Chapter e1: Health Literacy and Medication Use

Oralia V. Bazaldua; DeWayne A. Davidson; Ashley Zurek; Sunil Kripalani

INTRODUCTION

KEY CONCEPTS

- 1 Limited health literacy is common and must be considered when providing medication management services.
- 2 Some groups of people are at higher risk for having limited literacy skills, but in general, you cannot tell by looking.
- 3 Patients with limited health literacy are more likely to misunderstand medication instructions and have difficulty demonstrating the correct dosing regimen.
- 4 Limited health literacy is associated with increased healthcare costs and worse health outcomes, including increased mortality.
- 5 Despite numerous efforts to improve safe medication practices, current strategies have been inadequate, and this may have a larger impact in patients with limited literacy.
- 6 Most printed materials are written at higher comprehension levels than most adults can read.
- 7 The United States Pharmacopeia has set new standards for prescription medication labeling to minimize patient confusion.
- 8 Several instruments exist to measure health literacy, but some experts advocate “universal precautions” under which all patients are assumed to benefit from plain language and clear communication.
- 9 Obtaining a complete medication history and providing medication counseling are vital components in the medication management of patients with limited health literacy.

Every day, thousands of patients are not taking their medications correctly. Some take too much.

Others take too little. Some use a tablespoon instead of a teaspoon. Parents pour an oral antibiotic suspension in their child's ear instead of giving it by mouth because it was prescribed for an ear infection. Others are in the emergency department because they did not know how to use their asthma inhaler. It is not a deliberate revolt against the doctor's orders but rather a likely and an unfortunate result of a hidden risk factor—limited health literacy.

1 *Literacy*, at the basic level, is simply the ability to read and write. When these skills are applied to a health context, it is called *health literacy*, but health literacy is more than just reading and writing. *Health literacy*, as defined by the Institute of Medicine (IOM), is "the degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions." A growing body of evidence associates low health literacy with less understanding, worse outcomes, and increased cost. These poor outcomes have led this topic to receive national attention. Health literacy has been made "a priority area for national action" by the IOM[1,2] and Healthy People 2020.[3] As a result, federal policy initiatives promoting health literacy continue to be highlighted in Healthy People 2020, the Patient Protection and Affordable Care Act of 2010, and the Plain Writing Act of 2010.[4] A National Action Plan to Improve Health Literacy (**Table e1-1**) has also been developed by the Department of Health and Human Services (HHS).[5] Likewise, the Agency for Healthcare Research and Quality (AHRQ),[6,7] the National Institutes of Health (NIH),[8] and Centers for Disease Control and Prevention (CDC)[9] have each dedicated websites to this topic and have provided funding to support studies and interventions that are specifically relevant to health literacy. Additionally, state and private sector organizations, such as America's Health Insurance Plans (AHIP) and the American College of Physicians (ACP) Foundation, have led efforts to improve health literacy following the IOM's call to action.[10] Indeed, health literacy should be a national priority for the medical community as its consequences are far-reaching and cross-cutting.

TABLE e1-1 Goals of the National Action Plan to Improve Health Literacy[5]

Goal 1	Develop and disseminate health and safety information that is: • accurate • accessible • actionable
Goal 2	Promote changes in the healthcare system that improve: • health information • informed decision-making • communication • access to health services

Goal 3	Incorporate accurate, standards-based, and developmentally appropriate health and science information and curricula in child care and education through the university level
Goal 4	Support and expand local efforts to provide: • adult education • English language instruction • culturally and linguistically appropriate health information services in the community
Goal 5	Build partnerships, develop guidance, and change policies
Goal 6	Increase basic research and the development, implementation, and evaluation of practices and interventions to improve health literacy
Goal 7	Increase the dissemination and use of evidence-based health literacy practices and interventions

More than one of every three American adults has difficulty understanding and acting on health information.[11] Patients with limited health literacy have less knowledge about how to manage their disease;[12] they misunderstand dosing instructions and warning labels on medication containers;[13,14] they are less likely to read or even look at medication guides;[15] their ability for medication management is limited as these persons are less able to identify or distinguish their medications from one another;[16,17] and they are less able to use a metered-dose inhaler (MDI) properly.[18] Limited health literacy skills have also been documented in caregivers of seniors[19] and in parents of children.[20] There is no question that limited health literacy is associated with adverse health outcomes[21] including an increased mortality rate[22] and increased healthcare costs.[23]

Current strategies for safe medication use have not been effective for the general population and are likely less useful for persons with limited health literacy. All health professionals need to acknowledge that limited health literacy is common and may be a barrier to improving health outcomes in their patients. They need to implement strategies for clear communication in order to enhance appropriate medication management. This chapter will review what is known about health literacy and present the evidence available as it relates to medication use.

Clinical Controversy…

Is there a shared meaning of *health literacy*? While the IOM has provided a concise definition of health literacy, some argue that the field of health literacy has become so dynamic that experts in the field do not have a shared meaning for this term.

PREVALENCE

According to the National Assessment of Adult Literacy (NAAL), 36% of Americans have limited health literacy skills, meaning that out of four levels, they function at the lowest two.[11] The NAAL

survey was administered randomly to 19,000 adults (greater than or equal to 16 years of age) across the United States and final results were reported in four skill levels: below basic, basic, intermediate, and proficient. Fourteen percent of Americans had health literacy skills that were considered below basic, 22% were at the basic level, 52% were at intermediate, and only 12% were considered proficient (**Fig. e1-1**). The *below basic* level is substantially below that which is necessary to function within the healthcare setting. Individuals in the *basic* level have skills to perform simple everyday literacy activities. They can read, understand, and use information in short and "simple" documents. *Intermediate* literacy levels include skills necessary to perform moderately challenging literacy activities. (Note that the NAAL considered interpreting prescription drug labels an intermediate level task.) Individuals in the *proficient* level would have the least difficulty navigating the healthcare system. This group can analyze, integrate, and synthesize complex information. Approximately 3% of people surveyed were excluded from the analysis due to language barriers or cognitive disabilities. Thus, if you add this 3% to the 36% of people that measured at the two lowest levels and consider the estimated American population of 2020, approximately 130 million Americans have limited health literacy.[11,24]

FIGURE e1-1

Percent of adults in each health literacy level. Percentages are from Kutner et al.[11] The values in parentheses estimate the number of American adults (greater than or equal to 15 years of age) in each literacy level, based on 2015 population projections,(from *http://www.census.gov/population/projections/data/national/2012/summarytables.html*).

GROUPS AT HIGH RISK

2 It is generally not possible to tell if someone has limited health literacy simply by looking at or talking to them. Many persons with limited health literacy learn to hide it very well and many are known to keep this secret to themselves. In one study, two-thirds of persons surveyed (68%) admitted to not telling their spouse about their reading difficulties and more than one-half had not told their children.[25] In a study of internal medicine residents and students, few of them recognized low literacy as a potential factor in patient nonadherence and hospital readmission.[26] It is important to note that health literacy is a context-dependent skill, meaning that people who function well in one environment may still struggle when presented with healthcare tasks. Thus, even people with adequate education levels may find it difficult to navigate the healthcare system due to lack of familiarity with the context. While it is important to remember that people of all ages, nationalities, and income groups are at risk for limited health literacy, there are some groups that are at particularly high risk that should be mentioned (**Table e1-2**).[11] This information can help assess the potential risk of limited health literacy in the patient population being served.

TABLE e1-2 Groups at High Risk of Limited Health Literacy

Age 65 or older
Minorities

Spoke another language prior to formal education

Have less than a high school diploma

Live at or below the poverty line

Rate their overall health as poor

Have Medicaid, Medicare, or no insurance

Data from reference 11.

As the Latino population in the United States continues to increase to over 28% as it is projected by 2060,[24] this group and those with limited English proficiency (LEP) are at a high risk for limited health literacy and inappropriate medication management. Not only do they have lower health literacy scores than the overall population,[11] but more than one-half of Latinos are known to have LEP.[27] Unfortunately, most pharmacies in the United States are not equipped with appropriate translation or interpreter services. In a telephone survey of 764 pharmacies, nearly 57% reported limited or no translation services available.[28] In fact, 45% of pharmacies admit to not being satisfied with their ability to communicate with patients that have LEP. In 2012, the United States Pharmacopeia (USP) set new standards for prescription container labeling and recommends that whenever possible, directions be provided in the patient's preferred language as well as English to minimize the risk of misinterpretation.[29]

Practices that serve Latinos or patients with LEP should be cognizant of their high risk and employ strategies for providing clear communication about appropriate medication management.

Children

What happens when adults with limited literacy become parents? Not surprisingly, a systematic review of the literature concludes that child and parent literacy seem to be associated with important health outcomes.[30] Similar to data found in adults, children with limited literacy had worse health behaviors. If their parents had limited literacy skills, these children had worse health outcomes. In a study of 1,500 parents, Medicaid-insured parents had less education than those with commercial insurance and were more likely to request unnecessary antibiotics for their children.[31] In asthmatic children, limited parental health literacy is associated with a greater incidence of emergency department visits, hospitalizations, missed school days, and greater use of rescue medications.[32] In another study, caregivers with low health literacy were more likely to report use of a nonstandardized dosing instrument.[33]

While interventions in general are lacking, there are more that target improvement in knowledge than outcomes. One intervention using pictograms, brief counseling and the teach-back method improved the likelihood of parents correctly dosing medicines and adhere to the regimen.[34] Similarly, parents with low health literacy were less likely to make a dosing error with infant acetaminophen after receiving text-plus-pictogram instructions compared to text only recipients.[35] As in the adult

population, effective interventions that improve outcomes and minimize health disparities are needed.

CONSEQUENCES

Table e1-3 provides a comprehensive list of studies to date evaluating health literacy and medication use. In particular, it provides a summary of the studies evaluating the effect of health literacy on medication knowledge and understanding, medication management, and medication adherence. One study evaluated the effect of health literacy on adverse drug events and found no association.[36]

TABLE e1-3 Studies Evaluating Limited Health Literacy and Medication Use

Citation and Literacy Measurement	Results
	Knowledge
Williams et al.[37] (TOFHLA)	Decreased understanding of how to take medicines: • Take on empty stomach → 65% incorrect • How many pills to take → 70% incorrect • How many refills left → 42% incorrect
Davis et al.[13] (REALM)	Decreased understanding of instructions on prescription labels: • Two times more likely to misunderstand
Davis et al.[14] (REALM)	Increased misinterpretation of drug warning labels: • Three to four times more likely to misinterpret
Fang et al.[38] (S-TOFHLA)	Decreased understanding of mechanisms and side effects: • Warfarin works by thinning blood → 30% incorrect • Bleeding/bruising most common → 51% side effect incorrect
Yin et al.[33] (TOFHLA)	Decreased awareness of weight-based dosing among caregivers of children: • 88.6% unaware
Marks et al.[39] (REALM)	Decreased medication knowledge including name, dose, indication, and side effects: • 80% had medication knowledge score (MKS) below the median

Citation and Literacy Measurement	Results
Mosher et al.[36] (REALM)	Decreased medication knowledge (name/indication): Health literacy level — % correct of names — Indications • Low — 32.2 — 61.8 • Marginal — 54.6 — 77.4 • Adequate — 60.8 — 81.4 *P* < 0.001 — *P* < 0.001
	Medication Management
Williams et al.[18] (REALM)	Decreased ability for proper use of metered-dose inhaler (MDI): • 88% with limited literacy had poor the MDI technique, compared with 48% of those with higher literacy levels
Davis et al.[14] (REALM)	Decreased ability to demonstrate correct dosing: • 65% could not demonstrate, “Take two tablets by mouth twice daily”
Persell et al.[17] (S-TOFHLA)	Decreased ability to name their medications: • 40.5% of those with limited health literacy vs 68.3% of other patients
Kripalani et al.[16] (REALM)	Decreased ability to identify all of their medications: • 10-18 times the odds of being unable to identify
	Adherence
	Decreased adherence
Kalichman et al.[40] (WRAT-3) (TOFHLA)	Increased nonadherence to antiretroviral therapies: • Three to four times more likely to be nonadherent in last 2 days
Graham et al.[41] (REALM)	Decreased adherence to antiretroviral medications: • 40% of those with limited health literacy vs 64% of other patients
Wolf et al.[42]	Increased likelihood to be nonadherent with antiretroviral therapies: • 3.3 times more likely to be nonadherent

Citation and Literacy Measurement	Results
Kripalani et al.[43] (REALM)	Decreased adherence to medication refills: • Two times more likely to be nonadherent
Noureldin et al.[44] (S-TOFHLA)	Decreased medication taking adherence: • 54.2% of those with inadequate health literacy vs 69.4% of other patients
Lindquist et al.[45] (S-TOFHLA)	More likely to have unintentional nonadherence after hospital discharge • 47.7% (inadequate HL) vs 20.5% (adequate HL), $p = 0.002$
Bauer et al.[46] [3-item screener]	Patients with diabetes had more time without sufficient pill supply to newly prescribed antidepressants: • 41% vs 36%, $p < 0.01$
Karter et al.[47] [single question]	Nonadherent patients more likely to report inadequate health literacy: • 51% vs 30%
Osborn et al.[48] (REALM)	Health literacy was associated with medication adherence: • r = 0.12, $p < 0.02$
Hironaka et al.[49]	**Increased adherence** Increased adherence to daily multivitamins by infant caregivers: • Two times as likely to report high adherence
Gatti et al.[50] (REALM)	**No effect on adherence** Health literacy is not independently associated with adherence: • 52.4% vs 50.1% (difference not significant)
Paasche-Orlow et al.[51] (REALM)	Low health literacy not associated with lower odds of adherence: • Adjusted odds ratio = 1.93 (not significant)
Mosher et al.[36] (REALM)	Health literacy is not associated with medication adherence: Health literacy level % of medications taken ($p = 0.14$) • Low 84

Citation and Literacy Measurement	Results
	• Marginal 80 • Adequate 77
Bains et al.[52] (REALM-R)	Health literacy was not significantly related to medication adherence
	Inconclusive effect on adherence
Gazmararian et al.[53] (S-TOFHLA)	Suggestive but not conclusive that low health literacy predicts poor refill adherence
Kripalani et al.[43] (REALM)	No consistent relationship found between health literacy and self-reported adherence

Decreased Knowledge and Understanding

A number of studies have shown that patients with limited health literacy have less knowledge about their disease and how to manage it. For example, among patients with diabetes, 94% of those with adequate health literacy knew the symptoms of hypoglycemia, compared with only 50% of those with inadequate health literacy.[12] Similarly, persons with limited health literacy did not know about factors that could lower blood pressure such as weight loss and exercise. Other studies have also correlated limited health literacy with less knowledge about asthma, reproductive health, human immunodeficiency virus (HIV) infection, discharge instructions, and heart health.[21]

Several studies also confirm the association between limited health literacy and decreased understanding of appropriate medication use.[13,14,15,33,37,38,40,54] A study to examine patients' ability to understand instructions on medication labels concluded that lower health literacy was independently associated with misunderstanding of instructions.[13] Patients with inadequate and marginal health literacy had a relative risk of 2.32 and 1.94 of misunderstanding label instructions, respectively.

Warning labels are routinely used with prescription medications, yet a recent study indicated that these labels may not be useful for patients with limited health literacy. In fact, patients with low health literacy have a three times greater likelihood of incorrect interpretation of prescription warning labels and have a potential for misuse of their medications.[14] For example, in the warning label that states, "Do not chew or crush, swallow whole," some patients were interpreting it as "chew pill and crush before swallowing." Another study found an association between limited health literacy and deficits in warfarin-related knowledge.[38]

Lastly, patients with limited health literacy have difficulty understanding medication guides, which are educational materials mandated for some products by the FDA, and most admit to never looking at them.[15]

Decreased Ability for Medication Management

3 Limited health literacy has also been associated with a decreased ability for "medication management"—the ability to self-administer a medication regimen as it has been prescribed.[16] Examples of functional skills necessary for medication management include correct identification of medications, opening the appropriate containers, proper selection of the correct dose, and timing of administration,[54] as well as appropriate use of containers such as MDIs, nasal sprays, and eye drops.

Studies indicate that patients with limited health literacy are unable to name or identify their own medications.[16,17] Persell and colleagues conducted a study to assess the relationship between health literacy and patient recall of their antihypertensive medications.[17] He found that only 40.5% of patients with inadequate health literacy were able to name any of their antihypertensive medications, compared to 68.3% of those with adequate health literacy. In this same study, inadequate health literacy was also associated with a greater number of unreconciled medications (64.0% vs 37.8%). Similarly, in another study, patients with inadequate literacy skills had 10 to 18 times the odds of being unable to identify all of their medications, compared with those with adequate literacy skills.[16]

In a study to determine the relationship of literacy to the MDI technique of asthma patients, researchers concluded that inadequate literacy was strongly correlated with improper MDI use.[18] Compared with patients with adequate health literacy, more patients with inadequate health literacy were unable to demonstrate proper MDI use (88% vs 48%).

Uncertain Effect on Medication Adherence

Results of studies evaluating the relationship between limited health literacy and medication adherence are conflicting. Several studies in patients using antiretroviral medications for treatment of HIV infection indicate that patients with limited health literacy are less likely to be adherent to their medications.[40,41,42] Persons with inadequate health literacy were more likely to have lower refill adherence,[43] decreased medication taking,[44] and more likely to have unintentional nonadherence after a hospital discharge.[45] In contrast, several studies concluded that health literacy is not independently associated with adherence,[36,50,51,52] another study showed a strong trend,[53] and yet another study actually found an increase in adherence.[49]

A major barrier to consolidating data from adherence studies is that there is no generally accepted "gold standard" for measuring medication adherence, making overall conclusions difficult. Further studies are needed to adequately determine the true relationship between health literacy and medication adherence.

Clinical Controversy…

What is the effect of limited health literacy on medication adherence? Current evidence is inconclusive regarding the overall effect that limited health literacy has on medication adherence. Some studies show that limited health literacy decreases adherence, others show it actually increases adherence, yet others show no effect. More research is needed to answer this question.

Worse Health Outcomes

The AHRQ has published two reports that summarize the literature available regarding the association between health literacy and outcomes.[55,56] In the first report, they identify most of the studies evaluated as being "fair or good," and overall, they report that there is an association between lower literacy and adverse health outcomes.[55] In one study evaluating the association of health literacy with diabetes outcomes, the investigators found that patients with limited health literacy have worse control of their diabetes and are more likely to report complications such as retinopathy and cerebrovascular disease.[57] In a recent study, the majority of patients with poorly controlled diabetes (A1c greater than 8%) were more likely to believe that their diabetes was well controlled if they had low health literacy. Thus, they may be less likely to make changes to improve control.[58]

The second AHRQ report reinforces the initial link between limited health literacy and worse health outcomes.[56] Patients with limited health literacy have a higher risk for emergency care use, less use of preventive services, poorer skills in taking medications, and more hospitalizations. Low health literacy was also found to be a significant, independent risk factor for hospital reutilization within 30 days after hospital discharge.[59] This can be costly since accountable care organizations will be reimbursed less for hospital reutilization within 30 days of discharge.

Unfortunately, inadequate health literacy has even been linked to increased mortality in community-dwelling elderly persons.[22] Baker and colleagues studied 3,260 Medicare managed-care enrollees to determine whether low health literacy independently predicted all-cause mortality. Crude mortality for persons with inadequate health literacy levels was more than twice as high as in those with adequate health literacy (39.4% vs 18.9%). Even after adjusting for confounding factors such as demographics, socioeconomic status, and baseline health, participants with inadequate health literacy had a hazard ratio of death of 1.52 compared with participants with adequate health literacy. The authors concluded that inadequate health literacy independently predicts all-cause mortality in community-dwelling elderly persons. A different study of older adults confirmed the increased risk of mortality in those with low health literacy (hazard ratio = 1.40).[60] In a cohort study of patients hospitalized for acute heart failure, low health literacy was associated with a 32% increased risk of death. This increase was found after adjusting for age, gender, race, insurance, highest level of education, hospital length of stay, and comorbid conditions.[61]

Increased Healthcare Costs

4 A systematic review concludes that the economic implications of limited health literacy are substantial.[23] Patients with limited health literacy tend to seek medical care when they are sicker, leading to higher use of emergent care and longer hospitalizations. Thus, it is no surprise that caring for persons with limited health literacy is associated with higher healthcare costs. At the health system level, limited health literacy may account for a 3% to 5% increase in total costs.[23] The increased cost at the individual patient level may range anywhere from $143 to $7,798. Howard and colleagues found that persons with inadequate health literacy incur higher healthcare costs and use medical services inefficiently, especially emergency department care.[62] Another approximation of the cost of limited health literacy to the American economy ranged from $106 billion to $238 billion

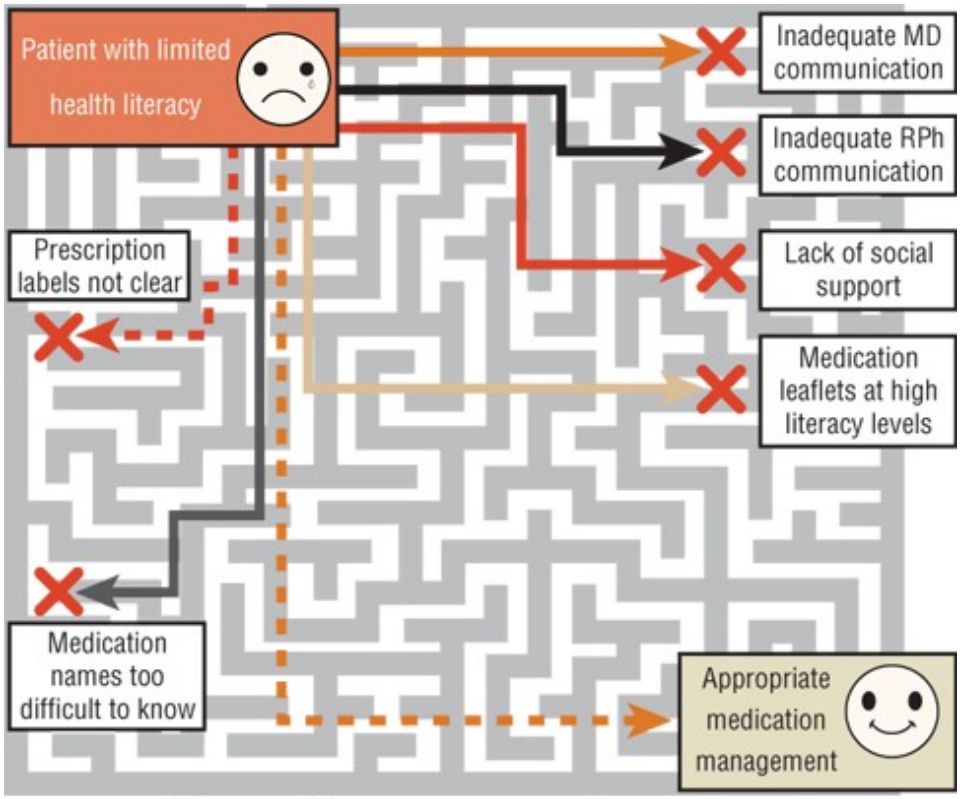
annually, equal to about 7% to 17% of all personal healthcare expenditures.[63] A large-scale study demonstrated higher healthcare costs in the Veterans Health Administration (VHA) patients. Of 92,749 veterans, the mean per patient cost for those with inadequate and marginal health literacy was significantly higher ($31,581) compared with the cost of those with adequate health literacy ($17,033). It is estimated that the healthcare cost of veterans with marginal and inadequate health literacy was $143 million dollars more over a 3-year period.[64] Victor Dzau, the president of the Institute of Medicine, stated that the lack of health literacy costs the United States more than $100 billion annually.[2]

SHORTCOMINGS OF CURRENT SAFE MEDICATION PRACTICES

5 Despite our most sophisticated efforts to encourage safe medication use, our current strategies have been insufficient and ineffective, especially for patients with limited health literacy. **Figure e1-2** depicts the maze of medication information that patients are expected to navigate and several of the barriers that patients with limited health literacy may encounter.

FIGURE e1-2

Medication information maze. Communication barriers and the complexity of current medication information make it difficult for a patient to achieve appropriate medication management. These barriers are even more significant in a patient with limited literacy skills. This figure depicts several of the barriers that patients may encounter in the process of obtaining medication information.



Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

Patient Information Leaflets

6 Numerous studies indicate that most health information handouts are written at a level far beyond that which an average adult can understand.[1] The average American adult reads at about the eighth grade level and most handouts exceed these levels. In a survey of 251 primary care adult patients, only 23% reported having ever looked at the accompanying medication guides.[62] Patients with lower literacy were less likely to have looked at the medication guides (16.7% vs 32.9%). Because of this, and the fact that the medication guides were written at the 11th and 12th grade level, the authors concluded that they probably were not useful to patients with limited literacy skills. Raynor and colleagues also found that consumer medication information handouts do not meet people's information needs.[65] People did not value the written information they received about medicines, and providing the leaflets did not increase their knowledge. People tended to want information that was tailored to them with a balance of both benefit and harm. They also wanted information before the drug was prescribed to decide if it was the right medicine for them; this is often not done. Overall, they found a gap between what the patients wanted and what the medicine leaflets provided.

Medication Labels

Poor medication labeling has been cited as a potential cause for medication errors. Indeed, the USP attributes about one-third of all medication errors to confusion with product labeling.[66] Shrank et al.

assessed 85 labels on pharmacy-dispensed medications for format, context, and variability.[67] Their evaluation concluded that the most prominent portion of the label included the name of the pharmacy or logo in 84% of all the labels reviewed. In addition, the smallest font sizes were used to display the medication name (an average of 8.9 points) and medication instructions (9.3 points). Color and boldface were used to highlight items most useful to the pharmacist as opposed to highlighting the information that is most useful to the consumer. Warning instructions were highly variable among all labels depending on the pharmacy.

7 A group of health literacy experts has pointed out, "Inadequate patient understanding of prescription dosing instructions and warnings is prevalent and a significant safety concern."[68] In a report published by the IOM, experts advocate for standardization of prescription medication labels in efforts to minimize patient confusion and improve patient safety. This report examines what is known about how medication-container labeling affects patient safety and discusses evidence-based approaches to address the identified problems. As precedents for such national standards, the report cites the successfully reformed nutrition facts food product label and standardization of over-the-counter labels by the FDA.

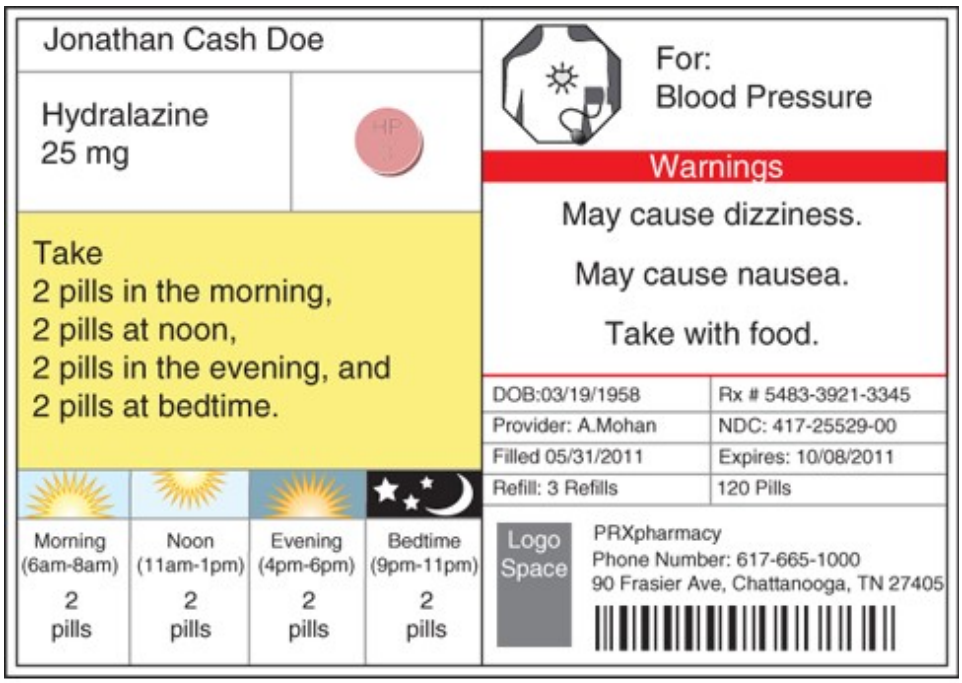
Based on the available evidence and expert recommendations, the USP released a new set of standards in 2012 for patient-centered medicine labels.[29] Enforcement will be at the discretion of each state, but it is expected that applying these standards will reduce adverse drug events and medication misuse. The standard provides a universal approach on how prescription labels should be organized in a "patient-centered" manner. For example, the label should include the indication for use and provide explicit instructions in the patient's preferred language. Medical jargon should be avoided. For instance, use *heart* instead of *cardiac* and use numeric instead of alphabetic characters (eg, *2*, not *two*). A list of USP standards is presented in **Table e1-4** with examples that incorporate them shown in **Fig. e1-3**.

TABLE e1-4 USP Prescription Container Label Standards to Promote Patient Understanding[29]

Standards	Description
Organize the prescription label in a patient-centered manner	Place label elements in an order and format that makes it easy for patients to find and understand
Emphasize instructions and other information important to patients	Format the label in a way to stress what is essential to the patient by: • Making prominent the information that patients must have in order to use medications correctly and safely (ie, patient name, drug name and strength, and directions) • Placing dosing instructions in the same order every time (ie, dose > route > frequency) • Making less prominent and placing away from dosing instructions less important information such as pharmacy name, prescriber, fill date, etc.

FIGURE e1-3

Examples of evidence-based medication labels incorporating recommendations from the ACP and United States Pharmacopeia Chapter 17.[70,71] Notice that the most important parts are in the left section, in larger font, and highlighted. Numbers are used instead of words; directions are explicit and on individual lines. These labels also include the indication for use in the upper right section, and a Universal Medication Schedule (UMS) graphic in the lower left. *(Data from references 69,70,71.)*



In addition to the USP standards, the ACP Foundation also recommends the use of a universal medication schedule (UMS) to convey and simplify dosage and/or use instructions; a visual aid with standard intervals (eg, morning, noon, evening, and night) can simplify dosing and reinforce text instructions (see bottom of Fig. e1-3).[68,69]

Counseling by Physicians and Pharmacists

Communication failure has been reported to be the underlying cause of about 10% of adverse drug events.[72] Patients with limited health literacy are significantly less likely to ask questions of their providers.[73] About one-half of the prescriptions taken each year are used improperly, and an estimated 96% of patients do not ask questions about their medications.[74]

Unfortunately, verbal counseling by prescribers and pharmacists has been disappointing. Though the exact prevalence of counseling behaviors is uncertain, one report indicated that patients received verbal counseling about 24% of the time from prescribers and only 14% of the time from pharmacists.[75] In addition, when physicians make an effort to communicate when prescribing new medications, they often fail to communicate critical elements of medication use. Tarn found that

physicians only communicate about three of the five expected elements of drug information (name of medication, purpose, dose and timing, duration, and adverse effects) when initiating new prescriptions.[76]

In efforts to improve these numbers and thus medication safety, Healthy People 2010 made verbal counseling by prescribers and pharmacists an objective. The goal is for 95% of patients to receive verbal counseling from prescribers and pharmacists on the appropriate use and potential risks of medications.[75]

Medication Names

Over the past decade, the FDA approved 293 new molecular entities, all of which needed brand and generic names.[77] Despite the intricate process of naming a drug and guidelines developed by the United States Adopted Names Council, drug mix-ups still occur in the dispensing process.[78] If these mix-ups occur with health professionals, imagine the confusion it causes to the consumer with limited health literacy. It can be overwhelming and dangerous.

A 2007 study assessed the relationship between health literacy and patient recall of their antihypertensive medications.[17] Overall, regardless of their literacy level, more than 40% of patients were unable to name any of their antihypertensive medications. When considering literacy levels, patients with limited health literacy fared worse in terms of recalling the names of their blood pressure-lowering medications (31.7% vs 59.5%). After adjusting for age and income, this difference was almost threefold (odds ratio, 2.9). In another survey of 100 patients, researchers found that participants could provide the names of only 55.8% of their medications.[79]

The United States Adopted Names Council follows a set of guiding principles when naming new medications. The very first guiding principle is "A nonproprietary name should be useful primarily to healthcare practitioners, especially physicians, pharmacists, nurses, educators, dentists, and veterinarians."[80] Notice that *consumers* or *patients* are not considered in this guiding principle, even though they are the very ones who need to know the name the most. We should "resolve to do better."[78]

METHODS FOR IDENTIFYING PATIENTS WITH LIMITED HEALTH LITERACY

Informal Assessments

The shame associated with limited literacy often prevents patients from receiving appropriate medical care, as they tend to hide their reading problem. In addition, healthcare providers often do not consider low health literacy in their patient care.[26,81] As previously mentioned, certain groups are at higher risk for limited health literacy, but even people with adequate literacy levels who are unfamiliar with the healthcare context may have difficulty navigating the healthcare system and often go undetected.

Common Signs

The following are common signs that may suggest a person has limited health literacy skills:[1,25,82]

1. Reads slowly
2. Has difficulty telling a coherent story
3. Fills out forms incorrectly or incompletely
4. Uses excuses such as, "I forgot my glasses," "I'll read this later," or "I don't have time to read this now. Can I take it home?"
5. Brings along a friend or family member for assistance
6. Fails to show up for appointments or is late for refills
7. Does not ask questions for clarification
8. Has difficulty following instructions
9. Nods in agreement or expresses understanding but does not truly understand information

Medication Review

A medication review may be very useful in identifying patients with limited health literacy skills. If the refill history is accessible, one might find that they often forget to refill their medications on time or never pick them up. They may not be able to verbalize a list of their medications despite having a short list. If the medication bottles are available, the patient can be asked to state the name, use, and dosing instructions for each of their medications. Patients with limited health literacy may not be able to respond accurately. They may say, "I take them just like it says on the bottle," or they have to look at the pill color and shape before they can respond.

If patients have a medication reconciliation list from their last visit, they may hand over the list to the health professional and say, "This is everything that I am taking." However, when probing a little further, they likely do not know the contents of that list, and it may not be exactly what they are taking. When asked to read a medication label that says, "Take one tablet by mouth once daily at bedtime," they may recognize the pill and say it reads, "Take one every day," because they have memorized the instructions that may or may not match the container label. When picking up refills, patients with limited health literacy may ask the pharmacist for the old bottles because they depend on their personal markings such as an *X* on the cap.[83]

Formal Measures

8 Because of the high prevalence of inadequate health literacy, many experts recommend that health professionals practice "universal precautions" by trying to communicate as clearly as possible

with *all* patients and family members.[84] Others suggest that professionals should screen patients' health literacy and then tailor communications accordingly. It is not clear which approach is best.

Clinical Controversy…

Should patients be tested for limited health literacy and then receive appropriately tailored health information? Although several instruments have been developed to screen and assess literacy levels, some advocate for the use of "universal precautions" so that *all* patients will receive clear communication in language that is plain and easy to understand.

A number of instruments have been developed to assess health literacy in both English and Spanish. These instruments can identify patients with "low," "marginal," "inadequate," or "below basic" skills, all of which mean that the patient has limited health literacy. An article by Mancuso provides a comprehensive review of health literacy assessment tools.[85]

Two of the most widely used measures of health literacy are the Rapid Estimate of Adult Literacy in Medicine (REALM)[86] and the Test Of Functional Health Literacy in Adults (TOFHLA).[87] These tests are mainly used in research, but they can be used in practice. Additionally, a survey revealed that patients do not mind having their literacy assessed in the clinical setting. More than 98% of patients agreed to a literacy assessment in a routine health visit, including 46% of patients with limited literacy skills.[88]

The REALM is a word-recognition test and estimates health literacy based on patients' ability to pronounce a list of medical terms. The TOFHLA consists of a reading comprehension section to measure prose literacy and a numeracy section. Passages with health information have words that have been deleted, and the patient is to choose the correct word from a list of four options. The Newest Vital Sign (NVS) assesses health literacy by having patients review a nutrition label and answer six questions about the label.[89]

While there are continued calls for comprehensive measures of health literacy, there is just as much interest in developing specialized versions as well as short versions of instruments for rapid assessment of literacy skills. Helitzer and others have developed a disease-specific web-based tool called TALKDOC which measures women's health literacy of Human Papilloma Virus and cervical cancer.[90] The Parental Health Literacy Activities Test (PHLAT) and its Spanish version have been developed to assess the literacy and numeracy skills, such as preparing infant formula correctly and dosing medication accurately, that parents need to safely care for infants and children.[91,92] In addition to shorter versions of the REALM (shortened-REALM)[93] and TOFHLA,[94] one-item measures have been developed and evaluated for rapid screening of health literacy skills which have subsequently been incorporated into a 4-item brief health literacy screening tool called BRIEF.[95,96,97,98,99]

As with all tests, each has its limitations. For example, S-TOFHLA does not assess numeracy unlike its parent test, TOFHLA. While the NVS was validated in people of all races with an average age of 41 years, a smaller study of African Americans with a mean age of 73.2 years determined that the NVS took 8 minutes longer to administer and was overall not as applicable in this age group.[100] Griffin et

al.[101] and Haun et al.[102] found significant variation in categorizing test-takers between inadequate and marginal health literacy in groups given both the REALM and S-TOFHLA assessments. Further, the BRIEF tool was validated in a predominately white male English-speaking veteran population which may not be generalizable to other populations.[95]

Table e1-5 provides a list of these commonly used assessment tools.

TABLE e1-5 Methods to Assess Health Literacy

One-Item Measures[96,97,98,99,103]	Length (minutes)	Interpretation/Scoring
"How confident are you filling out medical forms by yourself?" (0, extremely; 1, quite a bit; 2, somewhat; 3, a little bit; 4, not at all)	≤1	Positive answers for low health literacy are "somewhat," "a little bit," or "not at all"
"¿Qué tan seguro(a) se siente al llenar formas usted solo(a)?" (0, extremadamente; 1, mucho; 2, algo; 3, un poco; 4, para nada)		Positive answers for Spanish speakers are: "a little bit" or "not at all"
"How often do you have someone help you read hospital material?" (0, none of the time; 1, a little of the time; 2, some of the time; 3, most of the time; 4, all of the time)	≤1	Positive answers are "some of the time," "most of the time," and "all of the time"

Multi-item Measures

Assessment Tool	Description	No. of Items	Length (minutes)	Interpretation/Scoring
National Assessment of Adult Literacy (NAAL)[11]	Main purpose was to measure general literacy but included items specifically to assess health literacy	28	(Not for practice; survey done every 10 years)	Below basic Basic Intermediate Proficient
Shortened rapid estimate of adult literacy in medicine (Shortened-REALM)[93,a]	Word recognition list. Patients read a list of 66 common medical words and are scored on correct pronunciation	66	2-3	0-44 Low 45-60 Marginal 61-66 Adequate
Short test of functional health literacy in adults (S-TOFHLA)[94]	Patients must fill in words that have been deleted systematically from a sample text of common health instructions; words are selected from a list of	36	7	0-16 Inadequate 17-22 Marginal 23-36 Adequate

One-Item Measures[96,97,98,99,103]			Length (minutes)	Interpretation/Scoring
	multiple-choice options. Excludes numeracy testing			
Short Assessment of Health Literacy for Spanish Adults—50 (SAHLSA-50)[104,a]	Based on REALM and reading a list of common medical words in Spanish (includes two association words; key and distracter)	50	3-6	0-37 Inadequate
Newest Vital Sign (NVS)[89]	Patients review a nutrition label and answer 6 questions about the label	6	3	0-1 indicates >50% likelihood of marginal or inadequate literacy; 2-3 indicates possibility of limited literacy; and 4-6 adequate literacy
Short Assessment of Health Literacy—Spanish and English (SAHLS&E)[105,a]	Based on REALM and SAHLSA-50 (includes two association words; key and distracter). High correlation between words used in both versions and adequate to compare Spanish and English speakers together	18	2-3	0-14 Inadequate
Brief Health Literacy Screening Tool (BRIEF)[95]	Patients answer four questions and respond on a 5-point Likert scale	4	<2	4-12 Inadequate 13-16 Marginal 17-20 Adequate
Medical Term Recognition Test (METER)[106]	Self-administered medical word recognition test. Contains 40 medical words and 40 nonwords	80	2	0-20 Low 21-34 Marginal 35-40 Functional
Health Literacy Skills Instrument 10-item short form (HLSI-SF)[107]	Based on NAAL with four domains of health literacy skill assessment: reading/writing, numeracy, listening, and information seeking (Internet navigation)	10	5-10	<70% Below basic literacy 70-81% Basic literacy ≥82% Proficient literacy

[a]Except for the REALM, a Spanish version is available for all methods. SAHLSA-50 is available only in Spanish.

STRATEGIES FOR CLEAR COMMUNICATION ON MEDICATION MANAGEMENT

Increase Health Literacy Awareness

The first step toward improving communication on medication management in individuals with limited health literacy is to recognize that limited health literacy is very common. A survey revealed that pharmacists in only 7% of community pharmacies attempt to identify literacy-related needs among the individuals they serve.[81] Most pharmacists seemed to be surprised and unaware that some of their customers may have difficulty reading. In fact, only 12% of American adults have proficient health literacy skills.

Therefore, it is very likely that most health professionals, including pharmacists, will be serving individuals with limited health literacy skills. As such, it has been recommended that professional schools incorporate health literacy into their curricula and areas of competence.[1] Much work remains to be done in this area but efforts are under way. This chapter itself is a tribute to these efforts.

Some disciplines are promoting health literacy awareness by incorporating the need to address this cross-cutting topic in their accreditation standards.[108] Some pharmacy schools are developing pharmaceutical care labs to introduce pharmacy students to the implications of limited health literacy on medication management.[109] Students complete assigned readings on misunderstanding prescription labels, watch a video on health literacy, and are asked to lower the reading grade level of a patient education document. Most students were able to lower the reading grade level of the document but were surprised at the amount of effort required. The authors concluded that this exercise helps the students understand the complexities of limited health literacy and affects their ability to communicate appropriately with patients—especially those with limited health literacy. In an introductory program, third-year pharmacy students determined the impact of using health literacy communication tools in a group of independent-living senior residents. They found that using these health literacy tools increases patient understanding, empowerment, and commitment to medication adherence.[110] Medical schools and residency programs have also explored different ways to incorporate this topic in their training. A 2-hour workshop was developed for physician residents to improve assessment of adherence and their medication counseling skills. One month after this intervention, physicians reported a significant improvement in these areas.[111]

Obtain a Complete Medication History

Perhaps one of the most essential components necessary to improve medication management in patients is obtaining a thorough and complete medication history. This is important for all patients regardless of their health literacy level. However, because patients with limited health literacy have difficulty naming their medications and are more likely to mismanage their medications, taking a complete, baseline history of what they are taking is especially valuable.

Medication histories are equally important in all clinical settings, including hospitals, communities,

home health, long-term institutions, and ambulatory centers. The importance of medication reconciliation (comparing a medication list to what a patient should be receiving) is also acknowledged by the hospital accreditation body, the Joint Commission.[112] This organization recognized that this is a crucial step in promoting medication safety and minimizing medication errors. Implementation of this requirement continues, and research is necessary to examine its effectiveness and implementation.

Table e1-6 provides a list of recommended strategies and questions for obtaining a complete and accurate medication history.[113,114,115] A video example of how this can be done in a manner sensitive to health literacy is also available at: *https://youtu.be/It8KfitBeeE*.

TABLE e1-6 Helpful Strategies and Questions for Obtaining a Complete Medication History

Preparation

- Before speaking to the patient, if available, obtain a list of their most current medications from their medical records or electronic health system
- This will help elicit information that the patient may have forgotten
- A quick review may also reveal patterns about their refill history

Determine person responsible for medicine regimen

- Do you take your medications on your own, or does someone else like a family member or friend help you take them?
- If patient has a caregiver helping with the medication regimen, include them in the interview

General questions

- Do you have your medication containers with you?
- If yes, the patient may use them to proceed and answer the following questions
- If not, ask if they have a list of the medications they take and proceed
- What are your medication allergies?
- How many different doctors write prescriptions for you?
- Which pharmacies do you use to fill your prescriptions? What is their contact information (phone number and address)?
- How do you pay for your medicines? What is the name of your insurance plan?
- What language do you prefer to have on your medicine containers?

Determine complete list of medicines

For each medicine that you take, please tell me the (1) name and dose, (2) the reason you take it (indication), and (3) exactly how you take it… How many times a day?

Do you take any medicines that you buy over-the-counter without a prescription such as Tylenol or Advil?

Do you take any herbal products, home remedies, vitamins, or other dietary supplements?

Do you take any medicines that you bring from another country such as Canada or Mexico?

Do you take any medicines that are bought over the Internet?

Do you get medicines from other places such as a dialysis unit or another clinic (eg, vitamin B12 shots)?

Do you use medicines that are not taken by mouth? For example, patches, inhalers, suppositories, creams, drops, liquids, injectables, nasal sprays?

Do you have medicines that you take only once a week or once a month?

Assess adherence

How do you remember to take your medicines on a regular basis so that you do not forget a dose (eg, pill box, leave pill bottle by toothbrush, set alarm, line up pill bottles)?

How many doses of your medicines have you missed in the last week?

On a scale of 0-10, how well do you remember to take your medicines every day or as prescribed? 0 means you forget to take them all the time, and 10 means you never miss a dose.

When did you take the last dose of each medicine?

If medication containers are available, look at the last refill date and determine if the patient is current on his or her refills. Look at the date it was filled, how many doses were dispensed, and how many are left now as a rough indicator of adherence.

Conduct a Pharmacy Health Literacy Assessment

A pharmacy health literacy assessment measures how well the pharmacy is serving patients with limited health literacy skills.[116] It is an important first step to improve the quality of medication management for individuals with limited health literacy. The assessment tool developed with funding from AHRQ is comprehensive and is made up of three complementary parts: (a) an "assessment tour" completed by objective auditors (here, barriers for clear communication are noted as well as the physical environment of the pharmacy and staff interaction with patients), (b) a survey completed by staff (this helps determine how "friendly" the pharmacy environment is toward individuals with limited health literacy), and (c) focus groups with pharmacy patients (here, the intent is to collect detailed feedback from patients about their experience with pharmacy services). After all the data are collected and summarized, a tangible action plan should be developed for improved services to help individuals with limited health literacy.

Personalize Health Information

A study in hypertension knowledge demonstrated that personalizing health information to learning style preferences and literacy level improves patient understanding. Participants in the intervention group answered many more questions correctly than the control participants. The combination of assessing each person's health literacy as well as their learning preference provided a more powerful mechanism to enhance learning than either alone.[117]

Improve Medication Counseling Skills

Perhaps a key point to remember about this chapter is the vital importance of proper medication counseling. The National Conference of Pharmaceutical Organizations (NCPO) agreed that appropriate medication use should be a key goal of healthcare reform. In a policy statement of 2009 entitled, "From Reform to Revolution: Maximizing the Power of Proper Medication Use in Patient Care," the group emphasizes, "Policymakers must consider the importance of … appropriate counseling on the use of medications."[118] In a study to improve hospital discharge instructions, several interventions were implemented before the patients were sent home. The usefulness of each intervention was evaluated with a follow-up telephone call to 125 patients after discharge. The top three interventions that patients found most useful were (1) speaking with a pharmacist about their medications before discharge, (2) receiving an illustrated medication list, and (3) a follow-up telephone call after discharge. Patients with limited health literacy indicated the greatest benefit.[119]

The following ten points provide suggestions on how to improve medication-counseling skills. A video on how to improve the quality of discharge medication counseling is also available at: *https://youtu.be/BE-9CVVeZpA*.

1. *Take the time to counsel:* Despite the focus on increasing verbal counseling about medications by prescribers and pharmacists in Healthy People 2010 (objective 17-5),[75] progress has been limited. In fact, midterm review of the tracking data showed no change for prescribers and a 2% worsening by pharmacists.[120] Taking the time to provide verbal counseling about medications

is especially crucial in patients with limited health literacy.

2. *Create a relaxed and nonthreatening environment:* Many patients with low health literacy are embarrassed about the difficulty they have understanding health-related information. While they may not take the initiative to disclose this information, they are amenable to discussing health literacy and learning in the right environment. Thus, a first step toward effective medication counseling is to create a friendly and relaxed environment for the patient.[83] Take the time to listen and give the patient enough time to feel comfortable. Try to understand the patient's perspective.

3. *Use plain language:*[121] Speak clearly using plain and common words. Pay attention to the patient's own terms and use them back.[122] **Table e1-7** has examples of alternative lay terms to common medical terms. Avoid vague terms. For instance, oral and written instructions should be to "take medication 1 hour before breakfast," not "take medication on an empty stomach."

   Tell patients what you want them to do. Use instructions such as "Stop taking this medicine if you get pregnant" instead of "This medicine should not be taken during pregnancy." Another example is, "Do not drink alcohol with this medicine," which is preferred over, "Alcohol should not be mixed with this medicine." In addition, use identifiers such as the time of day. For example, say, "Take 1 tablet in the morning and 1 at bedtime," rather than, "Take twice daily."

4. *Show the patient each medication while counseling:* Open the medication containers so that the patient can see the colors and shapes of the tablets or capsules.[123] This will help them recall your instructions. For liquids, show patients or caregivers the correct dose with a marking on an oral syringe. This has been found to be the most accurate dosing method for liquids.[124]

5. *Focus on one to three key points and repeat them frequently:* Limit the number of messages and only tell patients what they *need* to know. Skip details that are "nice" to know.[121] Reinforce these same key messages by repeating them.

6. *Have patients repeat instructions:* An evidence-based strategy of verifying patient understanding is to use the "teach-back" method.[125,126] Patients are asked to repeat the instructions or information they were given to ensure that the key concept has been understood and remembered. If the concept is not repeated correctly by the patient, the health professional clarifies and tailors the explanation and reassesses patient recall. This cycle of explaining, assessing, and clarifying is repeated until the concept has been understood. It is termed "the interactive communication loop in clinician–patient education" by Schillinger and colleagues.[125] They found that when physicians applied this interactive communication strategy for their patients with diabetes, glycemic control improved.

   Findings of a study assessing patient understanding of prescription labels suggest that professionals should go further by asking patients to "demonstrate" or "show" how they will use medications. Davis and colleagues found that even though some patients could verbalize the correct instructions on the label (eg, take 2 tablets twice daily), they could not "demonstrate" the correct dose.[13] Of note, this group also included persons with adequate health literacy level.

7. *Encourage patients to ask questions:* Never ask, "Do you have any questions?" Instead, ask, "What questions do you have?"[122] Create an environment in which patients feel comfortable asking questions. The professional might say, "Sometimes I give people a lot of information about their medicines and it can be confusing … so I would like to ask you, what questions do you have?"

8. *Use pictures or illustrated medication schedules:* Research indicates that pictures help patients understand how to take their medicines,[127,128] and these may be particularly useful in patients with limited health literacy skills. A review of the literature found that pictorial aids improve recall, comprehension, and adherence.[128] Researchers have developed prototype illustrated medication schedules (**Fig. e1-4**),[129] as well as a guide on how to create simple versions using word-processing software.[130] These daily schedules provide the patient with a picture of the actual medicine, the name of the medicine, the indication, and specific dosing instructions. Assessment of such tools reveals that more than 80% of patients thought they were useful and easy to understand.[129] Other work confirms that these illustrated daily medication schedules improve medication self-efficacy and adherence among at-risk, community-dwelling older adults.[131]

9. *Supplement the interaction with patient-friendly educational material:* Written medication information can be helpful to supplement and reinforce specific counseling points if it is easy to read. Nonwritten material may also be useful in communicating medication information to patients. Alternative forms to written information include pictures/pictograms, videos,[132] audiotapes, modules on disks, and interactive Internet sites. Most of the health education available in these formats focuses on specific disease topics, and studies indicate that these modalities are increasingly effective.[133,134] However, some of these new media focus solely on medication information; research on their effectiveness is limited. **Table e1-8** provides some helpful resources for pharmacists and patients.

10. *Review complete regimen and consolidate all medicines into their daily schedule:* In addition to providing information about each individual medication to the patient, it is important to consider its use in the context of their full medication regimen. This is especially necessary when a regimen includes multiple medications each with specific requirements such as taking on an empty stomach or taking at bedtime. Patients may be easily confused with multiple requirements and either make their regimen more complicated than necessary or compromise their care by not taking their medications appropriately.

TABLE e1-7 Examples of Suggested Alternatives for Common Medical Terms[a]

Medical Term	Alternative
Angina	Chest pain
Fatigue	Tired
Adverse reaction	Side effect
Acid reflux	Heartburn

Medical Term	Alternative
Lipids	Cholesterol
Insomnia	Trouble sleeping
Subcutaneous	Under the skin
Nasal	Nose
Topical	On the skin
Administer	Give
Hypertension	High blood pressure
Contraception	Birth control

[a]Other examples of alternatives to medical terms are available in both English (*http://www.npsf.org/wp-content/uploads/2011/12/AskMe3_WordsToWatch_English1.pdf*) and Spanish (*http://www.npsf.org/wp-content/uploads/2011/12/AskMe3_WordsToWatch_Spanish1.pdf*) on the Ask Me 3 website of the National Patient Safety Foundation.

TABLE e1-8 Electronic Resources for Pharmacists and Their Patients

- **Websites**
  - For pharmacists
    - *http://tools.hospitalmedicine.org/resource_rooms/imp_guides/MARQUIS/marquis.html*
      - Includes taking the best possible medication history presentation, taking a good medication history video, best possible medication history pocket cards, good discharge counseling video, and ROI calculations
      - Requires user to sign up for free to access materials
    - HRSA health literacy section—free online course to improve communication with patients

CREATE EASY-TO-READ HANDOUTS

Numerous studies have proven that most health education handouts are written at a higher grade level than what most adults can read.[1] Most health information is written at a 12th grade level or higher, but the average American reads at about the 8th grade level. Thus, it is important to keep in mind some general principles that are known to make handouts easy to read. They may be helpful either in creating material or as a checklist for determining the appropriateness of a handout.

Some of the principles are very similar to the ones used in verbal communication such as using plain language, focusing on one to three key messages, and incorporating suitable illustrations. However, the reader is referred to a more comprehensive reference created by the NIH to improve communication between the government and the public.[135] This plain-language initiative provides a number of useful tips on creating written handouts that are easy to read.

TECHNOLOGY

Technology is now more pervasive and easier to access in the United States than ever. With cellular phones, tablets, computers, and other devices such as “smart” thermostats, watches, and medical

sensors becoming smaller, faster, and cheaper, their use and adoption has also increased. Having a computer in the home has risen from 8.2% in 1984 to 83.8% in 2013. Likewise, internet use at home has also risen from 18% in 1997 to 74.4% in 2013.[136]

Despite these advances, there are still stark disparities in technology use and internet access among different incomes, education levels, age groups, geography, and ethnicities (**Table e1-9**).

TABLE e1-9 Computer and Internet Use for Households: 2013[136]

Household Characteristics	% Households WITH computer	% Households WITH some Internet Access
Age of householder		
14-34 years	92.1	77.7
35-44 years	92.5	82.5
45-64 years	86.8	78.7
65 years and older	65.1	58.3
Race and Hispanic origin of householder		
White alone, non-Hispanic	85.4	77.4
Black alone, non-Hispanic	75.8	61.3
Asian alone, non-Hispanic	92.5	86.6
Hispanic (of any race)	79.7	66.7
Limited English-speaking household		
No	84.7	75.5
Yes	63.9	51.4
Metropolitan status		
Metropolitan area	85.1	76.1
Nonmetropolitan area	76.5	64.8
Household income		
< $25,000	62.4	48.4
$25,000-$49,999	81.1	69.0
$50,000-99,999	92.6	84.9

Household Characteristics	% Households WITH computer	% Households WITH some Internet Access
$100,000-$149,000	97.1	92.7
$150,000 and more	98.1	94.9
Educational attainment of householder		
Less than high school graduate	56.0	43.8
High school graduate (includes equivalency)	73.9	62.9
Some college or associate's degree	89.0	79.2
Bachelor's degree or higher	95.5	90.1

Adapted from: File T, Ryan C. Computer and Internet Use in the United States: 2013. American Community Survey Reports, ACS-28. Washington, DC: U.S. Census Bureau, 2014. http://www.census.gov/library/publications/2014/acs/acs-28.html.

A 2013 US Census Bureau report showed that the majority of households with a computer were English speaking, younger, had a higher income, more education and lived anywhere in the United States. A similar pattern can be seen with regards to internet access. Only 58% of the older population had internet access. Households that were black or Hispanic (61.3%, 66.7%) tended to have less internet access compared with whites and Asians (77.4%, 86.6%). Households with internet access also tended to be English speakers, have a higher income, more education, and live in metropolitan areas. The same report revealed that compared to having a computer at home, households that were most likely to have only handheld devices were low-income (7%), black or Hispanic (9.1% each), or younger (9.5%).[136]

A Pew Research Center survey in 2015 showed that 92% of Americans have a cell phone (68% smartphones, 34% traditional cell phones). An important finding was 7% were classified as "smartphone-dependent" users, meaning that they have a smartphone, but do not have internet at home other than their mobile data plan, nor do they have other device options for accessing the internet such as a computer or laptop. These users tended to be low-income, black, or Hispanic. In terms of how smartphones were used, 97% use their smartphone for text messaging, 92% for phone calls, 89% for internet, and 88% for email. Young users (age 18-29) also use their smartphones heavily for social networking services (91%) compared with other age groups. **Figure e1-5** shows that 62% of respondents have used their smartphone to look up information about a health condition.[137]

FIGURE e1-5

More than one-half of smartphone owners have used their phone to get health information, do online banking. (*Used with permission from "U.S. Smartphone Use in 2015." Pew Research Center,*

Technology and Health Literacy

As healthcare continues to shift to more electronic resources and connectivity, the most vulnerable populations may incidentally be left behind. While more than 90% of the US population has cell phones, there is a significant difference in how they are being used when comparing persons with marginal or low health literacy to those with adequate health literacy. Those with adequate health literacy were more likely to own a smartphone, text message, and access the Internet for email, web browsing, and health information. They were also more likely to contact their healthcare provider through these means compared to those with marginal or low health literacy.[138]

Though more than 50% of those with low health literacy were able to text message, less than half reported that they performed any of the other tasks including email. This was significantly less compared with at least 75% of those with marginal health literacy reporting they regularly perform all of those tasks on their phones.[138] Additionally, those with low health literacy were more likely to use social networking sites and phone apps than search engines to obtain health information, and also preferred text messaging and radio to receive this information.[139] *Thus, it appears that text messaging*

and social networking sites may be the best way to electronically reach those with low health literacy; however, these disparities should be a reminder that a digital divide exists especially with those with low literacy skills.

Unfortunately, when it comes to internet use for health access services, such as patient portals, patients with low health literacy were 70% less likely to sign on or complete their access despite having internet access.[140] Among the 59% of US elderly who use the Internet, an even smaller percentage of those with low health literacy (9.7%) used it for health information purposes compared with those with adequate health literacy (31.9%).[141] As more technology is incorporated into our healthcare system, our most vulnerable populations will need our close attention to minimize the already growing health disparities.

Technology and Medication Adherence

Table e1-3 shows that the current evidence for the association between health literacy and medication adherence is inconclusive. However, nationwide, an estimated 75% of Americans have trouble taking their medicine as directed; approximately 125,000 annual deaths are due to nonadherence. Indeed, poor adherence is a major public health challenge, and it makes sense that persons with low health literacy may have even a bigger challenge.

Current technology trends have helped to address primary nonadherence, which is not filling or picking up a prescription, by increasing the use of electronic health records (EHRs) to electronically transmit prescriptions or "e-Prescribe" medications directly to the pharmacy. This eliminates the need for patients to carry a paper prescription to the pharmacy. This solution has also allowed for prescription insurance formularies to be available to the prescriber at the point of entry to help reduce patient costs and waiting time by selecting drugs that are cheaper or do not require prior authorizations, both of which are barriers to obtaining medication. Prescription insurance plans and pharmacies have also begun to share patient claims information, refill history data, and missed refill alerts with connected providers to help reduce duplication, coordinate care, reconcile medications among other prescribers, and increase patient safety.[142]

While primary nonadherence and discontinuation of medications are being addressed on a national level, compromised execution or the inconsistent use of medication by the individual patient has been a bigger challenge. In efforts to improve medication adherence, different technologies are emerging to help with this issue. **Table e1-10** provides examples of technologies available to help with medication adherence. Two literature reviews provide evidence that text messaging improves medication adherence rates, at least in the first 6 months, but conclude that larger and longer studies need to be conducted.[143,144] Electronic medication dispensing devices, such as MedicaSafe, are available to not only help remind patients to take their medication but also allow prescribers to monitor progress.[145] This may have importance with medications that are costly such as recently marketed hepatitis C treatments or when adherence is extremely important such as with tuberculosis treatment or post-transplant immunosuppression.

TABLE e1-10 Examples of electronic technologies to improve medication adherence

	Examples	Comments
Electronic Reminders	• Alarm clock • Email reminder • Cell phone calendar • Text messaging • Dose-Alert Pill reminder	• Inexpensive • Easily accessible • Sound alerts
Smart Pills **Smart Bottles** **Smart Caps**	• Proteus Discover system • AdhereTech • GlowCap • SMARxT Med Reminder • e-pill Multi-Alarm TimeCap	• Costly • May require internet/cellular connectivity • Sound & light alerts • Notification and tracking systems • Caution with cap switching
Electronic Medication Dispensers	• MedicaSafe • Philips Medication Dispensing Service • Med-E-Lert Automatic Pill Dispenser	• Moderately expensive • Controlled access capability • Notification and tracking systems • Need to replenish monthly

Mobile Technology	• Cell phone apps:
	  ○ Pharmacy
	  ○ Insurance plan
	  ○ Medication adherence
		• Free or very inexpensive
		• Easy to difficult usability
		• Pictures & visual reminders
		• May require internet connection
		• Gamification and rewards
		• May be limited by operating system

Lastly, as mobile technology has become widely available, so have applications (apps) that can be used on smartphone devices. The results of using apps to improve medication adherence have been mixed, but there is some trend to overall improvement in self-care behavior and attitudes.[146] One randomized controlled study has shown that an app can improve medication adherence in the elderly who tend to use less modern technology.[147] Dayer et al. reviewed more than 160 apps available in 2012 and ranked them based on a number of attributes (**Table e1-11**).[148] Many other apps are available that connect patients directly to their pharmacy and are designed to provide refill reminders as well as easily request refills. Although more studies are needed to evaluate the effect of technology-based adherence interventions, current trials suggest combinations of in-person communication WITH automated reminders or triggers are more effective.[149]

TABLE e1-11 Top 10 Rated Medication Adherence Apps and Operating System[148]

Application Name	iPhone	Android
1. MyMedSchedule	**X**	**X**
2. MyMeds	**X**	**X**
3. MedSimple	**X**	**X**
4. Med Agenda	X	
5. RxmindMe Prescription	X	
6. Dosecast	**X**	**X**
7. TRxC (Beta)	X	X
8. MediMemory	X	
9. PillManager	**X**	**X**
10. MedsIQ Individual/Multi-user		X

Systems available in 2016 are shown in bold.

CONCLUSION

Limited health literacy is a prevalent problem that has often been overlooked. However, it is now considered a priority area by the federal government and a number of national organizations. Research is under way to better understand its effect on health and to develop effective interventions. The role of health literacy on medication use is still being evaluated, but there is no question that it is a significant one. Health professionals need to consider that many of their patients may have limited literacy skills. In particular, health literacy is an important concept to consider in efforts to improve appropriate medication use.

Chapter e2: Cultural Competency

FIGURE e2-1

Jeri J. Sias; Amanda M. Loya; José O. Rivera; Jessica M. Shenberger-Trujillo

CULTURE, COMMUNITY, AND SOCIAL DETERMINANTS OF HEALTH

KEY CONCEPTS

- 1 Healthcare providers should strive toward cultural competency to improve care and access unique resources for patients and communities from diverse cultures and backgrounds.
- 2 Changes in demographics in the United States, health disparities, and patient safety are among the reasons that cultural competency should be emphasized in healthcare.
- 3 A variety of models recognize cultural competency as a process, not an achievement.
- 4 Legal and regulatory issues surrounding cultural competency include understanding and interpreting accreditation standards for healthcare organizations and Title VI of the Civil Rights Act.
- 5 Patients may enter the healthcare setting with a different explanation of their illnesses than found in the Western biomedical model (WBM).
- 6 Cultural values and beliefs influence decisions and attitudes about healthcare, including race, ethnicity, age, gender, sexual orientation, and religious beliefs.
- 7 Developing communication skills to interact with diverse population involves recognizing personal styles and cultural values of communication as well as barriers to patient understanding.
- 8 Linguistic competency encompasses understanding the capacity of organizations and providers to communicate well with diverse populations such as patients with limited English proficiency (LEP), low literacy, or hearing impairments.
- 9 Before practitioners can understand other cultures, they should understand personal and organizational values and beliefs.
- 10 Skills for working with patients from diverse cultures include being able to listen to the patient's perception of health, acknowledging differences, being respectful, and negotiating treatment options.

Culture defines us.[1] Although our genetic makeup, which is largely nonmodifiable and affects our physical state of being, **social determinants of health** are also of great influence. Determinants of health describe the factors that affect the health of individuals. At the core of each person are their inherited traits as well as the choices that they make about their lifestyles (eg, diet, exercise, leisure activities). Their health is further marked by their exposure to healthy or risky behaviors based on the places where they live, work, worship, or go during the day and their built environment (eg, sidewalks, exposure to clean air, policies for healthy choices).[2] Basically, our socioeconomic status, race and ethnicity, gender, age, and communities (environments), as part of our cultures, shape us.[3]

Consider the following brief descriptions of three individuals and the determinants of health that influence them. Patient 1 is a 42-year-old bilingual Vietnamese American, Buddhist woman living on the West Coast whose family immigrated to the United States 35 years ago. Her lifestyle choices include a vegetarian diet, gardening, and daily meditation. She lives in a suburban community with her husband and three children, drives a hybrid electric/gas car to her work as a school teacher, and purchases food from a local farmer's market. She has health insurance and her city public policy includes no indoor smoking in public places and state policies include special low-emission requirements on vehicles. Weekend activities with the family include sports and dance for the kids along with others from the community center that serves a number of Asian-American families.

Patient 2 is a 27-year-old single African American, Muslim upper-middle-class man living in a major city in the Eastern Coast of the United States. Having just finished his graduate school degree, he lives in a high-rise apartment and walks or rides the subway to his work at a major corporation. In his leisure time, he enjoys reading and going to major sporting events with his college friends who come from diverse backgrounds. During the week, he also frequents the local mosque and community events that are supported by his neighborhood.

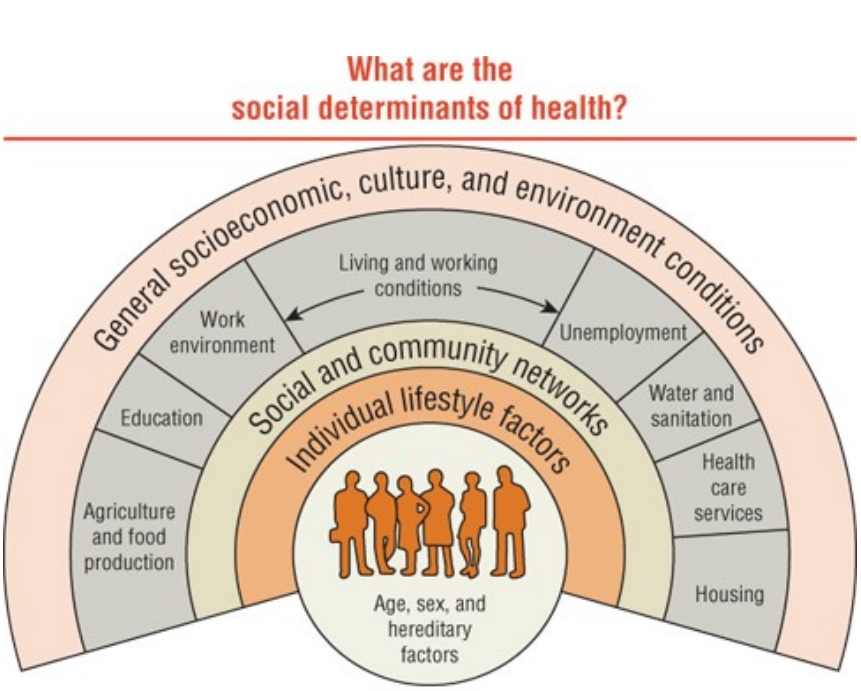
Patient 3 is a 55-year-old European American, Protestant middle class man living in the Midwest. His family moved from the rural South 2 years ago for a new full-time job. Due to recent economic changes in the community, he now has to work three part-time jobs (two in food industry and one in construction) so that he can help support his wife who is undergoing breast cancer treatment. As a result of his high work demands, he is not able to shop for groceries or exercise and so the couple often eats away from the home or they prepare quick and processed meals at home. He notices that he has gained about 10 pounds (4.5 kg) in the past 6 months and has difficulty sleeping. The family also has not had time to connect with their church or other friends due to his work and doctor appointments for his wife.

Can healthcare professionals assume that these three patients have the same healthcare beliefs, values, and approach to healthcare? While each of the patients described above will have a unique health situation, social determinants will influence their exposure to healthy conditions and their cultural backgrounds will also shape their health beliefs and behaviors.[4]

What is culture? **Culture** can be defined as "the learned and shared beliefs, feelings, and knowledge that individuals and/or groups use to guide their behavior and define their reality as they interact with the world."[5,6,7] However, to interact more effectively with individuals from different cultural backgrounds, providers should develop cultural and linguistic competencies.

FIGURE e2-1

Social Determinants of Health.



Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

Cultural competency may be described as the attitudes, knowledge, skills, and values that an individual has and uses in working effectively in a cross-cultural environment.[8,9] At an organizational level, cultural competency can be demonstrated by an organization having a defined set of values and principles (mission), policies, and structures for service delivery that incorporate community input and enable individuals in the organization to work effectively within cultures and cross-culturally.[8,10]

Linguistic competency is linked to cultural competency. It describes the "capacity of an organization and its personnel to communicate effectively and convey information in a manner that is easily understood by diverse audiences" (eg, persons of limited English proficiency [LEP], those who have low literacy skills, individuals with different hearing or sight abilities).[10]

The environments we live in—our communities—also define our health.[3,4,11] Research suggests that while we should address health at the individual level, providers and policymakers must also understand and address healthcare at the community and population level.[12,13] But what creates a community? **Communities** may be defined as organized groups of people with a shared identity that *may exist around* racial and ethnic groups, socioeconomic position, religion, age, gender, language, as well as other cultural ties.[14] Communities can also cut across these variables. **Community competency** encompasses cultural competency; however, it also recognizes the unique role of communities as a type of culture.[14] Within a community competency framework, clinicians will understand that at the core of a community are history, context, geography, and culture.[14] For example, given similar socioeconomic and educational backgrounds, an adolescent male raised in Chicago, Illinois, whose family is from Puerto Rico would have a different life experience (ie, a different community or environmental influence) than an adolescent male of a similar family background being raised in Greenville, South Carolina.

History helps describe the collective consciousness of a community. For example, a community's recent history may include the devastation of a flood or tornado. Political history can affect a refugee population's experience and the history of slavery in the United States affects multiple communities. The history of a community is not always considered in social determinants of health models, but understanding the history can enhance evaluating the social determinants of health. Context acknowledges the present situation of a community such as the quality of education, housing, or healthcare. Geography helps to distinguish differences between a male of Islamic

religion and Somali descent who is raised in Philadelphia, Pennsylvania, from one who is raised in St. Paul, Minnesota.

What is the difference between cultural and community competency? Cultural competency helps clinicians understand the individual; thus, "culturally competent care can be considered patient-centered care."[14,15] Community competency provides a broader context for clinicians to work with individuals and families, as it incorporates the influence of the population and environment on the individual. Although this chapter focuses on cultural competency and care of individuals, acknowledging the influence of community on individuals is significant.

1 Healthcare providers should strive toward cultural competency in the context of social determinants of health and community history to improve care and access unique resources for patients and communities from diverse cultures and backgrounds. This skill is increasingly important to healthcare practice as our society becomes more and more diverse. The healthcare provider tries to negotiate an approach to treatment that is respectful of patient beliefs, while integrating an effective course of therapy in a manner consistent with the patient's beliefs and understanding. This approach does not devalue the patient's cultural and community beliefs. As a result, better treatment adherence can occur.[16,17] The negotiation between provider and patient is the art of patient care and is a skill that requires continual practice.

A culturally competent approach to care incorporates—at all levels—the importance of culture, the assessment of cross-cultural relations, vigilance toward the dynamics that result from cultural differences, the expansion of cultural knowledge, and the adaptation of services to culturally unique needs of the patient.[8,16,17,18] In short, there is respectful acknowledgment of the patient's belief system. A culturally competent approach to care includes a set of behaviors and attitudes that enable a healthcare provider to work effectively in cross-cultural situations with humility, sensitivity, and cultural awareness.

Reasons for Cultural Competency

2 Changes in demographics, health disparities, patient safety, and healthcare workforce shortages are among the reasons for needing cultural and linguistic competency in healthcare.[16,17] In this section, the situation as it exists in the United States is detailed. The central concepts would be similar for other countries around the world, even though some of the specifics would vary.

The United States is diverse.[19] Approximately 40% of the population identifies as African American, Hispanic, Asian, American Indian, being of another race that is not white, or as coming from two or more races.[19] The United States is aging, with 14.5% of the population reported as being 65 years of age or older.[19] Furthermore, people have diverse religions, languages, and countries of origin. Nearly 84% of adults in the United States report identifying with a particular faith or religious group.[20] More than 300 distinct languages are spoken in American homes.[21] The three patients described in the beginning of the chapter highlight some of the diversity that might be encountered throughout our United States.

Regrettably, health disparities generally occur in populations who have systematically experienced a social, economic, or environmental disadvantage in society. While disparities are often linked to differences in race and cultural backgrounds, they also exist among groups based on religion, physical disability, sexual orientation, and age, among other characteristics. **Health disparities** refer to gaps in the quality of health and healthcare and can include differences in rates of disease or illness, access to healthcare, or general health outcomes.[22] One of the overarching goals of Healthy People 2020 (**Table e2-1**), which frames the national health agenda, is to eliminate health disparities that exist in our population and achieve health equity.[23]

TABLE e2-1 Overarching Goals of Healthy People 2020

- Attain high-quality, longer lives free of preventable disease, disability, injury, and premature death
- Achieve health equity, eliminate disparities, and improve the health of all groups
- Create social and physical environments that promote good health for all
- Promote quality of life, healthy development, and healthy behaviors across all life stages

Source: U.S. Department of Health and Human Services, Sept 25, 2015.[23]

Health disparities may vary based on the population and the health outcome measured. For example, adults in the United States who are African American experience higher mortality rates of heart disease compared to non-Hispanic whites.[24] Diabetes prevalence rates are greater among adults with lower household incomes, Hispanics, and African Americans than among Asians and non-Hispanic whites. Suicide rates are higher among men than women, with elevated rates found in American Indian/Alaska Native as well as Lesbian, Gay, Bisexual, and Transgender (LGBT) populations.[25] Smoking prevalence is higher among adults who have not graduated from high school when compared with adults with a college degree. These statistics and others like them underscore the need for improvements in the quality of healthcare for minorities.

A healthcare provider's cultural competency can help to address health disparities in their communities and empower patients from minority groups to improve their health.[26,27] By understanding the needs of underserved patients and by identifying the unique resources available within these populations, the healthcare provider can positively impact patient's healthcare experience. For example, a healthcare provider who understands the importance of community support in a Latino patient seeking healthcare can include a key community member (eg, a promotora or lay health worker) as an active member during treatment and posttreatment care.[28,29] By working within the patient's cultural needs and expectations, the provider can use otherwise overlooked support systems (eg, family, neighborhood friends, and religious ties) in a community with fewer or overtaxed resources. Using cultural competency skills to better identify cultural and community assets in minority and underserved populations allows the provider to go beyond basic awareness of and sensitivity to cultural differences to increase a patient's adherence with treatment and positively impact patient health outcomes.[30] Additionally, the provider's ability to empower patients through cultural competency will facilitate the development of trusting patient/community/provider relationships.[31]

Culture and language may also play a role in patient safety.[32] Errors and adverse events can occur because of differences in language between healthcare providers and patients, ineffective use of an interpreter, or inadequate translation of written material related to health. Poor judgment or lack of adherence to a treatment plan can occur because of discordance in a patient's cultural health belief system. Cultural "incongruences" among patients and providers may lead to making judgments about a patient's decision to use complementary and alternative medicine (CAM) or casting stereotypes based on personal biases about healthcare.[15]

While some areas of the country may have a surplus of providers, there are still shortages in healthcare providers across disciplines as well as lack of diversity among providers, which contributes to health disparities.[33] More than 54 million Americans live in areas that are designated by the Health Resources and Services Administration (HRSA) as primary care health professional shortage areas.[34]

To meet the healthcare needs of a multicultural society, there is a compelling need to equip current and new providers with the skills to provide a culturally competent approach to care. The education and recruitment of a

culturally diverse workforce can lead to greater provider-patient concordance (ie, ability for a patient to consult with a provider of similar cultural or linguistic background).[34,35]

Given the dynamic shifts in demographics in the United States and contrasts in health equity across cultures, healthcare providers cannot ignore the effects of culture on healthcare. If the healthcare system does not acknowledge and address cultural influences in patient care, patient safety can be compromised. Opportunities exist for educating providers and recruiting a more diverse workforce to care for society.

CULTURAL COMPETENCY MODELS

3 Several models are often used in healthcare to describe and understand cultural competency: the Cultural Competence Continuum by Terry Cross, the Purnell Model for Cultural Competence by Larry Purnell, and the Process of Cultural Competence in Delivery of Healthcare Services by Josepha Campinha-Bacote.[36,37,38] Across these models, a salient theme surfaces—cultural competency is a process rather than an achievement.[10,36,37,38]

In the Cross Cultural Competence Continuum, six stages are described in a stepladder model starting with cultural destructiveness and ascending toward cultural proficiency.[37] *Cultural destructiveness* in healthcare occurs when a person or an organization actively devalues or berates patients or a community based on their cultural background (eg, race, language, and religion). When persons or organizations are willing but unable to support culturally oriented practices, they demonstrate *cultural incapacity*. *Cultural blindness* results from an effort to treat every patient or family the same regardless of culture. However, the provider or organization can miss key elements in the patient's healthcare behavior that are attributable to their culture. Treating patients equally does not necessarily signify that patients should be treated the same. In *cultural precompetency*, individuals and organizational leaders recognize that culture is influential in healthcare and efforts are made to improve and adapt care related to culture. In this stage, providers and organizations often believe that making a few adjustments or changes in practice or policy to improve care to diverse cultures are sufficient. However, they do not embark on a continuous improvement plan.

Although cultural competency can really never be achieved, individuals and organizations demonstrating traits of *cultural competency* will value diversity and seek to continuously implement and evaluate new ideas and programs to improve their care to patients and families from different cultures. Those providers and organizations considered to be more *culturally proficient* will be viewed as leaders at the forefront of cultural competency who are actively educating others or conducting research in the field.

In the Campinha-Bacote model, five constructs with an interdependent relationship describe the providers developing process of cultural competence: cultural awareness, cultural knowledge, cultural skill, cultural encounters, and cultural desire.[38] By self-assessment of cultural and professional biases and beliefs, clinicians develop increased *cultural awareness*. This self-awareness helps clinicians to recognize the risk of imposing personal beliefs in patient care. As clinicians learn more about beliefs and practice, disease epidemiology, and the efficacy and acceptance of therapies that are found in diverse cultures, they expand their *cultural knowledge*. Providers acquire *cultural skills* as they learn how to collect subjective information and social histories as well as conduct physical assessments that are relevant to different cultures. The increased opportunity for *cultural encounters* through directly interacting with individuals and families from diverse groups helps providers to have practical experience with cultural norms and variations as well as language needs. At the intersection of awareness, knowledge, skills, and encounters is cultural desire. When providers want to learn and grow in the process of cultural competency and do not feel obligated to care for diverse cultures, then they expand their *cultural desire*. Cutting across all of these constructs is a sense of *cultural humility* in which providers recognize the continuous process of learning.

The Purnell model explores the relationship of family, community, and the global society as they influence the individual person.[36] The model further outlines 12 different cultural beliefs and traits that may affect the individual and are often interconnected, such as healthcare practices, spirituality, communication styles, and workforce issues. In this model, Purnell illustrates that healthcare providers and organizational leaders often experience a learning process related to their cultural consciousness. In this continuum, providers may move from being unconsciously incompetent (not aware of lack of competence), consciously incompetent (aware of lack of competence), consciously competent (aware of improving competence) toward unconscious competence. When a provider is unconsciously competent, they have been able to integrate skills, knowledge, and awareness of the varying cultural, familial, and broader community influences on a patient with fluency.

As clinicians use these models and work with new cultures and in new environments, they may feel that they regress and are not as competent. However, if organizations and clinicians recognize that they are on a path of continuous improvement and approach the care of patients and communities with an attitude of humility and sensitivity to potential opportunities and barriers in care, they will be taking great strides toward providing a positive healthcare environment for their patients and the communities they serve.

LEGAL, REGULATORY, AND ACCREDITATION REQUIREMENTS

4 Legal and regulatory issues surrounding cultural competency include understanding and interpreting Title VI of the Civil Rights Act and accreditation standards for healthcare organizations. Title VI "prohibits discrimination on the basis of race, color, and national origin in programs and activities receiving federal financial assistance."[39,40] In 2000, under Executive Order 13166 of Title VI, federal agencies became required to evaluate and develop services for persons with LEP and meaningful access to these services.[40,41]

The 2013 enhanced National CLAS Standards (Culturally and Linguistically Appropriate Services) provide a framework for health and healthcare organizations to promote health equity and quality for diverse populations.[42] The Standards open with an overarching principle to "Provide Effective, Equitable, Understandable, and Respectful Quality Care and Services." Fourteen standards grouped in three themes follow, including: (a) Governance, Leadership and Workforce (Standards 2-4), (b) Communication and Language Assistance (Standards 5-8), and (c) Engagement, Continuous Improvement, and Accountability (Standards 9-15). State and national policies have provided particular emphasis on access to language services including interpreters (**Table e2-2**).[41] Challenges persist to appropriately use, certify, and reimburse professional interpreters with a growing number of states also requiring cultural competency training for health professionals.

TABLE e2-2 Communication and Language Assistance Standards for Culturally and Linguistically Appropriate Services (CLAS) in Health and Healthcare[42]

Standard 5: Offer language assistance to individuals who have limited English proficiency and/or other communication needs, at no cost to them, to facilitate timely access to all health care and services.

Standard 6: Inform all individuals of the availability of language assistance services clearly and in their preferred language, verbally and in writing.

Standard 7: Ensure the competence of individuals providing language assistance, recognizing that the use of untrained individuals and/or minors as interpreters should be avoided.

Standard 8: Provide easy-to-understand print and multimedia materials and signage in the languages commonly used by the populations in the service area.

The Joint Commission, the primary national accrediting body for healthcare organizations and programs, supports CLAS standards through requirements for effective communication, cultural competence, and patient-oriented care.[43] This roadmap highlights the importance of integrating culturally competent care across the

organizational and professional structure from admission to dismissal.

Recognizing that improved patient safety occurs when providing appropriate language services and obtaining informed consent with well-translated and easily understandable forms, The Joint Commission has recommendations based on cultural and linguistic competency.[32,43] Considerations include collecting patient-level demographic data to report outcomes to better understand patterns in health disparities. HRSA has also developed indicators of cultural competence in healthcare organizations. The incorporation of cultural competency into Joint Commission and HRSA guidelines gives organizations and healthcare leaders further rationale to move toward more culturally competent care.

The Joint Commission emphasizes leadership involvement and ongoing staff education related to cultural competency. Further, five states in the United States have passed legislation requiring healthcare professionals to complete training in cultural competency or multiculturalism with additional states exploring similar legislation.[42,44]

The healthcare system must work to engage patients and their communities.[3] There are definite trends from stakeholders in managed care, government, and academe to incorporate cultural competence for the purpose of improving quality of care and in some cases as a business imperative.[45] Independent of the legal and regulatory requirements, the ultimate goal of a healthcare provider is to improve patient outcomes including understanding the culture and language of patients.

PATIENT EXPLANATORY MODEL

5 How do patients experience and understand their own health? According to medical sociologists, patients may enter the healthcare setting with a different explanation of their illness than the explanation found in the **Western biomedical model (WBM)**. This model proposes that there is a pathophysiologic or etiologic reason for disease. In many cultures, the source and meaning of illness may be attributed to a variety of other causes such as spiritual or religious influences or to retribution for previous deeds.[46] The term **disease**, from the view of Western medicine, is the result of a physiologic process. However, in most of the world cultures, the concept of **illness** is intimately related to the spiritual or religious aspects of their respective society. The clash of cultures can sometimes cause confusion in the patient and/or the provider about the true effects of a treatment or illness. This conflict can cause unfortunate outcomes on many levels. In an effort to help identify cultural differences in a clinical setting, providers can ask patients questions to help elucidate the previous unforeseen differences.

One of the most studied and widely used clinical models is the Patient Explanatory Model (PEM). It includes eight questions to evaluate a patient's explanation of disease (**Table e2-3**).[47] The model may best be used when clinicians sense discordance with the patient relating to adherence to a treatment plan or to the overall visit (see the Clinical Presentation box for an example of how to use the PEM).[48]

TABLE e2-3 Patient Explanatory Model—Eight Questions to Elicit Patient Understanding[47]

1. **What** do you think has **caused** your problem?
2. **Why** do you think it **started** when it did?
3. **What** do you think your **sickness does to you**?
4. **How severe** is your sickness? Will it have a short or long course?
5. **What kind of treatment** do you think you should receive?

6. **What** are the most important **results** you hope to receive from this treatment?
7. **What** are the **chief problems** your sickness has caused for you?
8. **What** do you **fear** most about your sickness?

CLINICAL PRESENTATION Using the Patient Explanatory Model versus the Western Biomedical Model (WBM)

A 55-year-old Latin American woman presents to the clinic for smoking cessation therapy. She reports smoking about 15 cigarettes a day, mostly when she is stressed and depressed. She lives in a rural, primarily Spanish-speaking community. Her education is limited to the fifth grade. In her home life, she is not able to make many financial decisions without permission from her husband.

When asked questions using Kleinman's patient explanatory model (PEM), the patient may have responded as follows (*assumptions in Western biomedical model [WBM] are included for comparison*). Review of the possible responses to the questions provides insight about how a disconnect can occur with patients or their family members in developing a treatment plan.

1. **What do you think caused your problem (smoking)?**

   PEM: Well, my blood sugar is high because I smoke.

   WBM: The patient has come in for smoking cessation with no mention of diabetes.

2. **Why do you think it started when it did?**

   PEM: My mother was sick and she passed away about 10 years ago. I started smoking then because of the stress. Right after that, the doctor told me I had diabetes.

   WBM: Type 2 diabetes onset can begin with a number of risk factors including family history and obesity. Tobacco use is a dependence disorder.

3. **What do you think your sickness does to you?**

   PEM: Smoking makes my blood sugar high. That's why I can't control my diabetes.

   WBM: Smoking can affect diabetes, but it also can lead to heart disease, lung disease, cancer, and a number of other comorbidities.

4. **How severe is your sickness? Will it have a short or long course?**

   PEM: My diabetes will not go away unless I quit smoking.

   WBM: Diabetes will continue lifetime. Smoking cessation can occur, and if maintained, a person can continue tobacco free for the remainder of their lifetime.

5. **What kind of treatment do you think you should receive?**

   PEM: If I quit smoking, my diabetes will go away. I will use the patch and gum like you told me. I know I can't pay for the other medicines.

   WBM: To quit smoking, the patient may incorporate behavioral support with nicotine products. With depression, bupropion may also be indicated. The diabetes will require different medications as well as lifestyle

support for diet and exercise.

6. **What are the most important results you hope to receive from this treatment?**

   PEM: That my diabetes will go away.

   WBM: That her general health will improve with smoking cessation. We can support improvement in her diabetes control.

7. **What are the chief problems her sickness has caused for her?**

   PEM: Smoking costs a lot of money, but I can buy cheaper cigarettes in Mexico. I am tired a lot.

   WBM: She may not feel the effects of smoking and may actually feel less anxious. However, lack of control of blood sugar can cause fatigue, frequent urination.

8. **What do you fear most about her sickness?**

   PEM: That I will die soon, like my mother.

   WBM: That smoking can lead to heart disease, lung disease, and cancer. The diabetes can also lead to negative health consequences and poor quality of life.

A modification of the PEM is the "4 Cs" (Call, Cause, Coping, Concerns), and this mnemonic device may be useful for providers.[15] Providers may ask the patient: (1) "What do you *call* the illness?"; (2) "What do you think *caused* the disease or illness?"; (3) "How do you *cope* with the disease or illness?"; and (4) "What *concerns* do you have about your disease or illness?" This simplified version of Kleinman's original questions still provides information about how the patient interprets illness. However, use of the full explanatory model can provide more revealing information.

USE OF COMPLEMENTARY AND ALTERNATIVE MEDICINE

Complementary and alternative medicine is defined as any practice for the prevention and treatment of disease that is not usual conventional medicine.[49] Classified under CAM are a broad range of practices that are grouped under four categories: biologically based practices, energy medicine, manipulative and body-based practices, and mind-body medicine. Specific examples of CAM may include dietary supplements, vitamins, herbal preparations, homeopathy, special teas, acupuncture, massage therapy, magnet therapy, spiritual healing, folk medicine, and meditation. Of these practices, the use of herbal medicines likely holds the most relevance in terms of its influence on conventional pharmacotherapy.

Worldwide, an estimated 80% of the population uses herbs; in the developing world, rates can be as high as 95%.[50] To further complicate this situation, recent trends include the use of combinations of herbal products or extracts, vitamins, and various other natural and synthetic ingredients that are packaged and marketed with a pharmaceutical appearance (nutraceuticals) or included in energy drinks. Also of concern is the recent trend of adding pharmaceutical compounds to products sold as "natural remedies."[51] Given the prevalence of herbal medicine use worldwide, the World Health Organization (WHO) has provided guidelines for the growth and collection[52] and manufacturing of these products.[53]

The use of traditional healers and CAM is a cross-cultural phenomenon. A holistic approach for the prevention and treatment of diseases has long been used by American Indians and practices from other cultures have also been important since Spaniards first came to the North American continent more than 500 years ago.[54,55] The

long-standing integration of traditional healing practices has taken a new dimension with globalization and increased Internet access by all populations. For example, Chinese practices of traditional medicine are expected to be easily found in United States cities with large populations of Asian heritage but they may also be common in cities where Asians-Americans are a relatively small part of the population.[56,57] Similarly, products like prickly pear cactus ("nopal"), a plant native to Mexico and the Southwest United States and used to treat diabetes, has been exported to and used in China.

In the United States, the most recent national survey documented CAM use in more than 35% of the population.[49] However, certain regions of the country with large populations of diverse racial and ethnic groups may actually use CAM more frequently. For example, in areas near the border with Mexico, herbal product usage rates have been documented at 65%.[56,57] In a 2012 systematic review of the prevalence of herb usage among racial and ethnic minorities, the overall (ranges) rates were reported as followed: African Americans 17% (1%-46%), Hispanics 30% (4%-100%), and Asians 30% (2%-73%).[58]

With increasing use of CAM, healthcare providers should consider potential problems with conventional pharmacotherapy. CAM practices generally are not considered standard medical approaches. Unlike standard treatments, they may not go through appropriate research methods or quality assurance to prove they are safe and effective; as a result, less is known about most types of CAM. In the United States, distributors of herbal products are not required to follow current Good Manufacturing Practices.

Surveys have demonstrated low disclosure rates of CAM use by patients to their healthcare providers. Minorities —including Asian Americans, Hispanics, and African Americans—may have lower disclosure rates than non-Hispanic whites for two reasons: conventional providers do not ask about CAM use, and/or patients may be concerned about disapproval from their providers.[59] One strategy for inquiring about CAM use is to ask open-ended questions and to avoid being judgmental when patients do report their use of CAM. For example, providers could ask, "What vitamins, herbal products, home remedies, or supplements do you use to treat (insert condition)?" instead of asking, "Do you take supplements?" A recent study has documented that Latinos disclose at higher rates when asked specifically about use of herbal medicine teas.[60] It is beneficial to have an understanding of patterns of CAM use by different racial, ethnic, or cultural groups, but it is equally important to evaluate each individual with an approach that encourages disclosure and inspires trust. When inquiring about the use of CAM, the approach of the healthcare provider must be open, neutral, nonjudgmental, and respectful of the individuals' cultural practices and their choice to use traditional medicine. In cases where the provider identifies any concerns or potential harm, when they approach the issue in the manner described above, they are in a better position to provide the patient with the necessary guidance. As health science training integrates more understanding of CAM practices, especially herbal medicines and dietary supplements, healthcare professionals will be better equipped to address CAM related issues and concerns.

CULTURAL VALUES AND BELIEFS

6 Numerous factors can influence cultural values and beliefs toward healthcare as suggested by social determinants of health. Age, gender, race, ethnicity, sexual orientation, religion, geography, neighborhood, acculturation, and linguistic identities all shape how people behave and what they value. One of the dangers of learning to work with patients and families from different cultures is confusing stereotypes with generalizations. **Stereotypes** may be damaging to patients as they are an end point or assumption about the way people will behave.[15] **Generalizations**, however, can provide a framework or beginning to understanding how patients *may* respond in healthcare situations.[15] When developing a framework to work with patients, understanding the degree to which individuals identify themselves within different cultures is worthy of consideration.

Social Identity

One aspect of culture is linked to how social identity is defined. **Social identity** can be described as a person's sense of self, based on memberships to various social groups.[61,62] Social group membership can be based on gender, age, ethnicity, race, family, sexual orientation, religion, or other cultural factors. Individuals' social identities consist of membership to multiple groups. For example, a person may identify as a young (age), Catholic (religion), female (gender), Hispanic (ethnicity), of African descent (race). Identification with a particular group (eg, Hispanic) is the individual's **ingroup**. Conversely, group in which the individual does not identify (eg, non-Hispanic Caucasian) is the individual's **outgroup**.[63]

An individual's identification with a social group is influenced by contextual factors,[64] such as individuals within the immediate environment. For example, an African American woman may identify more strongly with her gender ingroup in the presence of several African American males but identify more strongly with her racial ingroup in the presence of several white women. In other words, there are instances in which one social group membership may become more salient and thus be more influential on behaviors than other group memberships. Understanding how strongly a patient identifies with a particular social group will assist healthcare providers in identifying the influence of that social group's cultural norms and expectations on the patient's healthcare decision-making. For example, a patient who has recently immigrated must redefine how they identify with cultural ingroups or outgroups in the new context. This, in turn, defines how individuals experience the process of acculturation within dominant cultural groups in a new host country.

Acculturation

Culturally competent providers are familiar with the concept of acculturation and its role in the area of health. **Acculturation** can be defined as the process by which individuals from one cultural group experience changes in behaviors, attitudes, and beliefs as a result of continuous contact with a different culture.[65] Acculturation has been studied in relation to a number of health behaviors and its influence cannot be underestimated.[66]

Levels of acculturation have been associated with differences in help-seeking behavior, healthcare utilization rates, adherence, presentation and perception of illness, attitudes toward healthcare providers and treatment, and beliefs about healing.[67] Acculturation measurement tools have been used in research in an attempt to capture the relationship between acculturation and health disparities or health outcomes.[13] Research has been conducted in Mexican American populations with increasing studies in other racial, ethnic, and immigrant populations. Some weaknesses in theories of acculturation (in studies conducted in the United States) exist because assumptions are made that immigrant populations are able to choose to participate fully in American society and that the ultimate goal is to assimilate into American culture.[13]

Regardless of how acculturation is measured or researched, understanding concepts related to acculturation can be helpful to providers. One model of acculturation that provides a framework for understanding acculturation describes assimilation, integration, marginalization, and separation as four possible outcomes of the acculturation process. In this framework, there are two cultures of reference, the home culture (the culture *from* which the individual comes) and the host culture (the culture *to* which the individual is introduced or is immersed).[68] This relationship can have varying levels of effect on each other and can be bidirectional in nature.

Individuals may have the least difficulty adapting to the new host culture when they are able to assimilate or integrate.[68] In **assimilation**, individuals lose (willingly or unwillingly) much of their identity from their home culture and adopt the new host culture. In **integration**, the individual is able to adopt identities from both the host and home culture. These individuals may be considered bicultural or even bilingual.

Through the process of marginalization and separation, individuals have a more difficult time adapting to a new host culture.[68] When individuals are **marginalized**, they have strong identities to their home culture and may not be able to adapt well to the host culture. Marginalized individuals may include more recent immigrants or refugees. Persons who are in **separation** may never really understand their home culture or their host culture. They may live "in between" cultures, never fully learning the home culture or host culture. This phenomenon may occur in children who have never completed their basic education in either culture (thereby never mastering one language) or who do not have enough exposure to cultural events and traditions from their home or host culture to entirely understand or appreciate either heritage. When interacting with bicultural or bilingual patients, it is important for healthcare providers to consider the cultural group most salient to the patient's social identity as the influence of home or host culture can vary due to contextual influences.[69,70,71]

Individual versus Collective Influences

There are other factors that influence how persons interact in cultures. For example, different cultures place varying emphasis on the importance of individual and the collective influences on decision-making.[72] Those persons who come from more **individualistic cultures** (eg, the United States) are more likely to place greater emphasis on an individual's self-reliance and emotional distance from others within the individual's group.[73] Patients from individualistic cultures expect greater individual responsibility for healthcare decisions.[74]

Alternatively, persons who come from **collective cultures** experience greater emphasis on interdependence and family integrity.[73] Patients from collectivist cultures experience increased community participation with their healthcare decision-making.[75] It is important to note that some cultural groups (eg, Latino, African American, and American Indian) may identify as being particularly familistic—the family unit has a core influence on their cultural and community identity.[76] A greater emphasis on the family unit leads to different attitudes and behaviors such as different expectations for seeking healthcare (eg, an aunt or godmother caring for the ill) and the development of different beliefs, norms, and traditions.[77]

Clinical Controversy… APPLYING UNDERSTANDING OF ADDRESS BARRIERS IN HEALTH

Select any one of the patients from diverse backgrounds introduced at the beginning of the chapter. What are the factors that influence their health that are based on genetics? Individual and family choices? Community influences? Larger city and policy structures? Based on the information provided, what social identity and acculturation characteristics are involved? Look up information about healthcare beliefs and values based on how the patient self-identifies with religion and race or ethnicity. If approached by one of the patients, providers may argue that "we can't solve everything in healthcare. I only have so much time during a visit." How might you counteract those statements? What changes can be made at a provider level, clinic/hospital level, and at a larger system-wide level to improve care across cultures?

Health Beliefs and Practices Found in Various Cultures

Although it is not feasible to understand the intricacies of every culture, it is possible to explore common characteristics of various cultures in order to learn more about them. It is important to recognize that the traits identified in this text are generalizations about a particular cultural group. Not every member of these groups will demonstrate these characteristics. Ultimately, care should be individualized, but the following generalizations can serve as a guide to working with patients from a particular race, ethnicity, religion, or other cultural group. In some cases, clinicians can apply the mantra, "Treat others as *they* would want to be treated," also called the *Platinum Rule*.[67]

Individuals from different cultures may have different beliefs about the origins of health and illness and may not

subscribe to the WBM.[35,47] Some cultures may view health as the result of harmony with nature or the balance of natural forces. Still others may believe that health is a result of good luck or reward for good behavior. Views about the origins of illness may also differ depending on culture. Some believe that illness is the result of an imbalance in natural forces while members of other cultures may point to supernatural powers as the cause of disease or illness. Various cultures describe illnesses that are only recognized within that culture. These "culture-bound syndromes," also often referred to as folk-illnesses, are often manifested through changes in behavior, cognition or affect without the presence of signs or symptoms that can be objectively confirmed.[15,78] There are a variety of culture-bound syndromes that have been documented. For example, conditions, such as *empacho* (stomach pain caused by ball of food blocking the digestive tract), *susto* (illness arising from extreme fright), *mal de ojo* (illness caused by the "evil eye" resulting from excessive admiration or envy), or *caída de la mollera* (depression of anterior fontanelle in infant), can be found in Latin American cultures.[36,46] *Dhat* is a culture-bound syndrome reported in Indian cultures that manifests as fatigue, weakness, or sexual dysfunction thought to be caused by loss of semen during urination, masturbation, or nocturnal emission.[79] Culture-bound syndromes are also found in Western cultures. Anorexia nervosa, an eating disorder characterized by extreme weight-loss caused by self-starvation, is well-recognized in Western cultures but may not be acknowledged in other cultures.[80]

Certain healthcare practices may stem from historical events or experiences not explained by the WBM. Some African Americans, for example, may practice *geophagy* (eating of earth or clay).[46] This practice has historical significance and was noted among some slaves from Africa who may have focused on eating red clays, which are iron rich.[46] Additionally, African Americans may not trust the healthcare system or research projects because of previous injustices, including slavery and the Tuskegee syphilis study.[81] The latter example refers to research conducted by the United States Public Health Service from 1932 to 1972, in which African American men with syphilis were recruited to participate in a study to investigate the natural course of untreated disease.[81] This project continued until the early 1970s despite the availability of penicillin and confirmation in the 1940s that penicillin was an effective treatment for syphilis.

As discussed previously, it is important to recognize that members of various cultures may employ the use of traditional healers, CAM such as herbs, or other practices such as massage. Traditional healers who may be involved in the care of a patient include *curanderos(as)* in some Latin American cultures, "medicine men or women" in various American Indian communities, voodoo doctors by African Americans practicing voodoo, or *santeros* (mediums) among individuals practicing *Santería* (religious practice originating in Nigeria in which the gods [orishas] of the Yoruban people are matched to Catholic saints and connected to various health problems).[36,46]

Furthermore, religious rituals or ceremonies are often an important part of treatment in many cultures. Some American Indian cultures, for example, may practice divination (diagnosis) or singing in the treatment of illness. Three types of divination include *motion in the hand* (pollen or sand is sprinkled around the patient while song is sung and diagnostician moves hand to determine the cause), *stargazing* (prayer to star spirit is made by stargazer and rays of light thrown by star are used to determine cause of illness), and *listening* (diagnostician listens for certain sounds to help in diagnosis). For some members of American Indian cultures, these practices may have a profound psychologic effect and allow the patient to feel cared for in a personal way.[46] Patients from various religious backgrounds will include prayer as a way of coping with life stresses.[82]

Other culturally based healthcare practices may lead to physical signs on the body that might be taken as signs of injury or abuse. Patients of Asian descent may practice *coining* (coins are dipped in oil and heated and then rubbed on skin), *cupping* (heated glass cups are placed on skin to create vacuum), *moxibustion* (heated incenses or wood applied over the skin), or pinching of skin in order to draw out illnesses.[36] These practices may produce

bruises, burns, or welts on the skin that might be confused with signs of physical abuse.[46] Clinicians should be aware that cultural beliefs may have led to the practice of alternative forms of healing and this should be taken into consideration when evaluating a patient.

Family roles and communication styles may also differ based on culture. Certain cultures have strong family values or close-knit family structures. As a result, the healthcare encounter with patients from these cultures may involve the participation of other members of the family. Communication styles will also vary; thus, clinicians should be aware of communication characteristics when working with patients of various cultures. **Table e2-4** includes various characteristics related to healthcare beliefs, practices, and values that have been found in select racial and ethnic groups represented among the population of the United States.

TABLE e2-4 Cultural Beliefs, Values, and Practices Found in Selected Racial and Ethnic Groups[a,b]

	Beliefs on Health and Illness	Healthcare Practices	CAM Use	Family Role	Communication
African Americans[c]	Health may result from harmony with nature; illness results from disharmony Illnesses may be due to natural causes (God's plan, eating the wrong food, environmental) or unnatural causes (evil origins such as demons, spirits, "hexes") May distrust the healthcare system due to previous injustices (eg, slavery, Tuskegee syphilis study)	Time orientation may be focused on the "present" and may impede preventive care and follow-up Rural patients or patients of low socioeconomic status may wait for emergencies before seeking care Laxatives may be used to "keep the system running" or "open" Blood or organ donation may be rejected out of fear of hastening donor's death May refer to certain foods as causing "high" or "low" blood, which may be confused with blood pressure or blood count	May use traditional healers and folk medicine/CAM Examples include use of herbs, copper or silver bracelets to protect the wearer, poultices to draw out infections May consult magicians, priests, or voodoo doctor in the treatment of "unnatural" illnesses (regional)	Family structure is often strong Child rearing may be shared by grandparents Families often matriarchal (but father or eldest male may be the spokesperson) High esteem for elderly often found	Family members may not permit discussion of serious healthcare problems directly with patient May prefer to be addressed as "Mr." or "Mrs." or by professional title

	Beliefs on Health and Illness	Healthcare Practices	CAM Use	Family Role	Communication
East Asian (eg, Chinese, Japanese, Korean)	Health may involve the balance of yin (cold) and yang (hot); illness often caused by an imbalance A person's body may be viewed as a gift and should be cared for and well maintained May have a distrust of Western medicine Certain numbers, such as the number "4," may be viewed as signifying death	May use combination of Western medicine and traditional Chinese medicine May be upset by the practice of drawing blood (source of life for the body that may not be regenerated) Deep respect for the body may lead to refusal of painful procedures for diagnostic workups or surgery unless absolutely necessary Stigma related to mental illness	Traditional medicine may be used, including herbal products Other practices may include acupuncture, coining, pinching, cupping of skin to draw out illnesses, and moxibustion	Community may be more important than the individual, individual needs may be sacrificed for family Families are often closely bound and include the extended family Family matters are not often discussed in front of others Wives may defer to husbands for medical decisions	Emotions may be spared and physical distance may be preferred A Chinese patient may rarely complain about what is bothering him or her May avoid direct eye contact Hand gestures (eg, beckoning with index finger) may be interpreted as an insult
American Indian	Health may involve harmony with "Mother Earth" Bodies should be treated with respect, just as the Earth is treated with respect as a living organism To maintain health, one should maintain a relationship with nature	Traditions may be passed down through storytelling or oral history Storytelling may be incorporated in some educational settings to convey important messages in disease education May distrust	Traditional healers ("medicine men or women") and rituals/ceremonies are often used by some subcultures May use prayer/special ceremonies for diagnosis and cure of illnesses Examples of special ceremonies include "motion in the hand," stargazing, and listening	May value the group over the individual —cooperation, sharing, balance with nature is important Family and community may be closely connected Respect for elders is often important Family members	May be considered more appropriate to avoid direct eye contact or speaking directly to elders out of respect Important values: respect, equality, kindness, modesty, not drawing attention to oneself Loudness may be associated with aggressiveness

	Beliefs on Health and Illness	Healthcare Practices	CAM Use	Family Role	Communication
	The human body may be divided into two halves—a positive and a negative energy pole, and the energy of the body can be controlled by spiritual means Disease and illness often related to supernatural powers or evil spirits May not believe in the germ theory of modern medicine	documents such as informed consent or advanced directives because of previous historical injustices Cutting or shaving of hair should be discussed with patient as this practice may be associated with mourning	Other methods of treatment include massage, heat treatment, use of sweat baths May use herbal medicine or natural roots Herbs may be seen as "spiritual helpers" and gathered with great care to maintain harmony with nature	may accompany elderly patient to serve as interpreter or to help communicate health information Decision-making varies with kinship structure; women may be primary decision-makers in matrilineal tribes	among the Navajo
Hispanic/Latino	Health may be a matter of good luck or reward for good behavior Illnesses may be caused by imbalances between hot and cold or wet and dry May have pessimistic attitude toward recovery (fatalism)	Treatments may be determined based on the classification of the disease May use *curanderos/as* and CAM along with Western medicine Folk medicine diseases that may be referred to in Hispanic culture are *empacho, susto, mal de ojo, caída de la mollera* Time orientation may be focused on the "present"	May use home remedies and *curanderos/as* (traditional healers) May use religious rituals for treatment of illness, such as prayer offerings, use of medals/amulets /candle, visiting shrines, making promises (*promesas*) to God or to saints in return for recovery from illness Some Hispanics (especially of Puerto Rican or Cuban descent) may practice *Santería*	Families are often very important Families often have close-knit structure More than one family member may participate in the healthcare encounter Integration of the family in decision-making may be important for the success of a treatment plan Older,	Respect (*el respeto*) is often incorporated into the language and appropriate deference in relation to age, sex, and social status is important Developing and maintaining personal relationships (*personalismo*) and trust (*confianza*) toward their healthcare providers is often important

	Beliefs on Health and Illness	Healthcare Practices	CAM Use	Family Role	Communication
		and may impede preventive care and follow-up		traditional wives may defer to husbands for medical decision-making	
Middle Eastern	Cold, damp drafts, and strong emotions may lead to illness May have fatalistic attitude regarding health "Evil eye" (jealousy) may also cause illness Illness may be viewed as punishment for sins from higher being	Preventive care may not be a priority and medication use is common Patients may expect a prescription for illness from their provider Mental illness may be seen as a stigma and may prevent patients from seeking psychiatric care	Amulets may be used to protect the wearer from "evil eye" or other causes of illness Foods viewed as "hot" or "cold" may play a role in maintaining health May use herbal products to treat certain illnesses	May be appropriate to speak to family spokesperson Women may defer to husbands for medical decisions Personal problems may be taken care of by family	May prefer if provider shares information about themselves in order to facilitate building of relationships May avoid direct eye contact with members of opposite sex Sexual segregation may be preferred (eg, assign provider from same sex as patient) Appropriate conversational distance is short
South Asian/East Indian	Health may be due to connection of mind, body, and spirit Many may believe in the traditional Indian system of medicine, *Ayurveda* (*ayu* meaning "life" and *veda* meaning "knowledge") Ayurvedic medicine	Healthcare providers are often seen as authorities; patients may take a more passive role and prefer for a provider to make decisions Mental illness may be viewed as a stigma and may be concealed or presented as somatic	May practice Ayurvedic medicine for preventing and curing illness "Hot" or "cold" foods (based on qualities of the food and not temperature) are often suggested for certain conditions Practice of Ayurvedic medicine may recommend that certain herbs be used for healing May use other home	Close female family members often remain with the patient Father or eldest son may make decisions for family Husbands may answer questions for wives	Direct eye contact may seem disrespectful, particularly among the elderly Silence may indicate respect or approval Up-and-down head nod may signal disagreement where a side-to-side head bob may signal agreement

	Beliefs on Health and Illness	Healthcare Practices	CAM Use	Family Role	Communication
	involves maintaining a balance between the physical, mental, and spiritual being Some believe that mental illness is due to the "evil eye" Hindus may believe that illness is due to *karma*	complaints (eg, headaches, stomach pain) Sacred thread worn around the neck of women or chest of men should not be cut without permission of the patient or family	remedies for illness (massage, bathing)		Patients may prefer same-sex providers due to modesty May avoid shaking hands with females unless female offers first

CAM, complementary and alternative medicine.

[a]These practices and beliefs may be found among persons (not all) who identify with the racial or ethnic groups listed above.

[c]May be found in pockets in the United States and not necessarily found in recent immigrants from Africa.

Data from references 15, 35, 46, 83,84, 85.

The cultural influence of religion on healthcare can be critical. For example, a patient who comes from the Jewish or Muslim faith may be unwilling to accept omega-3 fatty acids as a therapy option for hypertriglyceridemia because the gelatin formulation may not adhere to the dietary restrictions of the religions.[46] A female patient whose religion embraces greater physical distance between women and men in social situations may not be comfortable working with a male healthcare provider. A devout Christian family may be concerned about discussions of contraception or emergency contraception. To elicit information about a patient's religious or spiritual concerns, providers may ask, "I feel that I can help you better if you can tell me what religious or spiritual needs I should consider in your healthcare." **Table e2-5** lists some health beliefs and practices found in common

worldwide religions.

TABLE e2-5 Healthcare Practices and Beliefs Found in Selected World Religions[a]

	Contraception	Medications or Special Dietary Restrictions	Healing Practices
Western Religions			
Catholic	Natural family planning No birth control	May use medications	Prayer, candles, laying on of hands Holy sacraments may be offered to ill Visits from priest
Protestant Christian	Varied beliefs	Varied restrictions	Prayer Diverse opinions of divine intervention Visits from pastor
Judaism	Permitted (often Orthodox may not)	Pork and shellfish products often forbidden Meat preparation meets Kosher standards Fasting during Yom Kippur (day of atonement)	Prayers Visits from rabbi
Islamic	Permitted	Pork and alcohol often prohibited Meat preparation meets *halal* ("lawful") standards Fasting during Ramadan	Some herbal remedies and faith Visits from imam
Eastern Religions			
Buddhism	Permitted	Vegetarian diet Some holy days require fasting	Prayer Picture of Buddha may be used to facilitate meditation
Hinduism	Permitted	Vegetarian diet; meat products often prohibited Several holy days require fasting Most medications permitted	Includes traditional faith healing

[a]These practices and beliefs may be found among persons (not all) who identify with the religions listed.

Data from references 46, 86.

A diverse society will yield diverse health beliefs and practices. Potential differences among individuals in their acculturation levels can affect observance of cultural practices. Developing a general understanding of common cultural health behaviors can help clinicians to approach patients in a culturally competent manner.

CROSS-CULTURAL COMMUNICATION

7 Developing communication skills to interact with diverse populations includes recognizing personal styles of communication. However, providers should have communication skills to recognize if a barrier may exist, and they should work to care for patients regardless of the language they speak. Understanding personal communication styles provides insight to clinicians so they may be able to prevent or acknowledge any bias or expectations during clinical encounters. By recognizing personal cultural biases, clinicians can better serve the patients.

Barriers related to cross-cultural communication can affect the provider-patient relationship. From the perspective of The Joint Commission, the threat to effective communication is threefold: language differences, cultural differences, and low literacy levels.[43,87] Patients can also have communication barriers because of differences in age or gender with the provider.[8] A person with a lower level of education may not be comfortable working with a provider who has obtained a college education and/or attended graduate school. An older patient may not believe that a younger provider has enough work or life experience to be qualified. A man from a more conservative religious upbringing may not feel it is appropriate to be counseled by a female provider. Other barriers to care may exist because of fear and distrust in the provider due to race or ethnic background, prejudices, or lack of familiarity or knowledge of the culture.[8,48] For example, a patient who is of Chinese descent may not feel comfortable with a provider who is Mexican American because of a perception of unfamiliarity and a lack of opportunity to interact with persons of the other background.

Communication Skills

Communication skills needed to work with patients from diverse cultures include looking for nonverbal cues.[8,46,48] Providers can often gain clues for how to interact with patients by observing their behaviors and following patients' mannerisms. Patients will have varying preferences of eye contact, personal space, and physical contact.[8,46] Some patients prefer indirect eye contact and may view direct eye contact as rude or intrusive. A comfortable distance for personal space also varies across cultures.[8,48,88] In some cultures, patients prefer only a handshake or a nod of acknowledgment for greetings, whereas in other cultures, patients will welcome a light tap on the shoulder or even a hug.

Verbal cues include recognizing whether patients prefer to be called using their first name or last name.[8,15,46] Some patients embrace the opportunity to talk and get to know their provider before jumping into medical information. Using a vocabulary that is consistent with the culture and education of patients is another strategy that can help providers gain trust.

To develop skill sets to work with patients from diverse communities, providers can identify cultural "brokers" or community liaisons.[17] These liaisons are often respected community members and leaders who recognize the importance of connecting the healthcare community with the community being served. Liaisons may be religious leaders or mothers and grandmothers in the community. The key is to align providers with these community liaisons to help interpret what cues (nonverbal and verbal) and ways of communicating are most appropriate.

Limited English Proficiency and Hearing Impairment

According to Census 2010 data, 20% of people living in the United States 5 years of age and older speak a language other than English in the home.[19] LEP occurs when a person is not able to communicate effectively (reading, speaking, writing, or understanding) in the English language because of English not being the primary language.[21,40]

8 Linguistic competency encompasses understanding issues related to working with patients with LEP and/or hearing impairments such as learning basic terms and greetings, working with an interpreter or language-assistance lines, and using non-English patient education/materials.

For healthcare providers to more effectively communicate information to patients with LEP, it is important to identify the most common languages spoken among their patients. As outlined in the CLAS standards, organizations receiving federal funds (indirect or direct) must provide meaningful access to persons with LEP.[21,39,40] Using professionally trained interpreters has been shown to improve clinical care, improve patient safety, and increase satisfaction for patients with LEP.[89,90,91,92] In addition to having qualified interpreters, it is important to train healthcare providers to use and interface with professional phone interpreter services.[93] A variety of online resources are available to begin learning about working with interpreters and translators (**Table e2-6**).

TABLE e2-6 Resources for Working with Interpreters and Translators

Tips for Working with Healthcare Interpreters:

Sight Translation and Written Translation: Guidelines for Healthcare Interpreters. The National Council on Interpreting in Health Care

www.ncihc.org/assets/documents/publications/Translation_Guidelines_for_Interpreters_FINAL042709.pdf

While interpreter services may exist, challenges persist to identify patients with language assistance needs as well as to maintain a consistent and qualified language assistance workforce in the healthcare system.[94] In the event that a trained interpreter is not available, the clinician may need to work with an ad hoc interpreter (eg, bilingual coworker, family member, and friend), which poses a greater risk for error.[48] Children (minors) should not be used as interpreters. Clinicians should be actively aware of the interpretation situation. If the interpretation appears to be muddled or the process seems confusing, then it is appropriate to insist upon finding a more reliable source of interpretation.

Organizations and clinicians can also create a positive environment for patients with LEP by having written materials translated into the common languages found in the served population. Materials should be translated by certified translators and not by staff members, family, or friends who state that they are bilingual.

Tools for Working Across Cultures

Clinicians should recognize that assessing culture in the patient encounter is not necessarily a new concept.[48] The "social history" of patients provides room to explore the patient's individual and family situation, work and home environment, unique dietary needs, and education background, among other sociocultural influences. 9 However, tools have been developed to help providers further address unique cultural situations that can arise in the patient encounter.

One model frequently cited for working with patients from diverse cultures is LEARN (listen, explain/empathize, acknowledge, recommend/respect, and negotiate).[88] In the LEARN model, providers are called to *listen* to their patients' perceptions of their health with an open mind. Providers should then take time to *explain* their perceptions and *empathize* with the patient. *Acknowledgment* of commonalities and differences in the approach to understanding health and treatment options for the patient can help to build trust.[88] When providers *recommend* a treatment plan in a way that is *respectful* of the patient's culture and beliefs, the provider and patient can find a common ground. With this baseline respect, a plan can be *negotiated* to *navigate* through the healthcare system.

While barriers do exist for cross-cultural communication, clinicians can overcome these challenges by understanding verbal and nonverbal cues to communication. They also should recognize that quality interpretation is essential in the patient encounter. Tools for navigating across cultures include learning how to listen, empathize, and negotiate a treatment plan with patients.

ORGANIZATIONAL AND INDIVIDUAL SELF-ASSESSMENT

Both individuals and organizations demonstrate the capacity for providing a culturally competent environment. 10 Before understanding other cultures*, individual practitioners* should understand their own personal values and beliefs. Additionally, assessment of attitudes, practices, policies and structures *within an organization* can assist in planning for and incorporating cultural competence into the provision of healthcare within organizations.[18]

The process of self-evaluation may begin with the simple act of a practitioner reflecting on the values and beliefs that shape their world view, their perceptions of health and illness, and the existence of stereotypes or myths about other cultures.[16] To assist in this process, self-assessment instruments have been developed to guide individual healthcare providers in their reflection of cultures, values, and beliefs.

A variety of assessment tools designed for use by individual practitioners are available in both written and online formats (**Table e2-7**).[95,96,97,98,99,100,101,102,103,104] Domains that are typically assessed by these instruments include values and belief systems, communication styles, experience in cultural diversity, materials and resource evaluations, and others.[96,97] Many of these tools pose specific examples or questions within each domain that allow practitioners to assign ratings that reflect their level of cultural competence. Although there are no correct answers, these instruments provide individuals the opportunity to identify personal attitudes, values, and beliefs that do not foster cultural competence. By becoming aware of these issues, the practitioner may then make plans to improve upon or change these characteristics and move toward a more culturally competent approach to providing healthcare.

TABLE e2-7 Assessment Tools for Practitioners and Organizations

Name	Domains Assessed	Description
Promoting Cultural and Linguistic Competency: Self-Assessment Checklist for Personnel Providing Primary Healthcare Services[9]	• Physical environment • Materials and resources • Communication styles • Values and attitudes	• 37-item checklist • Individual practitioners are asked to rate statements in each domain as something that they do "frequently, occasionally, rarely, or never"
Healthcare Provider Cultural Competence Instrument	• Awareness/sensitivity	• Developed to be applicable for

Name	Domains Assessed	Description
(HPCCI)[102]	• Behaviors • Patient-centered communication • Practice orientation • Self-assessment	health care providers from a variety of disciplines
Clinical Cultural Competency Questionnaire (CCCQ)[103,105]	• Knowledge of sociocultural issues • Skills in dealing with sociocultural issues • Comfort level in dealing with encounters/situations involving sociocultural issues • Attitudes • Education/training in cultural diversity	• 63-item measure designed to assess physicians' provision of culturally competent care • Has been evaluated and adapted for use in assessing pharmacy students' cultural competency • Can use this as a needs assessment in planning educational interventions that address cultural diversity
Self-Assessment of Perceived Level of Cultural Competence (SAPLCC)[104]	• Assesses six-domains of cultural competence (Knowledge, Skills, Attitudes, Encounters, Awareness, and Abilities)	• 68-item tool adapted from the CCCQ and the California Brief Multicultural Competency Scale (CBMCS) • Validated in pharmacy students and recommended for use in pharmacy schools
Cultural and Linguistic Competence Policy Assessment (CLCPA)[98]	• Knowledge of diverse communities • Organizational philosophy • Personal involvement in diverse communities • Resources and linkages • Human resources • Clinical practice • Engagement of diverse communities	• 51 broad categories for questions • 43-page manual, "A Guide for Using the CLCPA Instrument," is available
Organizational Cultural Competence Assessment	• Organizational values	• Provides an analytic, organizing framework that is adaptable to the

Name	Domains Assessed	Description
Profile[101]	• Governance • Planning and monitoring/evaluation • Communication • Staff development • Organizational infrastructure • Staff development	organization • Includes indicators of observable or measurable characteristics that signify cultural competence
Clearview Organizational Assessments-360 (COA360)[99]	• Based on CLAS Standards, Joint Commission Standards, and the Human Rights Campaign Foundation Healthcare Equality Index (HEI) • Includes assessments of patient/client attitudes and experiences adapted from the Hospital Consumer Assessment of Healthcare Providers and Systems (HCAHPS) • Consists of questionnaires to be completed by members of various unit constituent groups (eg, administrator, clinicians/service providers, staff, patients/clients)	• Provides a multidimensional "360-degree" view of the organization • Two versions are available: 1) COA360U for departments or units of a healthcare organization, 2) CAO360H for hospitals and healthcare organizations • Administered via the Internet at *www.clearview360.org*
Cultural Competency Assessment Tools for Hospitals (CCATH)[95,100]	• Clinical cultural competency practices • Human resources practices • Diversity training • Interpreter services (availability, policies, and quality) • Translation of written materials • Leadership and strategic planning • Performance management systems and continuous quality improvement • Data collection (inpatient	• Developed to assess adherence to CLAS standards • Includes domains based on the National Quality Forum's comprehensive framework and preferred practices for measuring and reporting cultural competency

Name	Domains Assessed	Description
	population, service area) • Community representation	

The assessment of the cultural competence of organizations and systems is just as important as individual assessments and should not be overlooked. Assessing the cultural competency of an organization promotes the principles of equal access and the provision of services in a nondiscriminatory manner.[9] To plan for and incorporate cultural competence into an organization, attitudes, policies, practices, and structure within the organization should be considered. An essential part of this assessment involves determining the needs, preferences, and satisfaction of patients and consumers who are served by the organization. Tools that may be used by organizations to assess cultural competence are also summarized in the accompanying table (see Table e2-7). Additionally, steps for planning and implementing an organizational self-assessment are summarized in **Table e2-8**.

