patients with severe congestive heart failure or renovascular disease not amenable to revascularization.

Nonsteroidal Antiinflammatory Drugs and Selective Cyclooxygenase-2 Inhibitors

The overall safety of NSAIDs is evidenced by the nonprescription availability in the United States of several drugs in the class (eg, ibuprofen, naproxen, ketoprofen). Although potential adverse renal effects from nonprescription NSAIDs had been a concern, conventional nonselective NSAIDs and selective cyclooxygenase-2 (COX-2) inhibitors are unlikely to acutely affect kidney function in the absence of renal ischemia or excess renal vasoconstrictor activity. Nevertheless, given their general safety and widespread availability, NSAIDs are among the most commonly used drugs, with approximately 111 million prescriptions worldwide and 30 billion over-the-counter doses of NSAIDs administered annually in the United States.[66]

Incidence

The incidence of NSAID-induced kidney injury is unclear. Historical reports suggest that 500,000 to 2.5 million people develop some degree of NSAID nephrotoxicity in the United States annually.[67]

Clinical Presentation

Nonsteroidal antiinflammatory drug- and COX-2-induced AKI usually occurs within 2 to 7 days of initiating therapy,[59,66] particularly with a short-acting agent such as ibuprofen, or within days of some other precipitating event (eg, intravascular volume depletion). Patients typically present with complaints of diminished urine output, weight gain, and/or edema. Urine sodium concentrations (less than 20 mEq/L [mmol/L]) and fractional excretion of sodium (less than 1% [0.01]) are usually low, and BUN, S_{cr}, potassium, and blood pressure are typically elevated. The urine sediment is usually bland and unchanged from baseline but may show occasional RTECs and granular casts.[59,66]

Pathogenesis

The pathogenesis of NSAID- and COX-2-induced AKI lies in the disruption of normal intraglomerular autoregulation.[59] Specifically, NSAIDs inhibit cyclooxygenase (COX)-catalyzed synthesis of vasodilatory prostaglandins, including prostaglandins I_2 (prostacyclin) and E_2, from arachidonic

acid.[66] These prostaglandins are synthesized in the renal cortex and medulla by vascular endothelial and glomerular mesangial cells, and their effects are primarily local and result in net afferent arteriolar vasodilation. Vasodilatory prostaglandins have limited activity in states of normal renal blood flow, but in states of decreased renal blood flow, their synthesis is increased and they serve a vital autoregulatory role in the protection against renal ischemia and hypoxia by antagonizing renal arteriolar vasoconstriction due to angiotensin II, norepinephrine, endothelin, and vasopressin. Thus, administration of NSAIDs in the setting of reduced renal blood flow will blunt the usual compensatory increase in prostaglandin activity, altering the normal autoregulatory balance in favor of renal vasoconstrictors, thereby promoting renal ischemia and a reduction in glomerular filtration.[66]

Risk Factors

Risk factors for NSAID- and COX-2-induced AKI include age more than 60 years, preexisting kidney disease, hepatic disease with ascites, congestive heart failure, intravascular volume depletion/dehydration, systemic lupus erythematosus, or concurrent treatment with diuretics, ACEIs, or ARBs.[61,65,66] The use of ACEIs, diuretics, and NSAIDs concurrently is associated with a greater than 30% increased risk for AKI, which increases to greater than 60% in patients over age 75 or with preexisting kidney disease.[61,65] The elderly are at higher risk because of multiple comorbidities, multiple-drug therapies, and reduced renal hemodynamics. Combined use of NSAIDs or COX-2 inhibitors and concurrent nephrotoxic drugs, particularly other drugs that affect intraglomerular autoregulation, should be avoided in high-risk patients.

Prevention

Nonsteroidal antiinflammatory drug- and COX-2 inhibitor-induced AKI can be prevented by recognizing high-risk patients, avoiding potent compounds such as indomethacin and using analgesics with less prostaglandin inhibition, such as acetaminophen, nonacetylated salicylates, aspirin, and possibly nabumetone. Nonnarcotic analgesics (eg, tramadol) may also be useful but do not provide antiinflammatory activity. When NSAID therapy is essential for high-risk patients, the minimal effective dose should be used for the shortest duration possible, and NSAIDs with short half-lives should be considered (eg, sulindac) along with optimal management of predisposing medical problems and frequent kidney function monitoring. Moreover, use of concurrent hypotensive agents and other drugs that affect renal hemodynamics (eg, ACEIs, ARBs, diuretics) should be discouraged in high-risk patients and dehydration avoided.[66]

Management

Nonsteroidal antiinflammatory drugs-induced AKI is treated by discontinuation of therapy and supportive care. Use of other nephrotoxic drugs should be avoided. Kidney injury is rarely severe, and kidney function generally recovers within 3 to 5 days.[59] Occasionally, the hemodynamic insult is sufficiently severe to cause ATN, which can prolong injury.

Cyclosporine and Tacrolimus

The calcineurin inhibitors cyclosporine and tacrolimus have dramatically enhanced the success of solid-organ transplantation. As many as 94% of kidney transplant patients are prescribed a calcineurin inhibitor-based immunosuppressive regimen.[68] Nephrotoxicity, however, remains a major dose-limiting adverse effect of both drugs. Although delayed chronic interstitial nephritis has also been reported,[69] acute hemodynamically mediated kidney injury is an important mechanism of calcineurin inhibitor-induced nephrotoxicity.

Incidence

Historically, reversible AKI occurred frequently in transplant recipients during the first 6 months of cyclosporine therapy. The 5-year risk of CKD after transplantation of a nonrenal organ ranges from 7% to 21%, depending on the type of organ transplanted, and the occurrence of CKD in these patients is associated with more than a fourfold increase in the risk of death.[70]

Clinical Presentation

The clinical presentation of acute nephrotoxicity associated with calcineurin inhibitors (ie, hemodynamically mediated AKI) is quite different from the presentation of chronic nephrotoxicity (see Chronic Interstitial Nephritis below).[71] AKI may occur within days of initiating therapy, manifesting as a rise in S_{cr} concentration and a corresponding decline in creatinine clearance. Hypertension, hyperkalemia, sodium retention, oliguria, renal tubular acidosis, and hypomagnesemia are frequently observed in the absence of urine sediment abnormalities or morphologic lesions.[68] On the other hand, renal biopsy may reveal thickening of arterioles, mild focal glomerular sclerosis, proximal tubular epithelial cell vacuolization and atrophy, and interstitial fibrosis. Biopsy is most useful to distinguish acute calcineurin inhibitor nephrotoxicity from acute cellular rejection of the transplanted kidney, the latter being evidenced by interstitial infiltrates composed of activated lymphocytes (see Chapter 90).[72]

Pathogenesis

The acute hemodynamic changes associated with calcineurin inhibitor nephrotoxicity result from an increase in potent vasoconstrictors including thromboxane A_2 and endothelin, activation of the renin–angiotensin and sympathetic nervous systems, as well as a reduction in the vasodilators nitric oxide, prostacyclin, and prostaglandin E_2.[68,70,71] The net effect is an imbalance in afferent and efferent tone, resulting in predominantly afferent vasoconstriction with reduced renal plasma flow and GFR. The mechanism of acute nephrotoxicity is generally thought to be dose related, since kidney function improves rapidly following dose reduction.[71]

Risk Factors

Risk factors include age over 65, higher dose, concomitant therapy with nephrotoxic drugs (particularly NSAIDs), and interacting drugs that inhibit calcineurin inhibitor metabolism and transport and thus increase systemic exposure, older kidney allograft age, salt depletion, diuretic use,

and polymorphic expression of P-glycoprotein.[68,72]

Prevention

Because acute hemodynamically mediated kidney injury secondary to cyclosporine and tacrolimus appears to be concentration related, pharmacokinetic and pharmacodynamic monitoring is an important means of preventing toxicity.[68] However, the persistent presence of therapeutic or low cyclosporine concentrations does not totally preclude the development of nephrotoxicity. Calcium channel blockers may antagonize the vasoconstrictor effect of cyclosporine by dilating glomerular afferent arterioles and preventing acute decreases in renal blood flow and glomerular filtration.[68] Lastly, decreased doses of cyclosporine or tacrolimus, primarily when used in combination with other nonnephrotoxic immunosuppressants, may minimize the risk of toxicity, but this may increase the risk of chronic rejection.

Management

Acute kidney injury usually improves with dose reduction and treatment of contributing illness or the discontinuation of interacting drugs. CKD is usually irreversible, but progressive toxicity may be limited by discontinuation of cyclosporine (or tacrolimus) therapy or dose reduction, with the continuation of other immunosuppressants.[68,71] S_{cr} and BUN should be closely monitored (daily if possible), as should cyclosporine or tacrolimus concentrations, to ensure that serum concentrations are within the narrow therapeutic range.

OBSTRUCTIVE NEPHROPATHY

Numerous medications may cause obstructive nephropathy, or kidney injury from deposition or precipitation within the renal tubules and/or collecting system. For example, the precipitation of drug crystals in distal tubular lumens can lead to intratubular obstruction, interstitial nephritis, and occasionally superimposed ATN, collectively termed crystal nephropathy. Nephrolithiasis, the formation of stones within the kidney, results from abnormal crystal precipitation in the renal collecting system, potentially causing urinary tract obstruction with kidney injury. Several medications that have been associated with development of obstructive nephropathy are listed in **Table 46-1**.

Crystal Nephropathy

Incidence

The incidence of crystal nephropathy is unclear for most of the implicated agents because histologically confirmed cases are rare, and many drugs cause kidney injury via multiple mechanisms.[73] For example, AKI develops in approximately 2% of patients who receive high dose methotrexate, likely due to a combination of direct toxic effects and crystal nephropathy.[74,75] Similarly, crystalluria is observed in 20% of patients receiving indinavir, but the number of patients developing crystal nephropathy is unknown.[76]

Pathogenesis

Drugs may induce intratubular obstruction and AKI by direct (precipitation of the drug itself) and indirect means (ie, promoting release and precipitation of tissue-degradation products or cellular casts). For example, antineoplastic drugs may cause acute renal tubular obstruction indirectly by inducing tumor lysis syndrome, hyperuricemia, and intratubular precipitation of uric acid crystals.[47] The diagnosis is supported by a urine uric acid-to-creatinine ratio greater than 1. Uric acid precipitation can be prevented by vigorous hydration with normal saline, beginning at least 48 hours prior to chemotherapy, to maintain urine output 100 mL/h in adults. Administration of allopurinol 100 mg/m^2 thrice daily (maximum of 800 mg/day) started 2 to 3 days prior to chemotherapy, and urinary alkalinization to pH 7 may also be of value. In patients at high risk of developing tumor lysis syndrome (ie, large tumor burden, pre-exisiting kidney disease, and older age), a single fixed dose of 3 mg rasburicase may be beneficial.[77]

Drug-induced rhabdomyolysis is another form of indirect toxicity, which can lead to intratubular precipitation of myoglobin and, if severe, AKI.[78] The most common cause of drug-induced rhabdomyolysis is direct myotoxicity from 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors or statins, including lovastatin and simvastatin.[79] The risk of rhabdomyolysis is increased when these drugs are administered concurrently with gemfibrozil, niacin, or inhibitors of the CYP3A4 metabolic pathway (eg, erythromycin and itraconazole).

Warfarin-related nephropathy (WRN) is characterized by glomerular hemorrhage with subsequent intratubular obstruction by red blood cell casts. Patients with underlying CKD appear to be at greatest risk. The incidence of WRN may be as high as 33% in CKD versus 16.5% in non-CKD patients. Other risk factors included age, diabetes mellitus, hypertension, and cardiovascular disease.[80]

Intratubular precipitation of drugs or their metabolites can also directly cause AKI. Precipitation of drug crystals is due primarily to supersaturation of a low urine volume with the offending drug or relative insolubility of the drug in either alkaline or acidic urine.[76] Volume depletion is an important risk factor for the development of AKI. Urine pH decreases to approximately 4.5 during maximal stimulation of renal tubular hydrogen ion secretion. Certain solutes can precipitate and obstruct the tubular lumen at this acid pH, particularly when urine is concentrated, such as for patients with volume depletion. For example, several antiviral drugs have been associated with intratubular precipitation and AKI.[81,82] Acyclovir is relatively insoluble at physiologic urine pH and is associated with intratubular precipitation in dehydrated oliguric patients.[76] Foscarnet complexation with ionized calcium may result in precipitation of calcium-foscarnet salt crystals in renal glomeruli, causing primarily a crystalline glomerulonephritis. The salt crystals may then secondarily precipitate in the renal tubules causing tubular necrosis.[23] The protease inhibitor indinavir has been associated with symptomatic crystalluria or nephrolithiasis in 20% to 33% of patients receiving chronic treatment.[76,82] Intratubular indinavir crystal precipitation can be prevented in most patients if the patient consumes adequate hydration to obtain a urinary output of at least 1,500 mL per day.[81] Sulfadiazine, when used at high doses, and methotrexate may also precipitate in acidic urine and can cause oligoanuric kidney injury.[76] Massive administration of ascorbic acid can also result in obstruction of renal tubules with

calcium oxalate crystals, leading to "oxalate nephropathy".[76] Triamterene and the quinolone antibiotic ciprofloxacin may also precipitate in renal tubules and cause kidney injury.[23,73]

Kidney injury caused by intratubular precipitation of most tissue-degradation products or drugs and their metabolites can be largely prevented and possibly treated by administering the drug after vigorously prehydrating the patient, maintaining a high urine volume, and urinary alkalinization.[81,82]

NEPHROCALCINOSIS

Nephrocalcinosis is a clinical pathologic condition characterized by extensive tubulointerstitial precipitation and deposition of calcium phosphate crystals leading to marked tubular calcification.[83] It is most commonly seen in clinical conditions associated with hypercalcemia and hypercalciuria, such as hyperparathyroidism, malignancy, and less frequently increased intake of calcium or vitamin D. However, nephrocalcinosis can also result from hyperphosphatemia and hyperphosphaturia in the absence of hypercalcemia, as is known to occur for patients who have received oral sodium phosphate solution (OSPS) as a bowel preparation.[84]

Acute Phosphate Nephropathy

The term acute phosphate nephropathy was coined specifically to describe OSPS-induced nephrocalcinosis, as its pathogenesis is the result of increased phosphate intake rather than hypercalcemia.[84] Nephrocalcinosis is associated with use of OSPS for bowel preparation prior to GI procedures, and strong associations have recently been demonstrated between exposure to OSPS and a decline in kidney function, particularly in the elderly and those with preexisting kidney disease.[84,85]

Incidence

The incidence of acute phosphate nephropathy is between 1 in 1,000 and 1 in 5,000 exposures, translating to roughly 1,400 to 7,000 new cases annually.[86]

Clinical Presentation

Patients usually present with AKI several days to months after exposure to OSPS. Low-grade proteinuria (less than 1 g/day), normocalcemia, and bland urinary sediment are usually observed. Extensive deposition of calcium phosphate in the distal tubules and collecting ducts without glomerular or vascular injury is the hallmark of acute phosphate nephropathy.[76]

Risk Factors

Risk factors include advanced age, preexisting kidney disease, female sex, hypertension, diabetes, bowel conditions associated with prolonged intestinal transit, high sodium phosphate dosage, volume depletion, and medications that affect renal perfusion or function (eg, diuretics, lithium,

NSAIDs, ACEIs, or ARBs).[84]

NEPHROLITHIASIS

Nephrolithiasis (formation of renal calculi or kidney stones) does not present as classic nephrotoxicity since GFR is usually not decreased. Drug-induced nephrolithiasis can be the result of abnormal crystal precipitation in the renal collecting system, potentially causing pain, hematuria, infection, or, occasionally, urinary tract obstruction with kidney injury. The overall prevalence of drug-induced nephrolithiasis is estimated to be 1% to 2% of all cases of nephrolithiasis.[82]

Kidney stone formation, possibly also accompanied by intratubular precipitation of crystalline material, has been a rare complication of drug therapy. Until the development of antiretroviral drugs, triamterene had been the drug most frequently associated with kidney stone formation, with a prevalence of 0.4%.[73] Sulfadiazine is a poorly soluble sulfonamide that may cause symptomatic acetylsulfadiazine crystalluria with stone formation and flank or back pain, hematuria, or kidney injury.[76] A high urine volume and urinary alkalinization to pH greater than 7.15 may be protective. Numerous other drugs have been implicated in the development of nephrolithiasis, including the antibacterial agents ciprofloxacin, amoxicillin, and nitrofurantoin, and various products containing ephedrine, norephedrine, pseudoephedrine, and melamine. Moreover, nephrolithiasis has become a well known complication of antiretroviral agents, including the protease inhibitors indinavir, atazanavir, nelfinavir, amprenavir, saquinavir, ritonavir and darunavir.[82]

GLOMERULAR DISEASE

Proteinuria, particularly nephrotic range proteinuria (defined as urine protein excretion greater than 3.5 g/day/1.73 m^2) with or without a decline in the GFR is a hallmark sign of glomerular injury (see Chapter 47). Glomerular injury associated with drug exposure is broadly classified into either direct cellular toxicity or immune mediated injury. Glomerular lesions associated with direct cellular toxicity include thrombotic microangiopathy (see Renal Vaculitis section), minimal change glomerular disease, and focal segmental glomerulosclerosis (FSGS). Lesions from immune-mediated injury include vasculitis (see Renal Vaculitis section) and membranous nephropathy.[87,88] Although drug-induced glomerular disease is uncommon, a variety of agents have been implicated.

Minimal Change Glomerular Disease

Drug-induced minimal change glomerular disease is frequently accompanied by interstitial nephritis and is most common during NSAID therapy. Lithium, pamidronate, interferon-α and interferon-β have also been implicated.[87] Patients present abruptly with nephrotic range proteinuria, hypoalbuminemia, and hyperlipidemia and rarely with hematuria and hypertension. The pathogenesis is unknown, but nephrotic range proteinuria as a consequence of NSAID therapy is frequently associated with a T-lymphocytic interstitial infiltrate, suggesting disordered cell-mediated immunity.[66] Proteinuria usually resolves rapidly after discontinuation of the offending drug, and a

course of corticosteroids may help resolve the lesion. That said, the majority of adults with NSAID induced minimal change glomerular disease achieve complete remission over the course of several months, even in the absence of corticosteroid treatment.[87]

Focal Segmental Glomerulosclerosis

Focal segmental glomerulosclerosis is characterized by patchy areas (ie, only some glomeruli are partially affected by the disease) of glomerular sclerosis with interstitial inflammation and fibrosis (see Chapter 47). It represents a pattern of glomerular injury, not a disease per se, and is the final common pathway by which normal glomerular components are replaced by fibrous scar tissue. FSGS has been described in the setting of chronic heroin abuse (known as *heroin nephropathy*).[89] The pathogenesis is unknown but may include direct toxicity by heroin or adulterants and injury from bacterial or viral infections accompanying IV drug use. The bisphosphonates pamidronate and zoledronate, commonly used to treat osteoporosis, malignancy-associated hypercalcemia, and Paget's disease, are associated with the development of a particularly aggressive variant of FSGS called *collapsing glomerulopathy*.[87] It presents with massive proteinuria (greater than 8 g/day), and it is typically characterized by rising S_{cr} at diagnosis and rapid progression to ESRD. Patients receiving IV formulations, high doses, or prolonged therapy are at highest risk. Interferon-α, interferon-β, lithium, sirolimus, and anabolic steroids have also been associated with FSGS.

Membranous Nephropathy

Membranous nephropathy is the most common etiology of nephrotic syndrome in Caucasian adults.[88] It is characterized by subepithelial immune complex formation along glomerular capillary loops and, although rarely seen, has classically been associated with gold therapy, penicillamine, captopril, and NSAID use.[88] Patients present with nephrotic range proteinuria and microscopic hematuria, with hypertension and elevated S_{cr} apparent for patients with more advanced disease. The pathogenesis may involve damage to proximal tubule epithelium with antigen release, antibody formation, and glomerular immune complex deposition.[88] Proteinuria usually resolves slowly after discontinuing the offending drug. Patients who remain nephrotic after 6 months should be treated with a 6- to 12-month course of immunosuppressive therapy, which typically consists of prednisone with or without cyclophosphamide.

TUBULOINTERSTITIAL NEPHRITIS

Tubulointerstitial nephritis refers to diseases in which the predominant changes occur in the renal interstitium rather than the tubules. The presentation may be acute and reversible with interstitial edema, rapid loss of kidney function, and systemic symptoms or chronic and irreversible, associated with interstitial fibrosis and minimal to no systemic symptoms.[90]

Acute Allergic Interstitial Nephritis

Incidence

5 The incidence of drug-induced acute allergic interstitial nephritis (AIN) is unclear and likely varies with clinical setting. For example, pathology registries indicate AIN as the histologic lesion in only 2% to 5% of kidney biopsies, but from 10% to 27% of kidney biopsies performed in hospitalized patients with unexplained AKI demonstrate AIN.[59] Multiple drugs have been implicated in the development of AIN (**Table 46-4**). It usually manifests 2 weeks after exposure to a drug but may occur sooner if the patient was previously sensitized.[91]

TABLE 46-4 Drugs Associated with Allergic Interstitial Nephritis

Antimicrobials	
Acyclovir	Indinavir
Aminoglycosides	Rifampin
Amphotericin B	Sulfonamides
β-Lactams	Tetracyclines
Erythromycin	Trimethoprim–sulfamethoxazole
Ethambutol	Vancomycin
Diuretics	
Acetazolamide	Loop diuretics
Amiloride	Triamterene
Chlorthalidone	Thiazide diuretics
Neuropsychiatric	
Carbamazepine	Phenytoin
Lithium	Valproic acid
Phenobarbital	
Nonsteroidal antiinflammatory drugs	
Aspirin	Ketoprofen
Indomethacin	Phenylbutazone
Naproxen	Diclofenac
Ibuprofen	Zomepirac
Diflunisal	Cyclooxygenase-2 inhibitors
Piroxicam	
Miscellaneous	
Acetaminophen	Lansoprazole
Allopurinol	Methyldopa
Interferon-α	Omeprazole
Aspirin	*P*-aminosalicylic acid
Azathioprine	Phenylpropanolamine
Captopril	Propylthiouracil
Cimetidine	Radiographic contrast media

Clofibrate	Ranitidine
Cyclosporine	Sulfinpyrazone
Glyburide	Warfarin sodium
Gold	

Clinical Presentation

Although methicillin-induced AIN is the prototype for AIN, it is now recognized that AIN is associated with all β-lactam antibiotics (including cephalosporins) and numerous other antimicrobials. Clinical signs present approximately 14 days after initiation of therapy and include (with their approximate incidence) fever (27%-80%), maculopapular rash (15%-25%), eosinophilia (23%-80%), arthralgia (45%), and oliguria (50%).[91] Historically, systemic hypersensitivity findings of the classic triad of fever, rash, and arthralgia, often along with eosinophilia and eosinophiluria, were strongly suggestive of the diagnosis of AIN. However, it is now recognized that this constellation of findings is not consistently reliable as one or more are frequently absent. In fact, the triad is seen in only 5% to 10% of patients with AIN, so caution is warranted in basing diagnosis on hypersensitivity findings alone.[92] Eosinophilia alone is insensitive, and eosinophiluria is insensitive and nonspecific, so urinary eosinophils are not considered a useful sign of AIN and are no longer recommended as a diagnostic test.[92] Anemia, leukocytosis, and elevated immunoglobulin E levels may occur. Tubular dysfunction may be manifested by acidosis, hyperkalemia, salt wasting, and concentrating defects.[91]

Nonsteroidal antiinflammatory drugs-induced AIN has a different clinical presentation than that seen with most other drugs.[91] Patients are typically over 50 years of age (reflecting NSAID use for degenerative joint disease), the onset is delayed a mean of 6 months from initiation of therapy compared with 2 weeks with β-lactams, and fever, rash, and eosinophilia are typically not observed in patients with NSAID-induced AIN.[91] Concomitant nephrotic syndrome (proteinuria greater than 3.5 g/day) occurs in more than 70% of patients. Prompt diagnosis of AIN is important as discontinuation of the offending drug may prevent irreversible renal damage. Renal biopsy is the most definitive method for diagnosis.

Pathogenesis

The pathogenesis of the majority of cases of AIN is considered to be an allergic hypersensitivity response. This is supported by the fact that AIN is characterized as a diffuse or focal interstitial infiltrate of lymphocytes, eosinophils, and occasional polymorphonuclear neutrophils.[90] Granulomas and tubular epithelial cell necrosis are relatively common with drug-induced AIN. Occasionally a humoral antibody-mediated mechanism is implicated by the presence of circulating antibody to a drug hapten–tubular basement membrane complex, low serum complement levels, and deposition of immunoglobulin G and complement in the tubular basement membrane. More commonly, a cell-mediated immune mechanism is suggested by the absence of these findings and the presence of a predominantly T-lymphocyte.[90]

Risk Factors

No specific risk factors have been identified because these are idiosyncratic hypersensitivity reactions. Individuals with other drug allergies may have increased risk and warrant close monitoring.