TABLE e2-8 Steps for Planning and Implementing Organizational Self-Assessment[107]

1. Cultivate leadership among members of the organization to promote self-assessment.
2. Get "buy-in" from personnel, consumers, communities.
3. Ensure community collaborations and partnerships.
4. Build support for the process by creating a committee, work group, or task force with responsibility for overseeing the self-assessment process.
5. Allocate personnel and fiscal resources.
6. Manage logistics.
7. Analyze and disseminate data.
8. Take the next step to establish organizational priorities and develop a strategic plan with goals and objectives.

Instruments that assist organizations to assess their level of cultural competence have also been developed (see Table e2-7). Some of these assessments focus on an evaluation of the practice setting or workplace, while others also consider the members of the healthcare staff working in the organization. The National Center for Cultural Competence created a guide to planning and implementing cultural competence in an organization (see Table e2-8). According to this guide, the proposed steps are useful for planning and implementing organizational self-assessment.

Regardless of which tool is used, an assessment of cultural competency should be conducted periodically on an ongoing, long-term basis.[18] Individuals and organizations are on a cultural-competency continuum at all times, with varying levels of awareness, knowledge, and skills. Periodic use of these tools can help individuals and organizations identify in which direction they are moving on the continuum in order to make necessary adjustments.[107]

Clinical Controversy… SUPPORTING CULTURALLY COMPETENT CARE

While knowledge of cultures and cultural competency can help to bring awareness, personal attitudes and actual experience working with diverse cultures help to build a more competent provider. In what environments could providers experience challenges to work with diverse cultures? For example, what organizational structures could inhibit provision of quality care? What hiring policies could be problematic? What if a patient refuse to care provided by a person from a different gender or culture? For patient-centered care to occur in diverse populations, what changes (structural or personal) could occur?[43,99,106]

Engaging in assessments of cultural competency can result in several benefits to the individual practitioner or organization.[18] One benefit includes the ability to determine whether providers or healthcare organizations are meeting the needs of the patients being served. Additionally, the process can improve patient and customer satisfaction, and allow for the identification of strengths that the individual practitioner or organization has to offer. Ultimately, conducting assessments allows for the recognition of opportunities for growth and improvement in order to create a healthcare environment that can achieve better patient outcomes.

CONCLUSION

The influence of culture on healthcare encompasses understanding social determinants of health and how environments and community networks help shape the health of individuals and families. The United States—with its culturally diverse society and health disparities, patient-safety concerns, and workforce shortages—has unique opportunities and challenges in patient care. To work in this environment, clinicians should understand legal and regulatory issues related to cultural and linguistic competency. To excel in diverse patient care, providers need the knowledge and skills to elicit patients' explanation of their health status, recognize potential cultural influences on healthcare beliefs and practices, and communicate effectively with patients from different languages and cultures. Individual and organizational self-assessments can reveal helpful information about attitudes, values, and capacity to provide culturally and linguistically responsive services to patients and communities. The ability for providers and organizations to navigate well in a diverse population can help to create a safer and positive healthcare environment for patients to receive care.

Chapter e3: Medication Safety Principles and Practices

Robert J. Weber

INTRODUCTION

KEY CONCEPTS

- 1 Medication errors (MEs) are defined as *any* mistake at *any* stage of the medication-use process; adverse drug events (ADEs) are the result of an injury as a result of an ME.
- 2 All MEs can be prevented, while ADEs can be categorized as preventable and potential.
- 3 MEs occur at an alarmingly high rate, with ADEs having fatal outcomes for patients.
- 4 MEs can occur at any step of the medication-use process: selection and procurement, storage, ordering and transcribing, preparing and dispensing, administration, or monitoring.
- 5 Determining the actual and potential root causes of MEs helps to correct future errors in the medication-use system.
- 6 Quality improvement methods that prevent MEs and thereby minimize ADEs include identifying the ME and/or ADE, understanding the reasons for the ME and/or ADE, designing and implementing changes to prevent an ADE or ME, and checking the outcome of that change.
- 7 Healthcare organizations have implemented various measures to reduce the incidence of MEs and ADEs, such as computerized physician order entry (CPOE), automated drug distribution systems, bar-code scanning, and “smart” infusion pumps with decision support and where information is passed in a bidirectional manner between the pump and the patient’s electronic medical record (EMR).
- 8 Medication reconciliation or comparing a patient’s current medication orders to *all* of the medications that the patient had been taking before any care transition (hospital admission,

transfer, or discharge) is a vital process in preventing MEs and ADEs.

- 9 A "just culture" of medication safety cultivates trust in the workplace that makes personnel feel comfortable sharing safety information (eg, unsafe situations) and assuming personal responsibility and accountability for complying with safe medication practices.

Medical errors are not a new phenomenon. Medical errors causing harm may lead to devastating effects on patients. In 1991, the Harvard Medical Practice Study showed that a significant number of people are victims of medication errors (MEs). This landmark study reviewed the incidence of adverse events and negligence in hospitalized patients in the state of New York showing that almost 4% of patients experienced an iatrogenic injury (one caused by healthcare practices or procedures), prolonging their hospital stays.[1] Importantly, nearly 14% of those mistakes were fatal. Examples of mistakes noted in the Harvard study included renal failure from angiographic dye and a missed diagnosis of colon cancer. Drug complications were the most common type of outcome attributed to negligence, accounting for 19% of these preventable adverse events.[1]

The goal of medication therapy is achieving defined therapeutic goals to improve a patient's quality of life while minimizing harm.[2] There are both known and unknown risks associated with the therapeutic use of prescription and nonprescription drugs and drug administration devices.[3] Mishaps related to medication therapy include both adverse drug events (ADEs) and MEs.[4]

Medication errors negatively affect patients' confidence in the healthcare system and increase healthcare costs. Research conducted by the American Society of Health-System Pharmacists (ASHP) showed that 61% of patients surveyed reported that they were "very concerned" about being given the wrong medicine during a hospital stay.[5] MEs are also very costly—to healthcare systems, patients and their families, and healthcare workers. The emotional cost of an ME is also significant, including the burden on the family for grieving loss or injury to the healthcare worker involved in an ME that caused harm.

Many MEs are not detected by standard reporting systems and often do not cause patient harm. According to the "Fourth Annual Report on Medication Errors in U.S. Hospitals" by the United States Pharmacopeia (USP), 49% of MEs never reach the patient.[6] Many MEs have little to no clinical importance or have minimal impact on patient care. According to the 2002 USP study of the anonymous Web-based reporting system MEDMARx, 98% of reported MEs (n = ~190,000) resulted in no harm to the patient. Tragically, however, MEs do sometimes result in serious patient morbidity and mortality.[7] In fact, preliminary data from the Centers for Disease Control and Prevention (CDC) list accidents (of which MEs are included) as the fifth leading cause of death in the United States in 2010.[8]

The 1999 report "To Err Is Human" by the Institute of Medicine (IOM), a preeminent source, irrevocably changed the way MEs were viewed in health systems. In many ways, this was the first comprehensive report that quantified the problem of medical errors in health systems. The report stated that medical mistakes kill 44,000 to 98,000 patients annually in the United States, causing more deaths than breast cancer, motor vehicle accidents, and infections of human immunodeficiency

virus.[9] In the years since this landmark publication, medication safety has become a priority across the country. Another IOM report in 2007, "Preventing Medication Errors," described system changes that are necessary to improve safety to include computerized physician order entry (CPOE), bar-code-assisted medication administration (BCMA), multidisciplinary communication, and the active involvement of patients in their treatment.[10]

As mentioned previously, medication safety has attracted the attention of government and regulatory agencies, including The Joint Commission (TJC) and the Centers for Medicare & Medicaid Services (CMS). Both of these organizations have revised their standards to emphasize a systematic approach to identifying and preventing MEs and ADEs. Healthcare professionals are obligated to ensure that medications are used safely and errors are prevented. Web addresses for those and other organizations and government agencies involved in medication safety are listed in **Table e3-1**.

This chapter provides the healthcare professional with fundamental background information on the principles and practices of medication safety and reviews definitions, prevalence, causes, and methods for preventing MEs and ADEs. As more is known about identifying and preventing MEs and ADEs, the healthcare system will become a safer environment.

DEFINING MEDICATION ERRORS AND ADVERSE DRUG EVENTS

1 Health professionals should use a standard definition of MEs and ADEs to foster a shared vision to reducing their prevalence. Doing so helps to ensure MEs and ADEs are viewed similarly among various disciplines and regions. It also helps to ensure continuity in their reporting based on published guidelines.

The IOM defines an ADE as an injury resulting from medical intervention related to a drug, which can be attributable to preventable and nonpreventable causes.[11] The National Coordinating Council for Medication Error Reporting and Prevention (NCCMERP) defines an ME as follows: "Any preventable event that may cause or lead to inappropriate medication use or patient harm while the medication is in the control of the healthcare professional, patient, or consumer."[11] This NCCMERP definition of MEs has recently been implemented in other agencies guidelines most notably CMS and TJC.[12,13]

Patients can experience an ADE even if the correct medication was prescribed and administered

because an ADE refers to the effect the drug had on the patient, not necessarily that an error occurred in the medication process. This is in direct contrast to MEs, which involve any mistake in the medication process, regardless of patient outcome. Not all MEs lead to serious consequences; however, preventing MEs at any point in the medication-use process has the potential to reduce harm (eg, ADEs). Although an ME in one patient may not cause harm, that same ME in another patient could prove to be fatal.

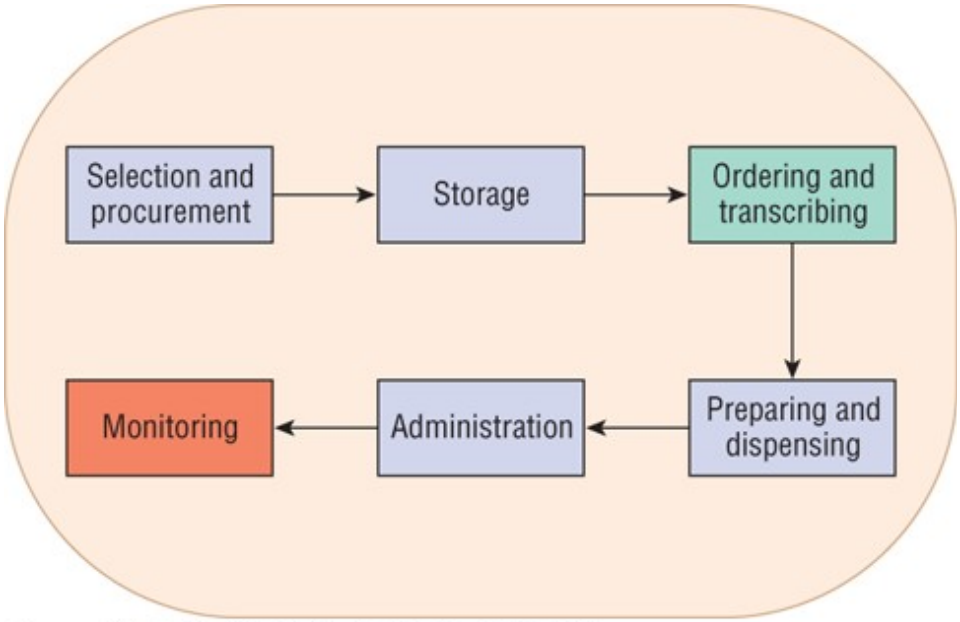
It is important to understand the difference between MEs and ADEs. Broadly speaking, MEs describe process errors and ADEs describe MEs causing negative clinical outcomes. The following example illustrates the differences between MEs and ADEs. Consider the case of two patients (patient A and patient B) who each received a dose of digoxin that was too high for their respective compromised renal function. An ME in prescribing occurred in patient A and patient B because the incorrect dose was prescribed for each patient. However, harm from this prescribing error (digoxin toxicity) occurred only in patient A. This event would be documented as an ME and ADE in patient A and an ME in patient B.

2 Put another way, all ADEs cause patient harm, but are not necessarily preventable. All MEs are preventable, but do not necessarily cause patient harm. ADEs can be categorized as preventable, nonpreventable, or, if they have not actually occurred, potential.

Medication errors can be categorized by the node of the medication-use process in which the error occurred. For the purpose of safe medication management, TJC divides the medication-use process into the six critical processes shown in **Fig. e3-1**. Although MEs can occur at any stage in the medication-use process, upward of 80% of errors reported are in either the ordering and transcribing or administration processes.[14]

FIGURE e3-1

Medication-use process. *Originally published in ASHP guidelines on preventing medication errors in hospitals. Am J Hosp Pharm 1993;50:305–314. © 1993, American Society of Health-System Pharmacists, Inc. All rights reserved. Reprinted with permission.*



Another common method to categorize MEs is the NCCMERP Index for Categorizing Medication Errors Algorithm shown in **Fig. e3-2**. This algorithm categorizes MEs according to the severity of the outcome.[15] The algorithm provides the user an easy method to categorize an ME that occurred. To fully understand and use this algorithm, it is necessary to understand the following terms:

1. *Harm:* impairment of the physical, emotional, or psychological function or structure of the body and/or pain resulting therefrom
2. *Monitoring:* to observe or record relevant physiologic or psychological signs
3. *Intervention:* changes in therapy, active medical and/or surgical treatments, or other responses of health professionals or the patient
4. *Intervention Necessary to Sustain Life:* cardiovascular and respiratory support or other measures that maintain basic physiologic functioning

By and large, the classification system developed by NCCMERP has gained widespread acceptance (**Fig. e3-3**). This system allows for comparison of numbers and types of MEs across health systems. It takes into account whether or not the patient received the medication, what if any treatment or monitoring was required, and lastly, the outcome. Note that the same ME could occur in two patients, but if they had different outcomes, the error categories would be different. For example, if patient A received a tenfold overdose of an opioid-containing medication and required naloxone to treat respiratory depression, this would be a category E error. However, if patient B received the same inappropriate dose of the same opioid-containing medication and was also treated with naloxone, but in this case the patient had to stay an extra night in the hospital, this would be a category F error. The NCCMERP Index for Categorizing Medication Errors, shown in Fig. e3-3, is a more concise diagram consisting of all the different categories.

FIGURE e3-3

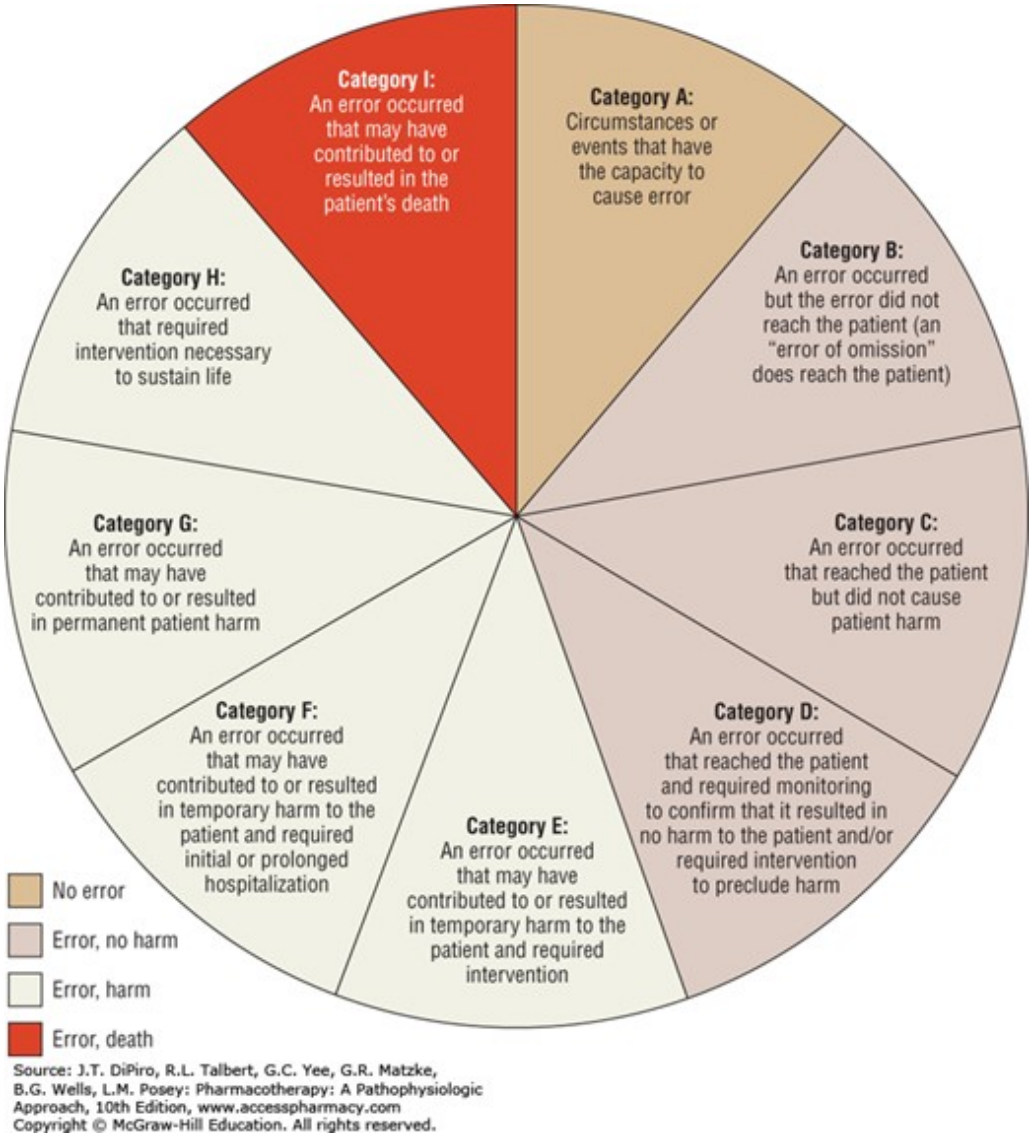
Categorizing Medication Errors.[15] *(Reprinted with permission. Copyright © 2001, National Coordinating Council for Medication Error Reporting and Prevention. All rights reserved.)*



It should be noted other approaches to categorization are sometimes used. One method is to simply judge whether or not MEs were clinically significant.[15] In addition, Hartwig, Denger, and Schneider developed a more elaborate, severity indexed classification program.[16,17]

PREVALENCE

3 It is estimated that each year in the US hospitals, 6.7% of all patients admitted will experience a medical error. Of these errors, 3.1% will cause harm, and 13% will have fatal outcomes. Surprisingly, a large percentage of medical errors occur frequently, and are both predictable and preventable. MEs and ADEs are both included in the broad category of medical errors. Preventable ADEs occur in 2% of hospitalized patients, and MEs resulting in harm contribute to approximately 7,000 deaths annually in the United States.[11]

Beyond their human toll, MEs and ADEs are economically costly as well. These errors can prolong

treatment courses and hospital stays as well as require therapeutic and pharmacologic intervention. The IOM report noted that the hospital cost of an ADE averaged $4,700.[11] Putting this figure in perspective is important for understanding the costs associated with ADEs. Using published data to extrapolate the incidence of ADEs in a given hospital (6.7% of hospital admissions), an organization with 15,000 admissions per year (~40/day) could expect approximately 1,100 ADEs yearly at a cost of $5.2 million annually. Most strikingly, cost projections compiled in 2000 at the University of Arizona showed that the morbidity and mortality costs for MEs were in the range of $177 billion among the US ambulatory population alone.[17,18] The types of mistakes examined in that analysis include incorrect medications, wrong-site surgeries, hospital- or treatment-acquired infections, and mistaken identities.

With the involvement of the IOM and significant impact of MEs, accrediting bodies have added detailed error prevention standards. TJC, a standard-setting organization for hospitals and other healthcare organizations, implemented yearly goals for patient safety that weigh significantly in the organization's accreditation review of a hospital.[18] CMS requires certain conditions of participation for healthcare institutions to receive federal funding for Medicare patients. An example includes prevention of hospital-acquired complications during or after procedures such as surgery and catheterization. This requirement is heavily weighed during reviews in an effort to ensure that hospitals have adequate processes and practices in place to prevent medical errors.[19]

PRIMUM NON NOCERE

From the Oath of Hippocrates, this means "First, Do No Harm" and reiterates the role of healthcare workers in preventing ADEs. Most MEs do not result in patient harm. If harm occurs, it can range from an extra day of monitoring in the hospital to permanent bodily damage or even death.

Medication errors that are most likely to cause harm to the patient include incorrect administration of medication (such as inappropriately crushing tablets), delivering drugs through the wrong route (such as IV vs intramuscular), and dispensing wrong medications. Insulin, morphine, and heparin are cited as being the agents most frequently involved in errors that result in harm to patients.[20,21]

Causes of Medication Errors

4 As shown in Fig. e3-1, medication selection and procurement is the first step in the medication process. MEs in this step include failing to order adequate stock of a medication to meet patient needs, ordering expired or adulterated medication, confusion with substitutions during product shortages and recalls, and ordering the incorrect product, strength, or dilution.

The second step is storage. An ME occurs when any medication that has been stored improperly is subsequently given to a patient. This could include failing to refrigerate a medication or failing to protect a medication from light.

The third step is ordering and transcribing. MEs in ordering occur when the drug selected and/or its dose, frequency, or dosing duration is not appropriate for the patient's disease or physiologic

condition. MEs in the transcribing phase include failure to correctly interpret the medication order.

During preparing and dispensing, health professionals must obtain and package the correct drug, dose, or dilution of a product. Medication dispensing errors are defined as any discrepancy between the medication dispensed and the original prescriber's order.

Likewise, an ME in administration is any discrepancy between how the medication is given to the patient and the administration directions from the physician or hospital guidelines.

Medication errors involved in monitoring and evaluating the effects of medication are defined as not ensuring proper follow-up of the therapeutic effect of a medication or failing to recognize an adverse effect of a medication.

One analysis showed that the most common errors involved prescriptions in which a medication was incorrectly prescribed (18.5%), dosage or quantity was incorrectly interpreted during dispensing (25.5%), and omission (25.6%), in which the prescribed medication was not administered.[21] Other studies have slightly different descriptions of the medication ordering process. Bates et al. found 49% of MEs occur during the ordering phase, 11% during the transcribing phase, 14% during the processing (preparing and dispensing) phase, and 26% in the administration phase.[22] A majority of errors in the ordering phase are wrong dose or frequency, known drug allergy, and drug-drug interactions.[23] Many errors occur in the administration phase, such as wrong dose or incorrect drug administration technique.[23]

Medication errors are preventable. ADEs are preventable if they result from an error. In one analysis, Leape et al. found two-thirds of ADEs to be preventable with an incidence of error caused by provider negligence at around 40%.[24] This same study categorizes errors as diagnostic, treatment, preventive, or other. The key is in finding the appropriate system or process at the correct step in medication distribution in an attempt to completely alleviate the risk of error.

Medication errors occur for a number of reasons, including the following:

1. Ambiguous strength designation on labels or in packaging
2. Drug product nomenclature (look-alike or sound-alike names, use of lettered or numbered prefixes and suffixes in drug names)
3. Equipment failure or malfunction
4. Illegible handwriting
5. Improper transcription
6. Inaccurate dosage calculation
7. Inadequately trained personnel
8. Inappropriate abbreviations used in prescribing

9. Labeling errors
10. Excessive workload
11. Lapses in individual performance
12. Medication unavailable

Preventing Medication Errors

It is important to understand that it is human nature to make mistakes. Furthermore, medication-use systems are extremely complex. Therefore, it is vital to create systems with built-in safeguards in order to reduce risk and promote safe use of medications. Systems for ordering, dispensing, and administering medications should be designed to minimize or prevent error.

5 Errors can occur at any step in the medication-use process. For each type of error, it is important to determine the root cause, or main reason, for the error. After researching the error and determining its root cause, a tracking system for MEs should be created. Multiple examples of tracking systems are available; errors may be grouped by the type of error or the extent of patient harm.

6 To design safer medication delivery systems, data must be collected, analyzed, and trended. MEs can be classified by the type of technical error that occurred. The ASHP Guidelines on Preventing Medication Errors in Hospitals classifies errors as shown in **eTable 3-2**. System failures teach health professionals a tremendous amount about the weaknesses inherent in today's complex medical delivery processes. Once tracking systems are in place for MEs and ADEs, processes and systems can be put in place to prevent errors. This may require an upgrade to the current computer program, an upgrade to that software, or an entirely new system. It may mean separating look-alike, sound-alike medications. It may mean creating preprinted orders based on guidelines to prevent inappropriate drug, dose, or monitoring. Training of staff may be required, and monitoring and follow-up are often needed.

TABLE e3-2 Types of Medication Errors

Type of Error[a]	Examples
Prescribing error	Incorrect drug selection (based on indications, contraindications, known allergies, existing drug therapy, or other factors), dose, dosage form, quantity, route, concentration, rate of administration, or instructions for use of a drug product ordered or authorized by physician (or other legitimate prescriber); illegible prescriptions or medication orders that lead to errors that reach the patient
Omission error[b]	Failure to administer an ordered dose to a patient before the next scheduled dose
Wrong time error	Administration of medication outside a predefined time interval from its scheduled administration time (this interval should be established by each

Type of Error[a]	Examples
	individual healthcare facility)
Unauthorized drug error[c]	Administration of medication not authorized by a legitimate prescriber for the patient
Improper dose error[d]	Administration of a dose that is greater than or less than the amount ordered by the prescriber or administration of duplicate doses to the patient (ie, one or more dosage units in addition to those that were ordered)
Wrong dosage-form error[e]	Administration of a drug product in a different dosage form than ordered by the prescriber
Wrong drug-preparation error[f]	Drug product incorrectly formulated or manipulated before administration
Wrong administration-technique error[g]	Inappropriate procedure or improper technique in the administration of a drug
Deteriorated drug error[h]	Administration of a drug that has expired or for which the physical or chemical dosage-form integrity has been compromised
Monitoring error	Failure to review a prescribed regimen for appropriateness and detection of problems, or failure to use appropriate clinical or laboratory data for adequate assessment of patient response to prescribed therapy
Adherence error	Inappropriate patient behavior regarding adherence to a prescribed medication regimen
Other medication error	Any medication error that does not fall into one of above redefined categories

[a]The categories may not be mutually exclusive because of the multidisciplinary and multifactorial nature of medication errors.

[b]Assumes no prescribing error. Excluded would be (1) a patient's refusal to take the medication or (2) a decision not to administer the dose because of recognized contraindications. If an explanation for the omission is apparent (eg, patient was away from nursing unit for tests or medication was not available), that reason should be documented in the appropriate records.

[c]This would include, for example, a wrong drug, a dose given to the wrong patient, unordered drugs, and doses given outside a stated set of clinical guidelines or protocols.

[d]Excluded would be (1) allowable deviations based on preset ranges established by individual healthcare organizations in consideration of measuring devices routinely provided to those who administer drugs to patients (eg, not administering a dose based on a patient's measured temperature or blood glucose level) or other factors such as conversion of doses expressed in the apothecary system to the metric system and (2) topical dosage forms for which medication orders are not expressed quantitatively.

[e]Excluded would be accepted protocols (established by the pharmacy and therapeutics committee or its equivalent) that authorize pharmacists to dispense alternate dosage forms for patients with special needs (eg, liquid formulations for patients with nasogastric tubes or those who have difficulty swallowing), as allowed by state regulations.

[f]This would include, for example, incorrect dilution or reconstitution, mixing drugs that are physically or chemically incompatible, and inadequate product packaging.

[g]This would include doses administered (1) via the wrong route (different from the route prescribed), (2) via the correct route but at the wrong site (eg, left eye instead of right), and (3) at the wrong rate of administration.

[h]This would include, for example, administration of expired drugs and improperly stored drugs.

7 Implementation strategies to reduce MEs:

1. Computerized physician order entry (CPOE)
2. Automated drug-distribution cabinets enabled with bar-code scanning
3. Bar-code-assisted medication administration (BCMA)
4. Smart IV infusion pumps with a two-way interface to an electronic medical record (EMR)

Studies have shown many MEs and ADEs are preventable. Numerous studies have shown roughly 25% of all MEs and ADEs would never have occurred if various strategies had been implemented. CPOE has been shown to reduce preventable ADEs by 17% and decrease nonintercepted serious MEs by 50%.[25]

Other strategies, such as automated drug-distribution cabinets enabled with bar-code scanning, help to decrease storage and dispensing errors. This strategy, however, is not without its own potential for error as pharmacy technicians and others, such as nurses and pharmacists, must use the bar-code scanner when filling the cabinets and removing medications to assure for the safety double check.

The use of BCMA is growing in popularity with many health systems already implementing this technology. When used appropriately, BCMA can decrease MEs by 65% to 86%.[26,27] BCMA has also been shown to prevent medication administration errors in outpatient areas—most notably the emergency department where BCMA is not routinely used.[28] The BCMA process involves using medications dispensed by the pharmacy with a bar code on the medication. This bar code is on all medications regardless of route including IV medications. If the incorrect medication is scanned, a warning will appear. As with other strategies, there is potential for error with bar-code administration as well. Examples would include nurses who override the warnings or who administer the medication

before scanning the bar code. Both of these instances could lead to either an ME or ADE or both.

Newer IV pumps called "smart pumps" are another newer method created to reduce errors. Smart pumps are used to deliver IV products to patients. These pumps allow the organization to program the pump with standard concentrations and standard infusion ranges, preventing the nurse from administering it outside specified limits for each drug. These pumps are also set up with soft and hard stops whereby if a nurse sets the pump outside specified ranges, the pump could alarm with a soft stop in which case the nurse could override it, or a hard stop in which case the nurse would be unable to override the alarm. The Institute for Safe Medication Practices cautions that while this technology can reduce MEs and ADEs, "smart pumps aren't smart by themselves." The information on most smart pumps cannot be viewed on the EMR as pump software is not owned by most EMR vendors. The next step to "close the loop" in preventing intravenous infusion errors is to integrate smart pumps with the EMR so that data are sent bidirectionally between the two technologies.

It is important to remember the significance of MEs and ADEs on patients and the healthcare system. The cost of improving systems and training is negligible compared with the value of lives saved.

MEDICATION RECONCILIATION

8 Medication reconciliation is one the most important safety practices to reduce MEs during care transitions. It involves comparing and reconciling hospital admission and discharge medication orders with patients' home medications. Many health systems are using the emergency department as the point to perform admission medication reconciliation since 30% to 40% of those patients are being admitted. This task can be performed by the pharmacist, pharmacy intern, or pharmacy technician depending on state rules and regulations.

Recent experience suggests that inadequate reconciliation accounts for 46% of all MEs and up to 20% of all ADEs among hospitalized patients.[29,30] Furthermore, MEs can be reduced by more than 76% when medication reconciliation is implemented at hospital admission, transfer between units in the hospital, and hospital discharge.[30]

Medication reconciliation involves the following steps: determining a current list of medications; developing a listing of medications to be prescribed; comparing the two lists; making clinical decisions based on the two lists, as well as finalizing and communicating the list of medications to the patient and other clinicians. Medication reconciliation at discharge is extremely important to not only ensure patients know how they should take their medications and any side effects that may occur, but alert them to any new additions or deletions to their medication list.

"JUST CULTURE" OF PATIENT SAFETY

9 An accepted idea in patient safety is the "just culture" concept. Introduced by the attorney David Marx in 2001, it focused on the sequence of events that led to the error, rather than the person who made the error.[31] This concept encourages internal risk transparency, coaching and counseling of

employees, avoiding negative retribution for errors, and gathering and then using information to prevent recurrence of the error.

Before "just culture," there were two main philosophies regarding errors in healthcare. These were the *punitive culture* and the *blame-free culture*. In the punitive culture, those who made an error were held personally responsible, regardless of the root cause. This was thought to discourage reporting of errors. The blame-free culture encouraged reporting of errors as there was no risk of punishment, regardless of the cause of the error. However, the lack of blame did not provide incentive against risky or even reckless behaviors.

The key distinguishing characteristic of "just culture" is that the focus is on the cause of the error, and therefore errors caused by system failures do not result in punishment. However, reckless or negligent behaviors that lead to errors are punished. Therefore "just culture" has an inherent accountability not seen in a pure blame-free culture.

"Just culture" does not negate previous information provided in researching MEs. Using "just culture" techniques for improving internal communication and reporting processes in addition to previous suggestions of error tracking can result in an effective, successful error-reporting process.

The introduction of "just culture" of patient safety has afforded a great opportunity to prevent MEs and ADEs. Employees are encouraged to help design systems to reduce human error and risky behaviors. It is a proactive approach in which risks are reviewed and outcomes of events are evaluated. The approach allows the staff to be a stakeholder in the process of risk reduction, encouraging health workers to discuss and review errors without fear of retribution. A 2009 publication by TJC describes "just culture" as "an environment where employees hunger for knowledge and eagerly seek to understand risk."[30] The main focus in "just culture" is on systems and improving system designs (**Table e3-3**).

TABLE e3-3 Goals for "Just Culture" of Patient Safety

The "just culture" model sets goals for an organization, including the following:

- Creating an environment of internal transparency around risk
- Striving to understand why human errors occur within the organization
- Striving to understand why at-risk behaviors occur within the organization
- Learning to see common threads in order to prioritize risk and interventions
- Working with staff to design systems that reduce the rate of human error and at-risk behavior or mitigate their effects
- Learning when to console and when to coach employees
- Limiting the use of warnings and punitive actions to the narrow circumstances where such use benefits organizational safety

- Avoiding traditional organizational biases by focusing on the risks inherent in systems and behavioral choices, not the actual outcomes of events
- Using data to build both unit and organizational models of risk
- Learning to measure risk, at both the unit and organizational levels

SUMMARY

Medication errors are a public health problem. They affect a large number of patients with the risk of causing severe patient harm. Errors can occur at any step in the medication-use process, from ordering to postadministration and monitoring.

Within a facility or health system, a set of clear definitions and guidelines of MEs and ADEs is needed. Once these definitions are set, a tracking process can be designed. The "just culture" approach encourages all employees to be stakeholders in the prevention of MEs and ADEs. The staff can design, follow, and review results of their own ME tracking process, all with this old adage in mind: "An ounce of prevention is worth a pound of cure."

Clinical Controversy…

On a busy Sunday morning at Cleveland's Rainbow Babies and Children's Hospital, a pharmacy technician prepared a chemotherapy admixture for a young child with 24.4% sodium chloride instead of normal saline, 0.9% sodium chloride. The pharmacist on duty, Eric Cropp, did not catch the mistake, and the patient died as a result. While the mantra in healthcare is for a systems approach to analysis of such situations, Cropp ended up before the Ohio State Board of Pharmacy and in a court of law. The board took his pharmacy license, and Cropp spent 6 months in prison after taking a plea bargain for an involuntary manslaughter charge. The case, which sparked much controversy within pharmacy, serves as a reminder that the systems approach to MEs is not universally understood or adopted. In addition, cases such as this make it more likely that people will try to cover up errors rather than operating in the transparent manner required in systems analysis.

Chapter e4: Clinical Pharmacokinetics and Pharmacodynamics

Larry A. Bauer

CLINICAL PHARMACOKINETICS AND PHARMACODYNAMICS: INTRODUCTION

Key Concepts

- 1 Clinical pharmacokinetics is the discipline that describes the absorption, distribution, metabolism, and elimination of drugs in patients requiring drug therapy.
- 2 Clearance is the most important pharmacokinetic parameter because it determines the steady-state concentration for a given dosage rate. Physiologically, clearance is determined by blood flow to the organ that metabolizes or eliminates the drug and the efficiency of the organ in extracting the drug from the bloodstream.
- 3 The volume of distribution is a proportionality constant that relates the amount of drug in the body to the serum concentration. The volume of distribution is used to calculate the loading dose of a drug that will immediately achieve a desired steady-state concentration. The value of the volume of distribution is determined by the physiologic volume of blood and tissues and how the drug binds in blood and tissues.
- 4 Half-life is the time required for serum concentrations to decrease by one-half after absorption and distribution are complete. It is important because it determines the time required to reach steady state and the dosage interval. Half-life is a dependent kinetic variable because its value depends on the values of clearance and volume of distribution.
- 5 The fraction of drug absorbed into the systemic circulation after extravascular administration is defined as its *bioavailability*.
- 6 Most drugs follow linear pharmacokinetics, whereby steady-state serum drug concentrations change proportionally with long-term daily dosing.

- 7 Some drugs do not follow the rules of linear pharmacokinetics. Instead of steady-state drug concentration changing proportionally with the dose, serum concentration changes more or less than expected. These drugs follow nonlinear pharmacokinetics.

- 8 Pharmacokinetic models are useful to describe data sets, to predict serum concentrations after several doses or different routes of administration, and to calculate pharmacokinetic constants such as clearance, volume of distribution, and half-life. The simplest case uses a single compartment to represent the entire body.

- 9 Factors to be taken into consideration when deciding on the best drug dose for a patient include age, gender, weight, ethnic background, other concurrent disease states, and other drug therapy.

- 10 Cytochrome P450 is a generic name for the group of enzymes that are responsible for most drug metabolism oxidation reactions. Several P450 isozymes have been identified, including CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4.

- 11 Membrane transporters are protein molecules concerned with the active transport of drugs across cell membranes. The importance of transport proteins in drug bioavailability, elimination, and distribution is continuing to evolve. A principal transport protein involved in the movement of drugs across biologic membranes is P-glycoprotein. P-glycoprotein is present in many organs, including the gastrointestinal (GI) tract, liver, and kidney. Other transport protein families include the organic cation transporters, the organic anion transporters, and the organic anion transporting polypeptides.

- 12 When deciding on initial doses for drugs that are renally eliminated, the patient's renal function should be assessed. A common, useful way to do this is to measure the patient's serum creatinine concentration and convert this value into an estimated creatinine clearance ($CL_{cr\ est}$). For drugs that are eliminated primarily by the kidney (more than or equal to 60% of the administered dose), some agents will need minor dosage adjustments for $CL_{cr\ est}$ between 30 and 60 mL/min (0.50 and 1.00 mL/s), moderate dosage adjustments for $CL_{cr\ est}$ between 15 and 30 mL/min (0.25 and 0.50 mL/s), and major dosage adjustments for $CL_{cr\ est}$ less than 15 mL/min (0.25 mL/s). For drugs approved after 2010, renal drug dosing adjustments may also include recommendations using estimated glomerular filtration rate (eGFR) in addition to $CL_{cr\ est}$. Supplemental doses of some medications also may be needed for patients receiving hemodialysis if the drug is removed by the artificial kidney or for patients receiving hemoperfusion if the drug is removed by the hemofilter.

- 13 When deciding on initial doses for drugs that are hepatically eliminated, the patient's liver function should be assessed. The Child-Pugh score can be used as an indicator of a patient's ability to metabolize drugs that are eliminated by the liver. In the absence of specific pharmacokinetic dosing guidelines for a medication, a Child-Pugh score equal to 8 or 9 is grounds for a moderate decrease (~25%) in the initial daily drug dose for agents that are

metabolized primarily hepatically (more than or equal to 60%), and a score of 10 or greater indicates that a significant decrease in the initial daily dose (~50%) is required for drugs that are metabolized mostly hepatically.

- 14 For drugs that exhibit linear pharmacokinetics, steady-state drug concentration (C_{ss}) changes proportionally with dose (D). To adjust a patient's drug therapy, a reasonable starting dose is administered for an estimated three to five half-lives. A serum concentration is obtained, assuming that it will reflect C_{ss}. Independent of the route of administration, the new dose (D_{new}) needed to attain the desired C_{ss}($C_{ss,new}$) is calculated as $D_{new} = D_{old}(C_{ss,new}/C_{ss,old})$, where D_{old} and $C_{ss,old}$ are the old dose and old C_{ss}, respectively.

- 15 If it is necessary to determine the pharmacokinetic constants for a patient to individualize his or her dose, a small pharmacokinetic evaluation is conducted in the individual. Additionally, Bayesian computer programs that aid in the individualization of therapy are available for many different drugs.

- 16 Pharmacodynamics is the study of the relationship between the concentration of a drug and the response obtained in a patient. If pharmacologic effect is plotted against concentration for most drugs, a hyperbola results with an asymptote equal to the maximum attainable effect.

Pharmacokinetic concepts have been used successfully by pharmacists to individualize patient drug therapy for about a quarter century. Pharmacokinetic consultant services and individual clinicians routinely provide patient-specific drug-dosing recommendations that increase the efficacy and decrease the toxicity of many medications. Laboratories routinely measure patient serum or plasma samples for many drugs, including antibiotics (eg, aminoglycosides and vancomycin), theophylline, antiepileptics (eg, phenytoin, carbamazepine, valproic acid, phenobarbital, and ethosuximide), methotrexate, lithium, antiarrhythmics (eg, lidocaine and digoxin), and immunosuppressants (eg, cyclosporine and tacrolimus). Combined with a knowledge of the disease states and conditions that influence the disposition of a particular drug, kinetic concepts can be used to modify doses to produce serum drug concentrations that result in desirable pharmacologic effects without unwanted side effects. This narrow range of concentrations within which the pharmacologic response is produced and adverse effects prevented in most patients is defined as the *therapeutic range* of the drug. **Table e4-1** lists the therapeutic ranges for commonly used medications.

TABLE e4-1 Selected Therapeutic Ranges

Drug	Therapeutic Range
Digoxin	0.5-2 ng/mL or mg/L 0.6-2.6 nmol/L
Lidocaine	1.5-5 mcg/mL or mg/L 6.4-21 µmol/L
Procainamide/*N*-acetylprocainamide (total)	10-30 mcg/mL or mg/L 42-127 µmol/L
Quinidine	2-5 mcg/mL or mg/L

Drug	Therapeutic Range
Amikacin[a]	6-15 µmol/L 20-30 mcg/mL or mg/L (peak) 34-51 µmol/L (peak) <5 mcg/mL or mg/L (trough) <9 µmol/L (trough)
Gentamicin, tobramycin, netilmicin[a]	5-10 mcg/mL or mg/L (peak) 10-21 µmol/L (peak) <2 mcg/mL or mg/L (trough) <4 µmol/L (trough)
Vancomycin	20-40 mcg/mL or mg/L (peak) 14-28 µmol/L (peak) 5-15 mcg/mL or mg/L (trough)[b] 3-10 µmol/L (trough)[b]
Chloramphenicol	10-20 mcg/mL or mg/L 31-62 µmol/L
Lithium	0.6-1.4 mEq/L 0.6-1.4 mmol/L
Carbamazepine	4-12 mcg/mL or mg/L 17-51 µmol/L
Ethosuximide	40-100 mcg/mL or mg/L 283-708 µmol/L
Lamotrigine	2-20 mcg/mL 8-78 µmol/L
Oxcarbazepine (as monohydroxy derivative)	3-35 mcg/mL or mg/L (12-139 µmol/L)
Phenobarbital	15-40 mcg/mL or mg/L 65-172 µmol/L
Phenytoin/Fosphenytoin[c]	10-20 mcg/mL or mg/L 40-79 µmol/L
Primidone	5-12 mcg/mL or mg/L 23-55 µmol/L
Valproic acid	50-100 mcg/mL or mg/L 347-693 µmol/L
Theophylline	10-20 mcg/mL or mg/L 56-111 µmol/L
Cyclosporine (blood)	150-400 ng/mL or mcg/L

Drug	Therapeutic Range
	125-333 nmol/L

[a]Using a multiple dose per day conventional dosage schedule. Using extended interval dosing, trough concentrations for gentamicin, tobramycin, or netilmicin are usually <1 mcg/mL.

[b]For patients with pneumonia or other life-threatening infections due to multidrug resistant bacteria trough concentrations as high as 15-20 mcg/mL or mg/L (10-14 µmol/L) have been recommended.

[c]Total (bound + unbound) concentrations. Therapeutic unbound or "free" concentrations are 1-2 mcg/mL.

Although most individuals experience favorable effects with serum drug concentrations in the therapeutic range, the effects of a given serum concentration can vary widely among individuals. Clinicians should never assume that a serum concentration within the therapeutic range will be safe and effective for every patient. The response to the drug, such as the number of seizures a patient experiences while taking an antiepileptic agent, should always be assessed when serum concentrations are measured.

Throughout this chapter, abbreviations for various pharmacokinetic parameters are used frequently. **Table e4-2** lists commonly used abbreviations.

TABLE e4-2 Pharmacokinetic Abbreviations

Abbreviation	Definition
CL	Clearance
k_0	IV infusion rate
C_{SS}	Steady-state concentration
D	Dose
τ	Dosage interval
F	Fraction of drug absorbed into the systemic circulation
Q	Blood flow
E	Extraction ratio
f_b	Fraction of drug in the blood that is unbound
Cl_{int}	Intrinsic clearance
$C_{ss,\ u}$	Steady-state concentration of unbound drug
V_D	Volume of distribution
LD	Loading dose
MD	Maintenance dose
$t_{1/2}$	Half-life
k	Elimination rate constant
k_a	Absorption rate constant

Abbreviation	Definition
α	Distribution rate constant
β	Terminal rate constant
t'	Postinfusion time
T	Duration of infusion
AUC	Area under serum or blood concentration-versus-time curve
V_{max}	Maximum rate of drug metabolism
K_m	Serum concentration at which the rate of metabolism equals $V_{max}/2$
C_{max}	Maximum serum or blood concentration
C_{min}	Minimum serum or blood concentration
DR	Dosage rate
P-gp	P-glycoprotein

CLINICAL PHARMACOKINETIC CONCEPTS

[1] Clinical pharmacokinetics is the discipline that describes the absorption, distribution, metabolism, and elimination of drugs in patients requiring drug therapy. When a drug is administered extravascularly to patients, it must be absorbed across biologic membranes to reach the systemic circulation. If the drug is given orally, the drug molecules must pass through the gastrointestinal (GI) tract wall into capillaries. For transdermal patches, the drug must penetrate the skin to enter the vascular system. In general, the pharmacologic effect of the drug is delayed when it is given extravascularly because time is required for the drug to be absorbed into the vascular system.

The vascular system generally provides the "transportation" for the drug molecule to its site of activity. After the drug reaches the systemic circulation, it can leave the vasculature and penetrate the various tissues or remain in the blood. If the drug remains in the blood, it may bind to endogenous protein, such as albumin and *α1*-acid glycoprotein. This binding usually is reversible, and an equilibrium is created between protein-bound drug and unbound drug. Unbound drug in the blood provides the driving force for distribution of the agent to body tissues. If unbound drug leaves the bloodstream and distributes to tissue, it may become tissue-bound, it may remain unbound in the tissue, or if the tissue can metabolize or eliminate the drug, it may be rendered inactive and/or eliminated from the body. If the drug becomes tissue-bound, it may bind to the receptor that causes its pharmacologic or toxic effect or to a nonspecific binding site that causes no effect. Again, tissue binding is usually reversible, so that the tissue-bound drug is in equilibrium with the unbound drug in the tissue.

Certain organs—such as the liver, GI tract wall, and lung—possess enzymes that metabolize drugs. The resulting metabolite may be inactive or have a pharmacologic effect of its own. The blood also contains esterases, which cleave ester bonds in drug molecules and generally render them inactive.

Drug metabolism usually occurs in the liver through one or both of two types of reactions. Phase I reactions generally make the drug molecule more polar and water soluble so that it is prone to

elimination by the kidney. Phase I modifications include oxidation, hydrolysis, and reduction. Phase II reactions involve conjugation to form glucuronides, acetates, or sulfates. These reactions generally inactivate the pharmacologic activity of the drug and may make it more prone to elimination by the kidney.

Other organs have the ability to eliminate drugs or metabolites from the body. The kidney can excrete drugs by glomerular filtration or by such active processes as proximal tubular secretion. Drugs also can be eliminated via bile produced by the liver or air expired by the lungs.

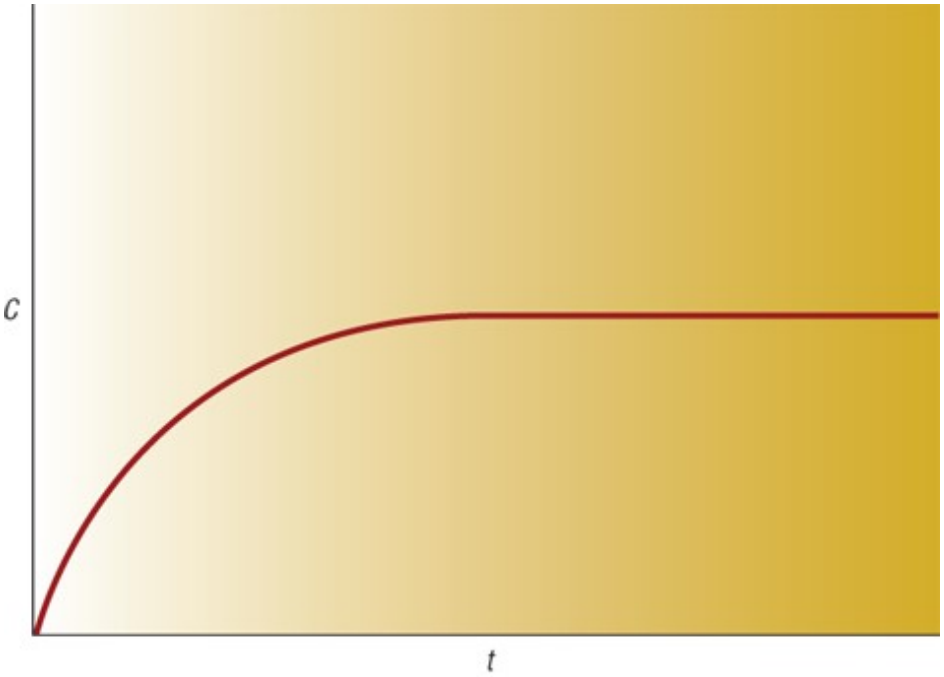
Linear Pharmacokinetics

6 Most drugs follow linear pharmacokinetics; serum drug concentrations change proportionally with long-term daily dosing. For example, if a drug dose were doubled from 300 to 600 mg daily, the patient's serum drug concentration would double.

When a drug is given by continuous IV infusion, serum concentrations increase until an equilibrium is established between the drug dosage rate and the rate of drug elimination. At that point, the rate of drug administration equals the rate of drug elimination, and the serum concentrations remain constant (**Fig. e4-1**). For example, if a patient were receiving a continuous IV infusion of theophylline at 40 mg/h, the theophylline serum concentration would increase until the patient's body was eliminating theophylline at 40 mg/h. When serum drug concentrations reach a constant value, steady state is achieved.

FIGURE e4-1

Typical serum concentration-time curve following a continuous IV infusion.



If the drug is given at intermittent dosage intervals, such as 250 mg every 6 hours, steady state is achieved when the serum-concentration-versus-time curves for each dosage interval are superimposable. The amount of drug eliminated during the dosage interval equals the dose.

Bioavailability and Bioequivalence

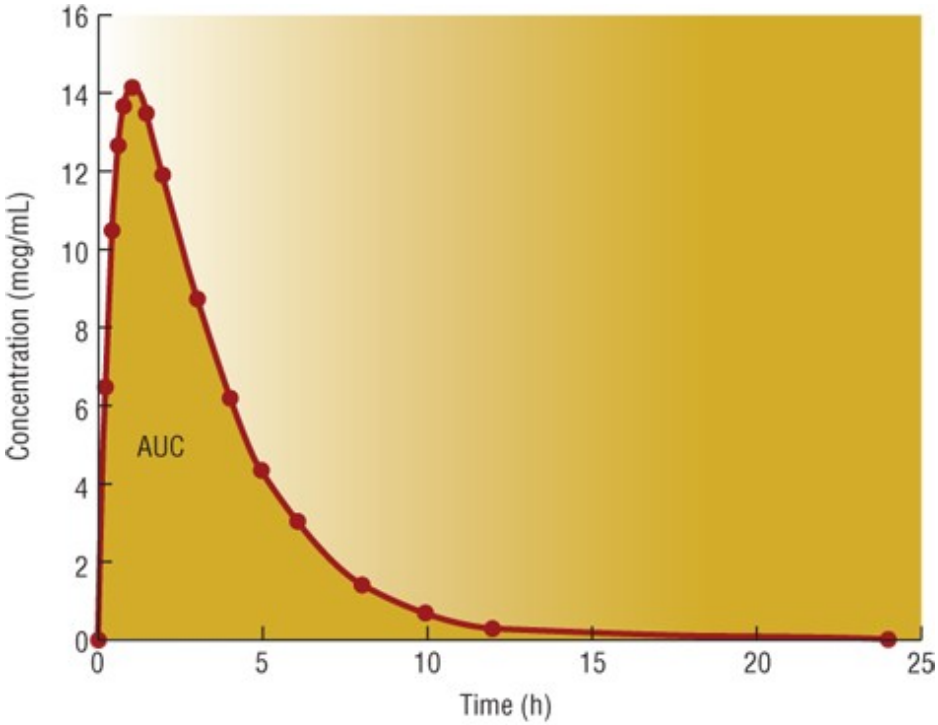
When drugs are administered extravascularly, drug molecules must be released from the dosage form (dissolution) and pass through several biologic barriers before reaching the vascular system (absorption). The fraction of drug absorbed into the systemic circulation (*F*) after extravascular administration is defined as its *bioavailability* and can be calculated after single IV and extravascular doses as[1]

$$F = \frac{D_{iv}(\mathrm{AUC}_{0-\infty})}{D(\mathrm{AUC}_{\mathrm{iv},0-\infty})}$$

where D and D_{iv} are the extravascular and IV doses, respectively, and $AUC_{iv,0-\infty}$ and $AUC_{0-\infty}$ are the IV and extravascular areas under the serum- or blood-concentration-versus-time curves, respectively, from time zero to infinity. The AUC represents the body's total exposure to the drug and is a function of the fraction of the drug dose that enters the systemic circulation via the administered route and clearance (**Fig. e4-2**). When F is less than 1 for a drug administered extravascularly, either the dosage form did not release all the drug contained in it, or some of the drug was eliminated or destroyed (by stomach acid or other means) before it reached the systemic circulation.

FIGURE e4-2

Area under the concentration-versus-time curve (AUC) after the administration of an extravascular dose. The AUC is a function of the fraction of drug dose that enters the systemic circulation and clearance. AUCs measured after IV and extravascular doses can be used to determine bioavailability for the extravascular dose.



When the extravascular dose is administered orally, part of the dose may be metabolized by enzymes or removed by transport proteins contained in the GI tract wall or liver before it reaches the systemic circulation.[2, 3] This occurs commonly when drugs have a high liver extraction ratio or are subject to GI tract wall metabolism because, after oral administration, the drug must pass through the GI tract wall and into the portal circulation of the liver. Transport proteins are also present in the GI tract wall that can actively pump drug molecules that already have been absorbed back into the lumen of the GI tract. P-glycoprotein (P-gp) is the primary transport protein that interferes with drug absorption by this mechanism. For example, if an orally administered drug is 100% absorbed from the GI tract but has a hepatic extraction ratio of 0.75, only 25% of the original dose enters the systemic circulation. This first-pass effect through the liver and/or GI tract wall is avoided when the drug is given by other routes of administration. The computation of *F* does not separate loss of oral drug metabolized by the first-pass effect and drug not absorbed by the GI tract. Special techniques are needed to determine the fraction of drug absorbed orally for drugs with high liver extraction ratios or substantial gut wall metabolism.

Two different dosage forms of the same drug are considered to be bioequivalent when the $AUC_{0-\infty}$, maximum serum or blood concentrations (C_{max}), and the times that C_{max} occurs (t_{max}) are neither clinically nor statistically different. When this occurs, the serum-concentration-versus-time curves for the two dosage forms should be superimposable and identical. Bioequivalence studies have become

very important as expensive drugs become available in less costly generic form. Most bioequivalence studies involve 18 to 25 healthy adults who are given the brand-name product and the generic product in a randomized, crossover study design.

Clearance

2 Clearance (CL) is the most important pharmacokinetic parameter because it determines the steady-state drug concentration (C_{ss}) for a given dosage rate. When a drug is given at a continuous IV infusion rate equal to k_0, the C_{ss} is determined by the quotient of k_0 and CL ($C_{ss} = k_0/CL$). If the drug is administered as individual doses (D) at a given dosage interval (τ), the average C_{ss} over the dosage interval is given by the equation[4]

$$C_{SS} = \frac{F(D/\tau)}{\mathrm{CL}}$$

where F is the fraction of dose absorbed into the systemic vascular system. The average C_{ss} over the dosage interval is the C_{ss} that would have occurred had the same dose been given as a continuous IV infusion (eg, 300 mg every 6 hours would produce an average C_{ss} equivalent to the actual C_{ss} produced by a continuous infusion administered at a rate of 50 mg/h).

Physiologically, clearance is determined by (a) blood flow (Q) to the organ that metabolizes (liver) or eliminates (kidney) the drug and (b) the efficiency of the organ in extracting the drug from the bloodstream.[5] Efficiency is measured using an extraction ratio (E), calculated by subtracting the concentration in the blood leaving the extracting organ (C_{out}) from the concentration in the blood entering the organ (C_{in}) and then dividing the result by C_{in}:

$$E = \frac{C_{\mathrm{in}} - C_{\mathrm{out}}}{C_{\mathrm{in}}}$$

Clearance for that organ is calculated by taking the product of Q and E ($CL = QE$). For example, if liver blood flow equals 1.5 L/min, and the drug's extraction ratio is 0.33, hepatic clearance equals 0.5 L/min. Total clearance is computed by summing all the individual organ clearance values. Clearance changes occur in patients when the blood flow to extracting organs changes or when the extraction ratio changes. Vasodilators such as hydralazine and nifedipine increase liver blood flow, whereas chronic heart failure (CHF) and hypotension can decrease hepatic blood flow. Extraction ratios can increase when enzyme inducers increase the amount of drug-metabolizing enzyme. Extraction ratios may decrease if enzyme inhibitors inhibit drug-metabolizing enzymes or necrosis causes loss of parenchyma.

Intrinsic Clearance

The extraction ratio also can be thought of in terms of the unbound fraction of drug in the blood (f_b), the intrinsic ability of the extracting organ to clear unbound drug from the blood (CL_{int}), and blood flow to the organ (Q):[6,7]

$$E = \frac{f_b(CL_{int})}{Q + f_b(CL_{int})}$$

By substituting this equation for *E*, the clearance equation becomes

$$CL = \frac{Q[f_b(CL_{int})]}{Q + f_b(CL_{int})}$$

Clearance changes will occur when blood flow to the clearing organ changes (in conditions where blood flow is reduced, eg, shock and CHF, or where blood flow is increased, eg, administration of medications, such as vasodilators, and resolution of shock or CHF), binding in the blood changes (eg, if the concentration of binding proteins is low or highly protein-bound drugs are displaced), or intrinsic clearance of unbound drug changes (eg, when metabolizing enzymes are induced or inhibited by other drug therapy or functional organ tissue is destroyed by disease processes).

If CL_{int} is large (enzymes have a high capacity to metabolize the drug), the product of f_b and CL_{int} is much larger than Q. When $f_b(CL_{int})$ is much greater than Q, the sum of Q and $f_b(CL_{int})$ in the denominator of the clearance equation almost equals $f_b(CL_{int})$:

$$f_b(CL_{int}) \approx Q + f_b(CL_{int})$$

Substituting this expression in the denominator of the clearance equation and canceling common terms leads to the following expression for drugs with a large CL_{int}: $CL \approx Q$. In this case, clearance of the drug is equal to blood flow to the organ; such drugs are called *high-clearance drugs* and have large extraction ratios. Propranolol, verapamil, morphine, and lidocaine are examples of high-clearance drugs. High-clearance drugs such as these typically exhibit high first-pass effects when administered orally.

If CL_{int} is small (enzymes have a limited capacity to metabolize the drug), Q is much larger than the product of f_b and CL_{int}. When Q is much greater than $f_b(CL_{int})$, the sum of Q and $f_b(CL_{int})$ in the denominator of the clearance equation becomes almost equal to Q: $Q \approx Q + f_b(CL_{int})$. Substituting this expression in the denominator of the clearance equation and canceling common terms leads to the following expression for drugs with a small CL_{int}: $CL \approx f_b(CL_{int})$. In this case, clearance of the drug is equal to the product of the fraction unbound in the blood and the intrinsic ability of the organ to clear unbound drug from the blood; such drugs are known as *low-clearance drugs* and have small extraction ratios. Warfarin, theophylline, diazepam, and phenobarbital are examples of low-clearance drugs.

As mentioned previously, the concentration of unbound drug in the blood is probably more important pharmacologically than the total (bound plus unbound) concentration. The unbound drug in the blood is in equilibrium with the unbound drug in the tissues and reflects the concentration of drug at its site of action. Therefore, the pharmacologic effect of a drug is thought to be a function of the concentration of unbound drug in the blood. The unbound steady-state concentration ($C_{ss,u}$) can be calculated by multiplying C_{ss} and f_b: $C_{ss,u} = C_{ss} f_b$. The effect that changes in Q, f_b, and CL_{int} have on $C_{ss,u}$ and therefore on the pharmacologic response of a drug depends on whether a high- or

low-clearance drug is involved. Because CL = Q for high-clearance drugs, a change in f_b or CL_{int} does not change CL or C_{ss}(i.e. $C_{ss} = k_0/CL$). However, a change in unbound drug fraction does alter $C_{ss,u}$(i.e. $C_{ss,u} = f_bC_{ss}$), thereby affecting the pharmacologic response. Plasma protein-binding displacement drug interactions can be very important clinically, but they are also dangerous because the changes in $C_{ss,u}$ are not reflected in changes in C_{ss} for high-clearance drugs. Because laboratories usually measure only total concentrations (concentrations of unbound drug are difficult to determine), the interaction is hard to detect. If CL_{int} changes for high-clearance drugs, CL, C_{ss}, $C_{ss,u}$, and pharmacologic response do not change. Changes in Q cause a change in CL; changes in C_{ss}, $C_{ss,u}$, and drug response are indirectly proportional to changes in CL.

For low-clearance drugs, total clearance is determined by unbound drug fraction and intrinsic clearance: $CL = f_b(CL_{int})$. A change in Q does not change CL, C_{ss}, $C_{ss,u}$, or pharmacologic response. However, a change in f_b or CL_{int} does alter CL and C_{ss} (i.e. $C_{ss} = k_0/CL$). Changes in CL_{int} will cause a proportional change in CL.

Changes in C_{ss}, $C_{ss,u}$, and drug response are indirectly proportional to changes in CL. Altering f_b for low-clearance drugs produces interesting results. A change in f_b alters CL and C_{ss} (i.e. $C_{ss} = k_0/CL$). Because CL and C_{ss} change in opposite directions with changes in f_b, $C_{ss,u}$ (i.e. $C_{ss,u} = f_bC_{ss}$) and pharmacologic response do not change with alterations in the fraction of unbound drug in the blood. For example, a low-clearance drug is administered to a patient until steady-state is achieved:

$$CL = f_b(CL_{int})$$

$$C_{ss} = \frac{k_0}{CL}$$

Suppose that another drug is administered to the patient that displaces the first drug from plasma-protein-binding sites and doubles f_b (f_b now equals $2f_b$). CL doubles because of the protein-binding displacement [$2CL = 2f_b(CL_{int})$], and C_{ss} decreases by one-half because of the change in clearance [$½(C_{ss}) = k_0/(2Cl)$]. $C_{ss,u}$ does not change because even though f_b is doubled, C_{ss} decreased by one-half ($C_{ss,u} = f_bC_{ss}$). The potential for error in this situation is that clinicians may increase the dose of a low-clearance drug after a protein-binding displacement interaction because C_{ss} decreased. Because $C_{ss,u}$ and the pharmacologic effect do not change, the dose should remain unaltered. Plasma protein binding decreases occur commonly in patients taking phenytoin. Low albumin concentrations (as in trauma or pregnant patients), high concentrations of endogenous plasma protein-binding displacers (as with high concentrations of bilirubin), or plasma protein-binding drug interactions (as with concomitant therapy with valproic acid) can result in subtherapeutic total phenytoin concentrations. Despite this fact, unbound phenytoin concentrations usually are within the therapeutic range, and often the patient is responding appropriately to treatment. Thus, in these situations, unbound rather than total phenytoin serum concentrations should be monitored and used to guide future therapeutic decisions.

Clearances for Different Routes of Elimination and Metabolic Pathways

Clearances for individual organs can be computed if the excretion the organ produces can be

obtained. For example, renal clearance can be calculated if urine is collected during a pharmacokinetic experiment. The patient empties his or her bladder immediately before the dose is given. Subsequent urine production is collected until the last serum concentration (C_{last}) is obtained. Renal clearance (CL_R) is computed by dividing the amount of drug excreted in the urine by $AUC_{0-t,last}$. Biliary and other clearance values are computed in a similar fashion.

Clearances also can be calculated for each metabolite that is formed from the parent drug. This computation is particularly useful in drug-interaction studies to determine which metabolic pathway is stimulated or inhibited. In the following metabolic scheme, the parent drug (D) is metabolized into two different metabolites (M_1, M_2) that subsequently are eliminated by the kidney (M_{1R}, M_{2R}):

$$D \xrightarrow{CL_{FM1}} M_1 \xrightarrow{\text{kidney}} M_{1R}$$
$$\downarrow CL_{FM2}$$
$$M_2 \xrightarrow[\text{kidney}]{} M_{2R}$$

To compute the formation clearance of M_1 and M_2 (CL_{FM1}, CL_{FM2}), urine would be collected for five or more half-lives after a single dose or during a dosage interval at steady state. The amount of metabolite eliminated in the urine is then determined. The fraction of the dose (in moles, because the molecular weights of the parent drug and metabolites are not equal) eliminated by each metabolic pathway ($f_{M1} = M_{1R}/D$ and $f_{M2} = M_{2R}/D$) can then be computed. Formation clearance for each pathway can be calculated using the following equations: $CL_{FM1} = f_{M1}CL_M$ and $CL_{FM2} = f_{M2}CL_M$, where CL_M is the metabolic clearance for the parent drug.

Volume of Distribution

3 The volume of distribution (V_D) is a proportionality constant that relates the amount of drug in the body to the serum concentration (amount in body = CV_D). V_D is used to calculate the loading dose (LD) of a drug that will immediately achieve a desired C_{ss} (LD = $C_{ss}V_D$). However, in practice, the patient's own V_D is not known at the time the loading dose is administered. In this case, an average V_D is assumed and used to calculate a loading dose. Because the patient's V_D is almost always different from the average V_D for the drug, a loading dose does not attain the calculated C_{ss}, but it ideally achieves a therapeutic concentration. As usual, steady-state conditions are achieved in three to five half-lives for the drug.

The numeric value for the volume of distribution is determined by the physiologic volume of blood and tissues and how the drug binds in blood and tissues:[8]

$$V_D = V_b + (f_b/f_t)V_t$$

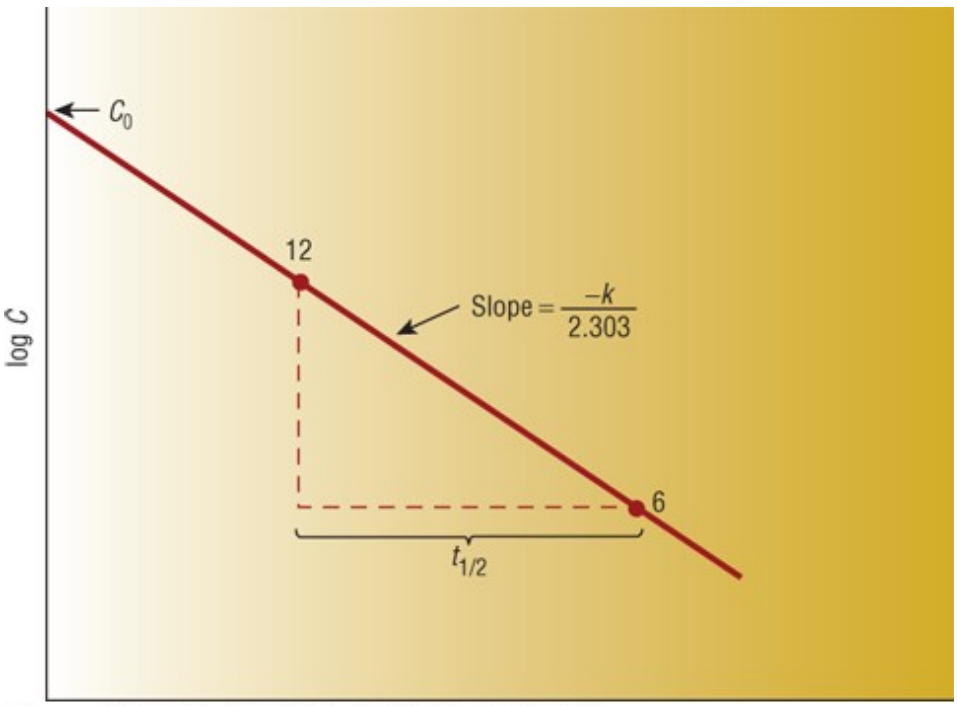
where V_b and V_t are the volumes of blood and tissues, respectively, and f_b and f_t are the fractions of unbound drug in blood and tissues, respectively.

Half-Life

4 Half-life ($t_{1/2}$) is the time required for serum concentrations to decrease by one-half after absorption and distribution are complete. It takes the same amount of time for serum concentrations to drop from 200 to 100 mg/L as it does for concentrations to decline from 2 to 1 mg/L (**Fig. e4-3**).

FIGURE e4-3

Calculation of the half-life of a drug following IV bolus dosing.



Half-life is important because it determines the time required to reach steady state and the dosage interval. It takes approximately three to five half-lives to reach steady-state concentrations during continuous dosing. In three half-lives, serum concentrations are at ~90% of their ultimate steady-state values. Because most serum drug assays have an ~10% error, it is difficult to differentiate concentrations that are within 10% of each other. For this reason, many clinicians consider concentrations obtained after three half-lives to be C_{ss}.

Half-life is also used to determine the dosage interval for a drug. For example, it may be desirable to maintain maximum steady-state concentrations at 20 mg/L and minimum steady-state concentrations at 10 mg/L. In this case, it would be necessary to administer the drug every half-life because the minimum desirable concentration is one-half the maximum desirable concentration.

Half-life is a dependent kinetic variable because its value depends on the values of CL and V_D.[8] The equation that describes the relationship among the three variables is $t_{1/2} = 0.693V_D/CL$. Changes in $t_{1/2}$ can result from a change in either V_D or CL; a change in $t_{1/2}$ does not necessarily indicate that CL has changed. Half-life can change solely because of changes in V_D. The elimination rate constant (k)

is related to the half-life by the following equation: $k = 0.693/t_{1/2}$. Both the half-life and elimination rate constant describe how quickly serum concentrations decrease in the serum or blood.

Nonlinear Pharmacokinetics

Michaelis-Menten Kinetics

7 Some drugs do not follow the rules of linear pharmacokinetics. Instead of C_{ss} and AUC increasing proportionally with dose, serum concentrations change more or less than expected (**Fig. e4-4**). One explanation for the greater-than-expected increase in C_{ss} and AUC after an increase in dose is that the enzymes responsible for the metabolism or elimination of the drug may start to become saturated. When this occurs, the maximum rate of metabolism (V_{max}) for the drug is approached. This is called *Michaelis-Menten kinetics*. The serum concentration at which the rate of metabolism equals $V_{max}/2$ is K_m. Practically speaking, K_m is the serum concentration at which nonproportional changes in C_{ss} and AUC start to occur when the dose is increased. The Michaelis-Menten constants (V_{max} and K_m) determine the dosage rate (DR) needed to maintain a given C_{ss}: $DR = V_{max}C_{ss}/(K_m + C_{ss})$. Most drugs eliminated by the liver are metabolized by enzymes but still appear to follow linear kinetics. The reason for this disparity is that the therapeutic range for most drugs is well below the K_m of the enzyme system that metabolizes the agent. The therapeutic range is higher than K_m for some commonly used drugs. The average K_m for phenytoin is about 4 mg/L (16 µmol/L). The therapeutic range for phenytoin is usually 10 to 20 mg/L (40-79 µmol/L). Most patients experience Michaelis-Menten kinetics while taking phenytoin.

FIGURE e4-4

Relationship of dose and steady-state drug concentration (C_{ss}) or area under the concentration-versus-time curve (AUC) under linear and nonlinear conditions.

Nonlinear Protein Binding

Another type of nonlinear kinetics can occur if C_{ss} and AUC increase less than expected after an increase in dose of a low-clearance drug. This usually indicates that plasma protein-binding sites are starting to become saturated, so that f_b increases with increases in the dose (see Fig. e4-4). For a low-clearance drug, CL depends on the values of f_b and CL_{int} ($CL = f_b CL_{int}$). When a dosage increase takes place, f_b increases because nearly all plasma protein-binding sites are occupied, and no binding sites are available. If f_b increases, CL increases, and C_{ss} increases less than expected with the dosage change ($C_{ss} = k_0/CL$). However, $C_{ss,u}$ increases proportionally with the dose because $C_{ss,u}$ depends on CL_{int} for low-clearance drugs ($C_{ss,u} = k_0/CL_{int}$). Valproic acid[9] and disopyramide[10] both follow saturable protein-binding pharmacokinetics.

Autoinduction

For some drugs, clearance increases as the dose or concentration of the drug increases. In this situation, increasing the drug dose or concentration increases the ability of the enzyme system to eliminate the compound and to clear the drug from the body. This is usually accomplished by inducing the enzyme system responsible for the metabolism of the drug, so that the intrinsic clearance of the drug increases. Because the drug itself is causing the induction effect, this process is called *autoinduction*. For some drugs, such as carbamazepine,[11] the autoinduction effect is continuous within the typical dosage range, which produces a curve for the dose versus C_{ss} or AUC plot similar to nonlinear protein binding (see Fig. e4-4). Detailed pharmacokinetic studies are conducted to differentiate between nonlinear protein binding and autoinduction when dose versus

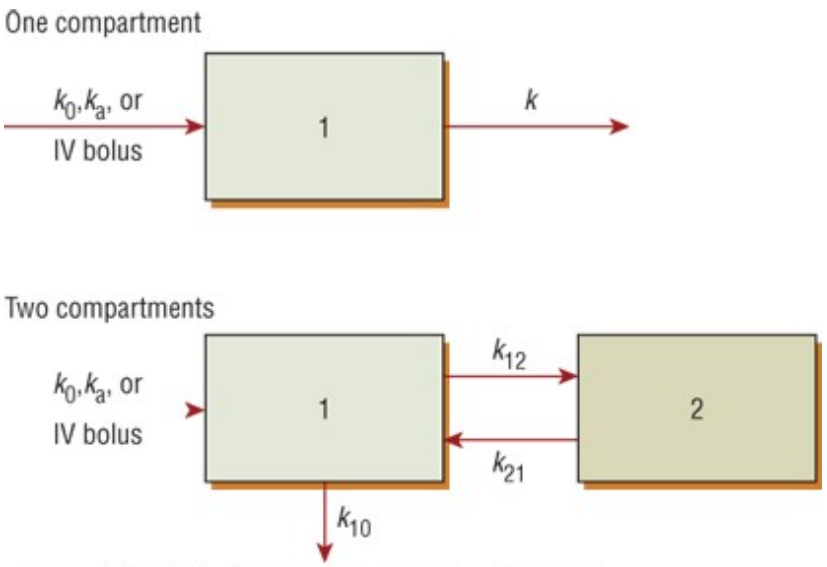
C_{ss} or AUC plots systematically deviate below the linear line.

Pharmacokinetic Models and Equations

8 Pharmacokinetic models are useful to describe data sets, to predict serum concentrations after several doses or different routes of administration, and to calculate pharmacokinetic constants such as CL, V_D, and $t_{1/2}$.[12] Compartmental models depict the body as one or more discrete compartments to which a drug is distributed and/or from which a drug is eliminated. The shape of the serum-concentration-versus-time curve determines the number of compartments in the pharmacokinetic model and the equation used in computations (**Fig. e4-5**). First-order rate constants, known as *microconstants*, describe the rate of transfer from one compartment to another. Each compartment also has its own V_D. For clinical dosage adjustment purposes using drug concentrations, a one-compartment model is the most commonly used pharmacokinetic model.

FIGURE e4-5

Visual representations of one- and two-compartment drug-distribution models.



One-Compartment Model

The simplest case uses a single compartment to represent the entire body (see Fig. e4-5). The drug enters the compartment by continuous IV infusion (k_0), absorption from an extravascular site with an absorption rate constant of k_a, or IV bolus (D). After an IV bolus, serum concentrations decline in a straight line when plotted on semilogarithmic coordinates (see Fig. e4-3). The slope of the line is $-k/2.303$; $t_{1/2}$ can be computed by determining the time required for concentrations to decrease by one-half ($t_{1/2} = 0.693/k$). The equation that describes the data is $C = (D/V_D)e^{-}kt$. V_D is calculated by dividing the IV dose by the y intercept (the concentration at time zero, C_0) of the graph. CL is

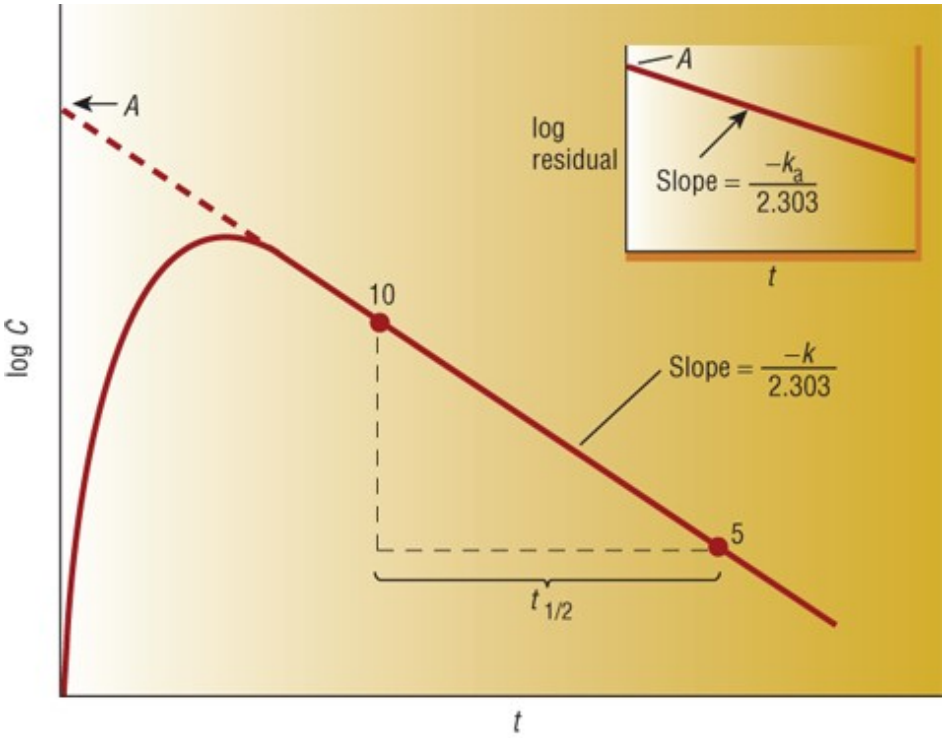
computed by taking the product of k and V_D. Once V_D and k are known, concentrations at any time after the dose can be computed [$C = (D/V_D)e^{-kt}$].

When an extravascular dose is given, one-compartment-model serum concentrations rise during absorption, reach C_{max}, then decrease in a straight line with a slope equal to $-k/2.303$. The equation that describes the data is $C = \{(FDk_a)/[V_D(k_a - k)]\}(e^{-kt} - e^{-kat})$, where F is the fraction of the dose absorbed into the systemic circulation. The absorption rate constant (k_a) is obtained using the method of residuals.

The method of residuals is used to obtain the individual rate constants (**Fig. e4-6**). A is determined by extrapolating the terminal slope to the y axis; k can be obtained by calculating the slope or $t_{1/2}$ and using the formulas given for the IV bolus case. At each time point in the absorption portion of the curve, the concentration value from the extrapolated line is noted and called the extrapolated concentration. For each point, the actual concentration is subtracted from the extrapolated concentration to compute the residual concentration. When the residual concentrations are plotted on semilogarithmic coordinates (see Fig. e4-6, inset), a line with y intercept equal to A and slope equal to $-k_a/2.303$ is obtained. When these values are calculated, they can be placed into the equation ($C = Ae^{-kt} - Ae^{-kat}$, where $A = FDk_a/[V_D(k_a - k)]$) and used to compute the serum concentration at any time after the extravascular dose. The intercepts and rate constants also can be used to compute CL and V_D: $CL = FD/(A/k - A/k_a)$ and $V_D = CL/k$, where F is the fraction of the dose absorbed into the systemic circulation.

FIGURE e4-6

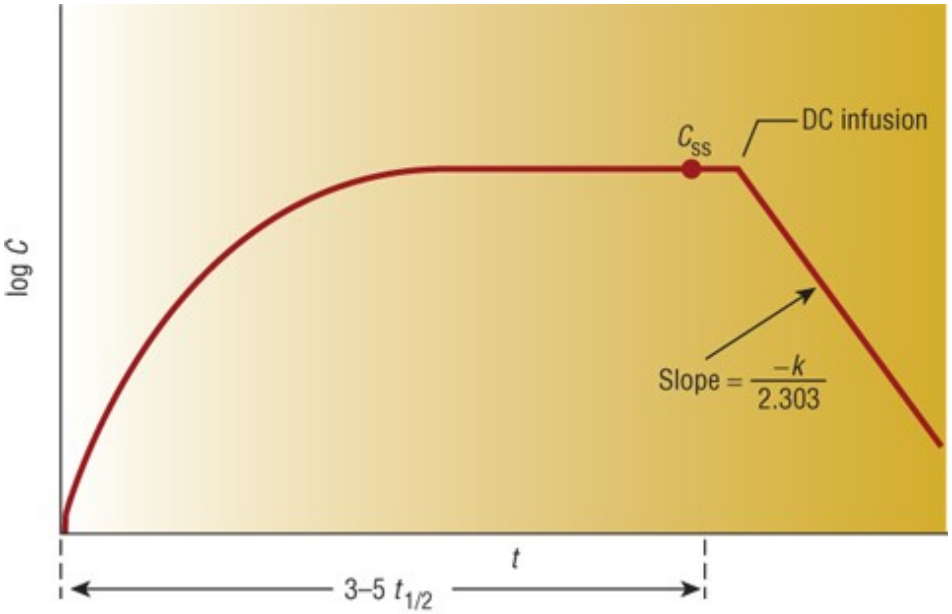
Calculation of the half-life of a drug following oral, intramuscular, or other extravascular dosing route. Inset shows calculation of the absorption rate constant (k_a) using the method of residuals.



During a continuous IV infusion, the serum concentrations in a one-compartment model change according to the following function: $C = (k_0/\text{CL})(1 - e^{-kt})$. If the infusion has been running for more than three to five half-lives, the patient will be at steady state, and CL can be calculated ($\text{CL} = k_0/C_{ss}$). When the infusion is discontinued, serum concentrations appear to decline in a straight line when plotted on semilogarithmic paper with a slope of $-k/2.303$. V_D is computed by dividing CL by k (**Fig. e4-7**).

FIGURE e4-7

Achievement of steady-state serum concentrations after three to five half-lives of a drug. Note the elimination phase after discontinuance of the infusion.



Multicompartment Model

After an IV bolus dose, serum concentrations often decline in two or more phases. During the early phases, the drug leaves the bloodstream by two mechanisms: (a) distribution into tissues and (b) metabolism and/or elimination. Because the drug is leaving the bloodstream through these two mechanisms, serum concentrations decline rapidly. After tissues and blood are in equilibrium, only metabolism and elimination remove the drug from the blood. During this terminal phase, serum concentrations decline more slowly. The half-life is measured during the terminal phase by determining the time required for concentrations to decline by one-half.

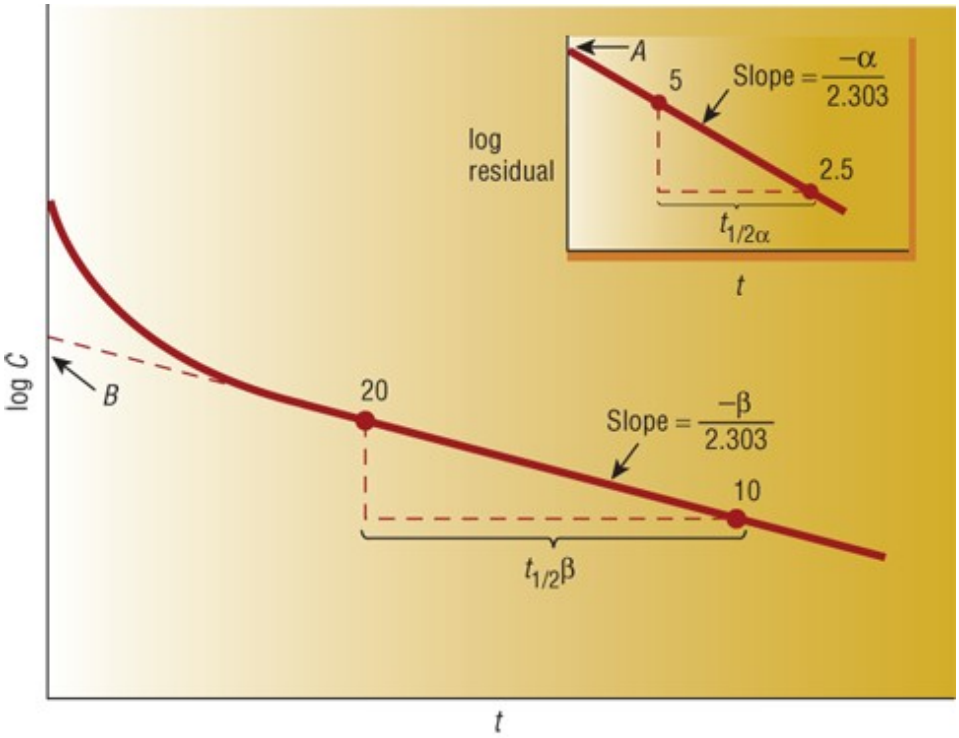
After an IV bolus dose, serum concentrations decrease as if the drug were being injected into a central compartment that not only metabolizes and eliminates the drug but also distributes the drug to one or more other compartments. Of these multicompartment models, the two-compartment model is encountered most commonly (see Fig. e4-5). After an IV bolus injection, serum concentrations decrease in two distinct phases, described by the equation

$$C = \frac{D(\alpha - k_{21})}{V_{D_1}(\alpha - \beta)} e^{-\alpha t} + \frac{D(k_{21} - \beta)}{V_{D_1}(\alpha - \beta)} e^{-\beta t}$$

or $C = Ae^{-\alpha t} + Be^{-\beta t}$, where k_{21} is the first-order rate constant that reflects the transfer of the drug from compartment 2 to compartment 1, V_{D1} is the V_D of compartment 1, $A = D(\alpha - k_{21})/[V_{D1}(\alpha - \beta)]$ and $B = D(k_{21} - \beta)/[V_{D1}(\alpha - \beta)]$. The rate constants α and β found in the exponents of the equations describe the distribution and elimination of the drug, respectively (**Fig. e4-8**). A and B are the y intercepts of the lines that describe drug distribution and elimination, respectively, on the log concentration-versus-time plot.

FIGURE e4-8

Calculation of α and β half-lives following IV dosing. Inset shows calculation of the distribution rate constant (α) using the method of residuals.



The residual line is calculated as before using the method of residuals (see Fig. e4-8, inset). The terminal line is extrapolated to the *y* axis, and extrapolated concentrations are determined for each time point. Because actual concentrations are greater in this case, residual concentrations are calculated by subtracting the extrapolated concentrations from the actual concentrations. When plotted on semilogarithmic paper, the residual line has a *y* intercept equal to *A*. The slope of the residual line is used to compute α (slope = $-\alpha/2.303$). With the rate constants (α and β) and the intercepts (*A* and *B*), concentrations can be calculated for any time after the IV bolus dose ($C = Ae^{-\alpha t} + Be^{-\beta t}$), or pharmacokinetic constants can be computed: $CL = D/[(A/\alpha) + (B/\beta)]$, $V_{D,\beta} = CL/\beta$, $V_{D,ss} = \{D[(A/\alpha^2) + (B/\beta)]^2\}/[(A/\alpha) + (B/\beta)]^2$.

If serum concentrations of a drug given as a continuous IV infusion decline in a biphasic manner after the infusion is discontinued, a two-compartment model describes the data set (**Fig. e4-9**).[13,14] In this instance, the postinfusion concentrations decrease according to the equation $C = Re^{-\alpha t'} + Se^{-\beta t'}$, where t' is the postinfusion time ($t' = 0$ when infusion is discontinued), and *R*, *S*, α, and β are determined from the postinfusion concentrations using the method of residuals with the *y* axis set at $t' = 0$. *R* and *S* are used to compute *A* and *B*. *A* and *B* are the *y* intercepts that would have occurred had the total dose given during the infusion ($D = k_0T$) been administered as an IV bolus dose:

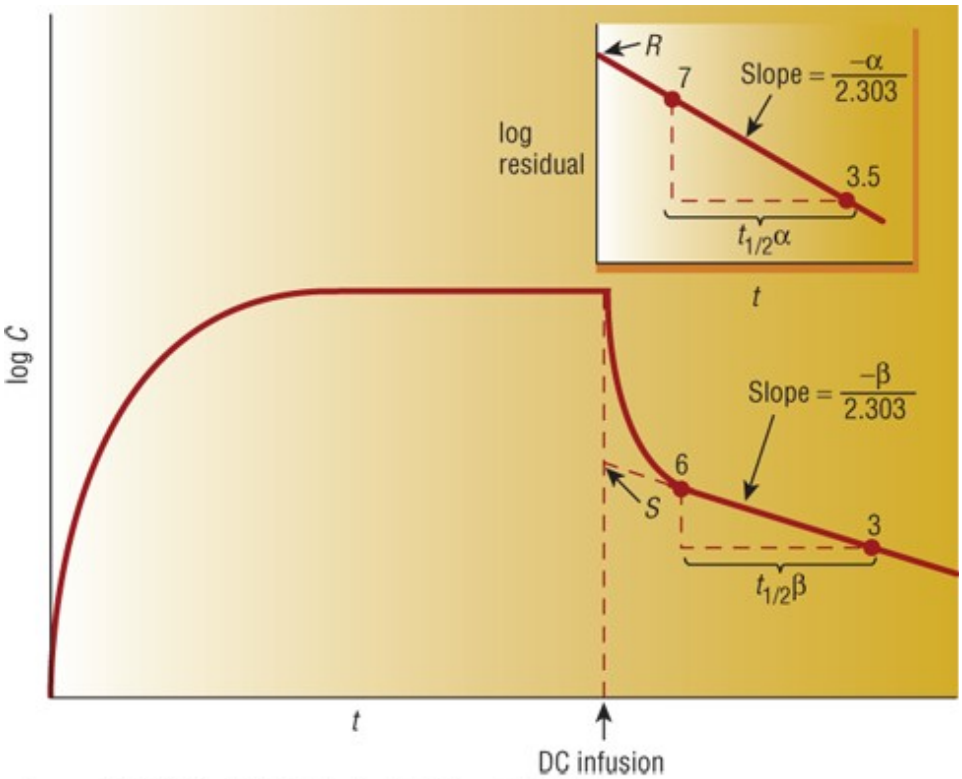
$$A = \frac{RD\alpha}{k_0(1-e^{-\alpha T})}$$

$$B = \frac{SD\beta}{k_0(1-e^{-\beta T})}$$

where T is the duration of infusion. Once A, B, α, and β are known, the equations for an IV bolus are used to compute the pharmacokinetic constants. Often, when a drug is given as an IV bolus or continuous IV infusion, a two-compartment model is used to describe the data, but when the same agent is given extravascularly, a one-compartment model applies.[15] In this case, distribution occurs during the absorption phase, so a distribution phase is not observed.

FIGURE e4-9

Calculation of α and β half-lives following a steady-state infusion. Inset shows calculation of the distribution rate constant (α) using the method of residuals.



Volumes of Distribution in Multicompartment Models

Two different V_D values are needed as proportionality constants for drugs that require multicompartment models to describe the serum-concentration-versus-time curve. The V_D that is used to compute the amount of drug in the body during the terminal (β) portion of the curve is called $V_{D,\beta}$ (amount of drug in body = $V_{D,\beta}$ C). During a continuous IV infusion at steady state, $V_{D,ss}$ is

used to compute the amount of drug in the body (amount of drug in body = $V_{D,ss}C$). $V_{D,ss}$ is also the V_D that can be computed using the physiologic volumes of blood and tissues and the ratio of unbound drug in blood to that in tissues ($V_{D,ss} = V_b + [f_b/f_t]V_t$). Because the value of $V_{D,\beta}$ changes when CL changes, $V_{D,ss}$ should be used to indicate if drug distribution changes during pharmacokinetic or drug-interaction experiments.

Multiple Dosing and Steady-State Equations

Any of these compartmental equations can be used to determine serum concentrations after multiple doses. The multiple-dosing factor $(1 - e^{-nK\tau})/(1 - e^{-K\tau})$ where n is the number of doses, K is the appropriate rate constant, and τ is the dosage interval, is simply multiplied by each exponential term in the equation, substituting the rate constant of each exponent for K. Time (t) is set at 0 at the beginning of each dosage interval. For example, a single-dose two-compartment IV bolus is calculated as follows: $C = Ae^{-\alpha t} + Be^{-\beta t}$. Thus, the equation for a multiple-dose two-compartment IV bolus is

$$C = Ae^{-\alpha t}\frac{1-e^{-n\alpha\tau}}{1-e^{-\alpha\tau}} + Be^{-\beta t}\frac{1-e^{-n\beta\tau}}{1-e^{-\beta\tau}}$$

A single-dose one-compartment IV bolus is calculated as $C = (D/V_D)e^{-kt}$. For a multiple-dose one-compartment IV bolus, the concentration is $C = (D/V_D)e^{-kt}([1 - e^{-nk\tau}]/[1 - e^{-k\tau}])$.

At steady state, the number of doses becomes large, $e^{-nK\tau}$ approaches zero, and the multiple-dosing factor equals $1/(1 - e^{-K\tau})$. Therefore, the steady-state versions of the equations are simpler than their multiple-dose counterparts:

$$C = \frac{Ae^{-\alpha t}}{1-e^{-\alpha\tau}} + \frac{Be^{-\beta t}}{1-e^{-\beta\tau}}$$

and

$$C = \frac{(D/V_D)e^{-kt}}{1-e^{-k\tau}}$$

for a steady-state two-compartment IV bolus and a steady-state one-compartment IV bolus, respectively.

Use of Pharmacokinetic Concepts for Individualization of Drug Therapy

9 Many factors must be taken into consideration when deciding on the best drug dose for a patient. For example, the age of the patient is important because the dose (in milligrams per kilogram) for pediatric patients may be higher and for geriatric patients may be lower than the typically prescribed dose for young adults. Gender also can be a factor because male and female patients metabolize and eliminate some drugs differently. Patients who are significantly obese or

cachectic also may require different drug doses because of clearance and volume of distribution changes. Other drug therapy that could cause drug interactions needs to be considered. Disease states and conditions may alter the drug-dosage regimen for a patient. Three disease states that deserve special mention are CHF, renal disease, and hepatic disease. Renal and hepatic diseases cause loss of organ function and decreased drug elimination and metabolism. CHF causes decreased blood flow to organs that clear the drug from the body.

Many drug compounds are racemic mixtures of stereoisomers. In most cases, one of the isomers is more pharmacologically active than the other isomer, and each isomer may exhibit different pharmacokinetic properties. Warfarin, propranolol, verapamil, and ibuprofen are all racemic mixtures of stereoisomers. Some drug interactions inhibit or increase the elimination of only one stereoisomer. The importance of the drug interaction depends on which isomer is affected. Other drugs, such as dextromethorphan, levofloxacin, and diltiazem, are composed of just one stereoisomer.

10 Genetics also plays a role in drug metabolism. *Cytochrome P450* is a generic term for the group of enzymes that are responsible for most drug metabolism oxidation reactions. Several cytochrome P450 (CYP) isozymes have been identified that are responsible for the metabolism of many important drugs ([57520422]). CYP2C19 is responsible for aromatic hydroxylation of (S)-mephenytoin, and CYP2D6 oxidizes debrisoquine.[16] These subsets of the CYP enzyme family are also responsible for the metabolism of several other drugs (CYP2D6: many tricyclic antidepressants, codeine, (S)-metoprolol; CYP2C19: most proton pump inhibitors, sertraline, voriconazole). CYP2C9, CYP2C19, and CYP2D6 isozymes appear to be under genetic control. As a consequence, there are "poor metabolizers" who have a defective mutant gene for the isozyme, cannot manufacture a fully functional isozyme, and therefore cannot metabolize the drug substrate very well. "Extensive metabolizers" have the standard gene for the isozyme and metabolize the drugs normally. Poor metabolizers usually are a minority of the general population. They may achieve toxic concentrations of a drug when usual doses are prescribed for them or, if the active drug moiety is a metabolite, may fail to have any pharmacologic effect from the drug. The ethnic background of the patient can affect the likelihood that the patient will be a poor metabolizer.[16] For example, the incidence of poor metabolizers for CYP2D6 is ~5% to 10% for whites and ~0% to 1% for Asians, whereas for CYP2C19, poor metabolizers make up ~3% to 6% of the white population and ~20% of the Asian population. Approximately 7% of the whites are poor metabolizers for CYP2C9 substrates (**Table e4-3A**).

TABLE e4-3A Cytochrome P450 Enzyme Family and Selected Substrates

- CYP1A2
    - Acetaminophen
    - Caffeine
    - Ondansetron
    - Tacrine

    - Theophylline
    - *R*-warfarin
    - Zileuton
- CYP2C9
    - Candesartan
    - Diclofenac
    - Ibuprofen
    - Losartan
    - Naproxen
    - Phenytoin
    - Tolbutamide
    - Valsartan
    - *S*-warfarin
- CYP2C19
    - Diazepam
    - Lansoprazole
    - (S)-mephenytoin
    - Nelfinavir
    - Omeprazole
    - Pantoprazole
    - Voriconazole
- CYP2D6
    - Carvedilol
    - Codeine
    - Debrisoquine

    - Dextromethorphan
    - Encainide
    - Fluoxetine
    - Haloperidol
    - (S)-metoprolol
    - Paroxetine
    - Propafenone
    - Risperidone
    - Thioridazine
    - Venlafaxine
- CYP2E1
    - Enflurane
    - Ethanol
    - Halothane
    - Isoflurane
- CYP3A4
    - Alfentanil
    - Alprazolam
    - Astemizole
    - Carbamazepine
    - Cyclosporine
    - Diltiazem
    - Erythromycin
    - Felodipine
    - Itraconazole

- Ketoconazole
- Lidocaine
- Lovastatin
- Midazolam
- Nifedipine
- Quinidine
- Simvastatin
- Tacrolimus
- Verapamil
- Ziprasidone

Other cytochrome P450 isozymes have been isolated.[16] CYP1A2 is the enzyme that is responsible for the demethylation of caffeine and theophylline; CYP2C9 metabolizes phenytoin, tolbutamide, losartan, and ibuprofen; some antiretroviral protease inhibitors, cyclosporine, nifedipine, lovastatin, simvastatin, and atorvastatin are metabolized by CYP3A4; and ethanol is a substrate for CYP2E1. It is important to recognize that a drug may be metabolized by more than one cytochrome P450 isozyme. Although most tricyclic antidepressants are hydroxylated by CYP2D6, *N*-demethylation probably is mediated by a combination of CYP2C19, CYP1A2, and CYP3A4. Acetaminophen appears to be metabolized by both CYP1A2 and CYP2E1. The 4-hydroxy metabolite of propranolol is produced by CYP2D6, but side-chain oxidation of propranolol is probably a product of CYP2C19. The CYP3A enzyme family comprises ~90% of the drug-metabolizing enzyme present in the intestinal wall but only ~30% of the drug-metabolizing enzyme found in the liver. The remainder of hepatic drug-metabolizing enzyme is ~20% for the CYP2C family, ~13% for CYP1A2, ~7% for CYP2E1, and ~2% for CYP2D6.

Understanding which cytochrome P450 isozyme is responsible for the metabolism of a drug is extraordinarily useful in predicting and understanding drug interactions. Some drug-metabolism inhibitors and inducers are highly selective for certain CYP isozymes.[16] Quinidine is an extremely potent inhibitor of the CYP2D6 enzyme system;[16] a single 50-mg dose of quinidine can change a rapid metabolizer of debrisoquine into a poor metabolizer. Ciprofloxacin and zileuton inhibit, whereas tobacco and marijuana smoke induces, CYP1A2. Some drugs that are enzyme inhibitors are also substrates for that same enzyme system and appear to cause drug interactions by being a competitive inhibitor. For example, erythromycin is both a substrate for and an inhibitor of CYP3A4. Obviously, if one knows that a new drug is metabolized by a given CYP enzyme system, it is logical to assume that the new drug will exhibit drug interactions with the known inducers and inhibitors of that CYP isozyme.

11 The importance of membrane transport proteins in drug bioavailability, elimination, and distribution is now better understood.[16,17,18] Membrane transporters are protein molecules concerned with the active transport of drugs across cell membranes ([57520426]). This results in the transfer of drug molecules either out of or into cells. Membrane transporters have been found in the intestine, liver, kidney, and the blood-brain barrier (**Table e4-3B**).

TABLE e4-3B Membrane Transport Proteins and Selected Substrates

- P-Glycoprotein (P-gp)
- *Sites: Intestinal enterocytes, kidney proximal tubule, hepatocytes (canalicular), brain endothelia*
    - Alfentanil
    - Aliskiren
    - Ambrisentan
    - Atorvastatin
    - Azithromycin
    - Cetirizine
    - Citalopram
    - Clopidogrel
    - Cyclosporine
    - Daunorubicin
    - Dexamethasone
    - Digoxin
    - Diltiazem
    - Doxorubicin
    - Erythromycin
    - Etoposide
    - Fexofenadine
    - Glyburide
    - Indinavir

    - Imatinib
    - Loperamide
    - Loratadine
    - Lovastatin
    - Morphine
    - Nelfinavir
    - Olanzapine
    - Ondansetron
    - Paclitaxel
    - Quinidine
    - Raltegravir
    - Ranolazine
    - Risperidone
    - Rifampin
    - Ritonavir
    - Saquinavir
    - Tacrolimus
    - Telaprevir
    - Verapamil
    - Vinblastine
    - Vincristine
- OAT1B1

    - Bosentan
    - Olmesartan

    - Repaglinide
    - Statins
    - Valsartan
- OAT1
- *Sites: Kidney proximal tubule, placenta*
    - Acyclovir
    - Cephradine
    - Ciprofloxacin
    - Methotrexate
    - Zidovudine
- OAT3
- *Sites: Kidney proximal tubule, choroid plexus, brain endothelia*
    - Bumetanide
    - Cefaclor
    - Ceftizoxime
    - Furosemide
    - NSAIDs
- OCT1
- *Sites: Hepatocytes (sinusoidal), intestinal enterocytes*
    - Metformin
    - Oxaliplatin
- OCT2
- *Sites: Kidney proximal tubule, neurons*
    - Amantadine
    - Amiloride

- Metformin
- Pindolol
- Procainamide
- Ranitidine

OAT, organic anion transporter; OCT, organic cation transporter; NSAIDs, nonsteroidal antiinflammatory drugs.

A principal transport protein involved in the movement of drugs across biologic membranes is P-gp. P-gp is present in many organs, including the GI tract, liver, and kidney. If a drug is a substrate for P-gp, its oral absorption may be decreased when P-gp transports drug molecules that have been absorbed back into the GI tract lumen. In the liver, some drugs are transported by P-gp from the blood into the bile, where the drug is eliminated by biliary secretion. Similarly, some drugs eliminated by the kidney are transported from the blood into the urine by P-gp. Digoxin is a substrate of P-gp. Other possible mechanisms for drug interactions are when two drugs that are substrates for P-gp compete for transport by the protein and when a drug is an inhibitor or inducer of P-gp. Drug interactions involving inhibition of P-gp decrease drug transportation in these organs and potentially can increase GI absorption of an orally administered drug, decrease biliary secretion of the drug, or decrease renal elimination of drug molecules. The drug interaction between amiodarone and digoxin probably involves all three of these mechanisms; this explains why digoxin concentrations increase so dramatically in patients receiving amiodarone. Many drugs that are metabolized by CYP3A4 are also substrates for P-gp, and some of the drug interactions attributed to inhibition of CYP3A4 may be a result of decreased drug transportation by P-gp. Drug interactions involving induction of P-gp have the opposite effect in these organs and may decrease GI absorption of an orally administered drug, increase biliary secretion of the drug, or increase renal elimination of drug molecules.

Other membrane transporter families include the organic cation transporters (OCT family), organic anion transporters (OAT family), and the organic anion transporting polypeptides (OATP family).

Selection of Initial Drug Doses

12 When deciding on initial doses for drugs that are eliminated renally, the patient's renal function should be assessed. A common, useful way to do this is to measure the patient's serum creatinine concentration and convert this value into a $CL_{cr\ est}$. Serum creatinine values alone should not be used to assess renal function because they do not include the effects of age, body weight, or gender. The Cockcroft-Gault equation[19] is probably the most widely used method to estimate creatinine clearance (CL_{cr}) (in milliliters per minute) in adults (age 18 years or older) who are within ~30% of their ideal body weight and have stable renal function:

$$\text{Men}: \text{CL}_{\text{cr est}} = \frac{(140 - \text{age})\text{BW}}{S_{\text{cr}} \times 72}$$

$$\text{Women}: \text{CL}_{\text{cr est}} = \frac{0.85(140 - \text{age})\text{BW}}{S_{\text{cr}} \times 72}$$

where BW is body weight (in kilograms), age is the patient's age (in years), 0.85 is a correction factor to account for lower muscle mass in women, and S_{cr} is serum creatinine (in milligrams per deciliter). For children, the following estimation equations are available according to the age of the child[20] age 0 to 1 year: $CL_{cr\ est}$ (in mL/min/1.73 m^2) = (0.45 × Lt)/S_{cr}; age 1 to 20 years: $CL_{cr\ est}$ (in mL/min/1.73 m^2) = (0.55 × Lt)/S_{cr}, where Lt is patient length in centimeters. (To use these equations, S_{cr}, if expressed in µmol/L, must first be divided by 88.4 to obtain conventional units of mg/dL. Conversion of CL_{cr} to units of mL/s/m^2 requires multiplication of CL_{cr} expressed in milliliters per minute per 1.73 m^2 by 0.00963.) Other methods to determine $CL_{cr\ est}$ for obese adults[21] and patients with rapidly changing renal function[22] are available. Creatinine is a by-product of muscle breakdown in the body, so none of these estimation methods work well in patients with muscle disease, such as multiple sclerosis, or diseases that alter muscle mass, such as cachexia, malnutrition, cancer, or spinal cord injury. Nomograms that adjust initial doses according to a patient's renal function are available for several drugs, including digoxin,[23] vancomycin,[24] and the aminoglycoside antibiotics.[25]

For drugs that are eliminated primarily by the kidney (more than or equal to 60% of the administered dose), some agents will need minor dosage adjustments for $CL_{cr\ est}$ between 30 and 60 mL/min (0.50 and 1.00 mL/s), moderate dosage adjustments for $CL_{cr\ est}$ between 15 and 30 mL/min (0.25 and 0.50 mL/s), and major dosage adjustments for $CL_{cr\ est}$ less than 15 mL/min (0.25 mL/s). Specific recommendations for dosage adjustments of other drugs for patients with renal disease are available.[26, 27] For drugs approved after 2010, renal drug dosing adjustments may also include recommendations using estimated glomerular filtration rate (eGFR) in addition to $CL_{cr\ est}$. The Modification of Diet in Renal Disease (MDRD) Study equation is one commonly used equation for this purpose: eGFR (mL/min/1.73 m^2) = 175 × $(Scr)^{-1.154}$ × $(Age)^{-0.203}$ × (0.742 if female) × (1.212 if African American). Since $CL_{cr\ est}$ and eGFR are not interchangeable, specific dosage guidelines for one test or the other should be followed. Supplemental doses of some medications also may be needed for patients receiving hemodialysis if the drug is removed by the artificial kidney or for patients receiving hemoperfusion if the drug is removed by the hemofilter.[27]

13 A similar assessment of liver function should be made for drugs that are metabolized hepatically. Unfortunately, there is no single test that can estimate liver drug-metabolism capacity accurately, and those that are used do not always prove accurate. High aminotransferase (aspartate aminotransferase [AST] and alanine aminotransferase [ALT]) and alkaline phosphatase concentrations usually indicate acute hepatic cellular damage and do not establish poor liver drug metabolism reliably. Abnormal values for three tests that usually indicate that drugs will be metabolized poorly by the liver are high serum bilirubin concentration, low serum albumin concentration, and a prolonged prothrombin time. Bilirubin is metabolized by the liver, and albumin and clotting factors are manufactured by the liver, so aberrant values for all three of these tests are a more reliable indicator of abnormal liver drug

metabolism. The Child-Pugh score,[28] a widely used clinical classification for liver disease that incorporates clinical signs and symptoms (ascites and hepatic encephalopathy), in addition to these three laboratory tests, can be used as an indicator of a patient's ability to metabolize drugs that are eliminated by the liver. A score in excess of 10 suggests very poor liver function. As a general rule, patients with cirrhosis have the most severe decreases in liver drug metabolism. Patients with acute or chronic hepatitis often retain relatively normal or slightly decreased hepatic drug-metabolism capacity. In the absence of specific pharmacokinetic dosing guidelines for a medication, a Child-Pugh score equal to 8 to 9 is grounds for a moderate decrease (~25%) in initial daily drug dose for agents that are metabolized primarily (more than or equal to 60%) hepatically, and a score of 10 or greater indicates that a significant decrease in initial daily dose (~50%) is required for drugs that are metabolized mostly by the liver. As in any patient with or without liver dysfunction, initial doses are meant as starting points for dosage titration based on patient response and avoidance of adverse effects.

Because there are no good markers of liver function, clinicians have come to rely on pharmacokinetic parameters derived in various patient populations to compute initial doses of drugs that are eliminated hepatically. **Table e4-4** contains average pharmacokinetic parameters for theophylline in several disease states. Initial doses of many liver-metabolized drugs are computed by determining which disease states and/or conditions the patient has that are known to alter the kinetics of the drug and by using these average pharmacokinetic constants to calculate doses. The patient is then monitored for therapeutic and adverse effects, and drug serum concentrations are obtained to ensure that concentrations are appropriate and to adjust doses, if necessary. The following computations illustrate the estimated IV loading dose and the IV continuous infusion necessary to achieve a theophylline concentration of 10 mg/L (10 mcg/mL; 55.5 µmol/L) for a 55-year-old man, weighing 70 kg (154 lb), with liver cirrhosis (mean kinetic parameters obtained from Table e4-4):

$$V_D = (0.5\,\text{L/kg})(70\,\text{kg}) = 35\text{L}$$

$$\text{LD} = C_{SS}V_D = (10\,\text{mg/L})(35\text{L})$$

$$= 350\,\text{mg theophylline infused over 20 to 30 min}$$

$$\text{CL(in L/h)} = \frac{(0.35\,\text{mL/min/kg})(70\,\text{kg})(60\,\text{min/h})}{1{,}000\,\text{mL/L}}$$

$$= 1.5\,\text{L/h}$$

$$k_0 = C_{ss}\text{CL} = (10\,\text{mg/L})(1.5\,\text{L/h})$$

$$= 15\,\text{mg/h of theophylline to begin after loading dose is given}$$

TABLE e4-4 Theophylline Pharmacokinetic Parameters for Selected Disease States/Conditions

Disease State/Condition	Mean Clearance (mL/min/kg)	Mean Dose (mg/kg/h)
Children 1-9 years old	1.4	0.8
Children 9-12 years old or adult smokers	1.25	0.7

Disease State/Condition	Mean Clearance (mL/min/kg)	Mean Dose (mg/kg/h)
Adolescents 12-16 years old or elderly smokers (>65years)	0.9	0.5
Adult nonsmokers	0.7	0.4
Elderly nonsmokers (>65 years)	0.5	0.3
Decompensated CHF, cor pulmonale, cirrhosis	0.35	0.2
Mean volume of distribution = 0.5 L/kg.		

CHF, chronic heart failure.

Data from Reference 52.

If theophylline is to be given as the aminophylline salt form, each dose would need to be changed to reflect the fact that aminophylline contains only 85% theophylline (LD = 350 mg of theophylline/0.85 = 410 mg of aminophylline infused over 20-30 minutes, k_0 = 15 mg/h of theophylline/0.85 = 18 mg/h of aminophylline to begin after loading dose is given).

Heart failure is often overlooked as a disease state that can alter drug disposition. Severe heart failure decreases cardiac output and therefore reduces liver blood flow. Theophylline,[29] lidocaine,[30] and drugs with high extraction ratios are compounds whose clearance declines with decreased liver blood flow. Initial dosages of these drugs should be reduced in patients with moderate to severe heart failure (New York Heart Association class III or IV) by 25% to 50% until steady-state concentrations and response can be determined.

Use of Steady-State Drug Concentrations

14 Serum drug concentrations are readily available to clinicians to use as guides for the individualization of drug therapy. The therapeutic ranges for several drugs have been identified, and it is likely that new drugs also will be monitored using serum concentrations. Although several individualization methods have been advocated for specific drugs, one simple, reliable method is used commonly. For drugs that exhibit linear pharmacokinetics, C_{ss} changes proportionally with the dose. To adjust a patient's drug therapy, a reasonable starting dose is administered for an estimated three to five half-lives. A serum concentration is obtained, assuming that it will reflect C_{ss}. Independent of the route of administration, the new dose (D_{new}) needed to attain the desired C_{ss} ($C_{ss,new}$) is calculated: $D_{new} = D_{old}(C_{ss,new}/C_{ss,old})$, where D_{old} and $C_{ss,old}$ are the old dose and old C_{ss}, respectively. To use this method, $C_{ss,old}$ must reflect steady-state conditions. Often patients are noncompliant with regard to their drug dosage and therefore are not at steady state. This occurs not only in outpatients but also in hospital inpatients. Inpatients can spit out oral doses or alter the infusion rates on IV pump rates after the nurse leaves the hospital room. Doses also can be missed if the patient is absent from his or her room at the time medications are to be administered. If $C_{ss,old}$ is much larger or smaller than expected for the D_{old} the patient is taking, one should suspect noncompliance and repeat the serum concentration determination after another three to five

half-lives or change the patient's dose cautiously and monitor for signs of toxicity or lack of effect.

Measurement of Pharmacokinetic Parameters in Patients

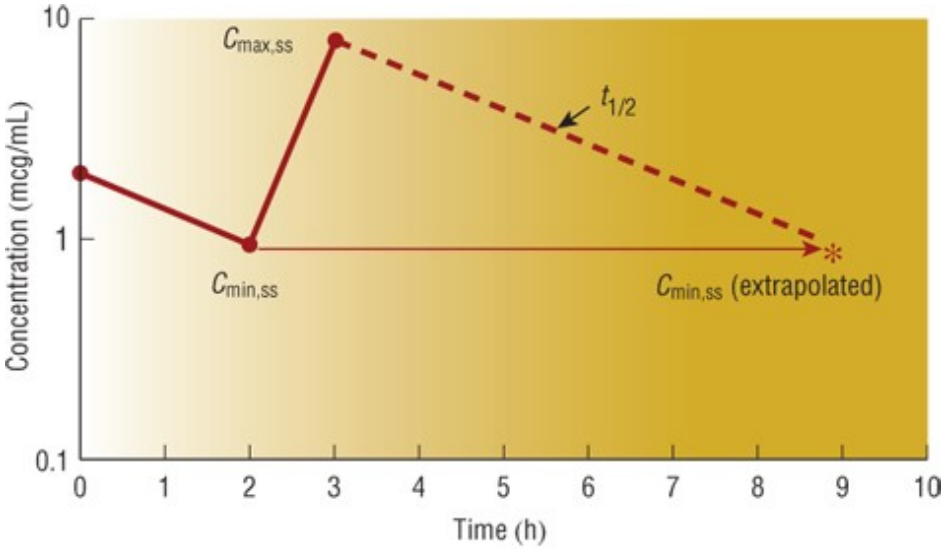
15 If it is necessary to determine the kinetic constants for a patient to individualize his or her dose, a small kinetic evaluation is conducted in the individual. In these cases, the number of serum concentrations obtained from the patient is held to the minimum needed to calculate accurate pharmacokinetic parameters and doses. The reason for using fewer serum drug concentration determinations is to be as cost-effective as possible because these laboratory tests generally cost $50 to $100 each.

Although many drugs follow two-compartment-model pharmacokinetics (especially after IV administration), a one-compartment model is used to compute kinetic parameters in patients because too many serum concentration determinations would be needed to determine accurately both the distribution and elimination phases found in the two-compartment model. Because of this, serum concentrations usually are not measured in patients during the distribution phase. Another important reason serum concentrations are not measured during the distribution phase for therapeutic drug-monitoring purposes in patients is that drug in the blood and drug in the tissues are not in equilibrium during this time, so that serum concentrations do not reflect tissue concentrations. When drug serum concentrations are obtained in patients for the purpose of assessing efficacy or toxicity, it is important that they be measured in the postdistribution phase when drug in the blood is in equilibrium with drug at the site of action.

In the case where the patient has received enough doses to be at steady state, pharmacokinetic parameters can be computed using a predose minimum concentration and a postdose maximum concentration. Under steady-state conditions, serum concentrations after each dose are identical, so the predose minimum concentration is the same before each dose (**Fig. e4-10**). This situation allows the predose concentration to be used to compute both the patient's $t_{1/2}$ and V, where $V = \text{Dose}/(C_{max,ss} - C_{min,ss})$. If the drug was given extravascularly or has a significant distribution phase, the postdose concentration should be determined after absorption or distribution is finished. To ensure that steady-state conditions have been achieved, the patient needs to receive the drug on schedule for at least three to five estimated half-lives. To make sure that this is the case, inpatients should have their medication administration records checked, and the patient's nurse should be consulted regarding missed or late doses. Outpatients should be interviewed about compliance with the prescribed dosage regimen. When compliance with the dosage regimen has been verified, steady-state conditions reasonably can be assumed.

FIGURE e4-10

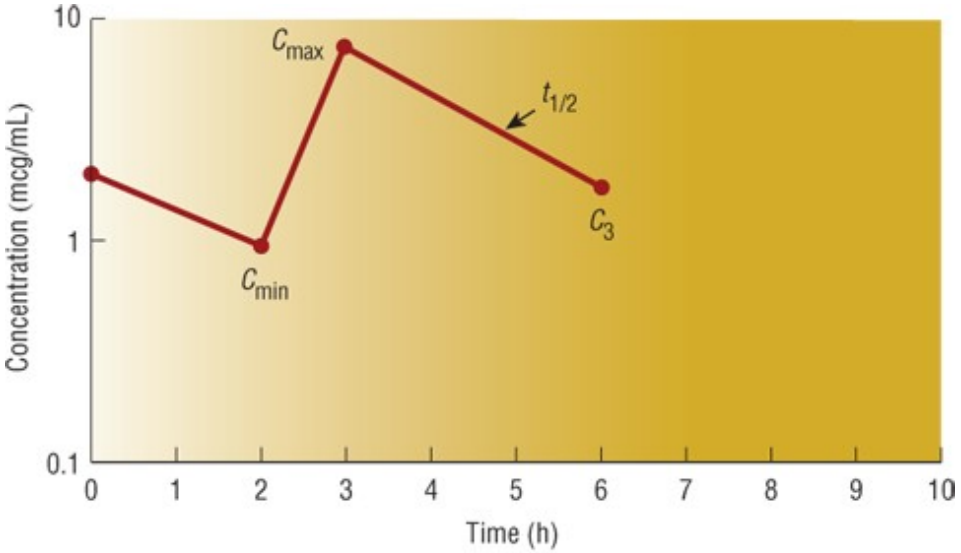
When a patient has received enough doses to be at steady state, steady-state maximum ($C_{max,ss}$) and minimum ($C_{min,ss}$) concentrations can be used to compute clearance, volume of distribution, and half-life. At steady state, consecutive $C_{min,ss}$ values are equal, so the predose value can be extrapolated to the time before the next dose and used to calculate the half-life (*dashed line*).



If the patient is not at steady state, an additional postdose serum concentration determination should be done to compute the patient's pharmacokinetic parameters. Ideally, the third concentration (C_3) should be acquired approximately one estimated half-life after the postdose maximum concentration. Determining serum concentrations too close together will hamper the drug assay's ability to measure differences between them, and getting the third sample too late could result in a concentration too low for the assay to detect. In this situation, the predose minimum and postdose maximum concentrations are used to compute V, where $V = \text{Dose}/(C_{max} - C_{min})$, and both postdose concentrations are used to calculate $t_{1/2}$ (**Fig. e4-11**).

FIGURE e4-11

If a patient has not received enough doses to be at steady state, or doses have been given on an irregular schedule, the minimum concentration (C_{min}), maximum concentration (C_{max}), and an additional postdose concentration (C_3) can be used to compute clearance, volume of distribution, and half-life.



After CL, V, and $t_{1/2}$ have been computed for a patient, the dose and dosage interval necessary to achieve desired steady-state serum concentrations can be calculated using one-compartment-model equations. Specific examples of these methods to calculate initial doses and individualized doses using serum concentrations are discussed later in this chapter for the aminoglycoside antibiotics, vancomycin, digoxin, theophylline, phenytoin, and cyclosporine.

Computer Programs

Computer programs that aid in the individualization of therapy are available for many different drugs. The most sophisticated programs use nonlinear regression to fit CL and V_D to actual serum concentrations obtained in a patient.[31] After drug doses and serum concentrations are entered into the computer, nonlinear least-squares regression programs adjust CL and V_D until the sum of the squared error between actual (C_{act}) and computerestimated concentrations (C_{est}) is at a minimum $\left[\Sigma(C_{est}-C_{act})^2\right]$. Once estimates of CL and V_D are available, doses are calculated easily.

Many programs also take into account what the CL and V_D should be on the basis of disease states and conditions present in the patient.[32] Incorporation of expected population-based parameters allows the computer to use a limited number of serum concentrations (one or two) to provide estimates of CL and V_D. This type of computer program is called Bayesian because it incorporates portions of Bayes' theorem during the fitting routine.[33] Bayesian pharmacokinetic dosing programs are used widely to adjust the dose of a variety of drugs. In the case of renally eliminated drugs (eg, aminoglycosides, vancomycin, and digoxin), population estimates for kinetic parameters are generated by entering the patient's age, weight, height, gender, and serum creatinine concentration into the computer program. For hepatically eliminated drugs (eg, theophylline and phenytoin), population estimates for kinetic parameters are computed using the patient's age, weight, and gender, as well as other factors that might change hepatic clearance, such as the presence or absence of disease states (eg, cirrhosis or CHF) or other drug therapy that might cause a drug interaction. The

population-based estimates of the pharmacokinetic parameters are then modified using nonlinear least-squares regression fits of serum concentrations to result in individualized parameters for the patient. The individualized parameters are used to compute doses for the patient that will result in desired steady-state concentrations of the drug.

Aminoglycosides

Although aminoglycoside pharmacokinetics follow multicompartment models,[34] a one-compartment model appears sufficient to individualize doses in patients.[35] Aminoglycosides usually are given as short-term intermittent IV infusions and administered as a single daily dose or multiple doses per day. Initial doses for aminoglycosides can be computed using estimated kinetic parameters derived from population pharmacokinetic data. The elimination rate constant is estimated using the patient's creatinine clearance in the following formula: $k(\text{in } h^{-1}) = 0.00293(CL_{cr}) + 0.014$, where CL_{cr} is the measured or estimated creatinine clearance in milliliters per minute. The volume of distribution is estimated using the average population value for normal-weight (within 30% of ideal weight) individuals equal to 0.26 L/kg [$V = 0.26(Wt)$, where Wt is the patient's weight] or for obese individuals (more than 30% of ideal weight)[36] by taking into account the patient's excess adipose tissue: $V = 0.26$ [IBW + 0.4 (TBW – IBW)], where TBW is total body weight, IBW is ideal body weight [IBW_{males} (in kilograms) = 50 + 2.3 (Ht – 60) or $IBW_{females}$ (in kilograms) = 45 + 2.3(Ht – 60), and Ht is the patient's height in inches] (height in cm can be converted to inches by multiplying by 0.394). Additional volume of distribution population estimates are available for other disease states and conditions, such as cystic fibrosis,[37] ascites,[38] and neonates.[39]

Appropriate $C_{max,ss}$ and $C_{min,ss}$ values are selected for the patient based on the site and severity of the infection and the sensitivity of the known or suspected pathogen, as well as avoidance of adverse effects. Optimal outcomes are usually associated with $C_{max,ss}$/MIC ratios equal to 8 to 10, where MIC is the minimum inhibitory concentration (MIC) for the bacteria causing the infection. For example, $C_{max,ss}$ values of 8 to 10 mg/L (8 to 10 mcg/mL) generally are selected for gram-negative pneumonia patients, whereas $C_{min,ss}$ values of less than 2 mg/L (2 mcg/mL; 4 µmol/L) usually are chosen to avoid aminoglycoside-induced nephrotoxicity when tobramycin and gentamicin are prescribed using conventional multiple-daily-dosing regimens. Once appropriate steady-state serum concentrations are selected, the dosage interval required to achieve those concentrations is calculated, and τ is rounded to a clinically acceptable value (eg, 8, 12, 18, 24, 36, or 48 hours): $\tau = [(\ln C_{max,ss} - \ln C_{min,ss})/k] + T$. Finally, a dose is computed for the patient using the one-compartment-model intermittent IV infusion equation at steady state, and the dose is rounded off to the nearest 5 to 10 mg:

$$D = TkV_D C_{max,ss} \frac{1 - e^{-k\tau}}{1 - e^{-kT}}$$

The Hull and Sarrubi aminoglycoside dosage nomogram (**Table e4-5**) is based on this dosage-calculation method and includes precalculated doses and dosage intervals for a variety of creatinine clearance values.[25] The nomogram assumes that $V_D = 0.26$ L/kg and should not be used to compute

doses for disease states with altered V_D.

TABLE e4-5 Aminoglycoside Dosage Chart

1. Compute the patient's creatinine clearance (CL_{cr}) using the Cockcroft-Gault method: CL_{cr} = [(140 −age)BW]/(S_{cr} × 72) where S_{cr} is expressed in units of mg/dL. Multiply by 0.85 for women. (S_{cr} expressed in μmol/L must be divided by 88.4 to obtain conventional units of mg/dL.)

2. Use the patient's weight if within 30% of IBW; otherwise use adjusted body weight ABW = IBW + [0.40(TBW – IBW)] where IBW and TBW are expressed in kg.

3. Select the loading dose in mg/kg to provide peak serum concentrations in the range listed below for the desired aminoglycoside antibiotic:

Aminoglycoside	Usual Loading Doses (mg/kg)	Expected Peak Serum Concentrations
Tobramycin	1.5-2	4-10 mcg/mL or mg/L 9-21 μmol/L
Gentamicin	1.5-2	4-10 mcg/mL or mg/L 8-21 μmol/L
Netilmicin	1.5-2	4-10 mcg/mL or mg/L 8-21 μmol/L
Amikacin	5-7.5	15-30 mcg/mL or mg/L 26-51 μmol/L
Kanamycin	5-7.5	15-30 mcg/mL or mg/L 31-62 μmol/L

4. Select the maintenance dose (as a percentage of the loading dose) to continue peak serum concentrations indicated above according to the desired dosage interval and the patient's creatinine clearance. To maintain the usual peak/trough ratio, use dosage intervals in clear areas.

		Percentage of Loading Dose Required for Dosage Interval Selected		
CL_{cr} (mL/min)[b]	**Estimated Half-Life (h)**	**8 h (%)**	**12 h (%)**	**24 h (%)**
>90	2-3	90	—	—
90	3.1	84	—	—
80	3.4	80	91	—
70	3.9	76	88	—
60	4.5	71	84	—
50	5.3	65	79	—
40	6.5	57	72	92
30	8.4	48	63	86
25	9.9	43	57	81
20	11.9	37	50	75
17	13.6	33	46	70

15	15.1	31	42	67
12	17.9	27	37	61
10[a]	20.4	24	34	56
7[a]	25.9	19	28	47
5[a]	31.5	16	23	41
2[a]	46.8	11	16	30
0[a]	69.3	8	11	21

ABW, adjusted body weight; BW, body weight; IBW, ideal body weight; S_{cr}, serum creatinine; TBW, total body weight.

[a]Dosing for patients with CL_{cr} ≤10 mL/min should be assisted by measuring serum concentrations.

[b]CL_{cr} expressed in mL/min can be converted to units of mL/s by dividing by 60.

Data from Reference 25.

An example of this initial dosage scheme for a typical case is provided to illustrate the use of the various equations. Mr. JJ is a 65-year-old, 80 kg (176 lb), 6-ft-tall (72 in. or 183 cm) man with the diagnosis of gram-negative pneumonia. His serum creatinine concentration is 2.1 mg/dL (186 µmol/L) and is stable. Compute a conventional gentamicin dosage regimen (infused over 1 hour) that would provide approximate peak and trough concentrations of $C_{max,ss}$ = 8 mg/L (8 mcg/mL; 17 µmol/L) and $C_{min,ss}$ = 1.5 mg/L (1.5 mcg/mL; 3.1 µmol/L), respectively. The patient is within 30% of his ideal body weight [IBW_{male} = 50 + 2.3(72 in – 60) = 78 kg] and has stable renal function, so the Cockcroft-Gault CL_{cr} estimation equation can be used: $CL_{cr\ est}$ = [(140 – 65 y)80 kg]/[72(2.1 mg/dL)] = 40 mL/min (i.e. 0.67 mL/s). The patient's weight and estimated CL_{cr} are used to compute his V and k, respectively: V = 0.26 L/kg(80 kg) = 20.8 L; k = 0.00293(40 mL/min) + 0.014 = 0.131 h^{-1} or $t_{1/2}$ = (0.693/0.131 h^{-1}) = 5.3 h. The dosage interval and dose for the desired serum concentrations would then be calculated: τ = [(ln 8 mg/L – ln 1.5 mg/L)/0.131 h^{-1}] + 1 h = 13.7 h rounded to 12 h; D = (1 h)(0.131 h^{-1})(20.8 L)(8 mg/L) [1 – $e^{-(0.131h^{-1})(12h)}$)/1 – $e^{-(0.131h-1)(1h)}$] = 140 mg. Thus, the prescribed dose would be gentamicin 140 mg every 12 hours administered as a 1-hour infusion. If a loading dose were deemed necessary, it would be given as the first dose (LD = [20.8 L][8 mg/L] = 166 mg rounded to 170 mg infused over 1 hour), and the first maintenance dose would be administered 12 hours (eg, one dosage interval) later. Using the Hull and Sarrubi nomogram for the same patient, the loading dose is 160 mg (gentamicin loading dose for serious gram-negative infection is 2 mg/kg: 2 mg/kg × 80 kg = 160 mg), and the maintenance dose is 115 mg every 12 hours (for a 12-hour dosage interval and $CL_{cr\ est}$ = 40 mL/min (i.e. 0.67 mL/s), maintenance dose is 72% of the loading dose: 0.72 × 160 mg = 115 mg).

For extended-interval therapy, $C_{max,ss}$ values of 20 to 30 mg/L (20 to 30 mcg/mL; 42-63 µmol/L) and $C_{min,ss}$ values less than 1 mg/L (1 mcg/mL; 2 µmol/L) generally are accepted as appropriate for gram-negative pneumonia patients. A minimum 24-hour dosage interval is chosen for this dosing

technique, and the dosing interval is increased in 12- to 24-hour increments for patients with renal dysfunction.

An example of this initial dosage scheme for the same case is provided to illustrate the use of extended-interval dosing. Mr. JJ is 65 years old, weighs 80 kg (176 lb). His height is 6 ft (72 in. [183 cm]) and his diagnosis is gram-negative pneumonia. His serum creatinine concentration is 2.1 mg/dL (186 µmol/L) and is stable. Compute an extended-interval gentamicin dosage regimen (infused over 1 hour) that would provide approximate peak and trough concentrations of $C_{max,ss}$ = 25 mg/L (25 mcg/mL; 52 µmol/L) and $C_{min,ss}$ = 0.5 mg/L (0.5 mcg/mL; 1 µmol/L), respectively. The patient is within 30% of his ideal body weight [IBW_{male} = 50 + 2.3 (72 in – 60) = 78 kg] and has stable renal function, so the Cockcroft-Gault CL_{cr} estimation equation can be used: $CL_{cr\ est}$ = [(140 – 65 y)80 kg]/[72 (2.1 mg/dL)] = 40 mL/min (i.e. 0.67 mL/s). The patient's weight and estimated CL_{cr} are used to compute his V and k, respectively: V = 0.26 L/kg (80 kg) = 20.8 L; k = 0.00293(40 mL/min) + 0.014 = 0.131 h^{-1} or $t_{1/2}$ = (0.693/0.131 h^{-1}) = 5.3 h. The dosage interval and dose for the desired serum concentrations would then be calculated: τ = [(ln 25 mg/L – ln 0.5 mg/L)/0.131 h^{-1}] + 1 h = 31 h rounded to 36 h; D = (1 h)(0.131 h^{-1})(20.8 L)(25 mg/L) [1 – $e^{-(0.131h^{-1})(36h)}$/1 – $e^{-(0.131h^{-1})(1h)}$] = 550 mg. Thus, the prescribed dose would be gentamicin 550 mg every 36 hours administered as a 1-hour infusion.

If appropriate aminoglycoside serum concentrations are available, kinetic parameters can be calculated at any point in therapy. When the patient is not at steady state, serum aminoglycoside concentrations are obtained before a dose (C_{min}), after a dose administered as an IV infusion of ~1 hour or as a 30-minute infusion followed by a 30-minute waiting period to allow for drug distribution (C_{max}), and at one additional postdose time (C_3) approximately one estimated half-life after C_{max}. The $t_{1/2}$ and k values are computed using C_{max} and C_3: k = (ln C_{max} – ln C_3)/Δt and $t_{1/2}$ = 0.693/k, where Δt is the time that expired between the times C_{max} and C_3 were obtained. If the patient is at steady state, serum aminoglycoside concentrations are obtained before a dose ($C_{min,ss}$) and after a dose administered as an IV infusion of ~1 hour or as a 30-minute infusion followed by a 30-minute waiting period to allow for drug distribution ($C_{max,ss}$). Because the patient is at steady state, it can be assumed that $C_{min,ss}$ is identical for each dosage interval. The $t_{1/2}$ and k values are computed using $C_{max,ss}$ and $C_{min,ss}$: k = (ln $C_{max,ss}$ – ln $C_{min,ss}$)/(τ – T) and $t_{1/2}$ = 0.693/k, where τ is the dosage interval, and T is the dose infusion time or dose infusion time plus waiting time.

Assuming a one-compartment model, the following equation is used to compute V_D:[35]

$$V_D = \frac{(D/T)(1-e^{-kT})}{k(C_{max,\,ss} - C_{min,\,ss}\,e^{-kT})}$$

where D is the dose, and T is the duration of infusion. Once these are known, the dose and dosage interval (τ) can be calculated for any desired maximum C_{ss} ($C_{max,ss}$) and minimum C_{ss} ($C_{min,ss}$):

$$\tau = \frac{\ln C_{max,\,ss} - \ln C_{min,\,ss}}{k} + T$$

$$D = TkV_D C_{max,\,ss} \frac{1 - e^{-k\tau}}{1 - e^{-kT}}$$

The dose and dosage interval should be rounded to provide clinically accepted values (every 8, 12, 18, 24, 36, and 48 hours for dosage interval, nearest 5-10 mg for conventional dosing; every 24, 36, and 48 hours for dosage interval, nearest 10-25 mg for extended interval dosing). This method also has been used to individualize IV theophylline dosage regimens.[40]

To provide an example of this technique, the problem given previously for conventional dosing will be extended to include steady-state concentrations. Please note that this method of dosage adjustment using serum concentrations can also be used for extended-interval dosing. Mr. JJ was prescribed gentamicin 140 mg every 12 hours (infused over 1 hour) for the treatment of gram-negative pneumonia. Steady-state trough ($C_{min,ss}$) and peak ($C_{max,ss}$) values were obtained before and after the fourth dose was given (more than three to five estimated half-lives), respectively, and equaled $C_{min,ss}$ = 2.8 mg/L (2.8 mcg/mL; 5.9 µmol/L) and $C_{max,ss}$ = 8.5 mg/L (8.5 mcg/mL; 18 µmol/L). Clinically, the patient was improving with decreased white blood cell counts and body temperatures and a resolving chest radiograph. However, the serum creatinine value had increased to 2.5 mg/dL (221 µmol/L). Because of this, a new dosage regimen with a similar peak (to maintain high intrapulmonary levels) but lower trough (to decrease the risk of drug-induced nephrotoxicity) concentrations was suggested. The patient's elimination rate constant and half-life can be computed using the following formulas: k = (ln 8.5 mg/L – ln 2.8 mg/L)/(12h – 1h) = 0.101 h^{-1} and $t_{1/2}$ = 0.693/0.101 h^{-1} = 6.9 h. The patient's volume of distribution can be calculated using the following equation:

$$V = \frac{(140\ \text{mg/1 h})(1 - e^{-[0.101\,h^{-1}][1\,h]})}{(0.101\ \text{h}^{-1})\left\{8.5\ \text{mg/L} - \left([2.8\ \text{mg/L}]e^{-[0.101\,h^{-1}][1\,h]}\right)\right\}} = 22.3\ \text{L}$$

Thus, the patient's volume of distribution was larger and half-life was longer than originally estimated; this led to higher serum concentrations than anticipated. To achieve the desired serum concentrations ($C_{min,ss}$ = 1.5 mg/L [1.5 mcg/mL; 3.1 µmol/L] and $C_{max,ss}$ = 8 mg/L [8 mcg/mL; 17 µmol/L]), the patient's actual kinetic parameters are used to compute a new dose and dosage interval: τ = [(ln 8 mg/L – ln 1.5 mg/L)/0.101 h^{-1}] + 1 h = 17.6 h, rounded to 18 h and

$$D = (1\ \text{h})(0.101\ \text{h}^{-1})(8\ \text{mg/L})\frac{\left(1 - e^{-(0.101\ \text{h}^{-1})(18\ \text{h})}\right)}{\left(1 - e^{-(0.101\ \text{h}^{-1})(1\ \text{h})}\right)}$$

$$= 157\ \text{mg, round to } 160\ \text{mg}$$

Thus, the new dose would be gentamicin 160 mg every 18 hours and infused over 1 hour; the first dose of the new dosage regimen would be given 18 hours (eg, the new dosage interval) after the last dose of the old dosage regimen.

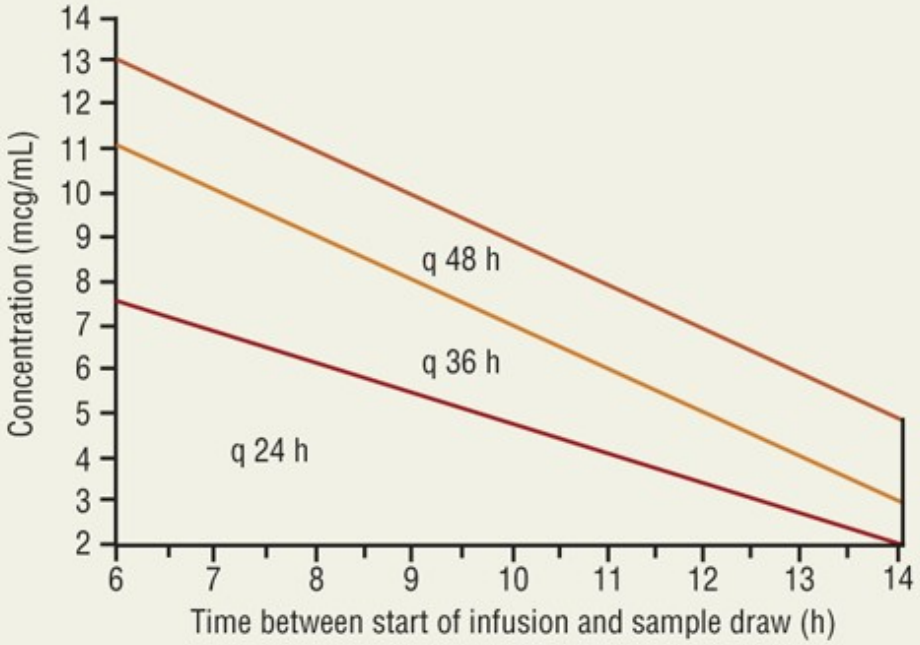
Because aminoglycoside antibiotics exhibit concentration-dependent bacterial killing, and the postantibiotic effect is longer with higher concentrations, investigators studied the possibility of giving a higher dose of aminoglycoside using an extended-dosage interval (24 hours or longer, depending on renal function). Generally, these studies have shown comparable microbiologic and clinical cure rates for many infections and about the same rate of nephrotoxicity (~5%–10%) as with conventional dosing. Ototoxicity has not been monitored using audiometry in most of these investigations, but loss of hearing in the conversational range, as well as signs and symptoms of vestibular toxicity, usually has been assessed and found to be similar to that with aminoglycoside therapy dosed conventionally. Based on these data, clinicians are using extended-interval dosing as the preferred method for most patients. For Pseudomonas aeruginosa infections where the organism has an expected (MIC) ≈ 2 mg/L, peak concentrations between 20 and 30 mg/L (20 and 30 mcg/mL; 40 and 65 µmol/L) and trough concentrations less than 1 mg/L (1 mcg/mL; 2 µmol/L) for gentamicin or tobramycin have been suggested.[41]

At the present time, there is no consensus on how to approach concentration monitoring using this mode of administration. Some clinicians obtain steady-state peak and trough concentrations and use the kinetic equations given earlier to adjust the dose and dosage interval in order to attain appropriate target levels. Other clinicians measure only trough concentrations, trusting that the large doses administered to patients achieve adequate peak concentrations.

Also, a nomogram that adjusts extended-interval doses based on a single postdose concentration to achieve these C_{ss} goals has been proposed (**Fig. e4-12**). The dose is 7 mg/kg of gentamicin or tobramycin. The initial dosage interval is set according to the patient's CL_{cr}. The Hartford nomogram includes a method to adjust doses based on serum concentrations. This portion of the nomogram contains average serum concentration time lines for gentamicin or tobramycin in patients with creatinine clearances of 60, 40, and 20 mL/min (1, 0.67, 0.33 mL/s, respectively). A serum concentration is measured 6 to 14 hours after the first dose is given, and this concentration/time point is plotted on the graph (see Fig. e4-12). The modified dosage interval is indicated by which zone the serum concentration/time point falls. Because cystic fibrosis patients have a different volume of distribution (0.35 L/kg) than assumed by this dosing technique, and extended-interval dosing has not been tested adequately in patients with endocarditis, the Hartford nomogram should not be used in these situations.

FIGURE e4-12

Hartford nomogram for extended-interval aminoglycosides. (*From Reference 41. Reproduced with permission from American Society for Microbiology*.) To determine the corresponding creatinine clearance in units of mL/s divide the value in mL/min by 60. Gentamicin levels in mcg/mL can be converted to units of µmol/L by multiplying by 2.09.



1. Administer 7 mg/kg gentamicin or tobramycin with initial dosage interval:

Estimated CL_{cr} (mL/min)	Initial dosage interval
≥60 mL/min	q 24 h
40-59 mL/min	q 36 h
20-39 mL/min	q 48 h
<20 mL/min	Monitor serial concentrations and administer next dose when <1 mcg/mL

2. Obtain timed serum concentration 6 to 14 hours after dose (ideally first dose)
3. Alter dosage interval to that indicated by the nomogram zone (above q 48 h zone, monitor serial concentrations and administer next dose when <1 mcg/mL)

To illustrate how the Hartford nomogram is used, the same patient example used previously will be repeated for this dosage approach. Mr. JJ weighs 80 kg (176 lb) and has a $CL_{cr\ est}$ of 40 mL/min (i.e. 0.67 mL/s). Using the Hartford nomogram, the patient would receive gentamicin 560 mg every 36 hours (7 mg/kg × 80 kg = 560 mg; the initial dosage interval for $CL_{cr\ est}$ = 40 mL/min [0.67 mL/s] is 36 hours). Ten hours after the first dose was given, the serum gentamicin concentration is 8.2 mg/L

(17 µmol/L). According to the graph contained in the nomogram, the dosage interval should be changed to 48 hours. The new dose is 560 mg every 48 hours.

Clinical Controversy…

Most clinicians use extended-interval dosing exclusively for patients requiring aminoglycosides, whereas others use a mix of conventional dosing or extended-interval dosing according to the perceived benefit to the patient. Definitive, authoritative recommendations to guide the choice of one method of aminoglycoside dosing over the other are not available.

Clinical Controversy…

"Trough only" measurement of steady-state vancomycin concentrations is a mainstream method to monitor therapy. The exact range for this value is uncertain. Some clinicians recommend 5 to 15 mcg/mL (5 to 15 mg/L; 3.5-10 µmol/L) for susceptible bacteria with lower MIC values. For selected sites of infection with specific organisms, such as hospital-acquired pneumonia caused by multidrug-resistant organisms, guidelines suggest vancomycin trough concentrations as high as 15 to 20 mcg/mL (15 to 20 mg/L; 10-14 µmol/L) may be necessary. Some clinicians continue to measure both steady-state peak and trough vancomycin concentrations. Optimal outcomes for methicillin-resistant *Staphylococcus aureus* (MRSA) infections are usually associated with AUC_{24}/MIC ratios greater than 400, where MIC is for the causative organism.

Vancomycin

Vancomycin requires multicompartment models to completely describe its serum-concentration-versus-time curves. However, if peak serum concentrations are obtained after the distribution phase is completed (usually 30 minutes to 1 hour after a 1-hour IV infusion), a one-compartment model can be used for patient dosage calculations. Also, because vancomycin has a relatively long half-life compared with the infusion time, only a small amount of drug is eliminated during infusion, and it is usually unnecessary to use more complex IV infusion equations. Thus, simple IV bolus equations can be used to calculate vancomycin doses for most patients. Although a recent review article[42] questioned the clinical usefulness of measuring vancomycin concentrations on a routine basis, other research articles[44, 45] have shown potential benefits in obtaining vancomycin concentrations in select patient populations. Most clinicians advocate monitoring only steady-state trough concentrations of vancomycin.[46] The decision to conduct vancomycin concentration monitoring should be made on a patient-by-patient basis.

Initial doses of vancomycin can be computed for adult patients using estimated kinetic parameters derived from population pharmacokinetic data. Clearance is estimated using the patient's creatinine clearance in the following equation:[43] CL (in mL/min/kg) = 0.695(CL_{cr} in mL/min/kg) + 0.05. The volume of distribution is computed assuming the standard value of 0.7 L/kg: V_D = 0.7(Wt), where Wt is the patient's weight. In the case of obese patients, actual or total body weight is used in the calculation of clearance, but ideal body weight is used to compute volume of distribution.[47] The elimination rate constant is calculated using clearance and volume of distribution estimates,

correcting for possible differences in units for these parameters: $k = CL/V_D$. A nomogram that uses this type of approach for vancomycin therapy is available to determine initial doses rapidly for patients who require trough concentrations of 5 to 15 mcg/mL (**Table e4-6**).[24]

TABLE e4-6 Vancomycin Dosage Chart

1. Compute patient's creatinine clearance (CL_{cr}) using the Cockcroft-Gault method: $CL_{cr} = [(140 - age)BW]/(S_{Cr} \times 72)$, where S_{cr} is expressed in units of mg/dL. Multiply by 0.85 for women. (S_{cr} expressed in µmol/L must be divided by 88.4 to obtain conventional units of mg/dL.)

2. Use the patient's TBW to compute doses.

3. Dosage chart designed to achieve peak serum concentrations of 30 mcg/mL (30 mg/L; 21 µmol/L) and trough concentrations of 7.5 mcg/mL (7.5 mg/L; 5 µmol/L).

4. Compute loading dose of 25 mg/kg.

5. Compute maintenance dose of 19 mg/kg given at the dosage interval listed in the following chart for the patient's CL_{cr}:

CL_{cr} (mL/min)[a]	**Dosage Interval (Days)**
≥120	0.5
100	0.6
80	0.75
60	1.0
40	1.5
30	2.0
20	2.5
10	4.0
5	6.0
0	12.0

BW, body weight; S_{cr}, serum creatinine; TBW = total body weight.

[a]Cl_{cr} expressed in mL/min can be converted to units of mL/s by dividing by 60.

Data from Reference 24.

For non-obese patients with moderate-to-normal renal function who require steady-state trough concentrations of 15 to 20 mcg/mL, a different dosage nomogram is available.[63]

Steady-state peak and trough concentrations are chosen for the patient based on the site and severity of the infection, as well as the known or suspected pathogen and avoidance of potential side effects. Optimal outcomes for methicillin-resistant *Staphylococcus aureus* (MRSA) infections are usually associated with AUC_{24}/MIC ratios greater than 400, where AUC_{24} is the area under the

vancomycin concentration/time curve for 24 hours and MIC is the for the bacteria causing the infection. $C_{max,ss}$ values of between 20 and 40 mg/L (20 and 40 mcg/mL; 14 and 28 µmol/L) and $C_{min,ss}$ values of between 5 and 15 mg/L (5 and 15 mcg/mL; 3.5 and 10 µmol/L) typically are used for patients with mild to moderate infections or sensitive bacteria with lower MIC values (less than 1 mcg/mL). For patients with pneumonia or other life-threatening infections due to multidrug-resistant organisms, $C_{min,ss}$ as high as 15 to 20 mg/L (15-20 mcg/mL; 10-14 µmol/L) have been suggested.[48] After appropriate steady-state concentrations are chosen, the dosage interval required to attain those concentrations is computed, and τ is rounded to a clinically acceptable value (8, 12, 18, 24, 36, 48, or 72 hours): $\tau = (\ln C_{max,ss} - \ln C_{min,ss})/k$. Finally, the maintenance dose is computed for the patient using a one-compartment-model IV bolus equation at steady state, and the dose is rounded off to the nearest 100 to 250 mg:

$$D = C_{max,\,ss} V_D (1 - e^{-k\tau})$$

If desired, a loading dose can be computed using the following equation:

$$LD = V_D C_{max,\,ss}$$

The following case will illustrate the use of this dosage methodology. Ms. HJ is 65 years old, weighs 68 kg (150 lb), and is 5 ft 4 in. (64 in. [163 cm]) tall. She has developed a surgical wound infection; *Staphylococcus epidermidis* is the suspected pathogen with an anticipated MIC = 0.5 mcg/mL. Her serum creatinine concentration is 1.8 mg/dL (159 µmol/L) and stable. Compute a vancomycin dosage regimen that would provide approximate peak (obtained 1 hour after a 1-hour infusion) and trough concentrations of 30 and 7 mg/L (30 and 7 mcg/mL; 21 and 5 µmol/L), respectively. The patient is within 30% of her ideal body weight [IBW_{female} = 45 + 2.3(64 in. – 60) = 54 kg] and has stable renal function, so the Cockcroft-Gault creatinine clearance estimation formula can be used: $CL_{cr\ est}$ = 0.85[(140 – 65 y)68 kg]/[72(1.8 mg/dL)] = 33 mL/min (0.55 mL/s). The patient's weight and $CL_{cr\ est}$ are used to calculate her estimated CL, V_D, and k, respectively: CL = 0.695 (33 mL/min/68 kg) + 0.05 = 0.387 mL/min/kg; V_D = 0.7 L/kg (68 kg) = 48 L; and k = [(0.387 mL/min/kg) (68 kg) (60 min/h)] / [(48 L)(1,000 mL/L)] = 0.033 h^{-1} or $t_{1/2}$ = 0.693/0.033 h^{-1} = 21 h. The dosage interval, maintenance dose, and loading dose for the desired serum concentrations can be computed: τ = (ln 30 mg/L – ln 7 mg/L)/0.033 h^{-1} = 44 h, rounded to 48 h; D = (30 mg/L) (48 L) (1 – $e^{-(0.033h^{-1})\,(48h)}$) = 1,145 mg, rounded to 1,250 mg; LD = (48 L)(30 mg/L) = 1,440 mg, rounded to 1,500 mg. Therefore, the prescribed dose would be vancomycin 1,250 mg every 48 hours administered as a 1-hour infusion. If a loading dose was used, it would be given as the first dose, and the first maintenance dose would be administered 48 hours (one dosage interval) later. Using the Matzke nomogram for the same patient, the loading dose would be 1,750 mg (vancomycin loading dose is 25 mg/kg: 25 mg/kg × 68 kg = 1,700 mg, rounded to 1,750 mg), followed by a maintenance dose of 1,250 mg every 48 hours (for $CL_{cr\ est}$ = 30 mL/min [i.e. 0.50 mL/s]), the maintenance dose is 19 mg/kg every 2 days: 19 mg/kg × 68 kg = 1,292 mg, (rounded to 1,250 mg).

If appropriate vancomycin serum concentrations are available, kinetic parameters can be computed at any point in therapy. When the patient is not at steady state, serum vancomycin concentrations are obtained before a dose (C_{min}), after a dose administered as an IV infusion of 1 hour followed by a

30-minute to 1-hour waiting period to allow for drug distribution (C_{max}), and at one additional postdose time (C_3) approximately one estimated half-life after C_{max}. The $t_{1/2}$ and k values are computed using C_{max} and C_3: $k = (\ln C_{max} - \ln C_3)/\Delta t$ and $t_{1/2} = 0.693/k$, where Δt is the time that expired between the times C_{max} and C_3 were obtained. If the patient is at steady state, serum vancomycin concentrations are obtained before a dose ($C_{min,ss}$) and after a dose administered as an IV infusion of approximately 1 hour followed by a 30-minute to 1-hour waiting period to allow for drug distribution ($C_{max,ss}$). The $t_{1/2}$ and k values are computed using $C_{max,ss}$ and $C_{min,ss}$: $k = (\ln C_{max,ss} - \ln C_{min,ss})/(\tau - T_{max})$ and $t_{1/2} = 0.693/k$, where τ is the dosage interval, and T_{max} is the dose infusion time plus waiting time.

Assuming a one-compartment model, the following equation is used to compute V_D:

$$V_D = \frac{D}{C_{max,\,ss} - C_{min,\,ss}}$$

where D is dose. Once these are known, the dose and dosage interval (τ) can be calculated for any desired maximum C_{ss}($C_{max,ss}$) and minimum C_{ss} ($C_{min,ss}$):

$$\tau = \frac{\ln C_{max,ss} - \ln C_{min,ss}}{k}$$

$$D = C_{max,ss} V_D (1 - e^{-k\tau})$$

The dose and dosage interval should be rounded to provide clinically accepted values (every 8, 12, 18, 24, 36, 48, or 72 hours for dosage interval, nearest 100-250 mg for dose).

To provide an example for this dosage-calculation method, the preceding problem will be extended to include steady-state concentrations. Ms. HJ was prescribed vancomycin 1,200 mg every 48 hours (infused over 1 hour) for the treatment of a surgical wound infection. Steady-state trough ($C_{min,ss}$) and peak ($C_{max,ss}$) values ($C_{max,ss}$ obtained 1 hour after the end of the infusion) were obtained before and after the third dose was given (more than three to five estimated half-lives), respectively, and equaled $C_{min,ss}$ = 2.5 mg/L (2.5 mcg/mL; 1.7 µmol/L) and $C_{max,ss}$ = 22.4 mg/L (22.4 mcg/mL; 15.5 µmol/L). Clinically, the patient had improved somewhat, but her white blood cell count was still elevated, and the patient was still febrile. Because of this, a modified dosage regimen with a $C_{max,ss}$ = 30 mg/L (30 mcg/mL; 21 µmol/L) and $C_{min,ss}$ = 7 mg/L (7 mcg/mL; 5 µmol/L) was suggested to maintain an AUC_{24}/MIC ratio greater than 400. The patient's actual elimination rate constant and half-life can be calculated using the following formulas: $k = (\ln 22.4\ mg/L - \ln 2.5\ mg/L)/(48\ h - 2\ h) = 0.048\ h^{-1}$ and $t_{1/2} = 0.693/0.048\ h^{-1} = 14.4\ h$. The patient's volume of distribution can be calculated using the following equation:

$$V_D = \frac{1{,}200\ mg}{22.4\ mg/L - 2.5\ mg/L} = 60\ L$$

Thus, the patient's volume of distribution was larger and half-life shorter than originally estimated; this led to lower serum concentrations than anticipated. To achieve the desired serum concentrations

($C_{max,ss}$ = 30 mg/L [30 mcg/mL; 21 µmol/L] and $C_{min,ss}$ = 7 mg/L [7 mcg/mL; 5 µmol/L]), the patient's actual kinetic parameters are used to calculate a new dose and dosage interval:

$$\tau = \frac{\ln 30\ \text{mg/L} - \ln 7\ \text{mg/L}}{0.048\ \text{h}^{-1}}$$

$$= 30\ \text{h, rounded to } 36\ \text{h}$$

$$D = (30\ \text{mg/L})(60\ \text{L})\left(1 - e^{-(0.048\text{h}^{-1})(36\text{h})}\right)$$

$$= 1{,}480\ \text{mg, rounded to } 1{,}500\ \text{mg}$$

The new dose would be vancomycin 1,500 mg every 36 hours (infused over 1 hour); the first dose of the new dosage regimen would be given 36 hours (the new dosage interval) after the last dose of the old dosage regimen.

For routine monitoring, many clinicians measure only steady-state vancomycin trough concentrations in patients. The justification for this approach is that because vancomycin exhibits time-dependent bacterial killing, the minimum concentration is the most important with regard to therapeutic outcome. Vancomycin pharmacokinetics also support this approach because the volume of distribution is relatively stable and is not changed by many disease states or conditions. Because of this important point, it is difficult to attain peak steady-state concentrations in the toxic range when the steady-state vancomycin trough is in the therapeutic range if typical doses are used (15 mg/kg or ≈ 1,000 mg for average-weight individuals). Also, toxic peak concentrations (generally greater than 80–100 mg/L [80–100 mcg/mL; 55-69 µmol/L]) are quite a bit higher than therapeutic peak concentrations, which adds a safety margin between effective concentrations and those yielding adverse drug effects.

Coupled with trough-only vancomycin concentration monitoring is a widening of the therapeutic steady-state trough concentration range from 5 to 15 mg/L (5 to 15 mcg/mL; 3.5-10 µmol/L). The justification for increasing the top of the range from 10 to 15 mg/L (10 to 15 mcg/mL; 7-10 µmol/L) comes from limited retrospective[45] and prospective[45] studies. Trough concentrations in the range of 15 to 20 mg/L (15 to 20 mcg/mL; 10-14 µmol/L) should be reserved for specific clinical situations, such as hospital-acquired pneumonia or other severe infections caused by multidrug-resistant organisms.[48] As previously mentioned, optimal outcomes for methicillin-resistant *Staphylococcus aureus* (MRSA) infections are usually associated with AUC_{24}/MIC ratios greater than 400, where MIC is for the causative organism.

When trough-only monitoring of vancomycin concentrations is chosen by a clinician, a simple variant of linear pharmacokinetics can be used to adjust the dose (D) and dosage interval (τ): $(D_{new}/\tau_{new}) = (D_{old}/\tau_{old})\ (C_{ss,new}/C_{ss,old})$, where *new* and *old* indicate the new target trough concentration and the old measured trough concentration, respectively. In practice, the dose (typically 1,000–1,500 mg) is often held constant, and only the dosage interval is changed. This equation is an approximation of the actual new steady-state trough concentration that will be attained in the patient because, mathematically, $C_{ss,new}$ is an exponential function of τ.

An example of this approach is given in the following case. Mr. MK is 72 years old, weighs 72 kg (158

lb), and measures 5 ft 9 in. (69 in. [175 cm]). He was prescribed vancomycin 1,000 mg every 12 hours (infused over 1 hour) for the treatment of an *S. epidermidis* central venous catheter infection. A steady-state trough ($C_{min,ss}$) value was obtained before the fifth dose was given (more than three to five estimated half-lives), and $C_{min,ss}$ = 19 mg/L (19 mcg/mL; 13 µmol/L). Clinically, the patient was improving, but the trough concentration was judged to be too high. Because of this, a modified dosage regimen with a $C_{min,ss}$ = 10 mg/L (10 mcg/mL; 7 µmol/L) was suggested to maintain an AUC_{24}/MIC ratio greater than 400. (D_{new}/τ_{new}) = (1,000 mg/12 h)(10 mg/L/19 mg/L) = 44 mg/h. Because the patient is near his ideal weight, the same dose of 1,000 mg can be used (D_{new}), and the new dosage interval (τ_{new}) can be computed: τ = 1,000 mg/44 mg/h = 23 h, rounded to 24 h. The new prescribed dose for the patient would be 1,000 mg every 24 hours.

Digoxin

Digoxin pharmacokinetics are best described by a two-compartment model. However, because digoxin has a long half-life compared with its dosage interval and a very long distribution phase, simple pharmacokinetic equations can be used to individualize dosing when postdistribution serum concentrations are used. Digoxin can be given as an IV injection and orally as elixir (*F* = 0.8) or tablets (*F* = 0.7). When given orally, the appropriate bioavailability fraction must be used to compute the correct dose. Initial doses of digoxin can be computed using population pharmacokinetic data obtained from published studies. Digoxin clearance is estimated using the patient's CL_{cr} in the following formula:[23] CL (in milliliters per minute) = 1.303 (CL_{cr} in milliliters per minute) + CL_m, where CL_m is metabolic clearance and equals 40 mL/min for patients with no or mild heart failure or 20 mL/min for patients with moderate to severe heart failure. The volume of distribution decreases with declining renal function and is estimated using the following equation:[23] V_D (in liters) = 226 + [298(CL_{cr} in milliliters per minute)]/(29.1 + CL_{cr} in milliliters per minute). The elimination rate constant can be computed by taking the quotient of CL and V_D: $k = CL/V_D$. For obese individuals, digoxin dosing should be based on ideal body weight.[49]

Appropriate C_{ss} values are chosen for the patient based on the disease state being treated, the goal of therapy, and avoidance of adverse effects. The inotropic effects of digoxin occur at lower concentrations than do the chronotropic effects. Therefore, initial serum concentrations of digoxin for the treatment of heart failure generally are 0.5 to 1 ng/mL (0.5-1 mcg/L; 0.65-1.3 nmol/L) or less and for the treatment of atrial fibrillation 0.8 to 1.5 ng/mL (0.8 to 1.5 mcg/L; 1.0-1.9 nmol/L). Once the appropriate C_{ss} is selected, a dose is computed for the patient: $D/\tau = (C_{ss}CL)/F$.

An example of this initial dosage scheme is provided in the following case. Mr. PO is 72 years old, weighs 83 kg (183 lb), and measures 5 ft 11 in. (71 in. [180 cm]). He was admitted to the hospital for the treatment of community-acquired pneumonia. His past medical history is positive for moderate heart failure. While in the hospital, Mr. PO develops atrial fibrillation, and the decision is made to treat him with digoxin to provide ventricular rate control. His serum creatinine concentration is 2.5 mg/dL (221 µmol/L) and stable. Calculate an IV loading dose and oral maintenance dose that will achieve a C_{ss} of 1.5 ng/mL (1.5 mcg/L; 1.9 nmol/L). The Cockcroft-Gault equation can be used to estimate the patient's CLcr because his serum creatinine concentration is stable, and he is within 30%

of his ideal body weight [IBW_{male} = 50 + 2.3(71 in – 60) = 75 kg]: CL_{cr} = [(140 – 72 y)83 kg]/[72(2.5 mg/dL)] = 31 mL/min (i.e. 0.52 mL/s). Using the estimated CL_{cr}, both CL and V_D can be computed:

$$CL = 1.303(31\ mL/min) + 20 = 60\ mL\ min$$

$$V_D = 226 + \frac{298(31\ mL/min)}{29.1 + 31\ mL/min}$$

The maintenance dose will be given as digoxin tablets, so F = 0.7 in the dosing equation: D/τ = [(1.5 mcg/L)(60 mL/min)(60 min/h)(24 h/day)]/[0.7(1,000 mL/L)] = 185 mcg/day, rounded to 187.5 mcg/day (given as 1 1/2 of 125 mcg tablets). The loading dose will be given IV as a digoxin injection: LD = (1.5 mcg/L)(380 L) = 570 mcg, rounded to 500 mcg. The loading dose would be given 50% now (250 mcg), 25% (125 mcg) in 4 to 6 hours after monitoring the patient's heart rate and blood pressure and assessing the patient for digoxin adverse effects, and the final 25% (125 mcg) 4 to 6 hours later after monitoring the same clinical parameters. The first maintenance dose would be given one dosage interval (in this case, 24 hours) after the first part of the loading dose was given.

Adjustment of digoxin doses using steady-state concentrations is accomplished using linear pharmacokinetics and dosage ratios: $D_{new} = D_{old}(C_{ss,new}/C_{ss,old})$. For example, Mr. PO's atrial fibrillation responded to digoxin therapy, and he was discharged after resolution of his pneumonia. A month later, he was followed up in the clinic with moderate nausea, possibly a result of digoxin toxicity. His heart rate was 51 beats per minute, and his serum creatinine was unchanged. A steady-state digoxin concentration was determined and reported by the clinical laboratory as 2.2 mcg/L (2.8 nmol/L). Compute a new dose for the patient to achieve a C_{ss} of 1.5 mcg/L (1.9 nmol/L). The digoxin C_{ss} and old dose would be used to calculate a new dose using the linear pharmacokinetic equation: D_{new} = 187.5 mcg/day[(1.5 mcg/L)/(2.2 mcg/L)] = 128 mcg/day, rounded to 125 mcg/day.

Theophylline

Theophylline disposition is described most accurately by nonlinear kinetics.[50,51] However, at the usual doses, theophylline acts as if it obeys linear kinetics in most patients. Initial theophylline doses are computed by taking a detailed medical history of the patient and noting disease states and conditions that are known to change theophylline disposition. Age, smoking of tobacco-containing products, heart failure, and liver disease are among the important factors that alter theophylline kinetic parameters and dosage requirements. Once the patient has been assessed, average theophylline kinetic parameters obtained from the literature for patients similar to the one being currently treated are used to compute either oral or IV doses. Dosage guidelines that take into account most common disease states and conditions that change theophylline kinetic parameters are available (see Table e4-4).[52] Once theophylline is administered, the patient is monitored for the therapeutic effect and potential adverse effects. Theophylline concentrations then are used to individualize the theophylline dose that the patient receives. An example of this approach was given previously for a patient in the section on drug dosing in patients with liver disease (see Selection of Initial Drug Doses above).

Continuous IV infusions of theophylline (or its salt, aminophylline) can be individualized rapidly by determining the patient's CL before steady state occurs.[53] Assuming that the patient receives theophylline only by continuous IV infusion (previous doses of sustained-release oral theophylline are completely absorbed), two serum theophylline concentration determinations are done 4 hours or more apart. The infusion rate (k_0) cannot be changed between the times the samples are drawn. With one-compartment model equations, the first (C_1) and second (C_2) theophylline concentrations are used to calculate theophylline CL:

$$\mathrm{CL} = \frac{2k_0}{C_1 + C_2} + \frac{2V_D(C_1 - C_2)}{(C_1 + C_2)(t_2 - t_1)}$$

V_D is assumed to be 0.5 L/kg, and t_1 and t_2 are the times at which C_1 and C_2, respectively, are obtained. Once CL is known, k_0 can be computed easily for any desired C_{ss} ($C_{ss} = k_0/\mathrm{CL}$). This method probably can be applied to other drugs that are administered as continuous IV infusions, such as IV antiarrhythmics, when rapid individualization of drug dosage is desirable.

An example of this approach can be obtained by continuing the theophylline patient case from the section on drug dosing in liver disease (see Selection of Initial Drug Doses above). In this example, a 55-year-old, 70 kg (154 lb) man with liver cirrhosis was prescribed a loading dose of theophylline 350 mg IV over 20 to 30 minutes, followed by a maintenance dose of 15 mg/h of theophylline as a continuous infusion. The infusion began at 9 am, blood samples were obtained at 10 am and 4 pm, and the clinical laboratory reported the theophylline serum concentrations as 10.9 and 12.3 mg/L (10.9 and 12.3 mcg/mL; 60.5 and 68.3 µmol/L), respectively. The patient's theophylline clearance and revised continuous infusion to maintain a C_{ss} of 15 mg/L (15 mcg/mL; 83.3 µmol/L) can be computed as follows (patient's V_D estimated at 0.5 L/kg):

$$\mathrm{CL} = \frac{2(15\ \mathrm{mg/h})}{10.9\ \mathrm{mg/L} + 12.3\ \mathrm{mg/L}} + \frac{2(0.5\ \mathrm{L/kg} \times 70\ \mathrm{kg})(10.9\ \mathrm{mg/L} - 12.3\ \mathrm{mg/L})}{(10.9\ \mathrm{mg/L} + 12.3\ \mathrm{mg/L})(16 - 10\ \mathrm{h})} = 0.59\ \mathrm{L/h}$$

$$k_0 = C_{ss}\mathrm{CL} = (15\ \mathrm{mg/L})(0.59\ \mathrm{L/h}) = 9\ \mathrm{mg/h\ theophylline}$$

If theophylline is to be given as the aminophylline salt form, the doses would need to be changed to reflect the fact that aminophylline contains only 85% theophylline (k_0 = 9 mg/h theophylline/0.85 = 11 mg/h aminophylline).

If continuous IV infusions or oral dosage regimens are given long enough for steady state to occur (three to five estimated half-lives based on previous studies conducted in similar patients), linear pharmacokinetics can be used to adjust doses for either route of administration: $D_{new} = D_{old}(C_{ss,new}/C_{ss,old})$. For example, a patient receiving 200 mg of sustained-release oral theophylline every 12 hours with a theophylline steady-state serum concentration of 9.5 mcg/mL (9.5 mg/L; 52.7 µmol/L) can have the dose required to achieve a new C_{ss} equal to 15 mcg/mL (15 mg/L; 83.3 µmol/L) computed by applying linear pharmacokinetics: D_{new} = 200 mg([15 mcg/mL]/[9.5 mcg/mL]) = 316 mg, rounded to 300 mg. Thus the new theophylline dose would be 300 mg every 12 hours.

Phenytoin

Phenytoin doses are very difficult to individualize because the drug follows Michaelis-Menten kinetics, and there is a large amount of interpatient variability in V_{max} and K_m. Initial maintenance doses of phenytoin in adults usually range between 4 and 7 mg/kg daily, yielding starting doses of 300 to 400 mg daily in most individuals. If needed, loading doses of phenytoin or fosphenytoin (a prodrug of phenytoin used IV) can be administered in adults at a dose of 15 mg/kg, which is approximately 1,000 mg in many individuals. Loading doses of phenytoin can be given orally but need to be administered in divided doses separated by several hours in order to avoid decreased bioavailability and intolerance (for total loading dose of 1,000 mg: 400 mg, 300 mg, then 300 mg with each dose separated by 4-6 h). Because phenytoin is metabolized hepatically, decreased doses may be needed in patients with liver disease. Because phenytoin follows dose-dependent pharmacokinetics, the half-life of phenytoin increases for a patient as the maintenance dose increases. Therefore, the time to steady-state phenytoin concentrations increases with dose. On average, at a phenytoin dose of 300 mg daily, it takes approximately 5 to 7 days to achieve steady state; at a dose of 400 mg daily, it takes approximately 10 to 14 days to achieve steady state; and at a dose of 500 mg daily, it takes approximately 21 to 28 days to achieve steady state. It should be noted that the injectable and capsule dosage forms of phenytoin are phenytoin sodium, and the labeled dosage amounts contain 92% of active phenytoin (300 mg phenytoin sodium capsules contain 276 mg [300 mg × 0.92 = 276 mg] of active phenytoin). Unbound phenytoin concentrations are useful in patients with hypoalbuminemia (eg, liver disease, nephrotic syndrome, pregnancy, cystic fibrosis, burns, trauma, and malnourishment, as well as in the elderly), in patients in whom displacement with endogenous compounds is possible (hyperbilirubinemia, liver disease, or end-stage renal disease), and in patients receiving other drugs that may displace phenytoin from plasma protein-binding sights (valproic acid, aspirin therapy more than 2 g daily, warfarin, and nonsteroidal antiinflammatory drugs with high albumin binding).[54]

After steady state has occurred, phenytoin serum concentrations can be obtained as an aid to dosage adjustment. A simple, easy way to approximate new serum concentrations after a dosage adjustment with phenytoin is to temporarily assume linear pharmacokinetics and then add 15% to 33% for a dosage increase or subtract 15% to 33% for a dosage decrease to account for Michaelis-Menten kinetics. To avoid large disproportionate changes in phenytoin concentrations when using this empirical method, dosage adjustments should be limited to 50 to 100 mg daily. This technique is intended only to provide a rough approximation of the resulting phenytoin C_{ss} after an appropriate dosage adjustment has been made.

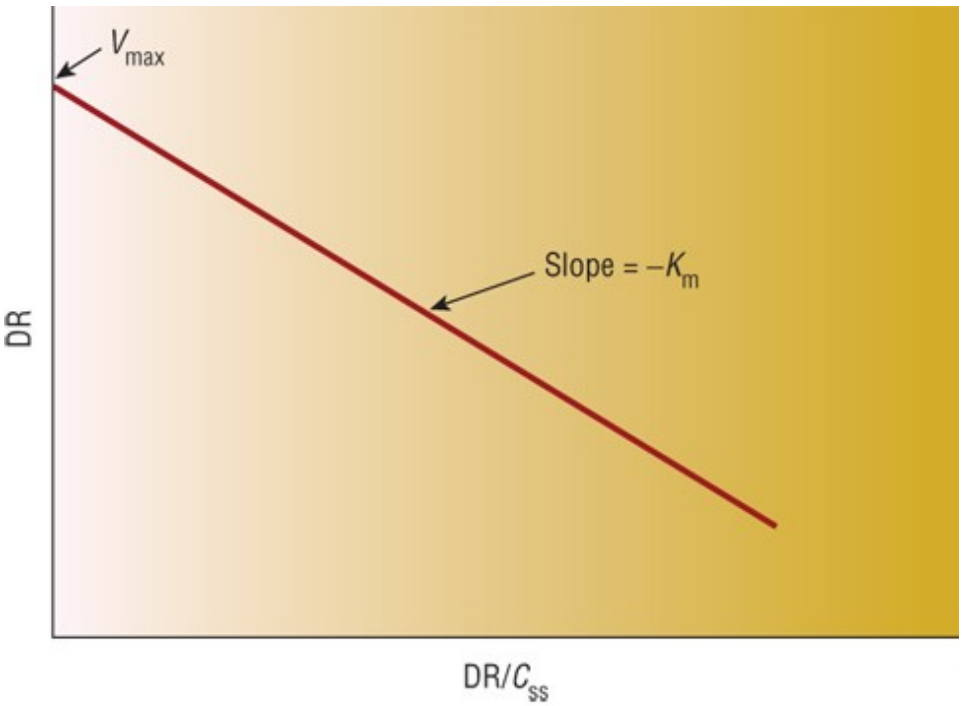
For example, Ms. PP is a 35-year-old, 65 kg (143 lb) patient with grand mal seizures who is receiving phenytoin capsules 300 mg orally at bedtime. A C_{ss} of 9.2 mcg/mL (9.2 mg/L; 37 µmol/L) is measured. It is observed that her seizure frequency decreased by only ~15%, and that she has had no adverse effects as a consequence of phenytoin treatment. Because of this, her phenytoin dose is increased to 400 mg orally at bedtime. The expected phenytoin C_{ss} would be estimated using linear pharmacokinetics ($C_{new} = [D_{new}/D_{old}]C_{old}$ = [400 mg/300 mg]/[9.2 mcg/mL] = 12.3 mcg/mL) and then increased by 15% to 33% to account for nonlinear kinetics (C_{new} = 1.15[12.3 mcg/mL] = 14.1 mcg/mL or C_{new} = 1.33 [12.3 mcg/mL] = 16.4 mcg/mL). Thus, the patient would be expected to have

a steady-state phenytoin concentration of approximately 14 to 16 mcg/mL (14 to 16 mg/L; 56-63 µmol/L) as a consequence of the dosage increase. An alternative approach would be to use a graphic Bayesian method that allows an estimate of V_{max} and K_m from one steady-state phenytoin concentration and the prediction of new steady-state concentrations when doses are changed.[55]

Other methods used to individualize phenytoin doses involve rearrangements of the Michaelis-Menten equation [DR = $V_{max}C_{ss}/(K_m + C_{ss})$, in which DR is the dosage rate at steady state] so that two or more doses and C_{ss} values can be used to obtain graphic solutions for V_{max} and K_m. One rearrangement[56] is DR = $-K_m(DR/C_{ss}) + V_{max}$. When DR is plotted on the *y* axis, and DR/C_{ss} is plotted on the *x* axis of Cartesian graph paper, a straight line with a y intercept of V_{max} and slope equal to $-K_m$ is found (**Fig. e4-13**). To use this method, patients are prescribed an initial phenytoin dose, and C_{ss} is obtained. The phenytoin dose is then changed, and a second C_{ss} from the new dose is obtained. Each dose is divided by its respective C_{ss} to derive DR/C_{ss} values. The DR/C_{ss} and C_{ss} values are plotted on the graph to calculate V_{max} (*y* intercept) and K_m (minus slope). The steady-state Michaelis-Menten equation can be used to compute C_{ss}.

FIGURE e4-13

Relationship between dosage rate (DR) and steady-state serum concentrations (C_{ss}).



Cyclosporine

Because of the large amount of variability in cyclosporine pharmacokinetics, even when concurrent disease states and conditions are identified, many clinicians believe that the use of standardized

initial cyclosporine doses for various situations is warranted. Indeed, most transplant centers use doses that are determined employing a locally derived cyclosporine dosage protocol. The original computations of these doses were based on the pharmacokinetic dosing methods described in preceding sections and subsequently modified based on clinical experience. In general, the expected cyclosporine C_{ss} used to compute these doses depends on the type of transplanted tissue and the posttransplantation time line. Generally speaking, initial oral doses of 8 to 18 mg/kg daily or IV doses of 3 to 6 mg/kg daily (one-third the oral dose to account for ~30% oral bioavailability) are used and vary greatly from institution to institution. For obese individuals (30% over ideal body weight), ideal body weight should be used to compute initial doses.

It is likely that doses computed using patient population characteristics will not always produce cyclosporine concentrations that are expected or desirable. Additionally, there is a very high amount of interday variation in cyclosporine concentrations. Because of pharmacokinetic variability, the narrow therapeutic index of cyclosporine, and the severity of cyclosporine adverse side effects, measurement of cyclosporine concentrations is mandatory for patients to ensure that therapeutic, nontoxic levels are present. When cyclosporine concentrations are measured in patients, and a dosage change is necessary, clinicians should seek to use the simplest, most straightforward method available to determine a dose that will provide safe and effective treatment. In most cases, a simple dosage ratio can be used to change cyclosporine doses using steady-state concentrations and assuming that the drug follows linear pharmacokinetics:

$$D_{new} = D_{old} \frac{C_{ss,new}}{C_{ss,old}}$$

The C_{ss} can be either a steady-state trough concentration or a C_{ss} measured 2 hours (±15 min) after a dose (C2). When C2 levels are used, recommended concentrations vary according to transplant type and posttransplant time (see **Table e4-7**).[57,58,59]

TABLE e4-7 Recommended 2-Hour (±15 Min) Postdose Steady-State Cyclosporine Concentrations (C2) for Various Solid Organ Transplant Types and Posttransplant Times

Renal Transplant

Posttransplant Time (Months)	C2 Level
1	1,500-2,000 ng/mL or mcg/L 1,248-1,664 nmol/L
2	1,500 ng/mL or mcg/L 1,248 nmol/L
3	1,300 ng/mL or mcg/L 1,082 nmol/L
4-6	1,100 ng/mL or mcg/L 915 nmol/L
7-12	900 ng/mL or mcg/L 749 nmol/L

Renal Transplant

Posttransplant Time (Months)	C2 Level
>12	800 ng/mL or mcg/L 666 nmol/L

Liver Transplant

Posttransplant Time (Months)	C2 Level
0-3	1,000 ng/mL or mcg/L 832 nmol/L
4-6	800 ng/mL or mcg/L 666 nmol/L
>6	600 ng/mL or mcg/L 499 nmol/L

Data from References 57, 58, and 59.

For example, LK is a 50-year-old, 75 kg (165 lb), 5 ft 11 in. (71 in. [180 cm]) male renal transplant recipient who is receiving oral cyclosporine 400 mg every 12 hours. The current steady-state blood cyclosporine concentration is 375 ng/mL (375 mcg/L; 312 nmol/L). To compute a cyclosporine dose that will provide a C_{ss} of 200 ng/mL (200 mcg/L; 166 nmol/L), linear pharmacokinetic equations can be used. The new dose to attain the desired concentration should be proportional to the old dose that produced the measured concentration (total daily dose = 400 mg/dose × 2 doses/d = 800 mg/d):

$$D_{new} = D_{old}\frac{C_{ss,new}}{C_{ss,old}} = 800\ \text{mg/day}\frac{200\ \text{ng/mL}}{375\ \text{ng/mL}}$$
$$= 427\ \text{mg/day, round to 400 mg/day}$$

The new suggested dose would be 400 mg/day or 200 mg every 12 hours of cyclosporine capsules to be started at the next scheduled dosing time.

CLINICAL PHARMACODYNAMICS

16 Pharmacodynamics is the study of the relationship between the concentration of a drug and the response obtained in a patient. Originally, investigators examined the dose–response relationship of drugs in humans but found that the same dose of a drug usually resulted in different concentrations in individuals because of pharmacokinetic differences in clearance and volume of distribution. Examples of quantifiable pharmacodynamic measurements include changes in blood pressure during antihypertensive drug therapy, decreases in heart rate during β-blocker treatment, and alterations in prothrombin time or international normalized ratio during warfarin therapy.

For drugs that exhibit a direct and reversible effect, the following diagram describes what occurs at

the level of the drug receptor:

$$\text{Drug} + \text{receptor} \leftrightarrow \text{drug} - \text{receptor complex} \leftrightarrow \text{response}$$

According to this scheme, there is a drug receptor located within the target organ or tissue. When a drug molecule "finds" the receptor, it forms a complex that causes the pharmacologic response to occur. The drug and receptor are in dynamic equilibrium with the drug–receptor complex.

The E_{max} and Sigmoid E_{max} Models

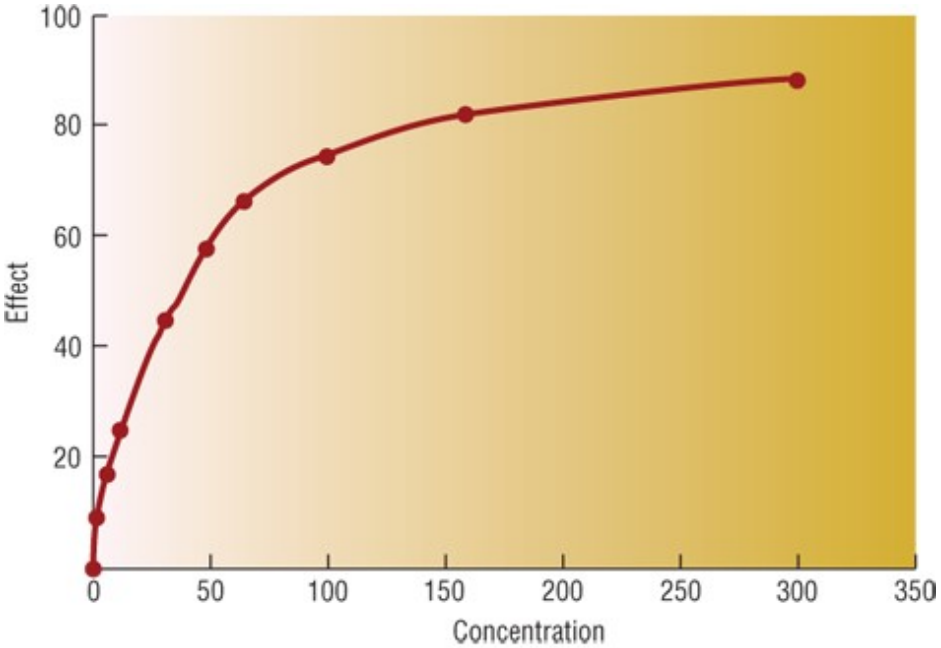
The mathematical model that comes from the classic drug receptor theory shown previously is known as the E_{max} model:

$$E = \frac{E_{max} \times C}{EC_{50} + C}$$

where E is the pharmacologic effect elicited by the drug, E_{max} is the maximum effect the drug can cause, EC_{50} is the concentration causing one-half the maximum drug effect ($E_{max}/2$), and C is the concentration of drug at the receptor site. EC_{50} can be used as a measure of drug potency (a lower EC_{50}, indicating a more potent drug), whereas E_{max} reflects the intrinsic efficacy of the drug (a higher E_{max}, indicating greater efficacy). If pharmacologic effect is plotted against concentration in the E_{max} equation, a hyperbola results with an asymptote equal to E_{max} (**Fig. e4-14**). At a concentration of zero, no measurable effect is present.

FIGURE e4-14

The E_{max} model [$E = (E_{max} \times C)/(EC_{50} + C)$] has the shape of a hyperbola with an asymptote equal to E_{max}. EC_{50} is the concentration where effect = $E_{max}/2$.



When dealing with human studies in which a drug is administered to a patient, and pharmacologic effect is measured, it is very difficult to determine the concentration of the drug at the receptor site. Because of this, serum concentrations (total or unbound) usually are used as the concentration parameter in the E_{max} equation. Therefore, the values of E_{max} and EC_{50} are much different than if the drug were added to an isolated tissue contained in a laboratory beaker.

The result is that a much more empirical approach is used to describe the relationship between concentration and effect in clinical pharmacology studies. After a pharmacodynamic experiment has been conducted, concentration–effect plots are generated. The shape of the concentration–effect curve is used to determine which pharmacodynamic model will be used to describe the data. Because of this, the pharmacodynamic models used in a clinical pharmacology study are deterministic in the same way that the shape of the serumconcentration-versus-time curve determines which pharmacokinetic model is used in clinical pharmacokinetic studies.

Sometimes a hyperbolic function does not describe the concentration–effect relationship at lower concentrations adequately.

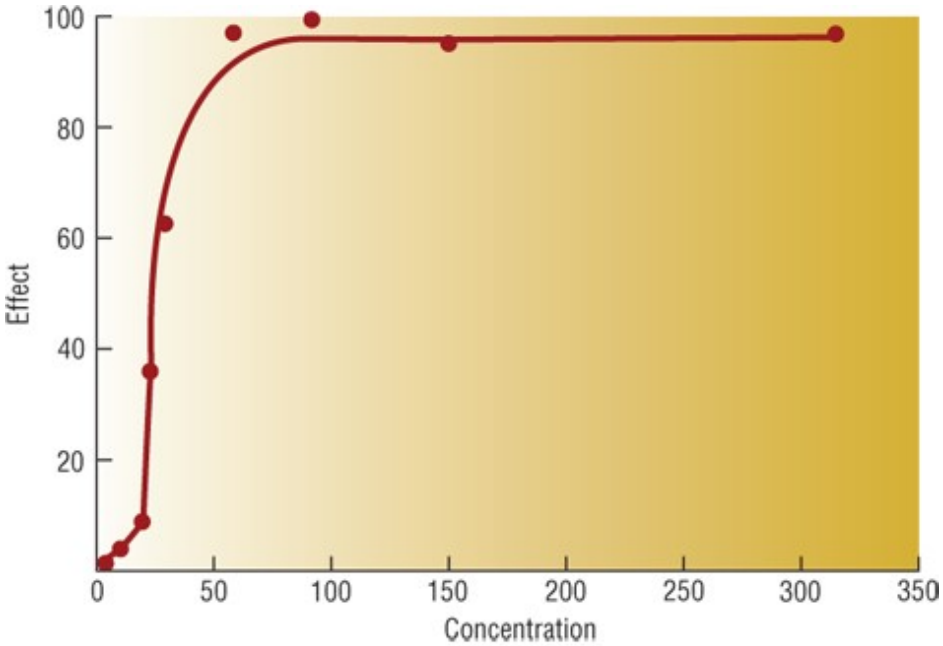
When this is the case, the sigmoid E_{max} equation may be superior to the E_{max} model:

$$E = \frac{E_{max} \times C^n}{EC_{50}^n + C^n}$$

where n is an exponent that changes the shape of the concentration–effect curve. When n greater than 1, the concentration–effect curve is S- or sigmoid-shaped at lower serum concentrations. When n less than 1, the concentration–effect curve has a steeper slope at lower concentrations (**Fig. e4-15**).

FIGURE e4-15

The sigmoid E_{max} model [$E = (E_{max} \times C^n)/(EC^n50 + C^n)$] has an S-shaped curve at lower concentrations. In this example, E_{max} and EC_{50} have the same values as in Figure e4-14.



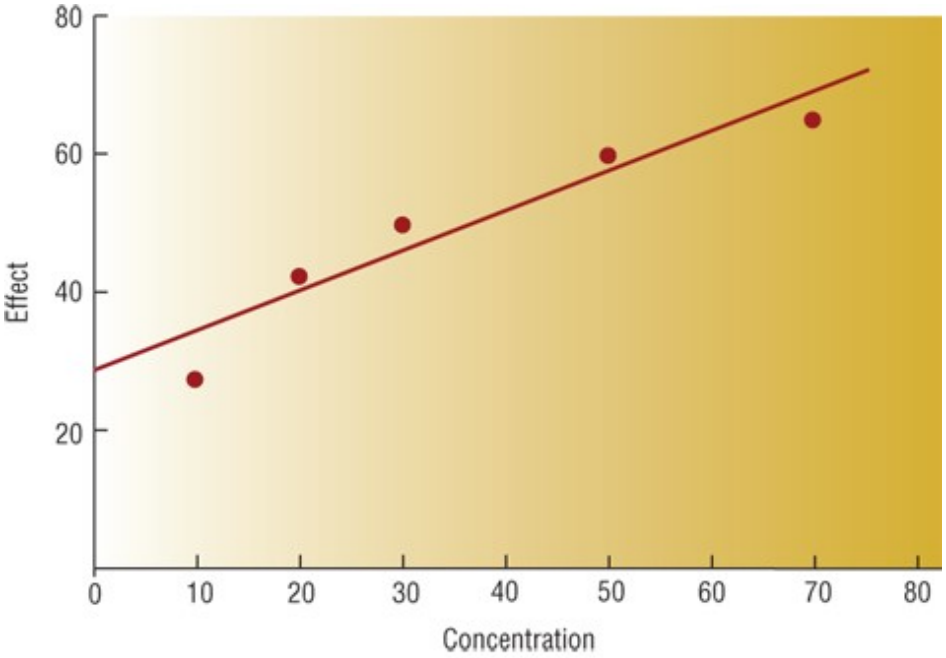
With both the E_{max} and sigmoid E_{max} models, the largest changes in drug effect occur at the lower end of the concentration scale. Small changes in low serum concentrations cause large changes in effect. As serum concentrations become larger, further increases in serum concentration result in smaller changes in effect. Using the E_{max} model as an example and setting E_{max} = 100 units and EC_{50} = 20 mg/L, doubling the serum concentration from 5 to 10 mg/L increases the effect from 20 to 33 units (a 67% increase), whereas doubling the serum concentration from 40 to 80 mg/L only increases the effect from 67 to 80 units (a 19% increase). This is an important concept for clinicians to remember when doses are being titrated in patients.

Linear Models

When serum concentrations obtained during a pharmacodynamic experiment are between 20% and 80% of E_{max}, the concentration–effect curve may appear to be linear (**Fig. e4-16**). This occurs often because lower drug concentrations may not be detectable with the analytic technique used to assay serum samples, and higher drug concentrations may be avoided to prevent toxic side effects. The equation used is that of a simple line: $E = S \times C + I$, where E is the drug effect, C is the drug concentration, S is the slope of the line, and I is the y intercept. In this situation, the value of S can be used as a measure of drug potency (the larger the value of S, the more potent the drug). The linear model can be derived from the E_{max} model. When EC_{50} is much greater than C, $E = (E_{max}/EC_{50})C = S \times C$, where $S = E_{max}/EC_{50}$.

FIGURE e4-16

The linear model ($E = S \times C + I$) is often used as a pharmacodynamic model when the measured pharmacologic effect is 20% to 80% of E_{max}. In this situation, the determination of E_{max} and EC_{50} is not possible. To illustrate this, effect measurements from Figure e4-14 between 20% and 80% of E_{max} are graphed using the linear pharmacodynamic model.



The linear model allows a nonzero value for effect when the concentration equals zero. This may be a baseline value for the effect that is present without the drug, the result of measurement error when determining effect, or model misspecification. Also, this model does not allow the prediction of a maximum response.

Some investigators have used a log-linear model in pharmacodynamic experiments: $E = S \times (\log C) + I$, where the symbols have the same meaning as in the linear model. The advantages of this model are that the concentration scale is compressed on concentration–effect plots for experiments where wide concentration ranges were used, and the concentration values are transformed so that linear regression can be used to compute model parameters. The disadvantages are that the model cannot predict a maximum effect or an effect when the concentration equals zero. With the increased availability of nonlinear regression programs that can compute the parameters of nonlinear functions such as the E_{max} model easily, use of the log-linear model has been discouraged.[60]

Baseline Effects

At times, the effect measured during a pharmacodynamic study has a value before the drug is administered to the patient. In these cases, the drug changes the patient's baseline value. Examples of these types of measurements are heart rate and blood pressure. In addition, a given drug may increase or decrease the baseline value. Two basic techniques are used to incorporate baseline values into pharmacodynamic data. One way incorporates the baseline value into the pharmacodynamic

model; the other transforms the effect data to take baseline values into account.

Incorporation of the baseline value into the pharmacodynamic model involves the addition of a new term to the previous equations. E_0 is the symbol used to denote the baseline value of the effect that will be measured. The form that these equations takes depends on whether the drug increases or decreases the pharmacodynamic effect. When the drug increases the baseline value, E_0 is added to the equations:

$$E = E_0 + \frac{E_{max} \times C}{EC_{50} + C}$$

$$E = E_0 + \frac{E_{max} \times C^n}{EC_{50}^n + C^n}$$

$$E = S \times C + E_0$$

When E_0 is not known with any better certainty than any other effect measurement, it should be estimated as a model parameter similar to the way that one would estimate the values of E_{max}, EC_{50}, S, or n.[61, 62] If the baseline effect is well known and has only a small amount of measurement error, it can be subtracted from the effect determined in the patient during the experiment and not estimated as a model parameter. This approach can lead to better estimates of the remaining model parameters.[62] Using the linear model as an example, the equation used would be $E - E_0 = S \times C$.

If the drug decreases the baseline value, the drug effect is subtracted from E_0 in the pharmacodynamic models:

$$E = E_0 - \frac{E_{max} \times C}{IC_{50} + C}$$

$$E = E_0 - \frac{E_{max} \times C^n}{IC_{50}^n + C^n}$$

$$E = E_0 - S \times C$$

where E_{max} represents the maximum reduction in effect caused by the drug, and IC_{50} is the concentration that produces a 50% inhibition of E_{max}. These forms of the equations have been called the *inhibitory* E_{max} and *inhibitory sigmoidal* respectively. In this arrangement of the pharmacodynamic model, E_0 is a model parameter and can be estimated. If the baseline effect is well known and has little measurement error, the effect in the presence of the drug can be subtracted from the baseline effect and not estimated as a model parameter. Using the inhibitory E_{max} model as an example, the formula would be $E_0 - E = (E_{max} \times C)/(IC_{50} + C)$.

When using the inhibitory E_{max} model, a special situation occurs if the baseline effect can be obliterated completely by the drug (eg, decreased premature ventricular contractions during antiarrhythmic therapy). In this situation, $E_{max} = E_0$, and the equation simplifies to a rearrangement known as the *fractional* E_{max} equation:

$$E = E_0\left(1 - \frac{C}{IC_{50} + C}\right)$$

This form of the model relates drug concentration to the fraction of the maximum effect.

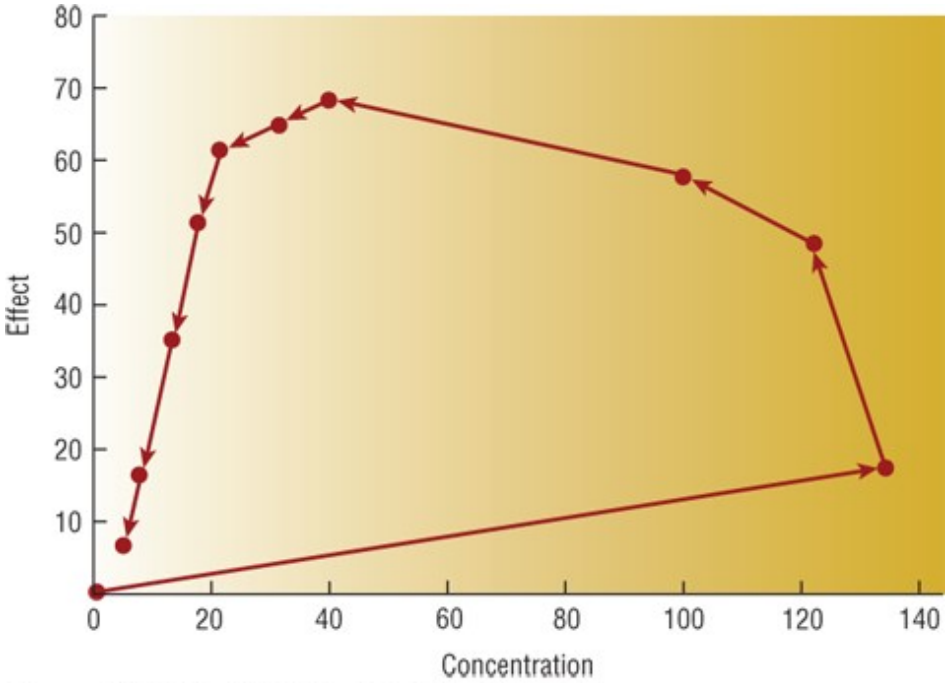
An alternative approach to the pharmacodynamic modeling of drugs that alter baseline effects is to transform the effect data so that they represent a percentage increase or decrease from the baseline value.[62] For drugs that increase the effect, the following transformation equation would be used: percent effect$_t$ = [(treatment$_t$ –baseline)/baseline] × 100. For drugs that decrease the effect, the following formula would be applied to the data: percent inhibition$_t$ = [(baseline – treatment$_t$)/baseline] × 100. The subscript indicates the treatment, effect, or inhibition that occurred at time *t* during the experiment. If the study included a placebo control phase, baseline measurements made at the same time as treatment measurements (heart rate determined 2 hours after placebo and 2 hours after drug treatment) could be used in the appropriate transformation equation.[62] The appropriate model (excluding E_0) then would be used.

Hysteresis

Concentration–effect curves do not always follow the same pattern when serum concentrations increase as they do when serum concentrations decrease. In this situation, the concentration–effect curves form a loop that is known as *hysteresis*. With some drugs, the effect is greater when serum concentrations are increasing, whereas with other drugs, the effect is greater while serum concentrations are decreasing (**Fig. e4-17**). When individual concentration–effect pairs are joined in time sequence, this results in clockwise and counterclockwise hysteresis loops.

FIGURE e4-17

Hysteresis occurs when effect measurements are different at the same concentration. This is commonly seen after short-term IV infusions or extravascular doses where concentrations increase and subsequently decrease. Counterclockwise hysteresis loops are found when concentration–effect points are joined as time increases (*shown by arrows*) and effect is larger at the same concentration but at a later time. Clockwise hysteresis loops are similar, but the concentration–effect points are joined in clockwise order, and the effect is smaller at a later time.



Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

Clockwise hysteresis loops usually are caused by the development of tolerance to the drug. In this situation, the longer the patient is exposed to the drug, the smaller is the pharmacologic effect for a given concentration. Therefore, after an extravascular or short-term infusion dose of the drug, the effect is smaller when serum concentrations are decreasing compared with the time when serum concentrations are increasing during the infusion or absorption phase.

Accumulation of a drug metabolite that acts as an antagonist also can cause clockwise hysteresis.

Counterclockwise hysteresis loops can be caused by the accumulation of an active metabolite, sensitization to the drug, or delay in time in equilibration between serum concentration and concentration of drug at the site of action. Combined pharmacokinetic/pharmacodynamic models have been devised that allow equilibration lag times to be taken into account.

SUMMARY

The availability of inexpensive, rapidly achievable serum drug concentrations has changed the way clinicians monitor drug therapy in patients. The therapeutic range for many drugs is known, and it is likely that more drugs will be monitored using serum concentrations in the future. Clinicians need to remember that the therapeutic range is merely an average guideline and to take into account interindividual pharmacodynamic variability when treating patients. Individual patients may respond to smaller concentrations or require concentrations that are much greater to obtain a therapeutic effect. Conversely, patients may show toxic effects at concentrations within or below the therapeutic range. Serum concentrations should never replace clinical judgment.

Three kinetic constants determine the dosage requirements of patients. Clearance determines the

maintenance dose (MD = CLC_{ss}), volume of distribution determines the loading dose (LD = $V_D C_{ss}$), and half-life determines the time to steady state and the dosage interval. Several methods are available to compute these parameters.

Methods available to individualize drug therapy range from clinical pharmacokinetic techniques using simple mathematical relationships that hold for all drugs that obey linear pharmacokinetics to very complex computer programs that are specific to one drug.

Chapter e5: Pharmacogenetics

Larisa H. Cavallari; Y. W. Francis Lam

PHARMACOGENETICS: INTRODUCTION

KEY CONCEPTS

- 1 Genetic variation contributes to pharmacokinetic and pharmacodynamic drug properties.
- 2 Genetic variation occurs for drug metabolism, drug transporter, and drug target proteins, as well as disease-associated proteins.
- 3 Single-nucleotide polymorphisms are the most common gene variations associated with drug response.
- 4 Genetic polymorphisms may influence drug effectiveness and risk for toxicity.
- 5 Pharmacogenetics is the study of the impact of genetic polymorphisms on drug response.
- 6 The goals of pharmacogenetics are to optimize drug efficacy and limit drug toxicity based on an individual's DNA.
- 7 Gene therapy aims to cure disease caused by genetic defects by changing gene expression.
- 8 Inadequate gene delivery and expression and serious adverse effects are obstacles to successful gene therapy.

Great variability exists among individuals in response to drug therapy, and it is difficult to predict how effective or safe a medication will be for a particular patient. For example, when treating a patient with hypertension, it may be necessary to try several agents or a combination of agents before achieving adequate blood pressure control with acceptable tolerability. A number of clinical factors are known to influence drug response, including age, body size, renal and hepatic function, and concomitant drug use. However, considering these factors alone is often insufficient in predicting the likelihood of drug efficacy or safety for a given patient. For example, identical antihypertensive therapy in two patients of similar age, sex, race, and with similar medical histories and concomitant drug therapy may produce inadequate blood pressure reduction in one patient and symptomatic

hypotension in the other.

[1][2] The observed interpatient variability in drug response may result largely from genetically determined differences in drug metabolism, drug distribution, and drug target proteins. The influence of heredity on drug response was demonstrated as early as 1956 with the discovery that an inherited deficiency of glucose-6-phosphate dehydrogenase (G6PD) was responsible for hemolytic reactions to the antimalarial drug primaquine. Variations in genes encoding cytochrome P450 (CYP) and other drug-metabolizing enzymes are now well recognized as causes of interindividual differences in plasma concentrations of certain drugs. These variations may have serious implications for narrow-therapeutic-index drugs such as warfarin, phenytoin, and mercaptopurine. Other variations associated with drug response occur in genes for drug transporters such as the solute carrier organic anion transporter (OAT) family member 1B1 (SLCO1B1) and organic cation transporter 1 (OCT1), as well as drug targets such as receptors, enzymes, and proteins involved in intracellular signal transduction. Genetic variations for drug-metabolizing enzymes and drug transporter proteins may influence drug disposition, thus altering pharmacokinetic drug properties. Drug target genes may alter pharmacodynamic mechanisms by affecting sensitivity to a drug at its target site. Finally, genes associated with disease severity have been correlated with drug efficacy despite having no direct effect on pharmacokinetic or pharmacodynamic mechanisms.

PHARMACOGENETICS: A DEFINITION

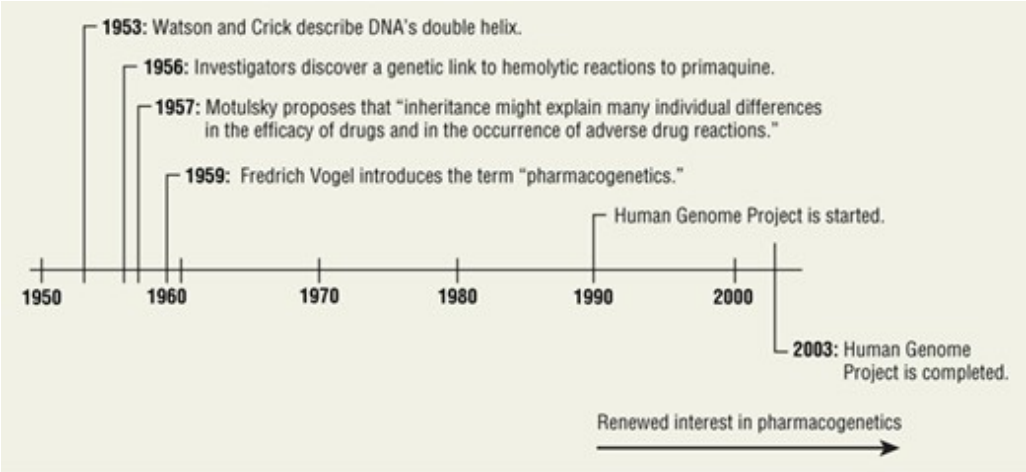
[3][4] Pharmacogenetics involves the search for genetic variations that lead to interindividual differences in drug response. The term *pharmacogenetics* often is used interchangeably with the term *pharmacogenomics*. However, pharmacogenetics generally refers to monogenetic variants that affect drug response, whereas pharmacogenomics refers to the entire spectrum of genes that interact to determine drug efficacy and safety. For example, a pharmacogenetic study would be one that examines the influence of the *CYP2C9* gene on warfarin dose requirements. A pharmacogenomic study might examine the interaction between the *CYP2C9*, vitamin K oxido reductase complex subunit 1 (*VKORC1*), and *CYP4F2* genes on warfarin dose requirements. Given that multiple proteins are involved in determining the ultimate response to most drugs, many investigators are taking a more pharmacogenomic approach to elucidating genetic contributions to drug response. For simplicity, this chapter treats pharmacogenetics and pharmacogenomics as synonymous.

[5] The goals of pharmacogenetics are to optimize drug therapy and limit drug toxicity based on an individual's genetic profile. Thus, pharmacogenetics aims to use genetic information to choose a drug, drug dose, and treatment duration that will have the greatest likelihood for achieving therapeutic outcomes with the least potential for harm in a given patient. Pharmacogenetic discoveries have provided opportunities for clinicians to use genetic tests to predict individual responses to drug treatments and specifically select medications for patients based on DNA profiles. Genotype-guided therapy is already a reality for some diseases, such as cancer and cystic fibrosis, where novel drugs have been developed to target specific mutations. Clinical implementation of pharmacogenetics is beginning to emerge in other therapeutic areas, such as cardiology, neurology, pain management, and infectious disease.

Although there has been considerable interest in genetic influences of drug response over the past decade, pharmacogenetics is not a new area. As shown in **Fig. e5-1**, in 1957, shortly after the discovery of a genetic predisposition toward primaquine-induced toxicity, Arno Motulsky proposed that inheritance might underlie much of the disparity among individuals in drug response.[1,2] Friedrich Vogel introduced the term *pharmacogenetics* 2 years later.[1] With the advent of the Human Genome Project in 1990 came a resurgence of interest in determining genetic contributions to drug response.

FIGURE e5-1

Timeline of genomic discoveries.



HUMAN GENOME PROJECT AND SUBSEQUENT EFFORTS IN PERSONALIZED MEDICINE

In 1988, the US Congress commissioned the Department of Energy and the National Institutes of Health to plan and implement the Human Genome Project with the goal of sequencing the entire human genome by 2005. The mapping of the human genome officially began in 1990. In April 2003, 50 years after James Watson and Francis Crick described the double-helix structure of DNA and more than 2 years ahead of schedule, researchers announced the completion of the Human Genome Project.[3] The final version contains 99% of the gene-containing sequence, with 99.9% accuracy.

To encourage research and ultimately maximize the societal benefits of the Human Genome Project, sequence data from the project were deposited into a freely accessible database run by the National Center for Biotechnology Information (*www.ncbi.nlm.nih.gov*).

The International HapMap Project followed the Human Genome Project and aimed to create a publicly accessible database of common patterns of heritability in the human genome (*www.hapmap.org*). The HapMap Project allows pharmacogenomic studies to extend beyond a candidate gene focus. Subsequent genome-wide association studies have led to discoveries of previously unsuspected genes linked to drug response, including the ataxia-telangiectasia mutated

(*ATM*) gene linked to metformin response in diabetes.[4] The 1,000 Genomes project followed the HapMap Project and led to the development of a comprehensive catalog of less common genetic variation through a DNA sequencing approach (www.1000genomes.org). The ENCyclopedia of DNA Elements (ENCODE) Project is developing a complementary catalogue of functional elements in the human genome.

In 2010, leaders of the National Institutes of Health (NIH) and US Food and Drug Administration (FDA) announced their shared vision of personalized medicine and outlined the scientific and regulatory structure necessary to address the challenges in advancing personalized medicine.[5] These challenges involve the accurate, unbiased determination of genetic variants linked to drug response, advanced technology to efficiently determine genotype, discovery of novel genetic targets for therapeutic intervention, appropriate integration of genetic testing into the therapeutic decision process, and coordinated approval of drug therapy and companion diagnostics. The Pharmacogenomics Research Network (PGRN) was a major NIH-funded effort to advance personalized medicine. The PGRN consisted of multiple research groups across the country with complementary expertise and led to a number of important pharmacogenetic discoveries across multiple therapeutic areas.[6] More recently, the NIH funded the Implementing Genomics in Practice (IGNITE) Network, with the goal of enhancing the use of genomic medicine in clinical care.

GENETIC CONCEPTS

The human genome contains more than 3 billion nucleotide base pairs, which code for approximately 20,000 protein-coding genes. Two purine nucleotide bases, adenine (A) and guanine (G), and two pyrimidine nucleotide bases, cytosine (C) and thymidine (T), are present in DNA, with purines and pyrimidines always pairing together as A-T and C-G in the two strands that make up the DNA double-helix. Most nucleotide base pairs are identical from person to person, with only 0.1% contributing to individual differences.

According to the central dogma, when one strand of DNA is transcribed into RNA and translated to make proteins, three consecutive nucleotides form a codon. Each codon specifies an amino acid or amino acid chain termination. For example, the nucleotide sequence, or codon, GGA specifies the amino acid glycine. The genetic code has substantial redundancy, in that two or more codons code for the same amino acid. For example, GGC, GGG, and GGT also code for glycine. Amino acids are the basic constituents of proteins, which mediate all cellular functions. Only 20 different amino acids, in various arrangements, form the basic units of all the proteins in the human body.

A gene is a series of codons that specifies a particular protein. Genes contain several regions: *exons* that encode for the final protein, *introns* that consist of intervening noncoding regions, and *regulatory regions* that control gene transcription. Introns may also contain regulatory sequences. In most cases, an individual carries two alleles, one from each parent, at each gene locus. An *allele* is defined as the sequence of nucleic acid bases at a given gene chromosomal locus. Two identical alleles make up a *homozygous* genotype, and two different alleles make up a *heterozygous* genotype. A *phenotype* refers to the outward expression of the genotype.

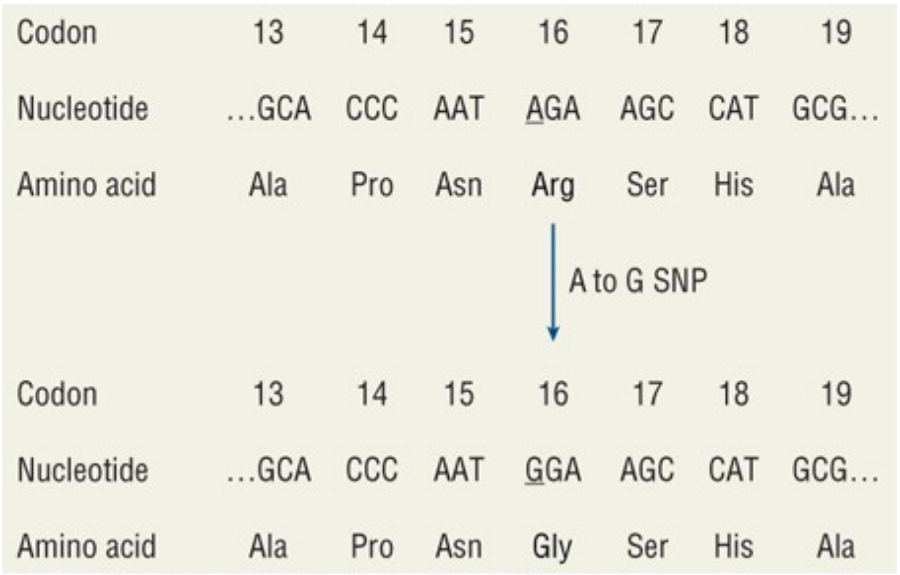
TYPES OF GENETIC VARIATIONS

Genetic variations occur as either rare defects or polymorphisms. *Polymorphisms* are defined as variations in the genome that occur at a frequency of at least 1% in the human population. For example, the genes encoding the CYP enzymes 2A6, 2C9, 2C19, 2D6, and 3A4 are polymorphic, with functional gene variants of greater than 1% occurring in different racial groups. In contrast, rare mutations occur in less than 1% of the population and cause inherited diseases such as cystic fibrosis, hemophilia, and Huntington's disease. Common diseases, such as essential hypertension and diabetes mellitus, are polygenic in that multiple genetic polymorphisms in conjunction with environmental factors contribute to the disease susceptibility.

6 Single-nucleotide polymorphisms, abbreviated as SNPs and pronounced "snips," are the most common genetic variations in human DNA, occurring once approximately every 300 base pairs. More than 20 million SNPs have been mapped thus far in the human genome. SNPs occur when one nucleotide base pair replaces another, as illustrated in **Fig. e5-2**. Thus, SNPs are single-base differences that exist between individuals. Nucleotide substitution results in two possible alleles. One allele, typically either the most commonly occurring allele or the allele originally sequenced, is considered the *wild type,* and the alternative allele is considered the *variant allele*.

FIGURE e5-2

Nucleotide sequence of the β_2-adrenergic receptor gene from codons 13 through 19. (A) Nucleotide sequence of the wild-type allele with adenine (A) at nucleotide position 46 (*underlined*) located in codon 16 of the β_2-adrenergic receptor gene. Arginine (Arg), with an average. The AGA codon designates the amino acid frequency of 39% in the human population. (B) Nucleotide sequence of the variant allele with guanine (G) at nucleotide position 46 (*underlined*), located in codon 16. The GGA codon designates the amino acid glycine (Gly), which occurs at an average frequency of 61%. Although the Arg16 polymorphism occurs less commonly than the Gly16 polymorphism, it is referred to as the wild type because it was identified first.



A SNP may result in amino acid substitution, which may or may not alter the function of the encoded protein. For example, in Fig. e5-2, guanine (G) is substituted for adenine (A) at nucleotide 46 in the β_2-adrenergic receptor gene. This results in the substitution of glycine for arginine at amino acid position (codon) 16 and alterations in receptor downregulation on prolonged exposure to β_2-receptor agonists.[7] SNPs such as this that result in amino acid substitution are referred to as *nonsynonymous*. SNPs that do not result in amino acid substitution are called *synonymous*, which in many cases are silent. Referring to a previous example of redundancy in the genetic code, replacement of adenine (A) with cytosine (C) in the codon GGA is an example of a synonymous SNP because both GGA and GGC code for glycine. Synonymous SNPs and variants occurring in regulatory regions of the gene are usually abbreviated based on the nucleotides involved and the nucleotide base position. For example, 1166A > C indicates that either adenine or cytosine may occur, with adenine occurring most often at position 1166 of a given gene region. Nonsynonymous SNPs usually are designated by the amino acids and codon involved. For example, Arg16Gly (or R16G using amino acid symbols) indicates that glycine may be substituted for arginine at codon 16. Alternatively, SNPs may be referred to by their reference SNP number (or rs number), as designated by the National Center for Biotechnology Information SNP database (dbSNP; *http://www.ncbi.nlm.nih.gov/sites/entrez?db=Snp*). If a SNP changes the amount or function of a protein that contributes to drug response, it may alter kinetic properties or a patient's sensitivity to a drug or predispose a patient to adverse reactions to drug therapy.

Other examples of genetic variants include:

1. *Insertion-deletion polymorphisms,* in which a nucleotide or nucleotide sequence is either added to or deleted from a DNA sequence.

2. *Tandem repeats,* in which a nucleotide sequence repeats in tandem (eg, if "AG" is the nucleotide repeat unit, "AGAGAGAGAG" is a five-tandem repeat).

3. *Frameshift mutation*, in which there is an insertion/deletion polymorphism, and the number of nucleotides added or lost is not a multiple of 3, resulting in disruption of the gene's reading frame.

4. *Defective splicing,* in which an internal polypeptide segment is abnormally removed, and the ends of the remaining polypeptide chain are joined.

5. *Aberrant splice site,* in which processing of the protein occurs at an alternate site.

6. *Premature stop codon polymorphisms,* in which there is premature termination of the polypeptide chain by a stop codon (specific sequence of three nucleotides that do not code for an amino acid but rather specify polypeptide chain termination).

7. *Copy number variants*, in which entire copies of genes or gene segments more than 1 kb in size are duplicated, deleted, or rearranged.

Single-nucleotide polymorphisms may occur in exon, intron, or regulatory regions of a gene. Those occurring in exons may alter protein function, whereas those in regulatory regions may alter gene expression and the amount of protein that is produced. Variations in the intron region may be silent unless they affect intron splicing or otherwise alter gene expression. Multiple SNPs may be in *linkage disequilibrium* with each other. This means that two or more SNPs are inherited together more frequently than would be expected based on chance alone. For example, if there are two possible SNPs, 46C > T and 72A > G, in a given gene, and a T at position 46 always occurs with a G at position 72 and vice versa, the two SNPs are said to be in *complete linkage disequilibrium*. A set of SNPs that are inherited together is called a *haplotype*.

POLYMORPHISMS IN GENES FOR DRUG-METABOLIZING ENZYMES

3 Polymorphisms in the drug-metabolizing enzymes represent the first recognized and, so far, the most documented examples of genetic variants with consequences in drug response and toxicity. The major phase I enzymes are the CYP superfamily of isoenzymes. *N*-acetyltransferase, uridine diphosphate glucuronosyltransferase (UGT), and glutathione *S*-transferase are examples of phase II metabolizing enzymes that exhibit genetic polymorphisms. Thiopurine *S*-methyltransferase (TPMT) and dihydropyrimidine dehydrogenase (DPD) are examples of nucleotide base-metabolizing enzymes. **Table e5-1** lists examples of polymorphic metabolizing enzymes and corresponding drug substrates whose plasma concentrations and pharmacologic effects may be altered as a consequence of genetic variation. Examples of such effects are discussed in the following sections.

TABLE e5-1 Examples of Substrates for Drug-Metabolizing Enzymes Exhibiting Genetic Variability

Enzyme	Drug Substrate
CYP2D6	Analgesics (codeine, tramadol) Antiarrhythmics (propafenone, flecainide) Atomoxetine

Enzyme	Drug Substrate
CYP2C9	Antipsychotics (haloperidol, perphenazine, thioridazine)
	β-blockers (metoprolol, carvedilol)
	Perhexiline
	Selective serotonin reuptake inhibitors (fluoxetine, paroxetine, sertraline)
	Tamoxifen
	Tricyclic antidepressants (desipramine, nortriptyline, amitriptyline, imipramine)
	Antidiabetic agents (tolbutamide, glimepiride, glipizide, glyburide, nateglinide)
	Warfarin
	Phenytoin
	Celecoxib
	Nonsteroidal antiinflammatory drugs (diclofenac, flurbiprofen, ibuprofen, indomethacin, naproxen, piroxicam)
CYP2C19	Antidepressants (citalopram, escitalopram)
	Clopidogrel
	Cyclophosphamide
	Diazepam
	Proton pump inhibitors (lansoprazole, omeprazole, pantoprazole)
	Voriconazole
CYP2B6	Cyclophosphamide
	Ifosfamide
	Efavirenz
Glutathione *S*-transferase	Cisplatin
	Primaquine
Thiopurine *S*-methyltransferase	Azathioprine
	Mercaptopurine
N-acetyltransferase	Isoniazid
	Procainamide
	Hydralazine
Uridine diphosphate glucuronosyltransferase	Sulfonamides
	Irinotecan

Cytochrome P450 Enzymes

Currently, 57 different CYP isoenzymes have been documented to be present in humans, with 42 involved in the metabolism of exogenous xenobiotics and endogenous substances such as steroids and prostaglandins.[8] Fifteen of these isoenzymes are known to be involved in the metabolism of drugs, but significant interindividual variabilities in enzyme activity exist as a result of induction, inhibition, and genetic inheritance. Functional genetic polymorphism has been discovered for *CYP2A6*, *CYP2B6*, *CYP2C9*, *CYP2C19*, *CYP2D6*, and *CYP3A4/5*, and their impacts on drug therapy are described hereunder.

CYP2D6

Polymorphisms in the *CYP2D6* gene are the best characterized among all of the *CYP* variants. Over the years, at least 100 gene variants and 120 alleles have been identified in the *CYP2D6* gene (*www.cypalleles.ki.secyp2d6.htm*). Despite the extensive number of alleles, Sistonen et al.[9] showed genotyping 12 SNPs that represent 20 different haplotypes could provide 90% to 95% accuracy in predicting the real phenotype (outward expression of genotypes). More specifically, different studies showed that the CYP2D6 phenotypes of extensive metabolizer (EM) carrying two functional alleles and poor metabolizer (PM) carrying two nonfunctional alleles could be predicted with up to 99% confidence with six genotypic variants. *CYP2D6*1* is considered the wild-type variant and exhibits normal enzyme activity. *CYP2D6*2* has the same activity as *CYP2D6*1* but is capable of duplication or amplification. Both these variants are present in EMs. The two null variants, *CYP2D6*4* (c.1846G>A, defective splicing) and *CYP2D6*5* (gene deletion), are predominantly found in white PMs (5%-10% of population) and result in an inactive enzyme and absence of enzyme, respectively. The predominant variants in people of Asian and African heritage are *CYP2D6*10* (c.100C>T, Pro34Ser) and *CYP2D6*17* (c.1023C>T, Arg296Cys), respectively, both resulting in single-amino-acid substitution and consequent reduction in enzyme activity. Other than **10* and **17*, **9, *29, *36,* and **41* variants are also associated with lower enzyme activity in the intermediate metabolizers (IMs) phenotype (carriers of one nonfunctional allele and one allele with diminished activity).[10] In addition to **2*, gene duplication or amplification had been documented for **1, *4, *6, *10, *17, *29, *35, *41, *43,* and **45* variants,[10,11] with resultant higher enzyme activity in the ultrarapid metabolizer (UM) phenotype (carriers of multiple copies of functional alleles).

The presence of two defective alleles (*CYP2D6*3, CYP2D6*4* [more common], *CYP2D6*5,* or *CYP2D6*6*) in PM results in significant impaired ability to metabolize CYP2D6-dependent substrates. Depending on the importance of the affected CYP2D6 pathway to overall drug metabolism and the drug's therapeutic index, clinically significant side effects may occur in PMs as a result of elevated drug concentrations,[12] for example, of atomoxetine (insomnia),[13] perhexiline (neuropathy), perphenazine (sedation and parkinsonism), and propafenone (proarrhythmic events).

The therapeutic implication of *CYP2D6* polymorphism is different if the substrate in question is a prodrug. In this case, PMs would not be able to convert the drug into the therapeutically active metabolite. Two examples of prodrugs dependent on CYP2D6-mediated conversion to active forms are codeine and tramadol. Codeine and tramadol are converted by CYP2D6 to morphine and *O*-desmethyltramadol, respectively, and CYP2D6 PMs would experience little analgesic relief after taking these drugs.[14,15] Another example is CYP2D6-catalyzed conversion of tamoxifen to the more

potent antiestrogen metabolite, endoxifen, in which case PMs have been shown to have shortened time to recurrence of breast cancer and worse relapse-free survival.[16]

Patients who are EMs have a wide range of CYP2D6 activity, with UMs possessing very high enzyme activity on one end of the spectrum and IMs possessing diminished activity on the other end. Both have clinical implications in terms of dosage adjustment for CYP2D6 substrates. For the CYP2D6 substrate nortriptyline, a patient with three copies of *CYP2D6*2* was shown to require doses threefold to fivefold higher than normally recommended to achieve therapeutic plasma concentrations (50-150 ng/mL [mcg/L; 190-570 nmol/L]).[17,18] In the same report, another patient with duplicated *CYP2D6*2* required twice the usual recommended daily dose (300 mg vs 25-150 mg) to achieve adequate therapeutic response.[18] There are similar reports of lower drug efficacy in UMs with antiemetics such as ondansetron.[19] Conversely, UMs administered the usual therapeutic dose of codeine or tramadol might exhibit symptoms of narcotic overdose associated with high morphine concentration. This toxicity potential had been reported in several case reports.[14,20] The FDA has issued warnings regarding the use of codeine or tramadol to manage pain after tonsillectomy in children because of the increased risk for respiratory depression in UMs.

Furthermore, the consequence of CYP2D6-mediated drug interactions can be different in patients with different metabolic phenotypes. The UM phenotype has been reported to affect the potential for drug interaction with paroxetine, a potent CYP2D6 inhibitor as well as a CYP2D6 substrate, whence a UM with three functional *CYP2D6* gene copies had undetectable paroxetine concentration with standard dosing and showed no inhibitory effect at CYP2D6.[21]

In general, the magnitude of drug interactions involving inhibition of CYP2D6 is much greater in EMs versus PMs, who have either little or no enzyme activity. For example, Hamelin et al.[22] showed that in EMs, but not PMs, hemodynamic responses to metoprolol (a CYP2D6 substrate) were pronounced and prolonged during concomitant diphenhydramine administration. Potent CYP2D6 inhibitors, such as paroxetine and fluoxetine, may reduce the metabolic capacity of EMs significantly so that they appear phenotypically as PMs.[23] Given the abundance and greater antiestrogenic activity of endoxifen,[16] the use of paroxetine or fluoxetine in tamoxifen-treated patients should best be avoided. When there is a need for concurrent antidepressant administration with tamoxifen, those with lesser extent of CYP2D6 inhibition, such as citalopram and venlafaxine,[23] would be better alternatives.

The high prevalence of *CYP2D6*10* (associated with lower enzyme activity) in the Asian population provides a biologic and molecular explanation for the higher drug concentrations and/or lower dosage requirements of neuroleptic medications and mianserin in people of Asian heritage.[24,25] The widespread presence of the *CYP2D6*17* variant among people of African heritage suggests that native African populations would metabolize CYP2D6 substrates at a slower rate than do other ethnic groups.[26,27] However, there are no genotype- and phenotype-based data to document the need for prescribing lower doses of psychotropics and other CYP2D6 substrates in native African populations.

In addition to the therapeutic implications of genetic polymorphisms, one study showed that the *CYP2D6* polymorphism also has an economic impact on the treatment of psychiatric inpatients.[28] The

annual cost of treating UMs and PMs was $4,000 to $6,000 higher than the cost of treating EMs or IMs. The cost of genotyping can be considerably less than that incurred in a patient with a serious adverse drug reaction. In 2005, the FDA approved the AmpliChip® CYP450 Test (Roche Diagnostics) for analyzing 27 *CYP2D6* alleles in addition to the *CYP2C19*1, *2,* and **3* alleles (discussed hereunder) to assist clinicians in individualizing therapy with drugs metabolized through the CYP2D6 and 2C19 pathways.

Clinical Controversy…

The CYP2D6 poor metabolizer phenotype has been associated with poor outcomes with tamoxifen in postmenopausal women with breast cancer. However, a group of investigators genotyped tumor tissue from tamoxifen-treated women with breast cancer who were enrolled in a large clinical trial and found no relationship between *CYP2D6* genotype and tamoxifen treatment response. More recently, several other well-known pharmacogenomics investigators called these findings into question, citing significant problems with distribution of the genotype frequencies.[29] Thus, the role of *CYP2D6* genotyping to predict tamoxifen response has yet to be resolved.

Clinical Controversy…

One of the obstacles facing the discipline is the need for cost-effectiveness data with genotype-guided therapies. Such data are important to convince third party payers to cover the cost of genetic testing to predict drug response. There are limited number of examples of cost effectiveness studies to date, which are described in this chapter. These include studies with pharmacogenomic dosing of proton pump inhibitors in patients with *H. pylori* and prediction of risk for severe cutaneous reactions to carbamazepine therapy. Ultimately, cost-effectiveness data may be the key to help move the field forward and increase uptake of pharmacogenomics in clinical practice.

CYP2C19

The principal defective alleles for the *CYP2C19* genetic polymorphism are *CYP2C19*2* (c.19154G > A, aberrant splice site) in exon 5 and *CYP2C19*3* (c.17948G > A, premature stop codon) in exon 2 of *CYP2C19*, resulting in inactive enzyme and the PM phenotype. The clinical relevance of the *CYP2C19* polymorphism has been demonstrated for proton pump inhibitors and clopidogrel.

Poor metabolizer for the *CYP2C19* polymorphism showed up to a 10-fold increase in the area under the curve (AUC) of omeprazole compared with EMs.[30] The presence of a defective *CYP2C19* allele has been associated with improved *Helicobacter pylori* cure rates after dual (omeprazole and amoxicillin)[31] and triple (omeprazole or lansoprazole, clarithromycin, and amoxicillin) therapy.[32] The cure rate achieved with dual therapy was 100% in PMs compared with 60% and 29% in heterozygous and homozygous EMs, respectively.[31] In two studies included in the meta-analysis of 20 studies using triple therapy,[32] EMs had *H. pylori* eradication rates of 74% to 83% versus 100% cure rates in all 15 PMs included in the two studies.

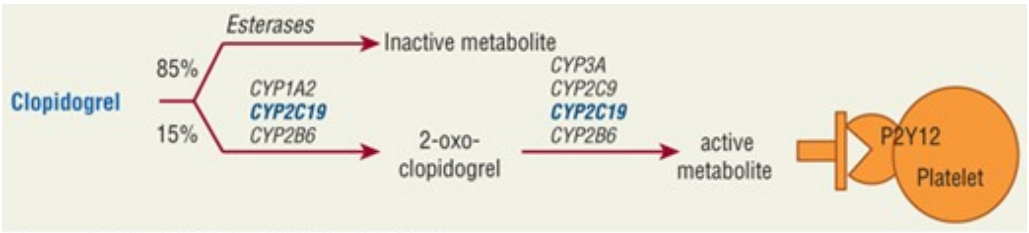
These differences likely reflect the higher achievable intragastric pH in the PM group.[30] Interestingly, EMs who failed initial triple therapy (lansoprazole, clarithromycin, and amoxicillin) and were retreated

with high-dose lansoprazole (30 mg four times daily) and amoxicillin achieved a 97% *H. pylori* eradication.[30] A gene–dose effect in attainment of desirable intragastric pH ranges and *H. pylori* eradication rate, as well as the cost effectiveness of pharmacogenomic-guided dosing was shown for lansoprazole.[30,33]

Conversely, IMs and PMs of *CYP2C19* may have reduced response to the antiplatelet agent clopidogrel. This is because clopidogrel is a prodrug that requires conversion via CYP2C19 to its active form, as shown in **Fig. e5-3**. In IMs and PMs, clopidogrel may be less effective at inhibiting platelet aggregation and preventing cardiovascular events than in EMs.[34] The data are strongest for patients who suffer an acute coronary syndrome and undergo percutaneous coronary intervention. In these patients, current CPIC guidelines recommend alternative therapy with prasugrel or ticagrelor for IMs and PMs in the absence of contraindications.[34] There is a FDA-cleared genotyping device for detecting the *CYP2C19*2* and **3* alleles with a turnaround time of approximately 1 hour,[35] which could facilitate use of *CYP2C19* genotyping in accordance to consensus-based guidelines.[34]

FIGURE e5-3

Clopidogrel bioactivation pathway. Approximately 85% of the drug is inactivated by esterases, and the remaining 15% is bioactivated to the active thiol metabolite that inhibits platelet activation via a 2-step process. Cytochrome P450 (CYP) 2C19 is involved in both steps of the process.



Similar to the *CYP2D6* polymorphism, people of Asian heritage also metabolize most *CYP2C19* substrates at a slower rate than do whites.[36] This is a reflection of a higher prevalence of both PMs (13%-22.5% vs 2%-6% in whites) and heterozygotes for the defective *CYP2C19* alleles (10%-30%) in Asians. This genotypic difference may explain the practice of prescribing lower diazepam dosages for patients of Chinese heritage.[37] Similar to *CYP2D6* alleles with high enzyme activity, the allelic variant *CYP2C19*17* is associated with a very rapid metabolism phenotype, and carriers of this allelic variant would likely require higher doses of proton pump inhibitors[38,39] and other *CYP2C19* substrates such as voriconazole.[40]

CYP2C9

Another polymorphic isoenzyme of CYP2C is CYP2C9, which metabolizes narrow therapeutic index drugs such as warfarin, phenytoin, and tolbutamide. Warfarin is a racemic mixture, and the more potent *S*-isomer is metabolized by CYP2C9. *CYP2C9*2* (p.Arg144Cys) and *CYP2C9*3* (p. Ile359Leu) are

the two most common *CYP2C9* variants in whites, and both exhibit single-amino-acid substitutions at positions critical for enzyme activity.[41] This could have clinically important consequences in warfarin-treated patients. For example, a 90% reduction in *S*-warfarin clearance was reported in *CYP2C9*3* homozygotes compared with subjects homozygous for the wild-type (**1*) variant,[42] requiring dose reduction to 0.5 mg/day in a report of a *CYP2C9*3* homozygote initially given usual doses of warfarin.[43] The clinical relevance of *CYP2C9* polymorphism in warfarin dosing was reviewed in a meta-analysis of 39 studies.[44] In one study included in the meta-analysis,[45] an overrepresentation of *CYP2C9* variant alleles was observed in 81% of patients requiring low-dose warfarin therapy (less than or equal to 1.5 mg/day). The low-dose group was reported to have more difficulty with warfarin induction, requiring longer hospital stays to stabilize the warfarin regimen and experiencing a higher incidence of bleeding complications. *CYP2C9* genotype also has implications for response to valproic acid. The contribution of CYP-mediated metabolism of valproic acid is more important in children than in adults. A recent study in 99 pediatric patients with partial or generalized seizures showed that *CYP2C9*-guided valproic dosing resulted in more patients achieving therapeutic concentrations and lower incidence of side effects.[46]

Both *CYP2C9*2* and *CYP2C9*3* are more common in whites than in Asians and Africans. The *CYP2C9*2* allele is rare to absent in Asian population. More recently, the *CYP2C9*8* allele was shown to reduce warfarin clearance and dose requirements.[47] The *CYP2C9*8* allele occurs in approximately 12% of African Americans and may have important implications for metabolism of *CYP2C9* substrates in this population. Ultrarapid CYP2C9-mediated metabolism has also been reported resulting in higher dosage requirements of phenytoin.[48]

Numerous studies have shown that the *CYP2C9* polymorphisms, in conjunction with a polymorphism in the *VKORC1* gene, influence warfarin dose requirements and form the basis for a consensus-based guideline.[41] The *CYP2C9* and *VKORC1* genotypes were also recently associated with an increased risk for major bleeding events with warfarin therapy.[49] The use of *CYP2C9* and *VKORC1* genotypes in dosing warfarin is discussed in section “Polymorphisms in Drug Target Genes” for more detail.

CYP2A6

In addition to the wild type *CYP2A6*1*, several variants for the *CYP2A6* polymorphism have been identified (*www.cypalleles.ki.se*): *CYP2A6*2* (single amino acid substitution), *CYP2A6*4* (gene deletion), *CYP2A6*5* (gene conversion), and *CYP2A6*20* (frameshift) are associated with abolished enzyme activity. Deletion of the *CYP2A6* gene is very common in Asian patients,[50] which likely accounts for the dramatic difference in the frequency of PMs in Asian (20%) versus white populations (less than or equal to 1%). Nicotine is metabolized by CYP2A6, and the clinical relevance of the *CYP2A6* polymorphism lies in management of tobacco abuse. Investigators reported that nonsmokers were more likely to carry the defective *CYP2A6* allele than were smokers. Smokers who had the defective *CYP2A6* allele smoked fewer cigarettes and were more likely to quit. The inability to metabolize nicotine, secondary to the presence of a defective *CYP2A6* allele, likely leads to enhanced nicotine tolerance and increased adverse effects from nicotine. Based on these observations, CYP2A6 inhibition may have a role in the management of tobacco dependency.[50]

CYP2B6

Although the role of CYP2B6 in the metabolism of anticancer drugs, such as cyclophosphamide and ifosfamide, has been studied, it is with the antiretroviral agents that its clinical relevance was revisited and highlighted. The nonnucleoside reverse transcriptase inhibitor efavirenz is metabolized by CYP2B6. Many patients receiving efavirenz experience central nervous system (CNS) adverse effects that are related to variable systemic exposure to the drug, which could be related to the lower metabolizing efficiency of the *CYP2B6*6, *16,* or **18* alleles.[51] A prospective study demonstrated that dose reduction for 6 months in 12 patients with high efavirenz concentrations secondary to *CYP2B6* polymorphism resulted in both effective anti-human immunodeficiency virus (HIV)-1 activity with HIV-1 load less than 50 copies/mL (50×10^3/L) as well as lower incidence of CNS adverse effects.[52]

CYP3A4/5

Within the *CYP3A* subfamily, at least three isoenzymes, namely, CYP3A4, CYP3A5, and CYP3A7, have been characterized. Despite as much as 40-fold interindividual variability in its expression, functional CYP3A4 is expressed in most adults, with intestinal expression playing a significant role in the first-pass metabolism of numerous drugs. Although several *CYP3A4* variants (eg, **6, *17,* and **20*) have been associated with reduced activity, their low frequency suggest limited clinical relevance.

CYP3A5 is reported to be polymorphic in 60% of African Americans and 33% of whites, with *CYP3A5*3* (c.6986A>G, aberrant splice site) in intron 3 as the primary allele variant. In contrast to individuals with the *CYP3A5*1* allele, subjects with *CYP3A5*3* have no functional CYP3A5 enzyme.[53] CYP3A4 and CYP3A5 mediate the metabolism of more than 50% of all clinically useful drugs. However, with overlapping substrate specificities, it remains unknown whether some drugs are substrates for *CYP3A5* but not *CYP3A4* and vice versa. Although variability exists between dose-adjusted concentration and *CYP3A5* genotypes, studies have shown a correlation between trough concentrations of tacrolimus and *CYP3A5* genetic constitution, and recent CPIC guidelines recommend increasing the starting dose of tacrolimus in patients with the CYP3A4 *1/*1 or *1/*3 genotype.

Phase II and Nucleotide-Base Metabolizing Enzymes

The clinical relevance of genetic polymorphisms in TPMT, DPD, and UGT enzymes has been demonstrated in the treatment of cancer. The *TPMT* gene has four mutant alleles: *TPMT*3A* (the most common), *TPMT*2, TPMT*3B,* and *TPMT*3C*. Thiopurine drugs, such as 6-thioguanine, 6-mercaptopurine, and its precursor, azathioprine, are inactivated by TPMT, and patients who are homozygous or heterozygous for the *TPMT* mutant alleles are at higher risk for developing serious hematological toxicities during treatment with the thiopurines.[56] DPD mediates the metabolism of 5-fluorouracil and its precursor capecitabine, and patients with a defective allele of the *DPYD* gene encoding for DPD cannot metabolize 5-fluorouracil and thus may experience enhanced drug-related neurotoxicity.[57] The camptothecin derivative irinotecan (CPT-11) is activated by carboxylesterase to SN-38, a potent topoisomerase I inhibitor. SN-38 is inactivated by glucuronidation via the polymorphic UGT1A1 enzyme, which may play a role in CPT-11-related toxicity. An extra thymine-

adenine (TA) repeat within the TATA section of the *UGT1A1* promoter results in the *(TA)7TAA* allele (also known as *UGT1A1*28*), which possesses lower enzyme activity than the wild-type *(TA)6TAA* allele. Impaired SN-38 glucuronidation secondary to the *(TA)7TAA* allele may result in abnormally high SN-38 concentrations. A prospective clinical trial demonstrated more severe diarrhea and neutropenia in irinotecan-treated patients who are homozygous or heterozygous carriers of the (*TA)7TAA* allele.[58] A subsequent meta-analysis showed dose-related increases in the risk for severe neutropenia with irinotecan with the *UGT1A1 (TA)7TAA* allele.[59] In 2005, the FDA approved the Invader® UGT1A1 Molecular Assay (Third Wave Technologies) to genotype for *UGT1A1* alleles, and the labeling for irinotecan was revised to recommend dose adjustment for individuals who are homozygous for the *(TA)7TAA* allele.

The antiretroviral protease inhibitor atazanavir is an inhibitor of UGT1A1. Atazanavir can inhibit UGT1A1-mediated glucuronidation and elimination of bilirubin, which can lead to hyperbilirubinemia and jaundice. This effect is more pronounced in individuals with the *UGT1A1*28* allele, and CPIC guidelines recommend using an alternative agents in homozygotes for the **28* allele.[60]

The clinical significance of *N*-acetyltransferase-2 polymorphism was demonstrated by investigators from the pharmacogenetics-based tuberculosis therapy research group in Japan. Early treatment failure with isoniazid was more common among rapid acetylators in the standard doing group (38%) than in the pharmacogenomics-guided dosing group (15%). Similarly, isoniazid-induced liver injury was more common in 78% of slow acetylators in the standard doing group but not present in slow acetylators from the pharmacogenomics-guided dosing group.[61]

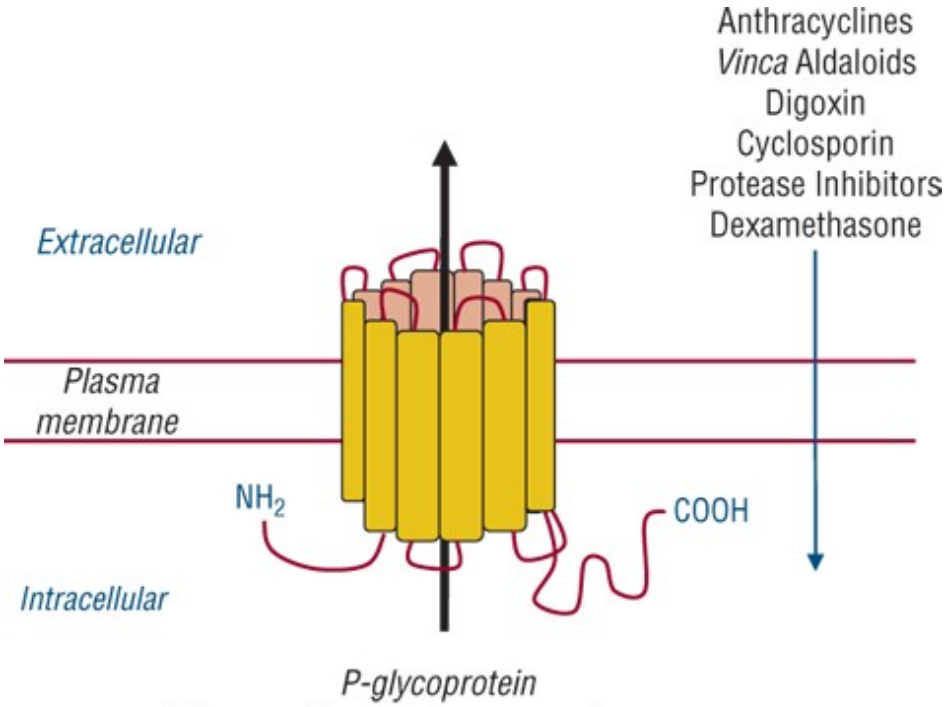
POLYMORPHISMS IN DRUG TRANSPORTER GENES

Certain membrane-spanning proteins facilitate drug transport across the gastrointestinal tract, drug excretion into the bile and urine, drug distribution across the blood–brain barrier, and drug uptake into target cells. Genetic variations for drug transport proteins may affect the distribution of drugs that are substrates for these proteins and alter drug concentrations at their therapeutic sites of action. P-glycoprotein is one of the most recognized of the drug transport proteins that exhibit genetic polymorphism. P-glycoprotein is an energy-dependent transmembrane efflux pump encoded by the *ABCB1* gene (also known as the multidrug resistance 1 gene), which is a member of the adenosine triphosphate (ATP)-binding cassette (ABC) transporter superfamily. P-glycoprotein was first recognized for its ability to actively export anticancer agents from cancer cells and promote multidrug resistance to cancer chemotherapy. Later, it was discovered that P-glycoprotein is also widely distributed on normal cell types, including intestinal enterocytes, hepatocytes, renal proximal tubule cells, and endothelial cells lining the blood–brain barrier. At these locations, P-glycoprotein serves a protective role by transporting toxic substances or metabolites out of cells. P-glycoprotein also affects the distribution of some nonchemotherapeutic agents, including digoxin, the immunosuppressants cyclosporine and tacrolimus, and antiretroviral protease inhibitors (**Fig. e5-4**). Increased intestinal expression of P-glycoprotein can limit the absorption of P-glycoprotein substrates, thus reducing their bioavailability and preventing attainment of therapeutic plasma concentrations. Conversely, decreased P-glycoprotein expression may result in supratherapeutic

plasma concentrations of relevant drugs and drug toxicity.

FIGURE e5-4

Active transport of drugs out of the cell by P-glycoprotein.



Numerous SNPs and insertion/deletion polymorphisms have been identified in the promoter and exon regions of the *ABCB1* gene and while there is evidence that *ABCB1* genotype influences response to digoxin and other P-glycoprotein substrates, the evidence has not reached a level sufficient for clinical implementation.