Prevention

No specific preventive measures are known because of the idiosyncratic nature of these reactions. Patients must be monitored carefully to recognize the signs and symptoms because promptly discontinuing the offending drug often leads to full recovery.[91]

Management

Corticosteroid therapy is beneficial and should be initiated immediately or soon after diagnosis of AIN along with discontinuance of the offending drug to avoid the risk of incomplete recovery of kidney function. While various regimens have been used, high-dose oral prednisone 1 mg/kg/day for 4 to 6 weeks with a stepwise taper over the next 4 weeks may be considered. However, if there is no significant improvement in kidney function after 3 to 4 weeks of treatment, then steroids should be discontinued.[90] Typical kidney function indices (eg, S_{cr}, BUN) and signs and symptoms of AIN should be monitored closely for improvement.

Chronic Interstitial Nephritis

Lithium, analgesics, calcineurin inhibitors, aristolochic acid, and only a few other drugs have been reported to cause chronic interstitial nephritis, which is usually a progressive and irreversible lesion.

Lithium

Incidence

The prevalence of non-dialysis-dependent CKD stemming from chronic lithium nephrotoxicity in the general population of patients treated with lithium is approximately 1%.[93,94] The prevalence of lithium-induced ESRD among all ESRD patients is between 0.2% and 0.8%.[93] Although several renal tubular lesions are associated with lithium therapy, an impaired ability to concentrate urine (nephrogenic diabetes insipidus) is seen in 20% of all patients receiving lithium therapy.[95]

Clinical Presentation

Lithium-induced nephrotoxicity is typically asymptomatic and develops insidiously during years of therapy. Blood pressure is normal and urinary sediment is bland, making detection difficult until the disease progresses significantly.[96] It is usually recognized by rising BUN or S_{cr} concentrations or the onset of hypertension. Polydipsia (excessive thirst) and polyuria (excessive urination) are observed in 40% and 20%, respectively, of patients with nephrogenic diabetes insipidus (see Chapter 49). Although interstitial fibrosis may be observed as early as 5 years after beginning therapy, lithium-induced CKD usually occurs after 10 to 20 years of lithium treatment.[96]

Pathogenesis

The precise mechanism of chronic lithium-induced nephrotoxicity is not well characterized. Impaired ability to concentrate urine is a result of a decrease in collecting duct response to antidiuretic hormone, which may be related to downregulation of aquaporin 2 water channel expression during lithium therapy.[96] Chronic tubulointerstitial nephritis attributed to lithium is evidenced most commonly by biopsy findings of interstitial fibrosis, tubular atrophy, and glomerular sclerosis. The pathogenesis may involve cumulative direct lithium toxicity since duration of therapy correlates with the decline in the GFR.[96]

Risk Factors

Historically, the duration of lithium therapy and cumulative dose was considered the major determinants of chronic nephrotoxicity. However, this is now questionable, with some suggesting that long-term lithium therapy in the absence of episodes of acute intoxication is not nephrotoxic.[97] Increased age may also be a risk factor, but daily dose is not.[94,96]

Clinical Controversy…

Some clinicians believe that long-term lithium therapy is associated with nephrotoxicity even in the absence of acute episodes of intoxication. Others believe that duration of therapy is not an independent predictor of kidney injury.

Prevention

Prevention of acute and chronic toxicity includes maintaining lithium concentrations as low as therapeutically possible, avoiding dehydration, and monitoring kidney function. It is unknown whether progression to CKD can be prevented by stopping lithium use when mild kidney injury is first recognized. This poses a dilemma as lithium is highly effective for affective disorders and the risks and potential benefits of discontinuing such a beneficial drug need to be carefully considered.[96] However, if lithium therapy is continued, kidney function must be monitored and therapy discontinued if it continues to decline. Amiloride has been used for prevention and treatment of lithium-induced nephrogenic diabetes insipidus, since it blocks epithelial sodium transport of lithium into the cortical collecting duct in the distal nephron.[96]

Management

Symptomatic polyuria and polydipsia can be reversed by discontinuation of lithium therapy or ameliorated with amiloride 5 to 10 mg daily during continued lithium therapy (see Chapter 49). If polyuria does not resolve within 7 to 10 days of therapy, then the amiloride dose should be increased to 20 mg daily. Progressive chronic interstitial nephritis is treated by discontinuation of lithium therapy, adequate hydration, and avoidance of other nephrotoxic agents. Lithium serum concentrations, as well as kidney function indices, including urine output, BUN, and S_{cr}, should be monitored closely for resolution of signs and symptoms of toxicity.[96]

Cyclosporine and Tacrolimus

Delayed chronic tubulointerstitial nephritis, considered the Achilles' heel of calcineurin inhibitor-based immunosuppressive regimens, has been reported after several months of therapy and can result in irreversible kidney disease.[68,69] Toxicity is progressive and usually manifests as a slowly rising S_{cr} concentration and decreased creatinine clearance that may not reflect the severity of histopathologic changes. All three compartments of the kidney can be affected, evidenced by typical biopsy findings that include arteriolar hyalinosis, glomerular sclerosis, and a striped pattern of tubulointerstitial fibrosis.[69] The pathogenesis appears to involve sustained renal arteriolar endothelial cell injury and increased extracellular matrix synthesis, which ultimately result in chronic ischemia of the tubulointerstitial compartment because of increased release of endothelin-1, decreased production of nitric acid, and upregulation of transforming growth factor-β. Unlike acute nephrotoxicity, chronic toxicity is not dose dependent.[68,69]

Aristolochic Acid

Incidence

Although the true incidence of aristolochic acid nephropathy is unknown, approximately 3% to 5% of patients who consume the natural product develop interstitial fibrosis with tubular atrophy.[98]

Clinical Presentation

Patients with aristolochic acid nephropathy typically present with mild-to-moderate hypertension, mild proteinuria, glucosuria, and moderately elevated S_{cr} concentrations. Anemia and shrunken kidneys are also common on initial presentation.[99] The overwhelming majority of cases reported to date have been in women. The main pathologic lesions observed in the kidneys are interstitial fibrosis with atrophy and destruction of proximal tubules throughout the renal cortex; in general, the glomeruli are not affected. Perhaps the most remarkable feature of aristolochic acid nephropathy is the rate at which it progresses. In most individuals, ESRD requiring dialysis or transplantation develops within 6 to 24 months of exposure. An alarming high prevalence (approximately 40%-45%) of urothelial transitional cell carcinoma has been observed in Belgian patients who underwent renal transplantation.[98,99]

Pathogenesis

Although the precise mechanism of aristolochic acid nephropathy and urothelial carcinoma has yet to be characterized. The major components of aristolochic acid are metabolized to mutagenic compounds called *aristolactam I* and *aristolactam II*, respectively, which have been demonstrated to form aristolochic acid–DNA adducts in humans. Recent data indicate that these adducts cause direct DNA damage and may lead to proximal tubular atrophy and apoptosis.[99]

Prevention

The primary means of preventing aristolochic acid nephropathy appears to be the limitation of exposure to compounds containing aristolochic acids. Several countries, including the United States, United Kingdom, Canada, Australia, and Germany, have banned the use of *Aristolochia*-containing herbs.[99]

Papillary Necrosis

Papillary necrosis is a form of chronic tubulointerstitial nephritis characterized by necrosis of the renal papillae, the regions of the kidney where the collecting ducts enter the renal pelvis, which leads to progressive kidney disease. Papillary necrosis is associated with diabetes, sickle cell disease, obstruction and infection of the urinary tract, and most commonly analgesic use.[100]

Analgesic Nephropathy

Incidence

Prototypical analgesic nephropathy is characterized by chronic tubulointerstitial nephritis with papillary necrosis.[100] Chronic excessive consumption of combination analgesics, particularly those containing phenacetin, was believed to be the major cause and led to the removal of phenacetin and phenacetin mixtures from most world markets. However, contemporary analgesics, particularly aspirin, acetaminophen, and NSAIDs, alone or in combination, are also associated with the development of analgesic nephropathy. The incidence of analgesic nephropathy has declined significantly since removal of phenacetin from many countries, with the prevalence estimated to now be less than 5% in the United States adult ESRD population.[100]

Clinical Presentation

Analgesic nephropathy is a progressive disease that evolves slowly over several years.[100] It is difficult to recognize in the early stages of the disease because patients are often asymptomatic, and it may be underdiagnosed as a cause of ESRD. It is seen more commonly in women than men. Early manifestations are generally nonspecific and may include headache and upper GI symptoms; later manifestations include impaired urinary concentrating ability, dysuria, sterile pyuria, microscopic hematuria, mild proteinuria (less than 1.5 g/day), and lower back pain. As disease progresses, hypertension, atherosclerotic cardiovascular disease, renal calculi, and bladder stones are common, and pyelonephritis is a classic finding in advanced analgesic nephropathy. The most sensitive and specific diagnostic criteria include (a) a history of chronic daily habitual analgesic ingestion (daily use for at least 3-5 years); (b) IV pyelography, renal ultrasound, or renal computed tomography imaging, which reveals decreased renal mass and bumpy renal contours; (3) elevated S_{cr}, that is, up to 4 mg/dL (354 µmol/L); and (4) papillary calcifications.[100]

Pathogenesis

Analgesic nephropathy originates in the papillary tip as a result of accumulated toxins, drugs and

metabolites, decreased blood flow, and impaired cellular energy production. The metabolism of phenacetin to acetaminophen, which is then oxidized to toxic free radicals that are concentrated in the papilla, appears to be the initiating factor that causes toxicity by mechanisms analogous to acetaminophen hepatotoxicity via glutathione depletion.[101] Cortical interstitial nephritis develops secondary to papillary necrosis. Salicylates potentiate these effects by also depleting renal glutathione, and inhibiting prostaglandin-mediated vasodilation, thus further predisposing the renal medulla to ischemic injury.[101]

Risk Factors

The epidemiology of analgesic use and analgesic nephropathy continues to evolve. The classic concept persists that risk for ESRD increases with cumulative consumption of combination analgesics, phenacetin, or acetaminophen and aspirin or NSAIDs. Caffeine contained in combination analgesics may increase risk, but the role is not clear.[100] Chronic use of therapeutic doses of NSAIDs or high-dose acetaminophen, but not aspirin or salicylates alone, can cause analgesic nephropathy.

Prevention

Prevention has depended primarily on public health efforts to restrict the sale of phenacetin and combination analgesics. However, risk continues with ongoing availability of nonprescription combination analgesics containing aspirin, acetaminophen, and caffeine in the United States and throughout the world.

Individuals requiring chronic analgesic therapy may reduce risk by limiting the total dose, avoiding combined use of two or more analgesics, and maintaining good hydration to prevent renal ischemia and decrease the papillary concentration of toxic substances. Acetaminophen remains the preferred nonopiate analgesic for patients with preexisting kidney disease.

Management

Treatment of established nephrotoxicity requires cessation of analgesic consumption.[101] This can prevent progression and may improve kidney function. Kidney function indices, including urine output, BUN, and S_{cr}, should be monitored every several months. Patients should also be monitored for the development of transitional cell carcinoma of the renal pelvis, calyces, ureters, and bladder, which may present years after analgesic nephropathy is diagnosed.

RENAL VASCULITIS, THROMBOSIS, AND CHOLESTEROL EMBOLI

Renal Vasculitis

Drug-induced renal vascular disease commonly presents as vasculitis, thrombotic microangiopathy, or cholesterol emboli.[88,102] Vasculitis implies inflammation of the vessel wall, capillaries, or glomeruli

and is typically classified according to vessel size (ie, small, medium, or large vessel vasculitis). Small vessel vasculitides usually affect multiple organ systems, including the kidneys and lungs, and are associated with nonspecific inflammatory symptoms such as fever, malaise, myalgias, arthralgias, and weight loss. Numerous drugs are associated with the development of renal vasculitis, including hydralazine, propylthiouracil, allopurinol, phenytoin, sulfasalazine, penicillamine, and minocycline (see Table 46-1).[88,102] Most drug-induced cases of vasculitis, including hydralazine, propylthiouracil, allopurinol, penicillamine, and the anti-TNF-α drug adalimumab have been implicated in the development of antineutrophil cytoplasmic antibody (ANCA)-positive vasculitis.[88,102,103] Patients present with hematuria, proteinuria, oliguria, and red cell casts, frequently along with fever, malaise, myalgias, and arthralgias.[102] Treatment typically consists of withdrawing the offending drug and administration of corticosteroids or other immunosuppressive therapy, and usually leads to resolution of symptoms within weeks to months.

Thrombotic Microangiopathy

Thrombotic microangiopathy is characterized clinically by microangiopathic hemolytic anemia, fragmented red cells, and thrombocytopenia and pathologically by vascular endothelial proliferation, endothelial cell swelling, and intraluminal platelet thrombi in the small vessels, particularly affecting the renal and cerebral capillaries and arterioles.[87,104] The absence of inflammation in vessel walls distinguishes thrombotic microangiopathy from vasculitis. Numerous medications, including oral contraceptive agents, cyclosporine, tacrolimus, muromonab-CD3, many cancer chemotherapeutic agents including antiangiogenesis drugs (eg, bevacizumab, sunitinib, and sorafenib), mitomycin C, cisplatin, and gemcitabine, interferon-α, ticlopidine, clopidogrel, quinine, and several antimicrobial agents (eg, valacyclovir, penicillins, rifampin, and metronidazole) are associated with the development of thrombotic microangiopathy.[87,104] Patients may present with fever, neurological dysfunction, elevated S_{cr} and BUN, and hypertension, along with microangiopathic hemolytic anemia and thrombocytopenia. Kidney injury can be severe and irreversible, although corticosteroids, antiplatelet agents, plasma exchange, plasmapheresis, and high-dose IV immunoglobulin G have each induced clinical improvement.[104]

Cholesterol Emboli

Anticoagulants (particularly warfarin) and thrombolytics (eg, urokinase, streptokinase, and tissue-plasminogen activator) are associated with cholesterol embolization of the kidney.[105] These drugs act to remove or prevent thrombus formation over ulcerative plaques or may induce hemorrhage within clots, thereby causing showers of cholesterol crystals that lodge in small diameter arteries of the kidney (renal arterioles and glomerular capillaries). Cholesterol crystal emboli induce an endothelial inflammatory response, which leads to complete obstruction, ischemia, and necrosis of affected vessels within weeks to months after initiation of therapy.[105] Purple discoloration of the toes and mottled skin over the legs are important clinical clues. Treatment is supportive in nature, since kidney injury is generally irreversible.

PHARMACOECONOMICS

The pharmacoeconomic implications of DIKD are enormous. In general, an episode of AKI leads to higher hospital resource use, with increases in the median direct hospital cost of $2,600 and the hospital length of stay by 5 days.[106] An increase in S_{cr} of greater than or equal to 0.5 mg/dL (greater than or equal to 44 µmol/L) is independently associated with a 6.5-fold increase in the odds of death, a 3.5-day increase in length of hospital stay, and nearly $7,500 in excess hospital costs even after adjusting for age, sex, and measures of comorbidity.[107] Amphotericin B-induced AKI leads to a mean increased length of hospital stay of 8.2 days and adjusted additional costs of $29,823 per patient.[108] The major driver of the increased costs associated with contrast-induced AKI was the cost of the longer initial hospital stay. The increased availability of automated clinical decision support systems and computer-guided medication dosing for hospital inpatients may improve the safety of potentially harmful drugs and minimize the occurrence of nephrotoxicity in this setting, thereby potentially lowering the corresponding economic consequences.[108]

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ACEI	angiotensin-converting enzyme inhibitor
AIN	allergic interstitial nephritis
AKI	acute kidney injury
ARB	angiotensin II receptor blocker
ATN	acute tubular necrosis
BUN	blood urea nitrogen

Chapter 47: Glomerulonephritis

Alan H. Lau

INTRODUCTION

KEY CONCEPTS

- 1 Glomerulonephritis is a collection of glomerular diseases mediated by different immunologic pathogenic mechanisms, resulting in varied clinical presentation and therapeutic outcomes.
- 2 The signs and symptoms associated with glomerulonephritis are commonly nephrotic in nature and characterized by proteinuria. At times, there may be nephritic features, characterized by inflammatory injury.
- 3 Supportive treatments for edema, hypertension, hyperlipidemia, and intravascular thrombosis are important in reducing the complications associated with glomerulonephritis. These are especially important since specific and effective therapy for many types of glomerulonephritis are not available. Reduction of proteinuria can often improve long-term kidney and patient outcomes.
- 4 To maximize therapeutic benefits and minimize drug-induced complications, patients have to be monitored closely to assess their therapeutic responses as well as the development of any treatment-induced toxicities.
- 5 Among all the types of glomerulonephritis, minimal-change nephropathy is most responsive to treatment. Steroids can induce good responses in most patients during initial treatment as well as relapse.
- 6 Because of the lack of consistently effective treatment for primary focal segmental glomerular sclerosis, angiotensin-converting enzyme inhibitors or angiotensin receptor blockers are commonly used for patients with mild disease to control symptoms. Steroids and immunosuppressive agents are reserved for the management of patients with severe disease.
- 7 The optimal treatment for lupus nephritis depends on the underlying lesion and disease

activity, as well as the severity and duration of the patient's condition.

- 8 The treatment of poststreptococcal glomerulonephritis is mainly supportive and symptomatic. Antibiotic therapy does not prevent subsequent disease development but may reduce the severity.

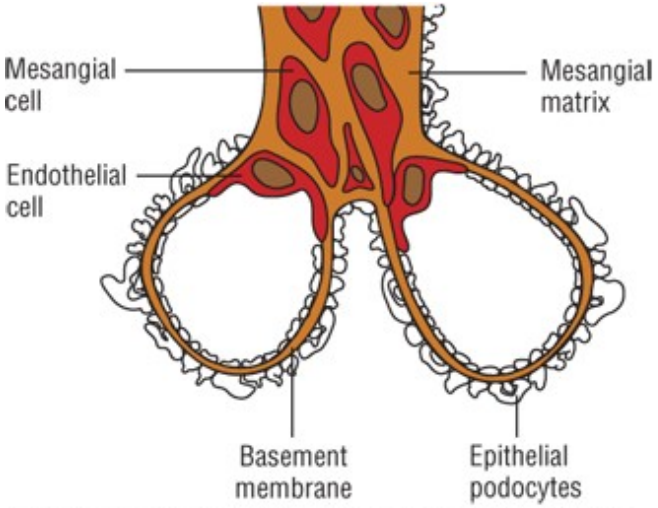
The precise pathogenetic mechanisms of many glomerular diseases remain unknown and the available therapeutic regimens are still far from optimal. This chapter provides an overview of the primary causes of glomerulonephritis with a focus on their etiology, the pathophysiologic mechanisms responsible for glomerular injury, and the clinical presentation of the eight predominant types of glomerulonephritis. Treatment options and monitoring approaches for each type of glomerulonephritis are also discussed. Diabetes mellitus is an important secondary cause of glomerular injury and a thorough discussion of the pathophysiology and management of this condition can be found in Chapter 74.

NORMAL GLOMERULAR ANATOMY AND FUNCTION

The glomerulus, which is enclosed within the Bowman's capsule, consists of two important components: the capillary wall and the mesangium (**Fig. 47-1**). The capillary wall, which serves as the primary filtration barrier, consists of three well-defined layers: fenestrated endothelium, glomerular basement membrane (GBM), and epithelial cell layer. The epithelial cells, also known as podocytes, have specialized foot processes embedded in the outer layer of the GBM. It is across this barrier that plasma water flows and ultimately becomes the ultrafiltrate. Under normal conditions, the GBM functions as a compact hydrated gel of matrix proteins with a pore-like structure. The mesangium, which consists of mesangial cells embedded in an extracellular matrix, provides support for the glomerular capillaries and also modulates blood flow through the capillaries.

FIGURE 47-1

Microanatomy of the glomerulus.



The unique capillary bed of the glomerulus allows small nonprotein plasma constituents up to the size of inulin, which has a molecular weight of 5.2 kDa, to pass freely while excluding macromolecules equal to or larger than albumin, which has a molecular weight of 69 kDa. The ease of solute passage through the glomerular membrane is impacted by both the size and charge of the solute. Fixed, negatively charged sites are found within all three layers of the glomerular capillary wall: the endothelium, the epithelium, and the GBM. The movement of negatively charged molecules is thus restricted more than that of neutral or positively charged molecules. Different glomerular diseases affect this size- and charge-selective barrier to different extents; consequently, glomerulopathies present with varied clinical features and solute-excretion patterns.

Some of the glomerular cells, such as the epithelial cells, have phagocytic function that can remove macromolecules trapped within the filtration barrier. They are also capable of synthesizing the GBM. In contrast, the mesangial cells regulate glomerular hemodynamics in response to angiotensin II and by producing prostaglandins. These cells also synthesize and respond to various cytokines and thus play a key role in immune-mediated glomerular diseases. Resident phagocytes in the mesangium are responsible for moving macromolecules trapped in the basement membrane into the urinary space. They are also involved in the development of both immune and nonimmune glomerular injury.

EPIDEMIOLOGY AND ETIOLOGY

In the United States in 2012, glomerulonephritis was the third most common cause of end-stage renal disease (ESRD), accounting for approximately 16% of all the living ESRD patients. About 9,100 patients (7.9% of all patients) develop stage 5 chronic kidney disease, which is also called ESRD, because of glomerulonephritis each year.[1] The life span of ESRD patients with glomerulonephritis is typically longer than those with other causes, such as diabetes and hypertension.

Humoral and cellular immunologic mechanisms participate in the pathogenesis of most glomerulonephritis. Abnormalities in coagulation and metabolism, as well as hereditary and vascular diseases, also contribute to glomerular damage. The histopathologic manifestations vary substantially

among the different types of glomerulonephritis. An overview of the primary pathogenetic mechanisms is presented in this section, and specific abnormalities for each of the primary types of glomerulonephritis are presented in subsequent sections.

PATHOPHYSIOLOGY

1 The glomerular lesion may be diffuse (involving all glomeruli), focal (involving some but not all glomeruli), or segmental, also known as local (involving part of the individual glomerulus). The pathologic manifestations may also be described as proliferative (overgrowth of epithelium, endothelium, or mesangium), membranous (thickening of GBM), and/or sclerotic.

The glomerular capillary wall is particularly susceptible to immune-mediated injury. Antigens and antibodies tend to localize in the glomerulus, probably because of its high blood flow and capillary hydrostatic pressure. Parenchymal damage can be induced as a result of humoral- and cell-mediated immune reactions. Antibodies and sensitized T lymphocytes are the primary mediators of glomerular injury.[2,3] There is an increasing body of evidence to show that infections initiate most forms of glomerulonephritis through different simultaneous and/or sequential pathways that begin with the activation of innate immune response to result in autoimmunity.[4]

Production of antibodies to endogenous or exogenous antigens that are recognized as foreign is the first step in humoral immunologic damage to the glomerulus. Endogenous antigens may be intrinsic glomerular antigens, such as Heymann antigen on the epithelial cell or Goodpasture antigen on the GBM, or previously sequestered antigens, such as DNA or thyroglobulin. Exogenous antigens are most often viral, bacterial, parasitic, or fungal in origin. Antineutrophil cytoplasmic autoantibodies (ANCAs) (ie, autoantibodies that react to the cytoplasmic components of neutrophils and monocytes) are found in patients with idiopathic crescentic glomerulonephritis.

Complexes of antigens and antibodies may be formed in the circulation and then passively entrapped in the glomerular capillary or mesangium. Alternately, experimental antibodies may combine with endogenous glomerular antigens or exogenous antigens entrapped in the glomerulus to form complexes locally, or in situ.[3] The type and extent of glomerular damage depend on the location of the immune complex formation and the rate at which it is removed. Impaired removal facilitates the growth of the complex and thus increases the likelihood of glomerular damage.

Subsequent to antigen–antibody formation, a series of biologic events is triggered that ultimately leads to glomerular injury. Noninflammatory lesions can result from the binding of noncomplement-fixing antibody to the glomerular epithelial cell (mechanism 1) or from the activation of the complement system to form the C5b-9 membrane attack complex (mechanism 2).[3] Both mechanisms can damage the glomerular epithelial cell and result in capillary wall injury and proteinuria. Inflammatory lesions are induced by glomerular infiltration of circulating inflammatory cells such as neutrophils, monocytes/macrophages, and platelets (mechanism 3) or by proliferation of resident glomerular mesangial cells (mechanism 4), resulting in GBM damage.[3] The migration of neutrophils and monocytes to the glomerular tufts is promoted by chemoattractants such as complement fragments (C3a and C5a), platelet-activating factor, interleukin-8, and monocyte chemotactic

protein-1.[5] Various cytokines, chemokines, and growth factors are then released to participate in the inflammatory process.[2]

T cells sensitized to glomerular antigen, macrophages, and resident mesangial cells are important participants in cell-mediated injury. Sensitized T cells can cause glomerular hypercellularity in the absence of antibody deposition.[2,3,4,5] Cytotoxic T cells may bind with the target cells and destroy them. Alternatively, a delayed-type hypersensitivity reaction may be initiated by activated T cells through the release of lymphokines to attract, activate, and transform monocytes into macrophages.[3] These humoral and cellular mediators, in conjunction with a host of toxic molecular entities including reactive oxygen species, proteinases, eicosanoids, and procoagulants, can alter the permeability, blood flow, and function of the glomeruli. Vascular constriction and occlusion follow and result in the eventual destruction of the glomeruli.