Other examples of polymorphic drug transporter proteins include the OAT and OCT, both members of the solute carrier (SLC) transporter family. The *SLC01B1* gene encodes for OAT polypeptide B1, which mediates the uptake of *β*-hydroxy-*β*-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins) into the liver. Although statins effectively lower total and low-density lipoprotein cholesterol and reduce the risk for cardiovascular events in coronary heart disease, their use is associated with an increased risk for myopathy (muscle pain or weakness with elevated creatine kinase levels), particularly with higher statin doses or concomitant drugs that increase statin bioavailability. Myopathy may rarely cause rhabdomyolysis, characterized by muscle breakdown and potentially leading to acute renal failure. The reduced function *SLC01B1* c.521T > C SNP, resulting in the p.Val174Ala substitution and contained within the *SLC01B1*5* haplotype, has been associated with higher statin concentrations.[62] Each copy of the *C* allele increased the risk for myopathy with simvastatin 80 mg/day by 4.5-fold in a genome-wide association study (GWAS), in which more than 300,000 SNPs were compared between 85 patients who developed myopathy with high-dose simvastatin (cases) and 90 controls without this adverse effect with simvastatin therapy.[63] In a

replication cohort of patients treated with simvastatin 40 mg/day, the relative risk for myopathy was 2.6 per copy of the 521C allele. The association between the 521C allele and statin-induced myopathy was further confirmed in later studies.

Similarly, the 521C allele was associated with an increased incidence of less severe yet troubling adverse effects that lead to statin discontinuation, including myalgias without significant creatine kinase elevation.[64] The data with the 521T>C allele and risk for myopathy are strongest for simvastatin and suggest that lower simvastatin doses or alternative statin drugs should be used in 521C carriers. CPIC guidelines support this.[62]

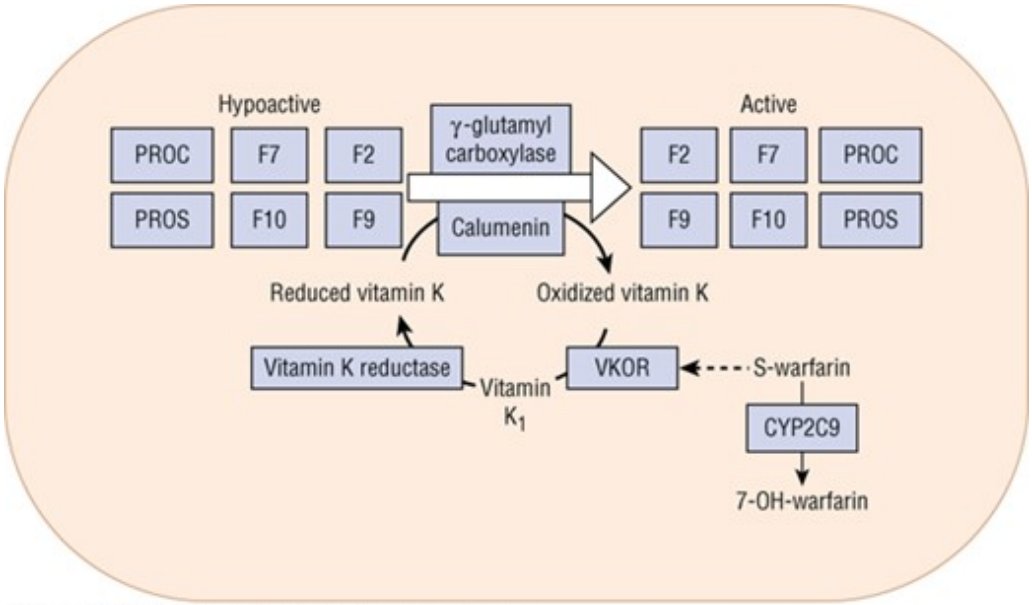
The *SCC22A1* gene encodes for the OCT1 transporter, and several SNPs: Arg61Cys (rs12208357), Gly401Ser (rs341303495), Met420del (rs7255276), and Gly465Arg (rs34059508) have been associated with decreased metformin transport and altered pharmacokinetics with increased plasma levels. A recent study compared the effect of carriers of reduced function of five OTC variants (Arg61Cys, Gly401Ser, Met420del, Gly465Arg plus Cys88Arg [rs55918055]) and concurrent administration of OTC1 inhibitor in 251 metformin-intolerant and 1,915 metformin-tolerant patients. Homozygous carriers of reduced-function *OCT1* alleles had greater intolerance (OR 2.41 [95% CI 1.48-3.93, $P < 0.001$]) when compared to heterozygous carriers or non-carriers of a deficient allele. A known OCT inhibitor was also associated with metformin intolerance (OR 1.63 [95% CI 1.22-2.17, $P = 0.001$]). Intolerance was four times more likely in homozygous carriers of reduced-function *OCT1* alleles who were taking an OCT1 inhibitor concurrently (OR 4.13 [95% CI 2.09-8.16, $P < 0.001$]).[65]

POLYMORPHISMS IN DRUG TARGET GENES

5 Genetic polymorphisms occur commonly for drug target proteins, including receptors, enzymes, ion channels, and intracellular signaling proteins. Drug target genes may work in concert with genes that affect pharmacokinetic properties (ie, genes for drug transporters and drug-metabolizing enzymes) to contribute to overall drug response. For example, the genes for *CYP2C9*, the major metabolizing enzyme for *S*-warfarin, and vitamin K oxidoreductase (VKOR), the target enzyme for warfarin, interact to influence warfarin dose response, as shown in **Fig. e5-5**. The following section highlights some of the receptor, enzyme, ion channel, and cell-signaling protein genes shown to influence the efficacy and safety of various pharmacologic agents.

FIGURE e5-5

Proteins involved in warfarin pharmacokinetics and pharmacodynamics. Warfarin inhibits VKOR, thus preventing formation of reduced vitamin K_1, which is a necessary cofactor for γ-carboxylation and activation of clotting factors II, VII, IX, X, and proteins C and S. (CYP2C9, cytochrome P450 2C9; F, clotting factor; PROC, protein C; PROS, protein S; VKOR, vitamin K oxidoreductase.)



Receptor Genotypes and Drug Response

The β_1-adrenergic receptor gene (*ADRB1*) has been the primary focus of research into genetic determinants of responses to β-adrenergic receptor antagonists in hypertension and cardiovascular disease. β_1-Receptors are located in the heart and kidney, where they are involved in the regulation of heart rate, cardiac contractility, and blood pressure. There are two common nonsynonymous SNPs in the *ADRB1* at codons 49 (p.Ser49Gly) and 389 (p.Arg389Gly). The Ser49Gly and Arg389Gly SNPs are in strong linkage disequilibrium. The Ser49-Arg389 haplotype is associated with an increased risk for death among patients with coronary heart disease.[66] The *ADRB1* Ser49Gly and Arg389Gly SNPs also appear to modulate blood pressure and clinical responses to β_1-receptor blockade. Specifically, hypertensive patients who were homozygous for the Ser49-Arg389 haplotype were found to have greater blood pressure reductions with metoprolol, compared with carriers of the Gly49 and/or Gly389 alleles.[67] In patients with coronary heart disease, atenolol treatment appears to abolish the increased risk for mortality associated with the Ser49-Arg389 haplotype.[66] Among patients with heart failure, the Arg/Arg389 genotype was associated with greater improvements in left ventricular ejection fraction with carvedilol and metoprolol treatment and greater survival benefits with bucindolol, an agent not approved for use in the United States.[67,69] Overall, these data suggest that *ADRB1* genotype may be an important determinant of blood pressure response to β-blockers in the management of hypertension, survival benefits with β-blockers in the management of coronary heart disease, and improvements in cardiac function and clinical outcomes in patients with heart failure. Given that a significant percentage of hypertensive patients fail to derive adequate blood pressure reduction with β-blocker monotherapy, the ability to predict the likelihood of response based on genotype would have important clinical implications. Specifically, β-blockers could be started in patients expected to respond well to this drug class based on their genotype, whereas other classes of antihypertensive agents could be used in those expected to respond poorly to β-blockers. β-blockers could also be used as first-line therapy for hypertensive patients with coronary heart

disease and *ADRB1* genotype predictive of poor survival. While β-blockers are currently indicated in all patients with heart failure, *ADRB1* genotype may be useful in identifying patients who may derive lesser benefits from β-blockers than others. Alternative or additional therapies may be warranted in such patients to improve their outcomes.

Enzyme Genes and Drug Response

Vitamin K oxido reductase is an example of an enzyme with genetic contributions to drug response. Warfarin exerts its anticoagulant effects by inhibiting VKOR and thus preventing carboxylation of the vitamin K-dependent clotting factors II, VII, IX, and X, as shown in Fig. e5-5. *VKORC1* encodes for the warfarin-sensitive component of VKOR. Mutations in the *VKORC1* coding region cause rare cases of warfarin resistance, with carriers of these mutations requiring either exceptionally high warfarin doses (more than 100 mg/wk) to achieve effective anticoagulation or failing to respond to warfarin at any dose.[70]

Aside from rare cases of warfarin resistance, there is substantial variability among patients in the dose of warfarin necessary to produce optimal anticoagulation, defined as an international normalized ratio of 2 to 3 for most indications. A common SNP in the *VKORC1* regulatory region significantly contributes to the interpatient variability in warfarin response. Specifically, the –1639 AA, AG, and GG genotypes lead to high, intermediate, and low sensitivity to warfarin, respectively. Corresponding warfarin dose requirements are approximately 3 mg/day with the AA genotype, 5 mg/day with the AG genotype, and 6 to 7 mg/day with the GG genotype. *VKORC1* genotype, together with *CYP2C9* genotype, explains approximately 30% of the interpatient variability in warfarin dose requirements.[41] Clinical characteristics (eg, age, body size) contribute to additional doe variability.

There is evidence of differences in warfarin dose requirements by ancestry, with higher dose requirements among individuals of African ancestry and lower requirements among Asians compared to Whites. This variability is largely explained by differences in *VKORC1* genotype frequency. Specifically, the low-dose AA genotype is most common in Asians, and the high-dose GG genotype is most common in African Americans, whereas the intermediate-dose AG genotype is most common in persons of European ancestry.

Warfarin-dosing algorithms that incorporate *CYP2C9* and *VKORC1* genotypes and nongenetic (eg, age, body size, interacting medications) factors are publically available to assist with warfarin dosing. In addition, the warfarin labeling now contains a dosing table based on *CYP2C9* and *VKORC1* genotypes (**Table e5-2**). A comparative effectiveness study demonstrated that use of genotype-guided warfarin dosing leads to better prediction of warfarin dose requirements, greater time spent within the therapeutic anticoagulation range, and may lower the incidence of serious adverse events during the initial months of warfarin therapy compared to traditional warfarin dosing.[71] Two clinical trials examining the efficacy of genotype-guided warfarin dosing were published in 2013. One trial was conducted in Europe and showed greater time in the therapeutic INR range with genotype-guided dosing compared to a standard dosing approach.[72] The other trial was conducted in a diverse US population, including a large number of African Americans and showed no difference in time spent in the therapeutic INR range with dosing using a pharmacogenomic algorithm compared to

dosing with a clinical algorithm.[73] A third trial is ongoing and examining the effect of genotype-guided warfarin dosing on risk for bleeding and thromboembolism among patients taking warfarin for prevention of venous thromboembolism after major orthopedic surgery.

TABLE e5-2 Initial Warfarin Dose Recommendations (in mg/day) According to the *CYP2C9* and *VKORC1* Genotypes Provided in the Warfarin Labeling

	CYP2C9					
VKORC1	****1/*1***	****1/*2***	****1/*3***	****2/*2***	****2/*3***	****3/*3***
AA	3-4	3-4	0.5-2	0.5-2	0.5-2	0.5-2
AG	5-7	3-4	3-4	3-4	0.5-2	0.5-2
GG	5-7	5-7	3-4	3-4	3-4	0.5-2

Clinical Controversy…

The disparate results from clinical trials of warfarin pharmacogenetics have led many clinicians to question the utility of a genotype-guided dosing approach. There are important differences between the two trials that may help explain the variable results, including differences in the comparator arm (standard dosing in the European trial and use of a clinical algorithm in the U.S. trial), lack of a loading dose in the US trial, and not accounting for many genotypes important for African Americans in the U.S. trial. For example, the *CYP2C9*8* allele is twice as common as the *CYP2C9*2* and **3* alleles combined in African Americans but was not genotyped. Recent data show that not accounting for genotypes important for African Americans lead to significant overdosing of warfarin in this population.

Clinical Controversy…

Clinicians have debated the strength of evidence necessary to prove the clinical utility of genotype-guided therapy. Randomized, controlled clinical trials are considered the gold standard for determining clinical utility of treatment approaches. However, these are costly and labor-intensive to perform, and may take years to complete. Thus, some argue that replication of genotype-drug response associations in multiple cohorts with evidence of utility from comparative effectiveness studies may be sufficient, particularly for narrow therapeutic index drugs where knowledge of patient-specific factors predisposing to risk for adverse events is needed to improve drug safety.

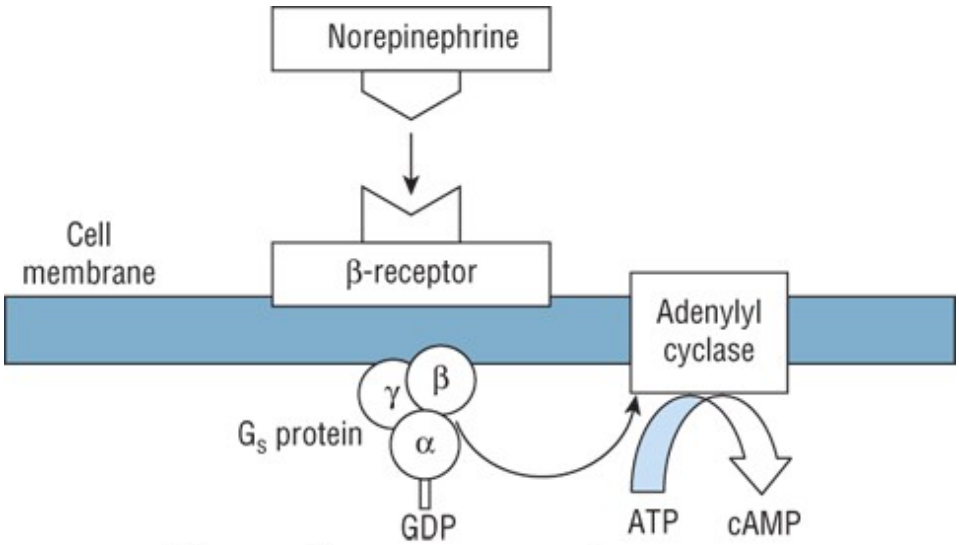
Genes for Intracellular Signaling Proteins, Ion Channels, and Drug Response

Cellular responses to many drugs are mediated through receptor-coupled guanosine diphosphate (GDP)-bound proteins also called *G-proteins*. G-proteins consist of *α, β,* and γ subunits. Following receptor activation, the receptor couples to the G-protein, resulting in dissociation of GDP from the *α* subunit in exchange for guanosine triphosphate (GTP) and activation of the *α, β,* and γ subunits. The *α* subunit and *β*γ subunit complex are released intracellularly and interact with various effectors (eg, adenylyl cyclase, phospholipase C) to produce a cellular response. The β_1-adrenergic receptor is an example of a G-protein–coupled receptor in which a stimulatory G protein (G_s protein) mediates the activation of the effector adenylyl cyclase and the generation of the second messenger cyclic

adenosine monophosphate (cAMP) following receptor stimulation (**Fig. e5-6**).

FIGURE e5-6

β_1-receptor coupled to intracellular signaling mechanisms by a stimulatory G-protein. (ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; GDP, guanosine diphosphate.)



G-protein coupled receptor kinase (GRK) phosphorylates β-adrenergic receptors causing the receptor to uncouple with the G protein. There is a polymorphism in the *GRK5* gene (Gln41Leu) influences outcomes with β-blocker therapy in heart failure. The Leu allele is 10-fold more common in persons of African versus European descent. Among African Americans with heart failure and the Gly/Gly genotype, β-blocker therapy was associated with greater transplant-free survival. However, no benefit was observed with β-blocker therapy among patients with a Leu41 allele.[74] A potential explanation for this finding is that the Leu41 variant acts to desensitize the β-adrenergic receptor and thus, may serve as a natural β-blocker eliminating the need for β-blocker therapy. Genes encoding pancreatic ATP-sensitive potassium (K_{ATP}) channels are examples of ion channel genes with implications for drug response. The potassium inwardly rectifying channel, subfamily J, member 11 gene (*KCNJ11*) and the sulfonylurea receptor gene (*ABCC8*) encode the Kir6.2 and sulfonylurea receptor-1 (SUR1) subunits of pancreatic K_{ATP} channels, respectively. K_{ATP} channels remain open in the presence of activating mutations in the *KCNJ11* and *ABCC8* genes, which leads to hyperpolarization of the pancreatic β-cell membrane and impaired insulin release.[75,76] Sulfonylureas are especially effective antidiabetic agents in patients with activating *KCNJ11* or *ABCC8* mutations, in whom they promote K_{ATP} channel closure.[75,77]

The large-conductance calcium and voltage-dependent potassium (BK) channel is another example of an ion channel with genetic contributions to drug response. The *KCNMB1* gene encodes for the β_1 subunit of the BK channel. There are two common SNPs in the *KCNMB1* gene, p.Glu65Lys and p.Val110Leu. Among patients with hypertension and coronary heart disease started on verapamil, the

Lys65 allele was associated with more rapid achievement of blood pressure control.[78] Verapamil-treated patients with the Leu110 allele had a lower risk for cardiovascular events compared with non-Leu110 allele carriers. These findings may have implications for individualized use of calcium channel blockers for blood pressure control in patients with coronary heart disease.

In patients with type 2 diabetes, a GWAS study reported a significant association between response to the biguanide metformin and polymorphism in the *ATM* gene. The *ATM* plays a significant role in activation of the adenosine monophosphate-activated protein kinase (AMPK), which is considered the mechanism of action of metformin. While the rs11212617 SNP, located near the *ATM* gene, only explains 2.5% of the variation of metformin response,[4] the initial result was replicated in a subsequent study with additional European cohorts.[79] This first GWAS study for antidiabetic drugs[4] suggests the utility of the GWAS approach in identifying viable genes that have potential implications for mediating glycemic response to drug therapy in a complex disease, such as diabetes, and may pave the way for a new era in anti-diabetic drug development.

DISEASE-ASSOCIATED GENES

Numerous genes have been correlated with disease outcomes, and many of these have been found subsequently to influence response to pharmacologic disease management. These gene–drug response associations often occur despite the lack of a direct effect on pharmacokinetic or pharmacodynamic drug properties. Examples of such disease-associated genes are discussed hereunder.

Human Leukocyte Antigen Gene and Hypersensitivity to Antiepileptic Drugs and Abacavir

The human leukocyte antigen (*HLA*) gene has been linked to serious, potentially life-threatening adverse skin reactions with carbamazepine and phenytoin, commonly prescribed antiepileptic agents.[80,81] Stevens–Johnson's syndrome (SJS) and toxic epidermal necrolysis (TEN) are hypersensitivity reactions characterized by blistering, mucosal erosions, and epidermal detachment. TEN is associated with more extensive skin involvement and a mortality rate approaching 25%.

Individuals with southeastern Asian ancestry (ie, southern China, Thailand, Malaysia, Indonesia, Taiwan, and Philippines) have a twofold to threefold higher prevalence of carbamazepine- or phenytoin-induced SJS and TEN than individuals from Japan, Korea, or European countries. The human leukocyte antigen type B (*HLA-B*)**1502* allele also occurs at a higher prevalence in individuals from the countries with higher prevalence of SJS and TEN. Individuals from south Asia, including India, have an intermediate prevalence of this allele (2%-4%). It occurs in less than 1% of those in Japan and Korea and is largely absent in the rest of the world. Thus, presence of the allele correlates highly with risk for drug-induced SJS or TEN.

While the mechanism by which the *HLA-B*1502* allele increases the risk for these toxic cutaneous reactions is unclear, it may involve activation and proliferation of T lymphocytes on carbamazepine exposure. The carbamazepine labeling was recently updated to recommend *HLA-B*1502* screening in individuals with ancestry from southern Asia prior to carbamazepine use (see Table e5-1). As

demonstrated in a large population screening study,[82] carbamazepine should be avoided in patients testing positive for the *HLA-B*1502* allele. Moreover, because of reports of phenytoin-induced SJS in the presence of the *HLA-B*1502* allele, phenytoin should also be avoided in individuals with the *HLA-B*1502* allele.[81] The cost effectiveness of universal *HLA-B*15:02* screening was demonstrated in a population from Thailand, where only about 340 patients need to be genotyped to prevent one case of SJS or TEN.[83]

The use of abacavir, a nucleoside reverse transcriptase inhibitor of HIV-1, has been associated with severe, and occasionally fatal, hypersensitivity reactions in some patients. The abacavir hypersensitivity reaction (AHR) is strongly associated with the presence of another allelic variant of the *HLA* gene, *HLA B*57:01*, and screening for *HLA B*57:01* has been shown to be associated with reduction of AHR incidence.[84] The screening recommendation has been incorporated into abacavir product labeling as well as treatment guidelines. [84,85]

Factor V and Prothrombin Genes and Oral Contraception

The use of estrogen-containing oral contraceptives is associated with an increased risk for developing thromboembolic disorders, including deep venous thrombosis, pulmonary embolism, and thrombotic stroke. Variations in the genes for the coagulation factors prothrombin and factor V Leiden also have been identified as risk factors for thromboembolic disorders.[86] In case-control studies, the presence of a factor V Leiden or prothrombin gene variation markedly increased the risk for deep vein thrombosis and cerebral vein thrombosis among estrogen-containing oral contraceptive users. These data suggest that alternative birth control measures should be employed in women known to carry a prothrombin or factor V Leiden mutation.

Congenital Long-QT Syndrome and Drug-Induced Torsade De Pointes

Drug-induced QT-interval prolongation may precipitate the serious, potentially life-threatening arrhythmia called *torsade de pointes*. It is well recognized that many antiarrhythmic drugs can cause QT-interval prolongation and torsade de pointes. In addition, numerous noncardiovascular agents can induce torsade de pointes, and many have been withdrawn from the market as a result. Such drugs include the antihistamines terfenadine and astemizole, the fluoroquinolone antibiotic grepafloxacin, and the motility agent cisapride. Given the serious and unpredictable nature of torsade de pointes, there has been great interest in identifying genetic markers that predispose individuals to its occurrence.

Abnormalities in ion flux across the cardiac cell membrane resulting in an excess of intracellular positive ions and delayed ventricular repolarization are characteristic of long-QT syndromes. Mutations in genes for the pore-forming channel proteins that affect potassium and sodium transport across the cardiac cell membrane, including the *KCNQ1*, *KCNE2, KCNH2,* and *SCN5A* genes, underlie congenital long-QT syndromes.[87] There is evidence that these and similar mutations also may increase the risk for drug-induced torsade de pointes.[87] Ultimately, the ability to screen for mutations associated with drug-induced torsade de pointes may enable identification of individuals with a genetic predisposition for this life-threatening arrhythmia who could be spared exposure to

potentially causative agents and treated with alternative therapies.

NOVEL SITES FOR DRUG DEVELOPMENT

The discovery of genes that confer disease has led to an improved understanding of the molecular mechanisms involved in disease pathophysiology. Once associations between genes and diseases are discovered, scientists can elucidate the functions of the encoded proteins and more clearly define the consequences of genetic mutations. Insight into the genetic control of cellular functions may reveal new strategies for disease treatment and prevention.

Targeted Therapies for Cancer. Overexpression of the human epidermal growth factor receptor 2 (HER2, also known as Her2/neu and ErbB2), secondary to *HER2* gene amplification occurs in 20% of metastatic breast cancers and is associated with more aggressive cancer and decreased survival.[88] The discovery of *HER2* overexpression and its effects on cancer prognosis led to the development of trastuzumab, a recombinant monoclonal antibody that targets HER2 and blocks HER2-stimulated growth and survival of cancer cells. The addition of trastuzumab to breast cancer chemotherapy significantly slows the progression of cancer and improves tumor response rates in women with HER2-positive tumors.[88] Testing for *HER2* overexpression is necessary to determine which patients may benefit from trastuzumab. The FDA has approved several tests that detect *HER2* overexpression either directly by measuring the amount of protein or indirectly by measuring gene amplification.

Similarly, overexpression of the epidermal growth factor receptor (EGFR, also known as HER1 or ErbB1) in head and neck, colon, and rectal cancer is associated with cancer growth and a poor clinical prognosis. Cetuximab and panitumumab are recombinant monoclonal antibodies that block activation of the EGFR. Both were shown to improve survival in metastatic colorectal cancer that overexpresses EGFR, and are thus indicated in this setting.[89,90] Erlotinib and gefitinib inhibit the intracellular phosphorylation of tyrosine kinase associated with the EGFR and are indicated in non-small cell lung cancer. Other examples of targeted chemotherapy developed based on genetic abnormalities include rituximab, a monoclonal antibody used to treat CD20-positive, B-cell non-Hodgkin's lymphoma and chronic lymphocytic leukemia; imatinib, dasatinib, and nilotinib, kinase inhibitors that blocks the product of a reciprocal translocation between chromosomes 9 and 22 in chronic myeloid leukemia (CML); and crizotinib, an anaplastic lymphoma kinase (ALK) and c-ros oncogene 1, receptor tyrosine kinase (ROS-1) inhibitor that targets the *EML4-ALK* gene fusion product in non-small cell lung cancer.

Targeted Therapy for Cystic Fibrosis. Cystic fibrosis is caused by genetic mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) protein, which is expressed in the airways, intestines, pancreas, bile duct, and sweat glands. In these locations, the CFTR protein serves a critical role in the regulation of fluid and ion transport. The CFTR is composed of two nucleotide binding domains and two transmembrane domains. The transmembrane domain forms a chloride channel, while the nucleotide binding domain acts as a gate to regulate chloride transport across the cell membrane. Mutations in the *CFTR* gene lead to altered fluid and ion transport and disrupt mucus clearance in the airways and intestinal tract resulting in airway obstruction and digestive problems.

Mutations in the *CFTR* gene affect protein synthesis, processing, regulation, or ion conductance. Ivacaftor was approved by the FDA in 2012 as the first drug to target defects in the CFTR.[91] Ivacaftor was initially approved for the treatment of cystic fibrosis in patients age 6 and older who have the Gly551Asp mutation, which occurs in about 4% of cystic fibrosis cases and causes defects in chloride transport through the ion channel. Ivacaftor potentiates chloride ion flow and resulted in rapid and sustained improvement in lung function compared to placebo in randomized controlled trials in patients with cystic fibrosis. The labeling for Ivacaftor was later updated to include additional variants (Gly1244Glu, Gly1349Asp, Gly551Ser, Ser1251Asn, Ser1255Pro, Ser549aSN, Ser549R, and Gly178Arg) that also disrupt chloride gating.

PHARMACOGENETIC DRUG LABELING AND GUIDELINES

The FDA is involved in a number of pharmacogenetic-related activities, including encouraging submission of exploratory genomic data from drug sponsors, providing guidance on incorporating pharmacogenetic principles into the drug development process, and updating drug labels to include pharmacogenetic information. More than 120 drugs now contain pharmacogenetic information in their FDA-approved labeling. Examples of these are shown in **Table e5-3**. The pharmacogenomic information appears in various sections of the label. For example, the information appears as a Boxed Warning for clopidogrel and carbamazepine because of the serious consequences of genetic variation on drug response. In the case of warfarin, mercaptopurine, and irinotecan, the pharmacogenomic information appears in the drug dosing section. The FDA maintains a table of pharmacogenomics biomarkers in drug labels on its website (www.fda.gov).

TABLE e5-3 Examples of Drugs with Pharmacogenomic Labeling

Drug	Gene	Content
Abacavir	*HLA-B*	The *HLA-B*57:01* allele increases the risk for abacavir hypersensitivity. Genotype screening is recommended prior to abacavir use. Abacavir should be avoided in patients with the *HLA-B*57:01* allele, unless the potential benefit of abacavir clearly outweighs the risk.
Atomoxetine	*CYP2D6*	*CYP2D6* poor metabolizers (PMs) may have 10-fold increased atomoxetine exposure compared with extensive metabolizers. A starting dose of 0.5 mg/kg/day is recommended in children and adolescents £70 kg (£154 lb) who are known to be *CYP2D6* PMs.
Azathioprine, 6-mercaptopurine	*TPMT*	Patients with a nonfunctional *TPMT* allele are at increased risk for serious, potentially life-threatening myelosuppression if given conventional doses of azathioprine. Consideration of either *TPMT* genotyping or phenotyping recommended, with dose reduction in patients with a reduced activity genotype or phenotype.

Drug	Gene	Content
5-Fluorouracil, capecitabine	*DPD*	*DPD* deficiency may rarely lead to severe toxicity (eg, diarrhea, neutropenia, neurotoxicity) with 5-fluorouracil. 5-fluorouracil should be avoided in patients with *DPD* deficiency.
Carbamazepine	*HLA-B*	The *HLA-B*1502* allele increases the risk for serious and potentially fatal dermatologic reactions (eg, Stevens–Johnson's syndrome and toxic epidermal necrosis) with carbamazepine. At-risk populations include those from south Asia who should be screened for the *HLA-B*1502* allele prior to starting carbamazepine. Carbamazepine should be avoided in *HLA-B*1502* carriers unless the potential benefit clearly outweighs the risks.
Celecoxib	*CYP2C9*	Celecoxib clearance is reduced in carriers of the *CYP2C9*3* allele. Celecoxib should be administered with caution and at lower doses in patients with the *CYP2C9*3* allele.
Cetuximab, panitumumab	*EGFR*	Cetuximab and panitumumab inhibit the EGFR. Candidates for these agents should have immunohistochemical evidence of EGFR expression.
	KRAS mutations	KRAS is a G protein in the EGFR pathway. Patients with a *KRAS* mutation in codon 12 or 13 may not derive any benefit from cetuximab or panitumumab, and use of these drugs is not recommended.
Clopidogrel	*CYP2C19*	*CYP2C19* is involved in the biotransformation of clopidogrel to its active form. Individuals with the *CYP2C19* PM phenotype secondary to genetic polymorphism may fail to derive sufficient protection against adverse cardiovascular events with clopidogrel. These risks are particularly high in patients who undergo coronary artery stent placement.
Fluoxetine	*CYP2D6*	Fluoxetine is a *CYP2D6* substrate and inhibitor. *CYP2D6* PMs may have increased fluoxetine exposure. In addition, fluoxetine use causes *CYP2D6* EMs to resemble PMs. Concomitant use of fluoxetine and other drugs that are metabolized by *CYP2D6* (eg, tricyclic antidepressants, phenothiazines, most atypical antipsychotic agents, propafenone, flecainide) should be done with caution.
Imatinib mesylate	*CD117*	Gastrointestinal stromal tumor cells possessing the *CD117* (or *c-Kit*) mutation have shown regression with imatinib, and imatinib is indicated for patients with the *CD117* mutation and unresectable or metastatic gastrointestinal stromal tumors.
Irinotecan	*UGT1A1*	The *UGT1A1*28* allele is associated with increased risk for irinotecan-induced neutropenia, with homozygotes having the highest risk. Lower irinotecan starting doses are indicated in

Drug	Gene	Content
		patients known to be homozygous for the *UGT1A*28* allele.
Lenalidomide	Chromosome *5q* deletion	Myelodysplastic syndromes with the chromosome 5q deletion are associated with increased risk of hematologic toxicity with lenalidomide. More frequent monitoring of complete blood counts is recommended during lenalidomide initiation in patients with the chromosome 5q deletion. Consider lenalidomide dose reduction or interruption and use of blood products and/or growth factors if CBC alterations are detected.
Maraviroc	*CCR5*	Maraviroc is a CCR5 receptor antagonist that is indicated for patients who are infected with CCR5-tropic HIV-1. Efficacy has not been demonstrated in patients with dual/mixed or CXCR4-tropic HIV-1. Testing for tropism is required prior to maraviroc use, and maraviroc is not recommended in patients with dual/mixed or CXCR4-tropic HIV-1.
Primaquine	*G6PD*	Genetic variation leading to *G6PD* deficiency increases the risk for primaquine-induced hemolytic anemia. Obtaining a *G6PD* level prior to primaquine use is recommended for patients of African or Mediterranean ancestry, who are at higher risk of *G6PD* deficiency, with the use of lower doses in patients who have a deficient level.
Rasburicase	*G6PD*	Genetic variation leading to *G6PD* deficiency increases the risk for rasburicase-induced hemolytic anemia. Obtaining a *G6PD* level prior to rasburicase use is recommended in patients of African or Mediterranean ancestry, who are at higher risk of *G6PD* deficiency. Rasburicase should be avoided in individuals with a *G6PD* deficiency.
Trastuzumab	*HER2*	Decreased tumor progression in breast cancer with trastuzumab has only been demonstrated when *HER2* is overexpressed. Overexpression of *HER2* should be confirmed by protein overexpression or gene amplification prior to trastuzumab initiation.
Voriconazole	*CYP2C19*	Patients with the intermediate or PM phenotype have twofold to fourfold higher voriconazole exposure, respectively. However, no recommendations are made for genetic screening or dose adjustment.
Warfarin	*CYP2C9, VKORC1*	The *CYP2C9*2* and *3 alleles are associated with reduced warfarin metabolism and increased bleeding risk, while the *VKORC1-1639A* allele is associated with increased warfarin sensitivity. Lower doses of warfarin should be started in patients known to have reduced function *CYP2C9* or *VKORC1* alleles. However, genetic testing is not mandated.

CBC, complete blood count; CXCR4, chemokine-related receptor; EGFR, epidermal growth factor receptor; HIV, human immunodeficiency virus.

Data from *www.fda.gov/cder/genomics/genomic_biomarkers_table.html*.

Guidelines are now available to assist with translating genotype results into actionable prescribing decisions for a number of drugs. Among these are guidelines from the Clinical Pharmacogenetics Implementation Consortium (CPIC). CPIC is an international collaboration of individuals from academic centers, clinical institutions, and pharmacy benefits management with expertise in pharmacogenomics or laboratory medicine that provides consensus-based guidelines on how to use genetic test results to optimize pharmacotherapy.[92] The consortium does not recommend whether genetic tests should be ordered, but rather, how to use existing genetic information.

Guidelines published as of mid-2015 are listed in **Table e5-4**. The CPIC guidelines, in addition to other pharmacogenetic information, are freely available through the Pharmacogenomics Knowledge Base (PharmGKB).

TABLE e5-4 Guidelines from the Clinical Pharmacogenetics Implementation Consortium

Drug(s)	Gene(s)	Summary of Recommendation
Azathioprine, mercaptopurine, and thioguanine	*TPMT*	Moderately reduced doses (30%-70% of the full dose) of thiopurines is recommended for heterozygous variant carriers, and drastically reduced doses (10-fold reductions) with less frequent administration or alternative therapy is recommended in homozygous variant carriers.[56]
Clopidogrel	*CYP2C19*	Alternative antiplatelet therapy (eg, prasugrel or ticagrelor) is recommended in *CYP2C19* poor metabolizers (PMs) (strong recommendation) and intermediate metabolizers (IMs) (moderate recommendation) because of a potential lack of efficacy.[34]
Warfarin	*CYP2C9, VKORC1*	Warfarin dosing based on *CYP2C9* and *VKORC1* genotypes is recommended when these genotypes are known.[41]
Codeine	*CYP2D6*	Avoidance of codeine and to a lesser extent tramadol, oxycodone, and hydrocodone is recommended in *CYP2D6* ultrarapid metabolizers (UMs) because of increased risk for toxicity and in PMs because of potential lack of efficacy.[14]
Abacavir	*HLA-B*	Recommend *HLA-B*57:01* screening before abacavir use and avoidance of abacavir in patients testing positive for the allele unless under exceptional circumstances where the potential drug benefits outweigh the risk of hypersensitivity.[84]
Simvastatin	*SLCO1B1*	A lower dose of simvastatin or consideration of an alternative statin is recommended in patients known to carry the *521C* allele.[62]

Drug(s)	Gene(s)	Summary of Recommendation
Allopurinol	*HLA-B*	Allopurinol is contraindicated in patients with a *HLA-B**58:01 allele because of increased risk for severe cutaneous adverse reactions.[100]
Tricyclic antidepressants	*CYP2C19, CYP2D6*	Avoid TCAs or use a higher starting dose in CYP2D6 UMs because of a potential lack of efficacy. Start with a lower TCA dose in IMs and consider therapeutic drug monitoring and avoid TCAs or use a lower dose with therapeutic drug monitoring in PMs because of an increased risk for toxicity. Recommend an alternative agent not metabolized by CYP2C19 in CYP2C19 UMs because of decreased efficacy. Recommend an alternative agent not metabolized by CYP2C19 in CYP2C19 PMs because of an increased risk of toxicity.[10]
Atazanavir	*UGT1A1*	Consider alternative therapy in patients with a reduced function genotype because of an increased likelihood of jaundice with atazanavir.[60]
Fluoropyrimidines (5-fluorouracil, capecitabine, tegafur)	*DPYD*	Recommend a decreased fluoropyrimidine dose in variant allele heterozygotes and avoidance of fluoropyrimidines in homozygotes because of an increased risk for severe or fatal drug toxicity in patients with a variant allele.[57]
Carbamazepine	*HLA-B*	Avoid carbamazepine if a *15:02 allele is present because of an increased risk of Stevens–Johnson's Syndrome and Toxic Epidermal Necrolysis.[80]
Selective serotonin reuptake inhibitors	*CYP2C19*	Consider an alternative drug in CYP2C19 UMs because of decreased efficacy of citalopram and escitalopram.[101] Consider a dose reduction of citalopram, escitalopram, or fluvoxamine or alternative therapy in CYP2C19 PMs because of an increased risk for toxicity.
Ivacaftor	*CFTR*	Ivacaftor is indicated for homozygotes or heterozygotes of the Gly551Asp, Gly1244Glu, Gly1349Asp, Gly178Arg, Gly551Ser, Ser1251Asn, Ser1255Pro, Ser549Asn, or Ser549Arg, mutation.[91]
Rasburicase	*G6PD*	Rasburicase is contraindicated in G6PD deficient patients.[102]
Tacrolimus	*CYP3A4*	Recommend increasing the starting dose by 1.5-2 times the recommended starting dose in CYP3A5 IMs or EMs, not to exceed 0.3 mg/kg/day.[55]

Drug(s)	Gene(s)	Summary of Recommendation
Phenytoin	*CYP2C9, HLA-B*	Avoid phenytoin if the HLA-B*15:02 allele is present because of an increased risk of Stevens–Johnson's syndrome and toxic epidermal necrolysis. CYP2C9 PMs may need a lower phenytoin dose.[81]

GENE THERAPY

Gene therapy has emerged as a possible approach to treating and curing disease by replacing a mutated gene with a nonmutated form, altering gene expression, or adding a new gene. Initially, the focus of gene therapy was for the treatment of inherited disorders such as cystic fibrosis, sickle cell anemia, hemophilia, and severe combined immunodeficiency. Gene therapy trials were later expanded to include patients with acquired diseases such as cancer, heart disease, and Parkinson's disease. The goal of gene therapy for inherited diseases is to correct or repair genetic defects permanently and thereby restore normal cellular function. Gene therapy for acquired diseases aims to cure disease by targeting pathogenic processes.

Most gene therapy techniques for inherited diseases attempt to replace defective genes with normally functioning ones. Exogenous genes, called *transgenes,* are transferred into somatic (body) cells of the recipient. Transfer of transgenes into germ line (egg or sperm) cells can result in passage of genetic alterations to offspring and is currently prohibited by the FDA.

The first clinical gene therapy trial began in 1990 for the treatment of adenosine deaminase deficiency. B and T lymphocytes fail to develop in this autosomal recessive disease, resulting in a severe combined immunodeficiency syndrome (SCID) made famous by the "bubble boys" whose lives were confined to tents in an effort to keep them in a germ-free environment. Only two patients were initially included in this trial, and although both continued to demonstrate clinical improvement 10 years later, gene therapy did not cure the disease, as investigators had hoped.

More than 3,000 clinical gene therapy trials have been registered around the world (*www.clinicaltrials.gov*). Most of these trials involve cancer patients; however, a number of studies also target heart disease and inherited disorders such as muscular dystrophy. The results of gene therapy trials to date have been largely disappointing, with reports of serious toxicities and few therapeutic successes.

Obstacles to Success

Reasons for limited success with gene therapy include inefficient gene delivery to target cells, inadequate gene expression, and unacceptable adverse effects.

Sufficient amounts of the transgene must be inserted into a sufficient number of recipient cells to produce a therapeutic response. In addition, the transgene must be inserted into the correct chromosomal position of the correct cell nucleus so as not to disrupt normal gene function and expression. Incorrect chromosomal insertion of the transgene is a problem referred to as *insertional*

mutagenesis. Once the therapeutic gene is integrated correctly into host DNA, it must be expressed at adequate levels and at appropriate times to restore normal cell function. Finally, the gene delivery system and delivery technique should lack any potential to cause unwanted effects in the transgene recipient.

Retroviral Gene Delivery

8 Because of their efficiency in integrating into human DNA, viruses are the most common vectors used to deliver therapeutic genes to recipient cell targets. Disease-causing genes are replaced with the desired therapeutic genes; the viral genes that control delivery mechanisms are retained.

The first viral vectors introduced were retroviruses, which are RNA viruses that integrate into the host cell genome and replicate during cell division. Thus, retroviral gene transfer is capable of permanently altering gene expression. Retroviruses may be used to deliver genes through either direct infusion into target organs or ex vivo manipulation of harvested cells followed by reinfusion into the recipient. The disadvantages of retroviral vectors are the limited size of the gene they can carry, relatively low efficiency, and the risk of insertional mutagenesis. In fact, the FDA temporarily halted retroviral gene delivery into hematopoietic stem cells in early 2003 after leukemia developed as a result of insertional mutagenesis in two of nine SCID-affected children treated with retroviral gene therapy.[93] Two other children later developed cancer, and one died. Gene therapy for X-linked SCID is currently restricted to patients who undergo unsuccessful bone marrow transplantation.

Since research with retroviral gene therapy has resumed, there has been some success with this mode of gene delivery in the area of oncology. In 2003, the FDA granted orphan drug status for a retroviral gene therapy that targets the cyclin *G1* gene in the treatment of pancreatic cancer, and later, this therapy gained orphan drug status in the treatment of osteosarcoma and soft tissue sarcoma. Phase I and II studies suggest that the drug is well tolerated and may control tumor growth and increase survival in patients with chemotherapy-resistant pancreatic cancer or osteosarcoma.[94] Lentiviruses are a type of retrovirus that also appear promising as they have a lower potential for causing cancer. Lentiviral vector-based gene delivery of three genes coding for enzymes that make dopamine to the brain of Parkinson's Disease patients has been shown to be well tolerated and improve motor function.[95]

Adenoviral Gene Delivery

Unlike retroviruses, adenoviruses do not integrate into the host genome and thus do not replicate. As a result, genes delivered by adenoviruses are only active temporarily. Adenoviral-mediated gene therapy is employed commonly in cancer patients because permanent gene expression is unnecessary in this patient population.

Tumor cells have been infused with adenoviral vectors carrying the herpes simplex virus-1 thymidine kinase gene and then exposed to valacyclovir as a mode of cancer chemotherapy. Thymidine kinase converts valacyclovir to its active, cytotoxic form, which is incorporated in the DNA of tumor cells, leading to their death. Adenoviruses can be grown in high titers and do not carry the risk of

insertional mutagenesis. The major disadvantage of adenoviruses is their immunogenic potential, which has resulted in one death and prompted federal oversight of gene therapy trials.

Adeno-Associated Viral Gene Delivery

Adeno-associated viruses are human DNA-containing viruses that do not appear to trigger immune responses on injection. Similar to retroviruses, adeno-associated viruses are incapable of carrying a large amount of genetic material, and their use entails the risk of insertional mutagenesis.

Investigators have had some success with adeno-associated viral gene delivery of SERCA2a in patients with advanced heart failure. Patients with advanced heart failure commonly have a deficiency in sarcoplasmic reticulum Ca(2+)-ATPase (SERCA2a), which is essential for maintaining cardiac function through regulation of cellular homeostasis of calcium. A single intracoronary infusion of adeno-associated virus 1/SERCA2a in nine patients appeared to have an acceptable safety profile.[96] With the exception of two patients found to have preexisting anti-AAV1 neutralizing antibodies, gene transfer was associated with improved symptomatic, functional, and cardiac parameters. In a followup phase 2 trial including 39 patients with advanced heart failure, intracoronary adeno-associated virus type 1/SERCA2a decreased the frequency of cardiovascular events at 12 months compared with placebo.[97]

Other Means of Gene Delivery

Scientists are also experimenting with nonviral delivery methods such as the use of direct DNA injection, liposomes, cationic polymers, and electroporation. There has been much interest in myocardial delivery of plasmid DNA encoding for vascular endothelial growth factor gene to promote formation of new coronary vessels (angiogenesis) in patients with severe, intractable angina. The procedure appeared promising in early clinical trials, with improved myocardial perfusion and angina in this patient population with few major adverse events. However, larger, more rigorously conducted trials have failed to demonstrate significant benefit of myocardial angiogenesis gene therapy.

Scientists have enjoyed few successes with gene therapy for inherited diseases. Improvements in gene delivery techniques and a better understanding of molecular processes controlling gene expression are necessary before gene therapy can correct genetic defects successfully and thus cure associated diseases without inducing adverse effects. Because of limited success with traditional approaches to gene therapy, scientists are exploring other strategies, such as repairing or regulating (“turning off”) defective genes rather than replacing them. Scientists have had more success with gene therapy for acquired diseases, such as cancer, and a number of phase II and III clinical trials in this area are under way. While gene therapy research is evolving, much progress has yet to be made before effective and safe therapies are available.

ETHICAL CONSIDERATIONS

Pharmacogenetics

Traditionally, *genetic testing* refers to screening human genetic material to identify genotypes associated with disease susceptibility or carrier status for heritable diseases, such as Huntington disease or breast cancer. This kind of testing can have profound ethical and social implications. For example, knowledge that a patient is at risk for developing a genetic disorder could result in emotional distress for the individual at risk and his or her family members and the fear of discrimination by employers or insurance companies.

Within the context of pharmacogenetics, however, testing involves searching for genetic variations linked to drug efficacy or toxicity rather than to disease susceptibility. In many instances, this form of testing will carry little risk for ethical, legal, and social concerns. For example, knowledge that a person has a genotype associated with poor response to clopidogrel may be of little consequence because there are alternative therapies available. However, more serious implications may arise if a person is predicted to respond poorly to a drug based on genotype, and treatment options are limited. To address concerns regarding the potential misuse of genetic and pharmacogenetic information by health insurance companies and employers, former President George W. Bush signed the Genetic Information Nondiscrimination Act (GINA) into law in May 2008 (Public Law 110-233). This act prohibits health insurance providers and employers from discriminating against an individual based on genetic information. However, GINA does not protect against discrimination related to disability, life, and long-term care insurance. In addition, it does not apply to employers with fewer than 15 employees. Thus, while GINA may minimize some concerns related to pharmacogenetic testing, ethical concerns and fears associated with pharmacogenetic testing may remain.

Gene Therapy

Many of the ethical concerns with gene therapy center on transgenic manipulation of somatic versus germ line cells. Somatic gene therapy only affects the recipient. That is, genetic alterations introduced by gene therapy are not passed on to future generations. In contrast, with manipulation of germ line cells, alterations are passed on to future children of the treated patient. Some argue that this is unethical because it violates the rights of future generations. Thus, gene therapy in the foreseeable future will focus on somatic gene transfer.

ROLE OF CLINICIANS

Pharmacogenetics provides opportunities to improve drug therapy outcomes, but requires that clinicians be knowledgeable about genetic determinants of drug response. A challenge to pharmacogenomics implementation is that genotype needs to be considered in the context of important clinical factors, such as age, body size, and concomitant drug therapy,[98] in making drug therapy decisions. Another challenge is that multiple genetic variants may affect response to some drugs. For example, as described previously, both the *CYP2C9* (drug metabolism) and *VKORC1* (target site) genes contribute to response to warfarin.

Pharmacists are broadly trained in a number of medication-related areas, including pharmacology, pharmacokinetics, and pharmacodynamics. This places pharmacists in a unique position in dealing with the complexities of the drug-decision process in the era of pharmacogenetics. Pharmacists will

be in key positions to play valuable roles on multidisciplinary teams charged with interpreting genetic test results and choosing the most appropriate drug for a given patient based on genotype. Thus, it will be essential for pharmacists to stay abreast of significant pharmacogenetic discoveries and guideline updates.

Recognizing the challenges in healthcare delivery with advancing genetic discoveries, the National Coalition for Health Professional Education in Genetics established core competencies related to genetics for healthcare professionals that are available through the coalition's website (*www.nchpeg.org*). The objective of these competencies is to encourage clinicians to incorporate genetics knowledge, skills, and attitudes into their clinical practices. Subsequently, the American Association of Colleges of Pharmacy developed recommendations to guide academic institutions in instilling these competencies in future pharmacists so that pharmacists will be prepared to provide appropriate pharmacotherapy in the age of genomics.[99]

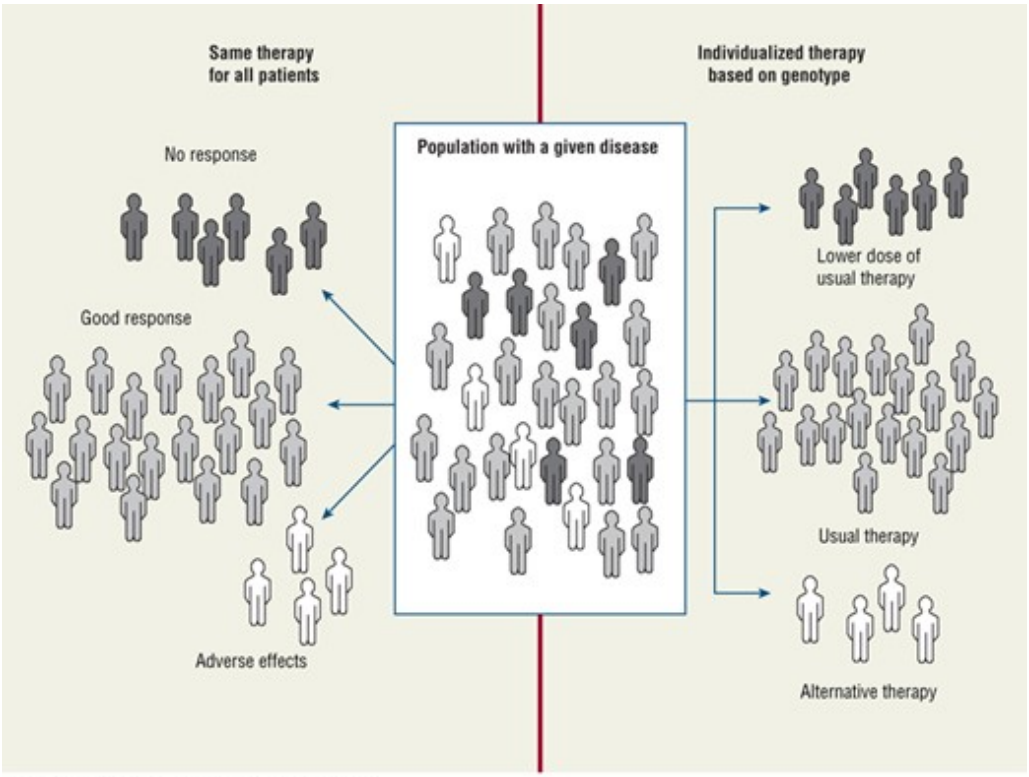
APPLICATION OF PHARMACOGENETIC DATA TO DISEASE MANAGEMENT

Pharmacogenetics has the potential to greatly improve drug use and therapy outcomes. Clinicians may be able to predict the likelihood that an individual will respond to a particular medication based on the patient's genotype. Medications may be avoided or prescribed in lower doses with careful monitoring in patients genetically predisposed to their adverse effects. This would be of particular benefit for narrow therapeutic index drugs. For example, warfarin may be initiated at lower doses with closer monitoring in patients with a *VKORC1* genotype associated with increased warfarin sensitivity or a *CYP2C9* allele associated with reduced warfarin metabolism.

With pharmacogenetics, it also may be possible to eliminate the trial-and-error approach to drug prescribing for many diseases. Instead, clinicians may be able to use genetic information to match the right drug to the right patient at the right dose while minimizing adverse effects. For example, the current approach to hypertension management involves the trial of various antihypertensives until blood pressure goals are achieved with acceptable drug tolerability. Commonly, the initial agent(s) fails to lower blood pressure to goal or produces intolerable adverse effects (**Fig. e5-7**). Trials of additional or alternative antihypertensive agents must be undertaken until treatment is deemed successful. In the interim, the patient remains hypertensive and at risk for hypertension-related target-organ damage. With pharmacogenetics, clinicians may choose the antihypertensive drug expected to provide the greatest response with the best tolerability for a particular patient based on his or her DNA.

FIGURE e5-7

Traditional and individualized approaches to pharmacologic management of disease.



New drugs may be developed based on knowledge about genetic control of cellular functions. For example, the discovery that CML was caused by chromosome translocation and consequent production of an enzyme capable of producing life-threatening lymphocyte levels led to accelerated FDA approval of imatinib (also known as STI-571), an inhibitor of the translocation-created enzyme, for treatment of CML.[101] In addition, future drug development may focus on treating specific genetic subgroups instead of broadly treating all individuals with a particular disease. Along these lines, the FDA is encouraging pharmaceutical companies to submit pharmacogenetic data during the drug development process. Ultimately, pharmacogenetics may improve the quality and reduce the overall costs of healthcare by decreasing the number of treatment failures and the number of adverse drug reactions and leading to the discovery of new genetic targets and therapeutic interventions for disease management.

Clinical Controversy…

For some drugs, such as warfarin and tricyclic antidepressants, variations in multiple genes may influence drug response. In the case of warfarin, genes affecting both pharmacokinetic and pharmacodynamic drug properties may interact to determine the ultimate effects from drug therapy. Both *CYP2D6* and *CYP2C19* genotypes affect response to some tricyclic antidepressants. Thus, the challenge for clinicians is to predict the ultimate response to medication based on a combination of gene variations. CPIC guidelines are available to assist with interpretation.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

A	adenine
ABC	ATP-binding cassette
ADRB1	β_1-adrenergic receptor gene
AHR	abacavir hypersensitivity reaction
ALK	anaplastic lymphoma kinase
AMPK	adenosine monophosphate-activated protein kinase
ATM	ataxia-telangiectasia mutated
ATP	adenosine triphosphate
AUC	area under the curve
C	cytosine
cAMP	cyclic adenosine monophosphate
CFTR	cystic fibrosis transmembrane conductance regulator
CML	chronic myeloid leukemia
CNS	central nervous system
CPIC	Clinical Pharmacogenetics Implementation Consortium
CYP	cytochrome P450
dbSNP	National Center for Biotechnology Information SNP database
DPD	dihydropyrimidine dehydrogenase
EGFR	epidermal growth factor receptor
EM	extensive metabolizer
ENCODE	ENCyclopedia of DNA Elements
FDA	Food and Drug Administration
G	guanine
G6PD	glucose-6-phosphate dehydrogenase
GDP	guanosine diphosphate
GINA	Genetic Information Nondiscrimination Act
GRK	G-protein coupled receptor kinase
GTP	guanosine triphosphate
GWAS	genome-wide association study
HER2	human epidermal growth factor receptor 2
HIV	human immunodeficiency virus
HLA	human leukocyte antigen
HMG-CoA	β-hydroxy-β-methylglutaryl-coenzyme A
IM	intermediate metabolizer
NIH	National Institutes of Health
OAT	organic anion transporter
OCT	organic cation transporter

PGRN	Pharmacogenomics Research Network
PharmGKB	Pharmacogenomics Knowledge Base
PM	poor metabolizer
SCID	severe combined immunodeficiency syndrome
SJS	Stevens–Johnson's syndrome
SLC	solute carrier
SNP	single nucleotide polymorphism
SSRI	selective serotonin reuptake inhibitor
SUR1	sulfonylurea receptor-1
T	thymidine
TA	thymine-adenine
TEN	toxic epidermal necrolysis
TPMT	thiopurine *S*-methyltransferase
UGT	uridine diphosphate glucuronosyltransferase
UM	ultrarapid metabolizer
VKOR	vitamin K oxidoreductase

Chapter e6: Pediatrics

Milap C. Nahata; Carol Taketomo

INTRODUCTION

KEY CONCEPTS

- 1 Children are not just “little adults,” and lack of data on important pharmacokinetic and pharmacodynamic differences has led to several disastrous situations in pediatric care.
- 2 Variations in absorption of medications from the gastrointestinal tract, intramuscular injection sites, and skin are important in pediatric patients, especially in premature and other newborn infants.
- 3 The rate and extent of organ function development and the distribution, metabolism, and elimination of drugs differ not only between pediatric versus adult patients but also among pediatric age groups.
- 4 The effectiveness and safety of drugs may vary among age groups and from one drug to another in pediatric versus adult patients.
- 5 Concomitant diseases may influence dosage requirements to achieve a targeted effect for a specific disease in children.
- 6 Use of weight-based dosing of medications for obese children may result in suboptimal drug therapy.
- 7 The myth that neonates and young infants do not experience pain has led to inadequate pain management in this pediatric population.
- 8 Special methods of drug administration are needed for infants and young children.
- 9 Many medicines needed for pediatric patients are not available in appropriate dosage forms; thus, the dosage forms of drugs marketed for adults may require modification for use in infants and children, necessitating assurance of potency and safety of drug use.

- 10 The pediatric medication-use process is complex and error prone because of the multiple steps required in calculating, verifying, preparing, and administering doses.

Remarkable progress has been made in the clinical management of diseases in pediatric patients. This chapter highlights important principles of pediatric pharmacotherapy that must be considered when the diseases discussed in other chapters of this book occur in pediatric patients, defined as those younger than 18 years. Newborn infants born before 37 weeks of gestational age are termed *premature;* those between 1 day and 1 month of age are *neonates;* 1 month to 1 year are *infants;* 1 to 11 years are *children;* and 12 to 16 years are *adolescents*. This chapter covers notable examples of problems in pediatrics, pharmacokinetic differences in pediatric patients, drug efficacy and toxicity in this patient group, and various factors affecting pediatric pharmacotherapy. Specific examples of problems and special considerations in pediatric patients are cited to enhance understanding.

1 Infant mortality up to 1 year of age has declined from 200 per 1,000 births in the 19th century to 75 per 1,000 births in 1925 and to 5.96 per 1,000 births in 2013.[1] This success has resulted largely from improvements in identification, prevention, and treatment of diseases once common during delivery and the infancy period. Although most marketed drugs are used in pediatric patients, only approximately one-fourth of the drugs approved by the US Food and Drug Administration (FDA) have indications specific for use in the pediatric population. Data on the pharmacokinetics, pharmacodynamics, efficacy, and safety of drugs in infants and children are scarce. Lack of this type of information led to disasters such as gray baby syndrome from chloramphenicol, phocomelia from thalidomide, and kernicterus from sulfonamide therapy. Gray baby syndrome was first reported in two neonates who died after excessive doses of chloramphenicol (100-300 mg/kg/day); the serum concentrations of chloramphenicol immediately before death were 75 and 100 mcg/mL (mg/L; 232 and 309 µmol/L). Patients with gray baby syndrome usually have abdominal distension, vomiting, diarrhea, a characteristic gray color, respiratory distress, hypotension, and progressive shock.

Thalidomide is well known for its teratogenic effects. Clearly implicated as the cause of multiple congenital fetal abnormalities (particularly limb deformities), thalidomide also can cause polyneuritis, nerve damage, and mental retardation. Isotretinoin (Accutane) is another teratogen, because it is used to treat severe acne vulgaris, which is common in teenage patients who may be sexually active but not willing to acknowledge that activity to healthcare professionals; isotretinoin has presented a difficult problem in patient education since its marketing in the 1980s.

Kernicterus was reported in neonates receiving sulfonamides, which displaced bilirubin from protein-binding sites in the blood to cause hyperbilirubinemia. This results in deposition of bilirubin in the brain and induces encephalopathy in infants.

Another area of concern in pediatrics is identifying an optimal dosage. Dosage regimens cannot be based simply on body weight or surface area of a pediatric patient extrapolated from adult data. Bioavailability, pharmacokinetics, pharmacodynamics, efficacy, and safety information can differ markedly between pediatric and adult patients, as well as among pediatric patients, because of differences in age, organ function, and disease state. Significant progress has been made in the area of pediatric pharmacokinetics during the past two decades, but few such studies have correlated pharmacokinetics with the outcomes of efficacy, adverse effects, or quality of life.

Several additional factors should be considered in optimizing pediatric drug therapy. Many drugs prescribed widely for neonates, infants, and children are not available in suitable dosage forms. For example, extemporaneous liquid dosage forms of amiodarone, baclofen, captopril, ursodiol, and spironolactone are prepared for infants and children who cannot swallow tablets or capsules, and injectable dosage forms of aminophylline, methylprednisolone, morphine, and phenobarbital are diluted to accurately measure small doses for neonates and infants. Alteration (dilution or reformulation) of dosage forms intended for adult patients raises questions about the bioavailability, stability, and compatibility of these drugs. Because of low fluid volume requirements and limited access to IV sites, special methods must be used for delivery of IV drugs to infants and children. As simple as it may seem, administration of oral drugs to young patients continues to be a difficult task for nurses and parents. Similarly, ensuring adherence to pharmacotherapy in pediatric patients poses a special challenge.

Finally, the need for additional pharmacologic or therapeutic research brings up the issue of ethical justification for conducting research. Investigators proposing studies and institutional review committees approving human studies must assess the risk-to-benefit ratio of each study to be fair to children who are not in a position to accept or reject the opportunity to participate in the research project.

Enormous progress in pharmacokinetics has been made in pediatric patients. Two factors have contributed to this progress: (a) the availability of sensitive and specific analytic methods to measure drugs and their metabolites in small volumes of biologic fluids and (b) awareness of the importance of clinical pharmacokinetics in optimization of drug therapy. Absorption, distribution, metabolism, and elimination of many drugs are different in premature infants, full-term infants, and older children, and this topic is discussed in detail in the next few sections.

ABSORPTION

Gastrointestinal Tract

2 Two factors affecting the absorption of drugs from the gastrointestinal tract are pH-dependent passive diffusion and gastric emptying time. Both processes are strikingly different in premature infants compared with older children and adults. In a full-term infant, gastric pH ranges from 6 to 8 at birth but declines to 1 to 3 within 24 hours.[2] In contrast, gastric pH remains elevated in premature infants because of immature acid secretion.[3]

In premature infants, higher serum concentrations of acid-labile drugs, such as penicillin,[4] ampicillin,[5] and nafcillin,[6] and lower serum concentrations of a weak acid such as phenobarbital[7] can be explained by higher gastric pH. Because of a lack of extensive data comparing serum concentration–time profiles after oral versus IV drug administration, differences in the bioavailability of drugs in premature infants are poorly understood. Although little is known about the influence of developmental changes with age on drug absorption in pediatric patients, a few studies with drugs (eg, digoxin and phenobarbital) and nutrients (eg, arabinose and xylose) have suggested that the processes of both passive and active transport may be fully developed by approximately 4 months of

age.[8] Little is known about the development and expression of the efflux transporter P-glycoprotein and the intestinal drug-metabolizing enzymes and their impact on drug absorption and bioavailability in infants and children.

Studies have shown that gastric emptying is slow in premature infants.[9] Thus, drugs with limited absorption in adults may be absorbed efficiently in premature infants because of prolonged contact time with gastrointestinal mucosa.

Intramuscular Sites

Drug absorption from an intramuscular site may be altered in premature infants. Differences in relative muscle mass, poor perfusion to various muscles, peripheral vasomotor instability, and insufficient muscular contractions in premature infants compared with older children and adults can influence drug absorption from the intramuscular site. The net effect of these factors on drug absorption is impossible to predict; phenobarbital has been reported to be absorbed rapidly,[10] whereas diazepam absorption may be delayed.[11] Thus, intramuscular dosing is used rarely in neonates except in emergencies or when an IV site is inaccessible.

Skin

Percutaneous absorption may be increased substantially in newborns because of an underdeveloped epidermal barrier (stratum corneum) and increased skin hydration. Furthermore, because the ratio of total body surface area (BSA) to total body weight is highest in the youngest group, the relative systemic exposure of topically applied drugs, including corticosteroids, may be higher in infants and young children than in adults. The increased exposure can produce toxic effects after topical use of hexachlorophene soaps and powders,[12] salicylic acid ointment, and rubbing alcohol.[13] Interestingly, a study has shown that a therapeutic serum concentration of theophylline can be achieved for control of apnea in premature infants less than 30 weeks' gestation after topical application of gel containing a standard dose of theophylline.[14] Use of this route of administration may minimize the unpredictability of oral and intramuscular absorption and the complications of IV drug administration for certain drugs. A transdermal patch formulation of methylphenidate has been approved for use in children 6 to 12 years of age for treatment of attention-deficit/-hyperactivity disorder (ADHD). The patch can be applied once daily and can remain on during normal activities such as bathing, swimming, and exercising.

Distribution

3 Drug distribution is determined by the physicochemical properties of the drug itself (pK_a, molecular weight, and partition coefficient) and the physiologic factors specific to the patient. Although the physicochemical properties of the drug are constant, the physiologic functions often vary in different patient populations. Some important patient-specific factors include extracellular and total body water, protein binding by the drug in plasma, and presence of pathologic conditions modifying physiologic function. Total body water, as a percentage of total body weight, has been

estimated to be 94% in fetuses, 85% in premature infants, 78% in full-term infants, and 60% in adults.[14] Extracellular fluid volume also is markedly different in premature infants compared with older children and adults; the extracellular fluid volume may account for 50% of body weight in premature infants, 35% in 4- to 6-month-old infants, 25% in 1-year-old children, and 19% in adults.[15] This conforms to the observed gentamicin distribution volumes of 0.48 L/kg in neonates and 0.20 L/kg in adults.[16] Studies have shown that the distribution volume of tobramycin is largest in the most premature infants and decreases with increases in gestational age and birth weight of the infant.[17]

Binding of drugs to plasma proteins is decreased in newborn infants because of decreased plasma protein concentration, lower binding capacity of protein, decreased affinity of proteins for drug binding, and competition for certain binding sites by endogenous compounds such as bilirubin. The plasma protein binding of many drugs, including phenobarbital, salicylates, and phenytoin, is significantly less in the neonate than in adults.[18] The decrease in plasma protein binding of drugs can increase their apparent volumes of distribution. Therefore, premature infants require a larger loading dose than older children and adults to achieve a therapeutic serum concentration of drugs such as phenobarbital[19] and phenytoin.[20]

The consequences of increased concentrations of free or unbound drug in the serum and tissues must be considered. Pharmacologic and toxic effects are related directly to the concentration of free drug in the body. Increases in free drug concentrations may result directly from decreases in plasma protein binding or indirectly from, for example, drug displacement from binding sites. Increased mortality from the development of kernicterus secondary to displacement of bilirubin from albumin and other serum proteins by sulfisoxazole in neonates is well documented.[21] However, because drug bound to plasma proteins cannot be eliminated by the kidney, an increase in free drug concentration also may increase its clearance.[22]

The amount of body fat is substantially lower in neonates than in adults, which may affect drug therapy. Certain highly lipid-soluble drugs are distributed less widely in infants than in adults. The apparent volume of distribution of diazepam has ranged from 1.4 to 1.8 L/kg in neonates and from 2.2 to 2.6 L/kg in adults.[23] In recent years, the number of mothers breastfeeding their infants has climbed. Thus, certain drugs distributed in breast milk may pose problems for the infants. The American Academy of Pediatrics (AAP) recommends that bromocriptine, cyclophosphamide, cyclosporine, doxorubicin, ergotamine, lithium, methotrexate, phenindione, codeine, and all drugs of abuse (eg, amphetamine, cocaine, heroin, marijuana, and phencyclidine [PCP]) not be used during breastfeeding. Use of nuclear medicines should be stopped temporarily during breastfeeding.[24] Note that these recommendations are based on limited data; other drugs taken over a prolonged period by the mother also may be toxic to the infant. For example, acebutolol, aspirin, atenolol, clemastine, phenobarbital, primidone, sulfasalazine, and 5-aminosalicylic acid have been associated with adverse effects in some nursing infants.[24] Unless the benefits outweigh the risks, the mother should avoid using any drug during pregnancy and while breastfeeding.

METABOLISM

Drug metabolism is substantially slower in infants than in older children and adults. There are important differences in the maturation of various pathways of metabolism within a premature infant. For example, the sulfation pathway is well developed, but the glucuronidation pathway is undeveloped in infants.[25] Although acetaminophen metabolism by glucuronidation is impaired in infants compared with adults, it is partly compensated for by the sulfation pathway. The cause of the tragic chloramphenicol-induced gray baby syndrome in newborn infants is decreased metabolism of chloramphenicol by glucuronyltransferases to the inactive glucuronide metabolite.[26] This metabolic pathway appears to be age related[27] and may take several months to 1 year to develop fully, as evidenced by the increase in clearance with age up to 1 year.[28]

Interestingly, higher serum concentrations of morphine are required to achieve efficacy in premature infants than in adults, in part because infants are not able to metabolize morphine adequately to its 6-glucuronide metabolite (20 times more active than morphine).[29] This is balanced to some degree by the fact that the clearance of morphine quadruples between 27 and 40 weeks of postconceptional age.

Metabolism of drugs, such as theophylline, phenobarbital, and phenytoin by oxidation, also is impaired in newborn infants. However, the rate of metabolism is more rapid with phenobarbital and phenytoin than with theophylline, perhaps because of the involvement of different cytochrome P450 (CYP) isozymes. Total clearance of phenytoin by CYP2C9 and, to a lesser extent, by CYP2C19 surpasses adult values by 2 weeks of age, whereas theophylline clearance is not fully developed for several months.[18] Two additional observations about theophylline metabolism by CYP1A2 in pediatric patients should be noted. First, in premature infants receiving theophylline for treatment of apnea, a significant amount of its active metabolite caffeine may be present, unlike the case in older children and adults.[18] Second, theophylline clearance in children 1 to 9 years of age exceeds the values in infants as well as adults. Thus, a child with asthma often requires markedly higher doses on a weight basis of theophylline compared with an adult.[30] Because of decreased metabolism, daily doses of drugs such as theophylline, phenobarbital, phenytoin, and diazepam should be decreased in premature infants.

The clearance of unbound *S*-warfarin, a substrate of CYP2C9, was substantially greater in prepubertal children than among pubertal children and adults even after adjustment for total body weight.[31] Finally, clearance of caffeine, metabolized by demethylation, declines to adult values when girls reach Tanner stage II (early puberty) and boys reach Tanner stages IV and V (late puberty).[32] The knowledge of pharmacogenetics and pharmacogenomics now is being applied to patient care in some instances. 6-Mercaptopurine (6-MP), a drug commonly used in pediatric leukemias, undergoes metabolism that is facilitated by thiopurine *S*-methyltransferase (TPMT). The inherited deficiency (an autosomal recessive trait), which occurs in 6% to 11% of patients, is primarily explained by three polymorphisms in the *TPMT* gene (**2*, **3A*, and **3C*). Children homozygous for one of the variant alleles require 6-MP dose reduction of approximately 90%, and heterozygotic children need a dose reduction of approximately 50% to achieve survival rates observed in patients receiving full doses in the absence of TPMT deficiency. Thus, *TPMT* screening is recommended to identify patients with genotypes associated with TPMT deficiency who may benefit from dose reductions to prevent toxicity.[33]

ELIMINATION

Drugs and their metabolites are often eliminated by the kidney. The glomerular filtration rate (GFR) may be as low as 0.6 to 0.8 mL/min per 1.73 m^2 (0.006-0.008 mL/s/m^2) in preterm infants and approximately 2 to 4 mL/min per 1.73 m^2 (0.02-0.04 mL/s/m^2) in term infants. The processes of glomerular filtration, tubular secretion, and tubular reabsorption determine the efficiency of renal excretion. These processes may not develop fully for several weeks to 1 year after birth.

Studies in infants have shown that tobramycin clearance during the first postnatal week may increase with an increase in gestational age.[17] In infants up to 1 month after birth, postnatal age also was correlated directly with aminoglycoside clearance.[28] Thus, premature infants require a lower daily dose of drugs eliminated by the kidney during the first week of life; the dosage requirement then increases with age.

Because of immature renal elimination, chloramphenicol sodium succinate can accumulate in premature infants. Although chloramphenicol sodium succinate is inactive, this accumulation may be the reason for an increased bioavailability of the biologically active, chloramphenicol in premature infants compared with older children.[27] These data indicate that dose-related toxicity may result from an underdeveloped glucuronidation pathway as well as increased bioavailability of chloramphenicol in premature infants.

DRUG EFFICACY AND TOXICITY

4 Besides the pharmacokinetic differences previously identified between pediatric and older patients, factors related to drug efficacy and toxicity also should be considered in planning pediatric pharmacotherapy. Unique pathophysiologic changes occur in pediatric patients with some disease states.

Examples of pathophysiologic and pharmacodynamic differences are numerous. Clinical presentation of chronic asthma differs in children and adults. Children present almost exclusively with a reversible extrinsic type of asthma, whereas adults have nonspecific, nonatopic bronchial irritability. This explains the value of adjunctive hyposensitization therapy in the management of pediatric patients with extrinsic asthma.[34]

The maintenance dose of digoxin is substantially higher in infants than in adults. This is explained by a lower binding affinity of receptors in the myocardium for digoxin and increased digoxin-binding sites on neonatal erythrocytes compared with adult erythrocytes.[35] Insulin requirements are highest during adolescence because of the individual's rapid growth. Growth hormone therapy has allowed children with growth hormone deficiency to attain greater adult height. However, a study has shown that in "normal" short children (without growth hormone deficiency), early and rapid pubertal progression by growth hormone therapy may lead to a shorter final adult height than may have been attained naturally.[36] This finding emphasizes the need for identifying specific indications for the effective and safe use of drugs in pediatric patients.

Certain adverse effects of drugs are most commonly seen in the newborn period, whereas other toxic effects may not be apparent for a long period of time because of difficulty in assessing extended medication safety. Promethazine now is contraindicated for use in children younger than 2 years because of the risk of severe respiratory depression. Chloramphenicol toxicity is increased in newborns because of immature metabolism and enhanced bioavailability. Codeine toxicity and death have been reported after tonsillectomy and adenoidectomy in children who were ultrarapid metabolizers receiving codeine within the typical dose range.[104] Thus, codeine should not be used in these patients. Similarly, propylene glycol, which is added to many injectable drugs, including phenytoin, phenobarbital, digoxin, lorazepam, vitamin D, and hydralazine, to increase their stability, can cause hyperosmolality in infants.[37] It is also present in formulations of oral drugs, including acetaminophen, diphenhydramine, furosemide, ibuprofen, and prednisone.

Benzyl alcohol was a popular preservative used in intravascular flush solutions until a syndrome of metabolic acidosis, seizures, neurologic deterioration, gasping respirations, hepatic and renal abnormalities, cardiovascular collapse, and death was described in premature infants. A decline in both mortality and the incidence of major intraventricular hemorrhage was documented after use of solutions containing benzyl alcohol was stopped in low-birth-weight infants.[38] It is also used as a preservative in parenteral dexamethasone, methylprednisolone, enoxaparin, midazolam, and multivitamin formulations.

Ethanol is present in certain oral drugs, including phenobarbital and ranitidine; and, sorbitol is used in oral liquids, including diphenhydramine, ferrous sulfate, furosemide, ondansetron, and prednisone. It is important to note that safe and acceptable levels of intake of many excipients have not been determined for infants and children.

The common cold occurs frequently in infants and children and is often treated with antihistamines, decongestants, antitussives, and expectorants. Given the lack of evidence for their efficacy and serious toxicities associated with overdoses, the FDA issued a public health advisory in 2008 recommending that these drugs not be used in children younger than 2 years of age. The manufacturers have voluntarily agreed to label these medications not for use in children younger than 4 years of age.

Tetracyclines are contraindicated for use in pregnant women, nursing mothers, and children younger than 8 years because these drugs can cause dental staining and defects in enamelization of deciduous and permanent teeth, as well as a decrease in bone growth.[39] However, the Centers for Disease Control and Prevention (CDC) has recommended the use of doxycycline for initial prophylaxis after suspected bioterrorism-related exposure to *Bacillus anthracis* (anthrax); the potential benefits outweigh potential risks among infants and children.

Clinical Controversy…

Are over-the-counter (OTC) cough and cold products effective and safe in young children? Young children get 6 to 8 episodes of colds each year and are thus treated with a variety of OTC medications, including nasal decongestants, antihistamines, expectorants, antitussives and combination products. Caregivers may believe them to be safe because they are sold without a

prescription. However, their efficacy in young children has not been documented. In addition, numerous reports from the literature and the CDC have raised concerns about their safe use. Thus, the FDA does not recommend use of these agents in children younger than 2 years of age. The manufacturers have voluntarily agreed to label these products not for children younger than 4 years of age.

Clinical Controversy…

Are fluoroquinolones safe in pediatric patients younger than 1 year? Antibiotics of the fluoroquinolone class (eg, ciprofloxacin) are generally not recommended for pediatric patients or pregnant women because of an association between these drugs and the development of permanent lesions of the cartilage of weight-bearing joints and other signs of arthropathy in immature animals of various species.[40] However, there are exceptions. The manufacturer states that ciprofloxacin can be used in pediatric patients younger than 18 years of age **only** for inhalation anthrax (postexposure) or for treatment of complicated urinary tract infections and pyelonephritis caused by susceptible *Escherichia coli*. The AAP and Infectious Disease Society of America suggest that their use may be justified for certain other conditions (eg, endocarditis and multidrug-resistant gram-negative infections). Reversible arthralgia, sometimes accompanied by synovial effusion, was associated with ciprofloxacin therapy in 1.8% of pediatric patients with cystic fibrosis.[40] Fluoroquinolones may also be associated with tendonitis and tendon rupture in certain patients. Although these drugs are used to treat certain infections in pediatric populations, additional safety data are needed before these drugs can be prescribed routinely, especially in patients younger than 1 year of age.

Some drugs may be less toxic in pediatric patients than in adults. Aminoglycosides appear to be less toxic in infants than in adults. In adults, aminoglycoside toxicity is related to both peripheral compartment accumulation and the individual patient's inherent sensitivity to these tissue concentrations.[41] Although neonatal peripheral tissue compartments for gentamicin have been reported to closely resemble those of adults with similar renal function,[16] gentamicin infrequently is nephrotoxic in infants. This dissimilarity in the incidence of nephrotoxicity implies that newborn infants have less inherent tissue sensitivity for toxicity than do adults.

The differences in efficacy, toxicity, and protein binding of drugs in pediatric versus adult patients raise an important question about the acceptable therapeutic range in children. Therapeutic ranges for drugs are first established in adults and often are applied directly to pediatric patients, but specific efficacy and safety studies should be conducted in pediatric patients to define optimal therapeutic ranges of drugs.

Clinical Controversy…

Are antidepressants safe and effective in children and adolescents? Because of observations of increased suicidality among adolescents (and adults, for that matter), experts are questioning whether these medications merely bring out an increased suicide risk that the patient has suppressed or has been too depressed to act on, or these medications actually increase the risk per se through some pharmacologic effect. Some selective serotonin reuptake inhibitors (SSRIs)—fluoxetine, sertraline, and fluvoxamine—are approved for use in pediatric patients in the United States. The

British regulatory agency banned the use of another SSRI, paroxetine, in 2003 after analysis of the data indicated the occurrence of suicidal thoughts or episodes of self-harm at a rate 1.5 to 3.2 times higher than that with placebo. Subsequently, the FDA added a black box warning about the use of and need for monitoring SSRI therapy in pediatric patients, and FDA action has continued in this arena; thus, these drugs should be used cautiously with consideration of risks versus benefits.

FACTORS AFFECTING PEDIATRIC THERAPY

5 Because most drugs are either metabolized by the liver or eliminated by the kidneys, hepatic and renal diseases are expected to decrease the dosage requirements in patients. Nevertheless, not all diseases require lower doses of drugs. For instance, patients with cystic fibrosis require larger doses of certain drugs to achieve therapeutic concentrations.[42]

Hepatic Disease

Because the liver is the main organ for drug metabolism, drug clearance usually is decreased in patients with hepatic disease. However, most studies on the influence of hepatic disease on dosage requirements have been performed in adults, and these data may not be extrapolated uniformly to pediatric patients.

Drug metabolism by the liver depends on complex interactions among hepatic blood flow, ability of the liver to extract the drug from the blood, drug binding in the blood, and both type and severity of hepatic disease. Routine hepatic function tests, such as determinations of serum aspartate aminotransferase, serum alanine aminotransferase, alkaline phosphatase, and bilirubin levels, have not correlated consistently with drug pharmacokinetics. Furthermore, because of different pathologic changes in various types of hepatic diseases, patients with acute viral hepatitis may have different abilities to metabolize drugs than patients with alcoholic cirrhosis.[43]

On the basis of hepatic extraction characteristics, drugs can be divided into two categories. The first category consists of drugs with a high hepatic extraction ratio (greater than 0.7; such drugs include morphine, meperidine, lidocaine, and propranolol). Clearance of these drugs is affected by hepatic blood flow. Decreased hepatic blood flow in the presence of disease states, such as cirrhosis and congestive heart failure, is expected to decrease the clearance of drugs with high extraction ratios. The second category consists of drugs with a low extraction ratio (<0.2) and a low affinity for plasma proteins. Metabolism of these drugs (eg, theophylline, chloramphenicol, and acetaminophen) is influenced mainly by hepatocellular function and not as much by changes in hepatic blood flow or plasma protein binding. One report suggested that theophylline clearance may decrease by 45% in a child with acute viral hepatitis.[43] Because of a lack of specific data on dosage adjustment in hepatic disease, drug therapy should be monitored closely in pediatric patients to avoid potential toxicity from excessive doses, particularly for drugs with narrow therapeutic indices.

Renal Disease

Renal failure decreases the dosage requirement of drugs eliminated by the kidneys. Again, because of

limited studies, dosage adjustments in pediatric patients are based largely on data obtained in adults. For many important drugs, such as aminoglycoside antibiotics, renal clearance or rate of elimination is directly proportional to the GFR, as measured by endogenous renal creatinine clearance.

In clinical practice, GFR can be estimated from prediction equations, such as the Schwartz formula, which takes into account serum creatinine concentration and the patient's height, gender, and age. The advantage of estimating GFR using the Schwartz equation is rapid determination and the avoidance of a cumbersome 24-hour urine collection.[44,45] The following formula is used to estimate GFR:

$$GFR = K \times L/S_{Cr}$$

where GFR is expressed in milliliters per minute per 1.73 m^2 of BSA, K = age-specific constant of proportionality (see below), L = child's length in centimeters, and S_{Cr} = serum creatinine concentration in milligrams per deciliter. Alternatively, for serum creatinine concentration expressed in µmol/L, the equation becomes: $GFR = K \times L \times 88.4/S_{cr}$. Conversion of GFR to units of mL/s/m^2 requires multiplication of GFR expressed in milliliters per minute per 1.73 m^2 by 0.00963.

Favorite Table | Download (.pdf) | Print

Age	*K*
<1 year of age, low-birth-weight infant	0.33
<1 year of age, full-term infant	0.45
2- to 12-year-old child	0.55
13- to 21-year-old female	0.55
13- to 21-year-old male	0.70

Studies comparing the Schwartz-predicted GFR versus measured GFR noted that the Schwartz formula overestimated GFR in patients with decreasing GFR. The formula may not provide an accurate estimation of GFR in patients with rapidly changing serum creatinine concentrations, as seen in the critical care setting; in infants younger than 1 week; and in patients with obesity, malnutrition, or muscle wasting. Factors that interfere with serum creatinine measurement also may cause errors in estimation of GFR.

Changes in laboratory methods for measuring serum creatinine levels have led to the development of an updated equation to estimate GFR in children with mild to moderate renal function impairment. Use of the old Schwartz equation with a serum creatinine level determined using current laboratory methods leads to an overestimation of GFR by approximately 10% to 20%.[46] Schwartz et al. assessed GFR in 349 children enrolled in the Chronic Kidney Disease in Children Study, ages 1 to 16 years, using plasma iohexol clearance.[47] The updated formula derived from changes in laboratory methods for serum creatinine measurement is as follows:

$$\text{eGFR}(\text{mL/min/1.73m}^2) = 39.1 \times (\text{height}[\text{m}]/S_{\text{Cr}}[\text{mg/dL}])^{0.516} \times (1.8/\text{cystatin C}[\text{mg/L}])^{0.294} \times (30/\text{BUN}[\text{mg/dL}])^{0.169} \times (1.099)^{\text{if male}} \times (\text{height}[\text{m}]/1.4)^{0.188}$$

A simplified prediction equation (frequently referred as Bedside Schwartz equation) was also proposed[48,49]:

$$\text{eGFR}(\text{mL/min/1.73m}^2) = 0.413\ (\text{height}[\text{cm}]/S_{\text{Cr}})$$

Note: The updated formulas do not provide an accurate estimation of GFR in patients with normal renal function or patients with advanced renal failure because these populations are outside the range of those enrolled in the Chronic Kidney Disease in Children Study. (To use these equations, S_{Cr} expressed in µmol/L must first be divided by 88.4 to obtain conventional units of mg/dL, and blood urea nitrogen expressed in mmol/L must be divided by 0.357 to obtain conventional units of mg/dL. Conversion of GFR to units of mL/s/m^2 requires multiplication of GFR expressed in milliliters per minute per 1.73 m^2 by 0.00963.) In addition, the estimated GFR values may be lower than actual for infants and adolescents and higher for low birth weight infants less than 1 year.

Serum drug concentrations should be monitored for drugs with narrow therapeutic indices and eliminated largely by the kidneys (eg, aminoglycosides and vancomycin) to optimize therapy in pediatric patients with renal dysfunction. For drugs with wide therapeutic ranges (eg, penicillins and cephalosporins), dosage adjustment may be necessary only in patients with moderate to severe renal failure.

Cystic Fibrosis

Drug therapy in pediatric patients with cystic fibrosis has been reviewed.[50] For unknown reasons, these patients require increased doses of certain drugs. Studies have reported higher clearance of drugs, such as gentamicin, tobramycin, netilmicin, amikacin, dicloxacillin, cloxacillin, azlocillin, piperacillin, and theophylline, in patients with cystic fibrosis compared with patients without the disease. The apparent volume of distribution of certain drugs also may be altered in cystic fibrosis.[50] The severity of the illness may influence the change in dosage requirements, but this is not certain. Chapter 18 reviews these changes in detail.

Obesity

1 Although there was a 43% drop in the obesity rate among 2-to-5 year-old children over the past decade as reported in 2012, one-third of American children and adolescents continue to be obese or overweight.[105] The prevalence of pediatric obesity has nearly tripled for children 2 to 5 years of age and for those 12 to 19 years of age; it has quadrupled for children 6 to 11 years of age over the past 30 years.[51,52] Children and adolescents are classified as being overweight or obese according to CDC age- and gender-specific percentiles for body mass index (BMI). The CDC and the AAP categorize overweight children as having a BMI percentile greater than 85th to less than 95th and obese

children as having a BMI percentile of greater than the 95th percentile.[53]

Obese children are at risk for metabolic complications and the development of comorbid conditions, including high blood pressure, high cholesterol, type 2 diabetes mellitus, nonalcoholic fatty liver disease, polycystic ovary disorder, cholecystitis, gastroesophageal reflux disease, and obstructive sleep apnea.[54] During a 1999 to 2008 study period, 49% of overweight and 61% of obese adolescents had one or more cardiovascular risk factor, which included prehypertension or hypertension, low high-density lipoprotein cholesterol and high low-density lipoprotein cholesterol, and elevated fasting glucose level.[55]

A 50% increased recurrence of acute lymphoblastic leukemia in obese children older than 10 years of age compared with lean children with cancer has also been reported.[56] Studies show that obesity can directly impair the antileukemia efficacy of first-line chemotherapeutic agents and accelerate leukemia progression.[57] Adipocytes attract acute lymphoblastic leukemia (ALL) cells to migrate closer to fat cells which absorb chemotherapy decreasing its exposure to the cancer cells. Adipocytes secrete asparagine, glutamine, and fatty acids that contribute to the survival of leukemia cells lessening the probability of the patient's survival.[106] In addition, higher rates of life-threatening or fatal complications to chemotherapy have been reported with obese children and adolescents than normal-weight children. A retrospective study compared safety and efficacy between obese and normal-weight children who received methotrexate, teniposide, etoposide, and cytarabine for treatment of acute lymphoblastic leukemia. No significant difference existed on the basis of BMI in the rate of complete remission, overall survival, incidence of relapse, and frequency of toxicity. Chemotherapy doses were based on BSA calculated using total body weight for all children. Findings suggest that the doses of cytarabine, etoposide, teniposide, and methotrexate in obese children should be based on BSA calculated using total body weight.[58] These findings are consistent with the recommendations for appropriate chemotherapy dosing in adult obese patients, which advise use of the patient's actual body weight when calculating the dose and not limiting the dose or using an adjusted ideal body weight unless there is an established dosing limit. Limiting the dose in obese patients may lead to poorer outcomes and undertreatment.[59] Obesity is also associated with cancer mortality. Calle et al.[107] found that obesity is responsible for more than 90,000 cancer deaths per year in the United States. However, obese patients who achieved normal or overweight status for greater than 50% of the treatment duration had outcomes comparable to those in normal or overweight individuals.[108]

Obese children have a higher proportion of body fat, which generally results in a higher volume of distribution (V_D) for lipophilic drugs and a lower V_D for hydrophilic medications compared with normal-weight children. Obese children have higher total body water, lower percent lean mass, increased organ mass, and greater cardiac output, GFR, and serum creatinine concentrations than normal-weight children.[60] Many antibiotics are hydrophilic medications that distribute to extracellular water. Adipose tissue contains approximately 30% water, meaning that many antibiotics will not distribute adequately in obese patients.

Correction factors have been used to adjust drug dosing in obese children. A correction factor is

multiplied by the actual body weight less the ideal body weight, and this figure is added to the ideal body weight. The drug dose is then determined based on this weight. Correction factors are 0.3 for β-lactams, 0.45 for ciprofloxacin, and 0.4 for aminoglycosides.

When possible, plasma drug level monitoring should be used to adjust dosing; very few studies have been conducted to establish effective drug dosing information for obese children.[61]

Vancomycin distributes into total body water and other tissues and is eliminated primarily by glomerular filtration. Vancomycin is empirically dosed using actual body weight in overweight and obese children; the dose is not capped at the usual maximum adult dose. Every-8-hour dosing is used initially; the frequency can be increased to every-6-hour dosing for complicated infections using serum concentration monitoring to individualize the dose.[62]

Obesity may affect warfarin dosage requirements in pediatric patients. Obese pediatric patients had an increased time to reach therapeutic INR values with the use of institutional dosing guidelines.[109] Additional studies are needed to determine warfarin dosage requirements in obese versus nonobese pediatric patients.

Pharmacokinetic studies of anesthetic agents in obese children have not been conducted to characterize distribution, adipose tissue accumulation, and elimination. One study showed that obese children lose consciousness at a significantly lower propofol dose than patients with a healthy weight. Whereas an IV propofol dose of 2 mg/kg was effective in 95% of children with BMIs above the 95th percentile, those with lower BMIs each required a higher dose of 3.2 mg/kg.[63]

Specific studies are needed to identify the effects of childhood obesity on pharmacokinetics, pharmacodynamics, and efficacy of medications so that optimal drug dosing can be determined for this population.

Other Conditions

Although specific dosage guidelines are not available, pediatric patients with gastrointestinal disease (eg, celiac disease, gastroenteritis, and severe malabsorption) may require dosage adjustments.[41] Hypoxemia also has been shown to decrease the elimination of amikacin in low-birth-weight infants.[64] Critically ill adult and pediatric patients with severe head trauma require higher than normal doses of phenytoin in part because of increased intrinsic clearance.[65]

ISSUES IN PEDIATRIC DRUG THERAPY

Pain Management

7 For many years, the term *pain* could not be found in the index of any major pediatric medicine or pediatric surgical textbook.[66] The prevailing wisdom was that neonates did not experience pain because of their inadequately developed neuroendocrine systems and nerve pathways. During the last years of the 20th century, however, many research and clinical studies were performed in the

areas of pain management and assessment of neonates, infants, children, and adolescents. Today, results of these discoveries have been incorporated into clinical practice, making effective pain therapy a standard of care and pain assessment the fifth vital sign in modern pediatric practice.[67]

The basic mechanisms of pain perception in infants and children are similar to those of adults, except that pain impulse transmission in neonates occurs primarily along slow-conducting, unmyelinated C fibers rather than along myelinated A-delta fibers. In addition, pain signal transmission in the spinal cord is less precise, and descending inhibitory neurotransmitters are lacking. As a result, neonates and young infants may perceive pain more intensely and be more sensitive to pain than older children or adults.[68] It is now known that previous pain experience leads to long-term consequences such as alterations in response to a subsequent painful event.[69] Taddio et al.[70,71] reported that boys circumcised with the topical anesthetic eutectic mixture of local anesthetics (EMLA) had lower pain responses to subsequent immunizations than those who were circumcised without topical anesthesia. An inadequately treated initial painful procedure may decrease the effect of adequate analgesia in subsequent procedures as a result of altered pain response patterns.

Children consistently report that needles and shots are what they fear most. However, with the current immunization schedule that recommends 14 to 33 injections before adolescence, interventions to decrease injection pain need to be performed (**Table e6-1**).[72,73,74,75,76,77]

TABLE e6-1 Techniques for Minimizing Pain Caused by Injection

Pharmacologic Methods	
EMLA[72,110]	*Advantages:* Penetrates the skin to provide anesthesia to a depth of 5 mm; effective in decreasing the pain of IM and subcutaneous injections, venipuncture, IV cannulation, lumbar puncture, circumcision, skin-graft harvesting, and laser dermal therapy; safe and effective in newborns >37 weeks' gestation. Disc formulation is easier to apply; no need for an occlusive dressing *Disadvantages:* Requires 1 hour before onset of adequate anesthesia, has a vasoconstrictive effect that may make starting IV catheters difficult, may induce methemoglobinemia
J-tip with buffered lidocaine[73,78]	*Advantages:* Provides dermal anesthesia to a depth of 5-8 mm within 1-3 minutes; effective in decreasing the pain of IV cannulation *Disadvantage:* Makes a popping noise; this can scare a patient who is not properly prepared
Vapocoolant sprays (ethyl chloride or dichlorodifluoromethane)[74]	*Advantages:* Vapocoolant is sprayed directly onto the skin or applied to a cotton ball that is held on the area to be anesthetized; provides local anesthesia within 15 seconds; effective in reducing injection pain in children 4–6 years of age *Disadvantages:* Brief duration of action, so procedure should be

	completed in 1 or 2 minutes; may not be effective in reducing injection pain in infants age 2-6 months *Advantage:* Reduces the pain of subsequent needle insertion
Local anesthetic (lidocaine)[75]	*Disadvantage:* Local anesthetic injection itself is associated with pain and burning sensation
	For preterm neonates: 0.1-0.4 mL of a 12%-24% sucrose solution (place on pacifier or the tongue 2 minutes before procedure); *for term neonates:* 1-2 mL of a 12%-24% sucrose solution (place on pacifier or the tongue 2 minutes before procedure)
Pacifier with sucrose[76]	*Advantage:* Noninvasive method to reduce pain associated with needle insertion in infants
	Disadvantage: Sucrose solution's effect in reducing pain gradually decreases over time; loses efficacy by 4 to 6 months of age
Other Techniques	
Site selection[77]	*For children older than 18 months:* Use of the deltoid muscle for IM injections is associated with less pain than injections administered in the thigh; *for children older than 3 years*: Use of the ventrogluteal area for injection is associated with less pain than the anterior thigh or dorsogluteal area
Z-tract technique	Z-tract IM injection technique is less painful (pull skin taut at the injection site, give injection, and then release the skin); use a higher-gauge needle when the injectable solution is not viscous
Behavioral	Use of distraction methods (eg, blowing bubbles, providing music by headphones, relaxation, imagery, self-hypnosis, or having parents present for the procedure) can be helpful

EMLA, eutectic mixture of lidocaine and prilocaine; IM, intramuscular.

Pharmacologic pain management for medical conditions and surgical and postoperative events has progressed considerably over the past decade with the use of continuous opioid infusions, epidural anesthesia, peripheral nerve blockade, local anesthetics, nonsteroidal antiinflammatory drugs, different routes for traditional agents (ie, transmucosal and transdermal), and nonopioid adjuvant drugs (**Table e6-2**).[79,80,81,82] New pain management techniques, education, research, and increasing awareness of pain management options have helped to improve the quality of life in children.

TABLE e6-2 Opioid Administration for Acute and Severe Pain

Intermittent IV or PO bolus administration (not as needed)	Weak opioids (eg, codeine, hydrocodone, and oxycodone) often are combined with acetaminophen or an NSAID for moderate pain. With dose escalation of combination oral products, be aware that the dose does not exceed recommended daily amounts for acetaminophen or ibuprofen. 1%-7% of the general population and up to 28% of some ethnic groups have a genetic variation in the enzyme

	cytochrome P450 2D6 that causes codeine to be converted to morphine faster and more completely. In 2012, the FDA issued a Drug Safety Communication stating that codeine use in certain children after tonsillectomy or adenoidectomy for obstructive sleep apnea syndrome has lead to deaths and life-threatening respiratory depression. Consider alternative analgesics for children undergoing tonsillectomy or adenoidectomy. If codeine or codeine-containing products are prescribed, use the lowest effective dose for the shortest period of time on an as-needed basis.[83] IV administration of codeine has been associated with allergic reactions related to histamine release. Parenteral administration of codeine is not recommended. Intermittent opioid administration is associated with wide fluctuation between peak and trough levels, so the patient may alternate between peak blood levels associated with untoward effects and trough levels associated with inadequate pain relief when being treated for severe pain. Oxycodone and morphine are available in a sustained-release formulation for use with chronic pain (not acute pain). The tablet must be swallowed whole and cannot be administered to patients through gastric tubes.
IV continuous infusion[79,80]	Loading dose is administered to achieve rapidly a therapeutic blood level and pain relief (ie, morphine loading dose of 0.05-0.15 mg/kg in children; 0.1 mg/kg infused over 90 minutes in neonates). Loading dose is followed by a maintenance continuous infusion. Doses that are considered safe in children can cause respiratory depression and seizures in neonates because of decreased clearance, immature blood–brain barrier at birth that is more permeable to morphine, and an increased unbound fraction of morphine that increases CNS effects of the drug.
PCA[81]	Gives patient some control over his or her pain therapy. PCA allows the patient to self-administer small opioid doses. The PCA-Plus (Abbott, Chicago, IL) pump allows the patient to receive a continuous infusion together with a set number of self-administered doses per hour. PCA helps to eliminate wide peak and trough fluctuations so that levels remain in a therapeutic range. Children as young as 6 or 7 years of age can master the use of PCA.
Epidural and intrathecal analgesia[82]	Effective in the management of severe postoperative, chronic, or cancer pain. Spinal opioids can be administered by a single bolus injection into the epidural or subarachnoid space or by continuous infusion via an indwelling catheter. Dosage requirement by these routes is significantly less than with IV administration (epidural opioid doses: 10-fold lower than IV doses; intrathecal opioid doses: 100-fold lower than IV doses). Morphine, hydromorphone, fentanyl, and sufentanil are effective when administered intrathecally. Bupivacaine is the most commonly used local anesthetic in continuous epidural infusions. Fentanyl, morphine, or hydromorphone usually is combined with bupivacaine for epidural infusions.
	Transdermal administration. Fentanyl and buprenorphine are available as a transdermal formulation. Multiple patches of an agent may be applied for patients who require higher doses.

	Disadvantage of transdermal administration is the requirement for an alternative short-acting opioid for break-through pain.
Transmucosal administration	Fentanyl lozenge is absorbed transmucosally. It is useful for providing analgesia during painful procedures. Advantages include rapid onset of action (within 15 minutes), short duration of action (60-90 minutes), and painless administration because no injection is needed. Common side effects are vomiting and mild to moderate oxygen desaturation. Doses of 10-15 mcg/kg provide blood levels equivalent to 3-5 mcg/kg IV.

FDA, Food and Drug Administration; IM, intramuscular; NSAID, nonsteroidal antiinflammatory drug; PO, by mouth; PCA, patient-controlled analgesia.

Drug Administration

8 Drugs often are given by the IV route to seriously ill patients. Syringe pumps are widely used for administration of IV drugs. Important steps in successfully administering IV drugs include selecting the drug, calculating the dose, preparing the infusion, programming the infusion pump, and delivering the infusion. Use of "smart" pumps is preferred because they can recognize syringes and have drug libraries and dose limits as safety features. The pumps should be accurate, precise, and easy to use; accept syringes and administration sets from various manufacturers; offer extensive delivery mode combinations, including milliliters per hour, body weight, mass, volume over time, custom dilution and intermittent, loading dose, bolus dose, standby, and volume limit; have wide-ranging flow rates and rate to keep vein open; and have an adequate internal battery capacity.

No single infusion system is ideal for delivery of all drugs in all institutions for all patients. Each facility must be cognizant of problems of drug delivery and develop specific guidelines for IV infusions. At each institution, specific guidelines should be provided for administration of each drug. These guidelines take into account various infusion rates and provide consistency of delivery with each dose. As long as the time for actual delivery is known, times to obtain blood samples for measurement of drug concentration can be adjusted accordingly to generate meaningful data.

Alteration of Dosage Forms

9 Many drugs used in pediatric patients are not available in suitable dosage forms. This necessitates dilution of high concentrations of drugs intended for adult patients. Examples of these drugs include atropine, diazepam, digoxin, fentanyl, epinephrine, hydralazine, insulin, morphine, phenobarbital, and phenytoin. Volumes ranging from 0.01 to 0.1 mL must be measured to dispense these drugs for use in infants. This obviously can be associated with large errors in measurements, and such errors have caused intoxication with digoxin[84] and morphine[85] in infants. One solution to this problem is to dilute these concentrated products, but such alterations can influence the stability or compatibility of these drugs. Because of limited data, pharmacists justifiably may be reluctant to alter dosage forms of certain drugs.

Selection of the appropriate vehicle to dilute the adult dosage forms for use in pediatric patients can

be difficult. Phenobarbital sodium contains propylene glycol in the original product to improve drug stability. Because propylene glycol can cause hyperosmolality in infants,[36] further addition of this vehicle may not be wise. Because of limited access to IV sites in pediatric patients, drugs must be administered through the same site; however, data on drug compatibilities often are missing. Newborn infants often require aminoglycosides for presumed or proven sepsis and calcium gluconate for correction of hypocalcemia or calcium supplementation. Tobramycin and calcium gluconate have been found to be compatible, at least during a 1-hour administration at the same site.[85]

Administration of oral drugs continues to challenge parents and nurses. Alteration of these drugs by crushing or mixing, refusal of patients to accept the medication, and loss of drug during administration are some factors that can affect pediatric therapy. A common practice is to mix medications in applesauce, syrup, ice cream, or other vehicles just before administration to make the drugs palatable. In 2015, the FDA has approved levetiracetam (Spritam) that uses 3D printing technology, paving the way for potential customization of drugs to meet the needs of pediatric patients. It uses a delivery system that creates premeasured doses which disintegrate in the mouth with a small volume of liquid.

A number of extemporaneous formulations for oral, IV, and rectal administration are included in a compilation of products for use in pediatric patients.[86] However, a specific reference on the stability of many drug formulations is lacking and emphasizes the need for continued research in this area.

Drug administration into the middle ear, nose, or eye of a child requires special attention. Certain drugs (eg, sodium valproate and morphine) can be administered rectally to infants who have limited access for IV drug administration or if oral drug administration cannot be accomplished.

Transdermal drug delivery can be used in pediatric patients (a) to avoid problems of drug absorption from the oral route and complications from the IV route and (b) to maximize duration of effect and minimize adverse effects of drugs. As discussed earlier in this chapter, methylphenidate (Daytrana) now is available as a transdermal patch for children with ADHD. Unfortunately, the commercially available transdermal dosage forms (eg, clonidine and scopolamine) are not intended for pediatric patients; these would deliver doses much higher than needed for infants and children.

Medication Adherence

The issue of medication adherence is more complex in pediatric patients than in adults. Caregivers of young patients must appreciate the importance of understanding and following the prescribing information.

In one study, medication adherence was considered to be a problem in nearly 60% of adolescents (age 12-15 years) with asthma. Approximately 40% of patients had severe denial regarding their asthma and its severity. Nearly 80% of patients had preventable asthma exacerbations.[87]

Among the factors that can negatively affect adherence are poor communication between the physician and patient or parent, insufficient prescribing information, lack of understanding about the

severity of illness by the patient or parent, lack of interest (eg, among adolescents), fear of side effects, failure of the patient or parent to remember to administer the drugs, inconvenient dosage forms or dosing schedules involving administration of three or more doses daily, and unpalatability of drug products.[88] Studies in pediatric volunteers have compared the palatability of antibiotics,[89] and the data may have important implications for adherence in children.

Dose Requirements

Medication doses often are based on the body weight of neonates, infants, and children (eg, milligrams per kilogram of body weight per day to be given in one or more portions daily). However, certain drugs, including antineoplastic agents, may be given based on BSA (eg, milligrams per square meter in one or more doses daily). In either case, the total amount of weight- or surface area-based individual or daily dose in a pediatric patient, especially an adolescent, should generally not exceed the amount of drug indicated in an adult patient.

An additional challenge in managing pediatric drug therapy is understanding the effects of obesity on a population that relies on weight-based dosing. As mentioned earlier, the number of children who are overweight or obese has increased markedly over the past 4 decades.[51,52] Using ideal body weight versus total body weight to calculate a weight-based dose or to determine BSA can result in a large variance in obese patients. Additional pharmacokinetic studies are needed to study the effects of obesity on drug distribution, protein binding, and clearance and to identify whether dosing should be adjusted according to total body weight or ideal body weight to achieve consistent drug exposure for individual drugs.[90,91] Generally, the highest drug dose recommended for a child is the maximum dose approved for adults. However, determining the highest dose of certain drugs for use in children without a known maximum dose for adults (eg, IV immunoglobulin, infliximab, rituximab, and liposomal amphotericin B [AmBisome]) can be difficult.

Drug Interactions

Drug interaction studies in pediatric age groups generally are lacking. The data often are extrapolated from studies in adult populations. Special attention should be given to adolescents, who may concurrently use alcohol, recreational or illicit drugs, or other prescription or nonprescription medications without the knowledge of the primary healthcare provider, who must attempt to determine their use to avoid drug interactions.

Complementary and Alternative Therapy

In a study of patients between 3 weeks and 18 years (mean, 5.3 years) of age, 45% of caregivers gave a complementary or alternative treatment to the children; 27% had given three or more products in the past year. The most commonly used products were aloe plant or juice (44% of those reporting use of herbal therapies), Echinacea (33%), and sweet oil (25%). The most dangerous combination was ephedra (which was withdrawn from the US market in 2004) with albuterol given to adolescents with asthma. Most caregivers did not recognize potential adverse effects or drug interactions associated with herbs. Friends or relatives were the main sources of information for 80% of caregivers.[92]

Little is known about the efficacy of herbal products in infants, children, and adolescents. Healthcare professionals must ask caregivers specifically about the use of complementary and alternative treatments to minimize the adverse effects and costs associated with ineffective therapies.

Marijuana has been used in pediatric patients with life-limiting or severely debilitating conditions (eg, cancer and epilepsy) when other treatments were ineffective. It should be noted, however, that no studies have documented the efficacy of marijuana for medical purposes in the pediatric population. A 2015 policy statement of AAP cited several studies documenting the adverse effects of marijuana in adolescents.[111] These have included impaired learning due to decreased short-term memory, attention span and problem solving ability; risks with motor vehicle driving associated with changes in motor control, coordination, judgement, and tracking ability; brain development; and drug dependence or addiction which may develop later in adulthood. AAP also recommended changing marijuana from schedule I to schedule II to facilitate research and development under FDA regulations to ensure standards including purity and potency, as well as short-term and long-term effectiveness and safety among children and adolescents.

Medication Safety

The Institute of Medicine reported that between 44,000 and 98,000 Americans each year die as a result of medical errors in hospitals.[93] According to this report, the vast majority of medical errors that cause harm to patients are preventable. Healthcare professionals have a responsibility for creating a safe medication environment and reducing risk to a vulnerable pediatric population.

Pediatric medication errors commonly occur at the medication-ordering step because of the multiple calculations required for weight-based dosing and the adjustments needed for providing therapy to the developing pediatric patient.[94,95,96] The United States Pharmacopeia (USP) Center for the Advancement of Patient Safety states that risk to patients when performing repeated calculations involving multiple steps can be minimized using computer-based algorithms.[97] Because the medication-preparation step is also a high-hazard point owing to the need for dilution or manipulation of commercially available products only available in adult doses, the USP recommends that compounded pediatric medications be prepared and labeled in the pharmacy and verified by a pharmacist. In 2006 and 2007, there were several reports of heparin-dispensing errors to neonatal patients caused by different concentrations of the same medication used to service the needs of neonates and adults (neonatal and adult product mix-up).[98,99,100,101,102] In 2008, The Joint Commission issued an alert on preventing errors related to commonly used anticoagulants.[103] Among drug administration–related errors, wrong dose, wrong technique, and wrong drug are the three most common errors and may be related to an inability to access pediatric drug information. In 2001, the Agency for Healthcare Research and Quality published an evidence-based assessment of patient safety practices that prevent or reduce medication errors.[98] Risk-reduction strategies include placing a clinical pharmacist on pediatric wards in hospitals, simplifying the medication-use system, ordering standardized concentrations and doses, implementing computerized physician order-entry systems with dose range checking, dispensing pharmacy-prepared or ready-to-administer doses, standardizing infusion equipment, using smart infusion pumps, using bar-coded medications and

bar-coding systems that check the medication at the point of care, and implementing computerized adverse event detection systems.[96,98,99,100] Identifying and understanding the high-hazard areas or points of failure in the medication-use process will help in designing strategies that prevent problems before they arise.

CONCLUSIONS

Although tremendous progress has been made in the area of pediatric pharmacotherapy, many questions remain unanswered. The pharmacokinetics of many important drugs have been elucidated, but their pharmacodynamics have not been explored fully. Similarly, the effect of disease states and patient characteristics, such as genetic status, has not been studied for most drugs. The effect of these factors on the development of CYP isozymes (eg, CYP3A4, CYP2D6, CYP1A2, CYP2C9, and CYP2C19), other enzymes, and P-glycoprotein needs to be studied (see eChaps. 5 and 6). Similarly, comparative efficacy and safety data for many therapies are unavailable. Studies on the influence of drug therapy on clinical and economic outcomes and on quality of life in pediatric patients are needed.

The development of new drugs has contributed to improved patient care. Food and Drug Administration regulations can require the industry to conduct studies and seek labeling of important drugs for use in pediatric patients. As an incentive, a 6-month patent extension and waiver of supplemental new drug application fee are offered to the industry. This should encourage the industry to develop and market more drugs for the pediatric population. However, greater emphasis also should be placed on disease prevention. Millions of children die because of preventable diseases, particularly in developing countries of the world. Administration of vaccines and control of diarrhea alone could save millions of these lives annually. However, many countries may lack resources for vaccinations. The infant mortality rate in the United States is nearly twice as high among blacks as whites. Improved prenatal care; educational programs; and avoidance of alcohol, smoking, and drugs of abuse during pregnancy may decrease mortality rates as well as morbidity from illnesses, including acquired immunodeficiency syndrome.

Finally, efforts should be made to offer evidence-based pharmacotherapy. This often is difficult in pediatric populations when the drugs must be used outside the guidelines and indications approved by the FDA. Institutions should develop guidelines for the use of drugs in specific diseases and for the use of high-cost drugs such as colony-stimulating factors, monoclonal antibodies, dornase alfa, epoetin alfa, immunoglobulins, surfactants, and growth hormones.

Although much needs to be learned about the optimization of therapy, it is encouraging to witness the continued growth of knowledge in this area that has improved the quality of life and survival from pharmacotherapy in pediatric patients.

INTRODUCTION

KEY CONCEPTS

- 1 The population of persons age 65 years and older is increasing.
- 2 Age-related changes in physiology can affect the pharmacokinetics and pharmacodynamics of numerous drugs.
- 3 Improving and maintaining functional status is a cornerstone of care for older adults.
- 4 Drug-related problems in older adults are common and cause considerable morbidity.
- 5 Pharmacists can play a major role in optimizing drug therapy and preventing drug-related problems in older adults.

Pharmacotherapy for older adults can cure or palliate disease as well as enhance health-related quality of life (HRQOL). Health-related quality of life considerations for older adults include focusing on improvements in physical functioning (eg, activities of daily living), psychological functioning (eg, cognition, depression), social functioning (eg, social activities, support systems), and overall health (eg, general health perception).[1]

Despite the benefits of pharmacotherapy, HRQOL can be compromised by drug-related problems. Prevention of drug-related adverse consequences in older adults requires that health professionals become knowledgeable about a number of age-specific issues. To address these knowledge needs, this chapter discusses the epidemiology of aging; physiologic changes associated with aging, with emphasis on changes that can affect the pharmacokinetics and pharmacodynamics of drugs; clinical

conditions commonly seen in older adult patients; epidemiology of drug-related problems in older adults; and an approach to reducing drug-related problems through the provision of comprehensive geriatric assessment.

EPIDEMIOLOGY OF AGING

1 The older American population is highly diverse and heterogeneous with respect to health status. The demographics and health characteristics of persons age 65 to 74 years differ from those of persons 85 years of age and older, as do those of persons who are institutionalized compared with those living in the community. Teasing apart the various threads of wellness and illness, independence and dependence, and function and dysfunction makes the available demographic and health status data relevant for clinical practice. Understanding the diversity and growth of older populations will allow society to plan for the training, research, and resources needed for future clinical practice and adequate healthcare.

The proportion of the population age 65 and older is increasing. In 2010, persons age 65 and older accounted for 13.0% (40 million) of the total US population, up from 12.4% in 2006. Among those older than 65 years, women accounted for 57% of this segment of the population. The gender gap widens with increasing age, with women accounting for 67% of the cohort 85 years and older.[2] In 2011, the first baby boomers turned 65 years old; this marked the beginning of a rapid increase in the older population. By 2030, this older population is projected to almost double in size; one in five Americans will be older than 65 years. This 20% projection will remain relatively stable through 2050. However, the proportion of the "oldest old" (greater than 85 years) will continue to grow; by 2050, almost one in four older adults will be 85 years or older.

The increase in the number of older persons is caused not only by the higher post-World War II birth rate but also by the declining mortality rate and overall improved health status among older adults.[3] The decline in early death and the better health of older adults arises from a variety of reasons: (a) public health measures affecting all age groups (eg, immunizations, prenatal care), (b) advances in medical technology, (c) promotion of a healthy lifestyle, and (d) improvements in living conditions.[4] More relevant to health professionals providing care to older Americans is the steadily increasing life expectancy at 65 and 85 years of age. In 2009, women 65 years of age could expect an average additional 20.30 years of life, and men could expect to live 17.6 additional years. Life expectancies are lower for black men and women.[2] Upon reaching 85 years of life, women may expect to live another 7.0 years and men another 5.9 years.[2] Nonetheless, the life expectancy at age 65 in the United States remains lower than that of many other industrialized countries. Interestingly, the number of centenarians (n = 53,364) increased by 5.8% between 2000 and 2010.

The older population will become more diverse in racial and ethnic composition, which will require greater flexibility in programs and services to meet the healthcare needs of this changing population. In 2010, an estimated 80% of persons age 65 years and older were non-Hispanic white, 9% were black, 7% were Hispanic, and 3% were Asian. By 2050, the older Hispanic group is projected to grow the fastest and will account for 20% of the older adult population. The percent of non-Hispanic white older adults is projected to decline to 58%, whereas increases are projected for blacks (12%) and

Asians (9%).[2] Most older persons are self-sufficient and live in the community. However, as they age in the community, the likelihood of living alone increases, more so for women than men. In 2010, only 3.1% of older persons resided in skilled-nursing facilities, representing a decrease since 1990 (5.1%). This decline may result from the improved health status of older adults or the use of alternative residential services (eg, assisted-living facilities and in-home healthcare). The proportion of older adults residing in skilled nursing facilities increases with age, rising sharply after 85 years of age. Of those 65 to 74 years old, only 0.9% resided in a nursing home compared with 10.4% and 24.7% of the population of 85 to 94 years and 95 years or older, respectively.[5]

As Americans live longer, there is a growing emphasis on healthy aging and improving the quality of remaining years of life. One important factor for healthy aging is regular physical activity, which has many positive health benefits, including disease reduction (eg, cardiovascular disease), weight maintenance, and reduction in physical disability. Physical activity is successful in improving mobility and functioning even among frail and very old adults. However, only 11% of older adults reported engaging in leisure-time physical activity (eg, aerobic and muscle-strengthening activities) that met the 2008 Federal physical activity guidelines, and this percentage decreases with increasing age.[2] Obesity in older adults has increased from 22% (1988-1994) to 38% (2009-2010). The prevalence of obesity is lower in those older than 75 years (29%) compared with those 65 to 74 years (44%).[2] Thus, efforts to improve physical activity and reduce obesity may be beneficial for improving health status in older adults.

An important goal in the care of older adults is to maintain independence and avoid the need for institutionalization for as long as possible. Functional loss or disability often is a common precipitant for institutionalization in older persons, especially among those older than 75 years. The most commonly referenced indicators of functioning in older adults include basic activities of daily living (ADLs; eg, dressing, bathing, transferring, feeding, and toileting), instrumental activities of daily living (IADLs; eg, use of telephone, housework, meal preparation, shopping or managing money), and aspects of physical function (eg, ability to lift 10 pounds, write, grasp small objects, walk two to three blocks, or reach overhead). Usual definitions of disability include limitations of ADLs, IADLs, or significant mobility problems.

In 2009, 25.0% of community-dwelling older adults reported difficulty with one or more ADLs, and 12.0% reported difficulty with one or more IADLs.[2] Limitations in physical function are also common, with 21.4% of women and 14.5% of men reporting an inability to walk 2 to 3 blocks. Disability and limitations in physical function increase with age and are higher in institutionalized older persons. Segments of the population that are especially vulnerable to disability include women, minorities, and those in lower socioeconomic classes.

Disability rates have declined since the 1980s, with significant declines over the 1990s. Trends in ADL and IADL disability have remained stable from 1998 to 2008 despite an increase in the prevalence of chronic disease.[6,7] Multiple factors are likely responsible for the decline in disability prevalence, including increased screening, improved medical treatment, changes in health behaviors (eg, reduced smoking), and widespread use of assistive devices.

Chronic diseases or sensory impairments, such as heart disease, stroke, and diabetes, are major causes of disability in older adults. Approximately two out of three older adults have multiple chronic conditions. Since 1998, those reporting four or more chronic conditions has increased from 11.6% to 17.4%.[7] Many chronic conditions can be prevented or improved with behavioral modification, such as diet and physical activity. The prevalence of select common conditions in 2009 to 2010 included hypertension (56%), arthritis (51%), heart disease (30%), any cancer (24%), diabetes (21%), asthma (11%), chronic obstructive pulmonary disease (10%), and stroke (9%).[2] The most common sensory impairments affecting older adults include difficulties with hearing (38%) and vision (14%).[2]

Unless more effective strategies for preventing and treating Alzheimer's disease (AD) are discovered, the United States is facing a huge public health crisis. In 2013, approximately 5 million Americans had a diagnosis of AD, which is expected to almost triple by 2050 (13.8 million).[8] Even in older adults who do not have dementia, cognitive decline is common with aging and may interfere with self-care. In a national survey, 12.7% of older adults reported increased confusion or memory loss in the preceding 12 months. Among those reporting increased confusion or memory loss, 35.2% reported experiencing functional difficulties and only 19.3% reported discussing these concerns with a healthcare provider.[9]

Chronic diseases are the primary cause of death in older adults. The leading causes of death among older adults have changed little over the past 25 years. **Figure e7-1** illustrates the leading causes of death in 2010. Some important trends have emerged over the past quarter century. First, the death rates for heart disease and stroke have decreased by 50%. This trend is a consequence of the gains made in the prevention and treatment of these diseases. Second, death rates associated with diabetes, chronic lower respiratory diseases, and Alzheimer's disease have increased significantly over this period.[10]

Older adults use more healthcare resources than any other group, including prescription medications. Among Medicare enrollees, the hospitalization rate increased from 306 hospital stays per 1,000 (1992) to 365 per 1,000 (1999). Subsequently, the rate decreased to 320 per 1,000 enrollees in 2009. The average length of a hospital stay decreased from 8.4 days in 1992 to 5.4 days in 2009.[2] The Medicare Prescription Drug, Improvement and Modernization Act began offering a voluntary outpatient prescription drug benefit for beneficiaries in January 2006. Based on CMS 2010 estimates, 10% of Medicare beneficiaries still did not have coverage under Medicare Part D or other sources of creditable coverage.[12] Part D spending for prescription drugs was expected to reach $76 billion in 2015, representing 14% of the total Medicare spending for 2015.[12] Although Medicare Part D benefit has improved prescription drug coverage for older adults, a concerning feature is the so-called "doughnut hole"—the gap in coverage lying between the initial coverage limit and the catastrophic coverage threshold. After surpassing the initial coverage of prescription drug plans, beneficiaries are financially responsible for the cost of prescription drugs until they qualify for the catastrophic coverage threshold. The Affordable Care Act (ACA) passed in 2010 is incrementally reducing the coverage gap for prescription drugs, with elimination slated for 2020.

HUMAN AGING AND CHANGES IN DRUG PHARMACOKINETICS AND PHARMACODYNAMICS

2 Many theories have been proposed to explain the human aging process. Clinical manifestations of normal aging include changes in the biochemical makeup of tissues, reduced capacity of body systems, reduced ability to adapt to physiologic stress, and increased vulnerability to disease.[13] Interindividual variability in physiology increases with age because individuals experience aging at different rates along with the development of disease processes.[14] Frailty—a syndrome associated with advanced age and characterized by weakness, fatigue, weight loss and functional decline—may

be more important than chronological age as a risk factor for altered pharmacokinetics and pharmacodynamics in older adults.[15] **Table e7-1** reviews some common physiologic changes associated with aging, with an emphasis on changes that can affect pharmacotherapy. For more detailed information, readers are referred to excellent reviews.[13,16,17]

TABLE e7-1 Physiologic Changes with Aging[13,18]

Organ System	Manifestation
Balance and gait	↓ Stride length and slower gait
	↓ Arm swing
	↑ Body sway when standing
Body composition	↓ Total body water
	↓ Lean body mass
	↑ Body fat
	↔ or ↓ Serum albumin
Cardiovascular	↑ α_1-Acid glycoprotein (↔ or ↑ by several disease states)
	↓ Cardiovascular response to stress
	↓ Baroreceptor activity leading to ↑ orthostatic hypotension
	↓ Cardiac output
	↑ Systemic vascular resistance with loss of arterial elasticity and dysfunction of systems maintaining vascular tone
	↓ Resting and maximal heart rate
Central nervous system	↓ Size of the hippocampus and frontal and temporal lobes
	↓ Number of receptors of all types and ↑ sensitivity of remaining receptors
	↓ Short-term memory, coding and retrieval, and executive function
	Altered sleep patterns
Endocrine	↓ Estrogen, testosterone, TSH, and DHEA-S levels
	Altered insulin signaling
	↓ Motility of the large intestine
Gastrointestinal	↓ Vitamin absorption by active transport mechanisms
	↓ Splanchnic blood flow

Organ System	Manifestation
	↓ Bowel surface area
	Atrophy of the vagina with decreased estrogen
Genitourinary	Prostatic hypertrophy with androgenic hormonal changes
	Detrusor hyperactivity may predispose to incontinence
	↓ Hepatic size
Hepatic	↓ Hepatic blood flow
	↓ Phase I (oxidation, reduction, hydrolysis) metabolism
	↓ Antibody production in response to antigen
Immune	
	↑ Autoimmunity
	Altered dentition
Oral	
	↓ Ability to taste salt, bitter, sweet, and sour
	↓ Respiratory muscle strength
	↓ Chest wall compliance
	↓ Arterial oxygenation and impaired carbon dioxide elimination
Pulmonary	
	↓ Vital capacity
	↓ Maximal breathing capacity
	↑ Residual volume
	↓ GFR
	↓ Renal blood flow
Renal	↓ Filtration fraction
	↓ Tubular secretory function
	↓ Renal mass
	Presbyopia (diminished ability to focus on near objects)
	↓ Night vision
Sensory	
	Presbycusis (high-pitch, high-frequency hearing loss)
	↓ Sensation of smell and taste
	↓ Skeletal bone mass (osteopenia)
Skeletal	

Organ System	Manifestation
Skin/hair	Joint stiffening caused by reduced water content in tendons, ligaments, and cartilage
	Thinning of stratum corneum
	↓ Langerhans cells, melanocytes, and mast cells
	↓ Depth and extent of the subcutaneous fat layer
	Thinning and graying of hair caused by more hairs in the resting phase and shortening of the growth phase as well as changes in follicular melanocytes

DHEA-S, dehydroepiandrosterone-S; GFR, glomerular filtration rate; TSH, thyroid-stimulating hormone.

Age-associated physiologic changes may result in reduced functional reserve capacity (ie, ability to respond to physiologic challenges or stresses) and reduced ability to maintain homeostasis, thus making older adults susceptible to decompensation in stressful situations.[13,16,18] Examples of homeostatic mechanisms that may become impaired include postural or gait stability, orthostatic blood pressure responses, thermoregulation, cognitive reserve, and bowel and bladder function. An event resulting in functional impairment may involve an insult for which the body cannot compensate, and relatively small stresses may result in major morbidity and mortality.[13,16,18]

The clinical response to a medication in an older adult is the net result of the interaction of a number of complex processes, including pharmacokinetics and pharmacodynamics. Age-related changes in physiology can affect drug pharmacokinetics and pharmacodynamics (see Table e7-1). Concurrent medications, comorbidities, and frailty also play vital roles. When applying general knowledge of pharmacokinetic and pharmacodynamic alterations in an older adult in the clinical setting, it is necessary to consider the patient's overall condition, age, diseases, and concurrent medications.

Altered Pharmacokinetics

Table e7-2 and the following discussion summarize what is known about the effect of aging on each of the four major facets of pharmacokinetics.[14,17,19] Of interest, when multivariate population pharmacokinetic analyses are conducted, age by itself seldom is a significant predictor of individual pharmacokinetic parameters (eg, clearance). Age-associated changes in drug absorption, distribution, metabolism, and elimination are more important predictors of altered pharmacokinetics than is age per se.

TABLE e7-2 Age-Related Changes in Drug Pharmacokinetics[14,17,19]

Pharmacokinetic Phase	Pharmacokinetic Parameters
Gastrointestinal absorption	Unchanged passive diffusion and no change in bioavailability for most drugs

Pharmacokinetic Phase	Pharmacokinetic Parameters
	↓ Active transport and ↓ bioavailability for some drugs
	↓ First-pass metabolism, ↑ bioavailability for some drugs, and ↓ bioavailability for some prodrugs
Distribution	↓Volume of distribution and ↑ plasma concentration of water-soluble drugs
	↑ Volume of distribution and ↑ terminal disposition half-life ($t_{1/2}$) for lipid-soluble drugs
Hepatic metabolism	↓ Clearance and ↑ $t_{1/2}$ for some drugs with poor hepatic extraction (capacity-limited metabolism); phase I metabolism may be affected more than phase II
	↓ Clearance and ↑ $t_{1/2}$ for drugs with high hepatic extraction ratios (flow-limited metabolism)
Renal excretion	↓ Clearance and ↑ $t_{1/2}$ for renally eliminated drugs and active metabolites

Absorption

Most drugs are taken orally; age-related changes in gastrointestinal physiology could affect the absorption of medications. Drug–food interactions, concurrent medication use, and comorbidities affecting gastrointestinal function must also be considered.

Fortunately, most drugs are absorbed via passive diffusion, and age-related physiologic changes appear to have little influence on drug bioavailability.[19] Nutrients absorbed by active transport, such as vitamin B_{12}, iron, calcium, magnesium, and leucine, may have impaired absorption in older adults.[17] There is evidence for a decreased first-pass effect on hepatic or gut wall metabolism that results in increased bioavailability and higher plasma concentrations of drugs such as propranolol and labetalol and reduced bioavailability of some prodrugs such as enalapril and codeine.[14,17]

Drugs requiring an acidic environment for absorption (ketoconazole, iron salts, digoxin, and atazanavir) may have reduced extent of absorption in a relatively small proportion of older adults with increased gastric pH caused by atrophic gastritis or in those taking medications that increase gastric pH.[14] The effects of aging on the absorption of modified-release orally administered dosage forms are not known, although changes in gastrointestinal motility or pH might affect absorption from some dosage forms in some patients.[14]

Distribution

The distribution of medications in the body depends on factors such as blood flow, plasma protein binding, and body composition, each of which may be altered with age. For example, the volume of distribution of water-soluble drugs (ethanol, gentamicin, digoxin, and cimetidine) is decreased, whereas lipophilic drugs (benzodiazepines, metronidazole, and rifampin) exhibit an increased volume

of distribution.[14,19] Changes in the volume of distribution can have a direct impact on the amount of medication that must be given as a loading dose. Older adults may also exhibit differences in the distribution of drugs to their sites of action. Tissue perfusion may decrease with aging, slowing the distribution to less highly perfused tissues such as muscle and fat.[14] Small changes in protein binding (decreased albumin and increased α_1-acid glycoprotein) have been documented with aging, but these changes do not generally have a significant effect on drug distribution except for drugs that are highly extracted by the liver, extensively protein bound, and administered IV.[14,19]

Blood–brain barrier permeability and transport function may also be altered in older adults, thereby affecting distribution of medications into and out of the central nervous system (CNS). As a result, the brain of elderly individuals may be exposed to higher than normal levels of drugs and toxins.[20]

Metabolism

The liver is the major organ responsible for drug metabolism, including phase I (oxidative) and phase II (conjugative) reactions. Variations in drug metabolism and consequently drug clearance are a major source of variability in the response to medications in older adults.[21] Hepatic metabolism of drugs depends on liver perfusion, capacity and activity of drug metabolizing enzymes, and protein binding, all of which may altered by the aging process.[19] For drugs that have high intrinsic clearance (high hepatic extraction ratio) and undergo rapid hepatic metabolism, drug clearance is dependent on hepatic blood flow (flow-limited metabolism). For drugs that have low intrinsic clearance (low hepatic extraction ratio) and are slowly metabolized by the liver, drug clearance is dependent on hepatic enzyme activity (capacity-limited metabolism).

Age-related decreases in hepatic blood flow can decrease significantly the metabolism of high extraction ratio drugs that undergo flow-limited metabolism. Hepatic blood flow may decline by 20% to 50%, and hepatic clearance of propranolol and amitriptyline may be reduced by 40% or more in older adults.[19] Other high-extraction-ratio drugs that have been shown to have reduced hepatic clearance in older adults include diltiazem, lidocaine, metoprolol, morphine, and verapamil.[22] Interpreting the effect of age on the metabolism of drugs that undergo capacity-limited metabolism is more complex. Hepatic clearance of capacity-limited drugs depends on the fraction unbound in blood and the intrinsic hepatic clearance. Most, but not all, studies have reported reduced liver size and enzyme content in older adults.[22] Total hepatic clearance of capacity-limited drugs, however, may be reduced (lorazepam, piroxicam, and warfarin), increased (ibuprofen, naproxen, and phenytoin) or unchanged (diazepam, temazepam, and valproic acid) with aging.[22] Hepatic clearance of the unbound drug, rather than the total hepatic clearance, which includes bound and unbound drug, may be more relevant in understanding the effect of age on hepatic clearance.[23]

Serum albumin concentrations decline with age. For capacity-limited drugs with extensive protein binding, older adults with reduced serum albumin concentrations may experience a significant increase in fraction unbound, leading to increased total hepatic clearance even though unbound clearance is significantly reduced. Naproxen, for example, has capacity-limited metabolism and is highly bound to albumin. Older adults experience reduced unbound clearance and increased total

clearance compared with younger adults.[22]

Most research on hepatic drug metabolism and aging has focused on age differences in phase I drug metabolism pathways. Generally, phase II metabolic pathways are preserved in healthy older people.[22] Frail older adults, however, experience reduced phase II metabolism. Frailty is a risk factor for declining health status and disability. Although frailty has proven difficult to define, it is characterized by reduced lean body mass, muscle loss, malnourishment, reduced function, and reduced endurance.[22] Frailty is associated with inflammation, which may downregulate drug metabolism and transport.[15]

Elimination

Renal excretion is the primary route of elimination for many drugs and metabolites. Age-related reductions in glomerular filtration rate (GFR) are well documented. However, as many as one third of "normal" older adult subjects may have no reduction as measured by creatinine clearance, and older adults maintaining a high protein diet have a GFR similar to younger adults.[24] Additionally, declines in kidney function may be more closely implicated to disease processes such as hypertension and heart disease than aging itself. Therefore, age alone may not have as great impact on renal excretion of drugs than previously thought.[17]

The estimation of creatinine clearance, although not entirely accurate in individual patients, can serve as a useful screening approximation for the purpose of dosage adjustments. Cockcroft and Gault created one of the most commonly used equations for adults with stable renal function whose actual weight is within 30% of ideal body weight[25]:

$$\text{Creatinine clearance} = \frac{(140 - \text{Age})\ (\text{Actual body weight})}{72\ (\text{Serum creatinine concentration})}$$

where age is given in years, actual body weight in kilograms, and serum creatinine concentration in milligrams per deciliter. The resulting creatinine clearance is in units of mL/min. For women, multiply this result by 0.85.

When serum creatinine is expressed in μmol/L, creatinine clearance in units of mL/min can be calculated by the following equation:

$$\text{Creatinine clearance} = \frac{(140 - \text{Age})\ (\text{Actual body weight})}{0.814\ (\text{Serum creatinine concentration})}$$

The Modified Diet in Renal Disease equation and the Chronic Kidney Disease Epidemiology Collaboration equation have become more widely used for estimation of GFR.[26,27] The validity of each of these equations for use in estimating GFR in older adults has been advocated and challenged.[28,29,30] However, dosing guidelines for medications that primarily are renally cleared are still based on estimated creatinine clearance determined using the Cockcroft and Gault equation, and current consensus is to continue to use this equation for renal drug dosing in older adults. New methods based on serum creatinine and cystatin C continue to be developed, so this

recommendation may change in the future.[31]

Consensus guidelines for oral dosing of primarily renally cleared drugs in older adults have been developed. Medications to avoid in older adults with creatinine clearance below 30 mL/min (0.5 mL/s) include colchicine, cotrimoxazole, glyburide, nitrofurantoin, probenecid, spironolactone, and triamterene. Oral medications with recommended dosage adjustments for reduce renal function in older adults include acyclovir, amantadine, ciprofloxacin, gabapentin, memantine, ranitidine, and valacyclovir.[32] Some hepatically metabolized medications can yield active, primarily renally excreted metabolites, such as *N*-acetylprocainamide, normeperidine, and morphine-6-glucuronide, which can accumulate with advancing age because of reduced renal function.

Clinical Controversy…

When using the Cockcroft and Gault equation to estimate creatinine clearance in older adults, some clinicians round the value up to 1 if the patient's serum creatinine concentration is less than 1 mg/dL (88 µmol/L). Rounding the serum creatinine concentration may provide an underestimation of creatinine clearance and result in improper dose adjustment of renally eliminated medications. It is important to realize that the equation is merely an estimate, and attempts should be made to determine creatinine clearance accurately when contemplating the use of certain medications (eg, gabapentin).

Altered Pharmacodynamics

Age-related changes in pharmacokinetics are well characterized compared with changes in pharmacodynamics. Understanding the effects of age on pharmacodynamics has proven to be complex.

There is a general trend of altered drug response or increased "sensitivity" in older adults. Possible mechanisms that have been proposed include (a) changes in concentrations of the drug at the receptor, (b) changes in receptor numbers, (c) changes in receptor affinity, (d) postreceptor alterations, and (e) age-related impairment of homeostatic mechanisms.[33,34] Differences in pharmacodynamics with age may be due to altered sensitivity (greater change in effect for a given change in drug concentration) but may also be due to differences in baseline performance or different concentrations of drug at the site of action between young and older adults.[19] Most studies of pharmacodynamic differences with age have focused on drugs acting on the CNS and cardiovascular system.

Older adults are particularly sensitive to the CNS effects of drugs. Changes in brain size and weight as well as changes in neurotransmitter systems have been reported with advancing age. In addition, drugs may penetrate the CNS more easily.[20] For example, there are multiple changes to the dopaminergic system with age, including decreased levels of the dopamine transporter, decreased number of dopaminergic neurons, and decreased density of several types of dopamine receptors. These changes are consistent with the increased sensitivity of older adults to the adverse drug effects of antipsychotics.[34] Increased sensitivity to the CNS effects of medications in older adults has been demonstrated for benzodiazepines, anesthetic agents, opioid analgesics, antipsychotics, lithium, and

anticholinergic medications.[33,34]

Aging is associated with numerous changes in the structure and function of the cardiovascular system that may predispose older adults to altered pharmacodynamic response to drugs acting on the cardiovascular system. Older adults are more likely to experience orthostatic hypotension as an adverse drug event.[34] Age-related changes in pharmacodynamics have been reported for calcium channel blockers (increased hypotensive and bradycardic effects), β-blockers (reduced blood pressure response), diuretics (reduced effectiveness), and warfarin (increased risk of bleeding).[33,34]

CLINICAL GERIATRICS

3 Maintenance of independence and prevention of disability are primary goals in the clinical care of persons 65 years of age and older. To achieve these goals, it is necessary that all healthcare professionals understand the concept of functional status. Functional status is a proxy measure of a patient's ability to live independently and can be determined, in part, by inquiring about an older person's ability to perform specific tasks. Two types of functional measurements are basic ADLs and the more complex instrumental ADLs.[1] To fully assess functional status, the patient's psychological state, financial resources, physical function, and social circumstances also must be considered.[1,35]

One of the challenges of maintaining and improving functional status in geriatric individuals is recognizing and managing conditions frequently seen in older adults. Problems found more commonly in older persons sometimes are referred to as the "*I*s of geriatrics" (**Table e7-3**).[36] These problems are often the result of underlying disease processes that may or may not be diagnosed. Examples of diseases and syndromes that can present as common problems in older adults include Parkinson's disease, falls, hip fractures, benign prostatic hypertrophy, dementia, glaucoma, and postherpetic neuralgia.

TABLE e7-3 The *Is* of Geriatrics: Common Problems in Older Adults[36]

Immobility	Instability
Isolation	Intellectual impairment
Incontinence	Impotence
Infection	Immunodeficiency
Inanition (malnutrition)	Insomnia
Impaction	Iatrogenesis
Impaired senses	

Another factor contributing to the challenge of clinical geriatrics is the unreliability of the classic medical models used to establish diagnoses given that approximately half of older patients present with atypical symptoms or complaints. For example, cardiac ischemia in an older person may present as syncope or weakness rather than the typical presentation of chest pain. Confusion may be the presenting symptom of an acute abdominal process rather than severe pain, rigid abdominal muscles, and leukocytosis. Serious adverse consequences may result if a diagnosis is delayed or

missed because of these atypical presentations. Such unusual presentations may be caused by age-related physiologic changes, the presence of multiple comorbid illnesses or compromised function, and the presence of psychological stressors.[37] **Table e7-4** lists other examples of medical illnesses that often present atypically in older adults.[37,38] For very frail older adults, delirium, falls, and nonspecific functional decline (eg, failure to thrive) frequently are presenting problems that may mask an underlying disease process.[37,38]

TABLE e7-4 Atypical Disease Presentation in Older Adults[37,38]

Disease	Presentation
Acute myocardial infarction	Only ~50% present with chest pain. In general, older adults present with weakness, confusion, syncope, and abdominal pain; however, electrocardiographic findings are similar to those in younger patients.
Congestive heart failure	Instead of dyspnea, older patients may present with hypoxic symptoms, lethargy, restlessness, and confusion.
Gastrointestinal bleed	Although the mortality rate is ~10%, presenting symptoms are nonspecific, ranging from altered mental status to syncope with hemodynamic collapse. Abdominal pain often is absent.
Upper respiratory infection	Older patients typically present with lethargy, confusion, anorexia, and decompensation of a preexisting medical condition. Fever, chills, and a productive cough may or may not be present.
Urinary tract infection	Dysuria, fever, and flank pain may be absent. More commonly, older adults present with incontinence, confusion, abdominal pain, nausea or vomiting, and azotemia.

Multiple coexisting chronic illnesses are another common threat to independence that distinguishes older adults from younger patients. Older patients usually have multiple comorbidities, such as osteoarthritis, heart disease, and diabetes. Although multiple comorbidities can have a substantial impact on a patient's functional status, the mere existence of multiple diseases alone does not determine functional impairment.

DRUG-RELATED PROBLEMS IN OLDER ADULTS

4 Although medications used by older adults can lead to improvement in HRQOL, negative outcomes caused by drug-related problems are considerable.[39,40] Three important and potentially preventable negative outcomes caused by drug-related problems are (a) adverse drug withdrawal events (ADWEs), which are clinically significant sets of symptoms or signs caused by the removal of a drug; (b) therapeutic failure (inadequate or inappropriate drug therapy and not related to the natural progression of disease); and (c) adverse drug reactions (ADRs), defined as reactions that are noxious and unintended and occur at dosages normally used in humans for prophylaxis, diagnosis, or therapy.[39]

Data on the prevalence of ADWEs and therapeutic failures in older adults are limited. Graves et al.

reported ADWEs in 38 of 124 male outpatients who had discontinued taking 238 medications.[41] Kaiser et al. reported that 11% of hospital admissions in a group of older frail men were related to therapeutic failure.[42] ADRs occur commonly in community-dwelling older adults. A study evaluating a comprehensive brown bag medication review reported that 25% of ambulatory seniors taking 5 or more medications experienced an ADR.[43] Another study found that 18.7% of older adults discharged home from the hospital experienced an adverse event within 45 days of discharge.[44] A review suggests that ADRs are the most common type of medication-related problem in elderly nursing home patients.[45]

ADRs and other drug-related problems (eg, ADWEs, therapeutic failure) are major threats to the HRQOL of outpatient elders and account for billions of healthcare dollars per year.[46] In the nursing home setting alone, a cost-of-illness study estimated that drug-related problems (including ADRs and therapeutic failure) cost $4 billion per year.[47]

Risk Factors

Polypharmacy

Polypharmacy can be defined as either the concomitant use of multiple drugs or the administration of more medications than are indicated clinically.[48] Polypharmacy is common and increasing among older adults.[49] Community-based surveys reveal that older adults take an average of 2 to 10 prescription and nonprescription medications each day.[48,50] Increased use of dietary supplements, such as herbal products, vitamins, and minerals, may add to the increase in polypharmacy. In a nationwide survey, Qato et al. found that 49% used at least 1 dietary supplement.[51] A study evaluating senior, adult oncology patients found that 26.5% took at least 1 complementary or alternative medication.[52] Outside of the community setting, a nursing facility survey found that institutionalized older persons took an average of 6.69 routine medications and 27.1% took 9 or more medications on a regular basis.[53] Drug-use studies that defined polypharmacy as use of one or more unnecessary medications showed that polypharmacy occurs in 55% to 59% of older outpatients.[48] A study of frail veterans at hospital discharge reported that 44% of patients were taking one or more unnecessary medications, with 25% of patients starting the medication(s) during hospitalization.[54] Polypharmacy has been strongly associated with ADRs, risk of geriatric syndromes (eg, falls, cognitive impairment), nonadherence, diminished functional status, and increased healthcare costs.[55]

Inappropriate Prescribing

Inappropriate prescribing can be defined as prescribing medications outside the bounds of accepted medical standards.[56] Studies using explicit drug-use review criteria have found that between 15% and 24% of community-dwelling older adults take one or more medications that have a dose, duration, duplication, or drug-interaction problem.[57,58,59] This phenomenon occurs commonly in older inpatients, as exemplified by one study in which 92% of patients were taking at least one medication

with one or more inappropriate ratings based on clinical review applying explicit criteria.[60]

Alternatively, inappropriate prescribing can be defined as prescribing drugs whose use should be avoided because their risk outweighs their potential benefit.[61] An Irish study found that 37% of older primary-care patients used at least one inappropriate medicine per the Screening Tool of Older Persons' Potentially Inappropriate Prescriptions (STOPP) criteria.[62] Studies of inappropriate drug use in US long-term care facilities found that 25% to 42% of residents took one or more inappropriate medications as defined by explicit criteria.[63,64]

Underuse

An important problem in older adults is underuse of medications, defined as the omission of drug therapy that is indicated for treatment or prevention of a disease.[56] The Assessing the Care of Vulnerable Elders (ACOVE) criteria includes measures for underuse involving bisphosphonates, anticoagulant or antiplatelet therapy, ACE inhibitors, and β-blockers.[65] Another tool, called Screening Tool to Alert Doctors to the Right Treatment (START), is focused on risks associated with underuse of appropriate medications for diseases involving cardiovascular, respiratory and endocrine systems in older adults.[66]

Although criteria and tools highlight the need for improvement of underuse, it still remains a problem that can impact health outcomes, including functional disability, health services use, and death.[56] A prospective population-based, cohort study evaluated the impact of potential underuse of cardiovascular medications. Medication underuse as determined by the START criteria was seen in that 69% of patients.[67]

Medication Nonadherence

Nonadherence involves patient-related factors, condition-related factors, therapy-related factors, and health system and social factors and is generally defined as "the extent to which a person's behavior corresponds with agreed recommendations from a healthcare provider."[68,69] The prevalence rate of medication nonadherence in older adults remains high and ranges from 40% to 86%.[70] Some evidence indicates that adherence may be better in older adults for some conditions.[71] Older patients may not adhere to their regimens because of possible adverse effects, complex regimens, or a lack of full understanding of information about the prescribed medication.[69] Unfortunately, cost and enrollment in Medicare Part D are also cited as reasons why older adults do not fill their prescriptions.[68,72]

Limited retrospective data suggest that nonadherence is associated with increased health services use and ADRs. Medication nonadherence has been implicated in approximately 4% to 11% of hospitalizations and 8% of emergency department visits.[70] Conversely, studies highlight the association between increased medication adherence and fewer hospitalizations and decreased costs in patients with certain chronic medical conditions (eg, diabetes, hypertension).[73]

PROVISION OF COMPREHENSIVE GERIATRIC ASSESSMENT

5 Given that drug-related problems are common, costly, and clinically important, proactive strategies for prevention and management are essential. A number of reviews and book chapters summarize the effectiveness of pharmacists in improving suboptimal prescribing and medication adherence and reducing ADR in older adults.[56,74,75,76,77] The following subsections provide an approach to comprehensive geriatric assessment that pharmacists in any practice setting (especially those providing medication therapy management services under the Medicare Part D program, conducting medication reconciliation, or performing a medication regimen review in a nursing home facility) can take to optimize medication use.

History Taking

According to a national survey, half of community-dwelling older adults take one or more over-the-counter drug products and one or more dietary supplements.[51] However, challenges associated with completing medication histories in older adults may make obtaining information about nonprescription agents difficult. Possible barriers include (a) communication problems dimpaired hearing and vision, (b) underreporting (eg, health beliefs, cognitive impairment), (c) altered presentation with vague or nonspecific symptoms, (d) presence of multiple diseases or use of multiple medications, (e) reliance on a caregiver for the history, and (f) limited access to medical records to confirm findings. Despite these potential difficulties, collecting information about nonprescription medications and dietary supplements is a vital component of a complete medication history, and its importance cannot be overstressed. To assist with collecting pertinent information, pharmacists may find the Tool to Improve Medications in the Elderly via Review (TIMER) a helpful modality.[78]

Asking older adults and caregivers about methods to organize medications is also important, as one recent study documented that more than three quarters of community elders use some type of management system. The most common strategies in rank order were (1) using a pill box; (2) laying out a whole day's medications in the morning or at meal times; (3) putting medications in a visible place as a reminder; and (4) creating and maintaining a checklist or calendar.[79] Understanding past and current medication management strategies facilitates the pharmacist's ability to design patient-specific solutions for any problems detected, and prevents implementation of previously-used but ineffective methods.

Patients and caregivers should be asked about potential risk factors for prescribing problems (eg, using multiple physicians and pharmacies) and both issues that may lead to either nonintentional and intentional nonadherence (eg, impaired hearing, vision, or cognition; inability to open safety caps, pay for medicines, or swallow medications; recognition of adverse effects; and perception of health risk).[69,80,81,82,83] Several approaches to formally assess medication adherence in older adults have been reported in the literature.[84] Because of the high frequency of medication-related problems, a complete drug history should conclude with an inquiry about allergies and current/previous adverse effects, unwanted reactions, or other concerns the patient may have with his or her medications.[81] In

addition, it is worthwhile to screen for geriatric syndromes (eg, falls, urinary incontinence, and cognitive impairment) because of their association with medication use.[85,86,87]

Assessing and Monitoring Drug Therapy

The first step in assessing medication appropriateness is to compare the patient's medical problem list with his or her drug list. This simple approach can identify two-thirds of prescribing problems (ie, overuse and underuse).[74] A drug may be considered unnecessary if it does not have an indication per the problem list, is not effective, the risks associated with its use outweigh the benefits, or there is evidence of therapeutic duplication (ie, two drugs from the same class).[88] Though no specific tool may be applicable to all patients, pharmacists may find explicit (criterion-based) or implicit (judgment-based) criteria helpful when evaluating medication regimens for potentially inappropriate medications (PIM).[56] Explicit measures such as the American Geriatrics Society's Beers criteria, STOPP, and European Union (EU)-(7) PIM list can be used to quickly identify drugs or medication classes considered harmful in older adults.[61,89,90] Similarly, three items from the implicit Medication Appropriateness Index (MAI), which is described in detail in the following paragraph, may also aid in detecting unnecessary drug use.[91,92]

The second step to evaluate medication appropriateness is to determine whether the patient has a chronic condition but is not receiving an evidence-based medication shown to improve outcomes (ie, potential prescribing omissions). Again, explicit criteria such as START and the implicit Assessment of Underuse (AOU) criteria may help clinicians identify evidence-based drugs for specific conditions from which older adults would benefit.[89,93] Next, select laboratory test results and vital signs should be examined to monitor the efficacy and toxicity of each medication.[94] **Table e7-5** lists laboratory monitoring recommendations and suggested monitoring parameters for medications used in long-term care facilities.[95,96,97]

TABLE e7-5 Examples for Monitoring of Medication Use in Older Long Term Care Facility Patients

Drug	Monitoring	Monitoring Interval (in mo)
Amiodarone	Hepatic function tests, TSH level	6
Antiepileptic agents (carbamazepine, phenobarbital, phenytoin, primidone, and valproate)	Drug levels	3-6
Angiotensin-converting enzyme inhibitors or angiotensin I receptor blockers	Potassium levels	6
Antipsychotic agents	Extrapyramidal side effects, fasting serum glucose, serum lipid panel	6
Appetite stimulants	Weight, appetite	*a*
Digoxin	Serum blood urea nitrogen, creatinine, trough drug level	6

Drug	Monitoring	Monitoring Interval (in mo)
Diuretics	Serum sodium and potassium levels	3
Erythropoiesis stimulants	Blood pressure, iron and ferritin levels, CBC	1
Fibrates	Hepatic function test, CBC	6
Hypoglycemic agents	Fasting serum glucose level or glycated hemoglobin level	6
Iron	Iron and ferritin levels, CBC	*a*
Lithium	Trough serum drug levels	3
Niacin	Blood sugar levels, hepatic function tests	6
Theophylline	Trough serum drug levels	3
Thyroid replacement	TSH level	6
Warfarin	Prothrombin time or international normalized ratio	1

CBC, complete blood count; TSH, thyroid-stimulating hormone.

[a]Consensus agreement about interval could not be reached.[95,96,97]

A similar list for laboratory tests for high-risk drugs to be monitored in the ambulatory care setting (regardless of age) has also been published.[98]

Finally, the pharmacist should assess the appropriateness of all remaining medications. A variety of approaches may be used.[84,99] The MAI, which consists of 10 questions that should be asked about each medication, is one standardized measure with demonstrated validity and reliability (**Table e7-6**).[100,101] Both the MAI and the 2015 American Geriatrics Society Beers criteria address drug-drug and drug-disease interactions, two factors strongly associated with ADRs.[58,61] Moreover, these tools cue providers to consider dosing appropriateness, which becomes especially important for renally-cleared medications.[61,100] Directions, therapy duration, and medication cost are other issues to consider during drug regimen review that could influence adherence and lead to subsequent drug-related problems, namely ADRs and potential therapeutic failures (**Table e7-7**).[69]

TABLE e7-6 Medication Appropriateness Index

Questions to Ask About Each Individual Medication

1. Is there an indication for the medication?
2. Is the medication effective for the condition?
3. Is the dosage correct?

4. Are the directions correct?
5. Are the directions practical?
6. Are there clinically significant drug–drug interactions?
7. Are there clinically significant drug–disease or drug–condition interactions?
8. Is there unnecessary duplication with other medication(s)?
9. Is the duration of therapy acceptable?
10. Is this medication the least expensive alternative compared with others of equal utility?

TABLE e7-7 Examples of Clinically Important Drug–Disease Interactions Determined by Expert Panel Consensus[61]

Drug	Disease
Acetylcholinesterase inhibitors	Syncope
α-Adrenergic blockers, peripheral	Syncope
	Urinary incontinence in women
Anticholinergic agents	Benign prostatic hyperplasia/lower urinary tract symptoms
	Dementia or cognitive impairment/delirium
Antipsychotics	History of falls or fracture
	Parkinson's disease
Aspirin (>325 mg/day)	Peptic ulcer disease
Benzodiazepine receptor agonists	Dementia or cognitive impairment/delirium
	History of falls or fracture
Bupropion	Chronic seizures or epilepsy
Calcium channel blockers (nondihydropyridine)	Heart failure (systolic dysfunction with reduced ejection fraction)
Chlorpromazine	Chronic seizures or epilepsy
Cilostazol	Heart failure
Corticosteroids	Delirium
	Peptic ulcer

Drug	Disease
Decongestants (oral)	Insomnia
Dronedarone	Heart failure (severe or recently decompensated
Estrogen (oral)	Urinary incontinence (women)
Histamine-2 receptor blockers	Delirium
Metoclopramide	Parkinson's disease
Non-aspirin nonsteroidal anti-inflammatory drugs	Chronic kidney disease Heart failure Peptic ulcer disease
Olanzapine	Chronic seizures or epilepsy
Pioglitazone	Heart failure
Selective serotonin reuptake inhibitors	History of falls or fracture
Thioridazine	Syncope
Tricyclic antidepressants	History of falls and fractures
Tramadol	Chronic seizures or epilepsy

Documenting Problems and Formulating a Therapeutic Plan

After conducting a comprehensive medication review, the clinician must document any drug-related problems identified, develop a therapeutic plan to resolve them, and establish age-appropriate therapeutic end points, keeping in mind that a desirable outcome for a 40-year-old patient may not be reasonable for an 80-year-old one. Because many older adults suffer from multiple chronic conditions, adhering to multiple disease guidelines may complicate medication regimens since guidelines often address diseases independently. One conceptual model to improve prescribing rationales takes into account remaining life expectancy, time until therapeutic benefit, treatment target, medication regimen complexity, and goals of care to help clinicians determine whether certain medications should be prescribed or continued.[102]

Consulting the Prescriber Regarding Problems and Concerns

To promote continuity of care and a team-based management approach, the pharmacist or other healthcare professional should contact a patient's prescriber regarding concerns that have been detected and documented. When discussing the older patient, the importance of optimizing prescribing *before* implementing strategies to enhance adherence cannot be overstressed. Otherwise, adherence interventions, if effective, may result in harm to patients who suddenly become adherent with medication regimens that may have been titrated inappropriately over time. Similarly, in institutional settings, strategies to reduce medication errors may not improve patient outcomes if prescribing problems are not corrected first.

Counseling and Adherence Devices

Before dispensing medications, it is important to think about general factors that may enhance adherence in older adults. The World Health Organization encourages clinicians to consider five dimensions when assessing medication adherence: social and economic factors (eg, cultural beliefs), provider-patient and provider-healthcare system factors (eg, provider-patient relationship), condition-related factors (eg, chronic conditions), therapy-related factors (eg, regimen complexity), and patient-related factors (eg, visual or hearing impairment).[103] Global approaches to improving adherence include modifying medication schedules to fit patients' lifestyles, prescribing generic agents to reduce costs, or selecting preferred agents within the insurance formulary to minimize copays for branded medications. In addition, offering easy-to-open bottles, easy-to-swallow dosage forms, and larger type on direction and auxiliary labels may improve medication regimen adherence.

When dispensing medications (particularly new medications or previously used medications that have changes in appearance or directions), the pharmacist should provide both written and oral drug information.[69] Other strategies to improve adherence include: recruiting active patient and caregiver involvement, stressing the importance of adherence, and recommending adherence-enhancing aids if necessary (eg, special packaging, medication record, drug calendar, medication boxes, magnification for insulin syringes, dose-measuring devices, and spacers for metered-dose inhalers). In institutional settings, it is prudent to discuss special considerations, such as medications that can be crushed and given via feeding tube and gradual dose reductions of psychoactive medications, with those healthcare professionals responsible for medication administration.[69]

Documenting Interventions and Monitoring Patient Progress

As with the identification of drug-related problems, all interventions provided to rectify issues must be documented. A thorough review of the older adult's medication profile must be repeated routinely and when a care transition (ie, moving from one level of care to another) is made. During follow-up contact, minimum inquiry should include asking patients if there are questions or concerns regarding medicines and determining whether previously-established therapeutic end points have been achieved.

Targeting High-Risk Older Adults

In busy practices, the outlined approach may not be feasible for every patient. Therefore, practitioners may consider targeting patients at high risk for developing drug-related problems. Geriatric experts have identified risk factors for preventable ADRs in older adult nursing home patients, which include polypharmacy (at least seven medications or more than three cardiac medications) and use of specific high-risk drugs (eg, anticoagulants, antidepressants, antiinfectives, antipsychotics, anticonvulsants, opioid analgesics, sedative-hypnotics, and skeletal muscle relaxants).[104] In ambulatory care patients, another study identified 21 risk factors, grouped as follows: (a) medication-related issues (ie, use of anticholinergics, benzodiazepines, corticosteroids, and nonsteroidal anti-inflammatory drugs), (b) patient characteristics (eg, multiple comorbidities, multiple prescribers, age older than or equals to 85 years, dementia, regular use of alcohol, and decreased renal function), (c) use of drugs with narrow therapeutic ranges (eg, lithium, warfarin), (d) history of an ADR, and (e) hospitalization within the previous 6 months.[88] Similarly, renal failure, increasing

number of medications, inappropriate medications, and age 75 years or older been associated with ADRs in hospitalized elderly.[99]

CONCLUSION

The number of people older than 65 years is growing in the United States and around the world, and individuals older than 85 years are the fastest growing segment of the US population. A number of physiologic changes associated with age, especially hepatic metabolism and renal excretion, affect the pharmacokinetics and pharmacodynamics of drugs. Improving and maintaining the patient's functional status and managing the patient's comorbidities are hallmarks of clinical geriatrics. Certain medical conditions are restricted to older adults, and drug-related problems represent a major concern for this group. Interprofessional approaches to care are needed to decrease the occurrence of these drug-related problems.

Chapter e8: Palliative Care

Nina M. Bemben; Mary Lynn McPherson

INTRODUCTION

KEY CONCEPTS

- 1 Palliative care may be provided to any patient with a serious illness, at any point in the course of the illness, including while a patient receives curative or disease-focused therapy.
- 2 Hospice is a form of palliative care, which has been defined by Medicare to encompass care solely focused on comfort and quality of life during the last 6 months of a patient's life.
- 3 Pain is a common symptom among patients receiving palliative care and may be managed safely and effectively using nonopioid, adjuvant, and/or opioid therapies.
- 4 Opioids are the drug of choice for the management of dyspnea.
- 5 Constipation, nausea, vomiting, anxiety, and delirium are common symptoms among patients receiving palliative care and may be managed effectively with drug and nondrug therapies.
- 6 End-of-life care can be provided to patients in the last days of their lives through palliative or hospice care, and provides management of common terminal symptoms.
- 7 Identifying a patient's goals and structuring care to achieve those goals is a key component of palliative care. Identifying a patient's goals of care involves communication with patients, their families and/or caregivers, as well as other healthcare professionals.
- 8 Addressing nonphysical needs, such as spirituality and faith, are key components of providing quality palliative care.

1 Palliative care, or palliative medicine, is specialized care provided to patients with serious illness with a goal of managing symptoms and helping patients to cope with their illnesses.[1] It is provided by an interdisciplinary team of healthcare professionals, including physicians, pharmacists, nurses,

nurse practitioners, social workers, chaplains, and others.[2] Palliative care is appropriate for any patient with a serious or potentially life-limiting illness, at any point during the time course of that illness. Common diseases for which palliative care is appropriate include cancer, heart failure, advanced lung disease such as chronic obstructive pulmonary disease (COPD), organ failure such as liver or renal failure, and neurologic diseases such as dementia and Parkinson disease.[2] Patients may receive palliative care throughout the course of a serious illness, including while the patient receives treatment aimed at managing or curing the disease. If or when the serious illness progresses and disease-focused therapies are no longer helpful or desired, palliative care continues to be provided to manage symptoms and maximize quality of life.

Provision of palliative and hospice care to patients with limited prognoses has been shown to improve patient and caregiver satisfaction,[3,4,5] reduce healthcare utilization,[3,4] and decrease healthcare costs.[3,4,6] In addition to providing symptom management, improving patient and caregiver satisfaction, and reducing healthcare costs, early integration of palliative care has been shown to increase survival among patients with advanced cancer.[7,8]

Because of the evidence supporting the benefits of palliative care, clinical practice guidelines for serious illnesses incorporate palliative care into treatment recommendations. The American Society of Clinical Oncology and National Comprehensive Cancer Network both recommend palliative care as a component of oncology management.[9,10] In addition, the American College of Cardiology Foundation/American Heart Association practice guideline for the management of heart failure supports the incorporation of palliative care into the management of patients with advanced heart failure due to its effectiveness in increasing quality of life.[11]

WHAT IS HOSPICE?

2 In the United States, hospice care is a Medicare-defined benefit and is a form of palliative care that is focused on caring for patients with a life expectancy of 6 months or less.[12] While palliative care may be provided at any stage in the course of serious disease, including alongside curative, or disease-focused therapy, hospice care is generally provided when a patient is no longer pursuing disease-focused therapies and the decision has been made to focus solely on comfort and quality of life.[12,13] Although commonly associated with end-stage cancer, the frequency of noncancer diagnoses among hospice patients more than doubled between 1998 and 2008.[14] In 2014, the most recent year for which data are available, the most common hospice diagnoses were: non-cancer diagnoses (63.4% of hospice admissions) such as dementia (14.8%), heart disease (14.7%), and lung disease (9.3%). Cancer diagnoses accounted for 36.6% of hospice admissions.[14]

SYMPTOM MANAGEMENT IN PALLIATIVE CARE

Based on the diseases frequently encountered in hospice and palliative care, the most common symptoms managed by palliative care practitioners include pain, dyspnea, constipation, nausea and vomiting, anxiety, and delirium. The management of these symptoms is discussed below.

Pain

3 Pain is a very common symptom among patients receiving palliative care, and providing effective pain management is a high priority of palliative care practitioners. A systematic review found that among studies of patients with cancer (any stage), 53% of patients experienced pain.[15] Among studies of patients with advanced cancer, 64% of patients experienced pain and more than 30% of patients who experienced cancer-related pain rated it as moderate or severe.[15] In an observational study of adults in the last 2 years of life with a variety of terminal diagnoses (eg, cardiac disease, cancer, frailty) the prevalence of moderate or severe pain was 26%; this increased to 46% during the last month of life.[16]

Developing an effective plan for pain management first requires pain assessment. Ascertaining the time course of a patient's pain can help to distinguish acute from chronic pain. In addition, assessing the severity of pain at its best and worst throughout the day, as well as with movement and at rest, can provide helpful information in determining a treatment plan.[17] Patient descriptions of pain, such as its quality, precipitating or palliating factors, region affected, radiation of the pain (if any), temporal factors associated with the pain (ie, worse at night), and impact on the patient's ability to function can be extremely helpful in identifying the cause of pain and appropriate treatment. In noncommunicative patients, palliative care practitioners should assess patients for nonverbal indicators of pain such as grimacing, agitation, restlessness, or resistance to personal care.[17,18] Family members or caregivers can also provide useful information when assessing pain, as can validated tools such as the Pain Assessment in Advanced Dementia (PAINAD), Checklist of Nonverbal Pain Indicators (CNPI), and the Mahoney Pain Scale.[17,18] When assessing a patient's complaint of pain, a key distinction is between nociceptive pain and neuropathic pain, as drug therapy selection requires an understanding of pain pathophysiology.

Nociceptive pain is commonly described by patients as achy, throbbing, and dull.[17] Traditionally, nonopioid analgesics such as acetaminophen and nonsteroidal anti-inflammatory agents (NSAIDs) are often considered first line for pain management. However, among the palliative care patient population, the severity of pain or contraindications to nonopioid agents often necessitate the use of opioid agents such as morphine, oxycodone, or hydromorphone.[17] For example, acetaminophen is contraindicated in patients with severe hepatic impairment, while NSAIDs can increase the risk of cardiovascular events and gastrointestinal bleeding and should not be used in patients with renal impairment.[17] In patients without contraindications, NSAIDs are helpful for mild to moderate nociceptive pain, especially pain due to inflammatory processes such as pain from bony metastases in advanced cancer.[18] Opioids are frequently required for the management of moderate to severe pain in palliative care.[18] Although the World Health Organization ladder recommends weak opioid agonists such as tramadol and codeine as an intermediate step between nonopioid analgesics and strong opioids such as morphine and oxycodone, current evidence supports using lower initial doses of strong opioids in place of weak opioids to achieve better results in the management of cancer pain.[19,20] Opioid agents do not have a maximum ceiling dose, and should instead be titrated to achieve acceptable pain relief while minimizing unacceptable adverse effects such as sedation and respiratory depression. After initiating opioid therapy, patients should be re-evaluated and doses

titrated as required. For patients continuing to experience moderate pain, a dose increase of 25% to 50% is appropriate, while a dose increase of 50% to 100% is reasonable for patients experiencing severe pain.[17]

Patients often describe neuropathic pain as tingling, sharp, burning, electric shock-like, or numbness. Neuropathic pain is caused by damage to the central or peripheral nervous system itself, rather than actual or potential tissue damage, which is a characteristic of nociceptive pain.[21] The distinct pathophysiology underlying neuropathic pain necessitates a different approach to treatment, where adjuvant agents (drugs not originally developed for use as analgesics) are considered first line for pharmacologic management. Evidence-based recommendations for drug treatment of neuropathic pain identify tricyclic antidepressants (TCAs), serotonin-norepinephrine reuptake inhibitors (SNRIs), and calcium channel alpha-2-delta ligands (gabapentin and pregabalin) as first-line therapies.[17,22] Traditional analgesics, such as opioids, are recommended as second-line (tramadol) or third-line therapy (morphine, oxycodone).[22]

When designing an analgesic regimen, the palliative care practitioner should first conduct a thorough assessment of the patient's pain to identify the pathophysiology whenever possible. For patients with persistent nociceptive pain, particularly that which is not expected to resolve (eg, pain due to advancing metastatic cancer without targeted interventions such as radiation), scheduling around-the-clock analgesics, rather than as-needed analgesics only is preferable. For patients receiving opioid therapy who require dosing throughout the day to maintain pain control, palliative care practitioners should consider initiation of a long-acting (LA) or extended-release (ER) formulation of an opioid.[17] Short-acting opioids should continue to be available for the management of "breakthrough" pain, which the patient may experience despite the LA or extended-release opioid.[17] When designing an opioid regimen consisting of LA and short-acting opioids, the basal, or LA, opioid is typically started at a dose representing 50% to 75% of a patient's total 24 hour opioid requirement, while the breakthrough, or short-acting, opioid is started at a dose representing 10% to 20% of the 24 hour opioid requirement.[17,23] If a patient's description or reason for pain is consistent with a neuropathic pathophysiology, adjuvant agents should be considered, and these agents should always be dosed around-the-clock.

When using opioid therapy as part of an analgesic regimen, palliative care practitioners must diligently monitor for and manage opioid adverse effects. Adverse effects frequently associated with opioid therapy include constipation, sedation, and confusion.[18] Adverse effects such as nausea, pruritus, urinary retention, and myoclonus may also occur with opioid therapy although they are less common.[18] Respiratory depression, the most severe and worrisome opioid adverse effect, is always preceded by sedation and thus can typically be caught early with careful monitoring and slow dose titration. While tolerance occurs to most opioid adverse effects after the initial days of therapy or after an increase in dose, tolerance to opioid-induced constipation never develops.[24] Therefore, all patients receiving opioid therapy must be simultaneously initiated on a bowel regimen containing a stimulant laxative.[18,19] Although opioid adverse effects are typically similar for all agents within the class, individual patients may respond more or less favorably to a particular drug. If patients experience unacceptable adverse effects with one opioid agent, rotation to another agent within the

class may provide analgesia while minimizing adverse effects.[19,24]

Dyspnea

4 Dyspnea, or the subjective sensation of breathlessness, is a common symptom in the palliative care patient population.[25] Although common among patients with advanced cancer, particularly those with lung tumors, dyspnea also occurs in patients with advanced cardiac and pulmonary disease such as heart failure and COPD.[26] Whenever possible, treating and reversing the underlying cause of dypsnea is preferred.[26] However, in patients with end-stage disease, reversing the underlying cause may no longer be possible, in which case symptoms should be controlled through pharmacologic and nonpharmacologic treatment.[25,26]

Opioids are first-line agents for the pharmacologic management of dyspnea.[25,26] When used for the management of dyspnea, opioids are equally effective given through either the enteral or parenteral route; however, less evidence supports their use through the nebulized route of administration.[25,26] The beneficial effect of opioids on dyspnea is postulated to occur through multiple mechanisms: a vasodilatory effect on the pulmonary vasculature, a decrease in oxygen consumption during rest and exertion, and changes in the effects of carbon dioxide, oxygenation, and inspiratory flow resistive loading on ventilation.[25]

Benzodiazepines have been studied for the management of dyspnea. A 2011 Cochrane review found no evidence of benefit for benzodiazepines in the management of dyspnea.[27] Benzodiazepines are considered second- or third-line agents, and are likely most useful in combination with opioid therapy in patients experiencing both dyspnea and related anxiety.[25,27]

Non-pharmacologic treatment strategies for dyspnea include use of a fan to create air movement across a patient's face, re-positioning, pulmonary rehabilitation, and complementary therapies such as relaxation strategies. Although commonly requested by patients due to the symptoms of breathless, supplemental oxygen has not been found to be beneficial for patients without hypoxia (PaO_2 < 55 mm Hg [<7.3 kPa]).[25]

Constipation

5 Constipation is a common symptom among patients receiving palliative care, due to both disease processes themselves (eg, tumor obstruction due to gastrointestinal cancers, electrolyte abnormalities, and impaired venous flow due heart failure) and the drugs used to manage other symptoms (eg, opioids, TCAs, antiemetics, and anticholinergics).[28] Estimates of the incidence of constipation vary widely, from 18% to 90% of patients, due to varying definitions of constipation.[28] Constipation generally includes the following symptoms: bowel movements that are difficult, painful, and/or infrequent; hard stools; and a sense of incomplete bowel evacuation.[28] The Rome III Criteria define functional constipation as "a functional bowel disorder that presents as persistently difficult, infrequent, or seemingly incomplete defecation, which do not meet [irritable bowel syndrome (IBS)]

criteria."[29]

Constipation can be managed through nonpharmacological therapies such as increased intake of fluid and fiber, and increased physical activity. However, among the palliative care patient population, pharmacologic therapy with laxatives is generally required. Bulk-forming laxatives such as psyllium are generally not preferred for palliative care patients due to the risk of bowel obstruction or fecal impaction with inadequate fluid intake.[28] In a review of randomized controlled trials evaluating laxatives in patients receiving palliative care, no differences in efficacy were found among lactulose, senna, magnesium hydroxide plus liquid paraffin, and docusate plus senna.[28] All patients receiving opioids for the management of pain or dyspnea should receive prophylactic stimulant laxatives to prevent opioid-induced constipation.[18,19]

When designing a therapeutic regimen for a palliative care patient experiencing constipation, it is reasonable to consider agent availability, patient preference, and onset of action, as the evidence does not support increased efficacy of one agent over another. Combination laxative therapy with agents having different mechanisms of action is likely more effective than restricting therapy to a single laxative.[19] Peripheral opioid antagonists such as methylnaltrexone, naloxegol, and alvimopan should be reserved for opioid-induced constipation that does not respond to traditional laxative therapy.[19]

Nausea and Vomiting

Although less common than pain and dyspnea, nausea and vomiting are distressing symptoms frequently encountered in the palliative care patient population.[30] When evaluating a patient's complaint of nausea and/or vomiting, the palliative care practitioner should attempt to identify the cause of nausea and/or vomiting to identify potentially reversible causes such as those due to hyperglycemia, electrolyte abnormalities, constipation, or medications.[31] Although the evidence base for treatment of nausea and vomiting in the palliative care population is limited, identification of causative factors can also guide rational drug therapy selection.[30,31] Causes of nausea and vomiting, and cause-directed therapies, are shown in **Table e8-1**. If the cause of nausea and/or vomiting is not identifiable or is multifactorial, dopamine antagonists such as haloperidol should be considered for first-line therapy because most symptoms of nausea and vomiting are due gastroparesis or irritation of the chemoreceptor trigger zone.[30] Little evidence supports the use of 5-HT_3 receptor antagonists outside of chemotherapy-induced and postoperative nausea/vomiting, and thus these agents have a limited role in palliative care.[30] Because patients may have multiple causes of nausea and vomiting that respond differently to different agents, use of more than one antiemetic from different classes may be required.[30] If symptoms are refractory to first- or second-line therapy, olanzapine may be useful due to its effect on multiple neurotransmitters involved in the emetic pathway.[30] Nonpharmacologic therapies for nausea and vomiting include relaxation therapy and distraction, provision of small, frequent meals with adequate liquids, and acupuncture.[18]

TABLE e8-1 Causes of Nausea and Vomiting and Treatment[30,31]

Cause of Nausea and Vomiting	Receptor Target	First-Line Treatment	Alternative Treatment
Chemical • Drugs: opioids, antimicrobials, antidepressants, antipsychotics • Metabolic: end-organ failure, electrolyte abnormalities • Toxins: disease-related (cancer), infection	D_2 $5\text{-}HT_3$ NK_1	Haloperidol	Ondansetron
Impaired Gastric Emptying • Drugs: opioids, tricyclic antidepressants, anticholinergics, phenothiazines • Ascites • Hepatomegaly • Tumor infiltration	$5\text{-}HT_4$ D_2	Metoclopramide Discontinuation of causative drugs (if possible)	
Visceral or Serosal • Bowel obstruction • Constipation • Metastatic disease	$5\text{-}HT_3$ ACh H_1	Promethazine Diphenydramine Meclizine	Prochlorperazine
Cranial • Increased intracranial pressure • CNS tumors • Radiation therapy	Ach $5\text{-}HT_3$ $5\text{-}HT_4$ NK_1 Mu	Chlorpromazine promethazine	Haloperidol Dexamethasone
Vestibular • Drugs: opioids	H_1 ACh	Chlorpromazine Promethazine	Scopolamine Prochlorperazine

Cause of Nausea and Vomiting	Receptor Target	First-Line Treatment	Alternative Treatment
• Motion sickness		Diphenhydramine	
Cortical • Pain • Anxiety	GABA	Lorazepam	
	H_1	Treatment of underlying pain or anxiety, if applicable	

D_2: dopamine type 2 receptor; 5-HT_3: serotonin type 3 receptor; NK_1: neurokinin 1 receptor; 5-HT_4: serotonin type 4 receptor; ACh: acetylcholine receptor; H_1: Histamine type 1 receptor; Mu: μ-opioid receptor.

Anxiety

Anxiety is a common symptom among palliative care patients, and may be an underlying condition, caused by the serious illness itself, or exacerbated by physical symptoms such as pain and dyspnea.[18] Communication with patients about their goals of care, and addressing spiritual concerns, discussed later in this chapter, are both essential components of managing anxiety in palliative care patients.[18] Other nonpharmacologic tools for managing anxiety, including relaxation techniques and psychotherapy, may also be useful.[18]

First-line pharmacologic therapy consists of benzodiazepines.[18] These agents may be combined with selective serotonin reuptake inhibitors (SSRIs), which have an anxiolytic effect in addition to their antidepressant activity. However, because SSRIs do not achieve efficacy until 4-6 weeks after initiation, they are not appropriate for patients with a life expectancy of less than 1 month.[18]

Delirium

Delirium is an acute decline in attention and consciousness combined with cognitive dysfunction and is a common symptom among patients receiving palliative care.[18] Among palliative care patients, 13% to 42% of patients have delirium upon admission to a palliative care unit, 26% to 62% of patients have delirium at some point during their admission to a palliative care unit, and 59% to 88% of patients experience delirium during the final weeks preceding death.[32] While delirium may be of a hyperactive, hypoactive, or mixed subtype, hypoactive delirium is most common and also more difficult to detect.[32]

Although often considered an indicator that a patient is approaching the final weeks to days of life, it is important to note that nearly half of delirium cases may be caused by reversible factors and these causes should be assessed and reversed if possible.[18,32] Potentially reversible causes of delirium

among palliative care patients include: uncontrolled pain; constipation; infections; electrolyte abnormalities; withdrawal from opioids, benzodiazepines, or alcohol; medication adverse effects; and lack of sleep.[18] When present, delirium can often be successfully managed or reversed; however, its presence is distressing to patients and caregivers, and can interfere with the assessment and management of other symptoms, such as pain.[32] Thus, assessment of delirium is critical to provide good palliative care. Tools such as the Bedside Confusion Scale (BCS), Confusion Assessment Method (CAM), Delirium Rating Scale, and Memorial Delirium Assessment Scale are available to assist in the recognition of delirium and have been validated in the palliative care patient population.[32]

Non-pharmacologic management of delirium includes patient reorientation, maintenance of a sleep-wake cycle, provision of a familiar environment (presence of family), and provision of assistive devices such as a patient's glasses and hearing aids.[33] Pharmacologic management should begin with avoiding medications that can precipitate or worsen delirium such as benzodiazepines, opioids, anticholinergics, corticosteroids, and beta blockers, as well as correcting reversible causes of delirium.[18,33] Drug therapy for the prevention and treatment of delirium has not been supported by existing evidence.[33] While some pharmacologic therapies have been found to reduce the rates of delirium among hospitalized patients, an impact on clinical outcomes, such as length of stay and mortality, has not been demonstrated.[33] First and second generation antipsychotics are widely used for the management of delirium symptoms among palliative care patients which are not reversible; however, more evidence is required to fully support their place in therapy.[18,33]

MEDICATION MANAGEMENT

An essential component of providing quality palliative care is ensuring that the treatments a patient receives are consistent with his or her wishes and goals of care. Palliative care providers also have a responsibility to ensure that the benefits of any therapy provided outweigh the risks and burdens associated with that treatment.

Deprescribing, the process of discontinuing drug therapy with a goal of improving care and minimizing unnecessary polypharmacy, is one tool palliative care practitioners can use to achieve this aim.[34] Successfully applied, deprescribing can reduce the burden to patients due to the adverse effects of individual agents, and also decrease the risks associated with polypharmacy such as drug interactions and use of potentially inappropriate medications.[34,35,36,37] When combined with palliative care, deprescribing has been shown to result in reduced medication burden, decreased mortality, reductions in hospitalizations, and improvements in patient-reported overall health.[34]

When evaluating medication regimens for candidates for deprescribing, practitioners should consider all drugs in a patient's regimen and the indication for each (if known).[34] Drug candidates for desprescribing include those without an indication, those whose potential harms outweigh potential benefits, drugs initiated to control adverse effects associated with another drug that may not be required, and preventive drugs whose benefit is unlikely to be realized given the patient's life expectancy.[34]

END-OF-LIFE CARE

6 As discussed earlier, palliative care can and should be provided in concert with curative efforts in patients with serious illnesses. At some point curative therapies are no longer viable, but aggressive palliative care efforts should continue to the point of death.

The final days of life present special challenges for pharmacotherapy specialists. First, recognizing when the end is near is important. The "Investigating the Process of Dying" study evaluated physical signs in more than 350 terminally ill cancer patients.[38] Looking at 10 target physical signs, three were considered "early" signs (high frequency and moderate predictive value of death within 3 days): decreased level of consciousness (Richmond Agitation Sedation Scale score of –2 or lower), decreased performance status (Palliative Performance scale less than or equals to 20%), and dysphagia of liquids.[38] Associated symptoms include pulselessness on the radial artery, respiration with movement, decreased urine output, Cheyne-Stokes breathing, death rattle, periods of apnea, and peripheral cyanosis.

The National Cancer Institute provides a superb overview of the "Last Days of Life (PDQ)—Health Professional Version."[39] Much of this information is also applicable to imminent death for patients with noncancer diagnoses. This review covers those symptoms seen in the final months, weeks and days of life, care decisions during this time period, forgoing potentially life-sustaining treatments, and more. Issues of particular relevance for pharmacotherapy specialists include attention to symptoms likely to arise or worsen such as delirium, dyspnea, fatigue, pain, cough, death rattle, myoclonus, fever, and palliative care emergencies such as catastrophic hemorrhage.

Medication management issues at this point in the patient's life clearly include elimination of medications unlikely to provide benefit at this time, and switching to nonoral routes of medication administration that are least likely to be invasive. For example, several opioids, lorazepam, dexamethasone, and haloperidol are available as "intensol" formulations. An intensol is a highly concentrated oral solution of a medication, such as morphine 20 mg/mL oral solution. Generally speaking up 1 mL can be instilled in the buccal cavity even if the patient is unconscious (the upper body should be propped up to 30° from horizontal to prevent aspiration). Medication management needs during final days should be anticipated and discussed with the family members and caregivers well in advance.

GOALS OF CARE

7 A critically important part of all patient care, but particularly while providing palliative care is to determine the patient's goals of care. As a matter of fact, the most common reason for referral to palliative care services is to have the "goals of care" discussion.[40] Meaningful conversations about the goals of care lead to significantly better patient and family outcomes including enhanced quality of life, less use of nonbeneficial medical care near death, better goal-consistent care, positive family outcomes, and reduced costs.[41]

Determining the patient's and family's wishes and goals of care requires excellent communication among health care providers, the patient, and the patient's family. There are many models that may be used to facilitate these discussions. Bernacki and colleagues provide an excellent review and synthesis of best practices for communication about serious illness care goals.[41] They suggest a "conversation guide" that includes probing the patient's understanding of their illness ("What is your understanding now of where you are with your illness?") and determining how much information that patient would like to know about their illness ("How much information about what is likely to be ahead with your illness would you like from me?"). The model continues with questions that help shape goals, solicit patient/family fears and worries, assess important functional goals, determine how much information the patient wants to share with others, and exploring the idea of "trade-offs." One suggested trade-off question is, "If you become sicker, how much are you willing to go through for the possibility of gaining more time?" This question may include advance directives such as "do not resuscitate" or "do not intubate" but also includes the patient's willingness to undergo potentially aggressive therapies such as continued chemotherapy, radiation, surgery, and hospitalization including intensive care unit admission. This conversation helps shape pharmacotherapy, frequently shifting from often futile curative therapies to supportive/palliative measures.

Kaldjian and colleagues reviewed the literature regarding goals of care at the end of life. They determined six overarching comprehensive goal categories most often brought up by patients: be cured, live longer, improve or maintain function/quality of life/independence, be comfortable, achieve life goals, and provide support for family/caregiver.[42] Again, the wish to "be comfortable" is highly relevant to pharmacotherapy specialists. Specific comfort goals that frequently populate a "top 10 wish list" for patients with a serious illness, and may be related to drug therapy include: to be free from pain (number 1), to be mentally aware, not being short of breath, not being connected to machines, and to be free from anxiety.[43] Understanding the advanced illness patient's goals of care, and cultural beliefs is critically important in the medication management process.

Clinical Controversy…

Current Controversy 1: While the imperative of providing pain management for patients facing serious illness is well recognized, using opioids for pain management while minimizing the risks of misuse, abuse, addiction, and diversion is a challenging issue facing the healthcare community at large. Since 1999, deaths from prescription opioids have increased 4-fold, with more than 16,000 Americans dying from prescription opioid overdoses in 2013.[48] Palliative care practitioners, along with all practitioners providing pain management, are challenged to effectively manage pain while also ensuring safe practices are followed when prescribing and dispensing opioids to minimize the associated risk of misuse, abuse, addiction, and diversion.

Current Controversy 2: Practitioner-assisted death is perhaps the most controversial issue facing the palliative care community today. Practitioner-assisted death refers to the provision of a lethal dose of medication by a healthcare practitioner at the request of patient with a terminal illness so the patient may choose to end his or her life in order to avoid intractable suffering.[49] While some view assisted death as crucial to providing patients with a dignified death, others view it as morally incompatible with a healthcare practitioner's duty to honor life. Despite the controversy and moral, spiritual, and

ethical issues surrounding assisted death, legislation permitting the practice has been passed or is in force in five states (Oregon, Washington, Montana, Vermont, and California) in the United States.[50]

SPIRITUAL CONSIDERATIONS

8 While physical comfort is paramount in caring for patients with advanced illnesses, nonphysical complaints such as spiritual concerns are an important component of total patient care. Palliative care providers span a range of health care disciplines, and it is critically important that all providers work collaboratively to achieve physical, psychological, social, and spiritual goals established by the patient. Spirituality is "the aspect of humanity that refers to the way individuals seek and express meaning and purpose and the way they experience their connectedness to the moment, to self, to others, to nature, and/or to the significant or sacred."[44]

Research has shown that a patient's religion and spirituality play an important role in coping with disease-related symptoms and affect the quality of life and medical decision-making.[45] The National Consensus Project (NCP) provides "Clinical Practice Guidelines for Quality Palliative Care," emphasizing spiritual, religious, and existential aspects of advanced illness care as one of the key elements of palliative care.[46] Pharmacotherapy specialists should be competent to perform an initial spiritual screening, with subsequent referral to a board-certified chaplain as appropriate. One instrument that has been developed to assist primary care practitioners and other nonspecialists perform a spiritual assessment is the FICA (F – faith and belief; I – important; C – community; A – address in care) tool developed by Puchalski and colleagues.[47]

CONCLUSION

Palliative care provides patients with serious illness with symptom management, attention to quality of life, and alignment of treatment with patient-identified goals. Providing palliative care requires healthcare practitioners to be competent in the management of pain, dyspnea, constipation, and other symptoms using pharmacologic and nonpharmacologic treatments. Practitioners are also challenged to address the nonphysical needs of patients with serious illness including spirituality and faith. Lastly, palliative care practitioners must continually strive to ensure that all treatments provided to patients with serious illness are consistent with the patients' goals of care, and are not associated with burdens that outweigh potential benefits.

Chapter e9: Clinical Toxicology

Peter A. Chyka

INTRODUCTION

KEY CONCEPTS

- 1 Poisoning can result from exposure to excessive doses of any chemical, with medicines being responsible for most childhood and adult poisonings.
- 2 The total number and rate of poisonings have been increasing, but preventive measures, such as child-resistant containers, have reduced mortality in young children.
- 3 Immediate first aid may reduce the development of serious poisoning, and consultation with a poison control center may indicate the need for further therapy.
- 4 The use of ipecac syrup, gastric lavage, whole bowel irrigation, and cathartics has fallen out of favor as routine therapies, whereas activated charcoal remains useful for gastric decontamination of appropriate patients.
- 5 Antidotes can prevent or reduce the toxicity of certain poisons, but symptomatic and supportive care is essential for all patients.
- 6 Acute acetaminophen poisoning produces severe liver injury and occasionally kidney failure. A determination of serum acetaminophen concentration may indicate whether there is risk of hepatotoxicity and the need for acetylcysteine therapy.
- 7 Anticholinesterase insecticides may produce life-threatening respiratory distress and paralysis by all routes of exposure and can be treated with symptomatic care, atropine, and pralidoxime.
- 8 An overdose of calcium channel antagonists will produce severe hypotension and bradycardia and can be treated with supportive care, calcium, insulin with supplemental dextrose, and glucagon.

- 9 Poisoning with iron-containing drugs produces vomiting, gross gastrointestinal bleeding, shock, metabolic acidosis, and coma and can be treated with supportive care and deferoxamine.
- 10 Acute opioid poisoning and overdose can produce life-threatening respiratory depression that can be treated with assisted ventilation and naloxone.
- 11 Chemicals can be used for mass poisonings by acts of terrorism and warfare and typically produce life-threatening effects within minutes to hours, which warrant emergency preparedness at healthcare facilities and communities.

Poisoning is an adverse effect from a chemical that has been taken in excessive amounts. The body is able to tolerate and, in some cases, detoxify a certain dose of a chemical; however, toxicity ensues once a critical exposure threshold is exceeded. Poisoning can produce minor local effects that may be treated readily in the outpatient setting or systemic life-threatening effects that require intensive medical intervention. Virtually any chemical can become a poison when taken in sufficient quantity, but the potency of some compounds leads to serious toxicity with small quantities (**Table e9-1**). Poisoning by chemicals includes exposure to drugs, industrial chemicals, household products, plants, venomous animals, agrochemicals, and weapons for warfare and terrorism. This chapter describes some examples of the spectrum of toxicity, outlines means to recognize poisoning risk, and presents principles of treatment.

TABLE e9-1 Serious Toxicity in a Child Associated with Ingestion of One Mouthful or One Dosage Unit

Acids[a]	Cocaine
Anticholinesterase insecticides[a]	Colchicine
Caustics or alkalis[a]	Cyanide[a]

Chloroquine	Methanol[a]
Clonidine	Phencyclidine or LSD

[a]Concentrated or undiluted form.

EPIDEMIOLOGY

Poisonings account for approximately 52,000 deaths, at least 2.3 million emergency department visits, and over 1.3 million nonfatal poisoning injuries each year in the United States.[1,2] Approximately 0.2% of poisoning deaths involve children younger than 5 years.[1] Of emergency department visits for drug-related poisoning, typically 1.1 million visits are made each year (3.5 per 100,000 population) with the highest rate observed for patients 20 to 34 years of age. One-fourth of emergency department visits for drug-related poisonings were hospitalized, which is twice the rate of other types of visits.[2] The age-adjusted death rates from poisonings from all circumstances have been increasing steadily, with a 224% increase from 2000 to 2014, representing 51,966 deaths in 2014 of which 91%

were drug-related poisonings. This increasing mortality trend has placed poisoning since 2008 as the leading cause of injury death in the United States.[1]

1 Several databases in the United States provide different levels of insight into and documentation of the poisoning problem (**Table e9-2**). Poisonings documented by U.S. poison centers are compiled in the annual report of the American Association of Poison Control Centers National Poison Data System (AAPCC-NPDS).[3] Although it represents the largest database on poisoning, it is not complete because it relies on individuals voluntarily contacting a poison control center. The AAPCC-NPDS data set captures approximately 2% of the annual number of deaths from poisoning tabulated in death certificates.[1,3] Despite these shortcomings, AAPCC-NPDS provides valuable insight into the characteristics and frequency of poisonings in the community at large. In the 2014 AAPCC-NPDS summary, 2,165,142 poisoning exposures were reported by 55 poison centers that served the entire United States.[3] Children younger than 6 years accounted for 48% of cases. A residence was the site of exposure in 93% of the cases, and a single substance was involved in 89% of cases. An acute exposure accounted for 88% of cases and 79% were unintentional or accidental exposures. Fatalities accounted for 1,173 (0.05%) cases, of which 48% resulted from suicide and 2% were children younger than 6 years of age. The distribution of substances most frequently involved in pediatric and adult exposures differed; however, medicines were the most frequently involved (48%) substances (**Table e9-3**). Sixty-eight percent of the poison exposures were treated at the scene. In summary, children account for most of the reported poison exposures, but a greater proportion of life-threatening poisonings are observed in adults.

TABLE e9-2 Comparison of Various Poisoning Databases

Database (Abbreviation)	Characteristics
Death certificates from state health departments compiled by the National Center for Health Statistics (NCHS) *www.cdc.gov/injury/wisqars/*	Compiles all death certificates whether the cause of death was by disease or external forces. Typically verified by laboratory and clinical observations.
National Electronic Injury Surveillance System—All Injury Program of U.S. Consumer Product Safety Commission (NEISS) *www.cpsc.gov/en/research--statistics/neiss-injury-data/*	Surveys electronically all injuries, including poisonings, treated daily at approximately 100 emergency departments. Used to identify product-related injuries.
The American Association of Poison Control Centers' National Poison Data System (AAPCC-NPDS) *www.aapcc.org*	Represents largest database of poison exposures with high representation of children based on voluntary reporting to poison control centers.

TABLE e9-3 Poison Exposures by Age Group and Fatal Outcome, Ranked in Decreasing Order[3]

Pediatric	Adult	Fatal Outcome
Medicines	Medicines	Medicines
Cosmetics, personal care items	Cleaning substances	Gases, fumes
Cleaning substances	Alcohols	Chemicals

Pediatric	Adult	Fatal Outcome
Foreign bodies, toys	Pesticides	Alcohols
Pesticides	Bites and envenomation	Pesticides
Plants	Cosmetics, personal care items	Automotive products
Dietary supplements	Gases, fumes	Cleaners, household

POISON PREVENTION STRATEGIES

2 The number of poisoning deaths in children has declined dramatically over the past five decades, due, in part, to the implementation of several poison prevention approaches. These include the Poison Prevention Packaging Act (PPPA) of 1970, the evolution of regional poison control centers, the application of prompt first aid measures, improvements in overall critical care, development of less toxic product formulations, better clarity in the packaging and labeling of products, and public education on the risks and prevention of poisoning. Although all these factors play a role in minimizing poisoning dangers, particularly in children, the PPPA has perhaps had the most significant influence. The intent of the PPPA was to develop packaging that is difficult for children younger than 5 years of age to open or to obtain harmful amounts within a reasonable period of time. However, the packaging was not to be difficult for normal adults to use properly. Safety packaging is required for a number of products and product categories (**Table e9-4**). Child-resistant containers are not totally childproof and may be opened by children, which can result in poisoning. Despite the success of child-resistant containers, many adults disable the hardware or simply use no safety cap, thus placing children at risk. Fatigue of the packaging materials can occur, which underscores the need for new prescription ware for refills, as required in the PPPA.[4] During 2007 to 2011, the number of emergency department visits for prescription drug ingestions by preschool-aged children has increased with most exposures due to opioids and benzodiazepines.[5] Patients should be encouraged to properly dispose of medications that are outdated or no longer indicated in order to eliminate the risk of poisoning and drug diversion (see *www.fda.gov/forconsumers/consumerupdates/ucm101653.htm*).

TABLE e9-4 Examples of Products Requiring Child-Resistant Closures

Acetaminophen	Kerosene
Aspirin	Methanol
Diphenhydramine	Naproxen
Ethylene glycol	Oral prescription drugs[a]
Glue removers containing acetonitrile	Sodium hydroxide
Ibuprofen	Sulfuric acid
Iron pharmaceuticals	Turpentine

[a]With certain exceptions such as nitroglycerin and oral contraceptives.

Poison prevention requires constant vigilance. New generations of families must be educated on

poisoning risks and prevention strategies. New products and changes in product formulations present different poisoning dangers and must be studied to provide optimal management. Strategies to prevent poisonings should consider the various psychosocial circumstances of poisoning (**Table e9-5**), prioritize risk groups and behaviors, and customize an intervention for specific situations.

TABLE e9-5 Psychosocial Characteristics of Poisoning Patients

Children	Adults	Elderly
Act purposefully or are poisoned by caretaker or sibling	Intentional abuse or suicidal intent is possible	Act with suicidal intent or unintentional misuse
Act with developmentally appropriate curiosity	Disregard or cannot read directions	Confuse product identity and directions for use
Attracted by product appearance	Do not recognize poisoning risk	Do not recognize poisoning risk
Ingest substances that adults find unpleasant	Reluctant to seek assistance until ill	Comorbid conditions complicate toxicity
React to stressful and disrupted household	Exaggerate or misrepresent situation	Unable or unwilling to describe situation
Imitate adult behaviors (eg, taking medicine)	Peer pressure to experiment with drugs	Multiple drugs may lead to adverse reactions

Recognition and Assessment

A clinician's initial responsibility is to determine whether a poisoning has occurred or a potential for development of a poisoning exists. Some patients provide a clear account of an exposure that occurred with a known quantity of a specific agent. Other patients appear with an unexplained illness characterized by nonspecific signs and symptoms and no immediate history of ingestion. Exposure to folk remedies, dietary supplements, and environmental toxins also should be considered. Patients with suicide gestures can deliberately give an unclear history, and poisoning should be suspected routinely. Poisoning and drug overdoses should be suspected in any patient with a sudden, unexplained illness or with a puzzling combination of signs and symptoms, particularly in high-risk age groups. Nearly any symptom can be seen with poisoning, but some signs and symptoms are suggestive of a particular toxin exposure. Compounds that produce characteristic clinical pictures (toxidromes), such as organophosphate poisoning with pinpoint pupils, rales, bradycardia, central nervous system depression, sweating, excessive salivation, and diarrhea, are most readily recognizable.[6] The recognition of chemicals responsible for acute mass emergencies resulting from industrial disasters, hazardous materials accidents, or acts of terrorism may be aided by evaluating characteristic signs and symptoms.[7] Some drugs may be adulterated or counterfeit products and delay appropriate recognition of a possible toxin.[8] Assessment of the patient may be aided by consultation with a poison control center. A center can provide information on product composition, typical symptoms, range of toxicity, laboratory analysis, treatment options, and bibliographic references. Furthermore, a center will have specially trained physicians, pharmacists, nurses, and toxicologists on staff or available for consultation to assist with difficult cases. Consultation with a

poison control center also may identify changes in recommended therapy. A nationwide toll-free poison center access number (1-800-222-1222) routes callers to the poison control center serving the locality of the caller.

When the circumstances of a poison exposure indicate that it is minimally toxic, many poisonings can be managed successfully at the scene of the poisoning.[3,9] Poison control centers typically monitor the victim by telephone during the first 2 to 6 hours of the exposure to assess the patient's status and outcome of first aid.

Once a poisoning is suspected and confirmation of the diagnosis is needed for medical or legal purposes, appropriate biologic material should be sent to the laboratory for analysis. Gastric contents may contain the greatest concentration of drug, but they are difficult to analyze. Blood, saliva or urine can be tested by qualitative screening in order to detect a drug's presence.[10,11] The results of a qualitative drug screen can be misleading because of interfering or low-level substances (**Table e9-6**); it rarely guides emergency therapy and thus has questionable value for nonspecific, general screening purposes.[10,11] Consultation with the laboratory technician and review of the assay package insert will help to determine the sensitivity and specificity of the assay. Quantitative determination of serum concentrations may be important for the assessment of some poisonings, such as acetaminophen, ethanol, iron, salicylates, and digoxin.[12]

TABLE e9-6 Considerations in Evaluating the Results of Some Common Immunoassays Used for Urine Drug Screening

Drug	Detection After Stopping Use	Comments
Amphetamines	2-5 days	Many sympathomimetic amines, such as pseudoephedrine, ephedra, phenylephrine, fenfluramine, and phentermine, may cause positive results
	Up to 2 weeks with prolonged or heavy use	Other drugs, such as selegiline, chlorpromazine, trazodone, ranitidine, and amantadine, may cause false-positive results depending on the assay
Benzodiazepines	Up to 2 weeks Up to 6 weeks with chronic use of some drugs 7-10 days	Ability to detect benzodiazepines varies by drug; oxaprozin, sertraline may cause false-positive results
Cannabinoid metabolite (marijuana)	Up to 1-2 months with prolonged or heavy use	Extent and duration of use will affect detection time. Drugs such as ibuprofen and naproxen may cause false-positive results depending on the assay
Cocaine metabolite (benzoylecgonine)	12-72 hours Up to 1-3 weeks	Cocaine is metabolized rapidly and specific metabolites are typically the substance detected. False-positive results from "caine" anesthetics and other drugs are unlikely

Drug	Detection After Stopping Use	Comments
	with prolonged or heavy use	
Opioids	2-3 days	Because the assay was made to detect morphine, detection of other opioids, such as codeine, oxycodone, hydrocodone, and other semisynthetic opioids, may be limited. Some synthetic opioids, such as fentanyl and meperidine, may not be detected. Drugs such as rifampin and some fluoroquinolones may cause false-positive results depending on the assay
	Up to 6 days with sustained-release formulations	
	Up to 1 week with prolonged or heavy use	
Phencyclidine	2-10 days	Drugs such as ketamine, dextromethorphan, diphenhydramine, venlafaxine, ibuprofen, meperidine, and tramadol may cause false-positive results depending on the assay
	1 month or more with prolonged or heavy use	

Pharmacogenetic Considerations

Pharmacogenetic factors responsible for poisoning risk among individuals have not been systematically studied, but unusual circumstances of poisoning cases have prompted the use of genotyping as a means to identify polymorphically expressed drug metabolizing enzymes. The following three examples demonstrate this phenomenon. The antitussive drug, dextromethorphan is abused to achieve euphoric effects, which are not universally experienced at comparable doses. The dextromethorphan metabolite dextrorphan is responsible for the euphoria, dysphoria, hallucinations, and hyperactive behavior. Individuals who are cytochrome P450 (CYP) 2D6 extensive metabolizers are more apt to experience these euphoric effects.[13] Codeine has produced severe toxicity and death in some breast-fed infants, healthy young children, and older adults following the ingestion of typical doses. These individuals were ultrarapid CYP2D6 metabolizers of codeine, which resulted in the generation of life-threatening or fatal amounts of morphine, a metabolite of codeine.[14,15] Lastly, hydrocodone administration at higher than recommended doses resulted in death to a child who was a CYP2D6 poor metabolizer which reduced the capacity to metabolize hydrocodone to hydromorphone.[16]

The pharmacokinetic characteristics of drugs taken in overdose may differ from those observed following therapeutic doses (**Table e9-7**).[17,18] These differences are the result of dose-dependent changes in absorption, distribution, metabolism, or elimination; pharmacologic effects of the drug; or pathophysiologic consequences of the overdose. Dose-dependent changes may decrease the rate and extent of absorption, whereas the bioavailability of the agent may be increased because of saturation of first-pass metabolism. Delayed gastric emptying by anticholinergic drugs or as the result of general central nervous system depression caused by many drugs may alter the rate and

extent of absorption. Patients with a drug overdose may inherently exhibit prolonged gastric emptying and gastric hypomotility.[19] The formation of concretions or bezoars of solid dosage forms may delay the onset, prolong the duration, or complicate the therapy for an acute overdose.[20] A combination of pharmacokinetic and pharmacodynamic factors may lead to delayed onset of toxicity of several toxins, such as thyroid hormones, oral anticoagulants, acetaminophen, and drugs in sustained-release dosage forms. The distribution of a compound may be altered because of saturation of protein-binding sites. Drug-induced hypoperfusion may affect drug distribution and result in reduced hepatic or renal clearance. Changes in blood pH may alter the distribution of weak acids and bases. Metabolism and elimination of a compound may be retarded because of saturation of biotransformation pathways leading to nonlinear elimination kinetics. Drug-induced kidney or liver injury also can decrease clearance significantly. Implications of these changes for poisoning management include delayed achievement of peak concentrations with a corresponding longer period of opportunity to remove the drug from the gastrointestinal tract. The expected duration of effects may be much greater than that observed with therapeutic doses because of continued absorption and impaired clearance. The application of pharmacokinetic variables, such as percentage protein binding and volume of distribution, from therapeutic doses may not be appropriate in poisoning cases.[17,18] Data on toxicokinetics, the application of pharmacokinetic principles in the setting of overdose and toxicity, often are difficult to interpret and compare because the doses and times of ingestion are uncertain, the duration of sampling is inadequate, active metabolites may not be measured, protein binding typically is not assessed, and the severity of toxicity may vary dramatically.

TABLE e9-7 Examples of the Influence of Drug Overdosage on Pharmacokinetic and Pharmacodynamic Characteristics

Effect of Overdosage[a]	Examples
Slowed absorption due to formation of poorly soluble concretions in the gastrointestinal tract	Aspirin, lithium, phenytoin, sustained-release theophylline
Slowed absorption due to slowed gastrointestinal motility	Benztropine, nortriptyline
Slowed absorption due to toxin-induced hypoperfusion	Procainamide
Decreased serum protein binding	Lidocaine, salicylates, valproic acid
Increased volume of distribution associated with toxin-induced acidemia	Salicylates
Slowed elimination due to saturation of biotransformation pathways	Ethanol, phenytoin, salicylates, theophylline
Slowed elimination due to toxin-induced hypothermia (<35°C)	Ethanol, propranolol
Prolonged toxicity due to formation of longer-acting metabolites	Carbamazepine, dapsone, glutethimide, meperidine

[a]Compared to characteristics following therapeutic doses or resolution of toxicity.

GENERAL APPROACH TO TREATMENT

Prehospital Care

First Aid

3 The presence of adequate airway, breathing, and circulation should be assessed and cardiopulmonary resuscitation should be started if needed. The most important step in preventing a minor exposure from progressing to a serious intoxication is early decontamination of the poison. Basic poisoning first aid and decontamination measures (**Table e9-8**) should be instituted immediately at the scene of the poisoning. If there is any question about the potential severity of the poison exposure, a poison control center should be consulted as soon as possible (1-800-222-1222). Placing the patient on the left side while awaiting transport may afford easier clearance of the airway if emesis occurs and may slow the absorption of drug from the gastrointestinal tract.[21]

TABLE e9-8 First Aid for Poison Exposures

Inhaled poison
Immediately get the person to fresh air. Avoid breathing fumes. Open doors and windows. If victim is not breathing, start artificial respiration.
Poison on the skin
Remove contaminated clothing and flood skin with water for 10 minutes. Wash gently with soap and water and rinse. Avoid further contamination of victim or first aid providers.
Poison in the eye
Flood the open eye with lukewarm or cool water poured from a glass 2 or 3 inches (~5-8 cm) before flushing the eye. Repeat for 10 to 15 continuous minutes. Remove contact lenses.
Swallowed poison
Unless the patient is unconscious, having convulsions, or cannot swallow, give 2 to 4 ounces (~60-120 mL) of water immediately and then seek further help.

Ipecac Syrup

4 Ipecac syrup had been used in the United States since the 1960s as a means to induce vomiting for treatment of ingested poisons, but its use is no longer recommended due to negligible benefit. In 2003 the American Academy of Pediatrics issued a policy statement indicating that ipecac syrup was no longer to be used routinely to treat poisonings at home and that parents should discard any ipecac.[22] In 2010 ipecac syrup was no longer manufactured for use in the US,[23] but it still may be found in some households. Nevertheless, in the 2014 AAPCC-NPDS report 132 individuals (0.006% of 2.17 million poison exposures) received ipecac syrup, with or without poison center direction.[3]

There are several contraindications to the use of ipecac syrup or any form of induced emesis, such as gagging. If the patient is without a gag reflex; is lethargic, comatose, or convulsing; or is expected to become unresponsive within the next 30 minutes, then emesis should not be induced. If a fruitful

emesis has occurred spontaneously shortly after ingestion, further emesis may not be necessary. Ingestions of caustics, corrosives, ammonia, and bleach are definite contraindications to induced emesis. Ingestion of aliphatic hydrocarbons (eg, gasoline, kerosene, and charcoal lighter fluid) typically does not require emesis. When the agent is definitely known to be nontoxic, induction of emesis is purposeless and potentially dangerous, for example, pulmonary aspiration of vomitus if unresponsiveness develops and the airway is not protected. The rapid onset of coma or seizures or the potential to exaggerate the toxic effects of the poison may preclude further the induction of emesis. Some examples include poisonings with opioids, clonidine, tricyclic antidepressants, hypoglycemic agents, nicotine, strychnine, β-blocking agents, and calcium channel blockers. Debilitated, pregnant, and elderly patients may be further compromised by induction of emesis.

Hospital Treatment

Supportive and symptomatic care is the mainstay of treatment of a poisoned patient. In the search for specific antidotes and methods to increase excretion of the drug, attention to vital signs and organ functions should not be neglected. Establishment of adequate oxygenation and maintenance of adequate circulation are the highest priorities. Other components of the acute supportive care plan include the management of seizures, arrhythmias, hypotension, acid-base balance, fluid status, electrolyte balance, and hypoglycemia. Placement of IV and urinary catheters is typical to ensure delivery of fluids and drugs when necessary and to monitor urine production, respectively.

Gastric Lavage

Gastric lavage involves the placement of an orogastric tube and washing out of the gastric contents through repetitive instillation and withdrawal of fluid. Gastric lavage is not recommended for routine use, if at all, and only by clinicians experienced in its use.[24]. It may be considered for potentially life-threatening ingestions, when the ingestion occurred within 1 hour as a general guide, or when the substance is not absorbed by activated charcoal. If the patient is comatose or lacks a gag reflex, gastric lavage should be performed only after intubation with a cuffed or well-fitting endotracheal tube. Relative contraindications for gastric lavage include ingestion of a corrosive or hydrocarbon agent. Complications of gastric lavage include aspiration pneumonitis, laryngospasm, esophageal and gastric perforation and fluid and electrolyte imbalance.[24] Use of gastric lavage has declined in recent years as evidenced by the finding that only 0.3% of 612,184 cases treated at a healthcare facility received gastric lavage in the 2014 AAPCC-NPDS report.[3]

Single-Dose Activated Charcoal

Reduction of toxin absorption can be achieved by administration of activated charcoal. It is a highly purified, adsorbent form of carbon that prevents gastrointestinal absorption of a drug by chemically binding (adsorbing) the drug to the charcoal surface. There are no toxin-related contraindications to its use, but it is generally ineffective for iron, lead, lithium, simple alcohols, and corrosives. It is not indicated for aliphatic hydrocarbons because of the increased risk for emesis and pulmonary aspiration. Activated charcoal is most effective when given within the first few hours after ingestion, ideally within the first hour.[25] The recommended dose of activated charcoal for a child (1-12 years

old) is 25 to 50 g; for an adolescent or adult, the recommended dose is 25 to 100 g. Children younger than 1 year can receive 1 g/kg. Activated charcoal is mixed with water to make a slurry, shaken vigorously, and administered orally or via a nasogastric tube. Activated charcoal is contraindicated when the gastrointestinal tract is not intact or when the airway is not protected.

Clinical Controversy…

Activated charcoal has been promoted for use at home as a replacement for ipecac syrup, but some have contended that little evidence indicates activated charcoal can be used safely and properly in this setting.

Activated charcoal is relatively nontoxic, but two risks include (a) emesis following administration and (b) pulmonary aspiration of charcoal and gastric contents leading to pneumonitis in patients with an unprotected airway or absent gag reflex.[25] Some activated charcoal products contain sorbitol, a cathartic that may be associated with an increased incidence of emesis following use. Activated charcoal has been promoted for treatment of poisonings at home, but issues of safety, patient compliance, and effectiveness have not been proven in the home setting.[22,26] Single-dose activated charcoal use has remained relatively steady during the past decade, with 2.1% of 2.17 million cases having received it according to the 2014 AAPCC-NPDS report.[3]

Cathartics

Cathartics, such as magnesium citrate and sorbitol, were thought to decrease the rate of absorption by increasing gastrointestinal elimination of the poison and the poison-activated charcoal complex, but their value is unproven. Poisoned patients do not routinely require a cathartic, and it is rarely, if ever, given without concurrent activated charcoal administration.[31] If used, a cathartic should be administered only once and only if bowel sounds are present. Infants, the elderly, and patients with impaired kidney function should be given saline cathartics cautiously, if at all.[27]

Whole-Bowel Irrigation

Polyethylene glycol electrolyte solutions, such as GoLYTELY and Colyte, are used routinely as whole-bowel irrigants prior to colonoscopy and bowel surgery. These solutions also can be used to decontaminate the gastrointestinal tract of ingested toxins.[28] Large volumes of these osmotically balanced solutions are administered continuously through a nasogastric or duodenal tube for 4 to 12 hours or more. It quickly causes gastrointestinal evacuation and is continued until the rectal discharge is relatively clear. Only 20% to 25% of patients complete a full regimen of whole bowel irrigation based on poison center recommendations. This procedure may be indicated for certain patients in whom the ingestion occurred several hours prior to hospitalization and the drug still is suspected to be in the gastrointestinal tract, such as drug smugglers who swallow condoms filled with cocaine.[29] In addition, patients who have ingested delayed-release or enteric-coated drug formulations or have ingested substances, such as iron, lithium and potassium, that are not well adsorbed by activated charcoal may benefit from whole-bowel irrigation.[28] It should not be used in patients with a bowel perforation or obstruction, gastrointestinal hemorrhage, ileus, or intractable

emesis. Emesis, abdominal cramps, and intestinal bloating have been reported with whole-bowel irrigation.[28] During 2014, whole-bowel irrigation was used in 0.3% of 612,184 cases managed at a healthcare facility.[3]

Perspectives on Gastric Decontamination

Although there are a variety of options for gastric decontamination, the American Academy of Clinical Toxicology and the European Association of Poison Centers and Clinical Toxicologists have concluded that no means of gastric decontamination should be used routinely for a poisoned patient without careful consideration (position statements are available at *www.clintox.org/positionstatements.cfm*).[24,25,27,28] Therapy is most effective within the first hour, and effectiveness beyond this time cannot be supported or refuted with the available data. A clinical policy statement by the American College of Emergency Physicians concludes that although no definitive recommendation can be made on the use of ipecac syrup, gastric lavage, cathartics, or whole-bowel irrigation, activated charcoal is advocated for most patients when appropriate.[30] The clinical policy also states that ipecac syrup is rarely of value in the emergency department and that the use of whole-bowel irrigation following ingestion of substances not well adsorbed by activated charcoal is not supported by evidence. In many cases treatment solely with activated charcoal or observation and supportive care should be considered. Poison control centers may be a source of guidance on the contemporary application of gastric decontamination techniques for a specific patient.

Enhanced Elimination

Of the methods tried to increase the rate of excretion of poisons from the body, only diuresis, multiple-dose activated charcoal, and hemodialysis have demonstrated usefulness in select situations. These approaches should be considered only if the risks of the procedure are significantly outweighed by the expected benefits or if the recovery of the patient is seriously in doubt and the method has been shown to be helpful.

Diuresis

Diuresis can be used for poisons excreted predominantly by the renal route; however, most drugs and poisons are metabolized, and thus only a good urine flow (eg, 2-3 mL/kg/h) needs to be maintained for most patients. Fluid and electrolyte balance should be monitored closely. Ionized diuresis by altering urinary pH may increase excretion of certain chemicals that are weak acids or bases by trapping ionized drug in the renal tubule and minimizing reabsorption.

Alkalinization of the urine to achieve a urine pH of 7.5 or greater for poisoning by weak acids such as salicylates or phenobarbital can be achieved by IV administration of sodium bicarbonate 1 to 2 mEq/kg (mmol/kg) bolus followed by an infusion of 100 to 150 mEq (mmol) in 1 liter of dextrose 5% in water at 1.5 to 2 times the rate of maintenance fluid administration. Complications of urinary alkalinization include alkalemia, hypokalemia, alkalotic tetany, and inability to achieve target urinary pH values.[31] Acid diuresis may enhance the excretion of weak bases, such as amphetamines, but it is

rarely used because it risks worsening amphetamine-related rhabdomyolysis with corresponding acute kidney injury. Generally, diuresis or ionized diuresis is rarely indicated for poisoned patients because it is inefficient relative to other methods of enhancing elimination, it is associated with a risk of unacceptable adverse effects, and renal elimination of most drugs is not enhanced dramatically.

Multiple-Dose Activated Charcoal

Multiple doses of activated charcoal can augment the body's clearance of certain drugs by enhanced passage from the bloodstream into the gastrointestinal tract and subsequent adsorption. This process, termed *charcoal intestinal dialysis* or *charcoal-enhanced intestinal exsorption*, describes the attraction of drug molecules across the capillary bed of the intestine by activated charcoal in the intestinal lumen and subsequent adsorption of the drug to the charcoal. Furthermore, it may interrupt the enterohepatic recirculation of certain drugs. Once the drug is adsorbed to the charcoal, it is eliminated with the charcoal in the stool. Systemic clearance of several drugs has been shown to be enhanced up to several-fold.[32] An international toxicology group's position statement on multiple-dose activated charcoal concluded that it should be considered only if a patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline.[32] Although a prospective, randomized study of the effects of multiple-dose activated charcoal on phenobarbital-overdosed patients demonstrated increased drug elimination, no demonstrable effect on patient outcome was observed.[33]

This approach provides a rapid onset of action that is limited by blood flow and a maximal "ceiling effect" related to the dose of charcoal present in the intestine. The response to multiple-dose activated charcoal is greatest for drugs with the following characteristics: good affinity for adsorption by activated charcoal, low intrinsic clearance, sufficient residence time in the body (long serum half-life), long distributive phase, and low or nonrestrictive protein binding. A small volume of distribution is desirable, but it has a marginal influence as an isolated characteristic,[34] particularly if multiple-dose activated charcoal is instituted during the toxin's distributive phase. A typical dosage schedule is 15 to 25 g of activated charcoal every 2 to 6 hours until serious symptoms abate or the serum concentration of the toxin is below the toxic range. This procedure has been used in premature and full-term infants in doses of 1 g/kg every 1 to 4 hours. Serious complications, such as pulmonary aspiration, occur in less than 1% of patients.[35] The risks of aspiration pneumonitis in obtunded or uncooperative patients and of intestinal obstruction in patients prone to ileus following a period of bowel ischemia (eg, after cardiopulmonary arrest in the elderly) may be higher.[33] Contraindications are the same as those for single-dose charcoal.

Hemodialysis

Intermittent hemodialysis or other extracorporeal dialytic therapies including continuous renal replacement therapies (eg, continuous veno-venous hemofiltration, CVVH) may be necessary for certain severe cases of poisoning. Dialysis should be considered when the duration of symptoms is expected to be prolonged, normal pathways of excretion are compromised, clinical deterioration is present, the drug is dialyzable (ie, cleared by dialysis hemofilters), and appropriate personnel and equipment are available. Drugs that are dialyzable typically exhibit similar physiochemical and

pharmacokinetic properties that collectively render them amenable to extracorporeal clearance. For example, drugs exhibiting a low molecular mass (<1,000 daltons), low protein binding (<80%), and a small to modest volume of distribution (<1 L/kg) are generally dialyzable.[36] The principles of hemodialysis for acutely ill individuals and patients with chronic kidney disease are described in Chapters 43 and 45, respectively. Although hemodialysis can provide an efficient means of enhanced elimination, it can pose serious risks related to anticoagulation, blood transfusions, loss of blood elements, fluid and electrolyte disturbances, and infection. Hemodialysis may be lifesaving for methanol and ethylene glycol poisoning and effective for other poisons, such as lithium, salicylates, ethanol, and theophylline. Another dialysis technique is CVVH that transports drugs across a semipermeable membrane primarily by convection in response to hydrostatic pressure gradients (described in Chapter 43).[37] Limited experience is reported with the use of hemofiltration for poisonings, but it may be attractive for the hemodynamically unstable patient who cannot tolerate hemodialysis.

Antidotes

5 The search for and use of an antidote should not replace good supportive care. Specific systemic antidotes are available for many common poisonings (**Table e9-9**).[38] Inadequate stocking, maintenance of supplies, and corresponding shortages of antidotes at acute care hospitals have been noted throughout the United States and can complicate the care of a poisoned patient.[38,39] An evidence-based consensus of experts has recommended minimum stocking requirements for 24 antidotes for acute care hospitals and that 12 should be available for immediate administration on patient arrival.[40] These recommendations may provide guidance to pharmacy and therapeutics committees in establishing a hospital's antidote needs. Drugs used conventionally for non-poisoning situations may act as antidotes to reverse acute toxicity, such as insulin-dextrose or glucagon for β-adrenergic blocker or calcium channel antagonist overdose and octreotide for sulfonylurea-induced hypoglycemia.[38,41] Commercially available IV lipid emulsions have been used to reduce cardiac and CNS toxicity from several lipid-soluble drugs and dramatically "rescue" patients with severe cardiac toxicity.[42,43] Some current hypotheses on the actions responsible for this effect include serving as a "lipid sink" for lipophilic drugs and as an energy substrate for affected organs. There are several dosing schemes that involve single or multiple boluses followed by a continuous infusion, but none are well studied. Further evidence is needed to define its place in therapy. Lastly, the use of toxin-specific antibodies (eg, fragment antigen binding [Fab] antibody fragments for digoxin or North American crotaline snake venom) has offered a new approach to treatment of poisoning victims.[38]

TABLE e9-9 Systemic Antidotes Available in the United States

Toxic Agent	Antidote
Acetaminophen	Acetylcysteine
Anticholinesterase insecticides	Atropine
Anticholinergics	Physostigmine
Anticoagulants	Phytonadione
Benzodiazepines	Flumazenil

Toxic Agent	Antidote
Botulism	Botulism antitoxin
Carbon monoxide	Oxygen
Cyanide	Sodium nitrate and sodium thiosulfate
Cyanide	Hydroxocobalamin
Digoxin	Digoxin immune Fab
Ethylene glycol, methanol	Ethanol
Ethylene glycol, methanol	Fomepizole
Heavy metals (copper, lead)	Dimercaprol
Heavy metals (copper, lead)	Penicillamine
Iron	Deferoxamine
Isoniazid	Pyridoxine
Lead	Edetate calcium disodium
Lead	Succimer
Methemoglobinemia	Methylene blue
Opioids	Naloxone
Organophosphate insecticides	Pralidoxime
Radioactive americium, curium, plutonium	Diethylenetriaminepentaacetate
Radioactive iodine	Potassium iodide
Scorpion	*Centruroides* immune Fab
Snake, coral	*Micrurus fulvius* antivenin
Snakes (rattlesnakes, cottonmouth, copperhead)	*Crotalidae* polyvalent immune Fab
Spider, black widow	*Lactrodectus mactans* antivenin
Thallium or cesium	Prussian blue
Tubocurarine	Neostigmine

Fab, fragment antigen binding.

Clinical Controversy…

Some have proposed starting intravenous lipid emulsion therapy prophylactically when a potentially life-threatening overdose is anticipated based on the history of the exposure, but evidence for the effectiveness and safety of this practice is lacking.

Assessing the Effectiveness of Therapies

Case reports, clinical studies, human volunteer studies, animal investigations, and in vitro tests have yielded findings with limited generalizability to the care of humans who have been poisoned. Case reports are difficult to assess because they are uncontrolled, the histories are uncertain, and multiple therapies frequently are used. Although clinical studies may describe tens to hundreds of patients,

they can exhibit serious shortcomings, such as weak randomization procedures, no laboratory confirmation or correlation with history, insufficient number of severe cases, no control group, and no quantitative measure of outcome. Extrapolation of data from human volunteer studies to patients who overdose is difficult because of potential or unknown variations in pharmacokinetics (eg, differing dissolution, gastric emptying, and absorption rates) seen with toxic as opposed to therapeutic doses,[17,18] differences in time to institute therapy in the emergency setting, and differences in absorption in fasted human volunteers compared with the full stomach of some patients who overdose. However, these studies provide the most controlled and objective measures of the efficacy of a treatment. Experiences from animal studies cannot be applied directly to humans because of interspecies differences in toxicity and metabolism. In vitro tests serve to screen the efficacy of some approaches, such as activated charcoal adsorption, but they do not mimic physiologic conditions sufficiently to allow direct clinical application of the findings. Despite their limitations, these data compose the evidence base for the therapy of poisoned patients and are tempered with the consideration of nonpoisoning-related factors such as a patient's underlying medical condition, age, and need for concurrent supportive measures.

CLINICAL SPECTRUM OF POISONING

Poisoning and drug overdose with acetaminophen, anticholinesterase insecticides, calcium channel blockers, iron, opioids, and weapons of mass chemical poisoning are the focus of the remainder of this chapter. These agents were chosen because they provide examples of different mechanisms of toxicity and the application of general treatment approaches, as well as some agent-specific pharmacotherapeutic interventions.

Acetaminophen

Clinical Presentation

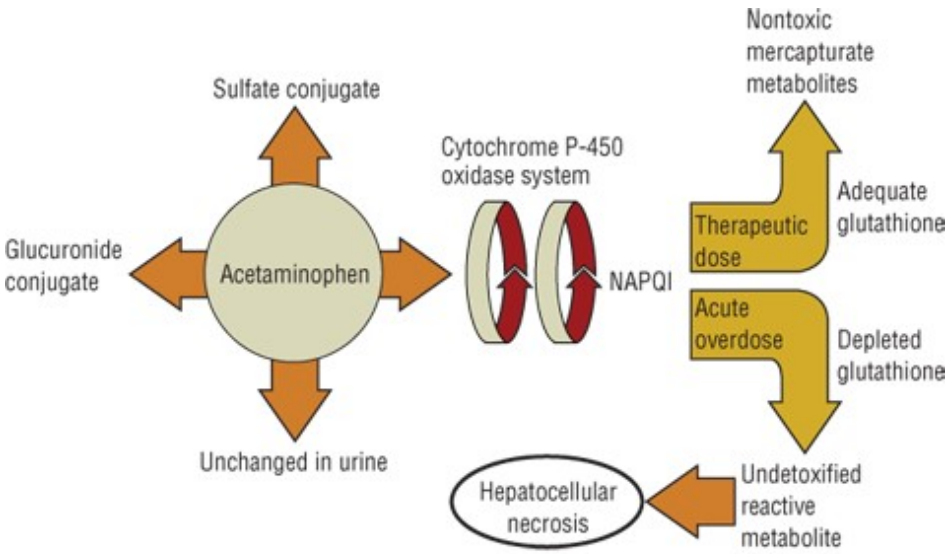
6 Acute acetaminophen poisoning characteristically results in hepatotoxicity[44] and is a leading cause of acute liver failure in the United States. Clinical presentation is dependent on the time since ingestion, presence of risk factors, and the ingestion of other drugs. During the first 12 to 24 hours after ingestion, nausea, vomiting, anorexia, and diaphoresis may be observed; however, many patients are asymptomatic. During the next 1 to 3 days, which is a latent phase of lessened symptoms, patients often have an asymptomatic rise in liver enzymes and bilirubin. Signs and symptoms of hepatic injury become manifest 3 to 5 days after ingestion and include right upper quadrant abdominal tenderness, jaundice, hypoglycemia, and encephalopathy. Prolongation of the international normalized ratio (INR) worsens as hepatic necrosis progresses and may lead to disseminated intravascular coagulopathy. Patients with severe hepatic damage may develop hepatic coma and hepatorenal syndrome, and death can occur.[44,45] Survivors of severe hepatotoxicity usually exhibit no residual functional or histologic abnormalities of the liver within 1 to 6 months of the incident.[46]

Mechanism of Toxicity

Acetaminophen is metabolized in the liver primarily to glucuronide or sulfate conjugates, which are excreted into the urine with small amounts (<5%) of unchanged drug. Approximately 5% of a therapeutic dose is metabolized by CYPs, primarily CYP2E1, to the reactive metabolite *N*-acetyl-*p*-benzoquinoneimine (NAPQI). Normally, NAPQI is subsequently conjugated with glutathione, a sulfhydryl-containing compound, in the hepatocyte and excreted in the urine as a mercapturate conjugate (**Fig. e9-1**).[44]

FIGURE e9-1

Pathway of acetaminophen metabolism and basis for hepatotoxicity. (NAPQI, *N-acetyl-p*-benzoquinoneimine, a reactive acetaminophen metabolite.)



CLINICAL PRESENTATION Acute Acetaminophen Poisoning General

- No or mild nonspecific symptoms within 6 hours of ingestion.

Symptoms

- Nausea, vomiting, and abdominal discomfort within 1 to 12 hours after ingestion.
- Right upper abdominal quadrant tenderness, typically within 1 to 2 days.

Signs

- Typically no signs present within first day.
- Jaundice, scleral icterus, and bleeding within 3 to 10 days.
- Oliguria occasionally within 2 to 7 days.
- With severe poisoning, hepatic encephalopathy (delirium, depressed reflexes, and coma) within

5 to 10 days.

Laboratory Tests

- Toxic serum acetaminophen concentration no earlier than 4 hours after ingestion by comparison with nomogram.
- Elevated aspartate aminotransferase (AST), alanine aminotransferase (ALT), serum bilirubin, and INR; hypoglycemia within 1 to 3 days.
- Elevated serum creatinine and blood urea nitrogen (BUN) within 2 to 7 days.

Sulfate stores are depleted in an acute overdose situation. This leads to increased acetaminophen metabolism via CYP2E1 and eventual depletion of the available glutathione used to detoxify NAPQI, which then reacts with other hepatocellular sulfhydryl compounds. This results in centrilobular hepatic necrosis.[44] Several other mechanisms, such as cytokine release and oxidative stress, also may be initiated by the initial cellular injury.[44]

In many cases of severe hepatotoxicity, impaired kidney function also is present and may range from oliguria to acute kidney injury. The etiology of the impaired kidney function may be a direct effect of NAPQI, generated by renal cytochrome oxidase, or a consequence of hepatic injury resulting in hepatorenal syndrome.[45]

Causative Agents

Acetaminophen, also known as paracetamol, is available widely without prescription as an analgesic and antipyretic. It is available in various oral dosage forms, including extended-release preparations and an intravenous formulation. Acetaminophen may be combined with other drugs, such as antihistamines or opioid analgesics, and marketed in cough and cold preparations, menstrual remedies, and allergy products. Some patients may not recognize that they are consuming several products containing acetaminophen, which can increase the total dose, systemic exposure, and the subsequent risk of hepatotoxicity.

Incidence

Acetaminophen is commonly ingested by small children and is used frequently in suicide attempts by adolescents and adults.[3] Each year acetaminophen accounts for approximately 78,000 emergency department visits with 78% related to acts of self-harm.[47] The 2014 AAPCC-NPDS report documented 50,331 nonfatal single-drug product exposures and 65 deaths from acetaminophen alone, with 58% of the exposures in children younger than 6 years. Another 22,951 exposures were from combination drug products containing acetaminophen.[3]

Age-based differences in the metabolism of acetaminophen appear to be responsible for major differences in the incidence of serious toxicity. Despite the common ingestion of acetaminophen by young children, few develop hepatotoxicity from acute overdosage.[3] In children younger than 9 to 12

years, acetaminophen undergoes more sulfation and less glucuronidation. The reduced fraction available for metabolism by CYPs may explain the rare development of serious toxicity in young children who take large overdoses. Earlier treatment intervention and spontaneous emesis also may reduce the risk of toxicity in children.

Risk Assessment

Acute, single-ingestion of at least 10 g or 200 mg/kg, whichever is less, of acetaminophen by patients 6 years or older is associated with development of hepatotoxicity (200 mg/kg or more of acetaminophen in children younger than 6 years).[48] Patients have survived much larger doses, particularly with early treatment. Initial symptoms, if present, do not predict the severity of the toxicity that eventually occurs.

Repeated ingestion of supratherapeutic doses of acetaminophen has been associated with hepatotoxicity in adults and children.[48,49,50,51] Patients who are fasting or have ingested alcohol in the preceding 5 days appear to be at greater risk.[50] Young children have a higher risk when they have been acutely fasting as the result of a febrile illness or gastroenteritis.[51] Patients should be referred for medical evaluation if there is evidence that the ingestion exceeded 4 g/day or 100 mg/kg/day, whichever is less for 2 or more days.[48]

Chronic exposure to drugs that induce CYPs—specifically CYP2E1, which is responsible for most of the formation of NAPQI—may increase the risk of acetaminophen hepatotoxicity. Poorer outcomes have been noted in patients who chronically ingest alcohol and those receiving anticonvulsants, both known to induce CYP2E1.[46] Patients with chronic alcoholism have a 3.5 greater odds of mortality with acute acetaminophen poisoning.[50]

The risk of developing hepatotoxicity with acute ingestion of acetaminophen may be predicted with a commonly used nomogram that is based on the acetaminophen serum concentration and time after ingestion.[52] The nomogram used in the United States is readily available in the FDA approved package insert for acetylcysteine (available at: *http://dailymed.nlm.nih.gov/*) and in several electronic information databases (eg, Micromedex, UpToDate). Treatment should be started if the patient's serum concentration is above the line on the nomogram that starts at 150 mcg/mL (1,000 µmol/L) at 4 hours. If the plasma concentration plotted on the nomogram falls above the nomogram treatment line, indicating that hepatic damage is possible, a full course of treatment with acetylcysteine is indicated. When the results of the acetaminophen determination will be available later than 8 hours after the ingestion, acetylcysteine therapy should be initiated based on the history and later discontinued if the results indicate nontoxic concentrations.[52]

The nomogram is not useful for assessing chronic or supratherapeutic exposures to acetaminophen. Some have advocated that patients with chronic alcoholism should be treated with acetylcysteine regardless of the risk estimation.[50,54] Assessment and management of IV administered acetaminophen is presently similar to the acute oral overdose.[55]

Management of Toxicity

Therapy of an acute acetaminophen overdose depends on the amount ingested, time after ingestion, and serum concentration of acetaminophen. When excessive amounts are ingested, the history is unclear, or an intentional ingestion is suspected, the patient should be evaluated at an emergency department and acetaminophen serum concentrations obtained. Prehospital care generally is not indicated.[48] If the patient presents to the emergency department within 4 hours of the ingestion or ingestion of other drugs is suspected, one dose of activated charcoal can be administered.

Acetylcysteine (also known as *N*-acetylcysteine), a sulfhydryl-containing compound, replenishes the hepatic stores of glutathione by serving as a glutathione surrogate that combines directly with reactive metabolites or by serving as a source of sulfate, thus preventing hepatic damage.[53] It should be started within 10 hours of the ingestion to be most effective.[52] Initiation of therapy 24 to 36 hours after the ingestion may be of value in some patients, particularly those with measurable serum acetaminophen concentrations.[53,56] Patients with fulminant hepatic failure may benefit through other mechanisms by the administration or initiation of acetylcysteine several days after ingestion.[53,56]

Oral and IV formulations of acetylcysteine are available for clinical use. While there is no clear evidence favoring one formulation over the other,[57] there are several notable differences between them (**Table e9-10**).[53,57,58] Most notable is the occurrence (approximately 10% of cases) of anaphylactoid reactions (see Chapter 89) following the IV infusion. Acetylcysteine IV was used 4.7 times more frequently than the oral form as reported in the 2014 AAPCC-NPDS.[3] When acetaminophen plasma concentrations are below the nomogram treatment line, there is little risk of toxicity, protective therapy with acetylcysteine is not necessary, and medical therapy likely is unnecessary.[52,53] The acetaminophen blood sample should be drawn no sooner than 4 hours after the ingestion to ensure that peak acetaminophen concentrations have been reached. If a concentration is obtained less than 4 hours after ingestion, it is not interpretable, and a second determination should be done at least 4 hours after ingestion. Serial determinations of a serum concentration, 4 to 6 hours apart, typically are unnecessary unless there is some evidence of slowed gastrointestinal motility as the result of the ingestion of certain drugs (eg, opioids, or anticholinergics), when an extended-release product is involved or if chronic or supratherapeutic overdoses are suspected. In these circumstances, therapy with acetylcysteine is continued if any concentration is above the treatment line of the nomogram, and provisional therapy is discontinued when both concentrations are below the treatment line. Several alternative dosing regimens for acetylcysteine with different duration, administration technique, and clinical endpoints have been proposed.[58,59]

TABLE e9-10 Comparison of IV and Oral Regimens for Acetylcysteine in the Treatment of Acute Acetaminophen Poisoning

Characteristic	IV	Oral
Regimen	150 mg/kg in 200 mL D_5W infused over 1 hour, then 50 mg/kg in 500 mL D_5W over 4 hours, followed by 100 mg/kg in 1,000 mL D_5W over 16 hours[a]	140 mg/kg, followed 4 hours later by 70 mg/kg every 4 hours for 17 doses diluted to 5% with juice or soft drinks

Characteristic	IV	Oral
Total dose (mg/kg)	300	1,330
Duration (h)	21	72
Adverse effects	Nausea, vomiting; anaphylactoid reactions (rash, hypotension, wheezing, dyspnea); acute flushing and erythema in first hour of the infusion that typically resolves spontaneously	Nausea, vomiting
Ancillary therapy, if needed	Antihistamines and epinephrine for severe anaphylactic reactions	Antiemetics
Trade name	Acetadote	Mucomyst
Available strength	20%	10%, 20%

D_5W, 5% dextrose in water for injection.

[a]For patients <40 kg and those requiring fluid restriction, the total volume for dilution should be reduced as directed in the package insert.

Clinical Controversy...

The 72-hour oral acetylcysteine and the 21-hour IV regimen are satisfactory for most patients, but some state that the 72-hour regimen is too long while others believe the 21-hour regimen is too short. Individualized therapy based on clinical end points, for example, absence of acetaminophen in the blood at the end of a regimen, presence of hepatic encephalopathy or ALT approaching normal range, has been proposed as an alternative to strict adherence to the duration in the package insert. Several alternative dosing regimens have been described recently in the literature, but the number of patients in the studies has been relatively small and the findings are not generalizable. Accepted and validated criteria are lacking at present.

Although young children have an inherently lower risk of acetaminophen-induced hepatotoxicity, these patients are managed in the same manner as adults. When acetaminophen serum concentrations predict that toxicity is probable, young children should receive acetylcysteine in the dosing regimen described previously.[59]

Hemodialysis may be considered in rare cases when serum acetaminophen concentrations are exceedingly high (>700-1,000 mcg/mL [>4,600-6,600 µmol/L]) with the early development of altered mental status and severe metabolic acidosis prior to the onset of hepatic failure.[60] If fulminant hepatic failure develops, the approaches described in Chapter 37 should be considered. In patients unresponsive to acetylcysteine, liver transplantation is a lifesaving option.[46]

Monitoring and Prevention

Baseline liver function tests (AST, ALT, bilirubin, INR), serum creatinine concentration, and urinalysis should be obtained on admission and repeated at 24-hour intervals until at least 96 hours have elapsed for patients at risk. Most patients with liver injury develop elevated transaminase concentrations within 24 hours of ingestion. Serum concentrations of AST or ALT greater than 1,000 international units per liter (IU/L) (16.7 μkat/L) commonly are associated with other signs of liver dysfunction and have been used as the threshold concentration in outcome studies to define severe liver toxicity.[52] The extent of transaminase elevation is not correlated directly with the severity of hepatic injury, with nonfatal cases demonstrating peak concentrations as high as 30,000 IU/L (500 μkat/L) between 48 and 72 hours after ingestion.[46]

Prevention of acetaminophen poisoning is based on recognition of the maximum daily therapeutic doses (4 g in adults), observance of general poison prevention practices, and early intervention in cases of suspected overdose. The frequent involvement of acetaminophen in poisonings and overdoses, whether or not declared by the patient, has led to the routine determination of acetaminophen concentrations in patients admitted to emergency departments for any overdose.[54]

Anticholinesterase Insecticides

Clinical Presentation

7 The clinical manifestations of anticholinesterase insecticide poisoning include any or all of the following: pinpoint pupils, excessive lacrimation, excessive salivation, bronchorrhea, bronchospasm, and expiratory wheezes, hyperperistalsis producing abdominal cramps and diarrhea, bradycardia, excessive sweating, fasciculations and weakness of skeletal muscles, paralysis of skeletal muscles (particularly those involved with respiration), convulsions, and coma.[61] Symptoms of anticholinesterase poisoning and their response to antidotal therapy depend on the action of excessive acetylcholinesterase at different receptor types (**Table e9-11**).

TABLE e9-11 Effects of Acetylcholinesterase Inhibition at Muscarinic, Nicotinic, and CNS Receptors

Muscarinic receptors	**Nicotinic-sympathetic neurons**
Diarrhea	Increased blood pressure
Urination	Sweating and piloerection
Miosis[a]	Mydriasis[a]
Bronchorrhea	Hyperglycemia
Bradycardia[a]	Tachycardia[a]
Emesis	Priapism
Lacrimation	**Nicotinic-neuromuscular neurons**
Salivation	Muscular weakness
CNS receptors (mixed type)	Cramps
Coma	Fasciculations
Seizures	Muscular paralysis

[a]Generally muscarinic effects predominate, but nicotinic effects can be observed.

CLINICAL PRESENTATION Anticholinesterase Insecticide Poisoning General

- Mild symptoms may resolve spontaneously; life-threatening toxicity may develop with 1 to 6 hours of exposure.

Symptoms

- Diarrhea, diaphoresis, excessive urination, miosis, blurred vision, pulmonary congestion, dyspnea, vomiting, lacrimation, salivation, and shortness of breath within 1 hour.
- Headache, confusion, coma, and seizures possible within 1 to 6 hours.

Signs

- Increased bronchial secretions, tachypnea, rales, and cyanosis within 1 to 6 hours.
- Muscle weakness, fasciculations, and respiratory paralysis within 1 to 6 hours.
- Bradycardia, atrial fibrillation, atrioventricular block, and hypotension within 1 to 6 hours.

Laboratory Tests

- Markedly depressed serum pseudocholinesterase activity.
- Altered arterial blood gases (acidosis), serum electrolytes, BUN, and serum creatinine in response to respiratory distress and shock within 1 to 6 hours.

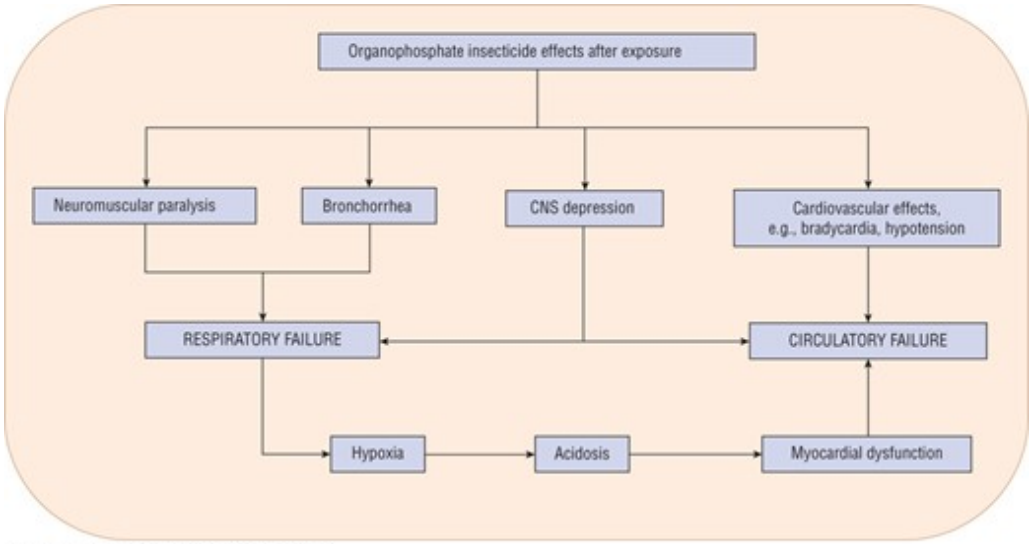
Other Diagnostic Tests

- Chest radiographs for progression of pulmonary edema or hydrocarbon pneumonitis in symptomatic patients.
- Electrocardiogram (ECG) with continuous monitoring and pulse oximetry for complications from toxicity and hypoxia.

The time of onset and severity of symptoms depend on the route of exposure, potency of the agent, and total dose received. Toxic signs and symptoms develop most rapidly after inhalation or IV injection and slowest after skin contact. Anticholinesterase insecticides are absorbed through the skin, lungs, conjunctivae, and gastrointestinal tract. Severe symptoms can occur from absorption by any route. Most patients are symptomatic within 6 hours, and death may occur within 24 hours without treatment. Death typically is caused by respiratory failure resulting from the combination of pulmonary and cardiovascular effects (**Fig. e9-2**).[61] Poisoning may be complicated by aspiration pneumonia, urinary tract infections, and sepsis.[61,62]

FIGURE e9-2

Pathogenesis of life-threatening effects of organophosphate poisoning.



Organophosphate poisoning has been associated with several residual effects, such as intermediate syndrome, extrapyramidal symptoms, neuropsychiatric effects, and delayed chronic neuropathy. Intermediate syndrome becomes manifest in some patients approximately 1 to 3 days after exposure and generally resolves within weeks of onset without further treatment. It is characterized by muscle weakness of proximal limbs, cranial nerve innervated muscles, and muscles of respiration. The inability of the patient to raise his or her head is often an initial sign. Extrapyramidal symptoms, which may develop 1 to 7 days after exposure, usually resolve spontaneously within a few days of onset. Neuropsychiatric effects, such as confusion, lethargy, memory impairment, headache, and depression, typically begin weeks to months after exposure and may last for years. Chronic neuropathy often presents as cramping muscle pain in the legs (upper extremities are sometimes involved), followed by rapidly progressive weakness and paralysis and develops 1 to 5 weeks after recovery from the acute poisoning exposure. Paresthesia and pain may persist and are unresponsive to further atropine or pralidoxime therapy. Improvement may be delayed for months to years, and in some cases the patient develops permanent disability. Chronic neuropathy is not associated with all organophosphates.[61]

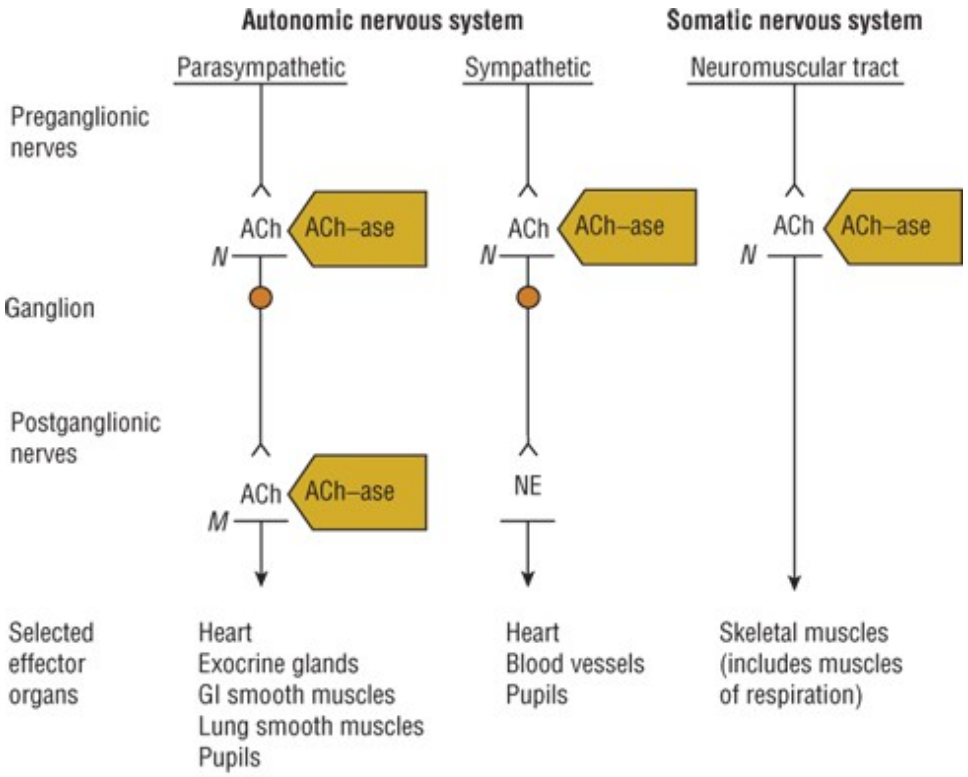
Mechanism of Toxicity

Anticholinesterase insecticides phosphorylate the active site of cholinesterase in all parts of the body.[61] Inhibition of this enzyme leads to accumulation of acetylcholine at affected receptors and results in widespread toxicity. Acetylcholine is the neurotransmitter responsible for physiologic transmission of nerve impulses from preganglionic and postganglionic neurons of the cholinergic (parasympathetic) nervous system, preganglionic adrenergic (sympathetic) neurons, neuromuscular junction in skeletal muscles, and multiple nerve endings in the central nervous system (**Fig. e9-3**).