Acute forms of glomerular injury frequently lead to chronic kidney disease (CKD), even though the immune factors that induced the initial glomerular injury have been resolved. A variety of factors may participate in the progression of renal injury including, systemic and glomerular hypertension, high dietary protein intake, proteinuria, glomerular hypertrophy, hyperlipidemia, activation of the coagulation system, abnormalities of calcium and phosphorus homeostasis, and tubulointerstitial injury. The degree of proteinuria not only is an index of the severity of glomerular disease but also has been associated with an increased rate of progression of renal injury. Proteinuria is also accompanied by an increased flux of macromolecules across the mesangium. The mesangial overload may then lead to structural damage. The passage of serum components, such as complement, across the GBM may alter the integrity of the glomerular filtration barrier. The damaging effects of macromolecules other than albumin, such as immunoglobulins, lipoproteins, transferrin, and complement, have not yet been characterized.

CLINICAL PRESENTATION

2 Although patients with glomerular disease may present with an array of signs and symptoms, they are often categorized into one of two broad classifications: nephritic syndrome or nephrotic syndrome (**Table 47-1**). The unique clinical presentation characteristics of the predominant glomerulopathies are described in the individual disease sections, presented later in the chapter.

TABLE 47-1 Tendencies of Glomerular Diseases to Manifest Nephrotic and Nephritic Features

	Nephrotic Features	Nephritic Features
Minimal-change nephropathy	++++	–
Membranous nephropathy	++++	+
Diabetic glomerulosclerosis	++++	+
Amyloidosis	++++	+
Focal segmental glomerulosclerosis	+++	++
Mesangioproliferative glomerulonephritis	++	++
Membranoproliferative glomerulonephritis	++	+++

	Nephrotic Features	Nephritic Features
Proliferative glomerulonephritis	++	+++
Acute poststreptococcal glomerulonephritis	+	++++
Crescentic glomerulonephritis[a]	+	++++

[a]Can be immune complex-mediated, antiglomerular basement membrane antibody-mediated, or associated with antineutrophil cytoplasmic autoantibodies.

Nephritic syndrome reflects glomerular inflammation and frequently results in hematuria. White cells and cellular and granular casts are commonly found in the urine as well. In contrast, nephrotic syndrome results in few cells or cellular casts in the urine and initially, little or no reduction in glomerular filtration rate (GFR) may be noted.

Hematuria occurs when red blood cells leak through the openings of the GBM. The presence of red cell casts is highly indicative of glomerulonephritis or vasculitis. The presence of dysmorphic red blood cells, those damaged as they pass through the openings in the GBM or as the result of osmotic injury, in the urine is suggestive of glomerular disease. The presence of proteinuria indicates a defect of the size- and/or charge-selective barriers within the GBM. Albuminuria, above the normal threshold of 30 to 300 mg/day, is associated with increased all-cause mortality, progression to ESRD as well as fatal and non-fatal cardiovascular events.[6] Normal urinary protein excretion is between 40 and 80 mg/day, with a maximum of 150 mg. Most of the albumin that enters the glomerular filtrate is either reabsorbed or catabolized by the tubular epithelium. The dipsticks that are commonly used to identify proteinuria detect only albumin; they become positive when protein excretion is more than 300 to 500 mg/day. They are therefore unable to detect the early stages of renal injury secondary to diabetes mellitus or hypertension, which often result in microalbuminuria with urinary albumin excretion ranges between 30 and 300 mg/day. Chemstrip Micral-Test II (Roche Diagnostics, Indianapolis, IN), a simple immunoassay on a dipstick, permits specific and semiquantitative determination of urinary albumin concentrations at five levels: 0, 10, 20, 50, and 100 mg/L. Another qualitative test, Micro-Bumintest (Bayer Diabetes Care, Mishawaka, IN), registers a positive reading when the urine albumin concentration is greater than 40 mg/L.

CLINICAL PRESENTATION Nephritic and Nephrotic Syndromes General

- The patients are generally not in acute distress

Symptoms

- The patients may not experience any major symptoms

Nephritic Signs

- Hematuria
- Hypertension and edema as renal function declines

Nephrotic Signs

- Edema
- Weight gain
- Fatigue

Laboratory Tests

- Proteinuria up to 3 g/day
- Pus, cellular and granular casts in urine is common
- Hypoproteinemia
- Hypercoagulable state for some patients
- Proteinuria, greater than 3.5 g/day/1.73 m^2
- Hyperlipidemia
- Lipiduria

Hypertension is common among patients with glomerular diseases, as a result of renal salt retention and the resultant plasma volume expansion. In contrast, increased activity of vasoconstrictors such as angiotensin II is often the cause of chronic glomerular diseases. Scarring of the glomerulus resulting in regional ischemia is thought to be responsible for the hypertension. Activation of the sympathetic nervous system and the release of vasoconstrictor substances may also contribute.

Nephritic Syndrome

Glomerular bleeding resulting in hematuria is typical in nephritic syndrome. Dysmorphic red cells, especially acanthocytes, are a sensitive and specific marker of glomerular bleeding. The presence of pus and cellular and granular casts in the urine is common. The extent of proteinuria is variable. Patients with severe nephritic glomerular injury tend to have reduced GFR because of the reduced glomerular surface area available for filtration, as a result of constriction of the capillary lumen by proliferating mesangial or inflammatory cells.

Nephrotic Syndrome

Nephrotic syndrome is characterized by proteinuria greater than 3.5 g/day/1.73 m^2, hypoproteinemia, edema, and hyperlipidemia. A hypercoagulable state may also be present in some patients. The syndrome may be the result of primary diseases of the glomerulus, or be associated with systemic diseases such as diabetes mellitus, lupus, amyloidosis, and preeclampsia. Hypoproteinemia, especially hypoalbuminemia, results from increased urinary loss of albumin and an increased rate of catabolism of filtered albumin by proximal tubular cells. The compensatory increase in hepatic synthesis of albumin is insufficient to replenish the protein loss, probably because of malnutrition.

Edema formation in patients with nephrotic syndrome was traditionally thought to be driven by the reduced plasma oncotic pressure secondary to hypoalbuminemia. If the oncotic pressure was low, the movement of fluid from the vascular space to the interstitial compartment results in a reduction of the plasma volume, which can trigger compensatory renal sodium and water retention by activation of the renin–angiotensin–aldosterone axis, vasopressin, and the sympathetic nervous system (the "underfill" mechanism). However, since experimental data reveal that the plasma volume is actually normal or elevated, hypoalbuminemia may not cause edema until the serum albumin concentration is less than 2 g/dL (20 g/L). In addition, the transcapillary oncotic pressure gradient is not as high as previously thought because increased lymphatic flow reduces the interstitial oncotic pressure by removing protein and fluid from the interstitium, thereby reducing the transcapillary oncotic pressure gradient. Instead, fluid retention is likely mediated by a primary increase in sodium reabsorption at the distal nephron, which is probably caused by tubular resistance to the action of atrial natriuretic peptide (the "overflow" mechanism).[7] Albuminuria greater than 3 g daily is associated with a significant increase in serum cholesterol concentrations for patients with primary glomerular disease.[8] Hyperlipidemia in nephrotic syndrome is characterized by elevated serum total cholesterol, triglyceride, very-low-density lipoprotein (VLDL), and low-density lipoprotein (LDL) cholesterol concentrations. The reduced plasma oncotic pressure as a result of hypoalbuminemia may lead to increased VLDL production and increased liver cholesterol synthesis, along with a decrease in LDL receptor activity, which can then lead to an increase in LDL cholesterol concentration. In addition, reduced serum albumin or the loss of a liporegulatory substance may result in reduced VLDL clearance.[9] Nephrotic patients with hyperlipidemia, especially those with concomitant hypertension, are presumed to have an increased risk for atherosclerotic vascular disease. Hyperlipidemia also promotes the progression of glomerular injury, as evidenced by glomerulosclerosis, mesangial expansion, and hyalinosis.[9,10]

Many patients with nephrotic syndrome have a hypercoagulable state as the result of defects in the function of several control proteins in the coagulation cascade. The concentration of the coagulation inhibitors antithrombin proteins C and S, along with increased concentrations of factors V, VIII, and fibrinogen as well as abnormal platelet function, may all contribute to the hypercoagulable state. The net result of these alterations in coagulation is an increased risk for arterial and venous thrombosis, especially in the deep and renal veins. As many as 25% of patients with membranous nephropathy may have renal vein thrombosis.

DIAGNOSTIC CONSIDERATIONS

Patients with suspected glomerular disease should undergo an extensive medical history to identify potential systemic causes (**Table 47-2**). Medication, environmental, and occupational histories may also help identify exposure to potentially nephrotoxic agents. A comprehensive physical examination and laboratory evaluation may reveal the presence of systemic diseases that may contribute to the development of glomerular disease (**Fig. 47-2**). In addition, the patient's age, gender, and ethnic background may be helpful in pinpointing the specific type of glomerular disease. For example, proliferative glomerulonephritis is more common in those less than 40 years of age, whereas the incidence of membranous glomerulonephritis is dramatically higher in those greater than 50 years of

age.

TABLE 47-2 Evaluation of Patients Suspected of Having Glomerular Disease

Medical history

To identify symptoms of medical conditions that may cause glomerular disease

- Diabetes mellitus
- Amyloidosis
- Systemic lupus erythematosus
- Other familial conditions associated with renal disease

To identify symptoms suggestive of nephrotic syndrome

- Reduced appetite
- Fatigue
- Weight gain
- Edema

Medication, environmental, and occupational histories

To identify possible exposure to potentially nephrotoxic drugs, toxins, or chemicals

Physical examination

To identify signs and symptoms associated with systemic diseases

- Hypertension
- Rash
- Arthritis
- Retinopathy
- Neuropathy
- Lymphadenopathy
- Hepatomegaly

- Malignancy

Laboratory evaluation

Urinalysis

- To determine nephrotic nature of glomerular disease
    - Proteinuria, >3.5 g/day/1.73 m^2
    - Lipiduria
- To determine nephritic nature of glomerular disease
    - Hematuria
    - Pyuria
    - Cellular, granular casts

Glomerular filtration rate

- To determine extent of glomerular damage

Other tests

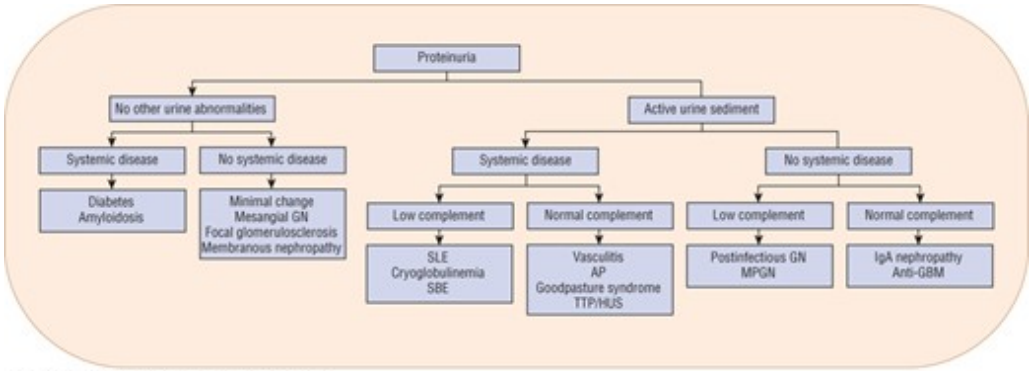
- To identify type and etiology of glomerular disease
    - Serum complement concentration
    - Antinuclear and anti-DNA antibodies
    - Antistreptolysin antibodies
    - Circulating antiglomerular basement membrane antibodies
    - Cryoglobulins

Percutaneous renal biopsy

- To provide definitive diagnosis of glomerular disease

FIGURE 47-2

Clinical presentations of glomerulonephritis. (AP, anaphylactoid purpura; GBM, glomerular basement membrane; GN, glomerulonephritis; HUS, hemolytic uremic syndrome; IgA, immunoglobulin A; MPGN, membranoproliferative glomerulonephritis; SBE, subacute bacterial endocarditis; SLE, systemic lupus erythematosus; TTP, thrombotic thrombocytopenic purpura.)



Urinalysis can help differentiate the nephrotic or nephritic nature of the disease. The GFR may be used to determine the extent of glomerular damage. In the early stages of the disease, the GFR may remain normal. Initial injury to the glomerulus primarily lowers the permeability coefficient (K_f) of the GBM by reducing the surface area available for filtration. The reduced permeability is compensated by an elevation in the glomerular capillary hydrostatic pressure through afferent arteriolar dilation and efferent arteriolar constriction. Extensive glomerular damage may therefore be present before a substantial reduction of total GFR is evident.

Although the cause of glomerular disease may be established from clinical and laboratory evaluation, sometimes percutaneous renal biopsy is needed to provide a definitive diagnosis.

TREATMENT

General Approach to Treatment

In secondary glomerular diseases, such as poststreptococcal glomerulonephritis (PSGN), after the initiating factor is removed, the prognosis of the renal disease is often good. In contrast, the rates of renal function deterioration among the primary glomerulonephritides vary markedly. The majority of patients with minimal-change disease, IgA nephropathy, and membranous nephropathy have a good prognosis. However, those with focal segmental glomerulosclerosis (FSGS) who are resistant to therapy, as well as those with rapidly progressive glomerulonephritis (RPGN) who are untreated, are likely to experience rapid loss of renal function. In some instances, half of the renal function may be lost within a 3-month period. Some entities, such as minimal-change nephropathy, are very responsive to treatment while patients with membranous proliferative glomerulonephritis are rarely responsive to existing therapies.

Because of the variable clinical courses exhibited by the different glomerulonephritides, specific treatment approaches have been developed for each disease. The potential therapeutic benefits of treatment regimens should always be weighed against the patient risks. When satisfactory regimens are not available to treat the primary disease, appropriate supportive measures should be employed:

optimization of systemic and glomerular blood pressure, reducing proteinuria, and possibly controlling hyperlipidemia may all improve the long-term outcome as well as the quality of life of these patients.

Kidney Disease: Improving Global Outcomes (KDIGO) a global nonprofit foundation dedicated to improving the care and outcomes of kidney disease patients worldwide has promoted coordination, collaboration, and integration of initiatives to develop and implement clinical practice guidelines for many kidney diseases.[11] Many of these clinical practice guidelines are referenced in the ensuing sections which are focused on the treatment of individual primary glomerular diseases.

Nonpharmacologic Therapy

3 For patients with nephrotic syndrome, dietary measures involve restriction of sodium intake to 50 to 100 mEq/day (mmol/day),[12] protein intake of 0.8 to 1 g/day,[12,13] and a low-fat diet of less than 200 mg cholesterol per day. Total fat should account for less than 30% of daily total calories.[12] Sodium restriction is important not only in the control of edema, but also for the control of hypertension and proteinuria. Similarly, protein restriction not only helps to reduce proteinuria but also has a potential role in decreasing the progression of renal disease. Patients should also stop smoking because it is associated in a dose-dependent fashion with an increased risk for ESRD in men with primary inflammatory (immunoglobulin A glomerulonephritis) or noninflammatory (polycystic kidney disease) renal diseases.[14]

Because many immune factors are implicated in the pathogenesis of glomerulonephritis, plasmapheresis or plasma exchange, may be used to remove these mediators.[15] During the procedure, whole blood is removed from the body and centrifugation is used to separate the cellular elements from the plasma. The cells are then infused back to the patient after resuspension in saline or plasma substitute. The plasma proteins, presumably including the pathogenic immune factors, are thereby removed from the patient.

Pharmacologic Therapy

Immunosuppressive Agents

Immunosuppressive agents, alone or in combination, are commonly used to alter the immune processes that are responsible for several of the glomerulonephritides. Corticosteroids, in as a result of their immunosuppressive and antiinflammatory activities reduce the production and/or release of many substances that mediate the inflammatory process, such as prostaglandins, leukotrienes, platelet-activating factors, tumor necrosis factors, and interleukin-1 (IL-1). The immunosuppressive effects of corticosteroids are mediated through the inhibition of the release of IL-1 and tumor necrosis factor by activated macrophages, and interleukin-2 by activated T cells. In addition, the actions of migration-inhibiting factor and γ-interferon are inhibited. Cytotoxic agents, such as cyclophosphamide, chlorambucil, or azathioprine, are commonly used to treat glomerular diseases. Cyclosporine can reduce lymphokine production by activated T lymphocytes, and it may decrease proteinuria by improving the permselectivity of the GBM. Mycophenolate mofetil is useful in some

glomerulonephritides because of its effects on T- and B-cell lymphocytes.

Several new agents, such as mTOR inhibitors (sirolimus and everolimus), monoclonal antibodies (rituximab, ocrelizumab, abatacept, and belimumab), imidazole nucleoside (mizoribine), and dihydroorotate dehydrogenase inhibitor (leflunomide), are now being evaluated for their usefulness to control the disease, preserve renal function, and improve patient outcome.[16]

Diuretics

Management of nephrotic edema involves salt restriction, bed rest, and use of support stockings and diuretics. However, severe salt restriction is difficult to achieve and prolonged bed rest can predispose nephrotic patients to thromboembolism. Hence the use of a loop diuretic such as furosemide is frequently required. Although the delivery of diuretic to the kidney tubules is normal, the presence of large amounts of protein in the urine promotes drug binding, and thereby reduces the availability of the diuretic to the luminal receptor sites. In addition, reduced sodium delivery to the distal tubule secondary to decreased glomerular perfusion may also alter diuretic effectiveness. Large doses of the loop diuretic, such as 160 to 480 mg of furosemide, may be needed for patients with moderate edema (see Chapter 49). In some instances, a thiazide diuretic or metolazone may be added to enhance natriuresis.[12,17] Alternatively, continuous IV infusion of a loop diuretic, such as furosemide 160 to 480 mg/day, may be employed.[18] For patients with morbid edema, albumin infusion may be used to expand plasma volume and increase diuretic delivery to the renal tubules, thus enhancing diuretic effect. However, it may precipitate congestive heart failure and may also reduce therapeutic response to steroids in patients with minimal-change nephropathy. For patients with significant edema, the goal of treatment should be a daily loss of 1 to 2 lb (0.45-0.9 kg) of fluid until the patient's desired weight has been obtained.

Antihypertensive Agents

Optimal control of hypertension for patients with glomerular disease is important in reducing both the progression of renal disease and the risk for cardiovascular disease[13] (see Chapters 13 and 44). According to JNC 8 guidelines, the target blood pressure for patients with chronic kidney disease defined by GFR less than 60 mL/min/1.73 m^2 (less than 0.58 mL/s/m^2) is less than 140/90 mm Hg.[19] However, the recently completed NIH-sponsored SPRINT trial showed that targeting a systolic blood pressure of less than 120 mm Hg, as compared with less than 140 mm Hg, resulted in lower rates of fatal and non-fatal major cardiovascular events and death from any cause.[20] As of this time, the authors have not proposed new recommendations for patients with CKD.

Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin II receptor blockers (ARBs) delay the loss of renal function for patients with diabetic and nondiabetic (primarily glomerulonephritis) renal diseases.[21] Nondihydropyridine calcium channel blockers (eg, diltiazem and verapamil) reduce proteinuria and preserve renal function and could be used as an additional agent. In contrast, the dihydropyridine calcium channel blockers (eg, nifedipine, amlodipine, or nisoldipine) are effective in lowering blood pressure, but without the benefit of proteinuria reduction.[22]

Antiproteinuria Agents

Dietary protein restriction reduces proteinuria and may minimize renal function deterioration. Secondary analysis of the Modification of Diet in Renal Disease Study for patients with moderate renal insufficiency (GFR of 25-55 mL/min/1.73 m^2 [0.24-0.53 mL/s/m^2]) revealed that reduced protein intake (0.66 g/kg/day) delayed the rate of GFR deterioration for patients with severe renal insufficiency (GFR of 13-24 mL/min/1.73 m^2 [0.13-0.23 mL/s/m^2]).[23] Consequently, modest protein restriction of 0.8 g/kg/day is reasonable for patients with moderate renal insufficiency. Decreasing dietary protein also reduces the intake of phosphorus and potassium. In many instances, the potential benefits of protein restriction have to be balanced against the nutritional deficiencies which may develop. For nondialyzed patients who have GFRs of less than 25 mL/min/1.73 m^2 (0.24 mL/s/m^2), dietary protein intake should be reduced to 0.6 g/kg/day.[14]

Angiotensin-Converting Enzyme Inhibitors and Receptor Blockers

Since proteinuria is recognized to be an independent risk factor for renal function decline and cardiovascular disease, reducing proteinuria can retard renal function loss and delay the progression to ESRD.[21] Disruption of the renin-angiotensin system (RAS) by ACEI, ARB and direct renin inhibitors (DRIs) can all reduce angiotensin II.[24] The antiproteinuric effect of ACEIs is associated with a fall in filtration fraction, suggesting a reduction in intraglomerular pressure. ACEIs and ARBs may also have direct effects on podocytes, resulting in reduction of proteinuria and glomerular scarring.[21] In addition, angiotensin-converting enzyme (ACE) inhibition may also reduce the effect of angiotensin II on renal cell proliferation, thereby reducing sclerosis. These beneficial effects on proteinuria are beyond what can be attributed by the drug's antihypertensive effects (see Chapters 13 and 44).

Clinical Controversy…

Angiotensin-converting enzyme inhibitors and ARBs can reduce proteinuria through different mechanisms and combined use has been shown to be more effective than monotherapy. However, the risk of combination therapy has become a concern recently. Some clinicians therefore recommend the use of monotherapy while others consider the combination a powerful tool for renal preservation.

Combined use of ACEI and ARB maximizes blockade of the renin–angiotensin system by counteracting the effects of angiotensin II produced by non-ACE pathways. In addition, with the blockade of the angiotensin II type 1 receptor, the angiotensin II produced by the non-ACE pathways may still act on the angiotensin II type 2 receptors, further facilitating vasodilation.[21] An angiotensin II receptor antagonist would provide additional benefit for those patients who do not attain full and persistent remission of proteinuria with an ACEI alone. Such ACEI and ARB combination therapy reduces proteinuria and the rate of renal function decline more than either treatment alone.[25] However, the ONTARGET trial showed that the combination was not more effective than single-drug therapy in patients with minimal proteinuria.[26] The VA NEPHRON-D trial was terminated early because of increased risk of hyperkalemia and acute kidney injury in patients receiving lisinopril-

losartan combination, compared with those receiving losartan monotherapy.[27] In addition, results of the ALTITUDE trial showed that adding the renin inhibitor aliskiren to ACEI or ARB monotherapy increased non-fatal strokes in type 2 diabetes patients with overt nephropathy.[26] In view of these findings, RAS blockage by dual therapy should be avoided because of potential increase in adverse effects, however, there are clinicians recommending the judious use of combination therapy to take advantage of the powerful proteinuria reduction.[24] It is anticipated that results from ongoing studies may help define the best use of these agents for renal protection.

A thorough review of the combined use of ACEs and ARBs for diabetic nephropathy and proteinuria reduction can be found in Chapter 44.

Nonsteroidal Antiinflammatory Agents

Nonsteroidal antiinflammatory drugs (NSAIDs) probably reduce proteinuria through prostaglandin E_2 inhibition, resulting in a reduction of intraglomerular pressure, a decrease in GFR, and restoration of the barrier size selectivity of the GBM.[13] Indomethacin and meclofenamate, the two most evaluated NSAIDs have similar efficacy to ACEIs, and combined treatment with an ACEI results in additional proteinuria reduction.[28] However, adherence to a low-sodium diet or concurrent use of a diuretic is needed to maximize the antiproteinuric effect. Because of their potential for nephrotoxicity, especially for patients with preexisting CKD, long-term use of an NSAID for renoprotection is not commonly prescribed.[26]

Adrenocorticotropin

A synthetic adrenocorticotropic hormone (ACTH) analog has been used in Europe for proteinuria reduction associated with nephrotic syndrome. It was reported to have effects similar to alternating months of steroids and cyclophosphamide.[29] Instead of the synthetic analog, a natural, purified ACTH gel is available in the United States and is approved by the FDA for inducing a remission of proteinuria of the idiopathic type or that due to lupus erythematosus. Favorable response was reported in an observation series of 21 patients in the United States.[30] However, the authors cautioned that the data were not derived from a controlled, randomized study and the patients had different glomerular diseases and the long-term effect was not reported.

Statins

It is important to treat patients with persistent nephrotic syndrome, especially those with high VLDL and LDL cholesterol levels (see Chapters 21 and 44). Therapy is especially needed for those with concurrent atherosclerotic cardiovascular disease, or with additional risk factors for atherosclerosis, such as smoking and hypertension.[8]

β-Hydroxy-β-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors, also known as “statins” such as lovastatin, pravastatin, simvastatin, fluvastatin atorvastatin and rosuvastatin, are considered the treatment of choice.[31] They reduce total plasma cholesterol concentration, LDL cholesterol, and

total plasma triglyceride concentrations.[8] Aside from the lipid-lowering effects, statins can reduce cardiovascular risk independent of serum lipid concentrations. Such 'pleiotropic' effects are mostly mediated through inhibition of protein prenylation, altering signaling pathways that regulate gene expression, membrane trafficking, cell proliferation, migration and apoptosis.[32] Renoprotection is conferred through the reduction of cell proliferation and mesangial matrix accumulation and their antiinflammatory and immunomodulatory effects.