FIGURE e9-3

Organization of neurotransmitters of the peripheral nervous system and site of acetylcholinesterase

action. (ACh, acetylcholine; ACh-ase, acetylcholinesterase; M, muscarinic receptor; N, nicotinic receptor; NE, norepinephrine.)



Causative Agents

Anticholinesterase insecticides include organophosphate and carbamate insecticides. These insecticides are currently in widespread use throughout the world for eradication of insects in dwellings and crops. Carbamates typically are less potent and inactivate cholinesterase in a more reversible fashion through carbamylation compared with organophosphates.[61] The prototype anticholinesterase agent is the organophosphate, which is the focus of this discussion. A large number of organophosphates are used as pesticides (eg, dichlorovos, disulfoton, malathion, parathion, mevinphos, and phosmet), and several were specifically developed for use as potent chemical warfare agents and adapted as terrorist chemical weapons (see the section later in this chapter).[7,61] An anticholinesterase insecticide typically is stored in a garage, chemical storage area, or living area. Anticholinesterase agents also can be found in occupational (eg, pest exterminators) or agricultural (eg, crop dusters or farm workers) settings. These agents also have been used as a means for suicide or homicide.

Incidence

Anticholinesterase insecticides are among the most poisonous substances commonly used for pest control and are a frequent source of serious poisoning in children and adults in rural and urban settings. The 2014 AAPCC-NPDS report documented 4,208 nonfatal single-product exposures and 4

deaths and 30 severe cases from anticholinesterase insecticides alone or in combination with other pesticides, with 38% of exposures in children younger than 6 years.[3]

Risk Assessment

The triad of miosis, bronchial secretions, and muscle fasciculations should suggest the possibility of anticholinesterase insecticide poisoning and warrants a therapeutic trial of the antidote atropine. In cases of low-level exposure, failure to develop signs within 6 hours indicates a low likelihood of subsequent toxicity.[61] Ruling out other chemical exposures may be guided initially by symptoms at presentation.[6,7]

Although the lethal dose for parathion is approximately 4 mg/kg, as little as 10 to 20 mg can be lethal to an adult and 2 mg (0.1 mg/kg) to a child. Small children may be more susceptible to toxicity because less pesticide is required per body weight to produce toxicity.[61] Estimation of an exact dose is impossible in most cases of acute poisoning; thus, tabulated "toxic" doses generally are not helpful in assessing risk of toxicity. Generally, ingestion of a small mouthful (approximately 5 mL in adults) of the concentrated forms of an organophosphate intended to be diluted for commercial or agricultural use will produce serious, life-threatening toxicity, whereas a small mouthful of an already diluted household product, such as an aerosol insecticide for household use, typically does not produce serious toxic effects.[63]

Measurement of acetylcholinesterase activity at the neuronal synapse is not feasible clinically. Cholinesterase activity can be measured in the blood as the pseudocholinesterase (butyrylcholinesterase) activity of the plasma and acetylcholinesterase activity in the erythrocyte. Both cholinesterases will be depressed with anticholinesterase insecticide poisoning.[61,63] Severity can be estimated roughly by the extent of depressed activity in relation to the low end of normal values. Because there are several methods to measure and report cholinesterase activity, each particular laboratory's normal range must be considered. Clinical toxicity usually is seen only after a 50% reduction in enzyme activity, and severe toxicity typically is observed at levels 20% or less of the normal range.[61] The intrinsic activity of acetylcholinesterase may be depressed in some individuals, but the absence of any manifestations in most people does not permit recognition of the relative deficiency in the general population. Therapy should not be delayed pending laboratory confirmation when insecticide poisoning is clinically suspected. Based on a history of an exposure and presence of typical symptoms, anticholinesterase toxicity should be readily recognized.[6]

Management of Toxicity

At the scene of the incident, move the patient away from area containing the organophosphate and decontaminate affected body surfaces with conventional first aid measures (see Table e9-8). Remove all contaminated clothing. People handling the patient should wear gloves and aprons to protect themselves against contaminated clothing, skin, or gastric fluid of the patient.[61,63] Because many insecticides are dissolved in a hydrocarbon vehicle, there is an additional risk of pulmonary aspiration of the hydrocarbon leading to pneumonitis when ingested. The risks and benefits of gastric decontamination (eg, gastric lavage, activated charcoal) should be considered carefully and should

involve consultation with a poison control center or clinical toxicologist. Symptomatic cases of anticholinesterase insecticide exposure typically are referred to an emergency department for evaluation and treatment.

If the poison has been ingested within 1 hour, gastric lavage should be considered and followed by the administration of activated charcoal. For the patient with large-surface skin contamination, contaminated clothing should be removed and the patient washed with copious amounts of soap and water before he or she is transported and admitted to the emergency department or other patient care area. An alcohol wash may be useful for removing residual insecticide because of its lipophilic nature. A surgical scrub kit for the hands, feet, and nails may be useful for exposure to those areas. Supportive therapy should include maintenance of an airway (including bronchotracheal suctioning), provision of adequate ventilation, and establishment of an IV line.

Pharmacologic management of organophosphate intoxication relies on the administration of atropine and pralidoxime.[61,63] Atropine has no effect on inhibited cholinesterase, but it competitively blocks the actions of acetylcholine on cholinergic and some central nervous system receptors. It thereby alleviates bronchospasm and reduces bronchial secretions. Although atropine has little effect on the flaccid muscle paralysis or the central respiratory failure of severe poisoning, it is indicated in all symptomatic patients and can be used as a diagnostic aid. It should be given IV and in larger than conventional doses of 0.05 to 0.1 mg/kg in children younger than 12 years and 2 to 5 mg in adolescents and young adults.[62] It should be repeated at 5- to 10-minute intervals until bronchial secretions and pulmonary rales resolve. Some recommend aggressive escalation of doses (eg, doubling of each successive dose) in cases with severe toxicity.[64] Therapy may require large doses over a period of several days until all absorbed organophosphate is metabolized, and acetylcholinesterase activity is restored.

Clinical Controversy…

Gastric lavage for organophosphate ingestions is performed routinely by some clinicians within 1 hour of ingestion. Evidence for the use of gastric lavage for organophosphates is based on reports of the lavage fluid having the odor of the insecticide. Others argue that excessive bronchial secretions and decreased mental status introduce substantial risk of pulmonary aspiration during gastric lavage.

Restoration of enzyme activity is necessary for severe poisoning, characterized by a reduction of cholinesterase activity to less than 20% of normal, profound weakness, and respiratory distress. Pralidoxime (Protopam), also called 2-PAM or 2-pyridine aldoximemethiodide, breaks the covalent bond between the cholinesterase and organophosphate and regenerates enzyme activity. Organophosphate-cholinesterase binding is reversible initially, but it gradually becomes irreversible. Therefore, therapy with pralidoxime should be initiated as soon as possible, preferably within 36 to 72 hours of exposure.[63] The drug should be given at a dose of 25 to 50 mg/kg up to 1 g IV over 5 to 20 minutes. If muscle weakness persists or recurs, the dose can be repeated after 1 hour and again if needed. A continuous infusion of pralidoxime has been shown to be effective in adults when administered at 2 to 4 mg/kg/h preceded by a loading dose of 4 to 5 mg/kg[65] and in children at 10 to 20 mg/kg/h with a loading dose of 15 to 50 mg/kg.[66] Both atropine and pralidoxime should be

given together because they have complementary actions (**Table e9-12**). Carbamate insecticide poisonings typically do not require the administration of pralidoxime.

TABLE e9-12 Comparative Characteristics of Atropine and Pralidoxime for Anticholinesterase Poisoning

Characteristic	Atropine	Pralidoxime
Interaction	Synergy with pralidoxime	Reduces atropine dose requirement
Indication	Any anticholinesterase agent	Typically needed for organophosphates
Primary sites of action	Muscarinic, CNS	Nicotinic > muscarinic > CNS
Adverse effects	Coma, hallucinations, tachycardia	Dizziness, diplopia, tachycardia, headache
Daily dose[a]	2-1,600 mg	1-12 g
Total dose[a]	2-11,422 mg	1-92 g

[a]Range of reported cases; higher doses may be required in rare cases.

One of the pitfalls of therapy is the delay in administering sufficient doses of atropine or pralidoxime.[61,64] The adverse effects of atropine and pralidoxime, which can be minimized by decreasing the dose, are predictable extensions of their anticholinergic actions and are minimally important compared with the life-threatening effects of severe anticholinesterase poisoning.

Monitoring and Prevention

Poisoned patients may require monitoring of vital signs, measurement of ventilatory adequacy such as blood gases and pulse oximetry, leukocyte count with differential to assess development of pneumonia, and chest radiographs to assess the degree of pulmonary edema or development of hydrocarbon pneumonitis. Workers involved in the formulation and application of pesticides should be monitored by periodic measurement of cholinesterase activity in their bloodstream. Untreated, acetylcholinesterase activity returns to normal values in approximately 120 days. Long-term follow-up for severe cases of poisoning may be necessary to detect the presence of delayed or persistent neuropsychiatric effects.

Many anticholinesterase insecticide poisonings are unintentional as a result of misuse, improper storage, failure to follow instructions for mixing or application, or inability to read directions for use. Training and vigilant adherence to directions may minimize some poisonings. Storing pesticides in original or labeled containers can minimize the risk of unintentional ingestion. Keeping pesticides out of children's reach may decrease the risk of childhood poisoning.[67]

Calcium Channel Blockers

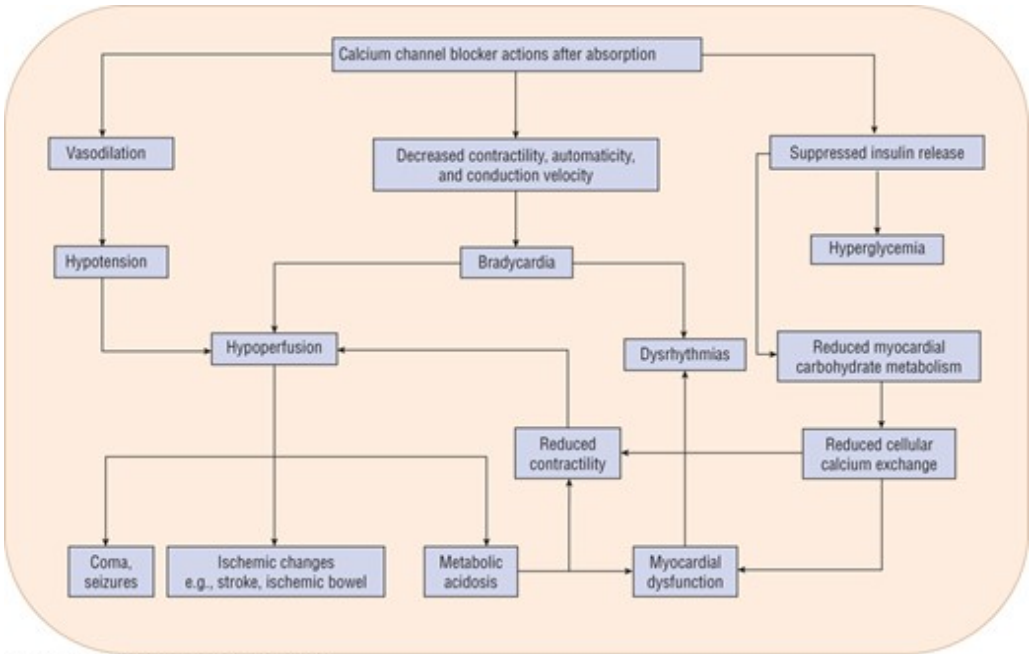
Clinical Presentation

8 Overdosage with calcium channel blockers typically results in bradycardia and hypotension (**Fig. e9-4**). Many patients become lethargic and may develop agitation and coma. If the degree of

hypotension becomes severe or is prolonged, the secondary effects of seizures, coma, and metabolic acidosis usually develop. Pulmonary edema, nausea and vomiting, and hyperglycemia are frequent complications of calcium channel blocker overdoses. Paralytic ileus, mesenteric ischemia, and colonic infarction have been observed in patients with severe hypotension. Many symptoms become manifest within 1 to 2 hours of ingestion. If a sustained-release formulation is involved, the onset of overt toxicity may be delayed by 6 to 18 hours from the time of ingestion. Severe poisoning can result in refractory shock and cardiac arrest. Death can occur within 3 to 4 hours of ingestion.[68,69,70,71]

FIGURE e9-4

Pathophysiologic changes associated with calcium channel blocker poisoning.



Mechanism of Toxicity

Most toxic effects of calcium channel blockers are produced by three basic actions on the cardiovascular system: vasodilation through relaxation of smooth muscles, decreased contractility by action on cardiac tissue, and decreased automaticity and conduction velocity through slow recovery of calcium channels. Calcium channel blockers interfere with calcium entry by inhibiting one or more of the several types of calcium channels and binding at one or more cellular binding sites. Selectivity of these actions varies with the calcium channel blocker and provides some therapeutic distinctions, but these differences are less clear with overdosage.[71] Calcium channel blockers also inhibit insulin secretion, which results in hyperglycemia and changes in fatty acid oxidation in the myocardium that alter myocardial calcium flow and reduce contractility.[72] Current experiences suggest that the signs and symptoms of calcium channel blocker toxicity upon overdose or poisoning are similar among the drugs in this class.

CLINICAL PRESENTATION Calcium Channel Blocker Poisoning General

- Life-threatening cardiac toxicity (bradycardia, depressed contractility, and dysrhythmias) within 1 to 3 hours of ingestion, delayed by 12 to 18 hours if a sustained-release product is involved.

Symptoms

- Nausea and vomiting within 1 hour.
- Dizziness, lethargy, coma, and seizures within 1 to 3 hours.

Signs

- Hypotension and bradycardia within 1 to 6 hours.
- Unresponsiveness and depressed reflexes within 1 to 6 hours.
- Atrioventricular block, intraventricular conduction defects, and ventricular dysrhythmias on ECG.

Laboratory Tests

- Significant hyperglycemia (greater than 250 mg/dL [13.9 mmol/L]) may indicate severe toxicity and consideration for aggressive therapy.
- Altered arterial blood gases (metabolic acidosis), serum electrolytes, BUN, and serum creatinine in response to shock within 1 to 6 hours.

Other Diagnostic Tests

- ECG with continuous monitoring and pulse oximetry to monitor for toxicity and shock.
- Monitor for complications of pulmonary aspiration such as hypoxia and pneumonia by physical findings and chest radiographs.

Causative Agents

Several calcium channel blockers are marketed in the United States for treatment of hypertension, certain dysrhythmias, and some forms of angina. The calcium channel blockers are classified by their chemical structure as phenylalkylamines (eg, verapamil), benzothiapines (eg, diltiazem), and dihydropyridines (eg, amlodipine, felodipine, nicardipine, and nifedipine). Several of these drugs, including diltiazem, nicardipine, nifedipine, and verapamil, are formulated as sustained-release oral dosage forms or have a slow onset of action and longer half-life (eg, amlodipine), allowing once-daily administration.

Incidence

In 2014, the AAPCC-NPDS report documented 5,001 single-product toxic exposures to a calcium channel blocker; 86 patients exhibited and survived major toxic effects, and 20 died.[3]

Risk Assessment

Ingestion of an amount that exceeds the usual maximum single therapeutic dose or a dose equal to or greater than the lowest reported toxic dose (whichever is less) warrants referral to a poison control center and/or an emergency department. The threshold doses of several agents and dosage forms vary (eg, diltiazem: adults, greater than 120 mg for immediate release and chewed sustained release, greater than 360 mg for sustained release, greater than 540 mg for extended release; children younger than 6 years: >1 mg/kg).[73] Patients on chronic therapy with these agents who acutely ingest an overdose may have a greater risk of serious toxicity. Elderly patients and those with underlying cardiac disease may not tolerate mild hypotension or bradycardia. Concurrent ingestion of β-adrenergic blocking drugs, digoxin, class I antiarrhythmics, and other vasodilators may worsen the cardiovascular effects of calcium channel blockers.[69,71,73] The presence of persistent and significant hyperglycemia (>250 mg/dL [13.9 mmol/L]) has been suggested as a sign of grossly disturbed cardiac metabolism and physiology that merits attention and aggressive intervention.[72]

Management of Toxicity

There is no accepted specific prehospital care for calcium channel blocker poisoning, except to summon an ambulance for symptomatic patients.[84] The therapeutic options for management of calcium channel blocker poisoning include supportive care, gastric decontamination, and adjunctive therapy for the cardiovascular and metabolic effects. Supportive care consists of airway protection, ventilatory support, IV hydration to maintain adequate urine flow, and maintenance of electrolyte and acid-base balance. Maintaining vital organ perfusion is critical for successful therapy in order to allow time for calcium channel blocker toxicity to resolve.[70,71]

A single dose of activated charcoal should be considered if instituted generally within 1 to 2 hours after ingestion. Besides exhibiting a slower onset of symptoms, sustained-release formulations can form concretions in the intestine.[70,71] Whole-bowel irrigation with polyethylene glycol electrolyte solution may accelerate intestinal elimination of the sustained-release tablets and should be considered for ingestions of sustained-release calcium channel blocker formulations. However, it should be used with caution if hemodynamic instability is present.[28]

Adjunctive therapy is focused on treating hypotension, bradycardia, and resulting shock. Hypotension is treated primarily by correction of coexisting dysrhythmias (eg, bradycardia, heart block) and implementation of conventional measures to treat decreased blood pressure. Infusion of normal saline and placement of the patient in the Trendelenburg position are initial therapies. Further fluid therapy should be guided by central venous pressure monitoring. Dopamine and epinephrine in conventional doses for cardiogenic shock should be considered next; consider norepinephrine or phenylephrine when caused by vasodilation.[74] If hypotension persists, dysrhythmias are present, or other signs of serious toxicity are present, more specific therapy is indicated and intravenous lipid emulsion therapy should be considered.[42,43,71]

A calcium chloride bolus test dose (10-20 mg/kg up to 1-3 g) is the next specific therapy for patients with serious toxicity. In adults, calcium chloride 10% can be diluted in 100 mL normal saline and

infused over 5 minutes through a central venous line. If a positive cardiovascular response is achieved with this test dose, a continuous infusion of calcium chloride (20-50 mg/kg/h) should be started. Calcium gluconate is less desirable to use because it contains less elemental calcium per milligram of final dosage form. Atropine also may be considered for treatment of bradycardia, but it is seldom sufficient as a sole therapy.[70,74]

Clinical Controversy...

Some clinicians believe that hyperinsulinemia-euglycemia or glucagon therapy for calcium channel blocker poisoning should be used early in the course of therapy. Others reserve it for life-threatening symptoms not responsive to other therapy. More safety and effectiveness data are needed to define the place of these two agents in therapy.

For severe cases of calcium channel blocker toxicity refractory to conventional therapy, an infusion of high-dose insulin with supplemental dextrose and potassium to produce a state of hyperinsulinemia and euglycemia should be considered.[38,74,75] Case reports suggest that an IV bolus of regular insulin (0.5-1 U/kg) with 50 mL dextrose 50% (0.25 mg/kg for children) followed by a continuous infusion of regular insulin (0.5-1 U/kg/h) may improve myocardial contractility. The effect of insulin is presently unclear, but it may improve myocardial metabolism that is adversely affected by calcium channel blocker overdoses, such as decreased cellular uptake of glucose and free fatty acids and a shift from fatty acid oxidation to carbohydrate metabolism.[68,70,75] This insulin regimen is titrated to improvement in systolic blood pressure over 100 mm Hg and heart rate over 50 beats/min. Serum glucose concentrations should be monitored closely to maintain euglycemia. Patients with serum potassium concentrations less than 2.5 mEq/L (mmol/L) may need supplemental potassium IV (see Chapter 51). The insulin infusion rate can be reduced gradually as signs of toxicity resolve. Sodium bicarbonate IV may be also necessary to establish acid-base balance and correct the metabolic acidosis that is common with serious calcium channel blocker overdoses.

If the bradycardia and hypotension are refractory to the foregoing therapy, a bolus infusion of glucagon (0.05-0.20 mg/kg, initial adult dose is 3-5 mg over 1-2 min) should be considered. Benefit typically is observed within 5 minutes of administration and can be sustained with a continuous IV infusion (0.05-0.1 mg/kg/h) titrated to clinical response, but response is variable and its value is uncertain.[38,74] Glucagon possesses chronotropic and inotropic effects in part by stimulating adenylatecyclase and increasing cyclic adenosine monophosphate, which may promote intracellular entry of calcium through calcium channels. It thereby may improve hypotension and bradycardia.[38] Vomiting is not uncommon with these large doses of glucagon, and the airway should be protected to prevent pulmonary aspiration. Hyperglycemia may occur or be exacerbated in those patients receiving glucagon therapy. Therapies with glucagon and insulin are based on animal studies and case reports; clinical trials demonstrating effectiveness have not been performed to date.[38,75] Animal studies and case reports suggest that the emergent IV infusion of lipid emulsion can rapidly reverse the severe cardiac toxicity of calcium channel blockers by sequestering the drug in the circulation or serving as an energy substrate for the myocardium.[42,43] Further evidence is needed to define its place in therapy.

Several lifesaving options may be warranted for patients with cardiogenic shock that is refractory to conventional therapy, such as electrical cardiac pacing, intraaortic balloon counterpulsation or cardiopulmonary bypass. Measures to enhance elimination from the bloodstream by hemodialysis or multiple-dose activated charcoal have not been shown to be effective and are not indicated for calcium channel blocker poisoning.[32,69,71]

CLINICAL PRESENTATION Acute Iron Poisoning General

- Gastrointestinal symptoms shortly after ingestion with possible rapid progression to shock and coma.

Symptoms

- Vomiting, abdominal pain, and diarrhea within 1 to 6 hours.
- Lethargy, coma, seizures, bloody vomiting, bloody diarrhea, and shock within 6 to 24 hours.

Signs

- Hypotension and tachycardia within 6 to 24 hours.
- Liver dysfunction and failure possible in 2 to 5 days.

Laboratory Tests

- Toxic serum iron concentrations greater than 500 mcg/dL (90 µmol/L).
- Altered arterial blood gases and serum electrolytes associated with a high anion gap metabolic acidosis within 3 to 24 hours.
- Elevated BUN, serum creatinine, AST, ALT, and INR within 1 to 2 days.

Other Diagnostic Tests

- Guaiac test of stools for the presence of blood.
- Abdominal radiograph to detect solid iron tablets in gastrointestinal tract.

Monitoring and Prevention

Regular monitoring of vital signs and ECG is essential in suspected calcium channel blocker poisoning. Determinations of serum electrolytes, serum glucose, arterial blood gases, urine output, and kidney function are indicated to assess and monitor symptomatic patients. If serious toxicity is likely to develop, overt symptoms will manifest within 6 hours of ingestion.[73] For ingestions of sustained-release products in toxic doses, observation for 24 hours in a critical care unit may be prudent because the onset of symptoms may be slow and delayed up to 12 to 18 hours after ingestion.[68,73,75] Serum concentrations of these drugs in overdose patients do not correlate well with the ingested dose, degree of toxicity, or outcome.

Poisonings resulting from these drugs may be the result of an intentional suicide or unintentional ingestion by young children. Prevention of calcium channel blocker poisonings in children rests with the education of patients receiving these agents, particularly of grandparents and those who have children visit their homes infrequently, of their dangers on overdosage. Safe storage and use of child-resistant closures may reduce the opportunities for unintentional poisonings by children.[69]

Iron

Clinical Presentation

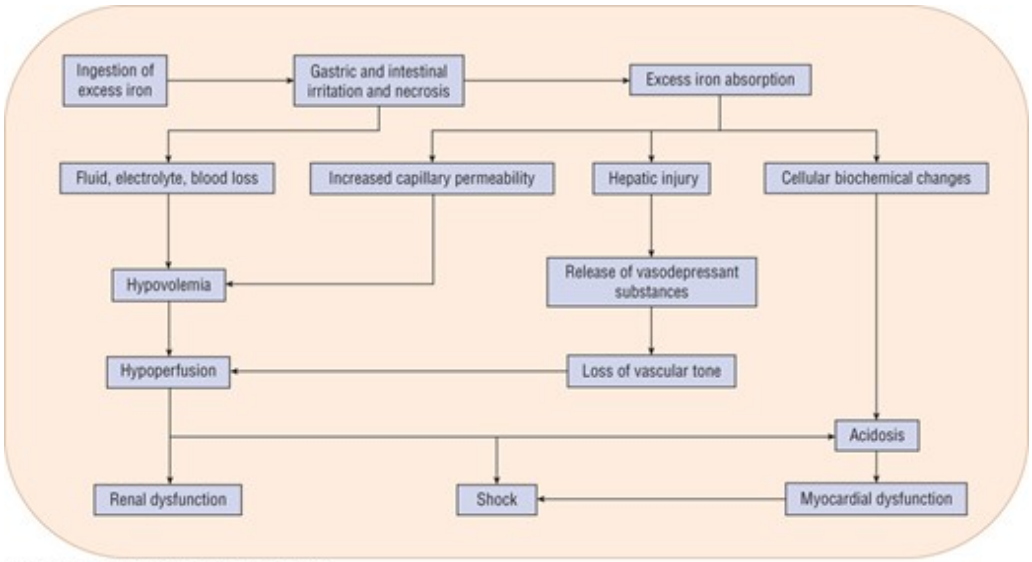
In the first few hours after ingestion of toxic amounts of iron, symptoms of gastrointestinal irritation (eg, nausea, vomiting, and diarrhea) are common. In certain severe cases, acidosis and shock can become manifest within 6 hours of ingestion. Some have observed a quiescent phase between 6 and 48 hours after ingestion when symptoms improve or abate, but this phenomenon is poorly characterized.[76] Continued gastrointestinal symptoms, poor peripheral perfusion, and oliguria should suggest the development of severe toxicity, with other effects still to become manifest. Generally, within 24 to 36 hours of the ingestion, central nervous system involvement with coma and seizures; hepatic injury characterized by jaundice, increased INR, increased bilirubin, and hypoglycemia; cardiovascular shock; and acidosis also develop.[76,77] Adult respiratory distress syndrome (ARDS) may develop in patients with severe cardiovascular shock and further compromise recovery. Coagulopathy with decreased thrombin formation is one of the early direct effects of excessive iron concentrations, and later disturbances of coagulation (after 24-48 hours of ingestion) are a consequence of hepatotoxicity.[78] Mucosal injury, an iron-rich circulation, or deferoxamine therapy may promote septicemia with *Yersinia enterocolitica* during iron overdose; other bacteria or viruses also may cause septicemia.[76] Two to 4 weeks after the exposure, a small percentage of patients experience persistent vomiting from gastric outlet obstruction as the result of pyloric and duodenal stenosis from the earlier gastric mucosal injury. Autopsy findings in children indicate prominent iron deposition in intestinal mucosa and periportal necrosis of the liver that correlate with the primary symptoms of serious iron poisoning.[79]

Mechanism of Toxicity

The toxicity of acute iron poisoning includes local effects on the gastrointestinal mucosa and systemic effects induced by excessive iron in the body.[76] Iron is irritating to the gastric and duodenal mucosa, which may result in hemorrhage and occasional perforations. Once absorbed, iron is taken up by tissues, particularly the liver, and acts as a mitochondrial poison. It occasionally causes hepatic injury. Iron may inhibit aerobic glycolysis and perturb the electron transport system. Further, iron may shunt electrons away from the electron transport system, thereby reducing the efficiency of oxidative phosphorylation. These biochemical factors, along with the cardiovascular effects of iron, lead to metabolic acidosis. The pathogenesis of shock is not well understood but may involve the development of hypovolemia and lactic acidosis, release of endogenous vasodilators, and the direct vasodepressant effects of iron and ferritin on the circulation (**Fig. e9-5**).

FIGURE e9-5

Pathophysiology of acute iron poisoning.



Causative Agents

Iron poisoning results from the ingestion and absorption of excessive amounts of iron from iron tablets, multiple vitamins with iron, and prenatal vitamins. Different iron salts and formulations contain varying amounts of elemental iron (see Chapters 44 and 101). Generally, children's chewable vitamins are less likely to produce systemic iron poisoning in part because of their lower iron content.[80]

Incidence

Acute iron poisoning can produce death in children and adults.[79,80] The 2014 AAPCC-NPDS report documented 4,024 single-agent iron ingestions, with 3.3% of the exposures exhibiting moderate to severe toxicity. Children younger than 6 years accounted for 52% of the exposures. Multiple vitamins with iron were involved in 11,354 cases, with 0.2% exhibiting moderate-severe toxicity. One death was associated with an iron product during this year.[3]

Risk Assessment

A patient who exhibits lethargy, paleness, persistent or bloody emesis, or diarrhea should be immediately referred to an emergency department.[80] Ingestion of 10 to 20 mg/kg elemental iron usually elicits mild gastrointestinal symptoms. Ingestion of 20 to 40 mg/kg is not likely to produce systemic toxicity, and typically these patients can be conservatively managed at home. Ingestions of 40 mg/kg or more of elemental iron are often associated with serious toxicity and require immediate medical attention.[80] Psychiatric as well as medical intervention is indicated for adults and adolescents who intentionally ingest iron as a suicide gesture.[76,80]

An abdominal radiograph may help to confirm the ingestion of iron tablets and indicate the need for aggressive gastrointestinal evacuation with whole-bowel irrigation. An abdominal radiograph is most useful within 2 hours of ingestion. The visualization of radiopaque iron tablets is confounded by the presence of other hard-coated tablets and some extended-release tablets that also are radiopaque. Furthermore, the radiopacity of iron tablets diminishes as the tablets disintegrate, and chewable and liquid formulations typically are not radiopaque.[81]

Iron poisoning causes vomiting and diarrhea, but these symptoms are poor indicators of later serious toxicity. The presence of a combination of findings such as coma, radiopacities, leukocytosis, and increased anion gap, however, is associated with dangerously high serum concentrations greater than 500 mcg/dL (90 µmol/L). The presence of single signs and symptoms, such as vomiting, leukocytosis, or hyperglycemia, is not a reliable indicator of the severity of iron poisoning in adults or children.[82,83]

Once iron is absorbed, it is eliminated only as the result of blood loss or sloughing of the intestinal and epidermal cells. Thus, iron kinetics essentially represent a closed system with multiple compartments. The serum iron concentration represents a small fraction of the total-body content of iron and is at its greatest concentration in the postabsorptive and distributive phases, typically 2 to 10 hours after ingestion. Serum iron concentrations greater than 500 mcg/dL (90 µmol/L) have been associated with severe toxicity, whereas concentrations less than 350 mcg/dL (62.7 µmol/L) typically are not associated with severe toxicity; however, exceptions have been reported for both thresholds.[84] Serious toxicity is best determined by assessing the development of gross gastrointestinal bleeding, metabolic acidosis, shock, and coma regardless of the serum iron concentration. The serum iron concentration serves as a guide for further assessment and treatment options. The ratio of the serum iron concentration to the total iron-binding capacity is unreliable, insensitive, and has little relationship to acute toxicity.[83]

Management of Toxicity

Many patients vomit spontaneously, and no iron-specific prehospital care is indicated.[80] At the emergency department, gastric lavage with normal saline can be considered if emesis with tablet fragments has not occurred. Lavage with normal saline may remove iron tablet fragments and dissolved iron, but because the lumen of the tube is often smaller than some whole tablets, effective removal is unlikely.[76] Activated charcoal administration is not useful because it adsorbs iron poorly. If abdominal radiographs reveal a large number of iron tablets, whole-bowel irrigation with polyethylene glycol electrolyte solution typically is necessary.[28] Early and aggressive decontamination and evacuation of the gastrointestinal tract usually will be adequate to minimize iron absorption and thereby reduce the risk of systemic toxicity. Lavage solutions of phosphate or deferoxamine have been proposed previously as a means to render iron insoluble, but they were found to be ineffective and dangerous.[80]

Deferoxamine is a highly selective chelator of iron that theoretically binds ferric (Fe^{3+}) iron in a 1:1 molar ratio (100 mg deferoxamine to 8.5 mg ferric iron) that is more stable than the binding of iron to transferrin. Deferoxamine removes excess iron from the circulation and some iron from transferrin by chelating ferric complexes in equilibrium with transferrin. The resulting iron—deferoxamine

complex, ferrioxamine, is then excreted in the urine. The action of deferoxamine on intracellular iron is unclear, but it may have a protective intracellular effect or may chelate extramitochondrial iron. The parenteral administration of deferoxamine produces an orange-red-colored urine within 3 to 6 hours because of the presence of ferrioxamine.[76] For mild-to-moderate cases of iron poisoning, where its use is unclear, the presence of discolored urine indicates the persistent presence of chelatable iron and the need to continue deferoxamine. The reliance on discolored urine as a therapeutic end point has been challenged because it is not sensitive and is difficult to detect.[85]

Patients with systemic symptoms (eg, shock, coma, or gross gastrointestinal bleeding or metabolic acidosis) should receive parenteral deferoxamine as soon as possible. If the serum iron concentration is greater than 500 mcg/dL (90 µmol/L), deferoxamine is also indicated because serious systemic toxicity is likely.[76] Its use is less clear in patients with serum iron concentrations in the range from 350 to 500 mcg/dL (62.790 µmol/L) because many of these patients do not develop systemic symptoms.[84]

Clinical Controversy…

There is little evidence to support the dose or duration of deferoxamine treatment for iron poisoning. The dosage regimen should balance the benefits of increased iron removal in patients with exceedingly high serum iron concentrations versus the risk of developing ARDS when therapy lasts for more than 1 to 3 days.

Generally, an initial IV infusion of deferoxamine 15 mg/kg/h is administered, although some have used up to 30 mg/kg/h for life-threatening cases. In these situations, the dose must be titrated carefully to minimize deferoxamine-induced hypotension.[76] The rapid IV infusion of deferoxamine (greater than 15 mg/kg/h) has been associated with tachycardia, hypotension, shock, generalized erythema, and urticaria.[76,86] Anaphylaxis has been reported rarely. The use of deferoxamine for more than 24 hours at doses used for treatment of acute poisoning has been associated with exacerbation or development of ARDS.[86,87] Although the manufacturer states that the total dose in 24 hours should not exceed 6 g, the basis for this recommendation is unclear, and daily doses as high as 37.1 g have been administered without incident.[88] Good hydration and urine output may moderate some of the secondary physiologic effects of iron toxicity and ensure urinary elimination of ferrioxamine. In the patient who develops acute kidney injury, hemodialysis or hemofiltration does not remove excess iron but it will remove ferrioxamine.[76]

The desired end point for deferoxamine therapy is not clear. Some have suggested that deferoxamine therapy should cease when the serum iron concentration falls below 150 mcg/dL (26.9 µmol/L). The decline of serum iron concentrations, however, may not account for the potential cellular action of deferoxamine irrespective of its effect on iron elimination. The cessation of orange-red urine production that is indicative of ferrioxamine excretion is not reliable because many individuals cannot distinguish its presence in the urine.[85] Considering these shortcomings, deferoxamine therapy should be continued for approximately 12 hours after the patient is asymptomatic and the urine returns to normal color or until the serum iron concentration falls below 350 mcg/dL (62.7 µmol/L) and approaches 150 mcg/dL (26.9 µmol/L).

Monitoring and Prevention

Once a poisoning has occurred, acid-base balance (anion gap and arterial blood gases), fluid and electrolyte balance, and peripheral perfusion should be monitored. Other indicators of organ toxicity, such as ALT, AST, bilirubin, INR, serum glucose and creatinine concentrations, as well as markers of physiologic stress or infection such as leukocytosis, also should be monitored.

Iron poisoning often is not recognized as a potentially serious problem by parents or victims until symptoms develop; thus, valuable time to institute treatment is lost. Parents should be made aware of the potential risks and asked to observe basic poison prevention measures. Some hard-coated iron tablets resemble candy-coated chocolates and are confused easily by children. Iron tablets are typically packaged in child-resistant containers, often in blister packs.

Opioids

Clinical Presentation

10 Acute opioid poisoning can produce life-threatening effects that typically include respiratory depression and coma that may lead to death.[89] Virtually all opioids produce these symptoms and some agents have additional toxic effects. The time of onset and severity of symptoms depend on the route of exposure, formulation of the drug product, potency of the opioid total dose received, concurrent drugs, coexisting conditions and pharmacogenetic characteristics. Toxic signs and symptoms develop most rapidly after IV injection (within minutes) or inhalation of fumes (heroin), followed by inhalation from snorting particles, powder, or solutions. Immediate-release tablets typically have an onset of toxicity within 1 to 4 hours, followed by sustained-release tablets and dermal patches on the skin, which exhibit the slowest onset. Severe symptoms can occur from absorption by any route. Death typically is caused by respiratory failure, the metabolic consequences of hypoxia, noncardiogenic pulmonary edema and, in some cases, pulmonary aspiration of gastric contents after vomiting. Opioid poisoning may be complicated by hypothermia, rhabdomyolysis, and resultant acute kidney injury. Seizures, arrhythmias, concurrent exposure to and toxicity from other medications and illicit drugs, and the presence of adulterants and contaminants may complicate the person's presentation. Finally, hepatotoxicity from the co-ingestion of acetaminophen-containing medications, and infectious diseases from IV drug use may occur.[89]

Mechanism of Toxicity

Action at the μ opioid receptor is primarily responsible for many of the life-threatening effects of opioids, such as respiratory depression and sedation, and all opioid analgesics appear to have some activity at this receptor. Meperidine's metabolite, normeperidine, produces CNS excitation that leads to delirium, tremor, and seizures. Meperidine also blocks the reuptake of serotonin and may produce serotonin syndrome particularly in patients taking monoamine oxidase inhibitors.[90] Methadone acts on the myocardium to block potassium efflux leading to arrhythmias, syncope, and sudden death.[91] Tapentadol and tramadol block reuptake of norepinephrine and serotonin, respectively, and are associated with seizures at high doses.[89]

Causative Agents

Many opioid drugs are available in the United States for the management of moderate to severe pain (see Chapter 44). These include drugs that are naturally found in opium (ie, opiates such as morphine and codeine), synthetic opiates (eg, fentanyl, methadone, and meperidine), and semisynthetic opiate derivatives (eg, hydromorphone, hydrocodone, and oxycodone). Heroin is a schedule I controlled substance and illicit drug. It produces a greater degree of euphoria than many other opioids and also produces the same life-threatening effects with added complications of adulterants and infections from IV drug use. Chemical analogs of legitimate opioids such as fentanyl are produced by clandestine laboratories. Illicitly manufactured analogs often have much greater potency unbeknownst to the user and thus increase the risk of a lethal overdose.[92]

Incidence

Acute poisoning and overdose from opioids have become the most frequent cause of drug-related death in the United States with a 200% increased death rate from 2000 to 2014 and accounted for 61% of all drug-related deaths in 2014.[93] During this same period heroin-related, age-adjusted death rates have increased by 340%.[93,94] Poisoning from opioids occurs in all age groups, from neonates through intrauterine exposure to the elderly, and in rural and urban areas. Poisoning can occur from a variety of circumstances such as the unintentional ingestion of medicines by young children. Inadvertent overdoses can occur in adolescents or adults from taking single or multiple "therapeutic" doses of opioids with several sedating drugs (particularly benzodiazepines). Using opioids to produce self-harm can end in suicide and abusing opioids as part of a substance use disorder may also lead to death. The 2014 AAPCC-NPDS report documented 19,645 nonfatal single-product exposures that were voluntarily reported to poison centers, 283 with severe symptoms, and 43 deaths from opioids alone; 40% of the cases were associated with intentional use and 22% of exposures occurred in children younger than 6 years of age.[3]

CLINICAL PRESENTATION Acute Opioid Poisoning General

- Life-threatening respiratory depression (12 or less breaths per minute) within minutes to hours of use depending upon the drug, route of administration, product formulation, and coexisting conditions; often delayed by 8 or more hours with ingestion of a sustained-release product.

Symptoms

- Lethargy progressing to coma.
- Flaccid extremities.
- Seizures associated with meperidine and tramadol.
- Acute muscular rigidity with rapid injection of fentanyl.
- Deafness with some overdoses.

Signs

- Depressed respiratory depth and rate leading to apnea.
- Pinpoint pupils (uncommon with meperidine, tramadol, and severe hypoxia).
- Unresponsiveness and depressed reflexes.
- Mild hypotension and bradycardia, worsening with increasing hypoxia.
- Absent bowel sounds, gastrointestinal hypomotility.
- Hypothermia if exposed to cold conditions.
- Frothy pink sputum, end-inspiratory crackles on auscultation, and shortness of breath several hours after exposure consistent with pulmonary edema.
- QT-interval prolongation leading to torsade de pointes on ECG with methadone.
- One or more opioid-containing drug patches (eg, fentanyl) on the skin.
- "Needle tracks" or skin infections if IV drug user.

Laboratory Tests

- Altered arterial blood gases (acidosis) and serum electrolytes in response to hypoxia.
- Serum glucose concentration.
- Determine serum acetaminophen concentration no earlier than 4 hours after ingestion and ALT in case an opioid-acetaminophen combination product ingested.

Other Diagnostic Tests

- Pulse oximetry and ECG with continuous monitoring.
- Monitor for complications of pulmonary aspiration such as hypoxia and pneumonitis by physical findings and chest radiographs.
- Monitor for complications of rhabdomyolysis (creatine kinase, electrolytes) and subsequent acute kidney injury (blood urea nitrogen [BUN], creatinine) if patient has been lying immobile for several hours.
- Evaluate for infectious diseases if IV drug use, and local- or systemic-infection suspected.

Risk Assessment

A patient's symptoms, presence of drugs or substance abuse paraphernalia at the scene, and availability of opioids can be helpful indicators of risk. The triad of depressed respirations (12 or less

breaths per minute), coma, and pinpoint pupils (miosis) with relatively acute onset should strongly suggest opioid poisoning and warrants a therapeutic trial of the antidote naloxone.[6,89] Measurement of opioid serum concentrations are not available in clinical laboratories and are not necessary to guide appropriate therapy. Therapy should not be delayed pending laboratory confirmation of an opioid in a routine drug screen because many opioids are not detected (see Table e9-6) and critical time will be lost awaiting results that will not guide therapy.

Management of Toxicity

The foundation of treatment of opioid poisoning is adequate respiratory support, and the administration of the opioid antagonist naloxone.[89] Symptomatic cases of opioid overdoses should be transported to an emergency department for evaluation and treatment. There is no conventional prehospital care except for cardiopulmonary resuscitation; however, naloxone can be administered at the scene by trained personnel.

If the opioid has been ingested within 1 hour, the administration of activated charcoal should be considered after weighing the risks of pulmonary aspiration (ie, if vomiting occurs in a patient with altered or worsening mental status).[25,89] Based on a history of an exposure, presence of typical symptoms and the response to naloxone, an acute opioid poisoning should be recognizable in most cases. Whole bowel irrigation should be considered for ingestions of extended-release formulations, packets of drugs such as heroin intended for smuggling, and fentanyl dermal patches once the patient is stabilized.[28,29,89]

Naloxone is a competitive opioid receptor antagonist that acts on known opioid receptors to reverse the toxic effects of opioids (**Table e9-13**) and can be life-saving. The goal of therapy is to restore adequate spontaneous respirations. It is typically administered by rapid IV injection, acts within 2 minutes and has a short duration of action of 20 to 90 minutes.[38] Intramuscular, intraosseous, intralingual injection and intranasal and intratracheal instillation are also effective if the IV route is not immediately available, but oral administration is ineffective. Naloxone for injection is available in concentrations of 0.02, 0.4, and 1.0 mg/mL. The effect of naloxone may not be evident in several circumstances (see Table e9-13) and the initial dose may not be sufficient.

TABLE e9-13 Responses to Naloxone in Opioid Poisoning

Therapeutic Reversal of Toxicity	Factors for Poor or No Response
Respiratory depression	Polydrug overdose (eg, benzodiazepines, sedatives, muscle relaxants, ethanol)
CNS depression	Inadequate dose of naloxone
Miosis	Concurrent head injury
Cardiovascular depression	Hypoglycemia
Gastrointestinal hypomotility	Hypoxic state (CNS, acid/base disorders)
Euphoria	Postictal state

Therapeutic Reversal of Toxicity	Factors for Poor or No Response
Dependence leading to withdrawal	No opioid involved

Clinical Controversy…

The initial dose of naloxone for opioid overdose varies. Earlier observations of inadequate response to an initial dose of 0.4 mg in some patients led to the dose being changed to 0.4 to 2.0 mg. Currently, initial doses of 0.04 to 0.05 mg are proposed by some clinicians to minimize the risks of abrupt withdrawal associated with adverse effects.

The dosing of naloxone should consider a balance of reversing toxic effects without causing abrupt withdrawal symptoms, which can produce agitation, hypertension, tachycardia, emesis with the risk of aspiration, and harm to the patient and caregivers from disorientation.[95] Dosage regimens have evolved from clinical experience and differ from the recommended starting dose of 0.4 to 2.0 mg in the package insert. A typical approach involves administering 0.04 to 0.05 mg (0.01 mg/kg in a young child) as the first dose. If there is no improvement in respirations within 2 minutes, 0.5 mg is administered to adults and children. At 2-minute intervals the dose can be increased to 2, 4, 10, and 15 mg until adequate respirations are achieved.[38,95] If there is no response at the 10 to 15 mg dose, confounding or other causes of the patient's condition should be considered. Other regimens with similar progressive increases in dose have been proposed. Overdoses with buprenorphine, fentanyl, and methadone often require doses in the upper range for a response.[95] The duration of naloxone's effect is generally shorter than many opioids, particularly for methadone and extended-release formulations, and requires close monitoring and repeated administration. If repeated doses of naloxone are required for maintenance of adequate respiration, a continuous infusion should be considered that is approximately two-thirds of the single-dose that produces a response given at an hourly rate.[38] The IM autoinjector delivers naloxone 0.4 mg per injection and the intranasal spray delivers 4 mg per use.

The adverse effects of large doses of naloxone are rare, minimal, and insignificant and it can be given safely to persons with acute poisonings of any cause. Rare isolated reports of hypertension, hyperventilation, and tachycardia in opioid-dependent patients may be related to the release of catecholamines and other mediators in response to stress from abrupt withdrawal.[95] The progressive escalation of naloxone doses to prevent abrupt withdrawal is partially based on its potential association with acute lung injury that may produce or exacerbate pulmonary edema.[38,96]

Monitoring and Prevention

Poisoned patients may require monitoring of vital signs, ventilatory adequacy (ie, blood gases and pulse oximetry), and chest radiographs to assess the degree of pulmonary edema or development of aspiration pneumonitis. Patients should also be monitored for the potential development of complications such as rhabdomyolysis, acute kidney injury, or seizures. Determination of a serum acetaminophen concentration is warranted to rule out the coincidental ingestion of acetaminophen

with an opioid-acetaminophen combination product.[89]

The rising number of deaths from prescription opioid analgesics has been categorized as an epidemic by the Centers for Disease Control and Prevention. Multiple strategies have been implemented and proposed to prevent opioid-related deaths.[97] A controlled substances monitoring database (also called a prescription drug monitoring program) has been implemented in nearly every state in order to identify individuals using frequent prescriptions of controlled substances from multiple prescribers ("doctor shopping") or fraudulent prescriptions.[98] Enforcement and implementation of laws on "doctor shopping," indiscriminant prescribing of controlled substances without a medical evaluation by "pill mills," and efforts to improve medical practice through educational programs and guidelines for the treatment of chronic pain are underway. The FDA has developed a Risk Evaluation and Mitigation Strategy for long-acting and extended-release opioids that involve prescriber training on appropriate prescribing practices. "Drug take-back" events to dispose of unneeded medications have been conducted in communities nationwide. Reducing the availability of medications, particularly opioids, in the home reduces the opportunity for stealing and diverting medications that can lead to overdoses and drug abuse. Most states have enacted laws to allow intranasal, intravenous, or intramuscular administration of naloxone by trained bystanders and law enforcement officers in the community to opioid-dependent individuals and heroin abusers at risk for life-threatening overdose in order to prevent death before an ambulance arrives.[99] Education of the general public on the risks of opioid poisoning and appropriate use and storage of opioid analgesics should be a routine practice in the prescribing and dispensing of opioid analgesics.

Weapons of Mass Chemical Poisoning

Clinical Presentation

11 Most chemicals used in warfare or terrorist attacks act immediately upon contact with the skin, mucous membranes or respiratory tract. The variety of potential agents has been generally categorized by the type of toxic action or target organ system (**Table e9-14**) that also reflects the anticipated signs and symptoms of poisoning. Typically clusters of victims have similar presentation, but the extent and onset of injury depends upon the person's level of exposure, which is related to their proximity to the source of the chemical, the method of deployment (eg, vapor, liquid, gas, and aerosol explosive device) and the mechanism of toxicity of the chemical. Inhalational exposures to nerve agents or cyanide will produce symptoms and sometimes death within minutes of exposure; whereas, slower absorption with dermal contact will delay the onset. Agents such as sulfur mustard and phosgene may take 4 to 6 hours for onset of toxicity.[7] Some toxins of biologic origin, such as ricin, often require days to weeks for characteristic symptoms to develop due to the mechanism of action. Nerve agents are highly potent anticholinesterases that have the same pathogenesis of toxicity (see Fig. e9-2) and produce the full spectrum of signs and symptoms of organophosphate insecticides (see Table e9-14).[7,100] One of the several major differences between nerve agents and organophosphate insecticides is the hyperacute onset of life-threatening symptoms, such as fulminant respiratory failure within seconds to minutes with nerve agents.[7] Another difference is the extreme oculogyric torsion with nerve agents that may require administration of tropicamide

ophthalmic drops to relieve eye pain. Moderate to severe poisonings from chemical warfare or terrorist agents will typically require care in an intensive care unit.[101]

TABLE e9-14 Categories of Chemicals of Mass Poisoning

Category and General Effects	Examples*
Biotoxins *(variety of toxicities from plant or animal origin)*	Ricin
Blister Agents/Vesicants *(severely blister the eyes, respiratory tract, and skin on contact)*	Mustards, sulfur mustard gas (H), lewisites (L), chloroarsine agents, phosgene oxime (CX)
Blood Agents *(interfere with the delivery and use of oxygen)*	Arsine (SA), carbon monoxide, cyanides, sodium monofluoroacetate
Choking/Lung/Pulmonary Agents *(cause severe irritation or swelling of the respiratory tract)*	Ammonia, chlorine, hydrogen chloride, methyl isocyanate, phosgene (CG), phosphine
Corrosives (Caustics, Acids) *(burn or corrode skin, eyes, and mucus membranes on contact)*	Hydrofluoric acid, hydrogen chloride, sulfuric acid
Incapacitating Agents *(cause an altered state of cognition and consciousness or unconsciousness)*	Fentanyl analogs and other opioids, "QNB" 3-quinuclidinyl benzilate (BZ)
Metals *(heavy metals that disrupt cellular function)*	Arsenic, mercury, thallium
Nerve Agents *(anticholinesterases that affect normal functioning of peripheral and central nervous systems)*	Sarin (GB), soman (GD), tabun (GA), VX
Riot Control Agents/Tear Gas *(cause significant irritation of the eyes, skin, and airway)*	Bromobenzylcyanide (CA), chloroacetophenone (CN), chlorobenzylidenemalononitrile (CS), chloropicrin (PS), dibenzoxazepine (CR)
Vomiting Agents *(cause severe nausea and vomiting)*	Adamsite (DM)

*North Atlantic Treaty Organization (NATO) code in parentheses.

Data from Emergency Preparedness and Response: Chemical Emergencies.

Centers for Disease Control and Prevention. Atlanta, GA. November 25, 2014. http://emergency.cdc.gov/chemical/index.asp

Mechanism of Toxicity

There is no single unifying mechanism of toxicity of the chemicals used for warfare or terrorism because of the variety of different agents involved (see Table e9-14). The mechanism for nerve agents is well characterized by its anticholinesterase action (see earlier section on Anticholinesterase Insecticides).[61,100] Some agents act by an extreme exaggeration of their pharmacologic actions such as BZ producing extreme anticholinergic CNS effects and fentanyl analogs producing extreme opioid toxicity (see **CLINICAL PRESENTATION BOX** for acute opioid poisoning). Vessicants, such as sulfur mustard, irreversibly alkylate DNA, RNA and proteins and produce burns, blisters, and tissue destruction.[100] Blood agents act in several ways, but ultimately interfere with the transport or utilization of oxygen by cells. Cyanide, for example, is a potent competitive inhibitor of cytochrome oxidase and other enzymes and stops cellular respiration throughout the body.[7,100] Pulmonary agents, such as chlorine or phosgene, both react with water to produce hydrochloric acid, which produces severe irritation and destruction to mucosal tissue, ocular surfaces, the airway and lungs.[100]

Causative Agents

Many different chemicals have been used or have been recognized for their potential for terrorism or warfare (see Table e9-14). Adaptation of other commercial chemicals, synthesis of analogs of existing toxins, or creation of novel chemicals may introduce additional hazards in the future.

Incidence

The use of chemical weapons during the past century has been documented in numerous warfare and terrorism settings that produced mass casualties. For example, during World War I, 100,000 deaths and 1.2 million casualties were attributed to attacks with chlorine, phosgene or mustard.[102] In 1995, terrorists released sarin in the Tokyo subway system, leading to 11 deaths and 5,510 people seeking medical attention including many first-responders.[103,104]

Risk Assessment

Assessment of injuries at the scene, triage stations, and healthcare facilities should identify victims at greatest risk and priority for treatment. The acute onset of serious symptoms in many victims without signs of trauma suggests a mass chemical exposure. Patients with typical clusters of symptoms, such as those associated with anticholinesterase agents, may provide clues to the type of chemical and guide treatment.[7,105]

Management of Toxicity

High priorities for managing exposures to chemical warfare or terrorism agents are to evacuate victims from the contaminated area, decontaminate any exposed surfaces with first aid measures (see Table e9-5), and removal of contaminated clothing.[105] First-responders should guard against being poisoned by wearing personal protective equipment, such as body suits, gloves, boots and air supply, as appropriate for the situation. Supportive and symptomatic care with attention to airway, breathing and circulation are critical for all types of exposures and may be the extent of treatment options useful for a toxin.[7,101,105,106] Most chemicals associated with mass poisoning exposures do not have a specific therapy or antidote. Several toxins, such as nerve agents, opioids, and cyanides, do have specific antidotes that may be life-saving (see Table e9-9). The sooner therapy can be instituted in the field, as in carrying atropine, pralidoxime, and diazepam autoinjectors in an area where a nerve agent attack is anticipated, generally the better the outcome will be. Depending upon the conditions, additional decontamination before a victim enters a healthcare facility may be necessary to avoid contaminating healthcare workers and other patients in the treatment area. Guidance on treatment for a specific chemical exposure is available at several websites of the Centers for Disease Control and Prevention (CDC) (*http://emergency.cdc.gov/chemical/index.asp; www.cdc.gov/NIOSH/ershdb/default.html; www.atsdr.cdc.gov*).

Monitoring and Prevention

Survivors of a chemical attack may develop long-term effects or life-long disabilities.[107] For example, vesicants have been associated with cancer, severe burns, and scars; pulmonary agents may produce permanent respiratory conditions; and nerve agents may lead to short- and long-term neuromuscular disabilities. Victims of any mass poisoning are at risk for developing psychological distress after the attack and warrant follow-up once the acute medical condition is stabilized.

Prevention of chemical attacks is beyond the scope of healthcare providers' standard responsibilities; however, preparation for mass chemical emergencies is a vital element of mass casualty preparedness. Working with local health department representatives, safety officials and other healthcare providers to develop a community plan is important because no single site can likely provide the necessary resources to treat the number of victims. The CDC has resources that provide guidance on medical management of chemical hazards (*http://emergency.cdc.gov/agent/agentlistchem.asp*), emergency healthcare preparedness (*http://www.cdc.gov/phpr/healthcare/index.htm*), and access to the Strategic National Stockpile (*http://www.cdc.gov/phpr/stockpile/stockpile.htm*) among other areas of interest.

Chapter e10: Clinical Management of Potential Bioterrorism-related Conditions

Colleen M. Terriff; Lisa T. Costanigro; Kimberly C. McKeirnan; Barbara J. Hoeben

INTRODUCTION

KEY CONCEPTS

- 1 The majority of emerging pathogens associated with public health outbreaks are zoonotic infections, passed from animals to humans.
- 2 Due to the high mortality rates with inhalation anthrax, postexposure prophylaxis may need to be rapidly offered to all people who were potentially exposed.
- 3 Pneumonic plague, one of the most lethal forms of plague, develops through primary (direct inhalation of infected droplets) or secondary exposure.
- 4 Rapid recognition of Ebola virus disease (EVD) is essential to initiate supportive care and infection control procedures.
- 5 While the incidence of measles-related deaths has, overall, significantly declined as the result of major global vaccination efforts, vigilance is still critical, since measles is extremely contagious and there are some gaps in vaccine coverage.
- 6 Middle Eastern Respiratory Syndrome (MERS) is an emerging viral respiratory illness, which can cause severe respiratory distress and has been fatal in one third of all patients who have contracted the disease.
- 7 A pertussis vaccination booster is recommended for all women during weeks 27 to 36 of gestation of each pregnancy to allow maximal maternal antibody response and passive in utero transfer of antibodies.
- 8 Infectious disease outbreaks following a natural disaster are common and usually attributable to critical infrastructure damage, limited access to quality healthcare, displacement, environmental and human condition changes, and vulnerability to pathogens.

Bioterrorism is characterized by an intentional exposure to animals or humans of an organism or toxin,

which subsequently causes disease and/or death. Historically, these acts were planned and carried out against military personnel or directed towards select segments of the civilian population. Examples include diseased bodies flung over city walls, poisons added to drinking water, bacteria used to taint salad bars, and weaponized ricin and anthrax.[1,2] In general, while there is no catastrophic destruction of property associated with most acts of bioterrorism, there usually is fear, anxiety and confusion, some ensuing morbidity and mortality, economic disruption, and definite pressure on healthcare and public health systems.

After the intentional release of anthrax in 2001 public health officials, first responders, healthcare workers, employers, school officials, parents and community members incorporated the term bioterrorism in their emergency and disaster preparedness and response vocabulary. Subsequently, these groups wrote plans, conducted response exercises for potential scenarios, such as smallpox outbreaks and mass exposures of plague, that have, thankfully, not occurred. While these traditional bioterrorism agents are still threats, public health officials and healthcare professionals are starting to turn their focus on new or re-emerging concerns, many tied to Mother Nature or unintentional human acts.

1 Similar to intentional acts of bioterrorism, disease outbreaks of Ebola and Middle Eastern Respiratory Syndrome Coronavirus (MERS) are a threat to global health security, associated with social unrest or instability and major economic disruption, in addition to significant morbidity and mortality.[3] The emergence and spread of these infectious diseases (ID) and the growing prevalence of drug resistance; ease of trade and travel; and rise of laboratories capable of creating dangerous microbes have heightened public concern.[3] Through a partnership of the Centers for Disease Control and Prevention (CDC), private and public stakeholders, and international organizations, The Global Health Security Agenda which focuses on efforts to prevent and reduce outbreaks, detect threats early to save lives, and rapidly and effectively respond to potential infectious disease threats has become a reality.[4] It is estimated that 75% of recently emerging infections are zoonotic, or passed between animals and humans.[5] The CDC recognizes the strong connection between humans, animals and the environment and has created the One Health Program to move forward an action agenda with both domestic and global activities. Initiatives of One Health are focused on improvements in research; detection or biosurveillance; clinical assessment, prevention and treatment; education and communication.[5] Many of these outbreaks, from pathogens like SARS and West Nile Virus, caused serious financial, political and public health ramifications, while eroding public confidence in the government's ability to anticipate and respond to these events.[5] Healthcare professionals are on the front lines of detection, clinical management and education related to these emerging zoonotic threats.

Since the early 2000s there has been an influenza pandemic, endless natural disasters, numerous disease outbreaks, and a large increase in the number of multidrug resistant bacteria.[6,7,8] Several recent threats have emerged that should be addressed by the development of mitigation and response strategies to minimize public health consequences. A heightened awareness of the impact of climate change and environmental transformations (ie, deforestation, modifying waterways, and urbanization), on the frequency of severe weather events and natural disasters as well as animal and human disease. The World Health Organization's (WHO) report on climate change addresses this association to and potential impact on infectious disease. For example, urban crowding has led to increases in water-collecting trash, a breeding ground for *Aedes aegypti*, the vector for Dengue.[9] In 2008 the Wildlife Conservation Society published a list of deadly diseases (**Table e10-1**), which were predicted to worsen with climate change. Many of their predictions, including algae blooms (off the coast of Florida) and Ebola outbreaks (West

Africa), have recently come true.[10] Ebola, a significant emerging global pathogen, will be a major focus of this chapter.

TABLE e10-1 Diseases that may Worsen with Climate Change

Bird flu
Babesiosis (ticks; endemic in tropics)
Cholera
Ebola
Parasites (ie, Baylisascaris procyonis; raccoons)
Lyme disease
Plague
"Red tides" (algal blooms)
Rift Valley fever (virus; mosquitoes)
Sleeping sickness (tsetse fly)
Tuberculosis
Yellow fever (mosquitoes)

Data from reference 10.

Every year hundreds of people in the United States experience a variety of food-related illnesses from bacteria such as *Escherichia coli, Salmonella* and *Listeria*. In 2014 the CDC lead 13 different investigations of multistate food-related outbreaks.[11] Healthcare providers combat annual influenza and pertussis epidemics. While the 2009 H1N1 influenza pandemic garnered much international attention, every year there are an estimated 3 to 5 million severe cases of influenza and nearly half a million deaths worldwide.[12] Over 28,000 cases of pertussis, or whooping cough, were reported to the CDC in 2014. While the number of cases and deaths seems to have peaked in 2012, the epidemic is far from over.[13] An average of 70 measles cases were reported to the CDC annually from 2001 to 2010.[14] Then in 2014 there were 23 outbreaks leading to over 600 measles cases and in 2015 another 183 cases, plus the first reported death in over 10 years.[15]

Middle Eastern Respiratory Syndrome Coronavirus, broke onto the world scene in April of 2012. By February of 2014 there were over 180 cases and nearly 80 deaths, with the epicenter located in Saudi Arabia.[16] By May 2014 the cases tripled and up to one in six were observed in healthcare workers who were taking care of patients who had MERS.[17] In 2014 West Africa experienced the worst Ebola outbreak in history with over 27,000 cases and 11,000 deaths. The outbreak centered in Liberia, Sierra Leone, and Guinea.[18] The United States had four Ebola cases, including one death: two people who traveled back from Africa and two who acquired the infection in the US after taking care of these returning from Africa.[19] WHO recognizes the threat Ebola poses to countries with weak health-systems as an "emergency within an

emergency." The attention and resources focused on this infection weakens future prevention and treatment efforts of other diseases like malaria in these impacted countries with limited resources.[20] With that high level of morbidity, mortality, and strain on health care systems, Ebola, although not released by a terrorist, definitely fits the description of an agent of bioterror.

While the "disease or disaster of the month" is seemingly overwhelming it is important to remember that planning for public health emergent outbreaks should be generalizable and include steps or procedures that would fit most scenarios. For instance, Ebola cases made every health system in the United States review and improve their plans for rapid diagnosis and infection control efforts for highly lethal, contagious organisms. The national news coverage also stimulated emergency providers to reflect on their triage protocols for returning travelers from Africa (ie, is this measles, malaria, or Ebola?), infection control procedures, and capabilities to manage rumors and misinformation. Measles outbreaks forced public health officials to update their plans for identification of possible exposures, quarantine, and preexposure as well as postexposure prophylaxis recommendations.

This chapter reviews key biological agents and the clinical considerations related to their significance, etiology, pathophysiology, presentation, diagnosis and management, including preexposure and postexposure prophylaxis and treatment of confirmed or suspected cases. The latest guidelines for diagnosis and management of high profile agents, such as anthrax, and "naturally occurring" diseases, such as plague and Ebola, will be presented. In addition, threats to public health associated with outbreaks of measles, MERS, and whooping cough and those diseases of concern for individuals displaced from a disaster area (Natural or man-made) and for the responders assisting in the management and recovery efforts will be discussed. Where appropriate, the role of vaccination for prevention, the types of efforts necessary to contain an outbreak, and considerations for special patient populations, such as pediatrics and pregnant women, will be included.

CATEGORIZATION OF CRITICAL BIOLOGICAL AGENTS

The CDC and National Institute of Allergy and Infectious Diseases have classified critical biological agents into three distinct categories (A, B, and C) based on their ability to be easily disseminated or transmitted person-to-person; cause a high degree of mortality, with the potential for major public health impact; cause public panic and social disruption; and require action of the public health enterprise.[21] For example, *Bacillus anthracis*, the bacteria which causes anthrax, is classified as a category A agent, since untreated inhalation anthrax has a very high mortality rate and cases would put great stress on any medical community. Category B agents are less lethal, contagious and/or concerning than Category A agents. Finally, Category C includes emerging pathogens, with potential to be recategorized in the future. **Table e10-2** includes a representative list of key pathogens within each defined category.

TABLE e10-2 Priority Categorization and Example Biological Threat Agents and their Threat Risk to National Security and Public Health

Classification	Characterization	Example Agents
Category A	• High mortality rate • Greatest potential for major public health and medical impact	• Anthrax (*Bacillus anthracis*) • Botulism (*Clostridium botulinum* toxin)

Classification	Characterization	Example Agents
Category A	• Easily disseminated or transmitted from person-to-person • Might cause public panic and social disruption • Require special action for public health preparedness	• Plague (*Yersinia pestis*) • Smallpox (variola major) and other related pox viruses • Tularemia (*Francisella tularensis*) • Viral hemorrhagic fevers (like Ebola)
Category B	• Result in moderate morbidity rates and low mortality • Lower medical and public health impact • Moderately easy to disseminate • Require specific enhancements of diagnostic capacity and disease surveillance	• *Brucella* species (brucellosis) • *Coxiella burnetii* (Q fever) • Diarrheagenic *E.coli* • Ricin toxin (Ricinus communis) • Staphylococcus enterotoxin B (SEB) • West Nile virus (WNV)

Category C	• Emerging infections that could be engineered for mass dissemination in future because of:
	  ○ availability
	  ○ ease of production and dissemination
	  ○ potential for high morbidity and mortality rates and major health impact
		• Chikungunya virus
		• Influenza virus
		• Prions
		• Rabies virus
		• Tuberculosis, including drug-resistant TB
		• Yellow fever virus

Data from reference 21.

Many of these infections in their naturally occurring state are very uncommon. For example, in the past decade there have been an average of seven cases a year of *Yersinia pestis,* predominantly in the form of bubonic plague, reported mostly in the rural Western areas of the United States secondary to rodent exposure.[22] However, an outbreak of multiple pneumonic plague cases would be suspicious for bioterrorism. Likewise, smallpox has been officially eradicated from the planet. Any new case of confirmed smallpox would be considered an intentional act of bioterrorism.[23] Another concern is that terrorist groups may hire researchers to genetically engineer less lethal or easy-to-treat organisms into multidrug resistant pathogens with higher virulence. This chapter will cover three pathogens classified as category A biological

agents: anthrax, plague, and Ebola; and MERS; a category C agent. Measles and pertussis, not officially classified as biological threat agents, will also be featured in this chapter to showcase reemerging infections which can tax our public health response.

RECOGNITION AND DIAGNOSIS

Whether a critical biological agent is released as a covert or hidden attack or there is a naturally-occurring exposure or outbreak, detection and appropriate diagnosis should be swift and accurate to avoid delays by public health responders. This may be due to unfamiliarity with the presenting signs and symptoms of the disease or infection, which may create confusion, misdiagnosis, and enhanced risk of unnecessary healthcare worker exposure. The resultant spread of contagious pathogens could lead to higher rates of complications or death. For example, the first US case of Ebola was in a returning traveler from Liberia who presented to an emergency department two days after becoming ill with vague symptoms and then returned two days later with illness progression.[24] Two healthcare workers subsequently contracted Ebola and the traveler expired eight days after confirmatory diagnosis.[25] Infections like Ebola remind us that when triaging patients it is important to gather relevant exposure history, including information about recent travel in the United States and abroad.

A delay in patients presenting after exposure allows for further spread of a contagious agent, like plague, Ebola, and measles. This slowed detection and commencement of infection control protocols, recognition of the need for personal protective equipment (PPE), postexposure prophylaxis (PEP), and prompt treatment may have great local, and in some cases global, public health implications. The clinical presentation section for each agent highlights the signs, symptoms, and laboratory characteristics most commonly seen to aid in their prompt and accurate recognition, so health care providers can be an instrumental part of the response efforts to contain the outbreak and minimize morbidity and mortality.

TREATMENT

General Concepts

Preexposure Prophylaxis

Vaccinations are an effective primary prevention tool, prompting the immune system to form antibodies in advance of possible exposure to an antigen or infectious agent. Healthcare providers, especially nurses and pharmacists, are accustomed to regularly administering vaccinations, which offer preexposure protection against a variety of infections, such as influenza, measles, pertussis, and polio. However, their familiarity with smallpox or anthrax vaccines, for example, or public health vaccination policies for mass vaccination clinics or postexposure vaccination efforts may be limited.[26] Until recently there was only sparse research focused on vaccine development for Ebola, and other emerging agents. Some vaccines, like the one available for plague, are restricted to certain populations, such as laboratory workers handling the pathogen. Vaccination efforts to address public health emergencies may involve an “all-hands-on-deck approach” with multidisciplinary efforts to establish mass vaccination clinics at public venues (ie, places of employment, sporting arenas, or worship centers) or outreach efforts where vaccinators go to the population at risk, such as homebound elders, prisoners, homeless, and other vulnerable groups. As relevant, vaccine specific details will be provided for each agent covered in this chapter.

Postexposure Prophylaxis

Postexposure prophylaxis involves dispensing or administering a medication, such as an antibiotic, immune globulin or even a vaccine, immediately or very soon after exposure to prevent the disease from developing, worsening or spreading to others. This public health practice is known as a secondary prevention measure. In 2001 close to 10,000 people (deemed potentially exposed to intentionally released anthrax) in the United States were offered PEP of ciprofloxacin, doxycycline or amoxicillin, to prevent inhalational anthrax. Overall adherence to the 60 day course of antibiotics was a disappointing 44%.[27] Two approaches for measles protection or PEP during an ongoing outbreak are vaccination within 72 hours or administration of immune globulin within 6 days of exposure.[28] Assessing who was truly exposed and knowing who is at risk of acquiring the infection and developing serious sequelae can be challenging. Efficient and expedited prophylaxis distribution and administration, and high-rates of adherence are also very important mitigation tactics. In most cases, because of the potential lethality of certain biological agents, like anthrax, more individuals will be given PEP than is probably necessary.

Suspected or Confirmed Cases

Treating confirmed or suspected cases of a biologic agent exposure can be challenging. First, people may not seek medical care until fulminant symptoms and signs are evident, which may thereby increase the likelihood of morbidity and mortality. The higher death rates seen with Ebola, for instance, are attributed to delay in seeking care, limited capabilities of certain health-systems, and the virulence of the strain.[29] Second, ill adults and children may present with nondescript, albeit severe, symptoms that mimic common infections, such as community-acquired pneumonia or influenza. Third, an infectious agent may require specific treatments that are not readily available in most hospitals, such as streptomycin for plague. Treatment should not be delayed until the results of confirmatory laboratory tests become available (days or weeks later). Suspected or confirmed cases require immediate treatment, including supportive care and in some cases empiric intravenous (IV) antimicrobial therapy with conversion to oral regimens when appropriate.

Special Populations

Special considerations are often necessary for patients who might be more susceptible to exposure or at high risk for developing serious sequela to an infection. Those in extremes of age, pregnant women, and patients with multiple chronic diseases, especially patients with immunocompromising conditions or those receiving immunosuppressive medications are generally considered high risk patients. For example, the initial prophylaxis and treatment options for suspected anthrax patients include a fluoroquinolone or doxycycline both of which are associated with warnings and adverse event concerns in pregnant women and young children. Drug dosing regimen adjustments for many antibiotics may be necessary in adults with chronic kidney disease and the elderly. Pediatric patients may need dosage individualization based on their weight and age. For patients with hepatic dysfunction there is often limited information to guide dosing regimen optimization. Another category of “special populations” are those patients needing extra assistance to access care, such as the hearing impaired, homebound elders, and homeless.

Desired Outcomes

The desired outcomes for individuals include prevention of disease progression, a reduction of sequelae, and prompt return to full health. From a public health perspective the desired outcomes are to decrease transmission (for those agents which are contagious), minimize anxiety and panic, and quickly restore

normalcy for the community. Maximizing safety and employing the most cost-effective modes of providing prophylaxis and treatment are also important. For example, the 2002 to 2003 smallpox vaccination campaign for United States military and select civilian populations was halted due to safety concerns because of the development of myopericarditis.[30] Of the over 5,000 who reported taking at least one dose of ciprofloxacin or doxycycline during the 2002 anthrax PEP campaign 57% noted an adverse event during the first 60 days, with gastrointestinal complaints and neurological symptoms leading the list.[27] Alternative therapies may thus need to be considered to optimize patient and community outcomes while minimizing the adverse consequences.

In the late 1990s and early 2000s the *Journal of the American Medical Association* published a series of consensus papers on identification and management of anthrax, botulism, smallpox, plague, tularemia, and viral hemorrhagic fever.[31,32,33,34,35,36] Comprehensive, up-to-date information on both traditional and emerging biological threats is available on the CDC website: http://emergency.cdc.gov/bioterrorism/.

ANTHRAX

The term *anthrax* is derived from the Greek word *anthrakis* meaning coal, because of the classic black eschar lesions (**Fig. e10-1**) caused by the cutaneous form of anthrax.[37] Anthrax was first described in the biblical era of Moses as the fifth Egyptian plague in Exodus 9. In the last four decades, numerous human cases have been reported: in 2009 to 2010 there were multiple cutaneous anthrax outbreaks in Bangladesh sickening 140 animals and 273 humans.[38] The human cases were all linked to the slaughtering of infected animals. An accidental environmental release from what was believed to be a bioweapons research center in Ekateringburg, Russia caused the death of 66 adults in 1979.[39] This raised the specter of a bioterrorism threat with weaponized anthrax. In the fall of 2001 several envelopes containing anthrax were discovered in the United States, which led to 22 confirmed and suspected cases and five deaths.[40] Ten thousand people were deemed "at risk" from possible exposure and given antibiotic prophylaxis. Since that act of domestic bioterrorism, there have been only anthrax hoaxes and false alarms. Allegedly, there have been over a thousand "white powder events" that were investigated since early 2007; and since 2001 the US has spent over $50 billion enhancing its biological defenses.[41] While naturally-acquired anthrax is considered a minimally concerning infection, this lethal pathogen, potentially released as an aerosol or powder, is still listed as a top national security bioterrorism threat.

FIGURE e10-1

Large cutaneous anthrax eschar. (Courtesy of the CDC and Archil Navdarashvili, Georgia (Republic). The eschar shown has the characteristic dark-brown to black-colored eschar that covers the lesion. (Source: CDC Public Health Image Library. Photo taken: August 25, 2012. *http://phil.cdc.gov/phil/home.asp*. Last accessed, September 2, 2015) PHIL:**19826**)

Epidemiology/Etiology

B. anthracis is a gram-positive, aerobic rod found endemically in the soil of many regions worldwide. This seemingly innocuous bacteria has the ability to produce endospores, which are resistant to most forms of sanitization and are capable of persisting for several years in contaminated environments.[1] These spores, which can then germinate and cause disease, can be ingested or inhaled, enter the skin through abrasions, or injected into cutaneous tissue or vasculature.[42,43,44] Domesticated and wild herbivores (eg, sheep, camels, elephants, horses, cattle, and goats) commonly acquire anthrax through ingestion of contaminated soil.[31] Humans then can be exposed through the slaughtering of infected animals or handling of products (ie, via wool shearing): cutaneous or inhalation anthrax may be the result of such exposures. Ingesting raw or undercooked infected meat can lead to gastrointestinal anthrax. While cutaneous anthrax is the most common manifestation of naturally occurring anthrax only 1 to 2 cases have historically been reported in the United States each year.[31] In contrast, from 2009 to 2010 over one hundred cases of anthrax in intravenous illicit drug users were reported in Scotland.[44] It was hypothesized that the heroin was contaminated either at the source in Afghanistan, the supply chain with cutting agents, or through animal hides used for drug transport.[43] This latest form of anthrax, coined injection anthrax, can cause cutaneous anthrax, or symptoms deeper in the tissue or vasculature, depending on site and mode of injection.[43,45] Gastrointestinal anthrax is also very rare; due to livestock vaccination and inspection practices.[45] In addition to the naturally-acquired or zoonotic exposures, since anthrax spores can be produced in a lab and placed in a powder, sprays, water or food, nearly all forms of exposure, depending on patient history, could be considered a bioterrorism act.[46] Anthrax is not considered a contagious pathogen. There is no documented human-to-human transmission from inhalation anthrax. However, the CDC reports that rare cases of person-to-person spread of cutaneous anthrax have occurred.[45]

Pathophysiology

Three clinical manifestations of anthrax have been observed: cutaneous (the most common, but least severe), inhalational (main bioterrorism concern), and gastrointestinal (very rare). Anthrax spores deposited into pulmonary alveoli may not germinate until taken up by alveoli macrophages and transported to regional lymph nodes, potentially taking weeks or months, which necessitates extended durations of antibiotic coverage. Replicating bacteria produce three proteins: protective antigen, lethal factor and edema factor; which combine to form toxins, leading to disruption of electrolyte and water transport across cellular membranes, extensive systemic edema, tissue damage, and shock.[37]

Clinical Presentation

The clinical presentation of anthrax, including signs and symptoms, diagnostic tests, and morbidity and mortality rates of the three variants, is summarized in **Table e10-3**. Cutaneous anthrax causes a unique black eschar which is a hallmark sign of the disease. Rapid and appropriate antibiotic treatment lowers the mortality rate from a relatively low 5% to 20% in untreated cases to less than 1%.[1,37] Most deaths, including those seen with injection drug users, are associated with disseminated disease or progression to sepsis.[1,37,43] Gastrointestinal anthrax might be more challenging to recognize since symptoms often closely mimic other gastrointestinal maladies. However, oropharyngeal ulcerations and bloody diarrhea might prompt an endoscopic examination and lead to a more definitive diagnosis. Mortality rates as high as 25% to 60% have been observed due to the difficulty in early detection.[37] Inhalation anthrax might be the most challenging form to diagnose based on initial presenting symptoms, which can mimic influenza or community-acquired pneumonia. As signs and symptoms progress, however, there are a few which differentiate inhalation anthrax: profuse, drenching sweats, and mediastinal widening or pleural effusions. Rare, but life-threatening neurologic complications, such as cerebral edema and hemorrhagic meningitis, are possible sequelae of all forms of anthrax.[47] Without prompt antibiotic initiation, the mortality rate may be as high as 85% within 24 to 36 hours after symptom onset.[1] Unfortunately, data from the outbreak in 2001 demonstrated that victims waited an average of 3.5 days to seek medical attention.[39] Gram stain, culture and polymerase chain reaction (PCR) testing of vesicular fluid, eschar material, or ulcer swabs, pleural fluid, cerebrospinal fluid, blood and stool samples are key for organism identification.[48] If a clinician suspects cutaneous anthrax obtaining a skin biopsy is also recommended. Likewise, it is advisable to obtain a bronchial or pleural biopsy for patients with signs and symptoms of inhalation anthrax.[48] Additional antibiotic susceptibility testing of cultures is crucial to optimize therapy, especially for children and pregnant women.

TABLE e10-3 Anthrax Clinical Presentation

Type	Exposure	Incubation Period	Symptoms	Diagnosis	Estimated Mortality
Cutaneous	Bacteria enters through cuts/abrasions; handling contaminated animal or animal products	1-12 days	Local edema progressing to papule, then ulcer, then black, painless eschar	Black eschar is key finding; gram stain of vesicular fluid; culture	5%-20% untreated; <1% treated; most deaths attributed to septic shock
Gastrointestinal	Ingestion of contaminated meat	1-7 days	Nausea and anorexia;	Mimics many GI conditions; culture	25%-60%*

Type	Exposure	Incubation Period	Symptoms	Diagnosis	Estimated Mortality
			oropharyngeal ulcers, sore throat and fever; then abdominal pain and bloody diarrhea	ulcerations (if possible)	
Inhalation	Intentional dispersal (powder form)	1-7 days	Influenza-like: fever, nonproductive cough, myalgia, fatigue, profuse, drenching sweats	Chest radiograph (widened mediastinum, pleural effusions); gram stain, cultures, PCR testing of blood, pleural fluid, cerebrospinal fluid	Up to 85%*

*High rates attributed to delay in seeking medical care or in diagnosis and treatment.

Data from references 1,31 and 37.

TREATMENT

In 2014 the CDC, the American Academy of Pediatrics, and the Association of Maternal and Child Health Programs, published updated anthrax prophylaxis and treatment guidances for adults, pediatric, pregnant and postpartum patients.[49,50,51] Their recommendations are summarized in **Tables e10-4** and **e10-5**. The desired treatment outcomes are to decrease the high mortality rate and minimize potentially devastating sequelae, such as septic shock and skin necrosis. Treatment recommendations are provided for preexposure and postexposure prophylaxis as well as directed therapy for those confirmed to have the disease.

TABLE e10-4 Primary and Secondary Prevention Strategies for Anthrax

	Adults	Pediatrics	Pregnancy/Postpartum	Comments
Preexposure Prophylaxis				
Vaccine	Anthrax Vaccine Adsorbed (AVA) 0.5 mL IM (preferred): 0 and 4 weeks; 6, 12, 18 months or SC (alternative): 0, 2 and 4 weeks; 6, 12 and 18 months with annual boosters, as indicated	Not recommended for preexposure prophylaxis	Not recommended for preexposure prophylaxis	Select, at-risk populations only; SC route is option for those with contraindication to IM injections

	Adults	Pediatrics	Pregnancy/Postpartum	Comments
Postexposure Prophylaxis (PEP)				
Empiric Oral Antibiotics (Preferred)	Ciprofloxacin 500 mg q 12 h or Doxycycline 100 mg q 12 h	Ciprofloxacin 15 mg/kg q 12 h (maximum 500 mg/dose) or Doxycycline: <45 kg: 2.2 mg/kg q 12 h ≥45 kg: 100 mg q 12 h (maximum 100 mg/dose)	Ciprofloxacin; No dosing adjustment is necessary	At least 60 days; Many alternative antibiotics, especially after sensitivities are available
Vaccine	AVA 0.5 mL SC at 0, 2, 4 weeks postexposure	Children ≥6 weeks: AVA 0.5 mL SC at 0, 2, 4 weeks postexposure	Neither pregnancy nor breast-feeding is a precaution or contraindication to AVA	Use in combination with course of antibiotics; IM is alternative route for AVA
Raxibacumab	See Table 10-6 (has PEP indication; but lack of data)	See Table 10-6	See Table 10-6	Use if no other PEP options are available/appropriate

Data from references 49,50,51,52.

TABLE e10-5 Treatment for Suspected or Confirmed Cases of Anthrax

Treatment	Adults	Pediatrics	Pregnancy/Postpartum	Comments
Empiric Antibiotics (Preferred)	Systemic infection with suspected meningitis: ciprofloxacin 400 mg IV q 8 h + meropenem 2 gm IV q 8 h + linezolid 600 mg IV q 12 h; Without meningitis: 2 antibiotics; Cutaneous: one antibiotic (cipro, doxy, levofloxacin or moxifloxacin PO)	≥1 month of age: Cutaneous: Ciprofloxacin or Doxycycline (see PEP dosing); Severe cases: 2 antibiotics recommended; Severe + suspected meningitis: 3 antibiotics; See guidelines for children <1 month and other details	These antibiotics have good transplacental passage: ciprofloxacin, levofloxacin, meropenem, ampicillin, penicillin, clindamycin, and rifampin. Same overall recommendations; no dosing adjustment necessary	Naturally-occurring cutaneous infection: 7-10 days; all other types: at least 14 days with treatment doses and then PEP to complete at least a total of 60 days; Change from IV to PO when clinically appropriate

Treatment	Adults	Pediatrics	Pregnancy/Postpartum	Comments
Antitoxin: **Raxibacumab IV**	40 mg/kg × 1	≤15 kg: 80 mg/kg; >15-50 kg: 60 mg/kg >50 kg: 40 mg/kg × 1 dose	Use only if clearly needed; Not approved; limited data; pregnancy category B; effect on nursing infant unknown	In combination with antibiotic therapy; Infuse over 2 hours and 15 minutes; Premedicate with diphenhydramine 1 hour prior to start of infusion
Anthrax Immune Globulin IV	≥17 years: 7 vials (420 units) × 1; for severe cases-consider a second dose; Infusion rate: initial (first 30 minutes)-0.5 mL/min; increase to 1 mL/min in 30 minutes then to max of 2 mL/min, if tolerated	<1 year-≤16 years: 1–7 vials (60-420 units) based on patient weight (see package insert for additional details; including infusion rates)	No data; Approved after 2014 anthrax guidelines; No formal recommendation for use	Must be used in combination with antimicrobials; Does not prevent or treat anthrax meningitis

Data from references 49,50,51,54,57.

Preexposure Prophylaxis

Anthrax preexposure prophylaxis is usually reserved for military personnel and select groups of people (ie, laboratory and veterinary workers) who have a potentially high exposure risk.[31,50,51,52] Anthrax vaccine adsorbed (AVA), FDA approved for 18 to 65 year olds, has a laborious administration schedule, requiring five IM injections (first three doses are considered primary series; subsequent two are considered boosters) or six SC injections over 18 months.[52] Annual boosters after a completed series are recommended for individuals who continue to remain at risk (see Table e10-4). Localized injection site reactions, such as tenderness, pain, and erythema, are the most common side effects; leading to the recommendation to rotate arms for each subsequent dose.[52] The vaccine is not readily available to the general public; and due to the complex schedule, mass vaccination for preexposure is not practical. Research is continuing to identify other vaccine candidates, such as a recombinant protective antigen, with hopes of developing options which are less immunogenic, while offering greater protection.[53]

Postexposure Prophylaxis

2 Due to the high mortality rates with inhalation anthrax, PEP should be rapidly offered to all people who were potentially exposed. Doxycycline and fluoroquinolones which are not usually used during pregnancy

and in pediatrics may empirically be started and continued until susceptibility data is available. The duration of PEP should be at least 60 days for inhalation anthrax, since spores may persist in lung tissue. PEP may be subsequently offered to a patient who has completed a treatment course for cutaneous anthrax, especially if aerosol exposure is suspected.[49] Combining vaccine with antibiotic therapy may be of value to enhance the antibody response after an anthrax exposure. In late 2015 the FDA approved AVA for SC administration in a three-dose series along with antibiotics for anthrax PEP.[52] When rabbits were exposed to *B. anthracis*, survival rates were dramatically higher when vaccine was used in combination with antibiotics compared to the use of antibiotics alone.[52]

Suspected or Confirmed Cases

Patients with suspected or confirmed anthrax, especially those with signs and symptoms of inhalational anthrax, meningitis, or cutaneous anthrax involving the head and neck, will most likely need intensive care management and intravenous antibiotics.[31,47] Drainage of pleural effusions, correction of electrolyte imbalances, fluid resuscitation, and early mechanical ventilation all appear to positively affect survival rates. Infectious diseases consultation, if available, is recommended; to assist with tailoring antibiotic therapy after sensitivities are available and switching from an intravenous to an oral regimen. Similar to *MRSA* and *C. difficile*, anthrax produces a toxin which can cause lethal sequela. Therefore most combination treatment regimens of 2 to 3 antimicrobials include a protein synthesis inhibitor, like clindamycin or linezolid, to decrease toxin release. One exception is arm or hand cutaneous anthrax, which can usually be treated with an oral course of a single antibiotic like ciprofloxacin or doxycycline. Finally, the possibility of latent spores dictates the duration of at least 60 days for suspected or confirmed inhalation anthrax.[49]

Another treatment option is to add a monoclonal antibody to the antimicrobial regimen. The antibody agents target anthrax protective antigen, blocking its binding to cell receptors, which then halts the internalization of edema and lethal toxins.[54,55] Raxibacumab, an FDA-approved monoclonal antibody, is administered intravenously.[54] Dosing specifics for treatment of adult and pediatric inhalation anthrax, and clinical considerations are highlighted in Table e10-5. Predosing with diphenhydramine decreases infusion-related adverse reactions.[54] Obiltoxaximab, another monoclonal antibody agent, is currently under review by the FDA, for both intravenous and intramuscular administration.[56] Both products will be available in the CDC's Strategic National Stockpile (SNS).[39]

One final treatment alternative is anthrax immune globulin, approved in March of 2015.[57] This IV agent, also only available through the Strategic National Stockpile, can be used in combination with antibiotics for the treatment of inhalation anthrax in infants, children, and adults.[57] Since this drug was approved after the 2014 anthrax treatment guidance update there is no formal recommendation for its use in pregnant or nursing women. Dosing specifics are included in Table e10-5.

PLAGUE

The term *plague* evolved to describe the "Black Death" or pestilence that killed millions of people in Europe during the Middle Ages. The causative agent of Black Death was *Yersenia pestis*, a zoonotic infection found in rodents and the fleas that infest them.[58] Recently, there has been a concerning uptick of naturally-acquired plague cases in the United States. As a bioweapon plague may be aerosolized, a capability developed by the US and the former Soviet Union, effectively removing the flea as a vector.[1] This agent is

of particular concern, because if sprayed into a gathering of people, it could manifest as inhalation plague, a form of the disease that is highly lethal and contagious. Large scale postexposure prophylaxis campaigns and treatment efforts would need to be rapidly activated to save lives and decrease further spread of the infection.

Epidemiology/Etiology

Y. pestis, is a gram-negative, non-spore-forming, coccobacilli. Rodent fleas maintain the zoonotic form of plague by infecting a variety of small mammals, including rats, ground squirrels, prairie dogs, ferrets, and rabbits.[58] New research indicates that Asian gerbils may have introduced the plague into Europe and that the black rat, as previously believed, may not have actively harbored the infection.[59] This infection is transmitted to humans from bites of fleas harboring the bacteria, direct contact with infectious tissues or exudates, and rarely by respiratory droplets from an animal or human.[58] In addition, domesticated dogs and cats can carry plague and transmit the infection through scratches and bites.[60] Worldwide, excluding pandemics, there are 1,000 to 2,000 reported human cases a year.[22] In the US between 1900 and 2012 only 1,006 confirmed or probable human cases were reported.[22] However recent cases (12 people; 4 deaths) in seven Southwestern states from April to August of 2015 have garnered national attention. An elderly man, the first case of plague in Utah since 2009, died in early August 2015.[61] Most cases were linked to recent flea bites, contact with a dead animal and/or camping. The most intriguing outbreak was in Colorado, when a pit-bull acquired plague and developed a fever and cough. His owner and three others contracted pneumonic plague, which is very rarely spread directly from animals to humans.[62] If untreated pneumonic plague is highly lethal and contagious. *Y. pestis* is less hardy than anthrax and can be rendered non-viable when exposed to high temperatures, sunlight, and drying. Common household disinfectants can kill the bacteria in a few minutes.[58]

Pathophysiology

Similar to anthrax, plague can manifest in many forms. Bubonic plague, the most common naturally occurring type, is a localized infection that results in swollen, painful abscessed lymph nodes (ie, bubo). After inoculation of thousands of organisms from the flea bite, *Y. pestis* then migrates from skin through cutaneous to regional lymph nodes.[58] Some patients bitten by fleas will not develop a bubo, but will present with primary septicemic plague. *Y. pestis* carries a multitude of virulence factors which contribute to this extracellular proliferation, that can ultimately cause bacteremia and inflammation in lymph nodes, liver, and spleen.[63] The resulting complications—sepsis, disseminated intravascular coagulopathy, multi-organ dysfunction, secondary pneumonia, and adult respiratory distress syndrome are associated with dire consequences. Untreated septicemic plague is nearly 100% fatal.[1] The term *black death* describes the classic presentation of gangrene of fingers, toes, and tips of the nose, which may occur during the advanced stages of sepsis. Inhalation plague most likely leads to primary pneumonic plague, which also has a high fatality rate, ranging from 57% (recent outbreaks) to 100% if untreated.[1,34,58]

Clinical Presentation

There are three main forms of plague: bubonic, septicemic, and pneumonic.[64] Bubonic plague presents as a swollen lymph node or nodes in the groin, cervical or axillary region. The buboes or infected lymph nodes are so painful that the patient may limit their limb movement in the affected region and become guarded

during physical exam.[65] As the infection progresses and leads to transient or fulminant bacteremia (septicemic), sequelae may include gastrointestinal symptoms (such as nausea, vomiting, diarrhea, and abdominal pain), abscesses in liver or spleen, generalized lymphadenopathy, and meningitis.[58]

3 One of the most lethal forms, pneumonic plague develops through primary (direct inhalation of infected droplets) or secondary exposure (from bubonic or septicemic plague). Pneumonic plague causes vague symptoms which include: sudden onset of fever, chills, headache, body aches, chest discomfort, and weakness. As pneumonia develops, patients also can present with productive cough, with either watery, frothy, blood-tinged or purulent sputum, shortness of breath, and hypoxia.[34, 64] This severe pneumonia can progress to respiratory failure requiring mechanical ventilation and septic shock has also been noted. A less-common manifestation of inhalation of *Y. pestis* is pharyngitis, as evidenced by swollen tonsils and inflamed lymph nodes.[58]

CLINICAL PRESENTATION Plague Bubonic Plague

- Tender, swollen lymph node in the groin, axilla or cervical regions.

Septicemic Plague

- May present with nausea, vomiting, diarrhea, and abdominal pain.
- Sequelae such as abscesses in liver or spleen, generalized lymphadenopathy, and plague meningitis.

Inhalation Plague

- Sudden onset of fever, chills, headache, body aches, chest discomfort, and weakness.
- Productive cough, shortness of breath, hypoxia, and hemoptysis.
- Watery, frothy, blood-tinged, bloody, or purulent sputum.
- Chest radiograph may show segment or lobar infiltrates or consolidation, which may evolve bilaterally; cavitary lesions, pleurisy, or adult respiratory distress syndrome may be evident.

Laboratory Tests

- Gram stain, culture and sensitivity of lymph node aspirate, blood cultures, sputum aspirate, cerebrospinal fluid, or bronchial/tracheal washings.

Diagnosis of plague can be confirmed by testing bodily fluids or tissue, such as lymph node aspirate, blood cultures, sputum aspirate, cerebrospinal fluid, or bronchial/tracheal washings.[65] While patients in early stages of suspected bubonic plague may have negative blood gram stains, cultures may yield the organism. Serological testing can ultimately confirm diagnosis, but can take weeks. Unfortunately, rapid diagnostic testing, utilizing PCR or direct immunofluorescence testing of fluid or cultures, is not widely available. Additional microbiology work-up for antibiotic susceptibilities is key to tailor antibiotic therapy, especially for high risk patients, like pregnant women and pediatrics.

TREATMENT

Patient risk factors, such as travel history and exposure to rodents or fleas, should be assessed prior to

starting therapy. Suspicion of a bioterrorist event should be raised when an outbreak of severe pneumonia occurs without a common source or prior rodent deaths in the area.[58] Quick preliminary diagnosis and aggressive empiric treatment may help decrease risk of death and spread of this contagious pathogen. Although limited data is available from epidemics occurring prior to the era of antibiotics, time from plague inhalation exposure to death is estimated to be 2 to 4 days, but can occur within 24 hours.[34,58]

Preexposure Prophylaxis

Currently, there is no vaccine available to protect the general public and very little information is available on plague vaccine candidates, most of which are being studied in partnership with the NIAID and the Department of Defense.

Postexposure Prophylaxis

Postexposure prophylaxis is crucial to prevent its spread.[65] Data elucidating which agent is best for prophylaxis is lacking in animals and limited to a few human case reports. While most previously analyzed naturally-occurring strains were susceptible to a variety of antibiotics, multidrug-resistant *Y. pestis* is a major public health concern during natural bacterial evolution (acquiring new resistance genes from other bacteria) and intentionally bioengineered strains.[66] Ciprofloxacin and doxycycline are considered preferred agents (dosing specifics listed in **Table e10-6**). Empiric PEP, for all known or suspected exposures, should be commenced as soon as possible and continued for 7 days or until sensitivities are known. The short duration of the recommended regimen may make a change in therapy unnecessary or impractical. If a person develops a fever and cough a treatment course should commence immediately, due to the high morbidity and mortality with plague.

TABLE e10-6 Empiric Postexposure Prophylaxis Strategies for Plague

	Adults	Pediatrics	Pregnant	Comments
Empiric Oral Antibiotics (Preferred)	Ciprofloxacin 500 mg q 12 h or Doxycycline 100 mg q 12 h	Ciprofloxacin 20 mg/kg PO q 12 h (maximum 1 gm/day) or Doxycycline: <45 kg: 2.2 mg/kg twice daily (max 200 mg/day) ≥45 kg: adult dose	Ciprofloxacin 500 mg q 12 h or Doxycycline 100 mg q 12 h	Duration: 7 days; counsel patient about symptoms of plague infection and have them seek medical care immediately

Data from reference 65.

Suspected or Confirmed Cases

While cultures (eg, blood or sputum) and sensitivity results are pending, empiric treatment should be started immediately in symptomatic patients. Although streptomycin is recommended for treating inhalation plague, most data is with the bubonic form and this drug has limited availability.[34] Gentamicin is considered an acceptable alternative to streptomycin; however, due to its poor abscess penetration, combination with another antimicrobial agent is recommended. Clinicians should monitor renal function

and aminoglycoside concentrations while patients are on therapy. Doxycycline and fluoroquinolones are also considered options, with dosing recommendations similar to those used for anthrax treatment, and patients can be started on IV therapy and switched to oral formulations when they are clinically improving. Chloramphenicol is an option especially if meningitis has developed, yet should be avoided in children who are younger than 2 years of age.[34,65] Recommended treatment duration is 10 to 14 days or 2 days after fever resolves.[65]

EBOLA

The multinational outbreak of Ebola in 2014 to 2015 alarmed global health experts and created a new sense of urgency in the infectious disease community.[67] The epidemic began in Guinea, spread to neighboring countries in West Africa and despite infection control measures, cases occurred in the United Kingdom, Italy, Spain, and the United States. This epidemic is the largest documented, greater than all previous outbreaks combined, and the case fatality rate was estimated to be 70%.[68]

Epidemiology/Etiology

Ebola virus disease, formerly known as Ebola hemorrhagic fever, is an acute, severe, and often fatal syndrome affecting multiple organ systems and is caused by the viruses of the *Ebolavirus* genus. Ebola viruses are non-enveloped, non-segmented, negative-sense, single-stranded RNA part of the *Filoviridae* family. The virus was first identified in 1976 in outbreaks in Zaire and Sudan, and is endemic in West Africa. Five species of Ebola virus have been identified: *Zaire ebolavirus*, *Sudan ebolavirus*, *Tai Forest ebolavirus*, *Bundibungyo ebolavirus* and *Reston ebolavirus* and the *Z. ebolavirus* was responsible for the latest outbreak.[69,70] Ebola virus is a highly contagious zoonotic pathogen transmitted from bats and non-human primates to humans. It is believed that several species of carpophagous (fruit-eating) bats may represent a natural reservoir. Non-human primates (ie, monkeys and apes) and humans can be infected with and transmit the virus.[69] Handling or consuming infected animals (bats and bushmeat) or contact with their feces and saliva (ie, eating fruit blemished by bats) can spread the disease from these natural vectors.[71]

Human-to-human transmission occurs primarily through direct contact with infected bodily fluids. While asymptomatic patients are not contagious, once symptoms occur the virus can be found in blood, urine, vomit, diarrhea, and semen. Ebola virus is not spread through water, or food (excluding bushmeat) and there is no evidence of airborne transmission.[72] The people at highest risk for infection are those in close, direct contact (ie, family and healthcare workers) with sick persons due to their exposure to virus-containing bodily fluids. In the healthcare and laboratory settings, use of improperly sterilized needles, contaminated syringes, and needle stick injuries represent a high risk exposure. As the infection progresses, the viral load in bodily fluids increases, thus the remains of those who succumbed to the disease are highly contagious.[69,72]

Pathophysiology

Ebola virus enters the human body by direct contact with breaks in skin surfaces, mucosal surfaces, or by parenteral transmission. The route of transmission affects the incubation period and patient outcome; with a shortened time and increased severity after parenteral transmission compared to contact exposures.[70] Upon inoculation, the virus replicates rapidly and infects numerous cell types and organ systems resulting

in apoptosis, tissue damage and necrosis. Ebola virus also triggers release of cytokines and inflammatory mediators causing subsequent vascular leak and a systemic inflammatory response. The insult to various cell types and organs, coupled with the inflammatory response causes a wide array of effects such as gastrointestinal dysfunction, hepatic injury, coagulation defects, immunosuppression, hypotension resulting in multi-organ failure, and shock.[73,74] The mortality rate is approximately 50%, with values ranging from a low of 25 up to 90%.[29]

Clinical Presentation

After an incubation period of 4 to 10 days (range 2-21 days), illness begins with an abrupt onset of flu-like symptoms: fever, chills, headache, malaise, and myalgia as well as nonspecific symptoms such as vomiting, diarrhea, and abdominal pain. A maculopapular rash can appear by day 5 to 7 of the infection.[70,74] The disease rapidly progresses and multiple organs are affected. Symptoms are severe and prolonged with reports describing more than 8 to 10 liters of stool and other bodily fluid losses over 24 hours, intractable nausea and vomiting that precludes oral hydration, significant weight loss, and high fever lasting more than 2 weeks.[75] Secondary bacterial infections can also occur from gut translocation.[76] Gastrointestinal manifestations lead to severe electrolyte imbalances, and with the progression of the infection patients ultimately may die of hypovolemic shock and multi-organ failure 6 to 16 days after onset of symptoms.[74] Although Ebola virus is classified as a viral hemorrhagic fever, major bleeding is not a defining symptom. In early outbreaks, severe bleeding diathesis occurred in less than half of the cases, at the peak of the illness and presented as petechiae, ecchymoses, oozing from venipuncture sites, mucosal hemorrhaging, and blood in the stool.[81] In the 2014 to 2015 outbreak, bleeding was documented in less than 20% of the cases.[78] Thus, the term EVD is now used rather than Ebola hemorrhagic fever to refer to the clinical syndrome.

Epidemiologic data from the outbreak of 2014 to 2015 revealed gender-specific differences in the clinical characteristics of EVD. Despite similar risk factors, a larger proportion of females were infected. Compared to males, females presented with symptoms earlier but had a significantly higher survival rate.[77] Predictors of mortality include early onset of severe symptoms, age greater than 45 years, unexplained bleeding, and an initial high viral load (greater than 10 million viral copies/mL [10×10^9/L]).[74,78] Patients who recover tend to begin to improve around day 6 as they develop an antibody response.

Recovery is a prolonged process and characterized by weakness, fatigue, asthenia, arthralgias, and failure to thrive. Viral persistence in various bodily fluids for months has been reported, with one study documenting the presence of Ebola virus RNA in semen up to 9 months after infection.[79] Long-term complications include hepatitis, myelitis, psychosis, uveitis, hearing loss, and tinnitus.[70,80]

Laboratory findings are usually nonspecific. In general, patients develop lymphopenia, neutrophilia, thrombocytopenia and increased liver enzymes with aspartate aminotransferase exceeding alanine aminotransferase. Significant electrolyte imbalances including hypokalemia, hyponatremia, hypocalcemia, and hypomagnesemia develop secondary to gastrointestinal losses. With disease progression, hyperamylasemia, and elevations in creatinine and blood urea nitrogen occur. Increased prothrombin time, activated partial thromboplastin time, and fibrin degradation products can also develop suggesting diffuse intravascular coagulation.[74]

Diagnosis of EVD is confirmed by detection of viral antigens or viral RNA from blood and other bodily

secretions using molecular techniques.[70] Reverse-transcriptase-polymerase-chain reaction (RT-PCR) assays are the most common detection method. They can be used remotely and provide results within 4 hours. RT-PCR is effective only after the onset of symptoms and it may take up to 3 days after the onset for viral loads to reach detectable levels.[82] For samples collected prior to this timeframe, testing should be repeated in 48 hours after a negative result.[80] Enzyme-linked immunosorbent assay (ELISA) can also be used to detect viral antigens and antibodies. Samples should be processed by national and international reference centers with high level of biosafety precautions.[80,81]

CLINICAL PRESENTATION Ebola Virus Disease General

- Acute onset of flu-like symptoms accompanied by nonspecific gastrointestinal symptoms.

Signs and Symptoms

- Initially an abrupt onset of fever, headache, fatigue, myalgia, weakness, anorexia, abdominal pain, diarrhea, and vomiting.
- Profound dehydration from significant gastrointestinal losses and intractable nausea vomiting.
- Maculopapular rash and unexplained hemorrhaging can occur as infection progresses.

Laboratory Tests

- Nonspecific, but in general include lymphopenia, neutrophilia, thrombocytopenia with increased liver enzymes with aspartate aminotransferase greater than alanine aminotransferase.
- Significant electrolyte losses: hypokalemia, hyponatremia, hypocalcemia, and hypomagnesemia.
- As infection progresses, hyperamylasemia, increased serum creatinine and blood urea nitrogen, and evidence of disseminated intravascular coagulation may be found (ie, prolonged bleeding time, elevated fibrin degradation products, and decreased fibrinogen).
- Reverse-transcriptase-polymerase-chain reaction, or Enzyme-linked immunosorbent assay tests to identify the virus can be performed at specialized laboratories with high level of biosafety precautions.

During the outbreak in West Africa of 2014 to 2015, it was recommended to screen all patients prior to entering healthcare facilities.[83,84] Patients manifesting with symptoms are further assessed for their risk of exposure to the virus: contact with an infected person with confirmed EVD within 21 days of the onset of infection, or travel to an endemic area (ie, West Africa). Asymptomatic individuals exposed to the virus should be monitored daily for 21 days from the last exposure for a fever greater than 38^{o}C (greater than 100.4^{o}F) and signs and symptoms of EVD. If there is a high degree of suspicion or signs and symptoms consistent with EVD, public health authorities should be immediately notified and medical evaluation and treatment begun while adopting the appropriate infection control precautions.[85] If a fever develops within the 21-day monitoring period, isolation and medical evaluation is begun, and evaluation for other fever-inducing pathogens should begin. During the influenza season, CDC recommends administration of influenza vaccine at the first contact of the monitoring period if the individual has not been previously vaccinated, while chemoprophylaxis (ie, oseltamivir) is recommended for those individuals who have been exposed to the influenza virus.[86]

While assessing a patient for EVD, it is important to consider alternative and concurrent conditions that may present in the same way. The differential diagnosis depends upon their symptoms, travel history, personal contacts, immunization status and comorbid conditions. In travelers from or residents of Africa, malaria is the most common febrile illness and should be ruled out before beginning a course of therapy.[87] Lassa fever (a viral hemorrhagic fever), dengue, and typhoid fever are also endemic in Africa. Other infectious causes to be considered include meningococcemia, pneumonia, and influenza.[74,82,86]

TREATMENT

4 Management of EVD is based on two main principles: rapid initiation of supportive care and infection control procedures. The desired outcome of patient care is to halt the natural course of the virus by preventing hypovolemic shock, while infection control procedures are focused on interrupting transmission. Ideally, patients should be treated at designated treatment facilities where personnel are properly trained and strict infection control procedures are in place. The spread of Ebola to two medical workers in a US hospital caring for an infected patient may have resulted from inadequate training and use of PPE.[88] The use of standard contact and droplet precautions is recommended.[89] Staff, laboratory personnel processing specimens, and clinicians must be using PPE (**Fig. e10-2**) that covers all exposed skin. Recommended PPE includes the use of double gloves, impermeable gown and apron, surgical mask, and eye protection. The use of shoe and leg coverings is recommended when copious secretions are produced. When aerosol generating procedures are to be done (ie, intubation), N95 masks are recommended and the patient should be placed in a negative pressure room. Non-disposable instruments and all objects which have been in contact with the patient or patient's bodily fluids need to be disinfected with cleaners that have high potency against enveloped viruses, such as 0.5% hypochlorite solution or 0.5% phenol.[90] Contaminated waste must be sealed and disposed of promptly and properly, utilizing autoclaves or incineration.[89,91] Standardized infection control processes and the use of dedicated and trained personnel to monitor and assure the proper use of PPE is recommended.

Preexposure Prophylaxis

Several vaccine candidates are in various phases of development and two vaccines are undergoing Phase 3 trials (**Table e10-7**). Chimpanzee adenovirus serotype 3-Ebola virus vaccine (ChAd3-EBOV) is a recombinant chimpanzee adenovirus serotype 3 that encodes for the surface glycoprotein of Ebola virus.[92] Two forms of the vaccine are being tested, a monovalent form based on *Z. ebolavirus* and a bivalent one that also includes *S. ebolavirus*.[93] Preliminary results of the monovalent ChAd3-EBOV *Z. ebolavirus* trial conducted in West Africa demonstrated that a single dose elicited an immunogenic response. A subset of participants received a second vaccine dose of a modified form as a booster which conferred high-level and long-term protection. Results from this trial identified the dose of vaccine to interrupt transmission and feasibility of using a boosted regimen for long-term protection that could be used by health care providers during an outbreak. At this time, further resources for studies of Ebola vaccines have shifted from ChAd3-EBOV to vesicular stomatitis virus-Ebola virus vaccine (VSV-EBOV).[94]

TABLE e10-7 Experimental Therapies in Clinical Development for Ebola Virus

Medication	Class/Mechanism of Action	Development Status	Route/Dosing	Experience With Ebola Virus	Other Information
ZMapp	Monoclonal antibody, combination of 3 antibodies Targets virus surface glycoprotein Neutralizes virus	Phase 1	IV Human dosing unknown	Used in 7 patients (including healthcare workers) during outbreak of 2014-2015, 5 patients survived	Derived from tobacco plant Current supplies depleted Requires frozen storage
TKM-Ebola	Small interfering RNA Fragments of RNA, inhibits viral messenger RNA and viral replication	Phase 1	IV 2.4 mg/kg/dose	Trials on hold due to fever/cytokine release Given to small number of patients under emergency use protocols use in Guinea	Available under compassionate use protocols Given fast track approval by FDA
Convalescent plasma and whole blood	Blood product: whole blood or plasma Transfusion containing Ebola-neutralizing antibodies from patients recovered from EVD Provides passive immunity	Phase 2, 3	IV	Used in previous outbreaks since 1977 In outbreak in 1995, 7 of 8 patients survived. In outbreak of 2014-2015, no improvement in survival in transfusion group Use approved by WHO	Studied in children and pregnant women Benefit in early stages of infection Level of antibodies in transfusion may influence response Proper collection, handling, and screening of blood for pathogens is required Blood types must match between donor and recipient
Brincidofovir (CMX-001)	Antiviral nucleotide analogue Inhibits DNA	Phase 2 trials for Ebola Phase 3 for	PO 200 mg once then 100 mg	Trials for Ebola withdrawn due to end of	Available under compassionate use protocols

Medication	Class/Mechanism of Action	Development Status	Route/Dosing	Experience With Ebola Virus	Other Information
	synthesis by incorporation into DNA chain	cytomegalovirus, adenovirus	twice weekly for 2 weeks	epidemic	Active against DNA viruses
Favipiravir (T-705)	Antiviral nucleoside analog Inhibits viral RNA-dependent polymerase causing mutagenesis	Phase 2 for Ebola Phase 3 for influenza	PO 6,000 mg on day 1, then then 1,200 mg BID for 9 days	Decreased mortality when used in early stages of EVD Used successfully in 1 nurse during outbreak of 2014-2015	Contraindicated in pregnancy Well established safety profile Activity against many RNA viruses Approved in Japan for treatment of influenza
AVI-6002	Antisense phosphorodiamidate morpholino oligomers, combination of AVI-7537 and AVI-7539 Target sequences of viral messenger RNA	Phase 1	IV Human dosing unknown	Evaluated for postexposure prophylaxis Phase 1 trial complete	Safe and well-tolerated
ChAd3-Ebola	Vaccine Three forms: monovalent *Zaire ebolavirus*, bivalent *Zaire ebolavirus* and *Sudan ebolavirus*, boosted monovalent *Zaire ebolavirus* Recombinant adenovirus encodes for surface glycoprotein of the Ebola virus Stimulates immune response to Ebola glycoprotein	Phase 2, 3	IM Single dose	Phase 1 trials demonstrated safety and immunogenicity Funding for Phase 2, 3 trials moved to studies of rVSV-Ebola	Requires frozen storage

Medication	Class/Mechanism of Action	Development Status	Route/Dosing	Experience With Ebola Virus	Other Information
rVSV- Ebola	Vaccine Virus vector encoding for Ebola virus surface glycoprotein Stimulates immune response to Ebola glycoprotein	Phase 3	IM Single dose	100% efficacy in large trial during outbreak of 2014-2015. Trial stopped early to allow early access to vaccine Possible role for postexposure prophylaxis during epidemic, or accidental exposures	Requires frozen storage Concerns for use in immunocompromized patients

Data from references 73, 92, 93, 94, 95, 96, 100, 101, 102, 103, 104, 105, 106, 107, 108.

Vesicular stomatitis virus-Ebola virus vaccine is a recombinant vesicular stomatitis virus (rVSV) vector encoding for Ebola virus surface glycoprotein.[92] Interim results from a Phase 3 trial conducted in Guinea during the outbreak of 2014 to 2015 demonstrated 100% efficacy (95% CI, 74.7%-100%) in more than 4,000 adults when the vaccine was administered within 21 days of contact with an infected case.[95] The method used in this trial was ring vaccination; identifying newly infected cases and administering vaccine to their contacts and contacts of contacts to surround the infected person with a ring of immunization. The trial stopped randomization early to allow those at risk for EVD to be able to receive the vaccine immediately.[96] A ring vaccination strategy with highly effective vaccine could protect health care providers and prevent the spread of EVD during outbreaks.

Postexposure Prophylaxis

There are no approved vaccines or treatment agents for postexposure prophylaxis of EVD. A published case report showed that a single dose of VSV-EBOV protected a physician after a high-risk needle stick. The vaccine was administered 43 hours after the exposure and resulted in a strong innate Ebola virus-specific adaptive immune response without evidence of EVD.[97] Additionally, based on the efficacy results of immediate VSV-EBOV administration to contacts as described above, vaccines may have a future role in postexposure prophylaxis.[96]

Suspected or Confirmed Cases

The mainstay of treatment is intensive supportive care, coupled with symptomatic management, since there is currently no commercially available targeted pharmacological therapy to reduce the high mortality rate associated with EVD.[98] Supportive care with aggressive fluid and electrolyte replacement is needed

due to large amounts of bodily fluid loss. Oral or intravenous routes can be used and the choice depends on the severity of illness, availability of intravenous fluids, and patient ability to tolerate the enteral route. Antiemetics and antimotility agents are recommended to alleviate vomiting and diarrhea and to facilitate hydration (see Chapters 35 and 36). The first line treatment for fever and pain is acetaminophen; nonsteroidal anti-inflammatory drugs and aspirin are not recommended due to their nephrotoxic potential and increased risk of bleeding as the result of their antiplatelet properties. Other supportive measures such as blood transfusions, inotropic support (see Chapters 23 and 24), respiratory support, and renal replacement therapy (see Chapter 43 and 45) may be needed based on the patient's clinical presentation.[82] For sepsis and possible concomitant infection from gut translocation, empiric broad spectrum antibiotics with coverage of gram negative organisms should be initiated.[75]

Currently, there are no approved medications for treatment of EVD. The antiviral ribavirin, which has some activity against other viral hemorrhagic fevers including viruses in the *Filoviridae* family, does not have an effect on Ebola viruses.[73] Several experimental therapies are under development and drugs developed for other purposes are being evaluated as potential EVD therapies. To date, investigational treatments include the use of monoclonal antibodies, convalescent therapies, antivirals, small interfering RNA's, and vaccines. Due to the severity of the Ebola outbreak of 2014 to 2015, WHO declared that the use of experimental drugs for treatment and prevention of EVD is ethical[99] (see Table e10-7).

Favipiravir (T-705) is an oral antiviral nucleoside analogue active against a wide range of RNA viruses. It is approved in Japan for the treatment of influenza and is undergoing Phase 3 studies in the US. Favipiravir inhibits viral RNA-dependent RNA polymerase.[92] Studies also suggest that it works by inducing viral mutations resulting in decreased infectivity and replication.[73] Preliminary results from a Phase 2 study of high dose favipiravir in Guinea demonstrated that it is not effective in the advanced stages of infection. However, the overall mortality rate decreased from 58% to 30% (p=0.05) for patients with moderate to low baseline viral loads as measured by RT-PCR, suggesting that high dose favipiravir may be effective in the earlier stages of EVD.[100] Convalescent therapies, transfusions of whole blood have been used for the treatment of EVD since 1976, and sporadically during various epidemics in a small number of patients. During the outbreak of 2014 to 2015 in Guinea, the Ebola-Tx trial evaluated use of convalescent plasma in patients with confirmed EVD and results were compared to historical controls. Use of convalescent plasma did not significantly improve survival in the 84 treated patients, but was found to be safe. The level of antibodies in the transfusions was unknown, thus it is theorized that plasma containing higher levels of neutralizing antibodies or increased number of transfusions may provide a benefit.[101] WHO approved the use of convalescent plasma for the treatment of patients with EVD and issued guidelines for the collection and administration of these therapies.[102,103] Many resources are required to meet the recommendations from the WHO for the safe use of convalescent therapies for the treatment of EVD.[73,103] It is currently undergoing Phase 2 and 3 clinical trials.[104]

EMERGING BIOLOGICAL AGENTS

Newly identified biological agents, such as MERS, and historic pathogens, like pertussis and measles, are associated with significant human morbidity and mortality and taxing public health response efforts in many countries. A recent epidemiological modelling study demonstrated that the pertussis resurgence may be due to both a lower efficacy rate and shorter duration of protection of the current vaccine.[109] Measles outbreaks have been blamed on an unfounded link between autism and measles, mumps and rubella

(MMR) vaccine and, subsequent low vaccination rates in some regions.[110]

MEASLES

Although the presence of measles in the United States has been minimal since the 1980s due to the initiation of widespread childhood vaccination efforts this infection remains one of the leading causes of death of young children worldwide. Globally 20 million people contract measles each year.[111]

Epidemiology/Etiology

5 While measles has not been utilized for bioterrorist purposes, unintentional measles infections are still responsible for 146,000 deaths annually.[111] The measles virus is transmitted through airborne particles from sneezes or coughs and through direct contact. Although measles is a human disease and is not known to occur in animals the measles virus can remain alive outside of a human host for up to two hours, contributing to its highly infectious nature.[112] Prior to worldwide measles vaccination efforts in 1980, 2.6 million people died annually from measles.[113] The major decline in measles-related deaths illustrates the effectiveness of the major global vaccination efforts. However, vigilance is still critical since outbreaks occur when unimmunized travelers visit countries where measles is still prevalent and in communities where vaccination rates are less than ideal.

Pathophysiology

Measles is a highly contagious respiratory illness caused by a single-stranded, enveloped RNA virus from the paramyxoviridae family, genus Morbillivirus.[110] The measles virus has two envelope proteins: the F protein, is necessary for the fusion of the virus to the host cell membranes and the H or hemagglutinin protein, is necessary for adsorption of virus to cells.[110] Measles is extremely contagious and approximately 9 out of 10 susceptible persons with close contact to someone who has measles will develop measles. The virus, transmitted by direct contact with infectious droplets spread when an infected person breathes, coughs, or sneezes, infects the respiratory epithelium of the nasopharynx. Two to three days after the initial infection primary viremia occurs infecting the reticuloendothelial system. Nearly one week after the initial infection secondary viremia occurs, spreading the virus to other organs, which can result in pneumonia, encephalitis, and other complications.[110]

Clinical Presentation

The prodrome lasts 2 to 4 days and commonly includes a fever, which may reach 105°F, cough, coryza, conjunctivitis, and Koplik spots, or small blue-white spots which appear on the buccal mucosa.[110] While measles has an incubation period from 7 to 21 days, the maculopapular rash (**Fig. e10-3**) commonly associated with measles usually begins to appear at the hairline 14 days after initial exposure and spreads from the head downward and outward to the extremities. The rash usually lasts 5 to 6 days and resolves in reverse order from appearance, from the extremities toward head.[110] Measles complications include otitis media that can result in permanent hearing loss, conjunctivitis that can result in blindness, as well as diarrhea, dehydration, and encephalitis. Cases are more severe and complications more likely in patients with vitamin A deficiency.[110] One in 20 children who contract measles develop pneumonia, which is the leading cause of measles-related death.[113]

FIGURE e10-3

Measles rash. (Courtesy of the CDC and Jim Goodson. This baby was hospitalized in early 2014 in the Philippines capital city of Manila with measles (rubeola) and a maculopapular rash, one of the hallmark symptoms of this disease. (Source: CDC Public Health Image Library. Photo taken in 2014. *http://phil.cdc.gov/phil/home.asp*. Last accessed, September 2, 2015.) PHIL: **19434**)

Specimens for virus culture can be collected from urine, nasopharyngeal aspirates, heparinized blood, or throat swabs. Ideally, clinical specimens should be collected within 3 days of rash appearance to increase the likelihood of isolating the virus. Specimens should be obtained from every person clinically suspected to have been infected with measles and sent to the state public health laboratory.[110] Serologic testing for IgM via enzyme-linked immunoassay (EIA) requires a single serum sample and is considered diagnostic for measles infection if positive.

TREATMENT

Risk factors, such as recent travel or close contact with a suspected or confirmed measles patient, and vaccination status should be assessed for all patients with potential exposure since measles is highly communicable. Measles may be transmitted from 4 days before to 4 days after rash onset with the maximum communicability occurring from onset of prodrome through the first 3 to 4 days of the rash.[111]

Preexposure Prophylaxis

The measles vaccine is one of medical sciences greatest success stories in recent history. Prior to the approval of the live measles vaccine in 1963, approximately 549,000 cases of measles, 48,000 measles-related hospitalizations, 1,000 cases of chronic disability due to measles-related acute encephalitis, and 495 measles-related deaths occurred annually in the United States alone.[111] In 1978 the CDC set a goal to eliminate measles in the United States. Disease elimination, defined as the absence of endemic measles virus transmission in a defined geographic area for 12 months or longer in the presence of a

well-performing surveillance system, however was not achieved until 2000.[113] Since 2000, the number of reported cases in the US has ranged from a low of 37 in 2004 to a high of 668 in 2014, with the majority of cases in people who were not vaccinated against measles.[111] From 2000 to 2013 measles vaccination was estimated to have prevented 15.6 million deaths worldwide.

The measles vaccine is highly effective and is comprised of a two-dose series. Usually the first dose is given at age 12 to 15 months and the second when the child is 4 to 6 years old; although the second dose can be administered sooner as long as it is given at least 28 days after the first dose. One dose of vaccine is 93% effective at preventing measles and two doses are 97% effective.[111]

Additional benefits of preventing measles infections through vaccination have recently come to light. After measles infection a patient may experience a transient immunosuppression, which increases the patient's risk of contracting other illnesses for several weeks to months.[114] Decreasing measles infections, therefore, may be beneficial to decreasing the rates of other infectious diseases. Another benefit to early childhood measles vaccination may be a reduction in development of asthma and allergies. A recent study demonstrated that children who were vaccinated with the MMR vaccine in early childhood showed a two-third reduction in the odds of asthma and hypersensitivity or allergy at age 5 and substantially decreased odds of asthma at age 13.[115]

Postexposure Prophylaxis

If exposure is suspected, providing the measles vaccine within 72 hours of exposure may prevent emergence of the disease. Immune globulin administered within 6 days postexposure can also provide protection and decrease the severity of the disease. The recommended dose of immune globulin is 80 mg IgG per kg of body weight given intramuscularly or IV immune globulin at 400 mg per kg of body weight.[111]

Suspected or Confirmed Cases

Currently, the most effective measles care plan available is quick identification of those infected with the virus, utilization of the measles vaccine, and immune globulin postexposure if appropriate, and provision of supportive care to correct vitamin A deficiency and prevent complications. There is a well-established link between poor nutrition and certain vitamin deficiencies and worse infectious diseases outcomes. In 1932 an association between vitamin A treatment and beneficial outcomes for severe measles cases was first reported. Then in 1990 researchers found that children, admitted to a regional medical center with measles and treated with vitamin A, more quickly recovered from pneumonia and diarrhea, were discharged sooner, and had less complications (ie, croup) and death, compared to those who received a placebo.[116] In developing countries or in areas such as southeast Asia and sub-Saharan Africa with known vitamin A deficiency, the WHO recommends those who have been diagnosed with measles receive vitamin A: 200,000 IU for children or 100,000 IU for infants for two days.[113] Other severe complications can be avoided by supportive care including hydration, good nutrition, and treatment of symptoms. Antibiotics can be given, as needed, to treat secondary ear, eye or lower respiratory tract infections.[111]

CLINICAL PRESENTATION Measles General

- Maculopapular rash beginning 14 days after initial exposure and lasting for 5 to 6 days.

Signs and Symptoms

- Fever, cough, coryza, and conjunctivitis.
- Koplik spots, small blue-white spots which appear on the buccal mucosa.
- Complications including otitis media, diarrhea, dehydration, and encephalitis.

Laboratory Tests

- Specimens for viral culture collected from urine, nasopharyngeal aspirates, heparinized blood, or throat swab.
- Serologic testing for IgM via EIA.

There is no FDA-approved antiviral therapy currently available for the treatment of measles. However, there is a promising new investigational pan-morbillivirus inhibitor, ERDRP-0519, which has shown effectiveness in treating ferrets infected with Canine Distemper Virus (CDV), a morbillivirus, similar to measles.[117] In the study ferrets treated prophylactically with ERDRP-0519 and then infected with CDV showed reduced viremia and prolonged survival. Ferrets receiving postinfection ERDRP-0519 treatment at the onset of viremia remained asymptomatic and recovered from infection. Animals who recovered from CVD were also protected against rechallenge with a lethal CVD dose.[117]

Clinical Controversy…

Experts predicted that the uptick in measles cases during the recent Disneyland outbreak in California was due to low vaccinations rates.[118] Researchers then estimated that in areas where secondary cases occurred, MMR vaccination rates ranged from as low as 50% to no greater than 86%. Unfortunately, herd immunity, indirect protection from a pathogen in a population where a high portion of members have immunity, is best achieved with rates ranging from 96% to 99%.[118] This study did not explain why vaccination rates were so low and if this was related to intentional refusal, lack of access to vaccination, or other reasons. Many assume the low rates are due to the unfounded link between autism and MMR vaccine. However, ongoing epidemiologic research and efforts to improve vaccination rates are needed.

MIDDLE EASTERN RESPIRATORY SYNDROME

6 Middle Eastern Respiratory Syndrome or MERS is a viral respiratory illness which can cause severe respiratory distress and has been fatal in 36% of all patients who have contracted the disease.[119] An emerging public health threat, the first known case of MERS was documented in 2012 in a patient residing in Saudi Arabia.[120] A recent outbreak of MERS in South Korea in 2015 was linked to a single traveler returning from the Arabian Peninsula.[121] During that outbreak, a total of 186 people were infected and 36 people died.

Epidemiology/Etiology

Middle Eastern Respiratory Syndrome is caused by a coronavirus (MERS-CoV) and is distinct from other coronaviruses, a virus family which also includes Severe Acute Respiratory Syndrome (SARS) and the

common cold. Coronaviruses have the ability to adapt to new environments, become more transmissible, gain virulence due to high mutation, and recombination rates.[121] These characteristics combined with the unknowns of MERS-CoV highlights the need for public health preparedness for this emerging infection. As the name implies, the majority of MERS cases have been reported from countries of the Middle East with 85% of known cases reported from Saudi Arabia.[122] MERS cases have also been reported from the United States, Europe, and the Philippines, but all can be linked back to the Arabian Peninsula.[121] Like the SARS virus, MERS-CoV was introduced into humans through zoonotic hosts. Bats are thought to be the species of origin and dromedary camels are believed to be intermediate hosts.[120] While the exact mode of camel-to-human transmission has not been confirmed, cases of MERS have been reported in people who have consumed camel milk.[120] Human-to-human transmission occurs through either direct contact with droplets produced during coughing or sneezing or contact with contaminated surfaces or devices.[122]

Pathophysiology

Middle Eastern Respiratory Syndrome-coronavirus is a positive-sense, enveloped, single-stranded RNA virus which is transmitted from host to host via respiratory secretions.[123] Initially, like infections with influenza A H5N1 and SARS viruses, a cytokine storm, or a massive release of cytokines as a proinflammatory and immunological reaction, was believed to lead to the cascade of complications and death associated with this virus.[124] However, lethality from this virus is not well understood. There are currently no published autopsy reports describing the pathological changes in the lungs in fatal cases of MERS. X-rays and clinical data from patients with severe cases of MERS reveal pneumonia with diffuse alveolar damage.[125] MERS-CoV binds to DPP4 receptors on target cells, including rabbit, bat, and human cells, and releases viral genetic material via membrane fusion like HIV and SARS-CoV. The exact mechanism of entry after receptor binding is still unknown.[120] New RNA and viral proteins are assembled into infectious virions and released out of host cell via vesicles and exocytosis.[124]

Clinical Presentation

The incubation period for MERS-CoV ranges from 2 to 14 days, but typically is 5 to 6 days.[119] The signs and symptoms associated with MERS include severe acute respiratory symptoms: fever, shortness of breath, malaise, myalgia, sore throat, headache, rhinorrhea, and coughing.[123] Patients also may experience gastrointestinal symptoms such as diarrhea, nausea, and vomiting. Fortunately, there are several available lab tests that can detect MERS-CoV. Immunofluorescence assays, both conventional and rapid, as well as ELISA are commercially available.[123] Western blot may be analyzed in the serological diagnosis of MERS-CoV, but caution should be used since MERS may cross-react with other coronaviruses such as SARS.[123] MERS is more deadly than SARS and is who died of MERS had a preexisting medical condition and developed severe complications including pneumonia and kidney failure.[119] The majority of patients develop dyspnea and 70% require admission to an Intensive Care Unit.[123]

CLINICAL PRESENTATION Middle Eastern Respiratory Syndrome (MERS) General

- Severe acute respiratory illness.

Signs and Symptoms

- Fever, dyspnea, malaise, and myalgia.
- Sore throat, rhinorrhea, and coughing.
- May cause diarrhea, nausea, and vomiting.

Laboratory Tests

- Conventional and rapid ELISA to detect MERS-CoV antibodies.

TREATMENT

While there are no specific guidelines for the treatment of MERS, current best practices for clinical management include preventing the spread of infection to others and minimizing disease complications.[119] Supportive care to alleviate symptoms remains the cornerstone of treatment. For severe cases the goal of treatment is to maintain organ function and prevent additional complications from developing.

Preexposure Prophylaxis

Travelers to the Middle East are encouraged to take precautions such as avoiding close contact with people exhibiting symptoms of acute respiratory illness, utilize personal hygiene measures such as hand washing and cough and sneeze etiquette, and avoiding unsafe water, undercooked meats, and consumption of raw fruits or vegetables.[126] To date there is no vaccine available for preventing MERS. Safety concerns with SARS virus vaccines will most likely be revisited with MERS virus candidates.[124] However, recent success with DNA expression vectors and soluble protein immunogens in mice look promising.[127]

Postexposure Prophylaxis

As of July 2015 public health officials in Canada are recommending that patients presenting to an emergency department with acute respiratory infection be asked if they have traveled to the Arabian Peninsula or been in a healthcare facility in the Republic of Korea in the past 14 days.[128] Travelers to the Arabian Peninsula should also be educated to identify the severe respiratory symptoms of MERS and to practice hand hygiene after any contact with camels.[119,129] Diagnosis of MERS can be challenging since the initial presenting symptoms are similar to other acute respiratory infections. Early identification of the disease is also key to prevent spreading the MERS-CoV to others. Healthcare facilities handling samples from patients with suspected or confirmed cases of MERS should take preventative measures to decrease the risk of transmission of the virus to other patients or healthcare providers.

Suspected and Confirmed Cases

While there is no specific antiviral treatment currently available for the treatment of MERS there are multiple experimental treatments in development including: anti-CD26 monoclonal antibodies, which could theoretically neutralize the virus; and human MicroRNAs, that might be useful as antiviral therapy.[123] Multiple trials have utilized currently available antiviral agents without evidence of success.[130] Ribavirin and interferon alpha-2B showed efficacy in rhesus macaques monkeys infected with MERS; yet when used as treatment for 5 patients who had multiple medical conditions prior contracting MERS these therapies did not prevent death.[131] Future anti-MERS treatments may target the initial fusion step, which occurs during

viral replication.[124]

ECMO or extracorporeal membrane oxygenation may be necessary to manage the ensuing severe pneumonia and respiratory failure.[124] Empiric antimicrobial therapy covering community acquired bacterial pathogens, based on local epidemiologic information, may be appropriate.[121] Steroids, which are sometimes used in patients with severe, inflammatory respiratory infections are not recommended for viral pneumonias due to coronaviruses like MERS.[130,132] Data about risks and benefits of steroid use in MERS patients has been extrapolated from SARS; the results show no mortality benefit and concerning short and long-term adverse effects.[130]

Convalescent therapy, using blood or plasma from patients who have recovered from the disease, may have a role for the treatment and prevention of MERS and was deemed by WHO and United Kingdom as a promising approach.[130,133] Plasma from individuals recently recovered from MERS contain high titers of viral antibodies. A clinical trial is in progress to evaluate the pharmacokinetics of immune response to 2 units of convalescent plasma to determine its safety and efficacy.[134]

PERTUSSIS

Prior to the development and administration of the pertussis vaccine there were between 100,000 and 250,000 cases of pertussis or "whooping cough" in the US each year.[135] A record low was reached in 1976 with barely 1,000 reported cases. Since the early 1980s a there has been a near doubling of cases every eight years.[135] This contagious, human bacterium is now considered a reemerging pathogen; and recent outbreaks have demonstrated it remains a serious public health issue in adults and at risk infants.

Epidemiology/Etiology

The causative agent of pertussis or "whooping cough" is *Bordetella pertussis;* a small, aerobic gram-negative rod.[136] Pertussis has been a killer of children, adults, and elderly for centuries. It is a highly contagious respiratory disease which can cause long, violent coughing fits and a "whooping" sound as those affected gasp for air.[137] Several recent epidemics of pertussis remind us that, although vaccination is available, epidemics are still possible. In 2014 the incidence of pertussis was more than five times greater than the baseline statewide incidence and reached 26 cases per 100,000 people.[138] In Washington a 2012 pertussis epidemic left the state reeling; the statewide incidence reached a staggering 37.5 cases per 100,000 (a 1,300% increase from 2011).[139] Improved diagnostics and increased awareness (leading to higher numbers of reported cases), decreased vaccination coverage and suboptimal vaccines, waning vaccine-induced immunity, and pathogen adaptation are believed to contribute to the reemergence of pertussis.[140]

Pathophysiology

Pertussis is a highly contagious respiratory disease transmitted directly from human to human via aerosolized respiratory droplets.[141] The bacteria attaches to the cilia of respiratory cells, which leads to inflammation and subsequent interference with the clearing of pulmonary secretions.[136] In addition, *B. pertussis* can produce many virulence factors, including toxins.[141] More virulent Pertussis strains from 1981 to 1992 through 1993 to 2004 which produce greater levels of toxin were associated with an increase in

hospitalizations, deaths, and lethality (number of deaths in hospitalized patients).[140] Another recent discovery was the appearance of pertactin-negative pertussis strains.[142] Pertactin, a protein which aids the bacterial attachment to the lining of the airways, is a key component of acellular vaccines.[142] One key public health concern was that the vaccine was creating selective pressure for the evolution of pertactin-negative strains. However, since pertactin is considered a virulence factor, it was assumed that patients infected with these strains may have less severe complications than those infected with pertactin-positive strains. Unfortunately, that projected upside has not been observed clinically.[143] Additional research is needed to examine the upsurge in virulence factors, their impact on outbreaks, and how we can prevent worsening morbidity and mortality related to these new strains.

CLINICAL PRESENTATION Pertussis General

- Nonproductive cough lasting 1 to 2 weeks, with or without a fever.

Signs and Symptoms

- Catarrhal Stage: sneezing, low-grade fever, runny nose, and occasional cough.
- Paroxysmal Stage: paroxysms or bursts of rapid, numerous coughs.
- Cough associated with high-pitched “whoop” due to long respiratory effort.
- Severe coughing episodes may cause vomiting, exhaustion, seizures, encephalopathy, and hernias.

Laboratory Tests

- Isolation of *B. pertussis* from nasopharyngeal swab or aspirate culture.

Clinical Presentation

Outbreaks of pertussis are difficult to identify and manage. Similar symptoms can be seen with numerous bacterial and viral illnesses making it difficult to diagnose.[144] Unfortunately, pertussis shares similar symptoms to the common cold; a non-productive cough lasting one to two weeks, with or without a fever. Differential diagnosis is often based on immunization status, community area trends (ie, exemptions for religious reasons), and income status (ie, low-income areas have lower immunization rates and access to health care).[145,146] The incubation period for pertussis is usually 5 to 10 days, but can be as long as 21 days.[147] The first stage is referred to as the catarrhal stage which lasts 1 to 2 weeks. Symptoms at this stage include sneezing, low-grade fever, runny nose, and an occasional cough.[136,148] This is the time period where healthcare providers, caregivers, and infants or neonates exposed to the patient are most vulnerable to acquire infection. The second stage is called the paroxysmal stage which lasts approximately 1 to 6 weeks. At this point, persons may have bursts or “paroxysms” of rapid, numerous coughs as they try to eliminate the thick mucus gathering in their tracheobronchial tree. At the end of a coughing episode, it is common to have a long respiratory effort that is associated with the high-pitched “whoop.”[136] It is common for this “coughing episode” to end in vomiting, exhaustion and in extreme circumstances, seizures, encephalopathy, and hernias.[136] However, before and after the coughing “attacks” the patient may not have any signs of illness. Finally, the third phase is called the convalescent stage; the cough may remain, but less severe, and the resolution of the illness is gradual.[136,147] Due to the nature of the illness, pertussis-related deaths are often due to a secondary bacterial pneumonia.

Several laboratory tests are available to diagnose *B. pertussis*. Isolation of *B. pertussis* from a nasopharyngeal swab or aspirate culture is considered the gold standard for confirmation of infection and can be used to test for antimicrobial susceptibility. Polymerase chain reaction tests are also available, but vary in specificity.[149] Where pertussis is suspected, waiting for laboratory confirmation should not delay the treatment of patients and prophylaxis of close contacts who are high risk of the infection as well.[149]

TREATMENT

Epidemiologic modeling has demonstrated that the recent rise in pertussis cases may be due to a decrease in vaccine efficacy and duration of protection when compared to previously utilized whole cell vaccine.[150] However, even though efficacy is compromised, changes in vaccine policy to include more frequent booster doses may have prevented some of the pertussis resurgence.[150] To date our best prevention modality is still vaccination. If there are probable cases early treatment of pertussis is critical to reduce the severity of infection and prevent spreading the disease to others-key outcomes for secondary prevention. While antibiotic therapy is effective in treating pertussis, patients treated with antibiotics after the first few weeks of illness has not altered the course of the disease or prevented the spread of illness to those in close contact with the patient.[136]

Preexposure Prophylaxis

When considering the role of vaccination in the prevention of pertussis, there is often confusion between Tdap (tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis) and DTaP (diphtheria and tetanus toxoids and acellular pertussis) vaccines. The component antigens in Tdap and DTaP are the same, but the relative amounts are much greater with the infant vaccination (DTaP). Tdap is used in adults as a booster.[151] Regardless of the pertussis-containing vaccine product chosen, the dose is 0.5 mL, given intramuscularly for both children and adults.[152] The primary DTaP series is composed of 4 doses: Doses 1 to 3; given at 4 to 8 week intervals (6 weeks-24 months of age), Dose 4; administered 6 to 12 months after 3rd dose, and Dose 5; "booster" upon entering school. See Chapter 126 for additional information about pertussis vaccine, including vaccine products, ages, and dose administration.

7 A pertussis vaccination (Tdap) booster is recommended for all women during weeks 27 to 36 of each pregnancy to allow maximal maternal antibody response and passive, in-utero transfer of these antibodies.[153,154] A lapse between doses, although not ideal, is not a reason to start the series over again. The CDC has specific schedules for routine vaccination and catch-up vaccination.[155] Local pain, swelling, and redness are to be expected post-vaccination. Also common, although rarely severe, are gastrointestinal symptoms, fatigue, and headache.[148] However, limb swelling, anaphylaxis, seizures, and temperature over 101°F (37.8°C) are possible.[136]

Postexposure Prophylaxis

Postexposure prophylaxis should be provided to all household contacts of a patient with pertussis, even those current with pertussis immunizations, within 21 days of onset of cough onset in the initial patient.[156] Additionally, any infants, neonates, women in their third trimester of pregnancy, asthmatics and other immunocompromised persons who came in contact with the initial patient should be treated within 21 days of exposure.[156] However, if therapy is started after 3 weeks of cough onset, there is limited benefit.[147]

Macrolides (erythromycin, clarithromycin, and azithromycin) are considered first line antibiotics for both postexposure prophylaxis and treatment of pertussis; with trimethoprim-sulfamethoxazole (TMP-SMX) as an alternative agent.[157] A decade ago erythromycin was the drug of choice for pertussis; however, poor gastrointestinal tolerability and the frequent dosing schedule led to this drug falling out of favor.[158] While azithromycin has the best tolerability profile and ease of administration schedule with once-a-day dosing it does carry a QTc prolongation warning that would be a concern for patients with an underlying cardiac conduction abnormality and/or on other medications known to prolong the QTc.[157] In children 1 month of age and older azithromycin is preferred over erythromycin due to the risk of infantile hypertrophic pyloric stenosis (IHPS) associate with erythromycin.[157] All four antibiotics have a liquid formulation, which is helpful for administering the medication to infants, small children, and down a feeding tube. For additional details about the pros and cons of these antibiotics see Chapters 106, 108, and 109. **Table e10-8** review dosing details for pertussis treatment and prophylaxis for different age categories. For exposed health care workers early identification and isolation of pertussis patients is critical to avoid the spread of the disease to other patients and staff. Postexposure prophylaxis for exposed health care workers is recommended, however, a nasopharyngeal culture should be obtained if possible.[159]

TABLE e10-8 Recommended Antibiotics for Pertussis Postexposure Prophylaxis and Treatment

Patient Age	Azithromycin	Erythromycin	Clarithromycin	TMP-SMX
<1 month	10 mg/kg/day (once daily) for 5 days	Not preferred; 40-50 mg/kg/ day (4 divided doses) for 14 days	Not recommended	Contraindicated
1-5 months	10 mg/kg/day (once daily) for 5 days	40-50 mg/kg/ day (4 divided doses) for 14 days	15 mg/kg/day (2 divided doses) for 7 days	Contraindicated <2 months: ≥2 months TMP 8 mg/kg (2 divided doses) for 14 days, SMZ 40 mg/kg/day (2 divided doses) for 14 days
>6 months and children	10 mg/kg (single dose) day 1, then 5 mg/kg/day (once daily) days 2-5 (MAX: 500 mg/day)	40-50 mg/kg/ day (4 divided doses) for 14 days (MAX: 2 g/day)	15 mg/kg/day (2 divided doses) for 7 days (MAX: 1 g /day)	TMP 8 mg/kg (2 divided doses) for 14 days, SMX 40 mg/kg/day (2 divided doses) for 14 days
Adults	500 mg (single dose) day 1, then 250 mg (once daily) days 2-5	2 g/day (4 divided doses) for 14 days	1 g/day (2 divided doses) for 7 days	TMP 320 mg/day, SMX 1,600 mg/day (2 divided doses) for 14 days

Data from reference 158.

Suspected or Confirmed Cases

The earlier pertussis treatment is begun, symptoms, such as coughing, may be reduced during the course of the illness.[131] Supportive therapy, which could include breathing treatments, oxygenation, rest and

proper nutrition, is the first step in care.[160] Like postexposure prophylaxis the antibiotic choices, dosing, and duration for treatment are the same. Clinicians need to anticipate possible complications, especially in the more vulnerable patient population, infants, and young children. The CDC reports that in infants younger than 1 year old approximately half will be hospitalized with severe pertussis and potentially life-threatening complications.[161] Diligent respiratory and neurological monitoring is required to anticipate and treat sequelae such as apnea, pneumonia, seizures, and encephalopathy. While symptoms of pertussis may be less severe in adolescents and adults, complications can include weight loss, urinary incontinence, and even rib fractures from violent coughing.[161]

NATURAL DISASTER-RELATED INFECTIOUS DISEASE

Throughout the centuries Mother Nature has unleashed catastrophic events, such as earthquakes, hurricanes, tsunamis, fire storms, and drought. Natural disaster-related mortality is predominantly caused by drowning, crush-related injury, and blunt trauma. Infectious disease outbreaks following natural disasters, as with intentional biological agent exposures, can also cause panic, social unrest, and tax any country's medical and public health system.

8 These disease outbreaks are usually attributable to critical infrastructure damage, limited access to quality healthcare, environmental and human condition changes and vulnerability to pathogens.[162,163,164] Haiti, one of the world's poorest countries, is still trying to contain the cholera outbreak which commenced after their devastating earthquake in 2010. As of July 2015 there have been over 740,000 cases and 8,825 deaths, with no signs of the outbreak relenting.[162] Continued inadequacies in the country's water and sanitation systems are the root cause of the ongoing epidemic. Ironically, the diarrhea-inducing, fatal cholera strain was most likely introduced by aid workers from countries where cholera was endemic, and not by contaminated local water supply.[165]

Survivors of natural disasters have a multitude of potential risks from the event itself or in the immediate aftermath and even during recovery efforts. Eighteen suspected cases of cutaneous, necrotizing mucormycosis were reported to CDC in people injured by a multiple-vortex EF5 tornado in Joplin, Missouri two months after touching ground in May 2011. Ten individuals required intensive care and 5 died.[166] The CDC has specific vaccination recommendations for displaced individuals for their individual protection and concerns about public health and safety, such as an outbreak of influenza, measles or chickenpox within a shelter and beyond.[167]

Responders and aid workers also have risks, which would include communicable diseases. For responders to disasters occurring in the US only tetanus and hepatitis B (HepB) vaccination are recommended: hepatitis A, cholera (there is no US vaccine), meningococcal, typhoid, and rabies vaccines are not recommended mainly due to the low probability of exposure.[168] Considerations for overseas humanitarian work include general safety concerns and ensuring responders have all vaccines (both routine and specific-travel related) recommended for travel to that country. Finally, the CDC has published recommendations on how to manage health and safety concerns, such as mold, animals and insects, related to Natural Disasters.[169] Healthcare providers should focus on preventing illness and injury, ensuring food and water safety, and creating or updating medical records. In addition to important acute medical care issues post the disaster the needs of displaced individuals for chronic medical needs and medication access should be addressed.

CONCLUSION

Healthcare providers, including pharmacists, play an integral role in emergency preparedness and response efforts for a variety of biological agent exposures, both from intentionally released bioterrorism agents to those emerging as new organisms or re-emerging as repeat threats. Through the decades the disease link with animals, humans, and the environment has been clearly established and is evident by the large number of disease outbreaks originating from animals and facilitated by climate and environmental changes. Improving our ability to detect, prevent, and treat these outbreaks; while enhancing research, education, and communication related to our preparation and response is a major focus of the CDC and WHO and dozens of participating partners and countries.

Front line healthcare provider teams need to be vigilant to detect potential exposures or outbreaks and aggressively and appropriately initiate treatment strategies. Ideally, preexposure prophylaxis, such as vaccination, if available, is best to protect the public prior to an outbreak. When an outbreak is ongoing postexposure prophylaxis may help deter further complications and decrease morbidity and mortality as well as the spread of infection. As ill patients present to our health systems the best supportive care combined with available antimicrobial or antiviral therapy will help save lives. While disease outbreaks of newly identified organisms, like MERS, or historical pathogens, like plague and pertussis, will forever occur, we must take the necessary steps to minimize adverse consequences, protect public health, and provide the best care possible.

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ap	acellular pertussis
AVA	anthrax vaccine adsorbed
BID	twice a day
CBC	complete blood count
CDC	Centers for Disease Control and Prevention
CDV	Canine Distemper Virus
ChAd3	chimpanzee adenovirus serotype
3D	diphtheria
DTaP	diphtheria and tetanus toxoids and acellular pertussis vaccine
EIA	enzyme-linked immunoassay
ELISA	Enzyme-linked immunosorbent assay
EVD	Ebola virus disease
FDA	Food and Drug Administration
FEMA	Federal Emergency Management
GI	gastrointestinal
HepB	hepatitis B
ID	infectious diseases
IHPS	infantile hypertrophic pyloric stenosis

IM	intramuscular
IV	intravenous
MERS	Middle Eastern Respiratory Syndrome
MERS-CoV	Middle Eastern Respiratory Syndrome-coronavirus
MMR	measles, mumps, rubella vaccine
MRSA	Methicillin-resistant *Staphylococcus aureus*
NIAID	National Institute Allergy and Infectious Diseases
PCR	polymerase chain reaction
PEP	postexposure prophylaxis
PO	by mouth
PPE	personal protective equipment

Chapter e11: Cardiovascular Testing

Richard A. Lange

INTRODUCTION

KEY CONCEPTS

- 1 A careful history and physical examination are extremely important in diagnosing cardiovascular disease; they should be performed before any testing.
- 2 Elevated jugular venous pressure (JVP) is an important sign of heart failure and may be used to assess its severity and the response to therapy.
- 3 Heart sounds and heart murmurs are important in identifying heart valve abnormalities and other structural cardiac defects.
- 4 Electrocardiography is useful for determining rhythm disturbances (tachy- or bradyarrhythmias).
- 5 Exercise stress testing provides important information concerning the presence and severity of coronary artery disease; changes in heart rate, blood pressure, and the electrocardiogram (ECG) are used to assess the response to exercise.
- 6 Echocardiography is used to assess valve structure and function as well as ventricular wall motion; transesophageal echocardiography is more sensitive than transthoracic echocardiography for detecting thrombus and vegetations.
- 7 Radionuclides, such as technetium-99m and thallium-201, are used to assess myocardial ischemia and myocardial viability in patients with suspected coronary artery disease.
- 8 When patients cannot exercise, pharmacologic stress testing is used to assess the likelihood of coronary artery disease.
- 9 Cardiac catheterization and angiography are used to assess coronary anatomy and ventricular performance.

In the United States, cardiovascular disease (CVD) afflicts an estimated 85.6 million people (ie, greater than 1 in 3 adults) and accounts for 31% of all deaths. By 2030, 44% of the US population is projected to have some form of CVD. In 2011, the estimated direct and indirect cost of CVD—which includes hypertension, coronary heart disease, heart failure, and stroke—was $320.1 billion.[1]

Atherosclerosis, the cause of most CVD events, is typically present for decades before symptoms appear. With a thorough history, comprehensive physical examination, and appropriate testing, the individual with subclinical CVD usually can be identified, and the subject with symptomatic CVD can be assessed for the risk of an adverse event and can be managed appropriately.

THE HISTORY

The elements of a comprehensive history include the chief complaint, current symptoms, medical history, family history, social history, and review of systems.

The chief complaint is a brief statement describing the reason the patient is seeking medical attention. The patient is asked to describe his or her current symptoms, including their duration, quality, frequency, severity, progression, precipitating and relieving factors, associated symptoms, and impact on daily activities.

The medical history may reveal previous cardiovascular problems, conditions that predispose the patient to develop CVD (ie, hypertension, hyperlipidemia, or diabetes mellitus) (**Table e11-1**), or comorbid conditions that influence the identification or management of CVD. The patient should be asked about social habits that affect the cardiovascular system, including diet, amount of regular physical activity, tobacco use, alcohol intake, and illicit drug use. At present, family history of early onset CVD is the best available

screening tool to identify patients with a genetic predisposition for CVD.

TABLE e11-1 Risk Factors for Cardiovascular Disease

Nonmodifiable
Advancing age
Male
Family history of early onset CVD
Postmenopausal status
Modifiable
Hypertension
Diabetes mellitus
Dyslipidemia
Cigarette smoking
Obesity
Physical inactivity
Excessive alcohol
Stress
Chronic inflammation (ie, gingivitis, arthritis, elevated C-reactive protein, etc.)
Illicit drug use (eg, cocaine or methamphetamine)

Cardiovascular History

1 Chest pain is a frequent symptom and may occur as a result of myocardial ischemia (angina pectoris) or infarction or a variety of noncardiac conditions, such as esophageal, pulmonary, or musculoskeletal disorders. The quality of chest pain, its location and duration, and the factors that provoke or relieve it are important in ascertaining its etiology.

Typically, patients with angina describe a sensation of heaviness or pressure in the retrosternal area that may radiate to the jaw, left shoulder, back, or left arm. It is precipitated by exertion, emotional stress, eating, smoking a cigarette, or exposure to cold, and it is usually relieved within minutes with rest or a sublingual nitroglycerin, although the latter also is effective in relieving chest pain due to esophageal spasm. Angina that is increasing in severity, longer in duration, or occurring at rest is called unstable angina; it should prompt the patient to seek medical attention expeditiously.

The patient with congestive heart failure (CHF) and pulmonary vascular congestion may complain of shortness of breath (dyspnea) with exertion or even at rest, orthopnea, paroxysmal nocturnal dyspnea, and nocturia. The patient with CHF and peripheral venous congestion may report abdominal swelling (from hepatic congestion or ascites), nausea, vomiting, lower extremity edema, fatigue, and dyspnea.

The New York Heart Association (NYHA) grading system is used to indicate whether a patient has angina or symptoms of CHF with vigorous (Class I), moderate (Class II), mild (Class III), or minimal/no (Class IV) exertion.

PHYSICAL EXAMINATION

The patient with suspected heart disease should undergo a comprehensive physical examination, with particular attention to the cardiovascular system. This should include an assessment of the jugular venous pulse/pressure (JVP), carotid and peripheral arterial pulses, examination of the heart and lungs (ie, palpation, percussion, and auscultation), and inspection of the abdomen and extremities.

Jugular Venous Pressure

2 The JVP is an indirect assessment of right atrial pressure. With the patient lying supine at 30 degrees and his/her head rotated slightly to the left, the height of the fluid wave in the right internal jugular vein is determined relative to the sternal angle. The normal JVP is 1 to

2 cm above the sternal angle. The JVP typically is elevated in the patient with heart failure. The extent of elevation can be used to assess the severity of peripheral venous congestion, and its diminution can be used to assess the response to therapy.

Arterial Pulses

The carotid arterial pulse is examined for its intensity and, concurrently with the apical impulse, for concordance within the cardiac cycle. Diminished carotid arterial pulsations may be the result of a reduced stroke volume, atherosclerotic narrowing of the carotid artery, or obstruction to left ventricular outflow due to aortic valve stenosis or hypertrophic obstructive cardiomyopathy. Conversely, very forceful, hyperdynamic, "bounding" carotid arterial pulsations may be palpated in the patient with an increased stroke volume and suggests the presence of chronic aortic valve regurgitation or a high cardiac output due, for example, to hyperthyroidism, an arteriovenous shunt, or marked anemia.

The pulses in the arms and legs are also examined. Diminished peripheral pulses suggest the presence of a reduced stroke volume or atherosclerotic peripheral arterial disease (PAD). Concomitant pallor, skin atrophy, hair loss, or ulcerations are consistent with PAD, which often coexists with coronary artery disease. To quantify the severity of PAD, systolic arterial pressure is measured in all four extremities. Normally, the systolic arterial pressure in the feet should be similar or even slightly higher than the pressure in the arms. Thus, the ratio of the systolic arterial pressures in the foot and arm (the so-called ankle-brachial index [ABI]) is normally greater than 1.0. An ABI less than 0.9 suggests PAD.[2]

Chest

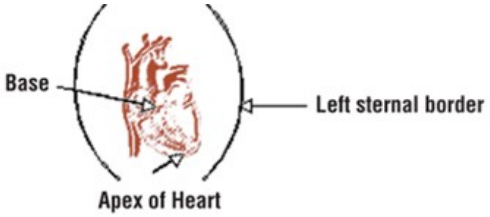
In the patient with chest pain, a thorough lung examination should be performed to exclude a pulmonary cause. The anterior chest wall is palpated to assess for the presence of tenderness in the sternal area, which may indicate that the patient has costochondritis. Percussion of the posterior chest is done to determine if a pleural effusion is present. Auscultation of the anterior and posterior lung fields is performed to assess for the presence of findings suggestive of pneumonia, airway obstruction, pneumothorax, pleural effusion, or pulmonary edema.

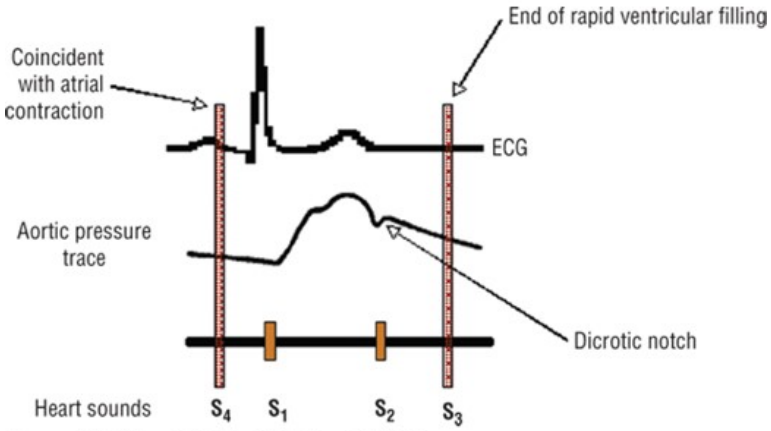
Heart Sounds

3 The typical "lub-dub" sound of the normal heart consists of the first heart sound (S_1), which precedes ventricular contraction and is due to closure of the mitral and tricuspid valves, and the second heart sound (S_2), which follows ventricular contraction and is due to closure of the aortic and pulmonic valves. Other heart sounds, which are normally not present (ie, a third heart sound [S_3], fourth heart sound [S_4], or murmur), may indicate the presence of underlying heart disease (**Fig. e11-1**).

FIGURE e11-1

Correlation of the electrocardiogram (ECG) with an aortic pressure tracing and heart sounds. Normal heart sounds are S_1 (mitral and tricuspid valve closure) and S_2 (aortic and pulmonic valve closure). The S_3 and S_4 "gallops" are usually abnormal. The S_3 occurs in early diastole as blood rapidly rushes into a volume-loaded ventricle (eg, with decompensated congestive heart failure). The S_4 occurs in late diastole and is caused by atrial contraction into a stiff, noncompliant ventricle (eg, hypertrophy due to hypertension).





Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

The S_3, a so-called ventricular gallop, is a low-pitched sound usually heard at the cardiac apex in early diastole (ie, immediately after S_2). It is caused by the vibrations that occur when blood rapidly rushes from the atrium into a volume-loaded ventricle. Thus, it is usually associated with decompensated CHF or intravascular volume overload. A so-called "physiologic" S_3 is heard commonly in healthy children (who often have an increased cardiac output) and may persist into young adulthood.

The S_4 is a dull, low-pitched sound that is caused by the vibrations that occur when atrial contraction forces blood into a stiff, noncompliant ventricle. It is audible at the cardiac apex just before ventricular contraction (ie, just before S_1); it is not present in the subject with a normal heart. An S_4 may be present in the patient with aortic stenosis, systemic arterial hypertension, hypertrophic cardiomyopathy, or coronary artery disease.

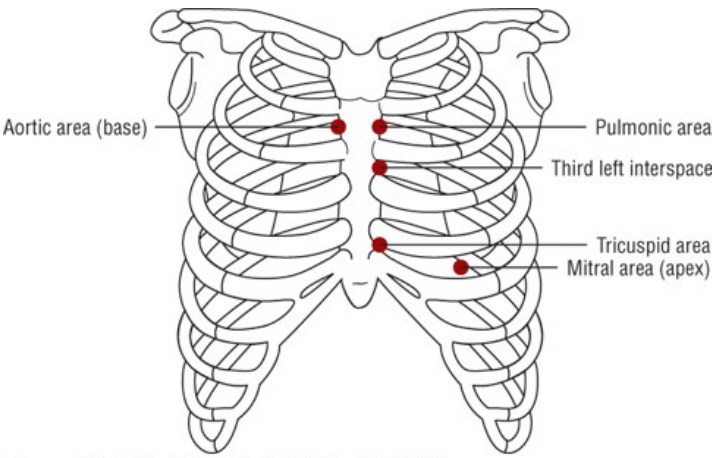
Murmurs are auditory vibrations resulting from turbulent blood flow within the heart chambers or across the valves. They are classified by their timing and duration within the cardiac cycle (systolic, diastolic, or continuous), location on the chest wall, intensity (grade 1 to 6, from softest to loudest), pitch (high or low frequency), and radiation (**Fig. e11-2** and **Table e11-2**). Some murmurs are said to be "innocent" or "physiologic" and result from rapid, turbulent blood flow in the absence of cardiac disease. Fever, anxiety, anemia, hyperthyroidism, and pregnancy increase the intensity of a physiologic murmur.

TABLE e11-2 Characteristic Murmurs

Murmur	Auscultatory Features	Example	Location
Midsystolic		Aortic or pulmonary stenosis	Upper sternal border
Holosystolic		Tricuspid regurgitation Mitral regurgitation	Lower sternal border Apex
Diastolic		Aortic or pulmonary regurgitation Tricuspid stenosis Mitral stenosis	Upper sternal border Lower sternal border Apex
Continuous		Arteriovenous connection Patent ductus arteriosus	Over location of connection Upper left chest

FIGURE e11-2

Schematic illustrations of topographic areas on the precordium for cardiac auscultation. Auscultatory areas do not correspond to anatomic locations of the valves but to the sites at which particular valvular sounds are heard best. *(Redrawn from Kinney MR, Packa DR, eds. Andreoli's Comprehensive Cardiac Care, 8th ed. St. Louis, MO: Mosby. Copyright © 1996, with permission from Elsevier.)*



Systolic murmurs occur during ventricular contraction. They begin with or after S_1 and end at or before S_2, depending on the origin of the murmur. They are classified based on time of onset and termination within systole: midsystolic or holosystolic (pansystolic).

Examples of midsystolic murmurs include pulmonic stenosis, aortic stenosis, and hypertrophic obstructive cardiomyopathy. Holosystolic murmurs occur when blood flows from a chamber of higher pressure to one of lower pressure throughout systole, such as occurs with mitral or tricuspid valve regurgitation or a ventricular septal defect.

Diastolic murmurs occur during ventricular filling. They begin with or after S_2, depending on the origin of the murmur. Aortic or pulmonic valve regurgitation causes a high-pitched diastolic murmur that begins with S_2, whereas stenosis of the mitral or tricuspid valves causes a low-pitched, "rumbling" diastolic murmur.

Continuous murmurs begin in systole and continue without interruption into all or part of diastole. Such murmurs are mainly a result of aortopulmonary connections (eg, patent ductus arteriosus) or arteriovenous connections (eg, arteriovenous fistula, coronary artery fistula, or arteriovenous malformation).

When a murmur is heard, the cardiac abnormality underlying it usually can be confirmed and assessed with echocardiography or other imaging modalities, such as cardiac angiography or magnetic resonance imaging (MRI).

PRACTICE GUIDELINES FOR DIAGNOSTIC AND PROGNOSTIC TESTING IN CARDIOVASCULAR DISEASE TESTING

The American Heart Association (AHA) and American College of Cardiology (ACC) Task Force on Practice Guidelines provides the indications and utility of various diagnostic cardiac tests (**Fig. e11-3**). Class I indications have unequivocal evidence or agreement that the specific procedure is useful and effective. Class II indications are those for which a divergence of opinion concerning the usefulness of the test is present: class IIa are those for which evidence or opinion in favor of the test exists, whereas class IIb are those for which less evidence favoring the test is present. Class III indications are those for which evidence or agreement exists that a diagnostic test is not useful.

FIGURE e11-3

Classification of recommendations and level of evidence.

Size of treatment effect

Estimate of certainty (precision) of treatment effect		Class I	Class IIa	Class IIb	Class III
		Benefit >>> Risk Procedure/Treatment SHOULD be performed/ administered	Benefit >>> Risk Additional studies with focused objectives needed **IT IS REASONABLE to perform procedure/ administer treatment**	Benefit ≥ Risk Additional studies with broad objectives needed; Additional registry data would be helpful **IT IS NOT UNREASONABLE to perform procedure/ administer treatment**	Risk ≥ Benefit No additional studies needed **Procedure/Treatment should NOT be performed/ administered SINCE IT IS NOT HELPFUL AND MAY BE HARMFUL**
	Level A Multiple (3-5) population risk strata evaluated General consistency of direction and magnitude of effect	• Recommendation that procedure or treatment is useful/effective • Sufficient evidence from multiple randomized trials or meta analyses	• Recommendation in favor of treatment or procedure being useful/effective • Some conflicting evidence from multiple randomized trials or meta analyses	• Recommendation's usefulness/efficacy less well established • Greater conflicting evidence from multiple randomized trials or meta analyses	• Recommendation that procedure or treatment not useful/effective and may be harmful • Sufficient evidence from multiple randomized trials or meta analyses
	Level B Limited (2-3) population risk strata evaluated	• Recommendation that procedure or treatment is useful/effective • Limited evidence from single randomized trial or non randomized studies	• Recommendation in favor of treatment or procedure being useful/effective • Some conflicting evidence from single randomized trial or non randomized studies	• Recommendation's usefulness/efficacy less well established • Greater conflicting evidence from single randomized trial or non randomized studies	• Recommendation that procedure or treatment not useful/effective and may be harmful • Limited evidence from single randomized trial or non randomized studies
	Level C Very limited (1-2) population risk strata evaluated	• Recommendation that procedure or treatment is useful/effective • Only expert opinion, case studies, or standard-of-care	• Recommendation in favor of treatment or procedure being useful/effective • Only diverging expert opinion, case studies, or standard-of-care	• Recommendation's usefulness/efficacy less well established • Only diverging expert opinion, case studies, or standard-of-care	• Recommendation that procedure or treatment not useful/effective and may be harmful • Only expert opinion, case studies, or standard-of-care

Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

For a specific clinical scenario, the guidelines also indicate the level of evidence for the recommendation. Level A evidence is said to be present if the recommendation is based on the results of multiple, randomized clinical trials. Level B evidence is said to exist if only a single randomized trial or multiple, nonrandomized trials exist. Level C evidence is said to be present if the recommendation is made solely on expert opinion.

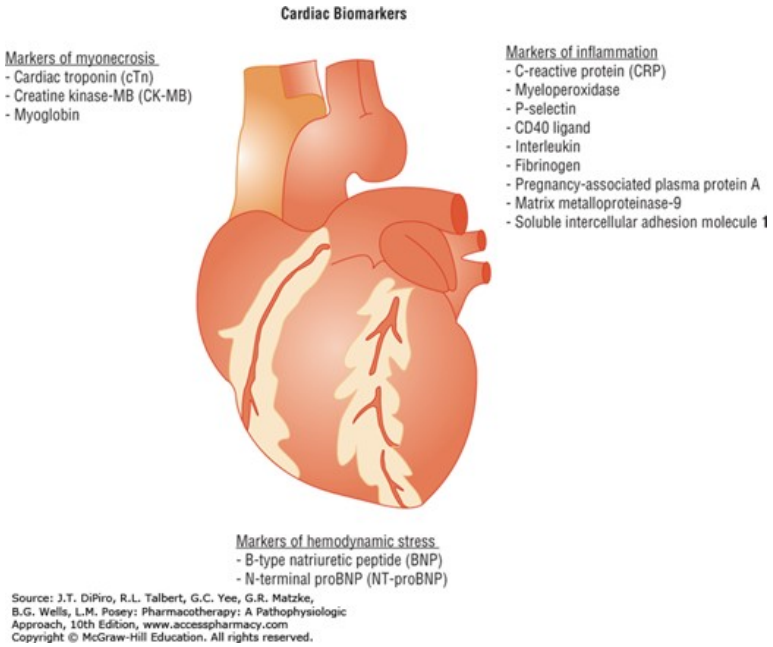
TESTING MODALITIES

Biomarkers

Blood tests are available for several substances that suggest the presence of myonecrosis (ie, recent death of myocardial cells), inflammation, or hemodynamic stress (**Fig. e11-4**).[3,4,5]

FIGURE e11-4

Cardiac biomarkers classified according to the different pathologic processes they indicate.



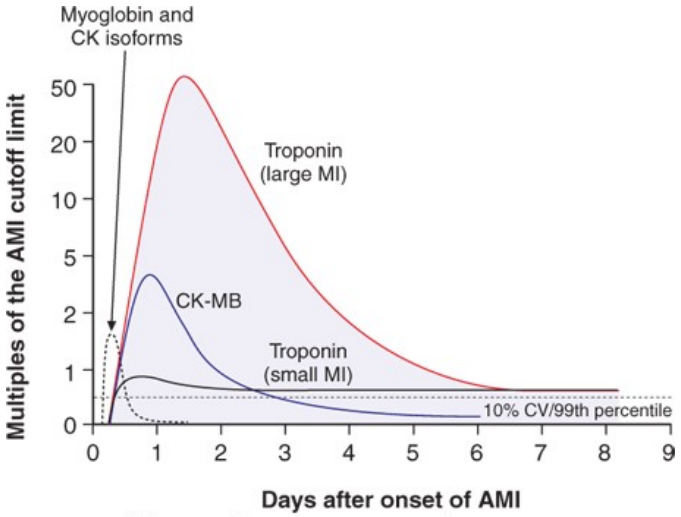
Markers of Myonecrosis

When myocardial infarction (myonecrosis) occurs, proteins from the recently necrotic myocytes are released into the peripheral blood, where they can be detected using specific biochemical assays. These biomarkers of myonecrosis (a) aid in the diagnosis (or exclusion) of myocardial infarction as the cause of chest pain; (b) facilitate triage and risk stratification of patients with chest discomfort; and (c) identify patients who are appropriate candidates for specific therapeutic strategies or interventions. Cardiac troponin (cTn) is the preferred biomarker for the diagnosis of myonecrosis.[5] Other available biomarkers of necrosis include creatine kinase-MB (CK-MB) and myoglobin.

Troponin I and T are contractile proteins found only in cardiac myocytes. In the patient with myocardial infarction, cTn is detectable in the blood 2 to 4 hours after the onset of symptoms and remains detectable for 5 to 10 days (**Fig. e11-5**). cTn is the preferred marker for evaluating the patient suspected of having a myocardial infarction, since it is the most sensitive and tissue-specific biomarker available. In the patient with ischemic chest pain and electrocardiographic (eg, ST segment) abnormalities, the presence of an elevated serum cTn concentration establishes the diagnosis of myocardial infarction, and the absence of such an elevation excludes it. The use of high-sensitive cTn assays improves the early diagnosis of patients with suspected myocardial infarction, particularly the early exclusion of it.[6]

FIGURE e11-5

Time course of the appearance of various markers in the blood after acute myocardial infarction. *(Reprinted from Jaffe AS, Babuin L, Apple FS. Biomarkers in acute cardiac disease: the present and the future. J Am Coll Cardiol 2006;48:4. Copyright © 2006, with permission from Elsevier.)*



In the patient with an acute coronary syndrome, detection and quantitation of cTn in the blood provide prognostic information and guide management. Acute coronary syndrome patients with an elevated serum cTn concentration have a roughly fourfold higher risk of death and recurrent myocardial infarction in the coming months when compared to those with normal cTn concentrations. They benefit (ie, have a reduced incidence of death, recurrent myocardial infarction, and recurrent ischemia) from more intensive antiplatelet and antithrombotic therapy as well as prompt coronary angiography and revascularization, whereas those with a normal serum cTn obtain no benefit from such intensive therapy.[7,8] Thus, serum cTn concentrations are used for diagnostic, prognostic, and therapeutic purposes in the patient with suspected or proven coronary artery disease.

On occasion, the serum cTn concentration may be elevated in a patient without coronary artery disease (CAD) in whom myonecrosis occurs because myocardial oxygen demands markedly exceed oxygen supply (caused, for example, by tachycardia or severe systemic arterial hypertension) or nonischemic cardiac injury occurs (ie, myocardial contusion caused by blunt trauma to the chest) (**Table e11-3**). In the patient with an elevated serum cTn concentration, the clinician must decide if the observed abnormal serum cTn concentration is the result of CAD or another condition.

TABLE e11-3 Conditions Associated with an Increased Serum Troponin Concentration

Myocardial infarction	Pulmonary embolism
Acute coronary syndrome	Strenuous exercise
Coronary intervention	Chemotherapy
Pericarditis	Severe asthma
Congestive heart failure	Respiratory distress
Cardiac defibrillation	Infiltrative disorders
Cardiac ablation	Acute limb ischemia
Cardiac contusion	Inflammatory disease
Tachycardia	Influenza
Aortic dissection	Hemodialysis
Stroke	Sepsis
Renal failure	Shock
Hypertension or hypotension	Rhabdomyolysis

When serum cTn measurements are not available, the best alternative is the MB isoenzyme of creatine kinase (CK-MB), which is a cytosolic carrier protein for high-energy phosphates that is released into the blood when myonecrosis occurs. Although it was initially thought to be cardiac specific, CK-MB is now known to be present in small amounts in skeletal muscle; as a result, it may be detectable in

the blood of patients with massive muscle injury, as occurs with rhabdomyolysis or myositis.

In the patient with a myocardial infarction, CK-MB can be detected in the blood 2 to 4 hours after symptom onset; its serum concentration peaks within 24 hours, and it remains detectable in the blood for 48 to 72 hours. To document the characteristic rise and fall of CK-MB concentrations, blood samples should be obtained every 4 to 8 hours. Although CK-MB is not as sensitive or cardiac-specific a biomarker as cTn, its blood concentration declines more rapidly than cTn, which makes it the preferred biomarker for evaluating suspected recurrent infarction in the patient who experiences recurrent chest pain within several days of myocardial infarction. With recurrent infarction, the typical rise and fall of the serum CK-MB concentration is interrupted by a second elevation. Conversely, serum cTn concentrations decline slowly following myocardial infarction; hence they are not as sensitive as CK-MB for diagnosing recurrent infarction.

The serum myoglobin concentration is elevated in the patient with myonecrosis, but it has a low specificity for myocardial infarction because of its high concentration in skeletal muscle. Because of its small molecular size and consequent rapid release (within 1 hour) following the onset of myonecrosis, it is utilized as a very early marker of myocardial infarction. When it is combined with a more specific marker of myonecrosis, such as cTn or CK-MB, myoglobin is useful for the early exclusion of myocardial infarction.

Markers of Inflammation

Inflammatory processes participate in the development of atherosclerosis and contribute to the destabilization of atherosclerotic plaques, which may ultimately lead to an acute coronary syndrome. Several mediators of the inflammatory response, including acute phase proteins, cytokines, and cellular adhesion molecules, have been evaluated as potential indicators of underlying atherosclerosis and as predictors of acute cardiovascular events.

C-reactive protein (CRP) is an acute-phase reactant protein produced by the liver.[9] Although a receptor for CRP is present on endothelial cells, controversy exists regarding whether CRP is simply a marker for systemic inflammation or participates actively in atheroma formation.[10,11] In the absence of acute illness or myocardial infarction, serum concentrations of CRP are relatively stable, although they are influenced by gender and ethnicity. To measure serum CRP concentrations accurately, a high-sensitive CRP (hs-CRP) assay is required.

Epidemiologic studies have shown that the relative risk of future vascular events increases as the serum hs-CRP concentration increases.[9] Values greater than 3 mg/L are associated with an increased risk for developing CVD; conversely, values less than 1 mg/L are associated with a low risk. Those between 1 and 3 mg/L are considered to be at intermediate risk. In an individual with an elevated serum hs-CRP concentration, the measurement should be repeated several weeks later to exclude the possibility that an acute illness was responsible for the elevation. Measurements should not be taken when subjects are acutely ill (eg, with any acute febrile illness) or have a known autoimmune or rheumatologic disorder. Serum CRP concentrations above 10 mg/L are likely caused by an acute or chronic systemic illness.

Although the relative risk of future vascular events increases as the serum concentration of hs-CRP increases, controversy continues as to whether hs-CRP concentrations provide sufficient incremental information above traditional risk factors to warrant routine testing in subjects without known CVD in an attempt to prevent an adverse event (so-called primary prevention).[9,12,13]

Clinical Controversy…

Assessing an individual's risk for CVD is important in guiding treatment. Many risk factors for CVD have been identified (ie, hypertension, hyperlipidemia, diabetes mellitus, cigarette smoking, and family history of CVD). Whether hs-CRP concentrations provide sufficient incremental information above traditional risk factors to warrant routine testing in subjects without known CVD in an attempt to prevent an adverse event (so-called primary prevention) is unknown.

Recent guidelines have suggested that hs-CRP is useful in patients who are considered (on the basis of traditional risk factors) to be at intermediate risk for CAD in an attempt to guide the intensity with which their risk factors are modified.[9,12] Only limited data have suggested that interventions that lower hs-CRP concentrations (ie, aspirin and statins) are beneficial.[14,15,16]

Multiple studies[17,18] of patients with acute coronary syndromes have demonstrated the capacity of hs-CRP concentrations—measured at the time of hospitalization or hospital discharge—to help predict cardiovascular outcomes during the hospitalization or during long-term follow-up. This prognostic information appears to be independent of and complementary to data obtained from the history and ECG. hs-CRP concentrations may be useful for monitoring the response to statin therapy, in that those with low hs-CRP concentrations after statin therapy have better clinical outcomes than those in whom these concentrations are high.[14,16] Based on these data, the measurement of serum hs-CRP concentrations in patients with acute coronary syndromes is recommended as reasonable (class IIa) for risk stratification when additional prognostic information is desired.[5] In contrast, its routine use is not recommended in the absence of compelling data identifying its role in guiding specific therapy.

Other novel markers of inflammation and/or plaque stabilization that have been shown to provide prognostic information in patients

with an acute coronary syndrome are myeloperoxidase, CD40 ligand, P-selectin, pregnancy-associated plasma protein A, interleukin 6, matrix metalloproteinase-9, soluble intercellular adhesion molecule 1, and fibrinogen.[3,5,19]

Markers of Hemodynamic Stress

B-type natriuretic peptide (BNP) and its precursor, N-terminal pro-brain natriuretic protein (NT-proBNP), are released from ventricular myocytes in response to increases in wall stress. As a result, their serum concentrations typically are increased in patients with CHF. They may also be elevated in patients with an acute coronary syndrome as a result of left ventricular systolic dysfunction, impairment of ventricular relaxation, and myocardial stunning.[5,20]

Since serum BNP and NT-proBNP concentrations manifest substantial biologic variability, their serum concentrations in an individual subject must increase or decrease at least twofold to provide assurance that a "real" change has occurred. In addition, when considering the normal range for an individual, one must be aware that considerable variation in serum concentrations exists according to age, gender, weight, and renal function. Women and older patients have a higher normal range, whereas obese patients have lower values than the nonobese. Patients with renal failure often have substantially higher values.

Elevated BNP and NT-proBNP concentrations support a suspected diagnosis of heart failure or lead to a suspicion of heart failure when a diagnosis is unclear. Conversely, a normal value (BNP less than 100 pg/mL or NT-proBNP less than 300 pg/mL) in an untreated patient strongly suggests that heart failure is not present.[20,21] In a study of 1,568 patients seeking medical attention after the abrupt onset of dyspnea, plasma BNP was significantly higher in those with clinically diagnosed heart failure than in those without (mean value, 675 compared with 110 pg/mL, respectively); those with known heart failure but with a noncardiac cause of dyspnea had intermediate values (mean, 346 pg/mL).[22]

Plasma BNP concentrations provide prognostic information in patients with acute decompensated heart failure: in-hospital mortality is threefold higher in those in the highest BNP quartile when compared to the lowest quartile.[23] Similarly, in patients with compensated CHF, plasma BNP concentrations provide valuable prognostic information, in that each 100 pg/mL increase in plasma BNP in these subjects is associated with a 35% increase in the relative risk of death.[24] Although the measurement of BNP can be used for prognostic purposes in patients with CHF, its role in assessing treatment efficacy and modifying drug therapy is not clearly established.

Elevated plasma concentrations of BNP and NT-pro BNP have been observed in subjects with heart failure with depressed left ventricular systolic function, heart failure with preserved left ventricular systolic function, elevated left ventricular filling pressures, left ventricular hypertrophy, atrial fibrillation, and myocardial ischemia. They may be elevated in certain noncardiac conditions, including pulmonary embolism, chronic obstructive pulmonary disease, hypoxemia, sepsis, cirrhosis, and renal failure. As a result, values of BNP or NT-pro BNP should not be used in isolation either to confirm or to refute a diagnosis of heart failure.

Elevated serum concentrations of BNP and NT-proBNP may be detected in patients with an acute coronary syndrome. Data from more than 30 studies have indicated that BNP and NT-proBNP are among the most robust predictors of death and heart failure in patients hospitalized with an acute coronary syndrome.[5,25,26,27] Nonetheless, data regarding the potential for these substances to guide specific therapeutic decisions, such as whether to perform coronary angiography and revascularization, have been mixed. At present, therefore, the use of BNP and NT-proBNP in patients with an acute coronary syndrome is limited to risk stratification, for which they can be used to help in the assessment of prognosis.

Chest Radiography

The chest X-ray provides supplemental information to the physical examination. Although it does not provide detailed information about internal cardiac structures, it can provide information about the position and size of the heart and its chambers as well as adjacent structures. The standard chest X-rays for evaluation of the lungs and heart are standing posteroanterior and lateral views taken with maximal inspiration; portable chest X-rays usually are less helpful. When possible, previous X-rays should be obtained for comparison.

The posteroanterior chest X-ray outlines the superior vena cava, right atrium, aortic knob, main pulmonary artery, left atrial appendage (especially if enlarged), and left ventricle. The lateral chest X-ray allows one to assess the right ventricle, inferior vena cava, and left ventricle. These structures are visualized as shadows of differing density rather than as discrete entities.

Cardiac enlargement is determined by the cardiothoracic ratio (CTR), which is the maximal transverse diameter of the heart divided by the maximal transverse diameter of the thorax on the posteroanterior view. The CTR normally is less than or equal to 0.45, but it may be higher (ie, less than or equal to 0.55) in subjects with a large stroke volume (eg, highly conditioned athletes). Certain cardiac conditions, such as heart failure and hypertension, may cause cardiac enlargement, with a resultant high CTR. Individual chamber enlargement can be seen on the chest X-ray. Left atrial enlargement is suspected if the left bronchus is elevated or the atrial appendage is enlarged. Left ventricular enlargement is the most common feature identified on chest X-ray and is seen as a lateral and downward displacement of the cardiac apex. Right ventricular enlargement is best seen on the lateral film, on which the heart appears to occupy the retrosternal space.

A large pericardial effusion may appear as a large heart on a chest X-ray, but, in contrast to heart failure, pulmonary vascular congestion is not present (see below).

The pulmonary vessels are examined for size and filling. With diminished pulmonary blood flow, as would be present in the patient with tetralogy of Fallot or pulmonic valvular stenosis, the peripheral pulmonary vessels are small in caliber and underfilled. Increased pulmonary blood flow, as occurs with a high cardiac output or left-to-right intracardiac shunting, may lead to enlargement and tortuosity of the central and peripheral pulmonary vessels. Pulmonary arterial hypertension (increased pulmonary resistance) is identified by enlargement of the central pulmonary arteries and diminished peripheral perfusion. Elevated pulmonary venous pressure—usually the result of an elevated left atrial pressure—is characterized by dilation of vessels in the upper lung zones (eg, cephalization of flow), owing to recruitment of upper lung vessels when blood is diverted from the constricted vessels in the lower lung zones.

CHF causes Kerley B lines (edema of interlobular septae), which appear as thin, horizontal reticular lines in the costophrenic angles. As pulmonary venous pressure increases, alveolar edema becomes evident, and pleural effusions may appear as blunting of the costophrenic angles.

Electrocardiography

4 The ECG is a graphic recording of the electrical potentials generated by the heart. The signals are detected by using electrodes attached to the extremities and chest wall (**Figs. e11-6** and **e11-7**), which are then amplified and recorded (**Fig. e11-8**). The ECG leads display the instantaneous differences in potential between electrodes. As electrical activity approaches the positive electrode of the lead, it registers a positive (upright) deflection on the ECG, whereas electrical activity in the opposite direction of the positive electrode of the lead registers a negative (downward) deflection.

FIGURE e11-6

With electrodes (depicted as dots) attached to each arm and leg, electrical activity on the torso (ie, frontal plane) is recorded from six different directions. These are known as the limb leads: leads I, II, III, aVF, aVL, and aVR. *(Source: Longo DL, Fauci AS, Kasper DL, Hauser SL, Jameson JL, Loscalzo J.* Harrison's Principles of Internal Medicine, *18th ed. FIGURE e11-8

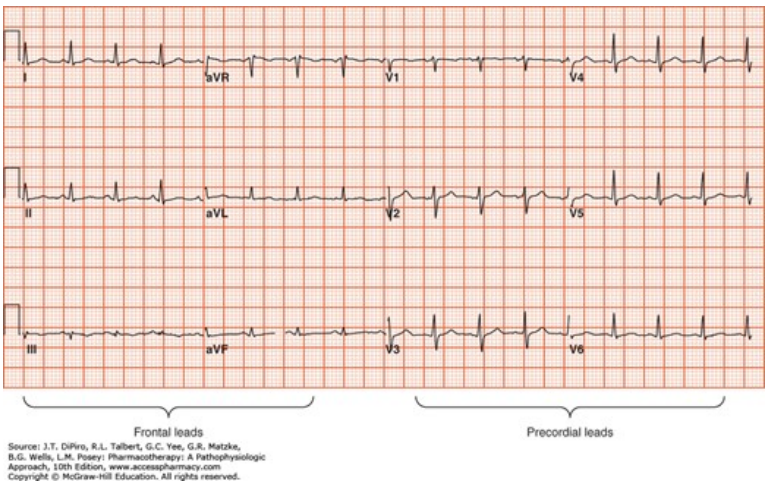
Standard 12-lead electrocardiogram, with six frontal and six precordial leads.



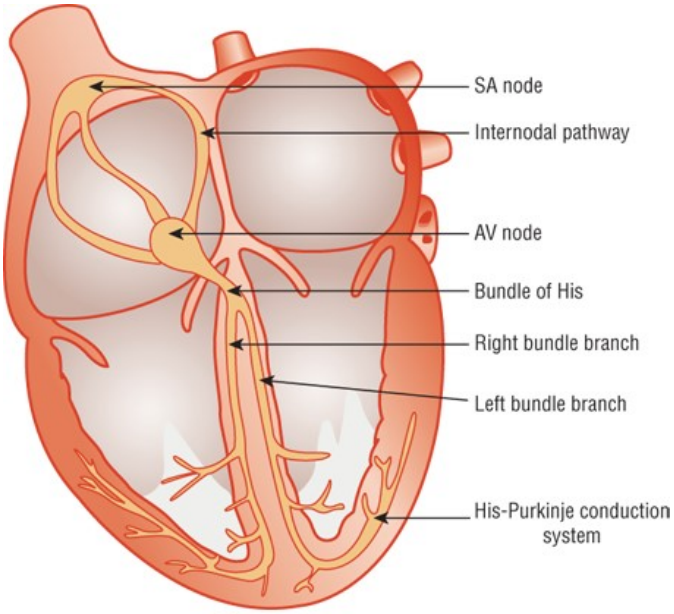
The ECG can be used to detect arrhythmias, conduction disturbances, myocardial ischemia or infarction, metabolic disturbances that may result in lethal arrhythmias (eg, hyperkalemia), and increased susceptibility to sudden cardiac death (eg, prolonged QT interval). It is simple to perform, noninvasive, and inexpensive.

Depolarization of the heart initiates cardiac contraction. The electrical current that depolarizes the heart originates in special cardiac pacemaker cells located in the sinoatrial (SA) node, or sinus node, which is located in the upper right atrium near the insertion of the superior vena cava (**Fig. e11-9**). The depolarization wave is transmitted through the atria, which initiates atrial contraction. Subsequently, the impulse is transmitted through specialized conduction tissues in (a) the atrioventricular (AV) node, which is located in the inferior right atrium near the tricuspid valve; (b) the bundle of His, which is located in the interventricular septum; and (c) the right and left bundles, which rapidly conduct the electrical impulse to the right and left ventricular myocardium via (d) the Purkinje fibers. The depolarization wavefront then spreads through the ventricular muscle, from endocardium to epicardium, triggering ventricular contraction.

FIGURE e11-9

Schematic representation of the cardiac conduction system. (AV, atrioventricular; SA, sinoatrial.) *(From Vijayaraman P, Ellenbogen KA. Bradyarrhythmias and pacemakers. In: Fuster V, O'Rourke RA, Walsh RA, Poole-Wilson P, eds.* Hurst's the Heart, *12th ed. New York:*

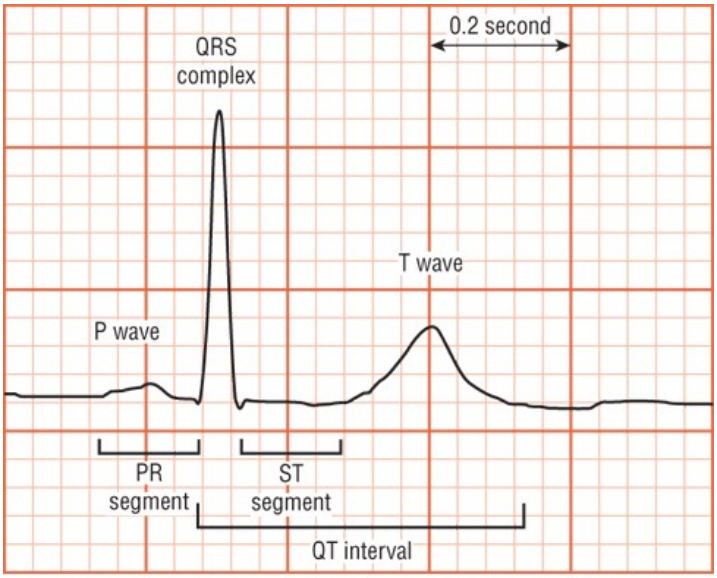
McGraw-Hill, 2004:1021.)



The ECG waveforms (**Fig. e11-10**), which are recorded during electrical depolarization of the heart, are labeled alphabetically and are read from left to right, beginning with the P wave, which represents depolarization of the atria. The normal duration of the P wave is up to 0.12 second. The *PR segment,* created by passage of the impulse through the AV node and the bundle of His and its branches, has a duration of 0.12 to 0.20 second. The *QRS complex* represents electrical depolarization of the ventricles. Initially, a negative deflection (the Q wave) appears, followed by a positive deflection, the R wave, and finally a negative deflection, the S wave. The normal duration of the QRS complex is less than 0.12 second. Since the left ventricle is much thicker than the right ventricle, most of the electrical wavefront is directed toward the former. Accordingly, the precordial leads positioned over the left ventricle (leads V_5 and V_6) demonstrate a positive (upright) QRS complex, whereas those positioned over the right ventricle (V_1 and V_2) record a negative (downward) QRS complex.

FIGURE e11-10

ECG waveforms are labeled alphabetically and are read from left to right. The *P wave* represents depolarization of the atria. The *PR segment* is created by passage of the impulse through the atrioventricular node and the bundle of His and its branches. The *QRS complex* represents electrical repolarization of the ventricles. The *T wave* results from ventricular depolarization. A plateau phase called the *ST segment* extends from the end of the QRS complex to the beginning of the T wave. The ST segment elevates with transmural (full thickness) ischemia and depresses with ischemia. The *QT interval*—measured from the beginning of the QRS complex to the end of the T wave—includes the time required for ventricular depolarization and repolarization.



Following the QRS complex is a plateau phase called the *ST segment,* which extends from the end of the QRS complex (called the *J point*) to the beginning of the T wave. When ischemia occurs, one may observe depression of the ST segment (**Fig. e11-11A**). When infarction from total obstruction of a coronary artery occurs, ST segment elevation may be observed (**Fig. e11-11B**). Repolarization of the ventricle leads to the T wave. The T wave usually goes in the same direction as the QRS complex.

FIGURE e11-11

A. Anterior wall ischemia with deep T-wave inversions and ST segment depressions in leads I, II, aVL, and V_3 to V_6. *(From Goldberger AL. Chapter e28. Atlas of Electrocardiography. In: Longo DL, Fauci AS, Kasper DL, Hauser SL, Jameson J, Loscalzo J. eds. Harrison's Principles of Internal Medicine, 18e. New York, NY: McGraw-Hill; 2012.) B*. Extensive anterior MI with marked ST elevations in leads I, aVL, V_1 to V_6, and small pathologic Q waves in V_3 to V_6. Marked reciprocal ST segment depressions in leads III and aVF. *(From Goldberger AL. Chapter e28. Atlas of Electrocardiography. A

B

The *QT interval*—measured from the beginning of the QRS complex to the end of the T wave—includes the time required for ventricular depolarization and repolarization, and it varies inversely with heart rate. A rate-related ("corrected") QT interval (QTc) can be calculated as QT√R-R interval; it should be less than 0.44 second. A prolonged QTc interval is caused by abnormalities in depolarization or repolarization that are associated with sudden cardiac death. QTc prolongation may be due to genetic defects in action potential ion channels (eg, congenital long QT syndrome), drugs (**Table e11-4**), or electrolyte disturbances (ie, hypokalemia, hypocalcemia, hypomagnesemia). Regardless of the cause, QT prolongation increases susceptibility to a potentially lethal arrhythmia, torsades de pointes (a type of ventricular tachycardia).

TABLE e11-4 Drugs with Known Risk of QT Interval Prolongation and Potentially Lethal Arrhythmia (Torsades de Pointes)

Generic	Brand
Amiodarone	Cordarone
Amiodarone	Pacerone
Arsenic trioxide	Trisenox
Astemizole	Hismanal
Bepridil	Vascor
Chloroquine	Aralen
Chlorpromazine	Thorazine
Cisapride	Propulsid
Clarithromycin	Biaxin
Disopyramide	Norpace
Dofetilide	Tikosyn
Domperidone	Motilium
Droperidol	Inapsine

Generic	Brand
Erythromycin	Erythrocin
Erythromycin	E.E.S.
Flecanide	Tambocor
Halofantrine	Halfan
Haloperidol	Haldol
Ibutilide	Corvert
Levomethadyl	Orlaam
Mesoridazine	Serentil
Methadone	Dolophine
Methadone	Methadose
Moxifloxacin	Avelox
Pentamidine	Pentam
Pentamidine	NebuPent
Pimozide	Orap
Probucol	Lorelco
Procainamide	Pronestyl
Procainamide	Procan
Quinidine	Cardioquin
Quinidine	Quinaglute
Sotalol	Betapace
Sparfloxacin	Zagam
Terfenadine	Seldane
Thioridazine	Mellaril
Vandetanib	Caprelsa

The 12 conventional ECG leads record the electrical potential difference between electrodes placed on the surface of the body (see Fig. e11-9). The six frontal plane and the six horizontal plane leads provide a three-dimensional representation of cardiac electrical activity. Each lead provides the opportunity to view atrial and ventricular depolarization from a different angle, much the same way that multiple video cameras positioned in different locations can view an event from different perspectives.

The six frontal leads can be subdivided into those that view electrical potentials directed inferiorly (leads II, III, aVF), laterally (leads I, aVL), or rightward (aVR). Likewise, the six precordial leads can be subdivided into those that view electrical potentials directed toward the septal (leads V_1, V_2), apical (leads V_3, V_4), or lateral (leads V_5, V_6) regions of the heart. Thus, when ischemia or infarction-related ECG changes occur, the region of the heart affected can be localized by determining which leads manifest abnormalities.

The mean orientation of the QRS vector with reference to the 6 frontal plane leads is known as the QRS axis. It describes the “major” direction of QRS depolarization, which is typically toward the apex of the heart (ie, toward the left side of the chest and downward). An abnormality in the direction of QRS depolarization (so-called axis deviation) may occur with hypertrophy or enlargement of one or more cardiac chambers or with remote myocardial infarction, since electrical depolarization does not occur in dead tissue. Hypertrophy or enlargement of the atria or ventricles may also affect the size of the P wave or QRS complex, respectively. Although specific ECG criteria have been developed for diagnosing hypertrophy, the ECG is neither sensitive nor specific for establishing the presence of atrial dilatation or ventricular hypertrophy. Other noninvasive modalities (ie, echocardiography or MRI) are superior to the ECG for evaluating

these conditions.

The origin of the electrical impulses (the so-called cardiac rhythm) and integrity of the conduction system can be assessed with a 12-lead ECG. If the SA node is diseased and unable to initiate cardiac depolarization, specialized cardiac pacemaker cells in the AV node or ventricle may initiate cardiac depolarization instead, albeit at a slower rate than the SA node. Alternatively, the SA node may initiate the electrical impulse, but its transmission through the specialized conduction system may be slowed or interrupted in the AV node or bundle of His, resulting in first degree or advanced (ie, second or third degree) AV block, respectively. Finally, disease in the left or right bundle may slow conduction of the electrical impulse, resulting in a left or right bundle-branch block, respectively.

The ECG provides an assessment of the heart rate, which is normally 60 to 100 beats per minute (bpm) at rest. Tachycardia is present when the heart rate exceeds 100 bpm, and bradycardia is present when it is less than 60 bpm. Tachycardia may originate in the SA node (sinus tachycardia), atrium (atrial flutter or fibrillation, ectopic atrial tachycardia, or multifocal atrial tachycardia), or AV node (junctional tachycardia or AV nodal reentry tachycardia). Collectively, these are termed supraventricular tachycardias. Alternatively, a tachycardia may have its origin in the right or left ventricle (ventricular tachycardia, ventricular fibrillation, and right ventricular outflow tract tachycardia).

Many drugs can affect the specialized cardiac pacemaker cells—causing tachycardia or bradycardia—or the conduction system, which may lead to AV block or sudden cardiac death. A resting ECG should be performed before and after the administration of such drugs, with examination of the rhythm, heart rate, and various intervals (ie, PR, QRS, and QT) to determine if substantial changes have occurred.

In the patient with chest pain, the resting ECG is examined for ST segment abnormalities that may indicate myocardial ischemia or infarction (ie, ST segment depression or elevation). In addition, the resting ECG may indicate if the patient has had a remote myocardial infarction.

The ECG is used often in conjunction with other diagnostic tests to provide additional data, monitor the patient, or determine if symptoms correlate with what is observed on the ECG. For example, the patient suspected of having CAD may undergo stress testing with ECG monitoring to assess the presence of provocable ischemia.

Signal-Averaged ECG

Survivors of myocardial infarction may be at risk for life-threatening arrhythmias. In these individuals, myocardial scar tissue creates zones of slow conduction that appear as low amplitude, high frequency signals that are continuous with the QRS complex. These small electrical currents (so-called late potentials) are not detectable on a routine, traditional ECG. By using computer programs that amplify and enhance the electrical signal, signal-averaged electrocardiography (SAECG) provides a high-resolution ECG that measures ventricular late potentials, thereby identifying patients at risk of sustained ventricular tachycardia after myocardial infarction.[28]

Patients with ischemic heart disease and unexplained syncope who are at risk for sustained ventricular tachycardia may be candidates for a SAECG. A SAECG may be useful in the patient with nonischemic cardiomyopathy and sustained ventricular tachycardia, detection of acute rejection following heart transplant, and assessment of the proarrhythmic potential of antiarrhythmic drugs.

Ambulatory Electrocardiographic Monitoring

Ambulatory electrocardiography (AECG), so-called Holter monitoring, can be used to detect, document, and characterize cardiac rhythm or ECG abnormalities during ordinary daily activities. Current continuous AECG equipment is capable of providing an analysis of cardiac electrical activity, including arrhythmias, ST segment abnormalities, and heart rate variability. An AECG can be obtained with continuous recorders (Holter monitors) or intermittent recorders.

During continuous Holter monitoring, the patient wears a portable ECG recorder (weighing 8-16 oz), which is attached to 2 to 4 leads placed on the chest wall. During monitoring, the patient maintains a diary, in which he/she records the occurrence, duration, and severity of symptoms (eg, lightheadedness, chest pain, palpitations, etc). The device is typically worn for 24 to 48 hours, after which the continuous ECG recording is scanned by computer to detect arrhythmias or ST segment abnormalities to determine if they are responsible for the patient's symptoms.

Intermittent recorders (also known as event monitors or loop recorders) are worn for longer periods of time (weeks to months). Although they continuously monitor the ECG, only brief (minutes) segments of it are recorded when the patient activates the device (ie, when symptoms occur) or a preprogrammed abnormal ECG event occurs. Some intermittent event recorders incorporate a memory loop that permits capture of a rhythm recording during fleeting symptoms, tachycardia onset, and, in some cases, syncope that occurs infrequently. When the patient activates a looping monitor, it records several minutes of the preceding rhythm as well as the subsequent rhythm.

When monitoring is performed to evaluate the cause of intermittent symptoms, the frequency of symptoms dictates the type of recording. Continuous recordings are indicated for the assessment of frequent (at least once a day) symptoms that may be related to disturbances of heart rhythm, for the assessment of syncope or near syncope, and for patients with recurrent unexplained palpitations. In

contrast, for patients whose symptoms are infrequent, intermittent event recorders may be more cost-effective in attempting to determine the cause of symptoms. For patients receiving antiarrhythmic drug therapy, continuous monitoring may be used to assess drug response and to exclude proarrhythmia.

Exercise Stress Testing

5 Exercise stress testing, a well-established, relatively low-cost procedure, has been in widespread use for decades. It may be performed (a) to evaluate an individual's exercise capacity; (b) to assess the presence of myocardial ischemia in the patient with symptoms suggestive of coronary artery disease; (c) to obtain prognostic information in the patient with known CAD or recent myocardial infarction; (d) to evaluate the severity of valvular abnormalities; or (e) to assess the presence of arrhythmias or conduction abnormalities in the patient with exercise-induced cardiac symptoms (ie, palpitations, lightheadedness, or syncope).

The patient who is to undergo an exercise stress test should fast for several hours beforehand and dress appropriately for exercise. Before exercise begins, a limited cardiac examination is performed (ie, auscultation of the lungs and heart); blood pressure and heart rate are recorded; and a standard 12-lead ECG is recorded. Exercise is then initiated, and the ECG, heart rate, and blood pressure are monitored carefully and recorded as the intensity of exercise increases incrementally. The patient is monitored for the development of symptoms (ie, chest pain, dyspnea, lightheadedness, etc), transient rhythm disturbances, ST segment abnormalities, and other electrocardiographic manifestations of myocardial ischemia. Exercise is terminated with the onset of limiting symptoms, diagnostic electrocardiographic (eg, ST segment) changes, arrhythmias, or a decrease in blood pressure greater than 10 mm Hg. Otherwise, exercise is continued until the patient achieves 85% of his or her maximal predicted heart rate or is unable to exercise further.

Both treadmill and cycle ergometer devices are available for exercise testing. Although cycle ergometers are less expensive, smaller, and quieter than treadmills, quadricep muscle fatigue is a major limitation in patients who are not experienced cyclists, and subjects usually stop cycling before reaching their maximal oxygen uptake. As a result, treadmills are much more commonly used for exercise stress testing, particularly in the United States.

With treadmill testing, the incline and/or speed of the treadmill is increased incrementally every 2 to 3 minutes. Several treadmill exercise protocols have been developed to accommodate the variations in fitness, age, and mobility of individuals. Accordingly, if the exercise capacity is reported in minutes, the details of the protocol should be specified. Alternatively, the translation of exercise duration or workload into metabolic equivalents (METs) (oxygen uptake expressed in multiples of basal oxygen uptake, 3.5 mLO_2/kg/min) has the advantage of providing a common measure of performance regardless of the type of exercise test or protocol used. Most domestic chores and activities require less than 5 METs, whereas participation in strenuous sports, such as swimming, singles tennis, football, basketball, or skiing, requires greater than 10 METs.

Interpretation of the results of exercise testing should include exercise capacity as well as the clinical, hemodynamic, and electrocardiographic responses. The occurrence of chest pain consistent with angina is important, particularly if it results in termination of the test. Abnormalities in exercise capacity, the response of systolic blood pressure to exercise, and the response of heart rate to exercise and recovery may provide valuable information. The most important electrocardiographic findings are ST segment depression and elevation. A positive exercise test is said to have occurred if the ECG shows at least 1 mm of horizontal or downsloping ST segment depression or elevation for at least 60 to 80 milliseconds after the end of the QRS complex.

ST segment changes suggestive of myocardial ischemia that occur at a low level of exercise (less than 6 minutes of exercise or less than 5 METs) are associated with more severe CAD and a worse prognosis than those that occur at a higher workload. An estimate of myocardial oxygen demands can be obtained by calculating the so-called "rate-pressure product" (double product) (ie, heart rate × systolic arterial pressure).

Most treadmill exercise testing is performed in adults with symptoms of known or suspected ischemic heart disease. In patients for whom the diagnosis of CAD is certain, stress testing is often used for risk stratification or prognostic assessment to determine the need for possible coronary angiography or revascularization. Patients who are candidates for exercise testing may (a) have stable chest pain; (b) be stabilized with medical therapy following an episode of unstable chest pain; or (c) be post-myocardial infarction or post coronary revascularization.

The ability of the exercise stress test to identify (or to exclude) individuals with CAD is influenced by (a) their exercise capacity (ie, can the individual perform maximal or nearly maximal exercise?); (b) the presence of baseline ECG abnormalities (ie, bundle-branch block or ST segment depression) that may interfere with evaluation of ST segment changes; (c) medications that affect the ECG or the hemodynamic response to exercise (ie, digoxin and beta-adrenergic blocking agents, respectively); and (d) concomitant cardiac conditions that are associated with ECG abnormalities (ie, left ventricular hypertrophy, paced rhythm, pre-excitation) (**Table e11-5**). Thus, patients who are unable to exercise or who have baseline ECG abnormalities require imaging (ie, radionuclide or echocardiographic) with stress testing to detect (or to exclude) coronary artery disease, since routine stress testing is unreliable in these individuals.

TABLE e11-5 Meta-Analyses of Exercise Testing

Grouping	Number of Studies	Total Number of Patients	Sens (%)	Spec (%)	Predictive Accuracy (%)
Meta-analyses of standard exercise test	147	24,047	68	77	73
Meta-analyses without MI	58	11,691	67	72	69
Meta-analyses without workup bias	3	>1,000	50	90	69
Meta-analyses with ST depression	22	9,153	69	70	69
Meta-analyses without ST depression	3	840	67	84	75
Meta-analyses with digoxin	15	6,338	68	74	71
Meta-analyses without digoxin	9	3,548	72	69	70
Meta-analyses with LVH	15	8,016	68	69	68
Meta-analyses without LVH	10	1,977	72	77	74

Sens, sensitivity; Spec, specificity; MI, myocardial infarction; LVH, left ventricular hypertrophy.

From Gibbons RJ, Balady GJ, Bricker JT, et al. ACC/AHA 2002 Guideline Update for Exercise Testing: A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on Exercise Testing). 2002.

The ability of the exercise stress test to identify the presence of CAD is influenced by the pretest probability of CAD in the population tested. For example, exercise-induced ST segment depression in a 60-year-old man with typical anginal chest pain and multiple risk factors for atherosclerosis (ie, a high pretest probability) is considered a "true-positive" stress test, whereas the same findings in a 30-year-old woman with chest pain believed to be atypical for angina (ie, a low pretest probability) is most likely to be a "false-positive" test. The relatively poor accuracy of the exercise ECG for diagnosing CAD in asymptomatic subjects has led to the recommendation that exercise testing not be used as a screening tool,[29] since false-positive tests are common among asymptomatic adults, especially women, and may lead to unnecessary testing and treatment. Controversy exists as to whether exercise testing should be performed in asymptomatic individuals at increased risk of CAD (ie, diabetics).

Clinical Controversy…

The relatively poor accuracy of the exercise ECG for diagnosing CAD in asymptomatic subjects has led to the recommendation that exercise testing not be used as a screening tool, since false-positive tests are common among asymptomatic adults, particularly women, and may lead subsequently to unnecessary testing and treatment. However, controversy exists as to whether exercise testing should be routinely performed in asymptomatic individuals at increased risk of CVD (ie, diabetics) to identify "silent" (asymptomatic) myocardial ischemia.

The ACC and AHA have jointly developed guidelines describing the indications for exercise stress testing.[29,30]

Exercise stress testing is relatively safe, with an estimated risk of myocardial infarction or death of 1 per 2,500 tests. It should be supervised by a physician or a properly trained health professional working directly under the supervision of a physician, who should be in the immediate vicinity and available for emergencies. Exercise stress testing is contraindicated in subjects who are unable to exercise or who should not exercise because of physiologic or psychological limitations (**Table e11-6**). Although unstable angina is usually a contraindication to exercise stress testing, it can be performed safely once the patient has responded appropriately to intensive medical therapy. Exercise testing is contraindicated in patients with untreated life-threatening arrhythmias or CHF. Patients with comorbid diseases, such as chronic obstructive pulmonary disease or peripheral vascular disease, may be limited in their exercise capacity. For patients with disabilities or other medical conditions that limit their exercise capacity, pharmacologic stress testing (with dipyridamole, adenosine, regadenosen, or dobutamine) is an alternative (see "Pharmacologic Stress Testing" below).

TABLE e11-6 Contraindications to Exercise Testing

Absolute
Acute myocardial infarction (within 2 days)
High-risk unstable angina
Uncontrolled cardiac arrhythmias causing symptoms or hemodynamic compromise
Symptomatic severe aortic stenosis
Uncontrolled symptomatic heart failure
Acute pulmonary embolus or pulmonary infarction
Acute myocarditis or pericarditis

Acute aortic dissection

Relative

Left main coronary stenosis

Moderate stenotic valvular heart disease

Electrolyte abnormalities

Severe arterial hypertension

Tachyarrhythmias or bradyarrhythmias

Hypertrophic cardiomyopathy and other forms of outflow tract obstruction

Mental or physical impairment leading to inability to exercise adequately

High-degree atrioventricular block

Adapted from AHA/ACC guidelines.

Drug therapy is not routinely altered before exercise stress testing, since few data suggest that doing so improves its diagnostic accuracy. Although patients receiving a beta-adrenergic or calcium channel blocker may have a blunted increase in heart rate and blood pressure with exercise, exercise stress testing in such patients nonetheless provides information regarding exercise capacity and ischemic ECG alterations. Nitrates do not directly alter exercise capacity, but they may increase the patient's exercise capacity by preventing or relieving exercise-induced angina. Digoxin produces an abnormal ST segment response to exercise in 25% to 40% of healthy subjects. Because of its long half-life, digoxin should be discontinued for 2 weeks before exercise stress testing to avoid such drug-induced ST segment changes.[30]

Echocardiography

6 Using echocardiography, one can evaluate cardiac function and structure with images produced by ultrasound. High frequency sound waves transmitted from a hand-held transducer "bounce" off tissue and are reflected back to the transducer, where the waves are collected and used to construct a real-time image of the heart.

With the exception of the ECG, echocardiography is the most frequently performed cardiovascular test. It is noninvasive, relatively inexpensive, safe, devoid of ionizing radiation, and portable, so that it can be done at the patient's bedside, in the operating room, or in a physician's office. Serial echocardiograms can be performed, especially following a cardiac procedure or a change in clinical condition, as well as to follow the progression of the underlying cardiac disease over time. It is the procedure of choice for the diagnosis and evaluation of many cardiac conditions, including valvular abnormalities, intracardiac thrombi, pericardial effusions, and congenital abnormalities. Echocardiography often is used to assess chamber sizes, function, and wall thickness. In the patient suspected of having CAD, echocardiography can be performed before, during, and immediately after exercise or pharmacologic stress (eg, dobutamine) to evaluate the presence of ischemia-induced ventricular wall motion abnormalities.

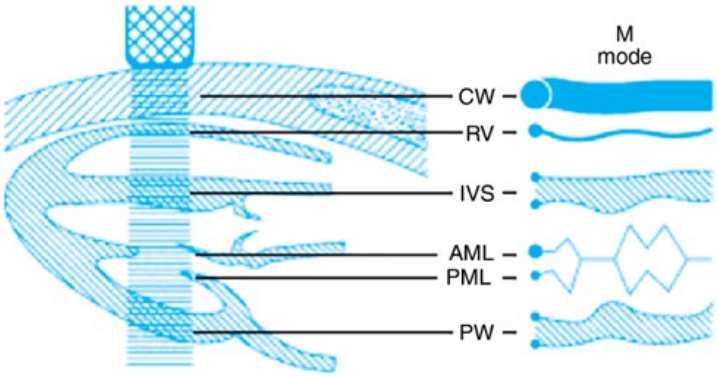
Two approaches to echocardiography are used in clinical practice. Transthoracic echocardiography (TTE) is performed with the transducer positioned on the anterior chest wall, whereas transesophageal echocardiography (TEE) is performed with the transducer positioned in the esophagus. Following transducer placement, several modes of operation are possible: M-mode (motion), two-dimensional (2D), three-dimensional (3D), and Doppler imaging.

With M-mode echocardiography, a transducer placed at a site on the anterior chest (usually along the sternal border) records the images of cardiac structures in one plane, producing a static picture of a small region of the heart, a so-called "ice pick view" (**Fig. e11-12**). Results depend on the exact placement of the transducer with respect to the underlying structures. Conventional M-mode echocardiography provides visualization of the right ventricle, left ventricle, and posterior left ventricular wall and pericardium. If the transducer is swept in an arc from the apex to the base of the heart, virtually the whole heart can be visualized, including the valves and left atrium.

FIGURE e11-12

M-mode echocardiogram. The transducer emits an ultrasound beam, which reflects at each anatomic interface. The reflected wave fronts are detected by the probe, which records the images of cardiac structures in one plane, producing a static picture of a small region of the heart, a so-called "ice pick view." (AML, anterior mitral leaflet; CW, chest wall; IVS, interventricular septum; PML, posterior mitral leaflet; PW, posterior wall; RV, right ventricle.) *(Modified from Hagan AD, DeMaria AN. Clinical Applications of Two-Dimensional Echocardiography*

and Cardiac Doppler. Boston, MA: Little, Brown, 1989, with permission. From Fuster V, O'Rourke RA, Walsh RA, Poole-Wilson P, eds. Hurst's the Heart, *12th ed., http://www.accessmedicine.com. Copyright © The McGraw-Hill Companies, Inc. All rights reserved.)*



Two-dimensional echocardiography employs multiple windows of the heart, and each view provides a wedge-shaped image (**Figs. e11-13** and **e11-14**). These views are processed to produce a motion picture of the beating heart. When compared to M-mode echocardiography, 2D echocardiography provides increased accuracy in calculating ventricular volumes, wall thickness, and the severity of valvular stenoses.

FIGURE e11-13

2D transthoracic echocardiography. *A*. Orientation of the sector beam and transducer position for the parasternal long-axis view of the left ventricle. *B*. 2D image of the heart, parasternal long-axis view. FIGURE e11-14

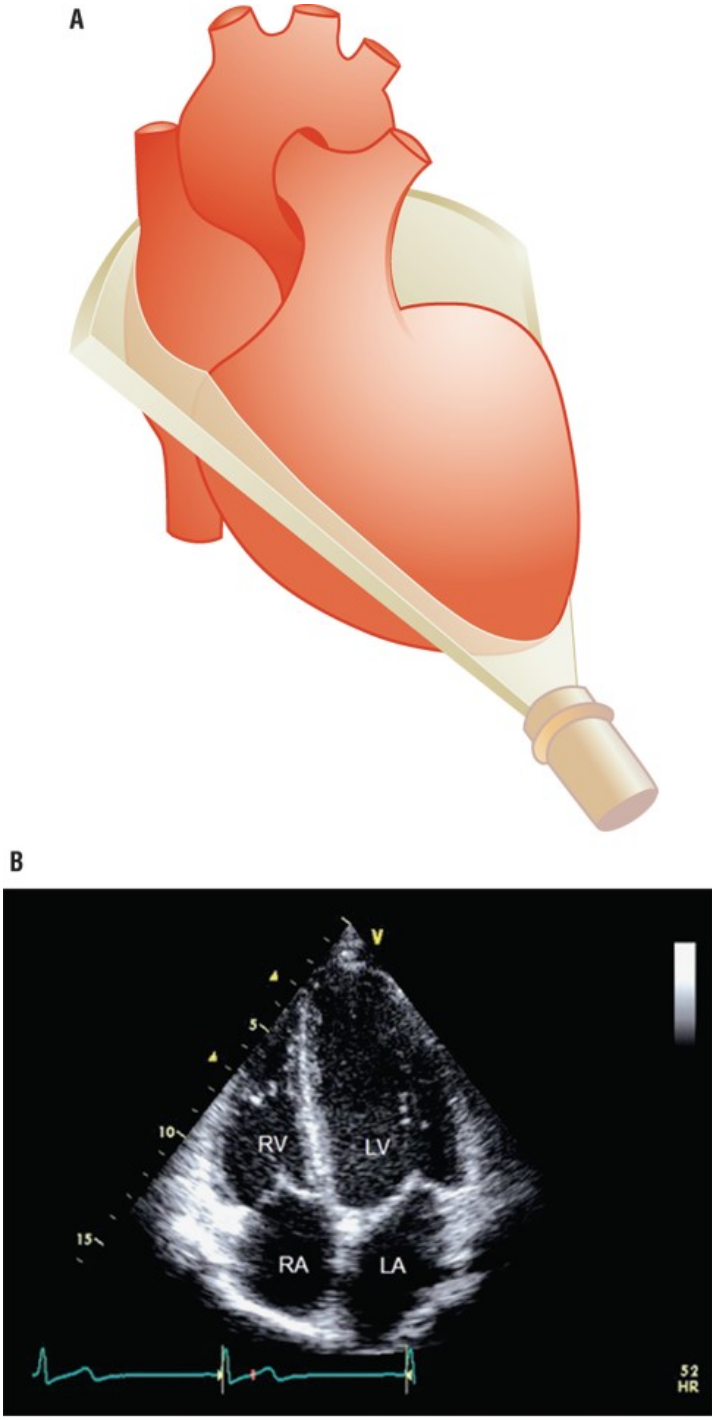
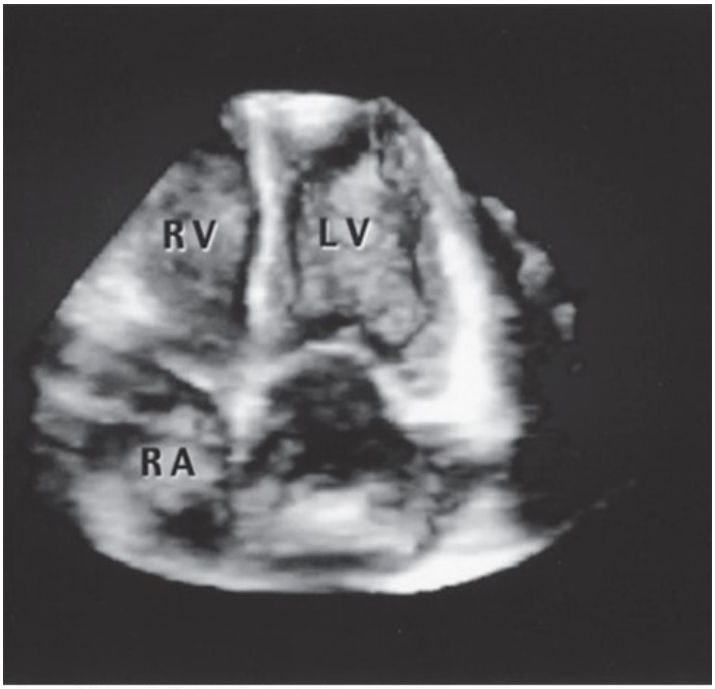
2D transthoracic echocardiography. *A*. Orientation of the sector beam and transducer position for the apical four chamber plane. *B*. 2D image of the apical four chamber plane. (LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.) *(From DeMaria AN, Daniel G, Blanchard DG. Echocardiography. In: Fuster V, O'Rourke RA, Walsh RA, Poole-Wilson P, eds.* Hurst's the Heart, *12th ed. New York: McGraw-Hill, 2004:372.)*



Three-dimensional echocardiography, which uses an ultrasound probe with an array of transducers and an appropriate processing system, enables a detailed assessment of cardiac anatomy and pathology, particularly valvular abnormalities as well as ventricular size and function (**Fig. e11-15**). The ability to "slice" the heart in an infinite number of planes in an anatomically appropriate manner and to reconstruct 3D images of anatomic structures makes this technique very powerful in understanding congenital cardiac conditions.[31]

FIGURE e11-15

Real-time 3D echocardiography image, apical four-chamber plane. *(From DeMaria AN, Daniel G, Blanchard DG. Echocardiography. In: Fuster V, O'Rourke RA, Walsh RA, Poole-Wilson P, eds. Hurst's the Heart, 12th ed. New York: McGraw-Hill, 2004:374.)*



Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

Doppler echocardiography is used to detect the velocity and direction of blood flow by measuring the change in frequency produced when ultrasound waves are reflected from red blood cells. Color enhancement allows blood flow direction and velocity to be visualized, with different colors used for antegrade and retrograde flow. Blood flow moving toward the transducer is displayed in red, and flow moving away from the transducer is displayed in blue; increasing velocity is depicted in brighter shades of each color. Thus, with Doppler echocardiography, information regarding the presence, direction, velocity, and turbulence of blood flow can be acquired. Cardiac hemodynamic variables (eg, intracardiac pressures) and the presence and severity of valvular disease can be assessed noninvasively with Doppler echocardiography.

When TTE is performed, the transducer is placed on the anterior chest wall, and imaging is performed in three orthogonal planes: long axis (from aortic root to apex), short axis (perpendicular to the long axis), and four-chamber (visualizing both ventricles and atria through the mitral and tricuspid valves) (see Figs. 11-13 and 11-14). Sound energy is poorly transmitted through air and bone, and the ability to record adequate images is dependent on a thoracic window that gives the ultrasound beam adequate access to cardiac structures. Accordingly, in approximately 15% of subjects, suboptimal TTE images are obtained, particularly those with large lung volumes (ie, chronic lung disease or those being ventilated mechanically) or marked obesity. In addition, TTE may not provide adequate or complete images of the posterior cardiac structures (ie, left atrium, left atrial appendage, mitral valve, interatrial septum, descending aorta, etc) that are located far away from the transducer.

With TEE, a flexible transducer is advanced into the esophagus and rests just behind the heart, adjacent to the left atrium and descending aorta. When compared with TTE, TEE provides clearer and more detailed images of the mitral valve, left atrium, left atrial appendage, pulmonary veins, and descending thoracic aorta. Because of the transducer's proximity to the heart, TEE allows one to delineate small cardiac structures (ie, vegetations and thrombi less than 3 mm in diameter) that may not be seen with TTE. As a result, TEE often is used to assess the presence of (a) mitral valve vegetations, (b) endocarditis complications (eg, myocardial abscess), (c) left atrial appendage thrombus in the patient with a stroke or under consideration for an elective cardioversion, and (d) aortic dissection.[32,33,34,35,36,37,38] In addition, the transducer can be advanced into the fundus of the stomach to obtain images of the ventricles. TEE is widely used intraoperatively to assess the success of mitral valve repair or replacement and to delineate cardiac anatomy in subjects with congenital heart disease at the time of surgical repair.

Although TEE is a low-risk invasive procedure, complications, such as tearing or perforation of the esophagus, esophageal burns, transient ventricular tachycardia, minor throat irritation, and transient vocal cord paralysis, occur rarely. TEE-related complications in ambulatory, nonoperative settings range from 0.2% to 0.5%, and mortality is less than 0.01%.[39] TEE is contraindicated in patients with esophageal abnormalities, in whom passage of the transducer may be difficult or hazardous (eg, esophageal strictures, tear, tumor, or varices).

The ACC/AHA task force has published guidelines for application of echocardiography and stress echocardiography.[35,40,41]

Nuclear Cardiology

7 Myocardial perfusion imaging, the most commonly performed nuclear cardiology procedure, is used to assess the presence, location, and severity of ischemic or infarcted myocardium. It consists of a combination of (a) some form of stress (exercise or pharmacologic), (b) administration of a radiopharmaceutical, and (c) detection of the radiopharmaceutical in the myocardium with a nuclear camera positioned adjacent to the subject's chest wall.

The most widely used radionuclides are technetium sestamibi or tetrofosmin-99m (^{99m}Tc-sestamibi or ^{99m}Tc-tetroforsmin) and thallium-201 (^{201}Tl). ^{99m}Tc is ideal for clinical imaging because it has a short half-life (about 6 hours) and can be generated in-house with a benchtop generator, thereby providing immediate availability. Because of its short half-life, repeat injections can be given to evaluate the efficacy of reperfusion therapy. ^{201}Tl has a much longer half-life (73 hours), which prevents the use of multiple doses in close temporal proximity but allows for delayed imaging following its administration. The production of ^{201}Tl requires a cyclotron. With both radiopharmaceuticals, myocardial perfusion images are obtained with a conventional gamma camera (see below).

Although both ^{99m}Tc- and ^{201}Tl-labeled compounds are useful for the detection of ischemic or infarcted myocardium, each offers certain advantages. ^{99m}Tc provides better image quality and is superior for detailed single photon emission computed tomography (SPECT) imaging (see below), whereas ^{201}Tl imaging provides superior detection of myocardial cellular viability.

With ^{201}Tl imaging, the radioisotope is injected intravenously as the patient is completing exercise or pharmacologic stress. Since thallium is a potassium analogue, it enters normal myocytes that have an active sodium-potassium ATPase pump (ie, viable myocytes). The intracellular concentration of thallium depends on the perfusion of the tissue and its viability. In the normal heart, homogeneous distribution of thallium occurs in myocardial tissue. Conversely, regions that are scarred due to previous infarction or have stress-induced ischemia do not accumulate as much thallium as normal muscle; as a result, these areas appear as "cold" spots on the perfusion scan.

When evaluating for myocardial ischemia, an initial set of images is obtained immediately after stress and ^{201}Tl injection, and the images are examined for regions of decreased radioisotope uptake. Delayed images are obtained 3 to 4 hours later, since ^{201}Tl accumulation does not remain fixed in myocytes. Continuous redistribution of the isotope occurs across the cell membrane, with (a) differential washout rates between hypoperfused but viable myocardium and normal zones and (b) wash-in to previously hypoperfused zones. Thus, when additional images are obtained after 3 to 4 hours of redistribution, viable myocytes have similar concentrations of ^{201}Tl. Consequently, any uptake abnormalities that were caused by myocardial ischemia will have resolved (ie, "filled in") on the delayed scan and are termed "reversible" defects, whereas those representing scarred or infarcted myocardium will persist as cold spots.

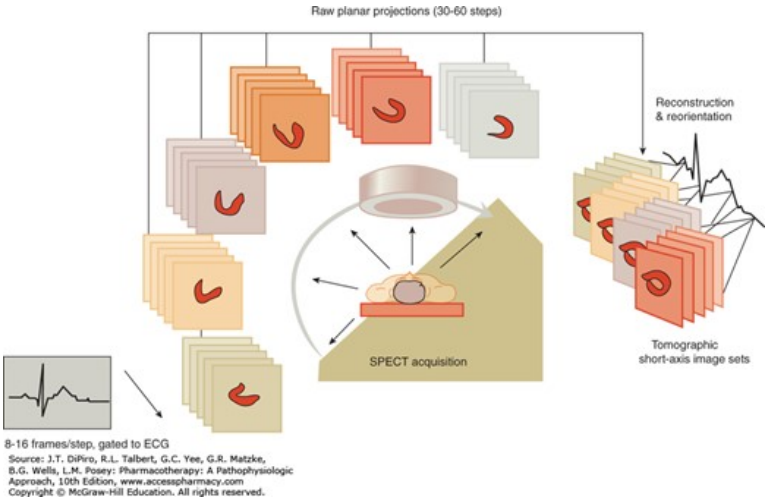
Myocardial segments that demonstrate persistent ^{201}Tl hypoperfusion with stress and redistribution imaging may represent so-called "hibernating myocardium." This markedly hypoperfused myocardium is chronically ischemic and noncontractile but metabolically active; as a result, it has the potential to regain function if perfusion is restored. Hibernating myocardium can often be differentiated from irreversibly scarred myocardium by injecting additional ^{201}Tl to enhance uptake by viable myocytes, then repeating the images 24 hours later.[42,43]

^{99m}Tc-sestamibi—also known as methoxy-isobutyl isonitrile (Tc-MIBI)—is the most widely used ^{99m}Tc-labeled compound. Similar to thallium, its uptake in the myocardium is proportional to blood flow, but its mechanism of myocyte uptake is different, in that it occurs passively, driven by the negative membrane potential. Once intracellular, it accumulates in the mitochondria, where it remains, not redistributing with the passage of time. Therefore, the myocardial distribution of sestamibi reflects perfusion at the moment of its injection. Performing a ^{99m}Tc-sestamibi procedure provides more flexibility than a ^{201}Tl procedure, in that images can be obtained for up to 4 to 6 hours after radioisotope injection and acquired again as necessary. A ^{99m}Tc-sestamibi study is usually performed as a 1-day protocol, with which an initial injection with a small tracer dose and imaging are performed at rest, after which (a few hours later) the patient undergoes a stress test, and repeat imaging is performed after injection of a larger tracer dose.

Myocardial perfusion imaging can be performed with either planar or single photon emission computed tomographic (SPECT) approaches. The planar technique consists of three 2D image acquisitions, usually for 10 to 15 minutes each. With SPECT, the camera detectors rotate around the patient in a circular or elliptical fashion, collecting a series of planar projection images at regular angular intervals (**Fig. e11-16**). The 3D distribution of radioactivity in the myocardium is then "reconstructed" by computer from the 2D projections. Gated SPECT is a further refinement of the process, whereby the projection images are acquired in specific phases of the cardiac cycle based on ECG triggering (so-called "gating"). With gated SPECT, myocardial perfusion and function can be evaluated.

FIGURE e11-16

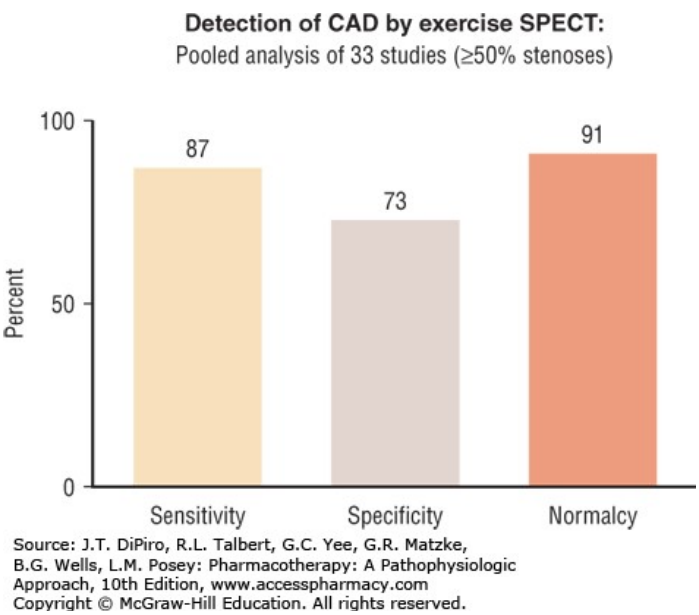
Schematic representation of ECG-gated SPECT imaging and acquisition. *(From Berman DS, Hachamovitch R, Shaw LJ, et al. Nuclear cardiology. In: Fuster V, O'Rourke RA, Walsh RA, Poole-Wilson P, eds.* Hurst's the Heart, *12th ed. New York: McGraw-Hill, 2004:545.)*



Although stress perfusion imaging with ^{99m}Tc- or ^{201}Tl-labeled compounds offers greater sensitivity and specificity than standard exercise electrocardiography for the detection of ischemia (**Fig. e11-17**),[43] they are considerably more expensive and expose the patient to ionizing radiation. As a result, they should be used judiciously. Stress perfusion scans are particularly useful in patients with an underlying ECG abnormality that precludes its accurate interpretation during conventional exercise stress testing, such as patients with a bundle branch block, previous myocardial infarction, baseline ST segment abnormalities, or taking medications that affect the ST segments (eg, digoxin).[44] When compared with standard exercise testing, nuclear perfusion imaging also provides more accurate anatomic localization of ischemia and quantitation of the extent of ischemia.[45]

FIGURE e11-17

Detection of CAD by exercise SPECT: pooled analysis of 33 studies (≥50% stenoses). Sensitivity, specificity, and normalcy rates from a pooled analysis of 33 studies in the literature using exercise single-photon emission computed tomography (SPECT) myocardial perfusion imaging for detection of coronary artery disease (CAD). Note that the normalcy rate, which is derived from the percentage of patients with normal scans who have less than 5% pretest likelihood of CAD, is shown. This normalcy rate of 91% is significantly higher than specificity.[43]



Technetium Scanning

Technetium scanning is used for the evaluation of cardiac function, myocardial perfusion, and the presence of infarcted myocardium.[43,46]

Radionuclide ventriculography—so-called MUGA (multigated acquisition) scanning—is a noninvasive method for determining right and left ventricular systolic function, detecting intracardiac shunting, estimating ventricular volumes, and assessing regional wall motion. For the most part, it has been replaced by other noninvasive techniques (ie, echocardiography and MRI) that provide similar information without ionizing radiation. Nonetheless, it may be performed in the subject in whom suitable echocardiographic images cannot be

obtained or who is unable to undergo an MRI study.

During radionuclide ventriculography, ^{99m}Tc-pertechnate is introduced into the blood stream and imaged as it circulates through the heart. The resulting images of the blood pool in the cardiac chambers are analyzed by computer to calculate right and left ventricular ejection fractions.

The radioactive marker can be introduced to the patient's blood in vivo or in vitro. With the in vivo method, stannous (tin) ions are injected intravenously, after which an intravenous injection of ^{99m}Tc-pertechnate labels the red blood cells in vivo. With the in vitro method, an aliquot of the patient's blood is withdrawn, to which the stannous ions and ^{99m}Tc-pertechnate are added, after which the labeled blood is reinfused into the patient. The stannous chloride is given to prevent the technetium from leaking from the red blood cells.

Once the radiolabeled red blood cells are circulating, the patient is placed under a gamma camera, which detects the radioactive ^{99m}Tc. As the images are acquired, the patient's heart beat is used to "gate" the acquisition, resulting in a series of images of the heart at various stages of the cardiac cycle.

Depending on the objectives of the test, the operator may decide to perform a resting or a stress MUGA. During the resting MUGA, the patient lies stationary, whereas during a stress MUGA, the patient is asked to exercise on a supine bicycle ergometer as images are acquired. The stress MUGA allows the operator to assess cardiac performance at rest and during exercise. It is usually performed to assess the presence of suspected coronary artery disease.

Infarct-avid radionuclides, such as technetium-pyrophosphate (^{99m}Tc-PYP), are used to assess the presence and extent of infarcted myocardium. Since ^{99m}Tc-PYP binds to calcium that is deposited in the infarcted area, it is known as *hot-spot scanning*. Hot spots appear where necrotic myocardial tissue is present, which may occur with recent myocardial infarction, myocarditis, myocardial abscesses, and myocardial trauma. Additionally, ^{99m}Tc-PYP uptake has been observed on occasion in patients with unstable angina, severe diabetes mellitus, and cardiac amyloidosis.

Uptake of ^{99m}Tc-PYP by necrotic myocardium is first detectable about 12 hours after the onset of myocardial infarction, with a peak intensity of ^{99m}Tc-PYP at 48 hours. Washout occurs over 5 to 7 days, so ^{99m}Tc-PYP is a useful late marker of infarction, especially in the patient suspected of having a painless (eg, "silent") infarction.

Pharmacologic Stress Testing

In the patient undergoing myocardial perfusion imaging for the evaluation of coronary artery disease, exercise stress is preferred over pharmacologic stress, since it allows an assessment of the patient's exercise capacity, symptoms, ST segment changes, and level of exertion that results in ischemia. In the individual who is unable to exercise adequately (because of orthopedic limitations or inability to ambulate), a pharmacologic stress test can be performed in conjunction with various imaging modalities, such as thallium planar scanning, SPECT, MRI, or echocardiography.[43,44,45]

Vasodilator Stress Testing

The vasodilators—dipyridamole, adenosine, and regadenosen—are the preferred pharmacologic stress agents for myocardial perfusion imaging. Following the administration of one of these, blood flow increases 3- to 5-fold in undiseased coronary arteries and minimally, or not at all, in arteries with flow-limiting stenoses. Since radioisotope uptake by the myocardium is directly related to coronary arterial blood flow, the region of myocardium perfused by an artery with a flow-limiting stenosis appears as a "cold spot" on the nuclear perfusion scan following vasodilator administration.

Adenosine and regadenosen dilate coronary arteries by binding to specific adenosine receptors on smooth muscle cells in the coronary arterial media. Dipyridamole causes coronary vasodilatation by blocking the cellular uptake of adenosine, thereby increasing the extracellular adenosine concentration. Currently, adenosine and regadenosen are used more often than dipyridamole because of their rapid onset and termination of action. Since methylxanthines (ie, caffeine and theophylline) block adenosine binding and can interfere with the vasodilatory effects of these agents, foods and beverages containing caffeine should not be ingested during the 24 hours before their administration.

During a vasodilator stress test, the patient normally manifests a modest increase in heart rate, a fall in blood pressure, and no or minimal electrocardiographic changes. Chest pain, shortness of breath, flushing, and dizziness occur commonly during vasodilator administration. As a result, the symptomatic, hemodynamic, and electrocardiographic responses to vasodilator administration do not provide insight into the presence or absence of coronary artery disease.

Dipyridamole is administered intravenously at 0.142 mg/kg/min for 4 minutes, with the maximal effect occurring 3 to 4 minutes after the

infusion has ended. Adenosine is administered intravenously at 0.140 mg/kg/min for 6 minutes, with the maximum effect occurring 30 seconds after the infusion is completed. Regadenosen has a 2- to 3-minute biological half-life—as compared with adenosine's 30-second half-life—so it is administered as a 0.4 mg intravenous bolus (given in less than 10 seconds) followed immediately by a saline flush. At the end of the dipyridamole infusion or regadenosen injection or 3 minutes after initiation of adenosine infusion, thallium is administered, after which nuclear imaging follows immediately and can be repeated 24 hours later to distinguish scarred from hibernating myocardium.

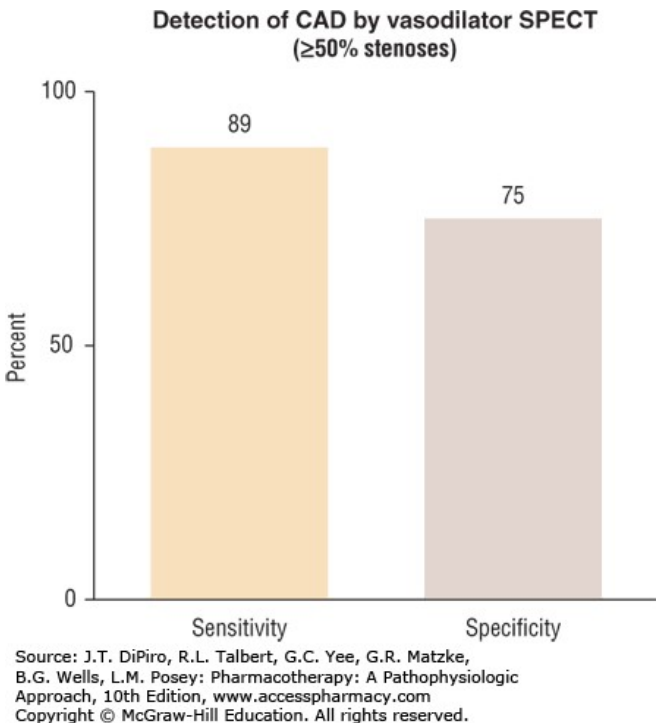
Since these agents may induce severe bronchospasm in subjects with a history of asthma, they should not be administered to such individuals. With adenosine and regadenosen, advanced AV block may occur. Fortunately, severe side effects are rare, occurring in only 1 in 10,000 patients receiving these agents, and they usually are reversed with intravenous aminophylline, 75 to 125 mg.

In the patient referred for stress testing to assess the presence of CAD, pharmacologic stress is indicated for those unable or with a contraindication to exercise. This includes patients with (a) a chronic debilitating illness, such as pulmonary, liver, or kidney disease; (b) older age and decreased functional capacity; (c) limited exercise capacity due to injury, arthritis, orthopedic problems, neurologic disorders, myopathic diseases, or peripheral vascular disease; (d) an acute coronary syndrome; (e) postoperative state; and (f) beta-blocker or other negative chronotropic agents that interfere with the subject's ability to achieve an adequate increase in heart rate in response to exercise.

Pharmacologic stress testing has a similar sensitivity and specificity to exercise stress testing (**Fig. e11-18**). In an analysis of 17 studies of almost 2,000 patients, pharmacologic stress testing had a sensitivity of 89% and a specificity of 75% for detecting ischemic heart disease.[43]As with routine stress testing, the sensitivity and specificity are affected by the prevalence and pretest likelihood of CAD in the population being studied.

FIGURE e11-18

Detection of CAD by vasodilator SPECT (stenoses of 50% or greater). Sensitivity and specifi city for detection of coronary artery disease (CAD) by vasodilator stress. The definition of a significant lesion was 50% or greater stenosis by coronary angiography. These data represent a pooled analysis from the literature.[43] (SPECT, single-photon emission computed tomography)



Dobutamine Stress Testing

The patient who is not a candidate for vasodilator stress testing (because of a history of bronchospasm, advanced AV block, or recent caffeine ingestion) or does not desire infusion of a radiopharmaceutical may undergo a dobutamine stress test with echocardiographic imaging. Dobutamine, a synthetic catecholamine, is an inotropic agent that increases heart rate and myocardial contractility, thereby increasing myocardial oxygen demands. In regions of the heart where myocardial oxygen supply is insufficient to meet the increased demands (because of a flow-limiting stenosis in the coronary artery supplying that region) ischemia develops and causes regional abnormalities in contraction that may be observed with echocardiography.

When used for stress testing, dobutamine is infused at 5 mcg/kg/min for 3 minutes, followed by infusions of 10, 20, 30, and 40 mcg/kg/min each at 3 minutes until a target heart rate is achieved. To achieve a further increase in myocardial oxygen demands, atropine (0.5-1 mg) may be injected to augment the dobutamine-induced increase in heart rate, and handgrip exercise may be performed concomitantly to achieve an increase in blood pressure. The ECG and blood pressure are monitored throughout the test, and echocardiographic images are obtained during the last minute of each dobutamine dose infusion and during recovery. For the patient with suboptimal echocardiographic images, dobutamine stress testing may be combined with radionuclide perfusion imaging, in which case thallium is injected 2 to 3 minutes before completion of the dobutamine infusion.

Since beta-blocker and calcium channel blocker therapy may interfere with the heart rate response to dobutamine, it is recommended that they be discontinued before the test. Dobutamine stress testing is relatively well tolerated, with ventricular irritability occurring rarely (0.05%). The dobutamine infusion is discontinued with the appearance of severe chest pain, extensive new wall motion abnormalities, ST segment changes suggestive of severe ischemia, tachyarrhythmias, or a symptomatic fall in systemic arterial pressure. Beta-blockers can be used to reverse most adverse effects if they persist. Dobutamine stress testing is contraindicated in patients with aortic stenosis, uncontrolled hypertension, and severe ventricular arrhythmias.

A review of 37 studies of 3,280 patients reported that dobutamine stress testing had a sensitivity of 82% and a specificity of 84% for detecting CAD (**Fig. e11-19**). The sensitivity was highest in subjects with three vessels CAD (92%).[47]

FIGURE e11-19

Sensitivity and specificity for exercise and dobutamine echocardiography. Note a slightly higher sensitivity for exercise echo compared with dobutamine echo.[47]

Computed Tomography

Computed tomographic (CT) scanning is becoming increasingly popular as a primary screening procedure in the evaluation of individuals with suspected or known CVD, since it provides similar information as other diagnostic modalities, such as echocardiography and catheterization and echocardiography, yet it is less invasive than the latter.[48,49,50] In recent years, technologic advances have enhanced CT's definition and spatial resolution of cardiac structures, such as coronary arteries, valves, pericardium, and cardiac masses. In addition, CT provides an accurate measurement of chamber volumes and sizes as well as wall thickness.

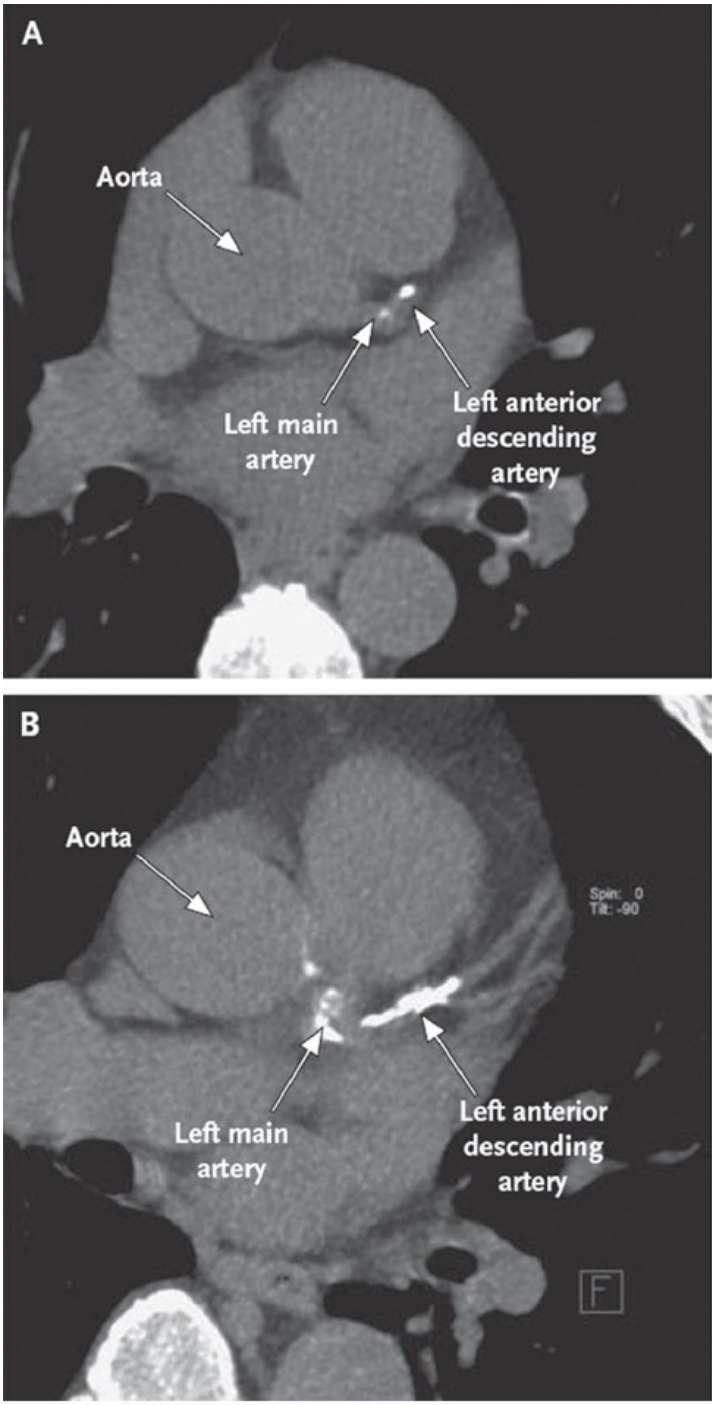
CT scanners produce images by rotating an X-ray beam around a circular gantry (eg, opening), through which the patient advances on a moving couch. Two types of CT scanners are used for cardiac imaging: electron beam computed tomography (EBCT) and mechanical CT.[50] With EBCT, the electron X-ray tube remains stationary, and the electron beam is swept electronically around the patient. With mechanical or conventional CT, the X-ray tube itself rotates around the patient, and the use of multirow detector systems rays (ie, multislice CT) allows acquisition of up to 320 simultaneous images, each 0.5 mm in thickness. With either type of CT, the image acquisition is gated to the ECG to minimize radiation exposure, and cardiac images are obtained at end inspiration (ie, during a breath hold) to minimize artifact caused by cardiac motion.