Meta-analysis of published studies showed that statins appear to reduce renal function decline and slow the progression of proteinuria moderately. The beneficial effect may be dose-related and duration-dependent.[33] One analysis revealed that patients with cardiovascular disease were most likely to benefit, compared with those with diabetes or hypertensive nephropathy or glomerulonephritis.[34] In contrast, a large randomized, controlled trial (SHARP) with 9,438 participants showed that simvastatin 20 mg plus ezetimibe 10 mg did not affect the progression of ESRD, although the lipid reduction prevented major cardiovascular events in predialysis CKD patients.[35]

Based on the available data, statins should be used to treat the dyslipidemia; however, their effect on renal function preservation is not as clear. The PCSK9 inhibitors, alirocumab and evolocumab, may be especially useful in treating hypercholestermia in patients who have nephrotic syndrome and those on peritoneal dialysis, since they tend to have high PCSK9 concentrations.[36] However, the effect of these agents on renal function needs to be demonstrated in large clinical trials.

Anticoagulants

Renal vein thrombosis, pulmonary emboli, or other thromboembolic events are serious and common complications of nephrotic syndrome, and are frequently seen in those with membranous nephropathy. Although patients who have documented thromboembolic episodes should be anticoagulated with warfarin until remission of nephrotic syndrome, the use of prophylactic anticoagulation is controversial. A decision analysis study suggested that prophylactic anticoagulation is beneficial for patients with membranous nephropathy.[37] Prophylactic anticoagulation is not recommended for all patients; rather, a "selective" approach or individualized assessment should be conducted to identify those at high risk (ie, those with severe nephrotic syndrome and a serum albumin concentration less than 2-2.5 g/dL [less than 20-25 g/L]).[37] Also at risk are those who require prolonged bed rest, those receiving high-dose IV steroid therapy, and individuals who are dehydrated as well as postsurgical patients.[13]

Evaluation of Therapeutic Outcomes

The management of patients with glomerulonephritis involves specific pharmacologic therapy for the glomerular disease they have in addition to supportive measures to prevent and/or treat the pathophysiologic sequelae, namely, hypertension, edema, and progression of renal disease. Although the course of the disease, as well as the specific treatment regimens, varies the efficacy monitoring parameters are similar.

4 Patients should be monitored closely for therapeutic response as well as the development of treatment-related toxicities. Although the rate of renal function deterioration is an important indicator of the long-term success of treatment, resolution of nephrotic and nephritic signs and symptoms are also important short-term therapeutic targets (**Table 47-3**).

TABLE 47-3 Monitoring Parameters to Assess Response to Glomerulonephritis Treatment

Renal function
Serum creatinine concentration
24-h urine collection for creatinine clearance determination
24-h urine collection for urinary protein excretion
Urine protein-to-creatinine ratio
Clinical signs and symptoms
Nephrotic syndrome
Proteinuria
Serum lipid concentrations
Edema
Nephritic presentations
Hematuria
Urinalysis
Complete blood count
Blood pressure
General well-being: appetite, energy level
Kidney biopsy to assess disease progression and response to therapy
Assessment of drug therapy adverse reactions and toxicities

The frequency of monitoring is dependent on the specific glomerulopathy and severity of the disease.

Serum creatinine concentration as well as creatinine clearance should be evaluated prior to and during treatment; 24-hour urine output should be collected to determine the extent of proteinuria. Alternatively, the daily urine protein excretion may be estimated from the urinary total protein-to-creatinine concentration ratio. After establishing the correlation between the 24-hour urinary

protein excretion and the protein-to-creatinine ratio, single, random urine specimens may be used in place of a 24-hour urine collection. Blood pressure should be monitored at each visit to assess the need for and/or the adequacy of antihypertensive therapy. The clinical signs and symptoms of edema and fluid overload should be assessed at each clinic visit to gauge the need for diuretic intitation or dosage escalation. For patients with nephrotic syndrome, serum lipid concentrations should be monitored, at least quarterly. If the patient has hematuria, urinalysis and a complete blood count should be obtained. The clinician should also be aware of the patient's appetite and energy level, because these are indicators of the patient's overall well-being. Renal biopsy is occasionally needed to assess response to treatment and disease progression, to determine future treatment strategy, and to confirm the initial diagnosis.

Patients receiving cytotoxic drug treatment should be evaluated to gauge their response and identify the presence of drug-related toxicities every week for a month and then monthly to quarterly there after. If a favorable response is obtained after a course of treatment, the patient may be evaluated every 3 to 4 months. The patient's renal function, proteinuria, urinalysis, blood pressure, lipid profile, and the overall state of health should be assessed during these regular follow-up visits.

Minimal-Change Nephropathy

Epidemiology and Etiology

Minimal-change nephropathy (also termed "nil disease") is most commonly observed in children, and accounts for 85% to 90% of all cases of nephrotic syndrome in children between 1 and 4 years of age. The percentage drops to less than 50% after age 10 and it accounts for less than 20% of all cases of idiopathic nephrotic syndrome in adults. Lipoid nephrosis is another term that has been used to describe this type of glomerular disease because lipids, as well as renal tubular cells, are found in the urine. Secondary causes of minimal-change nephropathy include drug exposure (eg, NSAIDs, lithium, and interferons), lupus, and various T-cell-related disorders, such as Hodgkin's disease and leukemias.

Pathophysiology

Minimal-change disease is characterized by the absence of definitive pathologic changes with light and immunofluorescence microscopy of a biopsy specimen. The characteristic lesion in patients with minimal-change disease, as visualized under electron microscopy, is the spreading and fusion of the foot processes of epithelial cells over an unchanged GBM. The pathogenesis of minimal-change disease is unknown, although some have proposed that altered cell-mediated immunologic response, specifically T-cell dysfunction or changes in the T-cell subpopulations, may be responsible. The activated lymphocytes are thought to secrete lymphokines that reduce the production of anions in the GBM and alter podocyte integrity. The permeability of the GBM to plasma albumin is increased as the result of the reduction of electrostatic repulsion. The loss of anionic charges also results in fusion of the epithelial cell foot processes.

Clinical Presentation

Most patients present initially with edema, frequently acute in onset, following a nonspecific upper

respiratory tract infection, allergic reaction, or vaccinations, which might have activated T lymphocytes. Nephrotic syndrome with massive proteinuria (substantially more than 40 mg/m^2/h for children and more than 3-3.5 g/day for adults), hypoalbuminemia, and hyperlipidemia is also common. The patient's weight may increase dramatically because of sodium and fluid retention. Nephritic features, such as gross hematuria, are uncommon. Hypertension and decreased renal function are uncommon in children but are frequently seen in older adults.

TREATMENT

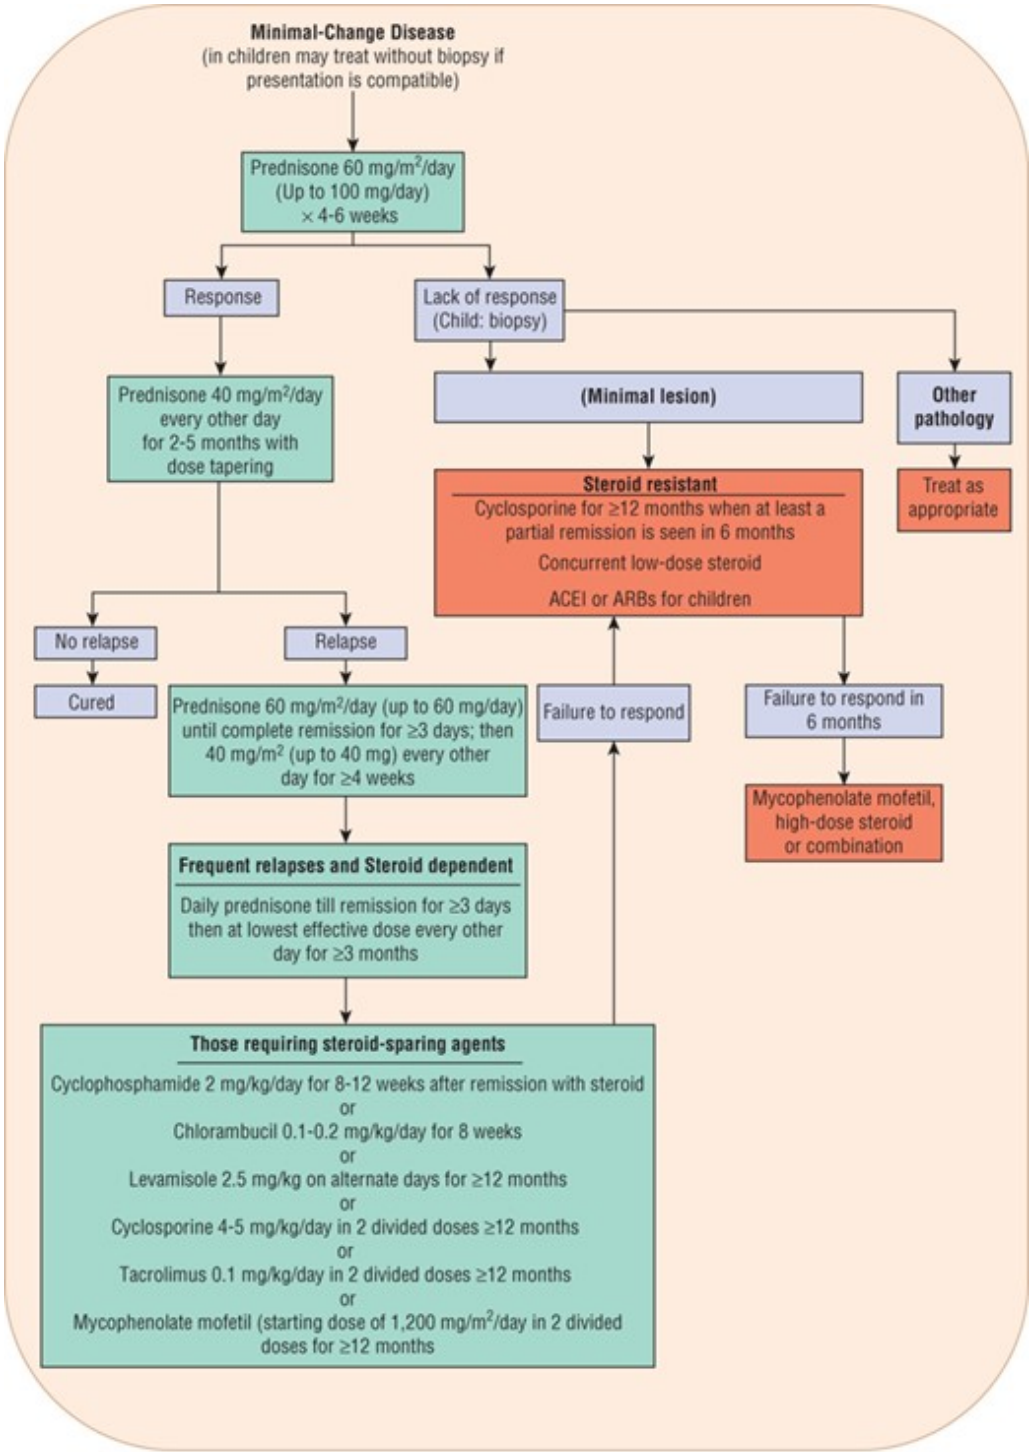
Pharmacologic Therapy

Steroids

5 Minimal-change disease is most responsive to initial treatment with corticosteroids. In children, steroid therapy is expected to reduce proteinuria in approximately 90% of the patients and the 10-year renal survival rate exceeds 95%. Because of the excellent response to steroids and the prevalence of this glomerular disease in children, reduction of proteinuria secondary to steroid treatment is considered diagnostic for minimal-change disease without the need for biopsy. Prednisone is commonly administered at 60 mg/m^2/day initially for 4 to 6 weeks. The dose is then reduced to 40 mg/m^2/day every other day for 2 to 5 months, with dose tapering (**Fig. 47-3**).[38] Proteinuria will disappear in 50% of patients after 1 week and in 94% of patients after 4 weeks of treatment. Commonly, the initial episode is treated with an extended course (months) of therapy, followed by shorter treatment (weeks) for relapses.[39]

FIGURE 47-3

Treatment algorithm for minimal-change disease according to KDIGO guidelines. (*Data from references 38 and 40.*)



Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

For adults, prednisone 1 mg/kg/day (maximum 80 mg) or alternate-day single dose therapy of 2 mg/kg (maximum of 120 mg) is given initially for a minimum of 4 weeks to maximum of 16 weeks and then tapered slowly with cessation by 6 months. 50% of the patients will respond after 4 weeks and an additional 10% to 25% will respond after 12 to 16 weeks of treatment.[40]

Relapse

As many as 80% to 90% of the patients who respond to initial steroid therapy (steroid sensitive) will

experience a relapse of proteinuria, within 6 to 12 months after disease onset. The risk of relapse is affected by the duration of initial steroid therapy.[12] Children who were asymptomatic with proteinuria diagnosed during routine urine screening tend to have less frequent relapses and a more favorable clinical course. In those who relapse, 50% to 65% may have steroid-responsive relapse episodes over the subsequent 3- to 5-years. The dose and duration of steroid treatment for relapse do not appear to influence the subsequent rate of relapse.[12] Commonly, 60 mg/m^2/day of prednisone is given until the urine is free of protein for 3 days, followed by 4 weeks of alternate-day prednisone at 40 mg/m^2 per dose.[38]

Frequent Relapse

Approximately 40% of children who are steroid responsive will experience frequent relapses or become steroid dependent, that is, requiring continuous low-dose alternate-day prednisone to maintain an extended relapse-free period.[38] A small number of patients eventually develop resistance to steroids, and a biopsy done at that time often reveals another pathology such as FSGS. It is controversial whether minimal-change disease progresses into FSGS or if FSGS was present at the time of initial clinical presentation.

Cytotoxic Agents

Cytotoxic agents are often considered for patients who are steroid resistant, as well as for those who require large doses of steroids to sustain remission (steroid dependent). These agents are also beneficial for pediatric patients who experience growth retardation secondary to chronic use of steroids. Cytotoxic agents are effective in inducing remission and the duration of remission tends to be longer than that induced by steroids. In those who relapse after cytotoxic therapy, they may regain or respond better to steroids than before.

Cyclophosphamide at 2 mg/kg/day for 8 to 12 weeks is very effective in inducing remission. Alternatively, chlorambucil at 0.1 to 0.2 mg/kg/day may be used. This agent, however, is associated with more adverse effects than cyclophosphamide. Azathioprine is no longer recommended since its effectiveness has not been substantiated in randomized trials.[38]

The immunosuppressive effect of cytotoxic agents can result in serious infections, which are the primary cause of death for patients with minimal-change nephropathy. Other toxicities associated with cyclophosphamide include gonadal fibrosis, which results in sterility, hemorrhagic cystitis, alopecia, and the potential development of malignancy in those on long-term treatment.

Calcineurin Inhibitors

Cyclosporine decreases lymphokine production by activated T lymphocytes and thereby reduces proteinuria by reversing the lymphokine-induced alterations in the anionic charge and permeability of the GBM to albumin. For patients with steroid-sensitive or steroid-dependent disease, cyclosporine induces remission in 80% to 85% of patients. However, the disease-free period is not often sustained, and relapse may occur as soon as the drug is tapered or discontinued. The steroid-sparing effect of

cyclosporine is useful for steroid-dependent patients, especially those who have experienced significant adverse effects.

Tacrolimus has been used in children with frequent relapse and steroid dependence, to avoid the cosmetic side effects of cyclosporine. While randomized trials are not available to substantiate its use, it is believed that the efficacy is similar to cyclosporine based on one observational study.[41]

Dosage

The usual starting dose of cyclosporine for remission induction is 4 to 5 mg/kg/day in 2 divided doses with the goal of achieving 12-hour trough serum concentrations of 80 to 150 ng/mL (mcg/L; 67-125 nmol/L). After achieving stable remission for 3 to 6 months, a lower serum concentration, perhaps at 60 to 80 ng/mL (mcg/L; 50-67 nmol/L), can be maintained to minimize cyclosporine-induced nephrotoxicity.[38] Therapy should be maintained for at least 12 months, since most patients experience relapse when treatment is stopped, especially those with a shorter duration of therapy. However, renal toxicity becomes a concern with longer term therapy. Tubulointerstitial lesions were found in 30% to 40% of patients after treatment of 12 months or more. Concuurent administration of ketoconazole can reduce the dose of cyclosporine, resulting in savings in drug cost with no compromise in efficacy.[42]

Adverse Events

Adverse events such as hypertrichosis, and gingival hyperplasia are quite common. Long-term therapy may result in persistent hypertension and progressive renal failure.

Mycophenolate Mofetil

Mycophenolate mofetil is an immunosuppressant that can suppress T- and B-cell lymphocyte proliferation, B-lymphocyte antibody production, and expression of adhesion molecules. It is reported to have steroid-sparing effects and is useful in frequently relapsing, steroid-dependent and steroid-resistant patients, as well as in those who fail cytotoxic therapy.[43] KDIGO guidelines recommend a starting dose of 1,200 mg/m^2/day in 2 divided doses. Therapy should be maintained for at least 12 months since most will relapse when the treatment is stopped.[38] For those who experience relapse, treatment should be continued or another agent started to maintain the remission.

Rituximab

Rituximab has been found to reduce relapse rate and the need for prednisone and cyclosporine treatment in steroid dependent patients.[44] As an antiCD20 monoclonal antibody, it may act on the CD20+ B cells or CD17+ B or T cells, or exert a direct effect on the podocyte actin cytoskeleton.[45] At this time, due to the lack of randomized trial data and the potential for serious adverse effects, the KDIGO guidelines recommend rituximab be considered only for steroid-dependent children who

have frequent relapses despite optimal combinations of prednisone and corticosteroid-sparing agents, and/or those who have serious adverse effects from such therapy.[38] Rituximab is not recommended for use in adult patients.

Levamisole

Levamisole, an immunostimulant, has been available for treatment for several decades. The drug is no longer available in the United States now; however, it is recommended by the KDIGO guidelines as a steroid-sparing agent.[38] Levamisole can promote the maturation of young T cells and restore their function as well as that of phagocytes. It may also inhibit the production of an immunosuppressive lymphokine. Levamisole was found to have a steroid-sparing effect and can enhance maintaining remission in children who had frequent relapse steroid-dependent nephrotic syndrome.[46] In addition, it is as effective as cyclophosphamide in reducing relapse rate and steroid dosages necessary to maintain remission.[47] The adverse effect of levamisole is uncommon and minor: mild neutropenia, which is generally reversible, and gastrointestinal upsets.

Steroid Resistant Nephrotic Syndrome

While the definition of steroid resistance varies among studies, the KDIGO guidelines define it as a minimum exposure to 8 weeks of prednisone 2 mg/kg/day or 4 weeks of 60 mg/m^2/day, followed by 1.5 mg/kg/day or 40 mg/m^2 per dose alternate-day for 4 weeks without clinical response. A kidney biopsy would be needed to identify the pathology in these patients.[48] Steroids may be continued for an additional 4 weeks for a total of 12 weeks while awaiting biopsy results.

Calcineurin inhibitor for at least 12 months is recommended as initial therapy for steroid-resistant nephrotic syndrome. ACE inhibitors or ARBs should also be used concurrently to reduce proteinuria. If no response is observed after 6 months, mycophenolate mofetil, high-dose steroid or a combination of these agents should be considered. Available evidences do not support the use of cytotoxic agents and rituximab.[48]

Prognosis

Typically, minimal-change nephropathy follows a course with spontaneous remission (30%-40%) and relapse. However, the long-term prognosis of most patients is good. The majority of pediatric patients will not experience any relapse of the disease 10 years after the initial onset, and most will be free of the proteinuria after puberty. In adults, an 85% to 90% survival rate is seen 10 years after disease onset. Although this condition may spontaneously remit in up to 70% of untreated adults, life-threatening complications may be associated with untreated nephrotic syndrome. Significant deterioration in renal function is uncommon in both adult and pediatric patients and is observed only in those who are steroid resistant or steroid dependent.

Most children and adults are expected to respond well to steroid therapy. Resistance may be due to undetected FSGS lesion, underlying malignancy or treatment non-compliance. For those patients with frequent relapses and steroid-dependence, KDIGO guidelines do not indicate a preference for

alkylating agents, levamisole, cyclosporine, tacrolimus or mycophenolate mofetil. Because of the overall favorable outcome of the disease and the relatively uncommon progression into chronic renal failure, aggressive use of cytotoxic agents is not indicated even for most patients with frequent relapses. Toxicities associated with aggressive therapy do not justify the need to induce remission in those patients who fail to respond to steroids and the nonaggressive use of cytotoxic agents. Symptomatic therapy with diuretics to control edema, in conjunction with a low-salt diet and albumin infusion as needed for acute development of anasarca, is often a more rewarding therapeutic approach. NSAIDs and ACEIs may also be used to reduce the proteinuria.

Focal Segmental Glomerulosclerosis

Etiology and Epidemiology

Focal segmental glomerular sclerosis is a clinicopathologic condition that can be idiopathic that is, primary or secondary to a variety of conditions such as sickle cell disease, cyanotic congenital heart disease, and morbid obesity which can induce hemodynamic stress on an initially normal nephron population and result in FSGS. FSGS accounts for less than 20% of the cases of idiopathic nephrotic syndrome in children and approximately 40% in adults;[49] however, it may account for 36% to 80% of the cases in African Americans, probably due to genetic predisposition. The incidence of FSGS has been rapidly increasing, so that it now is the most common glomerular disease that ultimately leads to ESRD. In the United States, FSGS is the most common etiology for proteinuria in African Americans and Hispanics. Severe glomerular injury can also be seen in patients with nephropathy associated with heroin abuse, human immunodeficiency virus (HIV) infection, and genetic mutations involving the podocin and WT1 genes. A recent case series identified the association of FSGS and proteinuria in bodybuilders after long-term anabolic steroid abuse.[50] In addition, heroin, pamidronate, and interferon have been associated with FSGS.[49] The primary and secondary sclerotic lesions may be morphologically similar, but they represent diseases with different courses and responses to therapy.

Pathophysiology

Sclerotic lesions are characteristically found in some of the glomeruli (focal) and usually involve only a portion of the glomeruli (segmental).[49] Similar to minimal-change disease, fusion of foot processes is commonly seen in those glomeruli that are not sclerotic. It is thought that both minimal-change disease and FSGS share similar pathogenetic mechanisms, with FSGS resulting in severe injury to the glomerular epithelial cells. During the early stage of FSGS, only a small number of glomeruli may have the segmental sclerotic lesion, and the disease may be confined to the juxtamedullary region. If an inadequate number of glomeruli are sampled during renal biopsy, the diagnosis of FSGS may be missed, or the patient may be thought to have minimal-change disease. Resistance to steroid therapy may thus be one of the first clues that the patient, indeed, has FSGS rather than minimal-change disease. Alternatively, a patient may have the steroid-sensitive minimal-change disease initially, which subsequently progresses to steroid-resistant FSGS.

Clinical Presentation

Almost all the patients present with proteinuria, and many of them have all the features of nephrotic syndrome. The proteinuria is nonselective, containing albumin and other higher-molecular-weight proteins, and is usually less severe when compared to patients who have minimal-change disease. Hypertension, microscopic hematuria, and renal dysfunction may be seen in up to half of the patients. Reduced renal function becomes more prevalent as the disease progresses.

The presenting clinical features in nephrotic adults with minimal-change nephropathy can be indistinguishable from that of FSGS, and renal biopsy is therefore critical in the diagnosis of adults with nephrotic syndrome. African Americans have a fourfold higher risk of developing FSGS than white or Asian patients. They tend to develop the disease earlier and present with nephrotic range proteinuria more often. They are less responsive to steroids and are more likely to experience a rapid decline in renal function, resulting in ESRD.

TREATMENT

Pharmacologic Therapy

The treatment of FSGS is controversial because of the lack of data from randomized, prospective, controlled trials.

Steroids

For patients with idiopathic FSGS and nephrotic syndrome, KDIGO guidelines recommend daily single dose of prednisone (1 mg/kg/day) or an alterntate-day dose regimen (2 mg/kg/day) for at least 4 weeks, up to a maximum of 16 weeks, or until complete remission, with subsequent tapering over 6 months after attaining complete remission.[51] Urinary protein excretion and serum albumin concentration should be monitored to assess efficacy. The median time to induce complete remission is 3 to 4 months, although 5 to 9 months may be needed in some patients. In general, 30% to 50% of all patients are expected to be resistant to steroids, after at least 4 months of therapy.

If the patient develops a relapse after an adequate response to the initial treatment, a second course of steroids is generally sufficient. In view of the lack of evidence specific for FSGS, the KDIGO recommendations for adults with minimal-change disease can be used to guide treatment of steroid-responsive primary FSGS. However, if relapse occurs frequently, cytotoxic agents or cyclosporine would be indicated.

Patients who are not nephrotic have a relatively favorable prognosis and thus their need for steroids or other immunosuppressive agents is unlikely. However, close follow-up and good blood pressure control with ACEIs/ARBs may be necessary to minimize disease progression.[49]

Most of the studies conducted predominantly included white patients. In a retrospective review of 72 patients that included 65 African American patients, steroid use was not associated with renal survival or the induction of proteinuria remission.[52] The initial creatinine level, blood pressure, and severity of renal lesions were significant predictors of renal survival. About one third of the patients who received steroids developed complications such as diabetes and significant weight gain.

Cytotoxic Agents

When used with steroids during initial therapy, cytotoxic agents were not found to offer any additional beneficial effect.[49,53] Randomized clinical trials are not available to support their use as first-line therapy.[51]

Calcineurin and Rapamycin Inhibitors

In patients with uncontrolled diabetes, psychiatric disorder, or severe osteoporosis, calcineurin inhibitors may be used as first-line therapy to avoid the potential steroid side effects on these conditions.[49,51] In steroid-resistant patients, KDIGO guidelines suggest using cyclosporine at 3 to 5 mg/kg/day in divided doses for at least 4 to 6 months. If there is a partial or complete remission, therapy may be continued for at least 12 months, followed by a slow taper.[51] Complete or partial remission was observed in 70% of patients, with a relapse rate of 47%.[54] Tacrolimus may also be used with similar effects.[55] The effect of sirolimus on proteinuria has been found to be conflicting; however, it may cause a rapid decline in GFR, and hence its use for FSGS is not recommended.[56]

Mycophenolate Mofetil

A randomized study in adult patients with FSGS and persistent nephrotic syndrome suggested that mycophenolate mofetil with low-dose prednisone might be beneficial for those who are unable to tolerate prolonged high-dose prednisone. Indeed comparable remission rates were found for both regimens.[57]

Mycophenolate mofetil has been reported to have favorable effects for patients who were steroid resistant. After inducing remission with high-dose IV methylprednisolone and oral cyclosporine, a combination of cyclosporine and mycophenolate, followed by mycophenolate alone, can sustain long-term remission, preserve renal function, and improve blood pressure control.[58] However, due to the varied experiences from different investigators, further studies are needed to define the role of this agent among the various treatment options.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin II Receptor Blockers

6 Because of the lack of a consistently effective regimen for primary FSGS, many patients with mild disease are treated conservatively. ACEIs and ARBs are effective in reducing proteinuria and stabilizing renal function in many patients with primary or secondary FSGS. Control of blood pressure and hyperlipidemia are important as well.[49] For patients who have nephrotic range proteinuria, an elevated serum creatinine concentration, and interstitial scarring on biopsy, corticosteroids with or without immunosuppressive agents are often used as combination therapy.

Steroid-Resistant FSGS

About 40% to 60% of patients with primary FSGS with nephrotic syndrome are resistant to steroid

treatment. KDIGO guidelines suggest following the guidelines for relapsing minimal-change disease in this population of patients: Cyclosporine 3 to 5 mg/kg/day in divided doses be given for at least 4 to 6 months. Therapy should continue for at least 12 months, followed by slow taper, if there is a partial or complete remission. For those who are unable to tolerate cyclosporine, mycophenolate mofetil and high-dose dexamethasone should be considered, although data supporting efficacy is weak.[51] At present, there is insufficient evidence to support the use of alkylating agents, sirolimus, rituximab and ACTH. Randomized controlled trials are needed to clarify the role of these agents.

Prognosis

End-stage renal disease develops within 10 years in 10% or less of the adults and children who attained complete remission.[54] For those patients who are resistant to therapy, the rate of renal function deterioration to ESRD may be rapid, within 1 year, or slow, over as long as 10 to 20 years; approximately 50% develop ESRD within 10 years. Those patients with severe proteinuria (more than 10-15 g/day), high serum creatinine concentration at diagnosis, initial steroid resistance, or interstitial fibrosis on renal biopsy are likely to have a more rapid decline in renal function. Kidney transplantation is often indicated for those patients who develop ESRD; however, FSGS has recurred in 40% of the renal allografts soon after transplantation.[49] Children, nonblack race, and those with severe disease or rapid progression to ESRD prior to transplantation are more likely to experience a recurrence. The proteinuria may reappear within hours after transplantation, and graft failure may occur in one third to one half of the patients. High-dose IV methylprednisolone and cyclosporine may reduce recurrences. Rituximab may also be helpful in patients who fail to respond to plasmapheresis.[51] ACEIs and plasmapheresis are also used to prolong graft survival. The effectiveness of these therapies and the rapid recurrence of the disease in the transplanted kidney substantiate the possibility that a circulating humoral mediator is responsible for the nephropathy. Plasmapheresis to remove the mediator was found to be effective in inducing a remission.[49]

Membranous Nephropathy

Etiology and Epidemiology

Membranous nephropathy had been the most common disorder responsible for idiopathic nephrotic syndrome in adults. However, in a recent large survey of renal biopsy results, membranous nephropathy was the third most common type of GN (7.5%), after IgA nephropathy (22%) and FSGS (12.4%).[59] It is also a frequent cause of renal failure secondary to glomerulonephritis. The hallmark histologic features of membranous nephropathy are glomerular capillary wall thickening with subepithelial deposits under light and electron microscopy. Autoimmunity is responsible for most of the cases. Autoantibodies toward phospholipase A2 receptor (PLA2R) have been found in 80% of patients with idiopathic membranous nephropathy. In addition, antibodies against neutral endopeptidase (NEP) have been discovered in rare cases of neonatal membranous nephropathy.[60] The presence of bovine serum albumin (BSA) and anti-BSA antibodies in certain patients suggests that food antigens may be involved in the pathogenesis. Further, anti-PLA2R antibodies appear to predict disease activity and response to therapy.[60]

About 25% of adults and 80% of children have secondary causes. In the United States, the most common etiologies are autoimmune diseases (eg, lupus), infection (eg, hepatitis B and C), syphilis, neoplasm (eg, carcinoma of the lung, breast, GI tract, or kidney), and medications (eg, gold, penicillamine, or captopril). Malaria and schistosomiasis are common causes in other parts of the world. De novo membranous nephropathy can also occur in the allografts of renal transplant patients. Because the responses to therapy as well as the prognosis for idiopathic and secondary membranous nephropathy are different, it is important to identify any potential underlying causes for the nephropathy prior to treatment. Although this glomerular disease can occur at any age, the peak incidence is between ages 30 and 50 years and is especially likely in patients older than age 50 years who present with nephrotic syndrome.

Pathophysiology

Examination of kidney tissue under light microscopy reveals normal mesangium and normocellularity. The glomerular capillary wall may be thickened in well-developed lesions. In the advanced stage, the epithelial side of the capillary wall is markedly thickened, and intramembranous deposits are found. Progressive changes in capillary lumen patency parallel those in the GBM, resulting in glomerulosclerosis with capillary collapse and tubular atrophy in end-stage membranous nephropathy. Immunofluorescence microscopy shows strong capillary wall staining of IgG and C3 on the epithelial side of the basement membrane. Antibody-mediated immune injury appears to be the main pathogenetic mechanism. The immune complex can be formed in situ or deposited from circulating immune complexes.

Clinical Presentation

Most patients with membranous nephropathy present with heavy proteinuria (exceeding 3.5 g/day). Those patients excreting large amounts of IgG and α_1-microglobulin, indicating more significant tubulointerstitial damage, have a lower remission rate, and are more likely to progress toward renal failure.

The signs and symptoms are usually insidious in onset and may consist of anorexia, malaise, edema, anasarca, or ascites, and pericardial and pleural effusions may also be present. As a result of a hypercoagulable state, pulmonary embolism may develop but rarely results in death. The incidence of renal vein thrombosis varies from 5% to 62%, and membranous nephropathy should be suspected when there is a sudden onset of hematuria, loin pain, pulmonary embolus, fluctuating or worsening proteinuria or GFR, renal tubular acidosis, or an increase in leg edema. Hypertension is found in approximately 30% of patients and is more common in those with renal insufficiency.

In addition to heavy proteinuria, urinalysis often reveals lipiduria and oval fat bodies. Microhematuria is seen in fewer than 25% of patients, and gross hematuria and red cell casts are rare. In idiopathic membranous nephropathy, the serum complement concentrations are normal. Low levels of complement should alert one to search for secondary causes, such as lupus, hepatitis B infection, or an alternative diagnosis. Similarly, antinuclear antibodies, anti-DNA antibodies, rheumatoid factor, hepatitis B serologies, and serum cryoglobulins are generally negative in idiopathic membranous nephropathy. Occult malignancy has been found in as many as 10% of elderly patients with

membranous nephropathy.

TREATMENT

The treatment of idiopathic membranous nephropathy is controversial and ranges from supportive therapy to immunosuppression. Conservative management of patients with mild disease includes edema control with salt restriction and diuretics[61] and reduction of proteinuria with protein restriction and ACEIs (**Fig. 47-4**).[11,62] Management of hypertension and hyperlipidemia is required for most patients, whereas prophylactic anticoagulation, despite having benefits shown to outweigh the risks, is usually given only for patients with renal vein thrombosis or documented pulmonary embolus.[37,62]

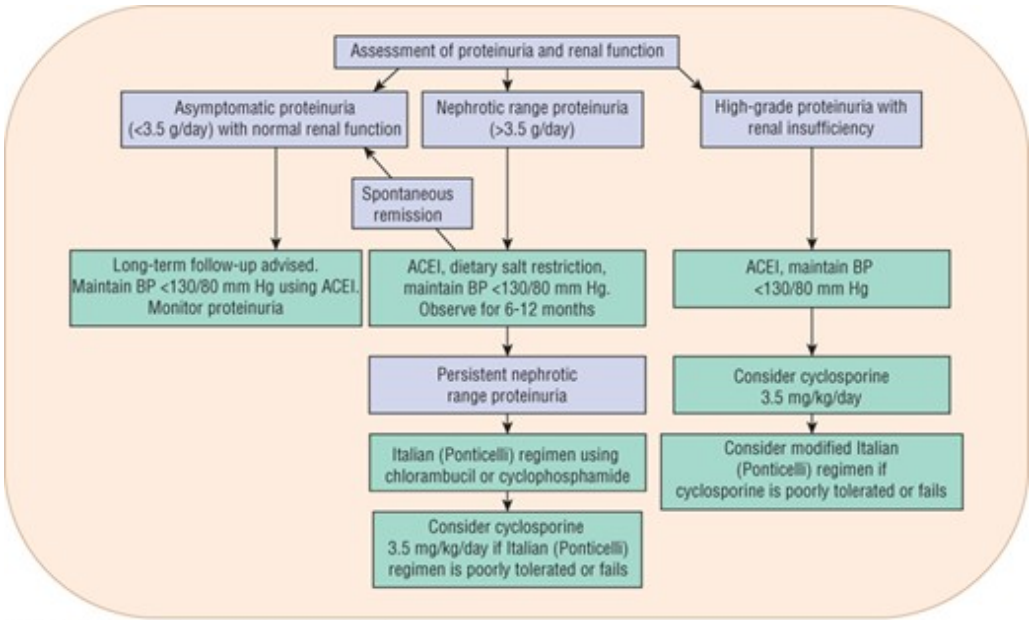
Treatment algorithm for idiopathic membranous nephropathy. *(Used with permission from Geddes CC, Cattran DC. The treatment of idiopathic membranous nephropathy. Semin Nephrol 2000;20:299-308. Copyright © 2000 Elsevier.)*



Pharmacologic Therapy

Due to the favorable long-term outcomes of patients presenting with mild disease, KDIGO guidelines recommend immunosuppressive therapy only for those with nephrotic syndrome, "severe, disabling or life-threatening symptoms" or with substantial elevation of serum creatinine within 6 to 12 months from time of diagnosis.[63] Since even partial remission of proteinuria improves long-term kidney and patient survival, inducing a lasting reduction of proteinuria is therefore the primary goal of treatment.

Steroids

Corticosteroids alone were ineffective in improving proteinuria remission rate in all controlled trials and in preventing progression.[64] The result of a meta-analysis also confirmed the lack of efficacy of steroids when used alone.[65]

Cytotoxic Agents

Cytotoxic agents, when used in conjunction with corticosteroids, are effective in increasing the remission rate of proteinuria and preserving renal function.[11] KDIGO guidelines recommend therapy based on a regimen developed by Ponticelli and colleagues: IV methylprednisolone (1 g) for 3 days followed by oral methylprednisolone (0.5 mg/kg) for the subsequent 27 days of months 1, 3, and 5; oral chlorambucil (0.15-0.2 mg/kg) or cyclophosphamide (2.0 mg/kg/day) daily in months 2, 4, and 6.[63,66] The 10-year renal survival with this regimen was 92% compared with 60% in the control group receiving only symptomatic therapy. Cyclophosphamide is preferred over chlorambucil for initial therapy, since both agents resulted in similar rates of proteinuria remission and relapse, but with fewer serious side effects in those who received cyclophosphamide.[67]

Results from a meta-analysis of randomized, controlled trials affirmed that cytotoxic agents, but not steroids, are effective in reducing nephrotic-range proteinuria, with cyclophosphamide having fewer adverse effects than chlorambucil.[64]

Calcineurin Inhibitors

Cyclosporine is effective in reducing proteinuria and rate of renal function decline as well as inducing remission of nephrotic syndrome. KDIGO guidelines recommend using cyclosporine (3.5-5.0 mg/kg/day orally in two equally divided doses 12 hours apart, with prednisone 0.15 mg/kg/day) or tacrolimus (0.05-0075 mg/kg/day orally in two divided doses 12 hours apart, without prednisone) for at least 6 months for those patients who have contraindications to receiving the cyclical 'Ponticelli' steroid/alkylating agent combination.[63] After attaining a response, the dosage can be reduced at 4 to 8 week intervals to about 50% of the starting dose and this regimen should then be maintained for at least 12 months. Serum drug concentrations should be monitored during initial therapy and when there is an unexplained rise in serum creatinine. Cyclosporine trough concentrations of 125 to 175 ng/mL (mcg/L; 104-146 nmol/L) and 2-hour post-dose concentrations of 400-600 ng/mL (mcg/L; 333-499 nmol/L) are generally considered nontoxic. Long-term use of calcineurin inhibitors may increase blood pressure and result in nephrotoxicity, especially in patients with preexisting renal function impairment.

Alternative Therapeutic Options

Because spontaneous remission is common and only approximately 25% of patients with new-onset idiopathic membranous nephropathy ultimately develop ESRD in 20 to 30 years, it is prudent not to aggressively treat all patients at the onset of the disease. Patients who have a low risk for renal disease progression can be managed with observation and symptomatic therapy. Normalizing the blood pressure and reducing proteinuria with ACEIs and/or ARBs are important as both hypertension and proteinuria are independent risk factors for the progression of renal failure.[61] Patients with low

risk for renal disease progression include children 2 to 16 years of age, adult males with proteinuria less than 2 g/day, or adult females with proteinuria less than 5 g/day and normal renal function.

In contrast, patients who have a high risk of developing renal failure, including those with proteinuria greater than 10 g/day with or without impaired renal function, and patients with symptomatic nephrotic syndrome with a plasma albumin of less than 2 g/dL (20 g/L) should be aggressively treated to induce remission. An alkylating agent such as cyclophosphamide or chlorambucil, combined with steroids, should be given to induce remission.

Recently, rituximab was shown to be effective in several small studies; however, randomized, controlled trials are not yet available to confirm its longer-term effects.[61,64] Treatment decisions should be made in light of the FDA black box warning for potentially fatal infusion reactions, mucocutaneous reactions as well as the risk for hepatitis B reactivation. Other monoclonal antibodies being evaluated include eculizumab, adalimumab, daclizumab, fresolimumab, belimumab and tocilizumab.[61]

Clinical Controversy…

Should mycophenolate mofetil be used in place of alkylating agent for initial treatment of idiopathic membranous nephropathy? Favorable results have been reported for mycophenolate mofetil by some investigators with conflicting efficacy by others.[64] It might be combined with steroid in place of an alkylating agent in the cyclical 'Ponticelli' regimen. However, the long-term efficacy of this combination has yet to be substantiated since relapse after mycophenolate mofetil treatment is frequent.

Tetracosactide, a synthetic analog of adrenocorticotropic hormone, as well as a natural highly purified ACTH gel, have been shown in small studies to offer favorable results.[68] Their mechanism of action in reducing proteinuria is not known. There might be a direct effect on podocytes since receptors for endogenous ACTH have been identified on the cells.

Relapse of Nephrotic Syndrome

Occurs in 25% to 30% of patients within 5 years after treatment with alkylating agents and 40% to 50% within 1 year after CNIs. KDIGO guidelines suggest reinstitution of the same regimen used for inducing the initial remission.[63]

Clinical Controversy…

Should patients with membranous nephropathy be given prophylactic anticoagulation? Patients with idiopathic membranous nephropathy are prone to developing deep vein thrombosis and pulmonary artery embolism. The quality of evidence supporting prophylactic anticoagulation is low, mainly based on Markov modeling of anticipated benefits and risks derived from observational studies. KDIGO guidelines suggest prophylactic warfarin for patients with nephrotic syndrome, serum albumin less than 2.5 g/dL (less than 25 g/L) and additional risk factors, such as BMI more than 35 kg/m^2, history of thromboembolism, documented genetic predisposition, NYHA class III or IV congestive

heart failure, recent abdominal or orthopedic surgery, prolonged immobilization.[63] However, the use of computerized algorithms in predicting morbidity and mortality has not been evaluated and there are many limitations that need to be considered.[69] Results from a randomized controlled trial are needed to elucidate the relative treatment benefits and risks.

Prognosis

The natural course of idiopathic membranous nephropathy is variable. Up to 30% of the patients experience spontaneous remission, commonly within 2 years of disease onset. Half of the remaining patients have persistent proteinuria with long-term preservation of renal function, while the other half has gradual loss of renal function. Heavy proteinuria (greater than 10 g/day), male gender, elevated serum creatinine concentration at the time of presentation; poorly controlled hypertension, advanced age at onset of disease, nonAsian race, certain human leukocyte antigen phenotypes, and tubulointerstitial fibrosis on initial renal biopsy are associated with progressive renal disease. A predictive algorithm, incorporating the level of proteinuria, initial creatinine clearance, as well as the slope of renal function decline over 6 months, has been developed to determine the risk for disease progression.[61]

In general, patients with idiopathic membranous nephropathy have a relatively benign course with mean 10-year survival of approximately 70%. Those who present with persistent nonnephrotic proteinuria seldom develop renal insufficiency and have a normal life expectancy. Fewer than 10% of patients develop a remitting and relapsing course. The prognosis for secondary membranous nephropathy depends on the underlying cause. Remission occurs when the infection resolves or when the causative medication is withdrawn. For patients with a transplanted kidney, both de novo and recurrent membranous nephropathy may occur. Patients with primary membranous nephropathy are more at risk. Recurrence is typically associated with nephrotic syndrome and a high risk of allograft failure from disease and/or rejection.

Membranoproliferative Glomerulonephritis

Etiology and Epidemiology

Membranoproliferative glomerulonephritis (MPGN) is one of the least-common renal morphologic entities that occur in older children and adults. Although it accounts for 7% to 10% of all case of biopsy-confirmed glomerulonephritis, MPGN is the third or fourth leading cause of ESRD among the primary glomerular diseases.[70] For some unclear reason, the incidence of MPGN has been decreasing over the past few decades in the United States and Europe. However, in Africa and Asia, idiopathic MPGN is still common, perhaps secondary to exposure to unrecognized infectious and parasitic agents.

Pathophysiology

Membranoproliferative glomerulonephritis is a “pattern of injury,” rather than a specific disease, caused by many disorders.[11] The several types of MPGN are classified according to the pathologic

features. Type I MPGN, also known as mesangiocapillary glomerulonephritis, is characterized by diffuse thickening of glomerular capillary walls and mesangial hypercellularity. Immune complexes are presumed to have a major role in the pathogenesis of type I MPGN, which is the most common type of primary, idiopathic MPGN.

Type II MPGN is also known as dense-deposit disease (DDD) because of the presence of dense deposits of C3 within the GBM, which gives rise to a ribbon-like appearance. Other variants of the disease include type III MPGN, which is seen rarely and consists of subendothelial and subepithelial deposits with lamination and disruption of the lamina densa of the GBM.

With the recent advances, MPGN is now classified according to the immunopathology, whether it is immune-complex-mediated or complement-mediated: Ig and C3 positive, C3 only or C3 dominant positive, and Ig and C3 negative.[70]

Clinical Presentation

Nephrotic syndrome is the most common presenting condition although some patients may also have a nephritic component (hematuria), hypertension, and progressive renal impairment. Hypocomplementemia is commonly seen.

TREATMENT

Pharmacological Treatment

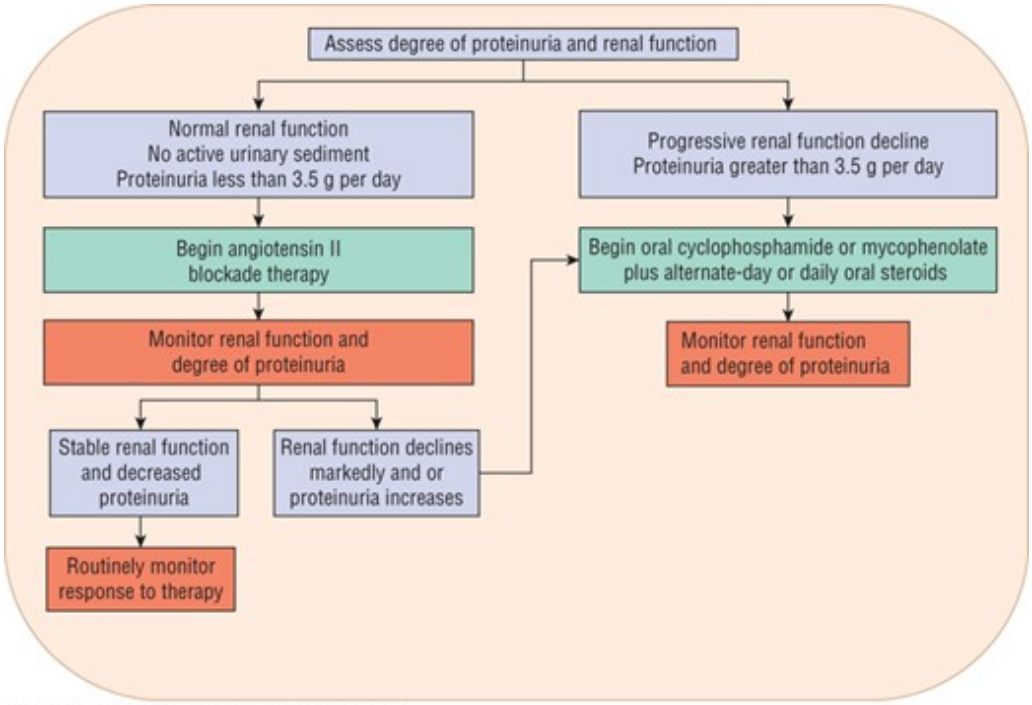
Steroids and Cytotoxic Agents

Results from small uncontrolled studies suggest that certain patients may benefit from various immunosuppressive regimens. However, the lack of randomized, controlled studies makes it difficult to make strong treatment recommendations.[70] For patients with idiopathic MPGN, nephrotic syndrome, and progressive decline of kidney function, the KDIGO guidelines recommend using oral cyclophosphamide or mycophenolate plus low-dose alternate-day or daily steroids for initial therapy trial of no longer than 6 months.[11]

In those with normal kidney function, no active urinary sediment, and nonnephrotic range proteinuria, one may use ACEIs to control blood pressure and reduce proteinuria in light of the favorable long-term outcomes.[70] Patients with secondary MPGN should receive therapy directed against the primary etiology. **Figure 47-5** presents an algorithm for a general approach for treatment and follow-up of MPGN.

FIGURE 47-5

Treatment algorithm for membranoproliferative glomerulonephritis.



Antiplatelet Agents

Although several studies have shown dipyridamole and aspirin to reduce proteinuria, reduction of GFR decline was not generally observed.[71] Consequently, the efficacy of antiplatelet therapy for idiopathic MPGN remains in doubt.[11] Similarly, the ability of heparin and warfarin, in combination with steroids and cytotoxic agents, to reduce renal function decline was not confirmed to be sustained.

Alternative Therapeutic Agents

Since steroids are not known to be effective for type II disease other yet-to-be-proven strategies such as rituximab, eculizumab, sulodexide, and plasma infusion or exchange may be considered.[72] It is difficult to conduct large-scale controlled trials for MPGN because of the low incidence of the disease. Based on the available studies, many of the drugs evaluated do not have any consistent, beneficial effect on renal function and proteinuria. Renal transplantation is an alternative; however, the recurrence rate is close to 100% for type II MPGN and is approximately 20% to 30% for type I MPGN. Half of the allografts ultimately fail.

Prognosis

Type I MPGN is a slowly progressive disease that accounts for 80% of all MPGN, but only 5% to 15% of all cases of nephrotic syndrome seen in pediatric and adult patients. It occurs most frequently for patients between 5 and 30 years of age, and because remissions are rare, many patients eventually develop ESRD. The renal survival is 60% to 65% at 10 years, and the presence of nephrotic syndrome, interstitial disease, and hypertension are poor prognostic indicators.[72] Type II MPGN is a more

aggressive disease that constitutes approximately 15% of all patients with MPGN. Only 20% of patients remain stable for more than a few years, and the median time before the development of ESRD is 7 years.

Immunoglobulin A Nephropathy

Etiology and Epidemiology

IgA nephropathy, also known as *Berger's disease*, was first described by Jean Berger in France in 1968. It now is the most common primary glomerulonephritis in the world and accounts for 10% of patients with ESRD in many countries. The prevalence among patients with glomerulonephritis or patients who had kidney biopsy varies from 30% to 35% to as high as 45% in Asia and 30% to 40% in Europe. In the United States, the overall prevalence is approximately 10% to 15% but is as high as 35% among Native Americans living in New Mexico.[73] These differences in prevalence may reflect variations in genetic predisposition, as well as the criteria used for urinary screening and kidney biopsy. The high biopsy rate tends to correlate with high frequency of the disease. Since the prevalence of clinically silent IgA nephropathy may be high, 16% in a study from Japan, the actual prevalence of the disease could be much higher than observed.[73]

IgA nephropathy is the most common primary glomerulapathy in young adult Caucasians[11] and is two to six times more common in males than in females. It is uncommon in blacks, both in the United States and in Africa.[73] IgA nephropathy was once thought to be a benign disease presenting with asymptomatic hematuria; however, its ability to present with any clinical syndrome associated with glomerular disease is now recognized. Some patients will develop ESRD over variable periods of time.

Pathophysiology

Primary IgA nephropathy is an immune-complex-mediated disease in which IgA deposits, either alone or with IgG, IgM or both as well as other pathologic lesions are found in kidney tissues. In contrast, Henoch–Schönlein purpura, a systemic disease that is believed to be closely linked to IgA nephropathy, shares similar immunohistologic findings in the kidneys. Both typically have vasculitis affecting the joints, skin, and GI tract, which may result from the same pathologic process of IgA nephropathy. The diagnosis of IgA nephropathy is established by the presence of mesangial IgA deposits upon immunofluorescence examination of the kidney biopsy. The IgA immune complex, composed of IgA antibody bound with an environmental antigen, such as a virus, bacteria, or food substances, is presumed deposited from the systemic circulation. Alternately, the complex may be formed in situ, with the IgA antibody bound with an endogenous antigen in the mesangium. In the mesangium, IgA can bind with receptors on the mesangial cells to induce proliferation and cytokine production. In addition, IgA can activate complement through the alternate pathway to induce glomerular damage. The extent of the injury depends on the characteristics of the IgA that favor mesangial deposition, the susceptibility of the mesangium toward deposition, the ability of the patient to mount an inflammatory response to the deposits, and the response of the kidney to the injury in a way that favors progressive renal damage. The key abnormalities and their implications on treatment was reviewed recently by Boyd et al.[74]

The Oxford histologic classification system has been developed to provide a uniform approach to biopsy evaluation and disease classification.[74,75] Further studies are needed to elucidate its ability to predict renal function loss and response to treatment.

Clinical Presentation

IgA nephropathy commonly presents in the second and third decades of life, but it can occur at any age. Many patients have microscopic hematuria and proteinuria for years, persistently or intermittently, during the early stages of the disease. In North America, about 75% of the patients present with gross hematuria concurrent with an infection, commonly in the upper respiratory or gastrointestinal tract.[73] The hematuria may occur 1 to 2 days after the onset of infection symptoms, which is different from the 10- to 14-day delay seen after the pharyngitis in PSGN. Proteinuria is common, and nephrotic range often indicates advanced disease. Hypertension and edema are infrequent but are common in PSGN.

Renal dysfunction is uncommon at the initial presentation; however, approximately 10% to 20% of the patients develop ESRD within 10 years, and 30% develop it after 20 years. The extent of proteinuria is one of the strongest predictors of poor long-term outcomes.[76] Uncontrolled hypertension, GFR reduction at disease presentation, and obesity are additional risk factors for developing renal failure.[11,76]

TREATMENT

General Approach to Treatment

Normotensive patients with normal renal function, isolated microhematuria, and minor proteinuria should be observed closely without specific treatment (**Fig. 47-6**).[76] Patients with minimal proteinuria of 0.5 to 1 g/day should receive optimized supportive therapy, using ACEIs or ARBs to attain BP of less than 130/80 mm Hg and urinary protein excretion of less than 500 mg/day.[27] However, the recently completed NIH-sponsored SPRINT trial showed that targeting a systolic blood pressure of less than 120 mm Hg, as compared with less than 140 mm Hg, resulted in lower rates of fatal and non-fatal major cardiovascular events and death from any cause.[20] As of this time, the authors do not have a separate recommendation for patients with CKD. Combined ACEI and ARB may be more effective than monotherapy; however, there is an increase in risk of adverse effects. For patients with persistent proteinuria greater than or equal to 1 g/day, the blood pressure goal would be less than 125/75 mm Hg, steroid therapy for 6 months should be used after 3 to 6 months of optimized supportive care and if the GFR is greater than 50 mL/min/1.73 m^2 (greater than 0.48 mL/s/m^2).[77] Fish oil may be used if desired. Immunosuppression should not be used for patients with GFR less than 30 to 50 mL/min/1.73 m^2 (less than 0.29-0.48 mL/s/m^2) because of the lack of trials to demonstrate beneficial effects.[76] Comprehensive support must be continued in these patients in an attempt to stabilize the renal function.

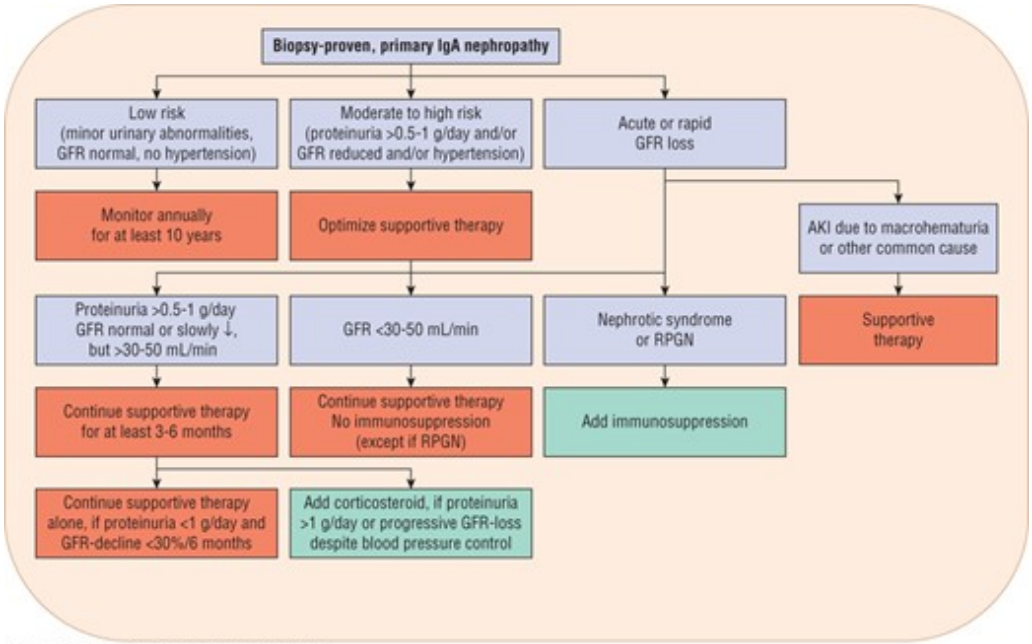
Treatment algorithm for biopsy-proven IgA nephropathy. Conversion form GFR units of mL/min to mL/s requires multiplication by 0.0167. *(Used with permission from Floege J, Eitner F. Current therapy for IgA nephropathy. J Am Soc Nephrol 2011;22:1785-1794.)*



Nonpharmacologic Therapy

Low-Gluten Diet and Tonsillectomy

Restriction of dietary gluten is effective for patients with celiac disease but not for patients with any identifiable nephritogenic antigens. Removal of the tonsils, which produce IgA_1 and may contribute to IgA nephropathy, may reduce proteinuria and hematuria, as shown in several small, nonrandomized trials in Japan.[74] However, such benefits were not seen in studies in Caucasians. Results from recent meta-analysis does not reveal efficacy when used alone.[78] The KDIGO guidelines therefore do not suggest using tonsillectomy for IgA nephropathy.[77] However, it may be helpful for patients who developed recurrent macroscopic hematuria as provoked by bacterial tonsillitis.

Pharmacological Therapy

Steroids

Corticosteroids with or without immunosuppressive agents have been used to treat IgA nephropathy for many years. A recent meta-analysis showed that steroid therapy is associated with reduction in proteinuria, risk for progression to ESRD, as well as the rate of renal function deterioration.[79] However, optimal antiproteinuric and antihypertensive therapy were not given in some of the studies.[77] Low-dose, short-term (less than 3 months) steroid therapy is not expected to yield favorable results. In contrast, larger doses of steroids (IV methylprednisolone 1 g/day for 3 days at months 1, 3, and 5 and oral prednisone 0.5 mg/kg every other day for 6 months) were able to reduce

proteinuria and renal function deterioration.[80] However, the risk for toxicity with such high doses of steroid might be considered high by some, yet the side effects were reported as minor.[80] The KDIGO guidelines therefore suggest a 6-month course of steroid for patients with persistent proteinuria greater than or equal to 1 g/day, despite 3 to 6 months of optimized supportive care and GFR of greater than 50 mL/min/1.73 m^2 (greater than 0.48 mL/s/m^2).[77]

Cytotoxic Agents and Mycophenolate Mofetil

Several studies have evaluated the efficacy of azathioprine and cyclophosphamide. In some of the studies, cyclophosphamide was used in conjunction with dipyridamole, heparin, and warfarin. It is difficult to assess which of these agents contributed to the limited favorable effects observed. In addition, in many of these studies, blood pressure control and ACE inhibition were not always optimal. At present, there is no clear evidence to support the use of these cytotoxic agents for IgA nephropathy[76] except for those with crescentic IgA nephropathy with rapidly deteriorating kidney function.[77]

Clinical Controversy…

Fish oil has been recommended by some while others have advocated the first-line use of mycophenolate mofetil for the management of patients with IgA nephropathy.

Mycophenolate mofetil has been evaluated for treating IgA nephropathy on the premise that it may reduce IgA synthesis and mesangial uptake and/or suppress the effects of proinflammatory or profibrogenic mediators.[81] Favorable results were observed in two studies in China; however, no such beneficial effects were seen in studies from Belgium or the United States.[77] These heterogeneous results, possibly due to differences in ethnicity and achieved drug concentrations, and the potential for adverse effects preclude to the widespread use of mycophenolate for IgA nephropathy.[77]

Fish Oil

The third approach is to reduce glomerular inflammation and glomerulosclerosis induced by IgA deposits. Antiinflammatory agents, antiplatelet drugs, and anticoagulants have been tried without success to decrease the production or action of mediators responsible for IgA immune-complex-induced glomerular damage. However, the *n*-3 fatty acids in fish oil reduce the production or action of prostaglandins and leukotrienes, thus limiting the renal damage caused by inflammation, platelet aggregation, and vasoconstriction.[27] In a controlled trial on patients with heavy proteinuria and mildly impaired renal function, daily use of fish oil delayed the progression of renal failure with modest reduction in proteinuria.[82] A meta-analysis of five controlled studies indicated that a minor, but not statistically significant, beneficial effect on renal function may be observed.[83] Results from several recent studies failed to confirm the beneficial effects reported earlier, and further studies are needed to confirm the role as well as the optimal dose. In many of the studies, 4 to 12 g/day were given for two or more years. Some of the fish oil preparations are rich in cholesterol; thus, it is appropriate to monitor the LDL cholesterol levels for patients receiving therapy. In view of the conflicting study results and the very low-risk profile, the KDIGO guidelines suggest using fish oil for

patients with persistent proteinuria of greater than or equal to 1 g/day, despite 3 to 6 months of optimized supportive care that includes ACEI or ARB and blood pressure control.[77]

Angiotensin-converting enzyme inhibitors and Angiotensin II receptor blockers

Because hypertension is a negative prognostic indicator of IgA nephropathy outcome and many of these patients already have left ventricular diastolic malfunction despite being normotensive, early antihypertensive intervention with ACEIs or ARBs is important.[73] Indeed, the KDIGO guidelines recommend using ACEI or ARBs for reducing proteinuria and blood pressure control.[76,77] Randomized controlled trials have shown that ACEIs and ARBs can reduce proteinuria and improve kidney function. However, the optimal duration of therapy for reducing the risk for ESRD is unknown. There are also no data to support if there is preference of ACEI over ARB, except perhaps a better side effect profile for ARB when compared with ACEI.[77] There are limited data to suggest that the combined use of ACEI with ARB may offer greater proteinuria reduction than monotherapy. However, further studies are needed to affirm such benefits for the combination therapy.

Alternative Therapeutic Approaches

Patients with IgA nephropathy have abnormal production of IgA and several different immunoglobulins. Immunoglobulins, administered IV initially and then intramuscularly, may have beneficial effects through immunomodulation, increased catabolism of autoantibodies, and blockade of receptors.[84] While favorable results were reported in one trial, large randomized controlled trials are needed to substantiate its efficacy.

Urokinase, danazol, dapsone, sodium cromoglycate, and plasma exchange have also been evaluated, but none is consistently effective nor shown to affect renal function. Cyclosporine, tacrolimus, sirolimus, and mizoribine have been evaluated in a limited number of studies; available results do not support its use for IgA nephropathy.

Antiplatelet agents are commonly used in Japan and rarely outside of Asia for IgA nephropathy.[85] A recent meta-analysis of seven trials (four in Japan and three in Hong Kong) revealed that these agents reduced proteinuria and stabilized renal function.[83] In view of the different agents and concurrent immunosuppressive regimens used among the trials, it would not be possible to derive a recommendation and the KDIGO guidelines do not recommend using these agents.[11]

Prognosis

The majority of the patients with IgA nephropathy have a clinically inconspicuous course and some may experience spontaneous remission. However, others may have an increase in proteinuria and decline in renal function. It is therefore important to follow the patients over a long period of time since progressive disease may appear in 30% of the patients.[76] Spontaneous remission is seen in only 10% to 25% of children and 5% to 7.5% of adults. Unfortunately, no therapy is known to be consistently effective for the treatment of IgA nephropathy. Because of the slow progression of the disease to ESRD, it is very difficult to conduct trials to evaluate the long-term effectiveness of specific

treatments. Since the pathophysiological mechanisms of this disease are not well defined, it has been difficult to design and evaluate results of clinical trials.[74]

Urinary protein excretion and the mean arterial blood pressure at follow-up correlate well with the progression of disease. The risk of developing ESRD is proportional to the amount of proteinuria, under the influence of ACEI and ARB therapy, after 1 year of follow-up.[86] For those patients who develop end-stage renal failure, transplantation is appropriate, especially for young adults. Recurrence of IgA mesangial deposits in the renal allograft may occur in up to 50% of patients in 5 years and be universally present at 10 years or more posttransplant, but the recurrence of clinical disease is only approximately 10% to 15%.[73] There is also no correlation between the aggressiveness of the primary disease and the rate of recurrence. Use of ACEI may improve graft survival[87] while immunosuppression with corticosteroids, azathioprine, and/or cyclosporine is not expected to prevent the recurrent nephropathy.[76] The KDIGO guidelines do not address the treatment of recurrent IgA nephropathy in patients who have received a kidney transplant. Applying the guidelines for treating native-kidney IgA nephropathy seems to be reasonable.[73]

Lupus Nephritis

Etiology and Epidemiology

Glomerulonephritis is one of the most serious complications of systemic lupus erythematosus (SLE) and accounts for much of the morbidity and mortality of patients afflicted with the disease. SLE predominantly affects young women between 15 and 40 years of age, with an incidence of 1 in 2,000 women in the United States. African Americans are more susceptible; they develop the disease at a younger age, have nephritis earlier in the course, and are more likely to progress to end-stage kidney disease.

The renal manifestations of lupus nephritis (LN) are variable and encompass a wide spectrum of histopathologic lesions.[88] The underlying histopathology is associated with different prognoses and responses to therapy, which cannot be predicted solely based on clinical manifestations. Thus, a renal biopsy is required to assess the severity of the disease and to predict the short-term and long-term outcomes associated with therapy. Drugs, such as hydralazine and procainamide, are known to precipitate a lupus syndrome; however, they are unlikely to cause disease that affects the kidney.

Pathophysiology

Immune complex deposits, whether formed in the circulation or in situ, can be found in various regions of the glomerulus, as well as the peritubular interstitium and vasculature outside the glomerulus. Based on light, immunofluorescence, and electron microscopy findings, LN can be categorized into six ISN/RPS (International Society of Nephrology/Renal Pathology Society) classifications: I, minimal-mesangial LN; II, mesangial-proliferative LN; III, focal LN; IV, diffuse LN; V, membranous LN; and VI, advanced sclerosing LN.[89]

The hallmark feature in the pathogenesis of SLE is B-cell hyperactivity and the dysregulated

production of autoantibodies against multiple antigens in the body, including DNA and various ribonucleoproteins.[88] The size and location of the immune complexes in the glomerulus correlate with the nature and severity of renal injury. Deposition of small numbers of stable immune complexes of intermediate size in the mesangium tends to produce less severe inflammation in the glomerulus. The sequestration of the immune complexes in the mesangium prevents them from activating inflammatory mediators. Hence, the lesion is noninflammatory in nature. In contrast, large numbers of intermediate-sized or large immune complexes result in infiltration of inflammatory cells and release of necrotizing enzymes. In addition, the kidney may also sustain damage through mechanisms related to thrombotic microangiopathy.

Clinical Presentation

Females have a higher risk for developing lupus, especially in the adult years. Nephritis is commonly seen within the first 4 years of diagnosis of SLE but may also be the first manifestation of the disease. The clinical presentation ranges from minimal hematuria and proteinuria to severe, rapidly progressive diffuse glomerulonephritis. Proteinuria is very common, and nephrotic syndrome is seen in most patients with membranous lesions. Microscopic hematuria is almost always present, whereas macroscopic hematuria, which commonly indicates severe renal involvement, is rare. Active urinary sediments (red cell casts, dysmorphic red cells, and hematuria) are suggestive of the diffuse proliferative lesion.[88] Hypertension is present in 25% to 45% of patients and is associated with a worse prognosis. Poor prognosis and higher risk for renal involvement were observed among African American, Hispanic, and Asian patients, compared with white and Puerto Rican–Hispanic patients.[11,90] Other conditions found to be associated with poor prognosis include elevated serum creatinine concentration, heavy proteinuria, anemia (hematocrit less than 26% [less than 0.26]), and disease onset during childhood or in those greater than 60 years of age. Most patients have hypocomplementemia and increased antibody titers for anti-double-stranded DNA, particularly those with focal or diffuse proliferative lesions. Serum creatinine concentration at the time of diagnosis is most predictive of short-term outcome.

TREATMENT

General Approach to Treatment

7 The choice of therapy depends on the underlying lesion and the activity, as well as the chronicity indices. Acute life-threatening disease involving multiple organs requires induction treatment that can suppress the disease promptly. In contrast, long-term management of chronic indolent disease requires therapy with more acceptable side-effect profiles. Corticosteroids are the cornerstone of therapy. However, for severe LN, primarily the diffuse proliferative type, alkylating agents may be needed to reduce or prevent the progression to ESRD. Newer alternatives with fewer side effects are now available.

Optimal blood pressure control is important. ACEIs or ARBs are commonly used to reduce proteinuria and blood pressure. It may also slow disease progression through reduction of inflammation and glomerular injury.[91] Patients with normal renal function and nonnephrotic range proteinuria (class I

LN and II LN) typically do not require therapy, except for the management of extrarenal lupus manifestations.[92,91] The prognosis of these patients is generally good, and renal biopsy can be delayed. However, close follow-up of renal function and urinalysis is required.

Acute Induction Treatment

Steroids and Cytotoxic Agents

Patients with nephrotic range proteinuria, deteriorating renal function, and/or active urinary sediments require a renal biopsy to define the underlying lesion and determine the activity and chronicity of disease. Patients with class II LN with proteinuria greater than 3 g/day, class III LN and class IV LN should be treated with steroids: oral prednisone of up to 1 mg/kg, followed by tapering over 6 to 12 months or pulse IV methylprednisolone followed by low-dose oral steroids.[92]

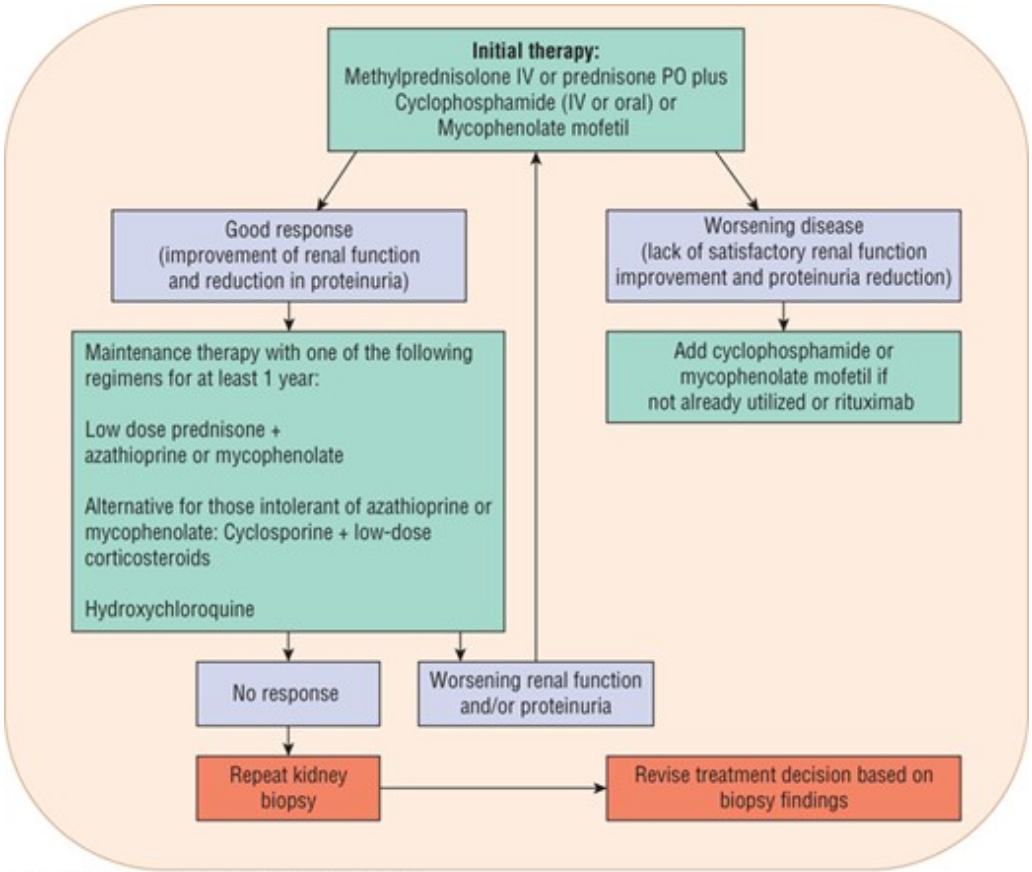
Cyclophosphamide is used concurrently because it is a powerful B-cell inhibitor and can suppress the resynthesis of autoantibodies to normal levels. Combined use of IV cyclophosphamide and methylprednisolone is more effective than either agent alone in inducing remission.[92,93] Alternately, cyclophosphamide may be given orally, but it was found by some to have more adverse effects because of higher cumulative exposure.[91] Azathioprine has also been used instead; however, it was reported to result in higher relapse rate and renal function decline.[92] The risk for adverse events, such as infection, gonadal damage, amenorrhea, and cervical dysplasia, and malignancy is increased with the cytotoxic regimens.

Mycophenolate Mofetil

Several trials have found that mycophenolate mofetil with concurrent steroid therapy is an effective agent for induction therapy.[94] It was as effective as cyclophosphamide in inducing remission but with fewer side effects. A recent meta-analysis of the literature corroborates to the fact that it is an excellent agent for the induction of remission and that continued use may reduce risk for death or development of ESRD.[90] Several recent trials that included African Americans, who are known to have a poorer prognosis, also show that mycophenolate mofetil was more efficacious than IV cyclophosphamide and resulted in fewer adverse effects.[91,95] Based on these data, mycophenolate mofetil is now considered an alternative to cyclophosphamide as initial therapy for patients with class III LN and class IV LN. However, cyclophosphamide may be preferred for severe class III/IV LN since the long-term outcome is not as well established for mycophenolate[92] (**Fig. 47-7**).

FIGURE 47-7

Treatment algorithm for class III (focal) and class IV (diffuse) lupus nephritis.



Chronic Maintenance Treatment

Steroids and Cytotoxic Agents

Oral steroid is commonly used as a component of maintenance treatment (less than or equal to 10 mg/day prednisolone).[91,92] Alternate-day regimens are often used in children to minimize growth retardation. Monthly pulse IV steroids in conjunction with cyclophosphamide resulted in more sustained remission, fewer relapses, and no significant increase in side effects.[96] Meta-analysis shows this combination to be more beneficial than steroid or cyclophosphamide alone. Cyclophosphamide, because of its bladder and gonadal toxicity, has been given as monthly and then bimonthly IV injection, instead of daily administration, for 2 or more years. However, toxicity is still a concern.

The efficacy of mycophenolate or azathioprine as maintenance therapy was evaluated against cyclophosphamide. Patients receiving mycophenolate or azathioprine were found to have better outcome and fewer side effects than cyclophosphamide. They are recommended by the KDIGO guidelines for maintenance therapy.[92] Depending on the study, mycophenolate was found to be either equivalent or better than azathioprine.[97,98] However, the drug should not be used during pregnancy since many lupus patients are women of child-bearing age.

Calcineurin Inhibitors

Cyclosporine may reduce proteinuria, stabilize renal function, and improve kidney morphology. It has been shown to have comparable efficacy and safety with azathioprine in preventing relapse for patients with diffuse proliferative LN.[99] It is recommended by the KDIGO guidelines for those who cannot tolerate the side effects of azathioprine or mycophenolate. Once initiated therapy should be continued for at least 1 year after complete remission is attained.[92]

Hydroxychloroquine

The antimalarial agent hydroxychloroquine can inhibit the toll-like receptors that contribute to autoimmunity. It was reported to be protective against the onset of LN, relapse of the disease, development of ESRD, venous thrombosis, and also a beneficial effect on lipid profiles.[92] Hydroxychloroquine is recommended by KDIGO guidelines for all patients of any class for those receiving the drug should have annual eye examination for possible retinal toxicity, especially after 5 years of continuous use.

Alternative Therapeutic Agents

Many new agents have been developed to target the various pathways, costimulatory molecules, and immune mediators responsible for the pathologic autoantibody production.[90] Ocrelizumab is an antiCD20 monoclonal antibody being evaluated as an adjunctive induction agent.[91] Abatacept, a selective T-cell co-stimulation modulator, is being studied as add-on induction therapy to cyclophosphamide or mycophenolate regimens. Belimumab, a monoclonal antibody that inhibits B-lymphocyte stimulating protein, appears to offer some promising effects for LN.[100] Abatecept, which may selectively modulate the CD80/CD86:CD28 costimulatory signal,[100] acthar gel, an ACTH formulation,[29] laquinimod (TV-5600 or ABR-215062), a oral immunomodulator that is a quinoline-3-carboxamide derivative, mizoribine, an imidazole nucleoside that inhibits *de-novo* purine synthesis and leflunomide, a lymphocyte proliferation inhibitor, are also currently being evaluated to gauge their role in the management of LN.[16,91]

Prognosis

The prognosis of patients with class II disease is generally good, and often no specific treatment is needed. For patients with class V disease, KDIGO guidelines recommend using antiproteinuric and antihypertensive medications. Steroids and immunosuppressives are used for extrarenal manifestations of systemic lupus and also for those patients with persistent nephrotic range proteinuria.[92] The survival of patients with classes III and IV disease has improved during the last two to three decades to approximately 74% to 80% at 10 years.[88] With the recent use of mycophenolate mofetil, better understanding of the optimal cytotoxic regimens, the use of lower steroid dosages, and better management of complications such as hypertension, infections, hyperlipidemia, and other metabolic complications of the disease, the long-term outcome has become more favorable. Lupus patients with end-stage kidney disease on dialysis fare as well as those with nonlupus-related renal disease. In those patients who received a renal transplant, the allograft outcome of patients with LN is favorable and comparable to those without lupus. Recurrence of lupus in the renal allograft can

occur but is usually of minor clinical importance.

Rapidly Progressive Glomerulonephritis

Etiology and Epidemiology

Rapidly progressive glomerulonephritis describes a clinicopathologic syndrome of rapid loss of renal function—usually a greater than 50% decrement of the GFR within 3 months. The predominant histologic finding of RPGN is extensive crescent formation, usually in more than 50% of the glomeruli. Hence, it is also known as *crescentic* glomerulonephritis. RPGN accounts for 2% to 7% of all renal biopsy findings and is responsible for up to 5% of patients with end-stage kidney disease. The age ranges of susceptible patients vary with the type of RPGN. For example, types I and II RPGN are more common in younger patients, whereas type III is seen more frequently in older individuals.

Rapidly progressive glomerulonephritis is not a single disease entity. A variety of glomerulonephritides with or without systemic diseases may present as RPGN, including anti-GBM glomerulonephritis, Goodpasture's syndrome, LN, PSGN, MPGN, IgA nephropathy, polyarteritis nodosa, Wegener's granulomatosis, and idiopathic crescentic glomerulonephritis.

Primary RPGN is categorized according to the immunofluorescence microscopic findings, indicating different immunopathogenesis, therapeutic approaches, and clinical outcomes. Type I is characterized by the linear localization of immunoglobulins, mainly IgG, along the GBM, signifying anti-GBM antibody-induced injury. Type II is defined by the coarse granular deposition of immunoglobulins and complement within the capillary walls and mesangium, indicating immune-complex–mediated injury. Type III is characterized by scanty or complete lack of immune complex deposits; consequently, it is also known as *pauci-immune RPGN*. Circulating ANCAs are often detected in type III RPGN.

Pathophysiology

Different etiologic factors are implicated as the cause of RPGN: toxins, drugs, viral and bacterial infections, neoplasms, autoimmune mechanisms, and various immunogenetic factors.[101] Regardless of the etiology and type of RPGN, damage in the glomerular capillary wall by both humoral and cellular pathways of inflammation is common. Activation of the terminal C5b-9 (membrane-attacking complex) of the complement system produces severe capillary wall injury. Proteinases and reactive oxygen species released by neutrophils and macrophages may result in severe glomerular injury. Platelets and the coagulation system are activated and result in capillary thrombosis. The ruptured capillaries release fibrinogen and procoagulants that may come into contact with thrombogenic tissue debris and lead to fibrinoid changes. In anti-GBM glomerulonephritis, the direct attack of the anti-GBM antibody on the GBM is responsible for the capillary wall injury.[101] For patients with ANCA-associated disease, the interaction of ANCAs with neutrophils and monocytes, which have been primed by concurrent infections or inflammatory processes, can lead to activation of these leukocytes and release of toxic oxygen species and lytic enzymes, resulting in vascular injury.

The disruption of the capillary wall allows movement of macrophages and other plasma constituents into Bowman's space and stimulates the formation of crescents, which are composed mainly of

parietal epithelial cells, as well as macrophages and fibroblasts. Crescent formation indicates the severity of the glomerular capillary disease but not its pathogenesis.

Clinical Presentation

Among the crescentic glomerulonephritides, the pauci-immune RPGN (type III) is the most frequent, accounting for more than 50% of cases, whereas the anti-GBM antibody-mediated RPGN (type I) is the least frequent, occurring in roughly 10% to 20% of patients. 60% to 70% of patients with type 1 RPGN may have concurrent pulmonary hemorrhage and Goodpasture's syndrome, which is caused by antibodies directed against the pulmonary alveolar basement membrane. Most patients with immune-complex–mediated RPGN (type II) have collagen vascular disease, systemic infections, or a severe form of primary glomerular disease. Approximately 70% of patients with type III RPGN also present with evidence of systemic vasculitis, such as Wegener's granulomatosis and polyarteritis nodosa. Some patients have only renal manifestations and are said to have idiopathic crescentic glomerulonephritis or renal vasculitis.

The clinical presentation is dominated by progressive renal insufficiency with complaints of tea-colored urine, malaise, anorexia, low-grade fever, and migratory polyarthropathy. Type I RPGN is more common in younger patients, whereas patients with ANCA-mediated disease tend to be older.[102] Urinalysis commonly shows nephritic sediments with hematuria, erythrocyte casts, and proteinuria. However, overt nephrotic syndrome is rare.

Serologic analysis is very useful in distinguishing the different types of RPGN. The detection of serum anti-GBM antibodies with the appropriate clinical presentation confirms the diagnosis of anti-GBM glomerulonephritis. More than 80% of patients with pauci-immune or idiopathic crescentic glomerulonephritis have circulating ANCAs. ANCAs are autoantibodies specific for the cytoplasmic constituents of neutrophil granules and monocyte lysosomes. Patients with ANCA-associated disease limited to renal involvement often have P-ANCA (perinuclear staining), whereas patients with Wegener's granulomatosis tend to have C-ANCA (cytoplasmic staining). Both the anti-GBM antibody and the ANCAs are absent in patients with type II RPGN. Measurements of circulating immune complexes are not useful for making a specific diagnosis, but detection of specific serum antibodies known to mediate immune-complex-associated nephritis is helpful, using anti-DNA antibody as a marker for LN and elevated antistreptolysin O (ASO) titers for PSGN.

TREATMENT

General Approach to Treatment

Early aggressive therapy has improved the renal prognosis of patients with crescentic glomerulonephritis. The rapid deterioration of renal function and the paucity of a large number of patients make randomized controlled studies very difficult to conduct. Based on the available data, immunosuppressive therapy alone appears to be ineffective for type I RPGN, while types II and III RPGN respond well to high-dose steroid therapy.[101,103] Because of the differences in response, the therapeutic approaches for each type of RPGN are presented separately below.

Specific Approaches to Treatment

Antiglomerular Basement Membrane Glomerulonephritis (Type I)

Steroids and cyclophosphamide, in conjunction with plasma exchange, are recommended by the KDIGO guidelines in all patients with anti-GBM glomerulonephritis except those who are dialysis-dependent, have 100% crescent in biopsy sample, and do not have pulmonary hemorrhage.[11] Plasma exchanges remove the pathogenic anti-GBM antibodies in circulation and are conducted for 2 weeks or until the antibodies disappear. Steroids (prednisolone 1 mg/kg/day, tapered over 6 months) and cyclophosphamide (2-3 mg/kg/day for 3 months) are then given to prevent new antibody production.[102,103] Patients with mild disease generally respond well to plasma exchange alone or immunosuppression (steroid and/or cytotoxic agents). For patients with severe disease (poor renal function and extensive crescent formation), most are expected to respond to the combination of plasma exchange and steroid/cytotoxic drug therapy. Pulse IV administration of corticosteroids (methylprednisolone 30 mg/kg/day for 3 days) has been used successfully to alleviate pulmonary hemorrhage, but the results are not as convincing for glomerulonephritis.[91,94] Because of the rapid decline in renal function, diagnosis should be established early so that therapy can proceed without delay. When the serum creatinine concentration is 6 mg/dL (530 µmol/L) or above or the patient is oliguric or requires dialysis, the response to therapy is usually poor, and the patient should be treated conservatively.[93,94] Poor response should also be expected when crescents are found in more than 85% of the glomeruli.

Immune-Complex-Mediated Glomerulonephritis (Type II)

Patients with postinfectious RPGN generally have a favorable prognosis even without treatment. Complete spontaneous recovery occurs in 50% of cases, whereas chronic renal failure develops in 32%.[101] Pulse doses of methylprednisolone (30 mg/kg/day, every other day × 3), followed by oral prednisone (1 mg/kg/day, tapered over several months) and then tapering, are beneficial in type II RPGN, with a response rate of 85% for patients with acute disease and 70% in those with more chronic disease.[101,103] Plasmapheresis does not appear to provide any additional benefit.[103]

Antineutrophil Cytoplasmic Autoantibody-Associated Glomerulonephritis (Type III)

Combined use of high-dose corticosteroids and cyclophosphamide induces remission in more than 90% of patients.[104] IV cyclophosphamide, possibly because of the lower cumulative dose administered, is associated with fewer infectious complications while being as effective as the oral route in inducing remission; however, the risk of relapse may be higher.[105] Because approximately 30% of the patients may relapse, cyclophosphamide also has been used for maintenance therapy. Rituximab and corticosteroids are recommended by the KIDGO guidelines as an alternative initial treatment in patients without severe disease or in whom cyclophosphamide is contraindicated.[11]

Maintenance therapy, using azathioprine or mycophenolate mofetil, is recommended for at least 18 months in patients who remain in remission, except those who are dialysis-dependent and have no

extrarenal manifestation of disease.[11] Trimethoprim-sulfamethoxazole is suggested to be used as an adjunct in patients with upper respiratory disease. However, etanercept is not recommended.

Mycophenolate mofetil and methotrexate are also being used, and they have been shown in limited studies to be effective.[103,105] Plasmapheresis is indicated for those with advanced kidney failure or diffuse pulmonary hemorrhage. However, its benefits for patients with better kidney function and mild to moderate disease is not clear.[11,105]

Renal Transplantation

Anti-GBM nephritis may recur in up to 55% of patients who received a renal transplant. However, only 25% of these patients showed clinical disease activity, with rare allograft failure. Because the frequency of recurrence and its severity are related to the presence of circulating anti-GBM antibody, it is recommended that transplantation should not be performed until the anti-GBM antibody is undetectable for at least 6 to 12 months. The recurrence rate of ANCA-associated nephritis is 17%, with the average time to relapse from transplantation of 31 months.[106]

Prognosis

Regardless of the type of RPGN, poor response to therapy and an ominous renal survival are expected if the patient presents with oliguria, has a serum creatinine concentration greater than 6 or 7 mg/dL (530 or 619 µmol/L), is dialysis dependent, or has a renal biopsy showing advanced chronic parenchymal disease.[104] For those patients who had received kidney transplant, recurrence of the disease is common.

Poststreptococcal Glomerulonephritis

Etiology and Epidemiology

PSGN and glomerulonephritis caused by other infectious agents, such as bacteria, viruses, and parasites, were once common. Improved sanitation, personal hygiene, medical care, and public health measures helped to decrease the incidence of group A streptococcal infection both in the United States and in other developed countries, resulting in a decline of PSGN. In contrast, glomerulonephritis secondary to other infectious agents, such as hepatitis C and HIV, is seen with increasing frequency.

PSGN is now the most common form of glomerulonephritis in children but is less common than the other types of glomerulonephritis in adults. PSGN is seen mostly in children aged between 5 and 15 years and is uncommon in children younger than 2 years of age and in adults older than 50 years of age. It normally follows pharyngeal or skin infection caused by the nephritogenic strains of group A streptococci; however, other strains of streptococci, such as groups C and G, have also been reported to cause PSGN. Streptococcal pharyngitis is more common in winter and early spring, whereas skin infection is frequently found in the summer. The risk for developing acute glomerulonephritis secondary to the nephritogenic strains of bacteria is approximately 10% to 15% for infected patients.

However, three to four times more patients may experience a subclinical form of the disease.

Pathophysiology

Streptococcal antigens may induce changes in the glomerular components rendering them immunogenic or autologous IgG may be altered to become antigenic. Alternately, the streptococcal antigens may induce antibodies that react with glomerular antigens. In situ immune complexes are then formed and result in a complement-mediated inflammatory response. The kinin and coagulation cascades are activated, and chemotactic factors are released to recruit neutrophils and monocytes, resulting in acute glomerular lesions.

Examination of the acute PSGN kidneys reveals hypercellular glomeruli with proliferation of mesangial and endothelial cells. Infiltration of neutrophils, monocytes, and eosinophils is apparent within the capillary lumen and also in the mesangial areas. Crescent formation may be seen for patients with severe disease, and if found in more than 30% of the glomeruli, RPGN may be present concurrently.[107] The prognosis is generally poor for these patients, and complete recovery is unlikely. Immunofluorescence examination reveals diffuse granular deposits of IgG and C3 along the GBM and also in the mesangium.

Clinical Presentation

The nephritis is preceded by a latent period following a streptococcal infection. The latent period is commonly 7 to 14 days for pharyngitis and 14 to 28 days for skin infection. An acute nephritic syndrome then develops, commonly with hematuria and edema. Gross hematuria is seen in 70% of patients, and microscopic hematuria can be found in all patients. Hypertension is usually mild to moderate and results from sodium and water retention. Many patients have signs and symptoms associated with volume overload, which include dyspnea, orthopnea, and cough. Urinalysis of patients with PSGN reveals hematuria, dysmorphic red blood cells, and red cell casts. Proteinuria is common but often not in the nephrotic range. Renal function is frequently mildly impaired.

Throat or skin culture may be positive for group A streptococci, despite the latent period following the initial infection. However, antibiotic therapy may render the culture result negative. Serologic measurements of antibodies to different streptococcal antigens can confirm recent exposure to the infection. Titers that can be measured include ASO, antistreptokinase, antihyaluronidase (AHase), antideoxyribonuclease B (ADNase B), and antinicotyladenine dinucleotidase (NADase).[108] For most patients with streptococcal pharyngitis, the ASO titers begin to rise about 10 to 14 days later, peak at 3 to 4 weeks, and persist for several months before decreasing. The rise in ASO titers can be reduced by antibiotic treatment and may not be seen for patients with streptococcal skin infection in whom the streptolysin may be bound to skin lipids. ADNase B and AHase titers should be used instead because they are specific and are positive in the majority of patients. The streptozyme test is a combined assay for ASO, ADNase B, NADase, and AHase. Antibodies to other antigens such as zymogen, streptococcal cationic proteinase exotoxin B (SPEB), and plasmin receptor (Plr) were evaluated recently.[109]

Serum complement levels are often decreased for patients with PSGN. If the C3 level is depressed for

more than 6 to 8 weeks, MPGN, LN, or glomerulonephritis related to endocarditis or occult visceral abscess should be suspected. Renal biopsy is not normally indicated unless the patient has prolonged hematuria, proteinuria, or depressed C3 level. Renal biopsy is needed to detect other types of glomerulonephritis such as lupus, RPGN, or MPGN.

TREATMENT

General Approach to Treatment

8 The treatment of PSGN is mainly supportive and symptomatic. Early antibiotic therapy does not prevent subsequent PSGN, but it may reduce the severity of the disease. It can, however, prevent the spread of the streptococcal infection to other family members. Antibiotic prophylaxis is not recommended because infected patients will develop long-lasting, often lifelong immunity against the strain of streptococci. Exposure to another nephritogenic strain of streptococci is possible, but unlikely.

Supportive measures should be used to control fluid volume and blood pressure. Because the hypertension is of the low-renin type, ACEIs and β-blockers are not expected to be useful. If the patient has crescentic disease, use of pulse steroids and/or immunosuppressive agents can be considered; however, the efficacy and safety of these agents have not been established for this condition.

Prognosis

The acute manifestations of PSGN are normally self-limited, and for more than 95% of patients renal function has returned to baseline within 3 to 6 weeks. Diuresis usually begins 7 to 10 days after onset of the acute episode, whereas hypertension and azotemia resolve in 1 to 2 acute. Gross hematuria lasts for 1 to 2 weeks, and proteinuria usually resolves within 6 months in more than 90% of children. However, microscopic hematuria may persist for up to 2 years. In general, children have more rapid recovery than adults. Prognosis is often better when PSGN occurs during an epidemic than in cases found sporadically. Most of the children will recover fully and be free from chronic complications of PSGN if they have no preexisting renal disorder, heavy proteinuria, or crescentic glomerular lesions or did not require hospitalization during the acute episode. In contrast, adult patients have a less favorable long-term outcome. As many as 50% of the patients may develop persistent proteinuria, hypertension, and renal insufficiency, with some resulting in end-stage renal failure.

CLINICAL BOTTOM LINE

A better understanding of the pathogenetic mechanisms leading to glomerular injury has led to marked improvements in the treatment of glomerulonephritis. However, the glomerulopathies are a heterogeneous group of immune disorders with different clinical courses, prognoses, and responses to current immunologic and nonimmunologic therapies. The optimal treatment strategy for individual patients should therefore be personalized based on the natural history and prognosis of each type of glomerulonephritis, the efficacy of different immunomodulation regimens in inducing

disease remission and preserving renal function, as well as the characteristics of at-risk patients who warrant aggressive therapy. Judicious use of immunosuppressive agents with careful monitoring of their adverse effects cannot be overemphasized. In addition, treatment of the disease complications and control of factors that lead to progression of renal disease are important in reducing the morbidity and mortality of patients with glomerulonephritis. The KDIGO guidelines offer clinicians many evidence-based recommendations that are useful for making individual patient treatment decisions. Since few randomized controlled trials are available for many of the glomerulonephritis, specific recommendations and suggestions based on sound evidence are currently not available.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ACE	angiotensin-converting enzyme
ACEI	angiotensin-converting enzyme inhibitors
ACTH	adrenocorticotropic hormone
ADNase B	antideoxyribonuclease B
AHase	antihyaluronidase
ANCA	antineutrophil cytoplasmic autoantibody
ARB	angiotensin II receptor blocker
ASO	antistreptolysin O
BSA	bovine serum albumin
DDD	dense-deposit disease
DRIs	direct renin inhibitors
ESRD	end-stage renal disease
GBM	glomerular basement membrane
GFR	glomerular filtration rate
FSGS	focal segmental glomerulosclerosis
HIV	human immunodeficiency virus
HMG-CoA	β-hydroxy-β-methylglutaryl-coenzyme A
LDL	low-density lipoprotein (cholesterol)
MPGN	membranoproliferative glomerulonephritis
NADase	antinicotyladenine dinucleotidase
NEP	neutral endopeptidase
NSAIDs	Nonsteroidal antiinflammatory drugs
PSGN	poststreptococcal glomerulonephritis
RAS	renin-angiotensin system
RPGN	rapidly progressive glomerulonephritis
SLE	systemic lupus erythematosus
VLDL	very-low-density lipoprotein (cholesterol)

Chapter 48: Drug Therapy Individualization for Patients with Chronic Kidney Disease

FIGURE 48-1

Marisa Battistella; Gary R. Matzke

INTRODUCTION

KEY CONCEPTS

- 1 Chronic kidney disease (CKD) results in minimal alterations in the absorption or bioavailability of most drugs.
- 2 The volume of distribution (V_D) of many drugs is increased in the presence of acute and CKD as a consequence of volume expansion and/or reduced protein binding.
- 3 In addition to the expected decrement in renal clearance, nonrenal clearance (ie, gastrointestinal and hepatic drug metabolism) of several drugs is also reduced in CKD patients.
- 4 Individualization of a drug dosage regimen for a patient with reduced kidney function is based on the pharmacodynamic/pharmacokinetic characteristics of the drug, the patient's degree of residual renal function, and their overall clinical condition.
- 5 The drug dosing guidelines for CKD patients in many drug information resources are highly variable and many are not optimal for clinical use.
- 6 The effect of hemodialysis (HD) or peritoneal dialysis on drug elimination is dependent on the characteristics of the drug and the dialysis prescription.
- 7 HD clearance data can be used to guide the initial drug dosage regimen recommendation for HD patients; however, prospective monitoring of serum concentrations is often warranted especially for narrow therapeutic index drugs.

Chronic kidney disease (CKD) is defined by the presence of abnormalities of kidney function or structure.[1] In its earliest stages it is characterized by either an estimated glomerular filtration rate (eGFR) less than 89 mL/min/1.73 m^2 or the persistence of one or more markers of kidney damage (eg, albuminuria) for more than 3 months in those with eGFR more than or equal to 90 mL/min/1.73 m^2. (see Chapters e42 and 44)[1] The Kidney Disease: Improving Global Outcomes (KDIGO) guidelines for evaluation and management of CKD eGFR and albuminuria categories are outlined in Tables 44-1 and 44-6. It is estimated that 10% to 15% of the global population has CKD and the number of deaths from CKD has risen by more than 80% in the past two decades.[2,3,4] The prevalence varies widely across the world in part because of true differences in the prevalence of CKD; heterogeneity of the laboratory methods used to detect CKD; environmental factors, public health policies, and genetics.[4] The incidence of CKD has more than doubled in the past 20 years in adults older than 65 years.[5] In part due to age-related reductions in kidney function, multiple medical comorbidities, and an increased use of medications that alter kidney function. Many drugs are predominantly eliminated by the kidney and even those that are highly metabolized may require dose adjustment in CKD patients to maximize therapeutic outcomes and to minimize adverse events. Medications which are predominantly renally eliminated unchanged (f_e) may accumulate in CKD patients, which can increase the risk of adverse effects. If 30% or more of a drug is eliminated unchanged in the urine, it will have a high likelihood of requiring dosage regimen adjustment in CKD patients, especially those with stage 3 to 5 disease.[6,7]

The pharmacokinetics of drugs with a fraction of drug eliminated unchanged in the urine less than 30% also may be affected and thus require a dose adjustment. In fact 32.2% of such drugs approved in the United States from 1998 to 2010 had a dosage-adjustment recommendation for CKD patients in the product labeling.[7] If there is no official dosage regimen recommendation in the product labeling, an adjustment may be calculated on the basis of the drug's f_e and the ratio of the patient's residual renal function relative to an age and gender normal value for estimated creatinine clearance (eCL_{cr}) or eGFR.[7,8] Despite increased conduction of renal studies by industry and improvements in approved product labeling language, challenges remain for dose adjustments in CKD patients especially for oncology and anti-retroviral agents.[7] Furthermore, physiologic and biochemical changes such as increased or decreased protein binding, altered cytochrome P450 enzyme activity, and transcellular transport systems that are associated with CKD may also independently impact serum and tissue drug concentrations and necessitate drug dosing adjustments.[6,9] Therefore in CKD patients, the dosage regimens of many drugs must be altered to prevent toxicity, without compromising the achievement of the desired therapeutic benefit.[6]

For medications that are extensively metabolized or for which dramatic changes in protein binding and/or distribution volume (V_D) have been noted, a complex adjustment strategy may need to be employed.[6,9] Despite extensive published evidence, dosing errors in CKD patients still occur at an alarming rate.[10,11,12,13] Studies have shown that the expanded use of electronic medical records has not resolved the need for clinician proactivity to optimize the use of medications in CKD patients; in these studies, up to 85% of the medications ordered had nephrotoxic potential and greater than 20% of the drugs ordered were not dose adjusted for the patient's kidney function.[14,15,16]

Clinicians thus will often need to design individualized therapeutic regimens to optimize achievement of the desired outcomes. In this chapter, the influence of CKD on absorption, distribution, metabolism and elimination of medications is characterized. A general approach to individualizing drug therapy for CKD patients is presented along with dosage recommendations for the most commonly used drugs in this patient population. Finally, the impact of chronic renal replacement therapy (ie, peritoneal dialysis and HD) on drug disposition is discussed and dosage recommendations for selected drugs are presented. Drug dosage regimen adjustment strategies for patients with acute kidney injury (AKI) including those who are receiving continuous renal replacement therapy are presented in Chapter 43.

PHARMACOKINETIC CHANGES IN CHRONIC KIDNEY DISEASE

The absorption, distribution, metabolism, and renal excretion of many drugs is altered by CKD. An understanding of why and how these processes are impacted by CKD provides a framework to project the influence of CKD on emerging drug therapies. In addition, when known, these effects can be factored into the clinician's dosage recommendations for individual CKD patients including those who are receiving chronic renal replacement therapy.

Drug Absorption

1 There is little quantitative information regarding the influence of CKD on drug absorption and bioavailability. The few studies evaluating the absorption of oral medications in CKD patients were not designed to provide an assessment of the drug's absolute bioavailability (eg, they did not include a comparison of the area under the concentration–time curve [AUC] after oral and intravenous [IV] administration of the drug). Rather, the principal outcomes that were documented were alterations in the peak concentration (C_{max}), time at which the peak concentration was attained (t_{max}), or the fractional amount of drug recovered in the urine in a finite time period.[17]

The absorption and bioavailability of some drugs is highly variable in CKD patients. The mechanisms responsible are multifactorial and include; drug interactions, delayed gastric emptying, and reduced gastric acidity. Decreased gastrointestinal (GI) motility secondary to gastroparesis in patients with diabetes may delay the t_{max} and may also reduce the C_{max}. For instance if a drug undergoes GI metabolism the slower transit time allows for more GI metabolism and thus lower C_{max} of the parent drug. Urea retention in CKD patients results in a high influx of urea into the gut, which in turn results in conversion of urea to ammonia by gastric urease. The subsequent increase in gastric pH may alter the dissolution or ionization properties of weakly basic drugs such as diazepam leading to changes in absorption.[18] A reduction in gastric acidity, that is, an increase in GI pH, associated with the concomitant administration of antacids, H_2-receptor antagonists, proton pump inhibitors, and phosphate binders has been associated with a reduction in bioavailability of several antibiotics and digoxin.[18] Finally antacids and vitamin supplements may decrease the bioavailability of some drugs as a result of the formation of insoluble salts or metal ion chelates.[19] Although this is not a disease-specific effect, since CKD patients are frequently taking these medications, the associated drug interactions will impact the absorption of other drugs. Edema of the GI tract, secondary to cirrhosis or

congestive heart failure that may be present in CKD patients, can also decrease the absorption of some medications, such as oral furosemide for which a decrease from 50% to 10% has been reported.[19]

The bioavailablity of only a few drugs (eg, dextropropoxyphene, dihydrocodeine, felodipine, sertraline, and cyclosporine) has been documented to be increased in CKD patients.[20,21,22] For these drugs, the mechanism is a reduction in metabolism during the drug's first pass through the GI tract and liver. Drug interactions can also independently alter bioavailability. Bioflavonoids in grapefruit juice can inhibit cytochrome P450 3A4 and noncompetitively inhibit the metabolism of drugs metabolized by this enzyme; this interaction can increase the bioavailability of cyclosporine by as much as 20%.[23,24,25]

Distribution

2 A drug's volume of distribution reflects the extent of distribution throughout the body. The V_D of many drugs is increased in category G3a, G3b, G4, and G5 CKD patients as well as those with preexisting CKD who develop AKI (**Table 48-1**) and can lead to a reduction in serum drug concentrations.[6,9,26,27,28] This increase in V_D may be the result of pathophysiologic alterations in body composition, fluid overload secondary to excessive fluid administration or intake, decreased protein binding, or increased tissue binding. Decreased tissue binding of drugs in CKD patients may result in a reduction in V_D, which has been reported for only a few medications (eg, digoxin and pindolol).[26]

TABLE 48-1 Volume of Distribution of Selected Drugs in Patients with ESRD

Drug	Normal (L/kg)	ESRD (L/kg)	Change from Normal
Increased			
Amikacin	0.20	0.29	45%
Cefazolin	0.13	0.17	31%
Cefoxitin	0.16	0.26	63%
Ceftriaxone	0.28	0.48	71%
Cefuroxime	0.20	0.26	30%
Doripenem	0.25	0.47	88%
Dicloxacillin	0.08	0.18	125%
Erythromycin	0.57	1.09	91%
Furosemide	0.11	0.18	64%
Gentamicin	0.20	0.32	60%
Isoniazid	0.60	0.80	33%
Minoxidil	2.60	4.90	88%
Naproxen	0.12	0.17	42%
Phenytoin	0.64	1.40	119%

Drug	Normal (L/kg)	ESRD (L/kg)	Change from Normal
Trimethoprim	1.36	1.83	35%
Vancomycin	0.64	0.85	33%
Decreased			
Atenolol	1.20	0.90	25%
Chloraphenicol	0.87	0.60	31%
Ciprofloxacin	2.50	1.95	22%
Digoxin	7.30	4.00	45%
Ethambutol	3.70	1.60	57%
Methicillin	0.45	0.30	33%
Metoprolol	5.60	1.00	82%
Pindolol	2.10	1.10	48%
Propranolol	4.40	3.60	18%

ESRD, end-stage renal disease.

Data from references 26 and 28.

Variability in fluid status is a common issue in patients with severe CKD (category G4 and G5), especially those that are critically ill. Many critically ill patients receive large volumes of IV fluids for resuscitation from shock, and can subsequently develop edema, pleural effusions, or ascites. These therapeutic interventions, in addition to reduced water excretion due to AKI or CKD, often lead to an increase in a drug's V_D and a decrease in its serum concentrations. This is especially problematic with hydrophilic drugs, such as aminoglycosides and cephalosporins for which the V_D may be increased by up to 150%.[29,30]

Effect of Altered Plasma Protein Binding

Protein binding limits drug distribution as only unbound or "free" drug is able to cross cellular membranes and distribute outside the vascular space. Many drugs have been reported to exhibit altered protein binding in CKD patients.[31,32] Protein binding of many acidic drugs such as penicillins, cephalosporins, aminoglycosides, furosemide, and phenytoin is reduced secondary to hypoalbuminemia, qualitative changes in the conformation of the protein binding site, and/or competition for binding sites by other drugs, metabolites, and endogenous substances.[26,32] The result of a decrease in protein binding is an increase in the apparent V_D. A new equilibrium is ultimately established as a result of increased drug elimination/distribution, such that the unbound concentrations remain comparable to those observed in patients with normal renal function despite the fact that total concentrations are reduced. Thus, the net effect is an alteration in the relationship between total drug concentration and pharmacodynamic effect. For example, protein binding of phenytoin (90% protein-bound, primarily to albumin) is significantly reduced secondary to decreased plasma phenytoin binding affinity for albumin, as well as low serum albumin: these changes alter the relationship between total phenytoin concentration and desired and toxic effects.[31] The resulting

increase in unbound fraction, from values of 10% in those with normal renal function to 20% or more in those with G5 CKD, results in increased hepatic clearance and decreased total concentrations. Thus, in patients with CKD, the therapeutic range based on total phenytoin concentration is shifted downward from normal values of 10 to 20 mg/L (mcg/mL; 40-79 µmol/L) to values as low as 4 to 8 mg/L (mcg/mL; 16-32 µmol/L). Since the unbound concentration therapeutic range is the same for all patients, 1 to 2 mg/L (mcg/mL; 4-8 µmol/L), this measurement provides the best target for individualizing phenytoin therapy in patients with CKD.

One can approximate the total phenytoin concentration that would be observed in category G5 CKD patients if they had normal plasma protein binding ($C_{normal\ binding}$). The estimated $C_{normal\ binding}$ total phenytoin concentration can then be interpreted in light of the usual total therapeutic range to assess the patient's response to therapy.[31]

For normal or low albumin (concentration expressed in g/dL) and category G5 CKD:

$$C_{total\ normal\ binding} = C_{total\ reported}/[(0.9)(0.48)\ (albumin/4.40)] + 0.1$$

where $C_{normal\ binding}$ = total phenytoin concentration that would be observed if patient had normal protein binding. $C_{reported}$ = patient's total phenytoin concentration reported by laboratory (represents decreased plasma protein binding).

For albumin expressed in g/L the equation becomes:

$$C_{total\ normal\ binding} = C_{total\ reported}\ /[(0.9)(0.48)\ (albumin/44)] + 0.1$$

The principal binding protein for several basic drugs is α1-acid glycoprotein, an acute-phase reactant protein, whose plasma concentrations are increased in CKD patients.[6] As a result of this increase, the unbound fraction of some basic drugs (eg, bepridil, disopyramide) may be significantly decreased and the V_D increased in CKD patients, especially renal transplant and HD patients.[6]

Effect of Altered Tissue Binding

Distribution also may be affected by altered tissue binding of drugs in CKD patients; this is relatively rare and limited to few drugs, such as pindolol, ethambutol, and most notably digoxin.[26] The V_D of digoxin is decreased by up to 50% in patients with category G5 CKD, leading to elevated serum concentrations.[33] In this case, the absolute amount of digoxin bound to the receptor is reduced and the resultant serum digoxin concentration is higher than anticipated. Thus, in CKD patients, particularly in those with category G5, a "normal" total drug concentration may be associated with either an adverse reaction secondary to elevated unbound drug concentrations, or a subtherapeutic response because of an altered plasma-to-tissue drug concentration ratio. The monitoring of unbound drug concentrations in CKD patients is thus warranted for those drugs that have a narrow therapeutic range, are highly protein bound (unbound fraction of less than 20%), and for which marked variability in the unbound fraction has been reported (eg, phenytoin and disopyramide).

Effect of V_D Calculation Method

Finally, the method used to calculate the volume of distribution may be influenced by renal insufficiency. The three most commonly used volume of distribution terms are: volume of the central compartment (V_c), volume of the terminal phase (V_β and V_{area}), and volume of distribution at steady state (V_{ss}). The V_c for many drugs approximates extracellular fluid volume and thus may be increased or decreased by acute changes. Oliguric AKI is often accompanied by fluid overload and a resultant increased V_c for many drugs. The V_{area} or V_β represents the proportionality constant between plasma concentrations in the terminal elimination phase and the amount of drug remaining in the body. V_β is affected by both distribution characteristics, as well as by the terminal elimination rate constant. V_β and V_{ss} will often be similar in magnitude, with V_β being slightly larger. Because V_{ss} has the advantage of being independent of drug elimination, it is the most appropriate volume term to use when one desires to compare drug distribution volumes between patients with renal insufficiency and those with normal renal function.[34]

ELIMINATION

Elimination of a drug from the body is characterized in pharmacokinetic terms as total systemic clearance (CL_T), which is the sum of all organ clearances. Typically CL_T is defined simply as the sum of renal clearance (CL_R) and nonrenal clearance CL_{NR}.[6,9]

Renal Clearance

Kidney function is the most quantifiable determinant of drug clearance. It is important to note that the term "kidney function" includes the combined processes of glomerular filtration, tubular secretion, and reabsorption, as well as endocrine and metabolic functions. Alterations in any or all of these functions secondary to CKD may have a dramatic effect on drug disposition (see Chapter e42). Reduction in kidney mass, the number of functioning nephrons, renal blood flow, GFR, and/or the rate of tubular secretion and reabsorption all contribute to the decreased renal excretory capacity observed in those with CKD.

Renal clearance (CL_R) of a drug is the composite of GFR, tubular secretion, and reabsorption ($CL_R = [GFR \times f_u] + [CL_{secretion} - CL_{reabsorption}]$), where f_u is the fraction of the drug unbound to plasma proteins. Drug elimination by filtration occurs by diffusion; while tubular secretion and reabsorption are bidirectional processes that involve carrier-mediated renal transport systems.[35] Renal transport systems have been broadly classified on the basis of substrate selectivity into the anionic and cationic renal transport systems, which are responsible for the transport of a number of organic acidic and basic drugs, respectively (**Table 48-3**).[26,35] Several drugs are actively secreted by one or more of these transporter families, which include organic cationic (eg, famotidine, trimethoprim, and dopamine), organic anionic (eg, ampicillin, cefazolin, and furosemide), nucleoside (eg, zidovudine), and P-glycoprotein (Pgp) transporters (eg, digoxin, vinca alkaloids, and steroids).[35,36] Alterations in filtration, secretion, or reabsorption, secondary to CKD may have a dramatic effect on drug disposition: for drugs that are primarily filtered, a reduction in GFR will result in a proportional decrease in renal drug clearance.

Nonrenal Clearance

3 The effect of CKD on CL_{NR} is less clear than its impact on CL_R, but there has been an increased interest and plethora of new findings in this area in recent years.[26,36,37,38] CL_{NR} encompasses all routes of drug elimination, excluding renal excretion of unchanged drug, and includes hepatic and extrahepatic metabolism and altered transcellular transport pathways (see **Tables 48-2** and **48-3**). It is mediated largely by renal disease effects on many cytochrome P450 (CYP) metabolic enzymes, such as CYP3A, and transporters including Pgp, organic anion-transporting polypeptides (OATPs), and multidrug resistance-associated proteins in the GI tract and hepatobiliary system.[36,37]

TABLE 48-2 Impact of ESRD on CL_{NR} of Selected Drugs

Drug Name	Decreased Change in CL_{NR}
Acyclovir	50%
Aztreonam	33%
Bupropion	↓
Captopril	50%
Carvedilol	↓
Cefotaxime	40%
Ceftriaxone	↓
Cimetidine	46%
Ciprofloxacin	33%
Doripenem	↓
Erythromycin	↓
Imipenem	58%
Isoniazid	↓
Ketorolac	↓
Losartan	↓
Lovastatin	↓
Metoclopramide	66%
Minoxidil	46%
Morphine	40%
Nicardipine	37%
Nimodipine	87%
Nortriptyline	↓
Procainamide	60%
Quinapril	↓
Raloxifene	↓
Repaglinide	↓

Drug Name	Decreased Change in CL_{NR}
Rosuvastatin	↓
Simvastatin	↓
Valsartan	↓
Vancomycin	43%
Verapamil	54%
Warfarin	50%

CL_{NR}, nonrenal clearance; ESRD, end-stage renal disease.

↓ a decrease is documented but not quantified.

Data from references 9 and 26.

TABLE 48-3 Major Pathways of Nonrenal Drug CL

CL_{NR} Pathway	Selected Substrates
Oxidative Enzymes	
CYP	
1A2	Polycyclic aromatic hydrocarbons, caffeine, imipramine, theophylline
2A6	Coumarin
2B6	Nicotine, bupropion
2C8	Retinoids, paclitaxel, repaglinide
2C9	Celecoxib, diclofenac, flurbiprofen, indomethacin, ibuprofen, losartan, phenytoin, tolbutamide, *S*-warfarin
2C19	Diazepam, *S*-mephenytoin, omeprazole
2D6	Codeine, debrisoquine, desipramine, dextromethorphan, fluoxetine, paroxetine, duloxetine, nortriptyline, haloperidol, metoprolol, propranolol
2E1	Ethanol, acetaminophen, chlorzoxazone, nitrosamines
3A4/5	Alprazolam, midazolam, cyclosporine, tacrolimus, nifedipine, felodipine, diltiazem, verapamil, fluconazole, ketoconazole, itraconazole, erythromycin, lovastatin, simvastatin, cisapride, terfenadine
Conjugative Enzymes	
UGT	Acetaminophen, morphine, lorazepam, oxazepam, naproxen, ketoprofen, irinotecan, bilirubin
NAT	Dapsone, hydralazine, isoniazid, procainamide
Transporters	
OATP	
1A2	Bile salts, statins, fexofenadine, methotrexate, digoxin, levofloxacin
1B1	Bile salts, statins, fexofenadine, repaglinide, valsartan, olmesartan, irinotecan, bosentan

CL_{NR} Pathway	Selected Substrates
1B3	Bile salts, statins, fexofenadine, telmisartan, valsartan, olmesartan, digoxin
2B1	Statins, fexofenadine, glyburide
Pgp	Digoxin, fexofenadine, loperamide, irinotecan, doxorubicin, vinblastine, paclitaxel, erythromycin
MRP	
2	Methotrexate, etoposide, mitoxantrone, valsartan, olmesartan
3	Methotrexate, fexofenadine

CL_{NR}, nonrenal clearance; CYP, cytochrome P450; NAT, N-acetyltransferase; MRP, multidrug resistance protein; OATP, organic anion-transporting polypeptides; UGT, uridine diphophate-glucuronlytransferase.

Data from references 9, 26, 36, and 37.

Alterations of CYP 450 Enzyme Activity and Transporters

There is now good basic science and emerging clinical evidence which suggests that CKD may lead to alterations in nonrenal clearance of many medications as the result of alterations in the activities of uptake and efflux transporters as well as CYP enzymes in the liver and other organs[26,27,36,38] (see Tables 48-2 and 48-3). The effect(s) of renal insufficiency on nonrenal drug clearance appear to depend on whether the reduction in renal function is acute or chronic in nature. For example, higher residual nonrenal clearance for vancomycin, meropenem, and imipenem has been documented in patients with AKI compared to CKD patients, who have comparable CL_{cr}.[39,40,41,42] In humans with renal insufficiency, the activities of CYPs appear to be relatively unaffected. It was reported that CYP3A4 activity was reduced,[26,37,38,43] but recent data indicate that OATP uptake activity is reduced and thus the perceived changes in CYP3A4 activity were likely due to altered transporter activity, not an alteration in CYP activity. The reduction of nonrenal clearance of several drugs that are metabolized by a CYP pathway as well as transported in CKD category G4 or G5 patients supports this premise (see Table 48-3). These studies must be interpreted with caution, however, because concurrent drug intake, age, smoking status, and alcohol intake were often not taken into consideration. Furthermore, pharmacogenetic variations in drug-metabolizing enzymes that may have been present in the individual before the onset of AKI or CKD must also be considered.[26,37,38] This differential effect on individual enzymes may help explain some of the conflicting reports of whether drug metabolism is altered in the presence of CKD. CYP3A activity as measured by the erythromycin breath test (EBT) is 28% lower in category G5 patients as compared with healthy controls.[44] Although baseline CYP3A activity was lower in these patients, the increase in CYP3A activity observed following enzyme induction with rifampin was similar.[44] Nolin and colleagues subsequently reported that EBT results are reduced more in those end-stage renal disease (ESRD) patients with higher blood urea nitrogen concentrations and that HD is associated with an acute improvement in the patient's metabolic activity.[43] These data suggest that CKD has a detrimental

effect on this important pathway of hepatic drug metabolism in humans.

Prediction of the effect of renal insufficiency on the metabolism of a particular drug is difficult and there is no quantitative strategy to predict changes for one drug based on data from another even if they are in the same pharmacologic class. However, some qualitative insight can be gained if one knows what enzyme is involved in the metabolism of the drug of interest and how the enzyme or transporter is affected by the presence of CKD.

Accumulation of Metabolites

Category G4 and G5 CKD patients who are receiving chronic drug therapy may experience significant accumulation of metabolite(s) as well as the parent compound if their ultimate route of elimination is via glomerular filtration. Metabolites of several drugs have been reported to have significant pharmacologic and/or toxicologic activity.[45,46] However, the pharmacokinetics and pharmacodynamics of metabolites are not often fully elucidated during the drug development process. In a sense, the patient with severe CKD is being exposed to a new pharmacologic entity since the sum of the serum concentrations of the metabolite and the parent compound maybe markedly different than those reported in patients with normal renal function.

The metabolite may have pharmacologic activity similar to that of the parent drug and thus contribute significantly to clinical response; that is true, for example, of oxypurinol, the active metabolite of allopurinol. Another example is morphine; the liver rapidly metabolizes morphine, into active metabolites, morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G) which readily cross the blood-brain barrier and bind to opiate receptors, exerting strong analgesic effects. In CKD patients, morphine is metabolized more slowly, and these active metabolites increase, making prolonged narcosis and respiratory depression more likely.[47] Alternatively, the metabolite may have qualitatively dissimilar pharmacologic action; for example, normeperidine has CNS stimulatory activity that reportedly produces seizures, whereas meperidine has CNS depressant actions.[48] Because of the multiplicity of potential interactions of compounds that are primarily metabolized, the practical consequences of metabolite accumulation are difficult to predict and are most often identified in those patients at risk serendipitously.

PHARMACOGENOMICS

Over the past two decades, genome-wide analyses have identified genetic variants that are associated with the risk of several diseases,[49,50] although most confer a very low discriminatory and predictive values.[51,52] Thus how CKD patients respond to medications is a consequence of alterations in pharmacokinetics and pharmacodynamics as well as pharmacogenomics.[50,53,54,55,56,57,58] Genotyping information is becoming more widely available than phenotyping data and this is generating demands for a more individualized approach to pharmacotherapy. Genotypic characterization now serves as the basis for dosing recommendations for some drugs,[59,60,61] and more than 120 US Food and Drug Administration (FDA)-approved drugs have pharmacogenomic information in their labeling, including fluoropyrimidines, codeine, Selective serotonin reuptake

inhibitors (SSRIs), tricyclic antidepressants, β-blockers, opiates, neuroleptics, antiarrhythmic agents, and statins.[61] However, the promise of pharmacogenomics has not always translated into improvements in patient care.[62,63]

One example of the real-life challenges associated with application of pharmacogenomics data is the anticoagulant, warfarin. Pharmacogenetic-based dosing of warfarin was associated with a significantly higher percentage of time in therapeutic range (TTR) compared to that achieved with standard dosing during initiation of warfarin therapy (67.4% vs 60.3%).[64] However, this improvement was not considered clinically significant. Moreover, the results of the study by Kimmel et al,[65] suggested that genotype-guided dosing of warfarin did not improve anticoagulation control during the initiation of warfarin therapy as compared with initiating warfarin using a clinically predicted maintenance dose.[65] Among 1,015 patients assigned to usual care or usual care plus genotype, international normalized ratio (INR) results showed that the mean percentage of time in the therapeutic range at 4 weeks was 45.2% in the genotype-guided group and 45.4% in the usual care group.[65] Moreover, rates of the combined outcome of any INR of 4 or more, major bleeding, or thromboembolism did not differ significantly according to dosing strategy.[65] Thus, at present, there is insufficient data to warrant genomic testing in persons with CKD to guide drug therapy. Future work will focus on the use of both pharmacokinetic and pharmacogenomic testing to improve drug dosing for CKD patients.

PHARMACODYNAMICS

CKD can affect multiple organ systems and consequently the response to a given drug many change beyond that predicted upon pharmacokinetic changes alone. For example, several studies have shown that enoxaparin dosage reduction is required in category G4 and G5 CKD patients.[66,67] This appears to be due to the accumulation of uremic toxins which results in complex disturbances of the coagulation system leading to an increase in bleeding. Therefore it seems that dosage adjustment based on kidney function such as eGFR may not always lead to optimal anticoagulation outcomes in CKD patients.

Successful antibiotic or antiviral treatment of CKD patients requires not only consideration of pharmacokinetic profiles, but also the drugs' pharmacodynamics, which links measures of drug exposure (such as peak and trough serum concentrations, and AUC) to bacteriologic activity.[68] Most antibiotics demonstrate concentration-dependent or time-dependent bacterial killing. In general, for concentration-dependent antibiotics such as fluroquinolones or aminoglycosides, a high ratio of the peak serum concentration to the minimum inhibitory concentration (MIC, the minimum concentration required to inhibit bacterial growth) has been associated with increased likelihood of clinical success; whereas for time-dependent antibiotics such as cephalosporins, the percentage of the dosing interval spent above the MIC is the most important pharmacodynamic parameter to maximize clinical success. This has led to the utilization of prolonged infusions or even in some cases to continuous infusions. Thus it is necessary to administer anti-infective drugs with a time-dependent action more frequently whereas anti-infective drugs with a concentration-dependent action should be administered with a higher maintenance dose and potentially a prolonged dosage interval to

increase efficacy while minimizing toxicity. Therefore both the pharmacodynamics and pharmacokinetics of drugs may need to be considered when initiating antimicrobial therapy in CKD patients. Pharmacodynamic modeling, however, doesn't accurately predict clinical success in some patient settings.[69] Thus large prospective clinical studies are needed to assure that this approach truly enhances patient outcomes.

Estimation of Kidney Function for Drug Dosage Regimen Individualization

Accurate assessment of kidney function is an essential component of determining appropriate drug dosing regimens. Because of the invasive nature and technical difficulties of directly measuring GFR in clinical settings, many equations for estimating GFR have been proposed. A detailed discussion of the pros and cons of estimating equations for GFR (Table e42-6) and creatinine clearance (Table e42-7) are presented in Chapter e42. The Cockcroft Gault (CG) equation has been the most commonly used method to estimate kidney function for drug dosing purposes for over 40 years.[70,71] The modification of diet in renal disease (MDRD) and the chronic kidney disease epidemiology collaboration equation (CKD-EPI) have been developed primarily for the identification and classification of CKD patients.[72,73]