Since EBCT has no moving parts, it requires a shorter image acquisition time and exposes the patient to less radiation when compared with conventional CT (less than 1.0 rad vs 15 rads, respectively). With EBCT, image resolution is sufficient to assess global and regional ventricular function and coronary anatomy, but it is insufficient to provide an accurate assessment of the presence and severity of CAD. However, it can reliably detect the presence and extent of coronary arterial calcification, which is expressed as a coronary artery calcium

score in Agatston units (**Fig. e11-20**). Although the presence of coronary arterial calcification correlates with the total atherosclerotic plaque burden in epicardial coronary arteries, it does not predict the presence or location of flow-limiting (greater than 50% luminal diameter narrowing) coronary arterial stenoses, nor does the lack of coronary arterial calcium exclude the presence of atherosclerotic plaque.[48,49,50]

FIGURE e11-20

CT scans of the left coronary artery in two asymptomatic men. Two asymptomatic men, 51 and 81 years of age, underwent coronary artery calcium (CAC) imaging with multidetector CT. There is calcification of the left main and proximal left anterior descending coronary arteries in both the younger patient (*A*) and the older patient (*B*). The CAC score for the younger man, although relatively low at 80, places him in the 85th percentile for severity of CAC for men in his age group. The older man's CAC score is higher, at 1,054, but the severity of his CAC relative to that for men in his age group is lower—in the 70th percentile. *(From Bonow RO. Should coronary calcium screening be used in cardiovascular prevention strategies?* N Engl J Med *2009;361:990-997. Copyright © 2009 Massachusetts Medical Society. All rights reserved.)*



Source: J.T. DiPiro, R.L. Talbert, G.C. Yee, G.R. Matzke, B.G. Wells, L.M. Posey: Pharmacotherapy: A Pathophysiologic Approach, 10th Edition, www.accesspharmacy.com

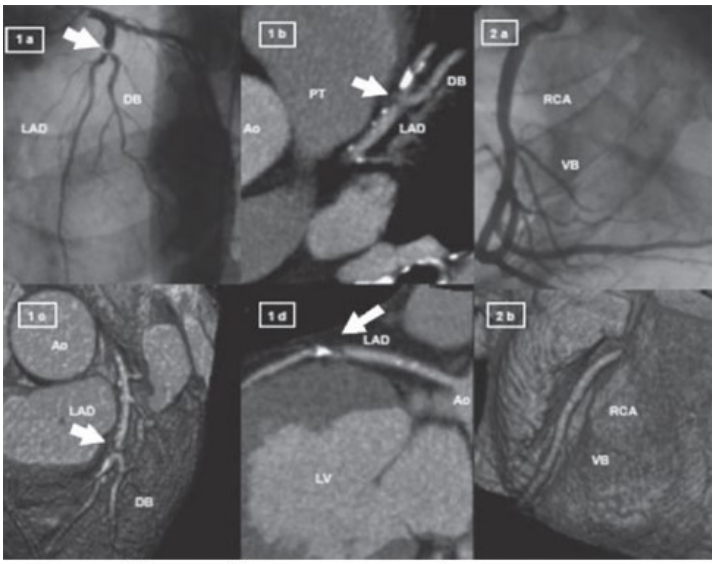
The distribution of calcification scores in populations of individuals without known heart disease has been studied extensively. These studies have shown that the amount of coronary arterial calcification increases with age, and men typically develop calcification 10 to 15 years earlier than women.[50] Coronary arterial calcification is detectable in the majority of asymptomatic men older than 55 years and women older than 65 years. The person who undergoes coronary calcium screening with EBCT receives a score in Agatston units as well as a calcium score percentile, with which his/her score is compared to a population of subjects of similar age and gender.

Unlike EBCT, multislice CT has sufficient resolution to visualize the coronary arteries (**Fig. e11-21**). To accomplish this, radiographic contrast material is administered intravenously, and a beta-blocker is given to slow the heart rate to less than 70 bpm in order to minimize motion artifact. Compared with conventional coronary angiography, cardiac CT has a sensitivity of 85%, a specificity of 90%, a positive predictive value of 91%, and a negative predictive value of 83% for detecting or excluding a coronary arterial stenosis of 50% or more luminal diameter narrowing.[51] It has limited diagnostic utility in patients with extensive coronary arterial calcification or a rapid heart rate, due to artifacts caused by high-density calcified coronary arterial stenoses or cardiac motion, respectively. Vessels with a luminal diameter less than 1.5mm cannot be assessed reliably with cardiac CT, since the resolution is insufficient. Recent advances in

cardiac CT technology have enabled the assessment of the physiologic significance of coronary arterial stenoses using myocardial CT perfusion imaging.[52]

FIGURE e11-21

Sixteen-slice MDCT in a 49-year-old man with chest pain. (*1a*) Coronary angiography showing a severe stenosis in the left anterior descending (LAD) artery. (*1b*) MDCT axial slice visualizing high-grade stenosis (arrow) and calcifi cation. (*1c*) MDCT three-dimensional volume-rendering technique showing the LAD stenosis. (*1d*) MDCT curved multiplanar reconstruction of the LAD. (*2a*) Coronary angiography of the right coronary artery (RCA), which is normal. (*2b*) MDCT volumerendering technique of RCA. (Ao, aorta; DB, diagonal branch; LV, left ventricle; MDCT, multidetector computed tomography; PT, pulmonary trunk; VB, ventricular branch.) *(Reproduced with permission from Berman DS, Hachamovitch R, Shaw LJ, et al. Roles of nuclear cardiology, cardiac computed tomography, and cardiac magnetic resonance: Assessment of patients with suspected coronary artery disease.* J Nucl Med *2006;47:74-82.)*



Independent of its use in assessing coronary arteries, cardiac CT often is used in the subject with suspected aortic dissection, in whom its accuracy in detecting dissection is greater than 90%. In the patient with possible constrictive pericarditis, the pericardium can be evaluated for thickening and calcification. In the patient with a possible cardiac mass, CT scanning allows one to assess the size and location of the mass, and tissue density differentiation may aid in its characterization. Cardiac CT can be used to calculate left ventricular volumes, ejection fraction, and mass, and these measurements obtained with CT scanning are superior in accuracy and reproducibility to those obtained with echocardiography or angiography. CT scans allow visualization of congenital heart defects. Although MRI may provide similar information without exposing the patient to ionizing radiation, many patients have contraindications to MRI (ie, those with an implanted metallic device). In such patients, cardiac CT is an alternative method for visualizing cardiac anatomy.

Positron Emission Tomography

Positron emission tomography (PET) is a relatively new modality for diagnostic imaging in patients with suspected or known CVD. Among imaging techniques, it is unique in its ability (a) to provide quantitative imaging with high temporal resolution; (b) to image a large number of physiologically active radiotracers; and (c) to apply tracer kinetic principles so that in vivo imaging can be performed. With PET, myocardial metabolic activity, perfusion, and viability can be assessed.[42,43] Using appropriate positron-emitting biologically active tracers, PET can measure regional myocardial uptake of exogenous glucose and fatty acids, quantitate free fatty acid metabolism, ascertain myocardial energy substrates, and evaluate myocardial chemoreceptor sites.

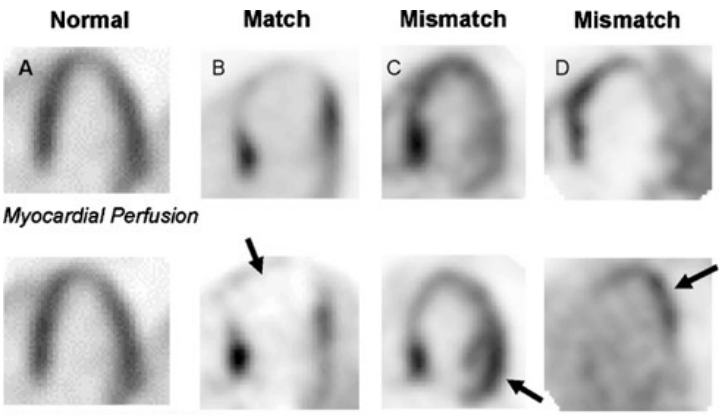
In the fasting state (ie, low serum glucose and insulin concentrations), fatty acids are the preferred energy source of the myocardium. Following the ingestion of carbohydrate, serum glucose and insulin concentrations increase, and glucose becomes the preferred myocardial fuel. Glucose also is the major myocardial fuel during ischemia, since ischemia impairs mitochondrial fatty acid oxidation. Using positron-emitting isotopes, such as oxygen-15 (^{15}O-oxygen), carbon-11 (^{11}C-palmitate or ^{11}C acetate), and fluoride-18 (^{18}F-fluorodeoxyglucose), myocardial oxygen consumption and substrate utilization can be measured, from which ischemic and nonischemic regions of the heart can be identified.[42] PET usually is used in conjunction with pharmacologic stress testing to provoke ischemia, with images obtained before and after stress.

Tracers such as rubidium 82 (^{82}Rb) and nitrogen 13 (^{13}N) are retained in the myocardium in proportion to blood flow. PET imaging with these agents allows one to measure myocardial blood flow at rest and during pharmacologically induced hyperemia. Thus, PET can be used to assess the physiologic significance of coronary arterial stenoses, which is useful when attempting to determine if a luminal diameter narrowing of intermediate severity (50%-70%) is causing ischemia.

In the patient with noncontractile myocardium, PET is considered to be the "gold standard" technique for distinguishing infarcted myocardium from chronically ischemic, metabolically active myocardium that has the potential to regain function if perfusion is restored (so-called "hibernating myocardium").[42] Myocardial infarction and ischemia can be distinguished by analysis of PET images of the glucose analog ^{8}F-fluorodeoxyglucose (FDG), which is injected after glucose administration, and the perfusion tracer ^{13}N-ammonia. Regions that show a concordant reduction in myocardial blood flow and FDG uptake ("flow-metabolism match") are considered to be irreversibly injured, whereas regions in which FDG uptake is relatively preserved or increased despite a perfusion defect ("flow-metabolism mismatch") are considered to be ischemic (**Fig. e11-22**). This approach more accurately predicts recovery of regional function after revascularization than does SPECT imaging. The magnitude of improvement in heart failure symptoms after revascularization in patients with left ventricular dysfunction correlates with the preoperative extent of FDG "mismatch."[53]

FIGURE e11-22

Patterns of myocardial perfusion (*upper panel*) and metabolism (with ^{18}F-fluorodeoxyglucose [^{18}F-FDG]; *lower panel*). *A*. Normal myocardial perfusion and metabolism. *B*. Severely reduced myocardial perfusion in the anterior wall associated with a concordant reduction in ^{18}F-FDG uptake (arrow), corresponding to a match. *C*. Mildly reduced perfusion in the lateral and posterior lateral wall associated with a segmental increase in glucose metabolism (mismatch). *D*. Severely reduced myocardial perfusion in the lateral wall with a segmental increase in ^{18}F-FDG uptake (arrow), reflecting a perfusion metabolism mismatch. *(From Schelbert HR. Positron emission tomography for the noninvasive study and quantitation of myocardial blood flow and metabolism in cardiovascular disease. In: Fuster V, O'Rourke RA, Walsh RA, Poole-Wilson P, eds.* Hurst's the Heart*, 12th ed. New York: McGraw-Hill, 2004:675.)*



The main strengths of PET compared with SPECT are its superior spatial resolution and ability to assess myocardial viability accurately.[42,43] The limited availability of PET scanners and the need for a cyclotron on site are its main limitations.

Cardiac Catheterization and Angiography

9 Cardiac catheterization plays a pivotal role in the evaluation of patients with suspected or known cardiac disease; in addition, it has become an important therapeutic alternative to cardiac surgery in many patients who require nonmedical therapy.

Indications

Diagnostic cardiac catheterization is appropriate under several conditions. First, it is often performed to confirm or to exclude the presence of a cardiac condition that is suspected from the patient's history, physical examination, or noninvasive evaluation. In such a circumstance, it allows an assessment of the presence and severity of cardiac disease. For example, in a subject with progressive angina pectoris or a positive exercise stress test, coronary angiography allows the physician to visualize the coronary arteries sufficiently to assess the presence and extent of coronary artery disease. Second, catheterization is often helpful in the patient with a confusing or difficult clinical presentation in whom the noninvasive evaluation is inconclusive. For instance, a hemodynamic evaluation or coronary angiography may be useful in the patient with unexplained dyspnea. Third, data obtained at catheterization may provide prognostic

information that is helpful in guiding therapy. Such is the case, for example, in the patient with cardiomyopathy, in whom the hemodynamic data obtained at catheterization are used to guide medical therapy and to assess the need for and timing of cardiac transplantation.

Contraindications

The only absolute contraindication to catheterization is the refusal of a mentally competent subject to provide informed consent. Relative contraindications (**Table e11-7**) mostly involve conditions in which the risks of the procedure are increased or the information obtained from it is potentially unreliable. In these circumstances, the benefits of having the data that are obtained at catheterization must be weighed against the procedure's increased risks. Catheterization usually is not performed in the patient who refuses therapy for the condition for which diagnostic catheterization is recommended.

TABLE e11-7 Relative Contraindications to Cardiac Catheterization

Decompensated heart failure (eg, pulmonary edema)
Uncontrolled ventricular irritability
Uncontrolled systemic arterial hypertension
Acute or severe renal insufficiency
Difficulty with vascular access
Electrolyte imbalance (ie, hypokalemia or hyperkalemia)
Digitalis intoxication
Active infection or febrile illness
Uncorrected bleeding diathesis
Severe anemia
Active bleeding from internal organ
Severe allergy to radiographic contrast material
Mental incompetence

Complications

Because catheterization is an invasive procedure, its performance is associated with major and minor risks. The incidence of a major complication (death, myocardial infarction, or cerebrovascular accident) during or within 24 hours of diagnostic catheterization is 0.2% to 0.3%. Deaths, which occur in 0.1 to 0.2% of patients, may be caused by perforation of the heart or great vessels, cardiac arrhythmias, acute myocardial infarction, or anaphylaxis to radiographic contrast material.

Numerous minor complications may cause morbidity but exert no effect on mortality. Local vascular complications occur in 0.5% to 1.5% of patients. The injection of radiographic contrast material occasionally is associated with allergic reactions of varying severity, and a rare individual has anaphylaxis. Of patients with a known allergy to contrast material, only about 15% have an adverse reaction with its repeat administration, and most of these reactions are minor (eg, urticaria, nausea, vomiting). In most patients with a previous allergic reaction to radiographic contrast material, angiography can be performed safely, but premedication with glucocorticosteroids and antihistamines and the use of a different contrast material usually are recommended. Use of excessive quantities of radiographic contrast material may result in renal insufficiency, particularly in patients with preexisting renal dysfunction and diabetes mellitus.

Techniques

Cardiac catheterization is generally performed with the patient in the fasting state and mildly sedated. Anticoagulants are discontinued before the procedure (warfarin, dabigatran, rivaroxaban or and apixaban for several days; heparin for 4-6 hours; and enoxaparin for 12 hours). Cardiac catheterization requires vascular access, which is usually obtained percutaneously via the femoral, brachial, or radial vessels.

With the *percutaneous approach,* the area overlying the vessel is aseptically prepared and locally anesthetized. The vessel is punctured with a needle, through which a flexible metal wire is advanced into the vessel's lumen, over which a sheath with a sideport extension is

advanced into the vessel. The sideport extension allows continuous monitoring of arterial pressure (through an arterial sheath) or infusion of fluids (through a venous sheath) as catheters are advanced through the sheath to the heart. When the procedure is completed, the catheters and sheaths are removed, after which local pressure is applied or a closure device is used to achieve hemostasis. If the femoral approach is used, the patient remains at bed rest for 2 to 8 hours to minimize the chance of hemorrhage. With the radial and brachial approach, bed rest following sheath removal is not necessary.

During routine right heart catheterization, measurements of pressures and blood oxygen saturations in the vena cavae, right atrium, right ventricle, pulmonary artery, and pulmonary capillary wedge position can be performed, and cardiac output can be quantified (**Table e11-8** lists normal values). The measurement of right-sided pressures helps the physician to evaluate the severity of tricuspid or pulmonic stenosis, to assess the presence and severity of pulmonary hypertension, and to calculate pulmonary vascular resistance. In the absence of pulmonary vein stenosis (a rare condition), the pulmonary capillary wedge pressure accurately reflects the left atrial pressure. Occasionally angiography is performed to define right-sided anatomic abnormalities or to evaluate the severity of right-sided valvular regurgitation.

TABLE e11-8 Normal Hemodynamic Values

Measurement	Value
Flows	
Cardiac index (L/min/m^2)	2.6-4.2
Stroke volume index (mL/m^2)	35-55
Pressures (mm Hg)	
Aorta/systemic artery	
Peak systolic/end-diastolic	100-140/60-90
Mean	70-105
Left ventricle	
Peak systolic/end-diastolic	100-140/3-12
Left atrium (PCW)	
Mean	1-10
a wave	3-15
v wave	3-15
Pulmonary artery

Oxygen consumption (mL/min/m^2)	110-150
AV O_2 difference (mL/dL)	3-4.5

AV, arteriovenous; PCW, pulmonary capillary wedge.

With left heart catheterization, mitral and aortic valvular function, left ventricular pressures and function, systemic vascular resistance, and coronary arterial anatomy can be assessed. To perform angiography or to measure the pressure in the left ventricle, a catheter is usually advanced retrograde across the aortic valve.

Hemodynamic Measurements

Cardiac Output

The blood flow measurement most often performed during catheterization is the quantitation of cardiac output. This variable allows an assessment of overall cardiovascular function, vascular resistances, valve orifice areas, and valvular regurgitation. In the catheterization laboratory, the three common methods of measuring cardiac output are the Fick principle, the indicator dilution technique, and angiography.

Fick Principle

The Fick principle is based on the fact that when a substance is consumed by an organ, its concentration is the product of blood flow to the organ and the substance's arteriovenous difference across the organ. Using the lungs as the organ of interest and oxygen as the substance, one can calculate pulmonary blood flow (eg, cardiac output) using the formula:

$$\text{Cardiac output (L/min)} = \text{Oxygen consumption (mL/min)} / \text{Arteriovenous oxygen difference (mL/L)}$$

Oxygen consumption is measured by analyzing the patient's exhaled air, and the arteriovenous oxygen difference is calculated by measuring the oxygen content in a blood sample procured from the aorta and the pulmonary artery.

Dilution Method

With indicator dilution, a known amount of indicator is injected as a bolus into the circulation and allowed to mix completely in the blood, after which its concentration is measured. A time-concentration curve is generated, and a minicomputer calculates the cardiac output from the area of the inscribed curve. The most widely used indicator for the measurement of cardiac output is cold solution. A balloon-tipped, flow-directed, polyvinyl chloride catheter (a so-called "Swan-Ganz catheter") with a thermistor at its tip and an opening 25 to 30 cm proximal to the tip is inserted into a vein and advanced to the pulmonary artery, so that the proximal opening is located in the vena cavae or right atrium and the thermistor is in the pulmonary artery. A known amount of cold fluid is injected through the proximal port; it mixes completely with blood in the right ventricle and causes a change in blood temperature, which is detected by the thermistor. The thermodilution method is relatively inexpensive, easy to perform, and does not require arterial sampling or blood withdrawal.

Angiographic Method

From the left ventriculogram, the volume of blood ejected with each heartbeat (stroke volume) can be determined. It is then multiplied by the heart rate, yielding the angiographic cardiac output. The measurement of cardiac output by the angiographic method is potentially erroneous in patients with extensive segmental wall motion abnormalities or misshapen ventricles, in whom the determination of stroke volume may be inaccurate.

Pressures

One of the most important functions of cardiac catheterization is to measure intracardiac pressures. Once a catheter is positioned in a cardiac chamber, it is connected through fluid-filled, stiff, plastic tubing to a pressure transducer, which transforms the pressure signal into an electrical signal that is recorded. During catheterization, pressures are usually measured directly from each of the cardiac chambers: right atrium, right ventricle, pulmonary artery, ascending aorta, and left ventricle. Because the left atrial pressure is transmitted to the pulmonary capillaries, it can be recorded "indirectly" as the pulmonary capillary "wedge" pressure. In addition to measuring pressures from each cardiac chamber, pressures from certain chambers are examined simultaneously to identify or to exclude a gradient between them indicative of valvular stenosis.

Resistances

The resistance of a vascular bed is calculated by dividing the pressure gradient across the bed by the blood flow through it. Thus,

$$\text{Systemic vascular resistance} = (\text{Mean systemic arterial pressure} - \text{mean right atrial pressure}) / \text{Sytemic blood flow}$$

and

$$\text{Pulmonary vascular resistance} = (\text{Mean pulmonary arterial pressure} - \text{mean left atrial pressure}) / \text{Pulmonary blood flow}$$

Because a properly obtained pulmonary capillary wedge pressure is similar to left atrial pressure, it can be substituted for it in the above equation. These formulae express resistances in arbitrary resistance units. Most often, these values are multiplied by 80 to express them in metric units of dynes-sec-cm^{-5}. Normal values are displayed in Table e11-8.

An elevated systemic vascular resistance is often present in the patient with systemic arterial hypertension. It may also be observed in patients with a reduced forward cardiac output and compensatory arteriolar vasoconstriction (often seen in patients with heart failure). Conversely, systemic vascular resistance may be reduced in patients with arteriolar vasodilation (due, for example, to sepsis) or those with an increased cardiac output (due, for example, to an arteriovenous fistula, severe anemia, fever, or thyrotoxicosis). An elevated pulmonary vascular resistance often is observed in patients with primary lung disease, pulmonary vascular disease, and a greatly elevated pulmonary venous pressure resulting from left-sided myocardial or valvular dysfunction.

Angiography

During angiography, radiographic contrast material is injected into the cardiovascular structure of interest, and the images are digitally recorded and stored on a computer-accessible medium (ie, CD-ROM, DVD, external memory drives, etc). The resultant angiogram permits the study of cardiac structures in real time, in slow motion, or by single frame.

Left Ventriculography

With angiography of the left ventricle, global and segmental left ventricular function, left ventricular volumes and ejection fraction, and the presence and severity of mitral regurgitation can be assessed. A segment of the left ventricular wall with reduced systolic motion is said to be hypokinetic; a segment that does not move is akinetic; and a segment that moves paradoxically during systole is dyskinetic.

Coronary Angiography

Selective coronary angiography is usually performed to determine the presence and severity of fixed, atherosclerotic CAD and to guide subsequent percutaneous (eg, angioplasty with or without stent placement) or surgical (eg, bypass grafting) therapy. Under fluoroscopic guidance, the ostia of the native right and left coronary arteries or bypass grafts are engaged selectively with a catheter, and radiographic contrast material is injected manually during digital image recording. Because atherosclerotic coronary arterial stenoses are often eccentric and the coronary vessels often overlap one another, images are obtained in multiple obliquities, thereby ensuring a complete angiographic assessment of each arterial segment.

Coronary angiography provides radiographic images of the coronary lumina but does not visualize the actual arterial walls. A stenosis is present when a discrete reduction in luminal diameter is noted, and its severity is assessed by comparing it with presumably normal adjacent segments of the same artery. Thus, if atherosclerosis is diffuse and involves the entire artery, angiography may lead to an underestimation of the severity of disease.

Aortography

Aortography is accomplished with the rapid injection of radiographic contrast material into the aorta. With proximal aortography, the severity of aortic valve regurgitation, the location of saphenous vein bypass grafts, and the anatomy of the proximal aorta and its branches can be assessed. Distal aortography usually is performed to assess the presence of vascular abnormalities, such as aneurysm, dissection, intraluminal thrombus, or branch vessel stenosis.

Valvular Stenosis or Regurgitation

In patients with valvular stenosis, the effective valve orifice area can be calculated with data obtained during catheterization using principles of standard fluid dynamics. The pressures on either side of a stenotic valve are recorded simultaneously, and the flow across it is measured, after which the valve area is calculated.

The presence and severity of valvular regurgitation may be evaluated qualitatively by observing the amount of radiographic contrast material that regurgitates in a retrograde direction across the valve. The magnitude of regurgitation is estimated as trivial (1+), mild (2+), moderate (3+), or severe (4+).

Endomyocardial Biopsy

Through a long sheath positioned across the tricuspid valve, a bioptome can be advanced to obtain small pieces (1-2 mm in diameter) of myocardial tissue from the right ventricular side of the interventricular septum. Endomyocardial biopsy is used most often to detect transplant rejection and to monitor immunosuppressive therapy in survivors of cardiac transplantation. Less commonly, it is undertaken in the patient with suspected infiltrative cardiomyopathy or active inflammation of the heart (eg, myocarditis). In experienced hands, complications are uncommon: cardiac perforation occurs in only 0.3% to 0.5%, and the procedure-related mortality is only 0.05%.

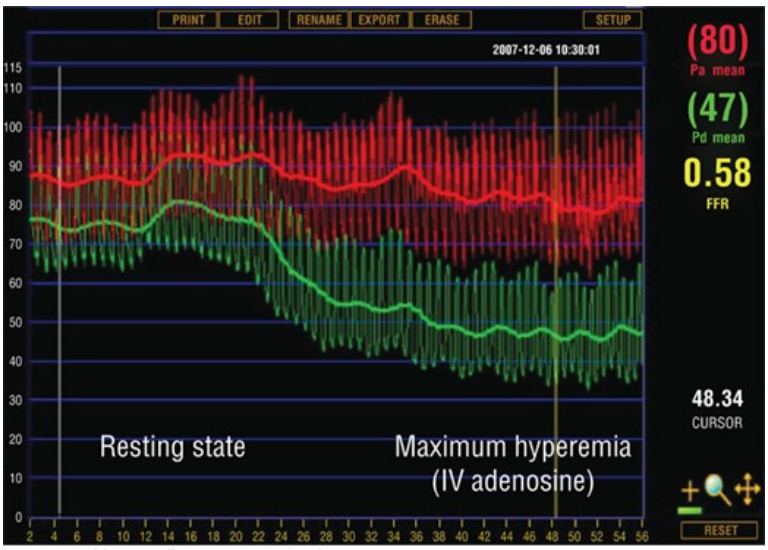
Fractional Flow Reserve

Although coronary angiography can identify the presence of a coronary arterial stenosis, it does not provide information regarding its functional significance (ie, whether it potentially may cause myocardial ischemia). The measurement of fractional flow reserve (FFR) is performed to assess the physiologic significance of a stenosis.[54] With this technique, the intraluminal pressure is measured proximal and distal to the stenosis during maximal blood flow (ie, hyperemia). FFR is defined as the mean pressure distal to the stenosis relative to the pressure proximal to the stenosis. For example, an FFR of 0.50 means a 50% drop in pressure across the stenosis was noted.

During coronary angiography, a catheter is inserted into the ostia of the coronary artery, through which a wire with a small sensor transducer positioned at its tip is advanced past the stenosis. The mean pressure distal to the stenosis is compared to the mean pressure proximal to it (measured through the catheter) both at rest and after hyperemia (which is induced by injecting a vasodilator, such as adenosine or papaverine). FFR is calculated as the ratio of mean arterial pressure distal to the stenosis and mean aortic pressure under conditions of maximal myocardial hyperemia (**Fig. e11-23**). An FFR of 1.0 is normal. An FFR below 0.75 to 0.80 is associated with myocardial ischemia. At this time, it is uncertain if coronary revascularization should be recommended or performed based on an abnormal FFR alone (in the absence of symptoms or other well established indications).

FIGURE e11-23

Simultaneous phasic and mean aortic pressure (Pa, shown in red) and distal coronary arterial pressure (Pd, shown in green) recordings at rest and during maximal hyperemia induced by an IV infusion of adenosine. Fractional flow reserve (FFR) is calculated as the ratio of mean Pd and Pa during maximal hyperemia, which in this case is 47/80 or 0.58. *(Reproduced with permission from Pijls NHJ, Sels JE. Functional measurement of coronary stenosis.* J Am Coll Cardiol *2012;59:1045-1057.)*



Clinical Controversy…

In the patient with minimal or no symptoms, it is unknown if the presence of myocardial ischemia is an indication for coronary revascularization.

Intravascular Ultrasound

Intravascular ultrasound (IVUS) employs a small catheter-mounted ultrasound transducer to provide detailed images of the coronary arterial wall and lumen. In contrast to coronary angiography, which does not visualize the actual arterial wall, IVUS provides quantitative information from within the vessel regarding vessel diameter, circumference, luminal diameter, plaque volume, and percent narrowing. Qualitative information regarding the amount of plaque stenosis, plaque composition (eg, calcific, fibrous, or fatty plaque), and the presence of plaque versus thrombus, thrombus versus tumor, and aneurysm and hematoma can be provided by IVUS. IVUS is used as a therapeutic adjunct to percutaneous coronary intervention, atherectomy, stent or graft placement, and fibrinolysis, although its routine use with these modalities may not be justified. These combination procedures may be monitored in real time as the procedure (eg, atherectomy) is being performed. In recent studies, IVUS has been helpful in the evaluation of the progression or regression of atherosclerosis. Current trials are testing medications for atherosclerosis regression and changes in plaque morphology.

Intravascular optical coherence tomography provides high-resolution, cross-sectional images of tissue with an axial resolution of 10

microns and a lateral resolution of 20 microns. Optical coherence tomographic images of human coronary atherosclerotic plaques are much more structurally detailed than those obtained with IVUS. Clinically, the detection of thin fibrous caps (vulnerable atheromas) (<65 microns) is below the resolution of the current 40-MHz IVUS (100-200 microns). A summary of testing modalities used in cardiovascular medicine is provided in **Appendices e11-1** and **e11-2**.

Chapter 12: Cardiac Arrest

Jeffrey F. Barletta

CARDIAC ARREST

KEY CONCEPTS

- 1 High quality cardiopulmonary resuscitation (CPR) with minimal interruptions in chest compressions should be emphasized in all patients following cardiac arrest.
- 2 The AHA algorithm for basic life support following cardiac arrest emphasizes circulation, airway, and breathing forming the pneumonic "CAB" versus the historic pneumonic "ABC."
- 3 The purpose of using vasopressor therapy following cardiac arrest is to augment low coronary and cerebral perfusion pressures encountered during CPR.
- 4 Vasopressin appears to offer no benefit as a substitute over epinephrine.
- 5 Amiodarone remains the preferred antiarrhythmic during cardiac arrest with lidocaine considered as an alternative.
- 6 Successful treatment of both pulseless electrical activity (PEA) and asystole depends almost entirely on diagnosis of the underlying cause.
- 7 Intraosseous administration is the preferred alternative route for administration if IV access cannot be achieved.

Cardiac arrest is defined as the cessation of cardiac mechanical activity as confirmed by the absence of signs of circulation (eg, a detectable pulse, unresponsiveness, and apnea).[1] While there is wide variation in the reported incidence of cardiac arrest, it is estimated that there are more than 320,000 people in the United States who experience emergency medical services (EMS)-assessed out-of-hospital cardiac arrest.[2] Survival to hospital discharge following out-of-hospital cardiac arrest is only 10.6% and survival with good neurologic function is only 8.3%.[2] While there has been minimal improvement in survival over the past 40 years, recent data have shown some progress from 2005 to 2012 (adjusted rate ratio = 1.47 [1.26-1.7]).[3] This improvement was attributed to both improved pre-hospital and in-hospital survival.

In-hospital cardiac arrests occur in roughly 200,000 patients in the United States annually and this rate may be increasing.[4] Similar to out-of-hospital arrests, some progress has been made over the past decade with survival rates to hospital discharge being 13.7% in 2000 and 22.3% in 2009.[5] Survival rates are substantially higher in victims with a shockable first documented rhythm as one study reported survival rates of 49% with ventricular fibrillation/pulseless ventricular tachycardia (VF/PVT) versus 11% with pulseless electrical activity (PEA)/asystole.[6]

EPIDEMIOLOGY

In adult patients, cardiac arrest usually results from the development of an arrhythmia.[7] Historically, VF and PVT have been the most common initial rhythm accounting for 40% to 60% of out-of-hospital arrests but their incidence now is estimated to be only about 24%.[8,9] In fact, data from the Cardiac Arrest Registry to Enhance Survival (CARES) project reported asystole to be the most common presenting rhythm (45%) which is similar to other registry data whereby nonshockable rhythms were more prevalent.[8,10,11] The reason for this change has not been firmly established. Possible explanations include the influence of noncardiac causes of arrest that typically present with apnea leading to bradycardia and then PEA or asystole. A second explanation is the increasing role of implantable pacemakers and defibrillators.[12] Finally, it has been suggested that beta-blockers and angiotensin-converting enzyme (ACE) inhibitors may shorten the duration of VF and the expanded use of these drug classes for ischemic heart disease and heart failure may account for the increased occurrence of non-VF/PVT rhythms.[9] Nonetheless, this declining incidence is particularly concerning as survival rates are substantially higher with shockable rhythms such as VF and PVT compared to nonshockable rhythms such as PEA and asystole. Survival rates with VF/PVT are roughly 27% versus 2% with asystole.[8]

A similar finding has been observed with in-hospital cardiac arrest. One study using the "Get with the Guidelines-Resuscitation" registry reported 79% of patients had an initial rhythm of asystole or PEA and 21% had VF or PVT.[5] Survival rates were 12.2% for asystole/PEA and 35% for VF/PVT. Similarly, a second study used the National Registry of CPR and noted the incidence of VF/PVT, PEA and asystole to be 24%, 37%, and 39%, respectively.[13] Survival rates were 37% for VF/PVT compared to 12% for PEA and 11% for asystole. Patients with VF/PVT were more likely to have myocardial infarction as the immediate factor pre-arrest while acute respiratory failure and hypotension were the immediate factors more commonly found in patients with PEA/asystole.

In pediatric patients, cardiac arrest typically results from respiratory failure and asphyxiation. As such, the initial rhythm most often encountered in out-of-hospital arrest is PEA or asystole.[14] Survival rates with out-of-hospital pediatric arrests range between 1% and 12% with lower rates in infants compared to children and adolescents.[15] Survival following in-hospital cardiac arrest appears higher with an overall rate of 34%.[16] Similar to the adult population, risk-adjusted survival rates have increased over the past decade from 14% in 2000 to 43% in 2009.[16]

ETIOLOGY

The most common clinical finding in adult patients who suffer cardiac arrest is coronary artery disease accounting for roughly 80% of sudden cardiac deaths.[7] Approximately 10% to 15% of sudden cardiac deaths occur in patients with cardiomyopathies (eg, hypertrophic cardiomyopathy, dilated cardiomyopathy) and the remaining 5% to 10% are composed of either structurally abnormal congenital cardiac conditions or patients with structurally normal but electrically abnormal heart. Unfortunately, in many patients (approximately two-thirds), cardiac arrest is the first clinical sign of coronary artery disease with no preceding signs or symptoms.[17]

In pediatric patients, cardiac arrest is often the terminal event of respiratory failure or progressive shock.[18] Out-of-hospital arrests frequently are associated with trauma, sudden infant death syndrome, drowning, poisoning, choking, severe asthma, and pneumonia. In-hospital arrests, on the other hand, are associated with sepsis, respiratory failure, drug toxicity, metabolic disorders, and arrhythmias.

PATHOPHYSIOLOGY OF CARDIAC ARREST

There are two distinctly different pathophysiologic conditions associated with cardiac arrest. The first is primary cardiac arrest whereby arterial blood is typically fully oxygenated at the time of arrest. The second is cardiac arrest

secondary to respiratory failure in which lack of ventilation leads to severe hypoxemia, hypotension, and secondary cardiac arrest. It is important to understand the specific condition at hand as different treatment approaches are likely necessary.[19]

CLINICAL PRESENTATION

Cardiac arrest is characterized by the cessation of cardiac mechanical activity therefore signs and symptoms are consistent with those encountered when there is no circulation. In the setting of cardiac causes of arrest, anxiety, crushing chest pain, nausea, vomiting, and diaphoresis can precede the event. Following an arrest, individuals are unresponsive, apneic, hypotensive and do not have a detectable pulse. Extremities are cold and clammy and cyanosis is common.

TREATMENT

Cardiopulmonary resuscitation (CPR) is an attempt to restore spontaneous circulation by performing chest compressions (to restore threshold blood flows, particularly to the heart and brain) with or without ventilations. There are two proposed theories describing the mechanism of blood flow during CPR.[20] The original theory is known as the cardiac pump theory and is based on the active compression of the heart between the sternum and vertebrae thereby creating forward flow. Echocardiography, however, has revealed that left ventricular size does not always change with compressions and the mitral valve may in fact be open.[20] The second theory is the thoracic pump theory. This theory is based on intrathoracic pressure alterations induced by chest compressions and the differential compressibility of the arteries and veins. In this model, the heart merely acts as a passive conduit for flow. It is likely that both models contribute to the mechanism of blood flow with CPR.

High-quality CPR continues to be emphasized in the latest guidelines published by the American Heart Association. Clinicians must focus on proper technique, including adequate rate and depth of compressions, allowance of chest recoil after each compression, avoiding excessive ventilation, and minimizing interruptions.[21] One study, in patients suffering out-of-hospital VF, reported an increased chance of survival as chest compression fraction increased (eg, the proportion of resuscitation time without spontaneous circulation where chest compressions were administered).[22] Unfortunately, the provision of high-quality CPR is frequently suboptimal particularly when rescuers become fatigued.[23] There are several devices available that provide prompts and/or feedback in “real time”; however, data illustrating improvement in survival are lacking.[23] Additionally, mechanical devices designed to improve hemodynamics have been studied but inconsistent results limit their applicability in routine practice.[24]

Desired Outcome

The global goals of resuscitation are to preserve life, restore health, relieve suffering, limit disability, and respect the individual’s decisions, rights, and privacy.[25] This can be accomplished via CPR by the return of spontaneous circulation (ROSC) with effective perfusion and ventilation as quickly as possible to minimize hypoxic damage to vital organs. Survival to hospital discharge with good neurologic function should be considered the primary treatment outcome sought by clinicians. Survival to hospital discharge in a vegetative or comatose state cannot be classified as a success and can impose a tremendous economic burden on the healthcare system. Additionally, most patients would choose not to continue living in a massively disabled state.[26]

The presence of a healthcare advanced directive allows patients to communicate their wishes and preferences regarding medical care and may lead to a “do not attempt resuscitation (DNAR)” order. As many cardiac arrests occur following terminal illnesses and end-of-life care, “allow natural death (AND)” has become a preferred term to replace DNAR.[27] These orders should explicitly state the resuscitation interventions that are to be performed and have clearly been communicated by the patient, their family or a surrogate decision maker.

General Approach to Treatment

Cardiopulmonary Resuscitation

Resuscitation techniques have been studied for many years. The first landmark article was published in 1960 and described the outcome of 20 patients who were given closed chest compressions at a rate of 60 per minute.[28] Artificial ventilation was used to augment the compressions, and three patients were given defibrillation for ventricular fibrillation. In this landmark article, all 20 patients had ROSC, and 14 lived for an extended period of time, with reported good neurologic status. Initial descriptions after this started to integrate the approach to cardiac arrest, including three phases.[29]

In 1966, the American Heart Association (AHA) first published guidelines for the treatment of cardiac arrest.[30] Since then, national conferences and organized committees have played a major role in encouraging widespread competency in CPR technique. There have been tremendous revisions of the guidelines over the years, and this is true of the most recent guidelines, published in 2015.[31] The 2015 guidelines represent a new era for the AHA Guidelines for CPR and Emergency Cardiovascular Care (ECC) because they will transition from a 5-year cycle of periodic revisions to a web-based format that is continuously updated. The intent is that this will allow for more rapid application of new research findings into daily patient care.

The 2015 guidelines continue to emphasize the "chain of survival" to highlight the treatment approach and illustrate the importance of a timely response. The updated guidelines however now includes two separate chains; one for out of hospital cardiac arrest and one for in-hospital cardiac arrest.[32] This has been done to reflect the differences in the steps needed to respond to a cardiac arrest in the in-patient and out-patient setting. The two chains converge in the hospital with post-cardiac arrest care as the last link. In summary, the five links in each chain of survival are as follows:

- Out of hospital
    1. Immediate recognition of cardiac arrest and activation of EMS.
    2. Early CPR with an emphasis on chest compressions.
    3. Rapid defibrillation.
    4. Effective advanced life support.
    5. Integrated postcardiac arrest care.
- In-hospital
    1. Appropriate surveillance and prevention of cardiac arrest.
    2. Prompt notification and response by a multidisciplinary team of professional providers.
    3. High-quality CPR.
    4. Prompt defibrillation and advanced life support when appropriate.
    5. Integrated postcardiac arrest care.

While all five links of the chain of survival are important, basic life support (BLS) is the foundation for saving lives after cardiac arrest (ie, immediate recognition, early CPR, and rapid defibrillation).[21] In fact, one large observational study compared the effects of BLS and advanced cardiac life support (ACLS) on outcomes following out-of-hospital

cardiac arrest and survival to hospital discharge was greater among patients receiving BLS (13.1% vs 9.2%).[33] CPR provides critical blood flow to the heart and brain, prolongs the time VF is present (prior to the deterioration to asystole) and increases the likelihood that a shock will terminate VF resulting in a rhythm compatible with life.[21] For every minute that elapsed from collapse to successful defibrillation during witnessed VF arrests, survival rates decrease by 7 % to 10% if no CPR is provided.[34] If immediate CPR is added, the decrease in survival is more gradual (down to 3%-4% per minute post-collapse).[35] In effect, CPR can increase the likelihood of survival threefold from arrest to survival. Basic CPR alone, however, is not likely to terminate VF and lead to ROSC.

1 As in previous AHA guidelines for CPR and ECC, the AHA continues to emphasize the provision of high-quality CPR with minimal interruptions in chest compressions. In addition, algorithms continue to be more simplified, with emphasis on the use of end-tidal carbon dioxide ($ETCO_2$) to guide resuscitation.[36] Furthermore, there is growing importance of post-arrest care, reflecting that optimization of many organ systems may help improve outcomes.[37] The use of drug therapy and airway adjuncts, on the other hand, have continued to devolve to a minimal role as survival to hospital discharge does not appear to be impacted.

Basic Life Support

The pneumonic for the CPR sequence is "CAB" which stands for circulation, airway, and breathing. 2 Historically, BLS and ACLS providers have been taught the pneumonic, "ABC." This change was made upon recognition of the importance of maintaining blood flow to the heart and brain and the consequences of delays or interruptions with chest compressions.

When first encountering a victim of cardiac arrest, the initial action is to determine responsiveness of the patient. If there is no response, the rescuer should immediately activate the emergency medical response team, and obtain (or call for) an automated external defibrillator (AED) (if one is available) and them immediately start CPR with chest compressions. A true cardiac arrest victim will be unresponsive, and agonal respirations can be confused with normal breathing. Thus, the "look, listen, and feel" for respirations is not recommended as part of the initial assessment.[21] Similarly, pulse recognition is often inaccurate, and it is recommended that lay rescuers not check for a pulse. Healthcare providers should assess for a pulse but take no more than 10 seconds to do so. If one is not detected within this short timeframe, then chest compressions should be initiated immediately.[21,38]

The prompt provision of chest compressions is thus of paramount importance, and rescuers should attempt them regardless of rescuer experience or skill level. The teaching of BLS now focuses on delivering high quality CPR with a rate of 100 to 120 beats/min, adequate depth (at least 2 inches in an adult), allowing full chest recoil, minimizing interruptions in compressions, and avoiding excessive ventilation.

While it is true that opening the airway has the potential to improve oxygenation and allow for better attempts at ventilation, this can be very challenging, especially if the rescuer is alone and is a novice. Thus, the simplified adult BLS algorithm calls for the initiation of CPR, with rhythm check every 2 minutes, shocking if indicated, with continued repetition.

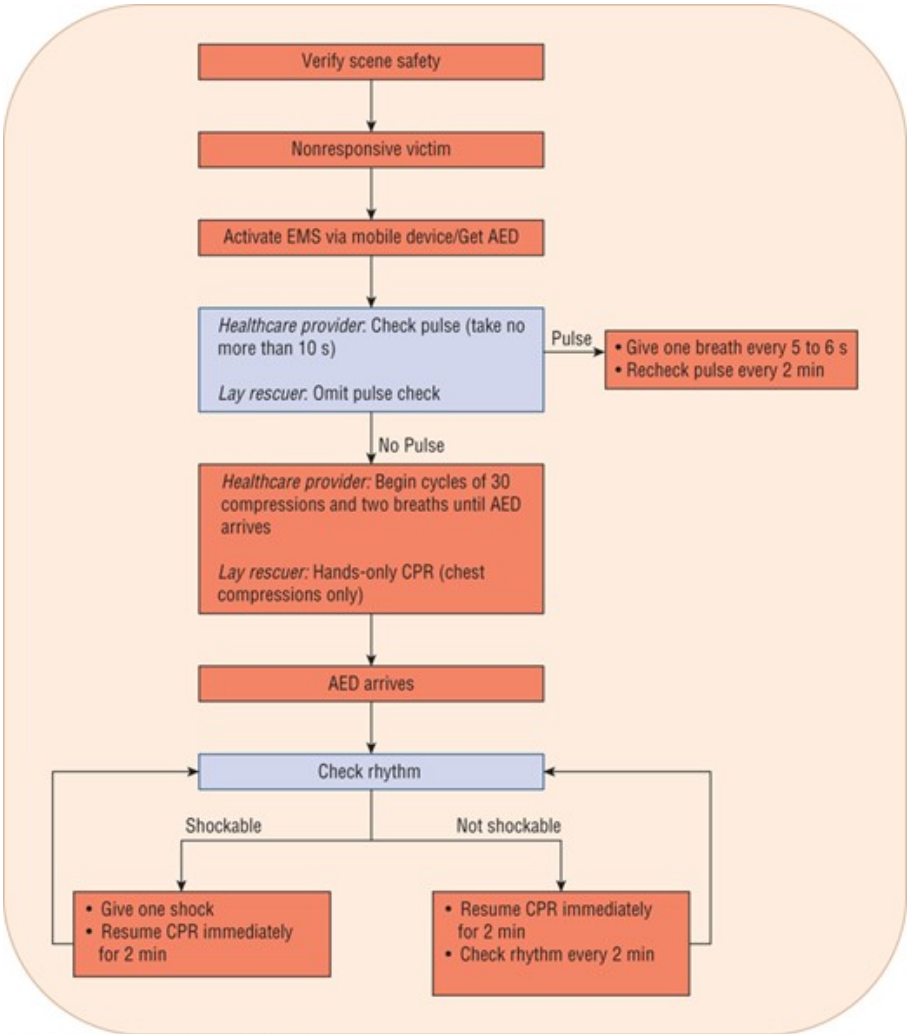
Once chest compressions have been started, it is then appropriate for a trained rescuer to attempt to deliver rescue breaths, either by mouth-to-mouth, or preferentially by bag-mask ventilation. The current guidelines recommend delivering a breath over one second, use enough volume to elicit a visible chest rise, and to use a compression to ventilation ratio of 30 to 2 for one rescuer.[21]

The 2015 AHA guidelines for CPR and ECC continue to stress that there should be minimal interruptions in chest compressions. If there is no AED available, then cycles of compressions/breaths should continue, with pulse checks every 2 minutes until help arrives or the patient regains spontaneous circulation. If there is an AED available, then the rhythm should be checked to determine if defibrillation is advised. If so, then one shock should be delivered

with the immediate resumption of chest compressions (and rescue breaths, if being provided). After 2 minutes (5 cycles of 30:2 compression to ventilation), the rhythm should be reevaluated to determine the need for defibrillation. This algorithm should be repeated until help arrives, or the rhythm is no longer "shockable." If the rhythm is not shockable, then chest compressions—rescue breath cycles should be continued until help arrives, or the victim recovers spontaneous circulation (**Fig. 12-1**).

FIGURE 12-1

Treatment algorithm for adult cardiac arrest: Basic life support (BLS).



Despite widespread dissemination of cardiac arrest guidelines and the ongoing education even of health care providers, there is ample evidence that chest compression quality remains poor in general. Furthermore, it have been reported that the rate of bystander CPR with out-of-hospital cardiac arrest in the United States is only 26%.[39] This has led to further educational interventions in an attempt to increase quality of CPR, and EMS dispatchers will often attempt to give instructions over the phone when EMS is activated.

There is now a push for hands-only CPR for lay persons, given data that show similar survival compared to the addition of rescue breaths. There has been reluctance on many bystanders to consider mouth-to-mouth, though one data set cites panic as a reason not to pursue bystander CPR rather than actual reluctance.[40]

Once ACLS providers arrive, then further definitive therapy is given. An advanced airway (endotracheal tube, laryngeal mask airway, or even bag-valve mask) can be used to provide ventilation. When this occurs, the rescuers no longer need to provide the cycles of 30:2 compressions to ventilations. Instead, continuous chest compressions are recommended without pauses for ventilations, and the rescuer providing the ventilations needs to deliver a breath once every 6 to 8 seconds.

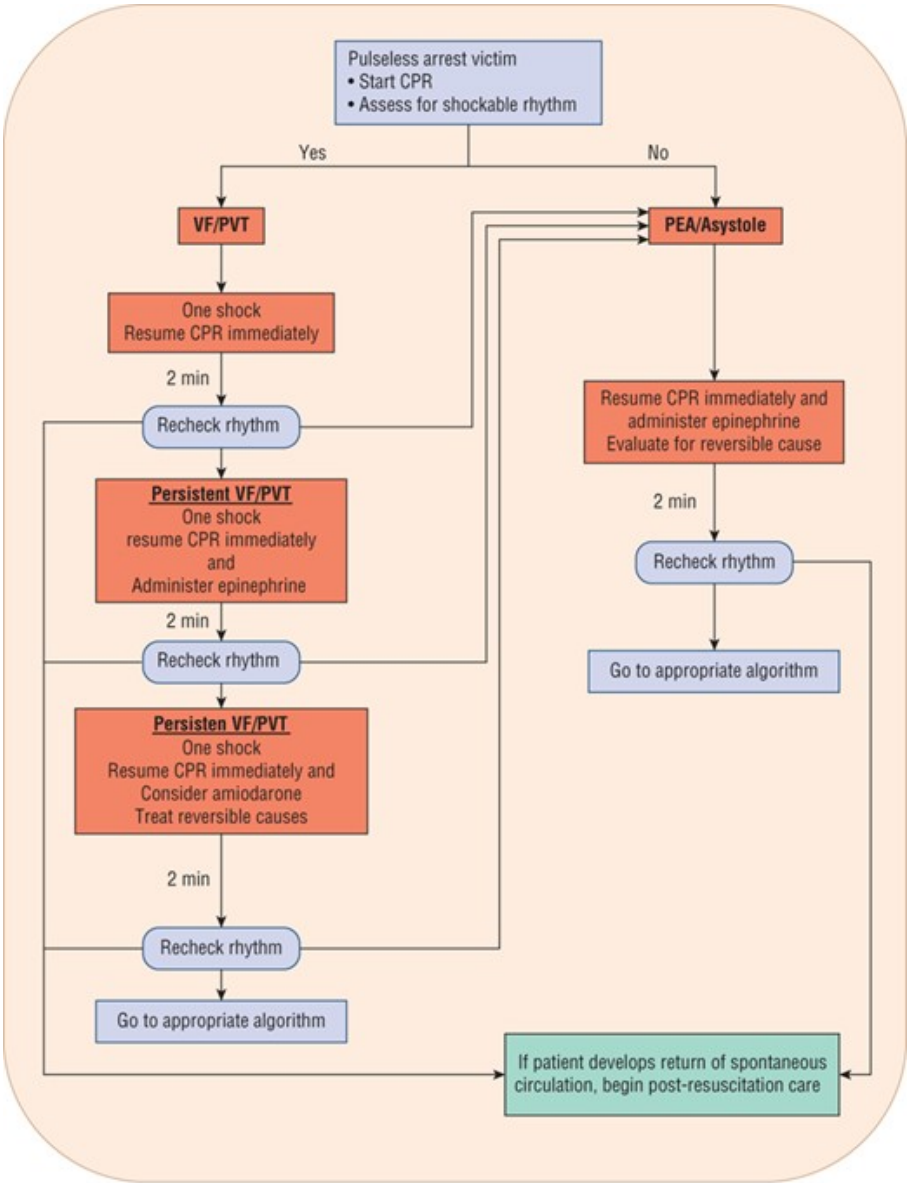
Monitoring during CPR has also evolved over time. Animal and human studies have shown that monitoring of $ETCO_2$, coronary perfusion pressure, and central venous oxygen saturation can provide valuable information as to the success of resuscitation.[36] Surprisingly, no study has ever shown the validity of checking a pulse during ongoing CPR. $ETCO_2$ is the concentration of carbon dioxide in exhaled air at the end of expiration. During cardiac arrest, the level of $ETCO_2$ decreases because there is no flow through the pulmonary circulation. Thus, a persistently low $ETCO_2$ (ie, less than 10 mm Hg) during CPR in intubated patients suggests that ROSC is unlikely.[36] In fact, one systematic review reported a mean $ETCO_2$ of 26 mm Hg in patients who achieved ROSC compared to 13 mm Hg in those who did not.[41] In patients without ROSC and persistently decreased $ETCO_2$, it is advised to evaluate the effectiveness of CPR, since good chest compressions can increase $ETCO_2$ somewhat. The latest guidelines recommend $ETCO_2$ monitoring during CPR if at all possible.[36]

Monitoring of coronary perfusion pressure and central venous oxygen saturation require more invasive monitoring and will not be covered.

If the cardiac rhythm is not deemed to be shockable, then it is likely to be either asystole or PEA (**Fig. 12-2**). For PEA, the rescuer must consider reversible causes. If the person is in VF or PVT, then one shock should be delivered (appropriate to the available electrical device), with the immediate resumption of chest compressions (using 30 compressions to 2 breaths for 5 cycles, or 2 minutes continuous compressions with assisted ventilations) prior to rechecking the rhythm or pulse. If there is still a shockable rhythm, then one shock should be delivered, and at this time pharmacologic intervention can be considered. Vasopressors are the initially recommended pharmacologic intervention at this point. After another unsuccessful shock, antiarrhythmics can be considered. Two minutes (five cycles of chest compressions: breaths) should be performed in between attempts at defibrillation. This algorithm will repeat until either a pulse is obtained with effective circulation, the rhythm changes, or the patient expires. For completeness, please refer to the guidelines published by the AHA.[36]

FIGURE 12-2

Treatment algorithm for adult cardiac arrest: Advanced cardiac life support (ACLS).



Cardiocerebral Resuscitation

In lieu of the relative lack of progress with survival rates following out-of-hospital cardiac arrest, an alternative approach for resuscitation was proposed called cardiocerebral resuscitation (CCR).[19] CCR has been embraced by the AHA guidelines, and is composed of three major components: a community component, an EMS component, and a hospital component.

The community component consists of prompt recognition (check), activation of EMS (call), and chest compression only CPR (compress). Chest compressions deliver a small but critical amount of oxygen to the brain and myocardium. Cerebral and coronary perfusion pressures, however, build up slowly once chest compressions are begun. These perfusion pressures are lost if chest compressions are stopped to deliver mouth-to-mouth ventilation. In fact, in earlier studies, approximately 16 seconds were required to deliver 2 breaths as recommended by earlier ECC guidelines.[42] The loss of perfusion during this time period has been shown to be extremely detrimental as ROSC is closely related to perfusion pressures generated during chest compressions.[43]

The EMS component of CCR consists of a revised ACLS algorithm. This protocol is based on the three-phase

time-sensitive model of cardiac arrest.[44] The first phase is the electrical phase (0-5 minutes), where prompt defibrillation is the most important intervention. The second phase is the hemodynamic phase (5-15 minutes), where adequate coronary and cerebral perfusion pressures, before and after defibrillation, are crucial. In fact, defibrillation prior to CPR in this phase commonly leads asystole or PEA. This is likely due to the presence of global tissue ischemia and the need for blood flow (via chest compressions) to "flush out" deleterious metabolic factors that have accumulated during ischemia. The third phase is the metabolic phase (beyond 15 minutes) in which survival is very low and hypothermia may be the most beneficial approach. In situations where EMS personnel witness the arrest, immediate defibrillation is attempted.[45] Alternatively, the EMS protocol of CCR emphasizes prompt initiation of 2 minutes of continuous chest compressions before and immediately after a single indicated direct current shock.

The third component of CCR is the hospital which calls for aggressive postresuscitation care. This consists of the use of hypothermia for all comatose patients and emergent cardiac catheterization and percutaneous coronary intervention (PCI) for patients with myocardial ischemia as a potential cause of their arrest. This would entail the designation of cardiac receiving centers or hospitals with a commitment and expertise in postresuscitative care.

Since its conception in 2003, clinical studies evaluating CCR have demonstrated an improvement in survival of 250% to 300% compared to conventional CPR.[19] One systematic review compared CCR with CPR (as per the 2005 AHA Guidelines) and the odds ratio (OR) for survival was 2.26 (95% confidence interval [CI] 1.64-3.12).[46] A registry study demonstrated better survival with CCR which was observed across multiple age groups.[47] The greatest difference was noted in those who were younger than 40 years (OR 5.94; [95% CI] 1.82-19.26). Additionally, patients who received CCR had better neurologic outcomes.

Ventricular Fibrillation/Pulseless Ventricular Tachycardia

Nonpharmacologic Therapy

Electrical defibrillation is the only effective method of restoring a perfusing cardiac rhythm in either VF or PVT; therefore, it is a crucial link in the "chain of survival," especially for a witnessed arrest.[36] The probability of successful defibrillation is directly related to the time interval between the onset of VF and the delivery of the first shock.[35] In one study, a 23% relative improvement in survival was observed with each 1 minute reduction in the time to defibrillation (OR 0.77; [95% CI] 0.73-0.81).[48] If fact, survival decreases an estimated 7% to 10% for each minute after arrest to defibrillation if no CPR is given.[34] When bystander CPR is delivered, this decrease in survival is cut almost in half.[35]

Although early defibrillation is crucial for survival following cardiac arrest, several studies have suggested that CPR prior to defibrillation (consistent with the CCR model) may lead to more successful outcomes. For in-hospital cardiac arrest, if an AED is available, CPR should begin while the AED is being placed. With out-of-hospital cardiac arrest, there is some evidence that CPR before defibrillation may be beneficial.[49,50,51,52] One randomized controlled trial revealed higher survival rates in patients with response intervals greater than 5 minutes when 3 minutes of CPR was administered prior to defibrillation (22% vs 4%; $p = 0.006$).[52] These findings were not confirmed in other randomized controlled trials.[53,54,55,56] An observational study found the provision of roughly 90 seconds of CPR prior to defibrillation was associated with an increased rate of hospital survival (compared with a historical control group) when response intervals were 4 minutes or longer (27% vs 17%; $p = 0.01$).[49] A second observational study noted an improvement in hospital survival (from 22% to 44%, $p = 0.0024$) in patients with witnessed VF using a modified resuscitation protocol which included 200 preshock chest compressions.[50] Finally, a pre-post study evaluated a protocol where each defibrillation, including the first, was preceded by 200 uninterrupted chest compressions.[51] An increase in total survival (57% [19/33] vs 20% [18/92], $p = 0.001$) and neurologically normal survival (48% [16/33] vs 15% [14/92], $p = 0.001$) was reported. Nevertheless, meta-analyses have failed to

demonstrate benefit with a delayed defibrillation approach.[57,58,59] Thus, this is an issue of ongoing debate and study. The latest guidelines state for a witnessed adult cardiac arrest, when an AED is immediately available, the defibrillator should be used as soon as possible. For adults with unmonitored arrests or when an AED is not immediately available, it is reasonable that CPR be initiated while the defibrillator is being retrieved but defibrillation be attempted as soon as the device is ready for use.[21]

The current guidelines continue to recommend one shock for VF or PVT (as opposed to stacked shocks) with the immediate resumption of chest compressions.[36] This is largely due to the prolonged time noted (approximately 55 seconds) to deliver three stacked shocks without providing adequate chest compressions.[60] The defibrillation attempt should be with 120 to 200 J (biphasic defibrillator) or 360 J (monophasic defibrillator). Defibrillators using biphasic waveforms are preferred to monophasic defibrillators. If an AED is available, it should be used as soon as possible. However, CPR should be started immediately (after EMS activation) while the AED is being prepared.

After defibrillation is attempted, CPR should be immediately restarted and continued for 2 minutes without checking a pulse. The omission of the pulse check after defibrillation is related to myocardial stunning with resultant poor perfusion and diminished cardiac output immediately after electrical therapy.[36] After 2 minutes of chest compressions, the rhythm should be rechecked and if there is still evidence of VF or PVT, pharmacologic therapy with repeat attempts at single-discharge defibrillation should be attempted.

Endotracheal intubation and intravenous (IV) access should be obtained when feasible, but not at the expense of stopping chest compressions. The 2015 AHA guidelines for CPR and ECC continue to strongly stress the need for uninterrupted CPR.[21] Once an airway is achieved, patients should be ventilated with 100% oxygen. There are several airway adjuncts that are potentially available, such as laryngeal mask airways and esophageal-tracheal combination tubes. However, the definitive airway is an endotracheal tube placed with direct laryngoscopy.

Other interventions are also being evaluated as nonpharmacologic therapy. In a porcine model of VF arrest, a percutaneously placed left ventricular assist device (LVAD) was shown to sustain vital organ perfusion.[61] As well, the performance of angiography and percutaneous coronary intervention during suspected myocardial infarction has been studied in both animals and anecdotally in humans refractory to traditional ACLS protocol without ROSC. A review of this topic suggests that this intervention is feasible and that further investigation is warranted.[62] Extracorporeal membrane oxygenation (ECMO) has also been evaluated and has been shown to improve outcomes in some series, but the logistics of widespread implementation is daunting.[63]

Pharmacologic Therapy

Sympathomimetics

Sympathomimetics continue to be the first pharmacologic agents administered in the setting of cardiac arrest despite limited evidence demonstrating their ability to increase neurologically intact survival to hospital discharge. Nevertheless sympathomimetics have been associated with an increased rate of ROSC and play a major role in the pharmacotherapy of cardiac arrest.

3 The primary goal of sympathomimetic therapy is to augment low coronary and cerebral perfusion pressures encountered during CPR. Chest compressions (via CPR) can provide some degree of blood flow to the heart and the brain but it is only about 25% of that encountered under basal conditions.[64] In fact, even with properly performed chest compressions, coronary perfusion pressures are only 10 to 15 mm Hg and systolic arterial pressure is rarely above 80 mm Hg.[65] Clinical data have indicated that ROSC is unlikely when coronary perfusion pressure is less than 15 mm Hg and animal studies have demonstrated higher rates of ROSC when coronary perfusion pressure was 31 versus 14 mm Hg.[66,67] Sympathomimetics therefore work to increase these pressures through their vasoconstrictive properties.

Epinephrine continues to be a drug of first choice for the treatment of VF, PVT, asystole, and PEA. Epinephrine is an alpha- and beta-receptor agonist causing both vasoconstriction and increased inotropic/chronotrophic activity on the heart. Its effectiveness however is primarily through its alpha effects, particularly alpha-2 activity.[68]

Prospective data evaluating epinephrine in the setting of out-of-hospital cardiac arrest are limited. In one study, patients were randomized to receive standard ACLS with IV drug administration or standard ACLS without IV drug administration.[69] There were 851 patients analyzed and VF/PVT was the initial rhythm in 34%. IV medications administered included epinephrine (79%), atropine (46%), and amiodarone (17%). A significant increase in ROSC (40% vs 25%, $p < 0.001$) and hospital admission (43% vs. 29%, $p < 0.001$) was noted in patients who received IV therapy. This difference was primarily observed in patients with initial rhythms other than VF/PVT. The role of epinephrine (vs other IV medications) in the contribution of these outcomes was not assessed. A second randomized, controlled trial compared epinephrine with placebo in 534 patients.[70] Ventricular fibrillation or PVT was the initial rhythm in 44% and 48% of patients in the epinephrine and placebo groups, respectively. Return of spontaneous circulation (23.5% vs 8.4%, $p < 0.001$) and survival to hospital admission (25.4% vs 13%, $p < 0.001$) was significantly higher with epinephrine but there was no difference in survival to hospital discharge (4% vs 1.9%, $p = 0.15$). While epinephrine was effective in achieving ROSC in both shockable (OR [95% CI] = 2.5 [1.2-4.5]) and nonshockable (OR [95% CI] = 6.9 [2.6-18.4]) rhythms, its effect was more pronounced in the latter cohort.

Several large observational studies have evaluated the impact of epinephrine on survival. One large registry study of over 400,000 patients failed to demonstrate a survival benefit with prehospital administration of epinephrine.[71] Despite a significant improvement in ROSC with epinephrine (adjusted OR [95% CI] = 2.36 [2.22-2.5]), 1-month survival (adjusted OR [95% CI] = 0.46 [0.42-0.51]) and survival with good neurologic function (adjusted OR [95% CI] = 0.31 [0.26-0.36]) were both lower in patients who received epinephrine. A second study of evaluated outcomes of patients with witnessed out-of-hospital cardiac arrest.[72] After propensity matching, epinephrine was associated with improvements in survival at 1 month or discharge (17% vs 13.4%) in patients with VF/PVT but no difference in neurologically intact survival (6.6% vs 6.6%). The lack of agreement between these two studies may be related to the fact that epinephrine administration occurred earlier in the latter study (ie, within 10 minutes).

The influence of timing of epinephrine has been described in other analyses and earlier administration appears to be more beneficial than later.[73,74,75,76,77,78] One study though found an adverse association between epinephrine and intact survival which worsened as epinephrine administration was delayed.[79] These findings were replicated in a second study whereby a significant decrease in survival was noted with each minute increase in the time to epinephrine administration (adjusted OR [95% CI] = 0.95 [0.92-0.97]).[75] The time to epinephrine administration may therefore be a key factor associated with survival and future studies must consider this as a potential confounding variable.

Clinical Controversy…

The time to epinephrine administration may be an important confounding factor for the value of epinephrine during out-of-hospital cardiac arrest.

Given the disparate results with epinephrine in published research, it can be considered both a cure and a curse in cardiac arrest. One possible explanation for the negative effects of epinephrine is related to its mechanism of action. Epinephrine causes alpha-mediated vasoconstriction which increases coronary perfusion but can decrease perfusion to other vital organs. In fact, animal research has linked epinephrine to a decrease in cerebral microvascular blood flow and increase in brain tissue ischemia during and after CPR.[80] Epinephrine also stimulates beta-receptors which can increase myocardial oxygen demand, impair lactate clearance and advance the severity of post resuscitation myocardial dysfunction.[81] This has led some investigators to evaluate simultaneous adrenergic antagonist administration in conjunction with epinephrine therapy (thereby isolating the alpha-2 effects) using an animal model.[82] This approach has not been extensively studied in humans.

Several studies have compared epinephrine with other adrenergic agonists such as pure alpha-1 agonists (phenylephrine and methoxamine) and agents with more potent alpha-activity (norepinephrine).[83] When compared to pure alpha-1 agonists, no advantage in long-term survival could be reported. One potential reason could be the potent alpha-2 effects with epinephrine and the fact that these receptors lie extrajunctionally in the intima of the blood vessels making them more accessible to circulating catecholamines.[84] Furthermore, during ischemia, the number of postsynaptic alpha-1-receptors decreases which suggests a greater role for alpha-2 agonists during CPR.[85] Epinephrine has also been compared with norepinephrine, a potent alpha-agonist (both alpha-1 and alpha-2) with some beta-1 effects. In the only large-scale randomized, double-blind, prospective trial in out-of-hospital cardiac arrest, there were no significant differences in ROSC, hospital admission or discharge.[86] A second, smaller study demonstrated higher resuscitation rates with norepinephrine compared to epinephrine (64% vs 32%) but no significant difference in hospital discharge.[87] Since the use of epinephrine has been established for many decades in evidence-based guidelines, strong outcome-related data (eg, survival to hospital discharge) would be required for an alternative to replace it. Consequently, epinephrine remains the first-line sympathomimetic for CPR.

The recommended dose for epinephrine is 1 mg administered by IV or intraosseous (IO) injection every 3 to 5 minutes[36] (**Table 12-1**). The recommended dose for epinephrine was derived from animal studies (0.1 mg/kg in a 10-kg dog) and equates to approximately 0.015 mg/kg for a 70-kg human.[88] Both animal and human studies have demonstrated a positive dose-response relationship with epinephrine suggesting that higher doses might be necessary to improve hemodynamics and achieve successful resuscitation.[83] These results, however, have not been replicated in human studies. In fact, some studies have reported increased morbidity with high epinephrine doses, indicative of catecholamine toxicity, including decreased cardiac indices, left ventricular dysfunction, and decreased oxygen consumption and delivery. This discrepancy between animal and human studies could be related to most victims of cardiac arrest having coronary artery disease, which is not encountered in an animal model. Additionally, atherosclerotic plaques (in humans) can aggravate the balance between myocardial oxygen supply and demand and the interval from arrest to treatment is longer in human studies than that encountered in an animal model. High dose epinephrine is not recommended for routine use in cardiac arrest.

TABLE 12-1 Evidence-Based Recommendations

Recommendations	Recommendation Grades[a]
Epinephrine	
Standard dose epinephrine (1 mg IV/IO every 3-5 minutes) may be reasonable for patients with cardiac arrest	Class IIb, LOE B-R
High dose epinephrine is not recommended for routine use in cardiac arrest	Class III: No benefit, LOE B-R
It may be reasonable to administer epinephrine as soon as feasible after the onset of cardiac arrest due to an initial nonshockable rhythm	Class IIb, LOE C-LD
Vasopressin	
Vasopressin offers no advantage as a substitute over epinephrine	Class III: No benefit, LOE B-R
Vasopressin in combination with epinephrine offers no advantage as a substitute for standard dose epinephrine	Class IIb, LOE B-R
For in-hospital cardiac arrest, the combination of intra-arrest vasopressin, epinephrine and methylprednisolone with post-arrest hydrocortisone may be considered	Class IIb, LOE C-LD
Amiodarone	
Amiodarone may be considered in patients with VF/PVT unresponsive to CPR, defibrillation, and a vasopressor.	Class IIb, LOE B-R
Lidocaine	

Recommendations	Recommendation Grades[a]
Lidocaine may be considered as alternative to amiodarone for VF/PVT that is unresponsive CPR, defibrillation, and a vasopressor.	Class IIb, LOE C-LD
Magnesium	
Magnesium is not routinely recommended for VF/PVT.	Class III: No benefit, LOE B-R
Thrombolysis	
Thrombolysis may be considered when cardiac arrest is suspected to be caused by pulmonary embolism.	Class IIb, LOE C-LD
Targeted Temperature Management	
Comatose adult patients with ROSC after cardiac arrest should have targeted temperature management.	Class I, LOE B-R (VF/PVT) Class I, LOE C-EO (non-VF/PVT and in-hospital arrests)
A constant temperature between 32°C and 36°C should be maintained.	Class I, LOE B-R
It is reasonable that targeted temperature management be maintained for at least 24 hours after achieving target temperature.	Class IIa, LOE C-EO
Routine prehospital cooling of patients after ROSC with rapid infusion of cold intravenous fluids is not recommended.	Class III: No benefit, LOE A
Miscellaneous	
Avoiding and immediately correcting hypotension (SBP <90 mm Hg or MAP <65 mm Hg) during postresuscitation care may be reasonable	Class IIb, LOE C-LD
The benefit of any specific target range of glucose management is uncertain	Class IIb, LOE B-R

CPR, cardiopulmonary resuscitation; IV, intravenous; IO, intraosseous, LOE, level of evidence; MAP, mean arterial pressure; PVT, pulseless ventricular tachycardia; ROSC, return of spontaneous circulation; SBP, systolic blood pressure; VF, ventricular fibrillation.

[a]Key for evidence-based classifications:

Class of recommendations:

- Class I (Strong). Benefit >>> Risk
- Class IIa (Moderate). Benefit >> Risk
- Class IIb (Weak). Benefit ≥ Risk
- Class III: No Benefit (Moderate). Benefit = Risk
- Class III: Harm (Strong). Risk > Benefit

Levels of evidence (LOE):

- Level A: High-quality evidence from more than 1 RCT, meta-analyses of high-quality RCTs, one or more RCT corroborated by high-quality registry studies.
- Level B-R (Randomized): Moderate-quality evidence form 1 or more RCTs, meta-analyses of moderate-quality RCTs.
- Level B-NR (Nonrandomized): Moderate-quality evidence from 1 or more well-designed nonrandomized

studies, observational studies or registry studies, meta-analyses of such studies.

- Level C-LD (Limited data): Randomized or nonrandomized observational or registry studies with limitations of design or execution, meta-analyses of such studies, physiological or mechanistic studies in human subjects.
- Level C-EO (Expert opinion): Consensus of expert opinion based on clinical experience.

Vasopressin

Vasopressin, also known as antidiuretic hormone, is a potent, nonadrenergic vasoconstrictor that increases blood pressure and systemic vascular resistance. Although it acts on various receptors throughout the body, its vasoconstrictive properties are due primarily to its effects on the V_1 receptor. Measurement of vasopressin levels in patients undergoing CPR has shown a high correlation between the levels of endogenous vasopressin released and the potential for ROSC.[89] In fact, in one study, plasma vasopressin concentrations were approximately three times as high in survivors compared with nonsurvivors, suggesting that vasopressin is released as an adjunct vasopressor to epinephrine in life-threatening events such as cardiac arrest.[90]

Vasopressin may have several advantages over epinephrine. First, the metabolic acidosis that frequently accompanies cardiac arrest can blunt the vasoconstrictive effect of adrenergic agents such as epinephrine. This effect does not occur with vasopressin. Second, the stimulation of beta-receptors caused by epinephrine can increase myocardial oxygen demand and complicate the postresuscitative phase of CPR. Because vasopressin does not act on beta-receptors, this effect does not occur with its use. Vasopressin also may have a beneficial effect on renal blood flow by stimulating V_2-receptors in the kidney, causing vasodilation and increased water reabsorption. With regard to splanchnic blood flow, however, vasopressin has a detrimental effect when compared to epinephrine.[89]

Despite these theoretical advantages with vasopressin, clinical trials have not consistently demonstrated superior results over that achieved with epinephrine (**Table 12-2**). In one large trial of out-of-hospital arrest, no significant differences were noted in ROSC, hospital admission rate or discharge rate.[91] Although, when patients were stratified according to their initial rhythm, patients with asystole had a significantly higher rate of hospital admission (29% vs 20%; $p = 0.02$) and discharge (4.7% vs 1.5%; $p = 0.04$) with vasopressin compared to epinephrine. In addition, a subgroup analysis of 732 patients who required additional epinephrine therapy despite the two doses of study drug revealed significant benefits in ROSC (37% vs 26%; $p = 0.002$), hospital admission rate (26% vs 16%; $p = 0.002$), and discharge rate (6.2% vs 1.7%; $p = 0.002$) with vasopressin. There was a trend, however, toward a poorer neurologic state or coma among the patients who survived to discharge and received vasopressin.

TABLE 12-2 Prospective, Randomized, Controlled Trials with Vasopressin in Cardiac Arrest

					Initial Resuscitation		Hospital Discharge	
Author	Setting	Initial rhythm	Intervention	*N*	Vasopressin	Epinephrine	Vasopressin	Epinephrine
Lindner et al[94a] (1997)	OOH	VF: 100%	Vasopressin 40 units vs epinephrine 1 mg for initial drug treatment	40	16/20 (80%)	11/20 (55%)	8/20 (40%)	3/20 (15%)

[a] $p < 0.05$.

The favorable results observed in the subgroup analysis led to a prospective study evaluating the combination of vasopressin and epinephrine versus epinephrine alone.[92] In this study, patients were randomized to receive either 1 mg of epinephrine followed by 40 units of vasopressin (in less than 10 seconds) or 1 mg of epinephrine plus saline placebo. Unfortunately, there were no significant differences between the combination therapy group and epinephrine only group in any of the outcome measures studied (ROSC, survival to hospital admission, survival to hospital discharge, 1-year survival, and good neurologic recovery at discharge). In contrast, a post-hoc subgroup analysis revealed a lower rate of survival (0% vs 5.8%, $p = 0.02$) with combination therapy when the initial rhythm was PEA.

The utility of a multidrug regimen that also included corticosteroids has been evaluated in the setting of in-hospital cardiac arrest.[93,94] The rationale is based on the hemodynamic effects of steroids along with their potential to impact the intensity of the postresuscitation systemic inflammatory response and organ dysfunction. In a single-center trial, patients were randomized to receive either epinephrine alone or 20 units of vasopressin plus 1 mg of epinephrine and 40 mg of methylprednisolone (followed by hydrocortisone in the postresuscitative phase). Vasopressin 20 units plus epinephrine 1 mg were repeated during each of four subsequent CPR cycles. Significant benefits were observed in ROSC (81% vs 52%, $p = 0.003$) and survival to hospital discharge (19% vs 4%, $p = 0.02$) with combination therapy including corticosteroids. These favorable results led to a multicenter trial conducted at three centers using the same drug regimen.[94] In this study, patients randomized to receive combination therapy had a higher probability for ROSC (84% vs 66%, $p = 0.005$) and a higher probability for survival to hospital discharge with good neurologic function (14% vs 5%, $p = 0.02$).

In lieu of the conflicting results with vasopressin therapy across randomized controlled trials, several meta-analyses have been performed.[95,96,97,98,99] The most recent study included 10 trials analyzing 6,120 patients (3 in-hospital arrest; 7 out-of-hospital arrest).[98] No significant improvements were noted with vasopressin therapy in ROSC (OR [95% CI] = 1.19 [0.93-1.52]), survival to hospital discharge (OR [95% CI] = 1.13 [0.89-1.43]) or favorable neurological outcome (OR [95% CI] = 1.02 [0.75-1.38]). Subgroup analyses revealed vasopressin may be associated with better outcomes in patients with in-hospital arrests or when used as repeated boluses of four or five times. These results may be confounded by the concomitant use of corticosteroids in some trials. A second meta-analysis included 4,745 patients from six studies (4 out-of-hospital arrest; 2 in-hospital arrest).[95] Similarly, no significant improvements were noted with vasopressin therapy in ROSC (OR [95% CI] = 1.25 [0.9-1.74]), long-term survival (OR [95% CI] = 1.13 [0.71-1.78]), or favorable neurologic outcome (OR [95% CI] = 0.87 [0.49-1.52]). When patients were stratified based on the presence of VF/PVT as their initial rhythm, the incidence of ROSC and long-term survival were similar with vasopressin but in patients with asystole, vasopressin was associated with superior long-term survival rates relative to control (OR [95% CI] = 1.8 [1.04-3.12]).

4 In summary, vasopressin appears to offer no benefit as a substitute over epinephrine. Additionally, vasopressin

co-administered with epinephrine offers no benefit compared to standard dose epinephrine alone. Vasopressin therefore has been removed from the 2015 cardiac arrest algorithm.[36] The combination of methylprednisolone, vasopressin and epinephrine can be considered as an alternative to epinephrine alone during CPR for in-hospital cardiac arrest. Future prospective trials are need to validate the role of vasopressin in certain sub-populations (eg, asystole).

Clinical Controversy…

The role of vasopressin continues to be debated due to lack of improvement in survival with good neurologic outcome. There are some sub-populations though where vasopressin may be beneficial. Future trials are needed in this area.

Antiarrhythmics

The purpose of antiarrhythmic drug therapy following unsuccessful defibrillation and vasopressor administration is to prevent the development or recurrence of VF and PVT by raising the fibrillation threshold. Clinical evidence demonstrating improved survival to hospital discharge however is lacking.[100,101]

5 Amiodarone is the recommended antiarrhythmic in patients with VF or PVT, unresponsive to CPR, defibrillation, and vasopressor therapy. Amiodarone is classified as a class III antiarrhythmic but possesses electrophysiologic characteristics of all four Vaughn Williams classifications. A large, randomized, double-blind trial in patients with out-of-hospital cardiac arrest secondary to VF or PVT (referred to as the ARREST trial) randomized individuals to receive either amiodarone 300 mg or placebo.[102] Recipients of amiodarone were more likely to be resuscitated and survive to hospital admission (44% vs 34%, p = 0.03) but there was no difference in survival to hospital discharge (13.4% vs 13.2%, p = NS). This was the first trial to demonstrate the benefit of an antiarrhythmic agent over placebo in patients with out-of-hospital cardiac arrest. A subsequent trial (known as the ALIVE trial) compared amiodarone 5 mg/kg with lidocaine 1.5 mg/kg in patients with out-of-hospital cardiac arrest due to VF.[103] In this trial, amiodarone was associated with a relative improvement of 90% in survival to hospital admission compared with lidocaine (22.8% vs 12%; OR 2.17 [95% CI 1.21-3.83]; p = 0.009). Similar to the ARREST trial, there was no difference in survival to hospital discharge (amiodarone, 5% vs lidocaine, 3%; p = 0.34). A large, multicenter trial is currently underway comparing amiodarone, lidocaine or placebo in patients with out-of-hospital cardiac arrest.[104] The results of this trial will be pivotal in defining the role of antiarrhythmic drug use in cardiac arrest.

Adverse effects of amiodarone encountered in cardiac arrest include hypotension and bradycardia.[105] The effects however are largely due to the intravenous vehicle, polysorbate 80 and benzyl alcohol. A formulation of amiodarone exists that does not contain these solvents and adverse hemodynamic effects appear to be minimized. Nevertheless, administration of a vasoconstrictor prior to amiodarone can potentially prevent hypotension.

Lidocaine is currently recommended as an alternative to amiodarone, if amiodarone is not available.[36] Minimal evidence exists supporting lidocaine use for VF/PVT. In the only published case-control trial where patients were classified according to whether they received lidocaine, no significant difference was noted in ROSC, admission to the hospital, or survival to hospital discharge between groups.[106] Similarly, a prospective study comparing the effectiveness of lidocaine with that of standard-dose epinephrine showed not only a lack of benefit with lidocaine but also a higher tendency to promote asystole.[107] In contrast, a retrospective analysis in patients with VF indicated that lidocaine was associated with a higher rate of ROSC and hospitalization (p < 0.01) but not an increase in the hospital discharge rate.[108]

Magnesium

Severe hypomagnesemia has been associated with VF/PVT but routine administration of magnesium during a

cardiac arrest has not demonstrated any benefit in clinical outcome. Two observation trials though have noted an improvement in ROSC in patients with arrests associated with torsades de pointes.[36] Therefore, magnesium administration should only be administered to those patients.

Thrombolytics

Since most cardiac arrests are related to either myocardial infarction or pulmonary embolism, several investigators have evaluated the role of thrombolytics during CPR. Earlier smaller studies have demonstrated some benefit with their use but in the two largest randomized controlled trials, no difference was noted.[105] In the first, 233 patients with PEA were randomized to receive either tissue plasminogen activator (tPA) or placebo.[109] The proportion of patients with ROSC was 21.4% and 23.3% for tPA and placebo treated patients, respectively. There was no significant difference in hemorrhage rates. The second study randomized patients with out-of-hospital cardiac arrest to receive either tenecteplase or placebo.[110] After a blinded review by the data and safety monitoring board, criteria for futility were met and enrollment was terminated. A total of 1,050 patients were analyzed and both ROSC (tenecteplase, 55% vs placebo, 55%; $p = 0.96$) and survival to hospital discharge (tenecteplase, 15.1% vs placebo, 17.5%, $p = 0.33$) were similar between groups. Furthermore, the incidence of intracranial hemorrhage was significantly greater with tenecteplase versus placebo (2.7% vs 0.4%, $p = 0.006$). Potential reasons for failure in this study include the omission of antiplatelet and antithrombin medication administration during CPR and decreased delivery of the thrombolytic to the coronary arteries (where the clots exist) due to impaired flow and perfusion. Given these results, fibrinolytic therapy should not be used routinely in cardiac arrest but when pulmonary embolism is suspected, their use is suggested.[111]

Pulseless Electrical Activity and Asystole

Nonpharmacologic Therapy

PEA is defined as the absence of a detectable pulse and the presence of some type of electrical activity other than VF or PVT. Several studies have documented that patients with PEA actually have mechanical cardiac contractions, but they are too weak to produce a palpable pulse or blood pressure. Although PEA is still classified as a "rhythm of survival," the success rate of treatment is much lower than the rates seen with VF/PVT.[112] PEA is often caused by treatable conditions, and the resuscitation team needs to identify and correct these conditions emergently if the resuscitation is to be successful (**Table 12-3**). Asystole is defined as the presence of a flat line of the electrocardiogram (ECG) monitor and often represents confirmation of death rather than a rhythm to be treated. Therefore, withdrawal of efforts must be strongly considered if there is not a rapid ROSC.[105] Like PEA, successful treatment of asystole depends almost entirely on diagnosis of the underlying cause.

TABLE 12-3 Underlying Causes of Pulseless Electrical Activity and Asystole

Condition	Clues	Treatment
Hypovolemia	History, flat neck veins	Intravenous fluids
Hypoxia	Cyanosis, blood gases, airway problems	Ventilation, oxygen
Hydrogen ion (acidosis)	History of bicarbonate-responsive preexisting acidosis	Sodium bicarbonate, hyperventilation
Hyper (Hypo) kalemia	History of renal failure, diabetes, recent dialysis, dialysis fistulas, medications	Calcium chloride, insulin, glucose, sodium bicarbonate, sodium polystyrene sulfonate, dialysis
Hypothermia	History of exposure to cold, central body temperature	Rewarming, oxygen, intravenous fluids
Hypoglycemia	History of diabetes	Glucose infusion

Condition	Clues	Treatment
Toxin (drug overdose)	Bradycardia, history of ingestion, empty bottles at the scene, pupils, neurologic examination	Drug screens, intubation, lavage, activated charcoal
Tamponade (cardiac)	History (trauma, renal failure, thoracic malignancy), no pulse with CPR, vein distention, impending tamponade-tachycardia, hypotension, low pulse pressure changing to sudden bradycardia as terminal event	Pericardiocentesis
Tension pneumothorax	History (asthma, ventilator, chronic obstructive pulmonary disease, trauma), no pulse with CPR, neck vein distention, tracheal deviation	Needle decompression
Thrombosis, coronary	History, ECG, enzymes	PCI, thrombolytics, oxygen, nitroglycerin, heparin, aspirin, morphine
Thrombosis, pulmonary	History, no pulse with CPR, distended neck veins	Pulmonary arteriogram, surgical embolectomy, thrombolytics
Trauma	History, examination	Volume infusion, intracranial pressure monitoring, bleeding control, surgical intervention

CPR, cardiopulmonary resuscitation; ECG, electrocardiogram.

Data from reference 36.

The algorithm for treatment of PEA is the same as the treatment of asystole. Both conditions require CPR, airway control, and IV access. Asystole should be reconfirmed by checking a second lead on the cardiac monitor. Defibrillation should be avoided in patients with asystole because the parasympathetic discharge that occurs with defibrillation may reduce the chance of ROSC and worsen the chance of survival. The emphasis in resuscitation is good quality CPR without interruption, and to try to identify a correctable cause. If available, transcutaneous pacing can be attempted.

Much like VF/PVT, there is an interest in hypothermia in these post-arrest patients. Metabolic parameters (eg, lactate and O_2 extraction) have been shown to be improved when post-arrest comatose adults survived their arrest and were treated with hypothermia.[113] A meta-analysis though has failed to demonstrate any benefit in survival or neurologic outcome.[114] Further studies are warranted in this area.

Pharmacologic Therapy

The primary pharmacologic agent used in the treatment of asystole or PEA is epinephrine; vasopressin is no longer recommended. While data evaluating these therapies solely in patients with asystole or PEA are limited, these rhythms represent a majority of patients included in the published research. For example, in the largest observational trial evaluating the role of epinephrine in out-of-hospital arrest, 93% had either PEA or systole as the first documented rhythm.[71] In this study, epinephrine was associated with a significant improvement in ROSC but one-month survival and survival with good neurologic function were lower with epinephrine. A second study revealed similar findings but worse neurological outcomes were noted when epinephrine administration time exceeded 10 minutes.[76] In one study of more than 25,000 patients with in-hospital arrest and either asystole or PEA, a step-wise decrease in survival was observed with each incremental delay in epinephrine administration.[74] As with VF/PVT, time to epinephrine administration appears to be an important confounding factor.

Inconsistent results have also been reported with vasopressin. In a post-hoc subgroup analysis of patients with

out-of-hospital arrest and asystole as the first identified rhythm, survival to hospital admission (29% vs 20%, p = 0.02) and discharge (4.7% vs 1.5%, p = 0.04) were significantly higher with vasopressin compared to epinephrine.[91] There was, however, a non-statistically significant increase in coma/vegetative state with vasopressin (40% vs 0%, p = 0.14). Similar findings were cited in a meta-analysis of randomized controlled trials comparing vasopressin with control.[95] Patients with asystole who had study drug administered within 20 minutes had higher rates of ROSC (OR [95% CI] = 1.7 [1.17-2.47]) and long-term survival (OR [95% CI] = 2.84 [1.19-6.79]). These results were largely influenced by the aforementioned trial which accounted for a majority of the weight in those statistics. In contrast to these findings, one randomized controlled trial, which evaluated combination therapy with vasopressin and epinephrine, did not report an advantage with vasopressin in patients with asystole.[92] In fact, a post-hoc subgroup analysis of patients with PEA as the initial rhythm, revealed a lower rate of survival (0% vs 5.8%, p = 0.02) with combination therapy compared to epinephrine alone.

Another agent that is no longer recommended in the setting of PEA or asystole is atropine.[36] Atropine is an antimuscarinic agent that blocks the depressant effect of acetylcholine on both heart rate and atrioventricular nodal conduction, thus decreasing parasympathetic tone. During asystole, parasympathetic tone may increase because of the vagal stimulation that occurs secondary to intubation, the effects of hypoxia and acidosis, or alterations in the balance of parasympathetic and sympathetic control.[115] Nevertheless, there are no prospective controlled trials showing benefit from atropine for the treatment of asystole or PEA and conflicting evidence exists across retrospective and observational reports. Therefore, atropine should not be routinely administered in this setting.

Acid-Base Management

Acidosis seen during cardiac arrest is the result of decreased blood flow (leading to anaerobic metabolism) or inadequate ventilation. Chest compressions generate only approximately 25% of normal cardiac output, leading to inadequate organ perfusion, tissue hypoxia, and metabolic acidosis. In addition, the lack of ventilation causes retention of carbon dioxide, leading to respiratory acidosis. This combined acidosis produces not only reduced myocardial contractility, but also the appearance of arrhythmias because of a lower fibrillation threshold. In early cardiac arrest, adequate alveolar ventilation has been considered the mainstay of control to limit the accumulation of carbon dioxide and control the acid-base imbalance.[105] With the evolution to CCR, however, there are experts arguing against ventilation because of the negative effects it can have on the effectiveness of CPR. This has led to evidence showing no negative effects if compression-only CPR is used for out-of-hospital cardiac arrest (exceptions being pediatric arrest, drowning, trauma, airway obstruction, non-cardiac etiology, or due to acute respiratory disease).[116] With arrests of long duration, buffer therapy is often considered, however few data support its use during cardiac arrest. In one randomized controlled trial, the early administration of bicarbonate (1 mEq/kg) had no effect on survival in pre-hospital cardiac arrest with only a trend toward improvement in prolonged arrest (more than 15 minutes).[117]

Although sodium bicarbonate was once given routinely to reduce the detrimental effects associated with acidosis (eg, reduced myocardial contractility), enhance the effect of epinephrine, and improve the rate of defibrillation, there are few clinical data supporting its use.[118] In fact, sodium bicarbonate may have some detrimental effects.[118,119] The effect of sodium bicarbonate can be described by the following reaction:

$[HCO_3^-] + [H^+] \leftrightarrow [H_2O] + [CO_2]$

When sodium bicarbonate is added to an acidic environment, this reaction will shift to the right, thereby increasing tissue and venous hypercarbia. The carbon dioxide generated by this reaction will diffuse into the cell and decrease intracellular pH. The accumulation of intracellular carbon dioxide, specifically within the myocardium, is inversely correlated with coronary perfusion pressure produced by CPR. Intracellular acidosis also will decrease myocardial

contractility, further complicating the low-flow state associated with CPR.[118] Furthermore, treatment with sodium bicarbonate often overcorrects extracellular pH because sodium bicarbonate has a greater effect when the pH is closer to normal.[119] The induced alkalosis, causes an increase in the affinity of oxygen to hemoglobin ("left shift"), thus interfering with oxygen release into the tissues.

Sodium bicarbonate can be used in special circumstances (ie, underlying metabolic acidosis, hyperkalemia, salicylate overdose, or tricyclic antidepressant overdose), however, the dosage should be guided by laboratory analysis if possible. Tromethamine (THAM) is an alternative buffering agent which acts as a proton acceptor but there is a dearth of clinical experience with this agent in cardiac arrest and outcome studies are not currently available. [105]

Postresuscitative Care

Following the ROSC from a cardiac arrest, a complex phase of resuscitation begins which has been termed post-cardiac arrest syndrome.[120] There are four main components of post-cardiac arrest syndrome highlighting succinct pathophysiologic processes and potential areas for treatment. These are: post-cardiac arrest brain injury, myocardial dysfunction, systemic ischemia/reperfusion response, and persistent precipitating pathology. In general, many of the concepts within these four components surround the principles of basic ICU care (eg, early hemodynamic optimization, circulatory support, sedation, etc). Post-arrest care has the significant potential to reduce early mortality from altered hemodynamics and later morbidity and mortality from multiple organ dysfunction and central nervous system injury.[37,120,121]

After ROSC, it is imperative to ensure adequate airway and oxygenation. Securing the airway to prevent inadvertent loss is an important step. If there is any question of cervical spine injury, the patient should have a cervical collar placed, with subsequent appropriate evaluation. The head of the bed should be raised to 30 degrees (if this can be tolerated hemodynamically) to reduce the risk for aspiration, ventilator-associated pneumonia, and cerebral edema. Usually 100% oxygen is used during the initial resuscitation effort. If ROSC is obtained and the patient is placed on a mechanical ventilator, the health care team should titrate the oxygen fraction down as tolerated to avoid oxygen toxicity. Overventilation is common in the postresuscitation timeframe; the advent of widespread $ETCO_2$ usage can avoid this pitfall (ie, targeting an $ETCO_2$ of 40-45 mm Hg).

Because the most common cause of cardiac arrest is ischemia, a rapid search for electrocardiographic changes consistent with acute myocardial infarction should be undertaken as soon as possible in the post-arrest timeframe.[122] If there is an acute myocardial infarction present, urgent revascularization should be enacted immediately.

Therapeutic hypothermia or targeted temperature management is an integral component of postresuscitative care. Restoration of blood flow following cardiac arrest can lead to several chemical cascades and destructive enzymatic reactions that can result in cerebral injury. These reactions include free-radical production, excitatory amino acid release and calcium shifts, which ultimately lead to mitochondrial damage and apoptosis (programmed cell death).[123] Hypothermia can protect from cerebral injury by suppressing these chemical reactions, thereby reducing the production of free radicals. Additionally, therapeutic hypothermia can decrease cerebral metabolism and oxygen consumption as for each 1°C drop in temperature, cerebral metabolism can decrease by 6% to 10%.[124]

Early human success with hypothermia was described in two pivotal trials published in 2002.[125,126] The first was conducted in nine centers in five European countries.[125] In this trial, patients who had been resuscitated after cardiac arrest due to VF but remained comatose were assigned randomly to undergo therapeutic hypothermia, targeting a temperature of 32°C to 34°C, for 24 hours. The primary endpoint was favorable neurologic outcome which was achieved in 55% of patients in the hypothermia group as opposed to 39% in the normothermia group ($p = 0.009$). Additionally, mortality rates were improved significantly in the hypothermia group (41% vs 55%; $p = 0.02$).

Based on this difference, seven patients would need to be treated with hypothermia to prevent one death. The second trial was conducted in four hospitals in Melbourne, Australia.[126] Entry criteria were similar to the previous trial, but the target temperature for hypothermia was 33°C, which was maintained for 12 hours. Forty-nine percent of patients in the hypothermia group had good neurologic function on discharge (to either home or a rehabilitation facility) compared with 26% of patients in the normothermia group (p = 0.046). Mortality rates were similar between the two groups (51% for the hypothermia group and 68% for the normothermia group; p = 0.145). Following these trials and widespread implementation across healthcare centers, there have been numerous observational studies describing the beneficial role of therapeutic hypothermia.[127] As a result, the utility of therapeutic hypothermia had markedly increased.[128]

Recently there have been 3 large-scale randomized controlled trials that have challenged the role of therapeutic hypothermia post-cardiac arrest.[129,130,131]

Clinical Controversy…

The role of therapeutic hypothermia has been challenged with the publication of recent studies. Some believe a temperature of 32°C to 34°C should be the target while others believe 36°C is the target with an emphasis on preventing hyperthermia.

The first was an international trial with 939 patients comparing targeted temperature management at 33°C versus 36°C.[131] The hypothermia intervention period was 36 hours. There was no significant differences noted in in all-cause, end of trial mortality (33°C, 50% vs 36°C, 48%, p = 0.51) or poor neurologic function (33°C, 54% vs 52°C, 48%, p = 0.78). The second trial assessed whether or not prehospital cooling improved survival in 1,364 patients.[129] Target temperature was less than 34°C which was reached approximately 1 hour sooner in the intervention group compared to controls. Prehospital cooling was not associated with increased survival to hospital discharge (63% vs 64%, p = 0.69) or improvement in neurological status (58% vs 62%, p = 0.69) in patients with VF. Similarly, prehospital cooling did not affect outcomes in patients without VF. Finally, the third study compared therapeutic hypothermia with therapeutic normothermia following out-of-hospital cardiac arrest in children.[130] In this study, the target temperature was 33°C (which was maintained for 48 hours) in the hypothermia groups and 36.8°C in the normothermia group. The primary outcome measure was survival with a good neurobehavioral outcome at 12 months using the Vineland Adaptive Behavior Scale, 2nd edition. No difference was noted between groups (20% vs 12%, p = 0.14).

Collectively, these studies raise the question of whether or not the benefits of hypothermia are related to hypothermia itself or avoidance of hyperthermia. In one of the earlier trials, that was pivotal to the widespread utilization of this intervention, there was no active temperature management in the control group. Mild fever, therefore occurred in some patients (average temperature was 37.8°C).[125] This is important because previous research has shown for each degree higher than 37°C, the risk of unfavorable neurologic recovery increases (OR ([95% CI] = 2.26 [1.24-4.12]).[132] Nevertheless, despite recent data showing no improvement in outcomes with hypothermia, the concept of targeted temperature management should not be abandoned. The most current guidelines recommend targeted temperature management (as opposed to no management) for all comatose adults patients after ROSC.[37] The target temperature should be between 32°C and 36°C and maintained for at least 24 hours. It is also reasonable to actively prevent fever following targeted temperature management. Further research is needed to discern the most appropriate temperature level, timing or subpopulations that may benefit from lower temperature targets.

Several methods exist to induce hypothermia which can be classified as surface cooling or invasive. Surface cooling devices are noninvasive and include simple ice packs, cooling blankets/gel pads, ice water immersion, and nasopharyngeal evaporative cooling devices.[133] Invasive cooling methods include ice cold intravenous fluids, endovascular cooling catheters, body cavity lavage, extracorporeal circuits, and selective brain cooling. While there

is no consensus on the optimal method to induce hypothermia, target temperatures should be reached as quickly as possible (eg, the induction phase).[124] During the maintenance phase, core temperature should be tightly controlled with little or no fluctuations. The rewarming phase should consist of slow and controlled warming at a rate of 0.2°C to 0.5°C per hour.

Hypothermia must be used with caution, however, as there are several complications that can develop. Shivering occurs during the induction phase and can increase metabolic rate and myocardial oxygen demand. Several strategies exist to blunt the thermoregulatory response to hypothermia and these measures should be implemented accordingly.[134,135] Coagulopathy, dysrhythmias, cardiovascular changes, hyperglycemia, electrolyte disorders, and infectious risks have also been described.[134] In addition, hypothermia can have profound effects on drug distribution and clearance.[134] Although the duration of hypothermia is typically short, careful monitoring during this time period is necessary, particularly with vasoactive agents, sedatives, and opiates. Further research is required in this area.

Special Populations

Asthma

Asthma is a very common disorder, and despite modern therapies, there are still in excess of 2 million emergency room visits and 5,000 to 6,000 asthma-related deaths annually in the United States.[136] True cardiac arrest in asthma is infrequent, as the primary pathophysiology is respiratory compromise and the inability to ventilate.[137] Asthma exacerbations are a combination of bronchoconstriction, airway inflammation, and mucous plugging. This leads to severe air trapping, hyperinflation, and hemodynamic compromise. While wheezing is common in an asthma exacerbation, it does not correlate with the degree of airway obstruction. In contrast, as the airflow decreases with worsening disease, wheezing can disappear. In addition, several other disease states cause wheezing, including pulmonary edema, pneumonia, anaphylaxis, foreign bodies, and tumors.[136]

Patients with life-threatening asthma need to be treated aggressively with bronchodilators and corticosteroids. Adjunctive therapies include anticholinergics, magnesium sulfate, ketamine, helium/oxygen mixtures, or even inhaled anesthetics.[138,139,140,141,142] Noninvasive ventilation can be attempted if the patient is deteriorating and still awake for short-term support, and may prevent the need for mechanical ventilation.[143] The decision to intubate an asthmatic is a clinical judgment; the clinician needs to remain keenly aware that the endotracheal tube will not solve the airway problem, and that ongoing aggressive asthma management needs to continue after intubation. Mechanical ventilation in the asthmatic can be very difficult, and the intubation and positive pressure can trigger further bronchoconstriction or hemodynamic compromise.

The provision of BLS in asthma is unchanged. Similarly, standard advanced cardiac life support measures should be followed.[136] However, since the effect of auto-positive end expiratory pressure (PEEP), known as breath stacking, in an asthmatic with cardiac arrest is likely to be severe, a strategy of low respiratory rate and volume ventilation may be appropriate.[136] Similarly, for cardiac arrest in asthma, especially when ventilation is difficult, tension pneumothorax should be strongly considered.[136]

Anaphylaxis

Anaphylaxis is a severe allergic reaction involving most organs, and can lead to airway obstruction and cardiovascular collapse.[136] It still accounts for between 500 and 1,000 deaths annually in the United States.[144] The initial signs can be nonspecific, but with a severe reaction a “sense of impending doom” is common.[136] Rhinitis often leads to laryngeal edema with stridor in the upper airway, and bronchoconstriction often mimics an acute asthma attack as described earlier.

Cardiovascular collapse is common in severe reactions due to vasodilation and increased capillary permeability. This can rapidly lead to myocardial hypoperfusion and ischemia and to full cardiac arrest. There are no randomized trials of algorithms for arrest due to anaphylaxis.[136] Because of this lack of evidence, standard basic and advanced life support should be provided.

Early advanced airway management is recommended due to the potential for rapid edema development. Epinephrine has been the main-stay of treatment for years, and continues to be listed first.[136] The recommended dose is 0.2 to 0.5 mg and should be administered via intramuscular injection to all patients with signs of systemic allergy.[136] This can be repeated every 5 to 15 minutes in the absence of clinical improvement. Vasopressin has been used successfully in patients who did not respond to standard therapy.[145] Fluid resuscitation is usually required for restoration of circulation and has been evaluated in one study where hypotension did not respond immediately to vasoactive drugs.[146] There are no prospective trials evaluating other agents in anaphylactic shock or arrest. Antihistamines, inhaled beta-agonists, and intravenous corticosteroids have been used successfully in anaphylaxis and may be considered in cardiac arrest due to anaphylaxis.[136]

Pregnancy

Pregnancy is a unique situation in that survival of both the fetus and the mother depend on CPR. Despite the fact that pregnant patients are younger than the traditional cardiac arrest patient, the incidence of cardiac arrest in pregnancy seems to be on the rise, approximately 1 in 12,000 admissions for delivery in the United States.[111] In addition, the mortality rate of cardiac arrest with pregnancy seems to be higher, with one series reporting a survival rate of just 6.9%.[136,147]

The best hope for survival of the fetus is maternal survival. Because of the gravid uterus, resuscitation needs to be modified. Since the vena cava and aorta can be obstructed by a uterus of approximately 20 weeks gestation or later, manual lateral uterine displacement is suggested (ie, pulling the uterus to the side).[111] An alternative approach is to tilt the patient laterally (approximately 30 degrees), however, CPR quality is decreased. Thus, the current guidelines suggest that manual lateral uterine displacement in the supine position be attempted to optimize CPR quality.[111]

Airway control is important in the pregnant patient. The airway may be smaller because of the hormonal changes and edema which accompany pregnancy.[148] Similarly, because of increased intra-abdominal pressure exerted by the uterus, as well as hormonal changes that change the resting state of the gastroesophageal sphincter, clinicians need to be acutely aware of the increased risk of aspiration. Because of this, cricoid pressure needs to be maintained continuously during airway manipulation. The rescuer may need to give smaller tidal volumes than normal because of the diaphragm elevation that accompanies the later stages of pregnancy. Because of the increased ventilatory needs in pregnancy as well as the anatomic changes, some authors have suggested that it is important to perform early intubation during cardiac arrest in pregnancy and cite this rapid intubation as a difference from non-pregnant patients.[148] Similarly, circulatory support also has to be adjusted. In particular, chest compressions need to be administered slightly above the center of the sternum to adjust for the anatomic changes of the pregnant uterus.[136]

In an arrest situation during pregnancy the ACLS provider needs to follow the standard guidelines, including the same use of defibrillation and medications. While it is true that vasoactive agents, such as epinephrine, can diminish uterine blood flow, safer alternatives do not exist.[136] Available literature, though scant, suggests that the energy requirements for defibrillation do not change in pregnancy.[149]

While etiologies of arrest in pregnancy are often the same as in the non-pregnant patient, there are several unique situations that need to be considered in the differential diagnosis of a pregnancy arrest. These include excess

magnesium sulfate administration (ie, iatrogenic from treating eclampsia) in which case the therapeutic administration of calcium gluconate can be lifesaving; amniotic embolism, which is associated with complete cardiovascular collapse during labor and delivery (cardiopulmonary bypass has been reportedly successful in salvaging this condition); pre-eclampsia/eclampsia developing after the 20th week of gestation producing hypertension and multiple organ dysfunction; as well as vascular events including acute coronary syndromes and acute pulmonary embolism.[148,150,151]

It is paramount to remember that unless circulation is restored to the mother, both the mother and the fetus will succumb, especially if standard therapy is not used correctly and promptly. Because of this, the resuscitation leader should consider the need for emergent cesarean delivery as soon as the arrest happens or if there is no immediate response after lateral uterine displacement and CPR.[111]

Hypothermia

Unintentional hypothermia (as opposed to the therapeutic hypothermia used post-arrest, described above) is defined by a body temperature less than 30°C (86°F), and is associated with marked derangements in body function. Because it can depress virtually every body system, including pulse and respiration, the patient may appear to be dead upon the initial evaluation. Hypothermia may lead to benefit on brain recovery after cardiac arrest (discussed earlier), thus aggressive intervention is clearly indicated when there is a hypothermic arrest victim.

If the patient still has a perfusing rhythm, therapy is mainly based upon rewarming techniques. For mild hypothermia (ie, more than 34°C [more than 93.2°F]), passive rewarming is recommended. For moderate hypothermia (ie, 30°C-34°C [86°F-93.2°F]), active external rewarming is recommended, and for severe hypothermia (ie, less than 30°C [less than 86°F]) active internal rewarming is recommended. These patients need to be manipulated very gently as VF is sometimes precipitated by movement.[152]

If the patient is in cardiac arrest, then the standard BLS algorithm should be followed. However, there are some modifications that the rescuer needs to consider. The rescuer should evaluate for pulse for a longer timeframe, since the heart rate may be slow or very difficult to palpate. If there is no pulse, then chest compressions and rescue breaths should ensue. If the patient is in VF or PVT then electrical therapy should be given in a standard manner. However, the hypothermic heart may be less responsive to medications or defibrillation, and thus there have been worries about the optimal temperature at which to start defibrillation attempts.[136] There are no published consensus guidelines regarding this, but animal data supports medications during CPR in cardiac arrest associated with hypothermia.[153] Immediately after defibrillation, CPR should resume as in the standard manner. During CPR, continued attempts at rewarming are of paramount importance. Included in this concept is preventing further heat loss (ie, removal of wet clothing, protection from the environment, etc). Patients often require significant volume challenges during the rewarming process. The use of steroids, antibiotics, and barbiturates has been proposed, but none of these agents have ever been shown to increase survival rates.[136]

It is debatable when to stop resuscitative efforts in the hypothermic patient. Many authors have proposed that a patient should not be pronounced dead until the core temperature has been restored to near normal.[136] Once the patient is in the hospital, it is still the judgment of the treating physician when efforts should be terminated.

Trauma

Cardiac resuscitation of the trauma arrest patient is basically performed with the same guidelines as any other arrest. There are some specific etiologies to rapidly consider however, since the survival of an out-of-hospital cardiac arrest due to trauma is rare.[136] The rescuer needs to consider airway obstruction, pneumothorax, tracheobronchial injury, cardiac or large arterial injury, cardiac tamponade, severe head injury with secondary cardiac collapse, and other injuries specific to the particular trauma.[136] The best survival seems to be in young

patients with treatable penetrating injuries.

Trauma patients often suffer head or cervical injuries; thus cervical spine precautions should be used in these patients. A jaw thrust maneuver is the preferred way to open the airway, with in-line stabilization during attempts at advanced airway placement.[136] The rescuer must be vigilant for the development of tension pneumothorax during ventilation. Inadequate ventilation of one side is usually due to tube malposition, tension pneumothorax, or hemothorax. These conditions are usually treated by medical personnel at the hospital after transport.

Chest compressions should be performed in a standard manner. Any visible hemorrhage should be controlled with direct pressure. Fluid resuscitation is done with a goal of adequate blood pressure and organ perfusion. The specific details of fluid resuscitation are highly controversial however, and the optimal volume infusion for trauma resuscitation is a subject of ongoing debate.

Open thoracotomy for trauma-induced arrest has been performed in many instances. For penetrating chest trauma patients who arrest immediately before arrival or in the emergency department, open thoracotomy can allow relief of tamponade, control of major vessel hemorrhage, or direct repair of cardiac insult.[136] Furthermore, some have suggested that a physician-led, out-of-hospital thoracotomy for penetrating trauma may have a higher chance of survival.[154] In the case of blunt trauma, however, open thoracotomy has not been shown to definitively improve outcome.

A unique phenomenon of cardiac arrest (usually VF) caused by a blow of the anterior chest or sternum during the repolarization part of the cardiac cycle is called "Commotio Cordis."[155] These events are commonly seen in young athletes, and can be caused by a myriad of mechanisms, from falling directly on the sternum, to the strike of a baseball or hockey puck. Prompt recognition is of paramount importance, as rapid defibrillation is often lifesaving. Provision of basic life support, the use of an automatic external defibrillator, and standard advanced cardiac life support is appropriate for this type of arrest.

For definitive post-arrest care, trauma patients should be rapidly transferred to a facility with expertise in the provision of trauma care, and practitioners should consult guidelines for terminating efforts of cardiac arrest published by the National Association of EMS Physicians and the American College of Surgeons Committee on Trauma.[136,156]

Drowning

Drowning is a process resulting in primary respiratory impairment from immersion in a liquid. It is a common, preventable cause of morbidity and mortality. The most important inciting event is the hypoxia induced by submersion. The most powerful predictor of outcome therefore is duration of submersion. In fact, in one study the adjusted RR (95% CI) for a good outcome was only 0.02 (0.01-0.04) when the submersion duration exceeded 10 minutes.[157] With submersion durations that exceed 25 minutes, resuscitation efforts may be futile.

The presumed etiology of the arrest in a drowning patient is hypoxia thus the traditional A-B-C approach should be used instead of C-A-B. Early care consists of immediate rescue breathing, even before they are removed from the water. Once the victim is removed from the water, immediate chest compressions should be started if they are pulseless. Drowning victims can present with any of the pulseless rhythms; standard guidelines need to be followed for therapy of these rhythms. A Drowning Chain of Survival has been proposed to improve chances of survival and recovery from drowning.[158] The five links in the chain are: prevent drowning, recognize distress, provide flotation, remove from water, and provide care as needed.

Electrocution/Lightning

There are many etiologies of electrical shock injuries, from lightning strike (mortality estimated to be 30%, with

70% of survivors sustaining significant morbidity) to high-tension current, to household current.[136] The severity of injury depends on the site, type of current, duration of contact, pathway, and the magnitude of delivered electricity.

Cardiac arrest is common in electrical injury due to current passing through the heart during the "vulnerable period" of the cardiac cycle. In large-current events, such as lightning strike, the heart undergoes massive depolarization simultaneously.[159] Sometimes the intrinsic pacemaker can restore an organized cardiac electrical cycle, but because of injury to other muscles, specifically the thoracic musculature, the patient cannot retain or sustain viable circulation due to the lack of ventilation and oxygenation.[160]

When approaching a victim of electrocution, the rescuer must first be certain of his or her own safety. Thereafter, standard BLS, prompt CPR, and ACLS when available is indicated. Electric shock is often associated with multiple trauma, including spinal injury, multiple injuries to the skeletal muscles, as well as fractures. These factors need to be evaluated by the resuscitation team.

Airway control may be difficult due to the edema that often accompanies such injuries; thus an advanced airway early in the treatment process is recommended.[136] With soft tissue swelling, there is often a need for aggressive fluid resuscitation in these patients. The underlying tissue, or visceral organ damage, is often worse than the external appearance. It is usually recommended that these patients be transferred to centers with expertise in dealing with these types of injuries.

Drug Administration

The routes of administration available for drug delivery during CPR include IV (both central and peripheral access), IO, and endotracheal. The chosen route represents a compromise between the availability of access and their apparent efficacy in introducing the drug into the central circulation. When selecting a route for drug administration, it is of utmost importance to minimize any interruptions in chest compressions during CPR.

Central venous access will result in a faster and higher peak drug concentration than peripheral access but central line access is not needed in most resuscitation attempts. If a central line is already present, however, it should be the access site of choice. An appropriately trained provider may consider placing a central line if one is not present but CPR should not be interrupted. Central lines located above the diaphragm are preferable to those located below the diaphragm because of poor blood flow during CPR.[161] If IV access (either central or peripheral) has not been established a large peripheral venous catheter should be inserted. It has been suggested that only one attempt at peripheral IV insertion be allowed.[162] If this is not successful, an IO device should be inserted. Peripheral drug administration yields a peak concentration in the major systemic arteries in roughly 1.5 to 3 minutes but circulation time can be shortened by up to 40% if the drug is followed by a 20-mL fluid bolus with elevation of the extremity.[161]

7 IO administration is the preferred alternative route for administration if IV access cannot be achieved.[105] Several studies have documented the effectiveness and safety of this administration route in both adults and children.[163] Pharmacokinetic data have demonstrated similar areas under the curve and times to peak concentration for sternal IO and central IV administration.[164] There appears to be variability, though, based on the anatomic site for insertion as IO administration via the tibia delivered only 65% of the dose compared to the sternum. Potential anatomic sites for insertion for an IO needle are the distal tibia, the proximal tibia, the distal femur, the sternum, and the humerus.[163,164] There are several IO access devices that are commercially available allowing for rapid insertion and are easy to use. In fact, clinical trials have documented success rates of approximately 80% with placement times of roughly 1 to 2 minutes.[163] The high success rates for achieving vascular access (upon first attempt) allow for more rapid drug administration (versus IV therapy) and could offset the pharmacokinetic differences observed with this approach. Future pharmacokinetic studies are needed to identify the most optimal anatomic site for IO placement and if current dosing recommendations are appropriate.

In the event that neither IV nor IO access can be established, a few drugs can be administered through an endotracheal tube. These drugs are atropine, lidocaine, epinephrine, naloxone, and vasopressin.[105] There are no data with amiodarone. Medications administered through the endotracheal route, however, will have both a lower and delayed peak concentration than when they are administered by the IV or IO routes. In fact, animal studies have suggested that the lower epinephrine concentrations achieved with endotracheal administration may lead to vasodilation through beta-receptor activity. Clinical trials in humans have also failed to demonstrate any benefit with using the endotracheal route.[165,166] In one clinical trial, a lower rates of ROSC (15% vs 27%, $p \leq 0.01$), hospital admission (9% vs 20%, $p \leq 0.02$), and hospital discharge (0% vs 5%, $p \leq 0.02$) was observed with endotracheal drug administration compared to IV.[166] If the endotracheal route is to be used, the recommended medication dose is 2 to 2.5 times larger than the IV/IO dose. Providers should dilute the medication in 5 to 10 mL of either sterile water or normal saline but better drug absorption may be achieved with sterile water.[105]

Personalized Pharmacotherapy

Several investigators have evaluated factors associated with good neurologic outcome following a cardiac arrest in an attempt to better predict prognosis, optimize resources, and decrease the percentage of patients who are left neurologically devastated. Many factors have been identified that are related to survival to hospital discharge. These include age, the occurrence of a witnessed arrest, rapid implementation of bystander CPR, presence of VF/PVT as the initial rhythm, early defibrillation therapy, achievement of ROSC in the field and time to ROSC.[167,168,169,170,171] In fact, one group developed a statistical prediction model whereby the probability for a good neurologic outcome was = exp(B)/1 + exp(B) where B = –0.02 (age in years) – 0.109 (time to ROSC in minutes) + 0.677 (ROSC prior to hospital arrival; 1 if yes, 0 if no) + 2.442 in patients with VF.[167] For patients with PEA/asystole, B = –0.037 (age in years) –0.076 (time to ROSC in minutes) + 1.735 (ROSC prior to hospital arrival; 1 if yes, 0 if no) + 1.462 (conversion to VF; 1 if yes, 0 if no) + 1.101. Areas under the receiver-operating characteristic curve were 0.867 for VF and 0.873 for PEA/asystole indicating a high predictive ability. A second study analyzed more than 390,000 cases of out-of-hospital cardiac arrest to develop a decision-tree prediction model for survival with good neurological outcome.[171] The single best predictor for survival with good neurological outcome was a shockable initial rhythm. Other identified predictors were age younger than 70 years, presence of a witnessed arrest or arrests witnessed by EMS personnel (**Table 12-4**). Other prediction models have been recommended which suggest a poor outcome is very likely if one or both of the following are present: bilateral absence of either pupillary and corneal reflexes and bilateral absence of the N20 wave of short-latency somatosensory evoked potentials, 72 hours post-ROSC.[37] A poor outcome is likely if two or more of the following are present: status myoclonus less than or equal to 48 hours post-ROSC, high neuron-specific enolase levels, unreactive burst-suppression, or status epilepticus on electroencephalogram (EEG) and diffuse anoxic injury on brain computed tomography/magnetic resonance imaging (CT/MRI). This prediction model does require a great deal of technical expertise which may not be available at every institution.

TABLE 12-4 Results from a Decision-Tree Model Identifying Prediction Groups for Out-of-Hospital Cardiac Arrest and Survival with Good Neurologic Outcome

	Criteria			
Initial Rhythm	**Age**	**Bystander Witnessed Arrest**	**EMS Witnessed Arrest**	**Survival with CPC Score 1 – 2**
Shockable	<70	Yes	-	20.3%
Shockable	<70	No	-	8.1%
Shockable	≥70	-	Yes	23.2%
Shockable	≥70	-	No	6.9%
Unshockable	-	Yes	-	1.4%
Unshockable	-	No	-	0.3%

CPC, cerebral performance category; EMS, emergency medical services.

Dash mark indicates the respective variable was not identified as a predictor on multivariate decision-tree analysis.

Data from reference 171.

Other studies have evaluated prognostic indicators to identify scenarios whereby little or no chance of survival may be evident and prehospital termination of resuscitation would be appropriate.[172,173,174] From these data, two rules have been developed. The first rule, referred to as the BLS rule, has 3 criteria: (1) the event was not witnessed by EMS personnel, (2) no AED was used or manual shock applied, and (3) ROSC was not achieved in the out-of-hospital setting. The second rule, referred to as the advanced life support rule, consists of the BLS criteria plus (1) the arrest was not witnessed by a bystander and (2) no bystander CPR administered. In one validation study of 5,505 patients, these rules accurately identified patients who were unlikely to benefit from rapid transport to a hospital with a positive predictive value of 0.998 (BLS rule) and 1.000 (ALS rule) when all criteria were met, respectively.[175]

Prediction models have also been investigated for in-hospital cardiac arrest. One study queried the Get With the Guidelines-Resuscitation registry over a ten year period (January, 2000-October, 2009) to develop a score card with 11 variables that were identified in a multivariate analysis[176] (**Table 12-5**). This prediction tool was called the Cardiac Arrest Survival Postresucitation In-hospital (CASPRI) score and was highly successful in predicting survival with favorable neurologic outcome ranging from 70% in the top decile and 2.8% in the bottom decile. A second prediction model also used the Get with the Guidelines-Resuscitation registry but limited their analysis to a three year period (2007-2009).[177] This model is referred to as the Good Outcome Following Attempted Resuscitation (GO-FAR) Score and was also successful in prediction survival with favorable neurologic outcome (see Table 12-5). While these scoring systems are not designed to identify scenarios where resuscitation may be futile, they can provide useful prognostic information for the medical team, patients, and families.

TABLE 12-5 Prediction Tools for Survival following In-Hospital Cardiac Arrest

Cardiac Arrest Survival Postresuscitation In hospital (CASPRI) Scorecard

Predictor	Points
Age group (years)	
<50	0
50-59	0
60-69	1
70-79	2
≥80	4
Initial arrest rhythm	
VF/PVT time to defibrillation	0
≤2 minutes	0
3 minutes	2
4-5 minutes	3
>5 minutes	6
	7

Cardiac Arrest Survival Postresuscitation In hospital (CASPRI) Scorecard

Predictor	Points
PEA	0
Asystole	2
Prearrest CPC score	
1	0
2	2
3	9
≥4	9
Hospital location	
Telemetry unit	0
Intensive care unit	1
Nonmonitored unit	3
Duration of resuscitation (minutes)	
2	0
2-4	0
5-9	3
10-14	5
15-19	6
20-24	6
25-29	6
≥30	8
Mechanical ventilation	3
Renal insufficiency	2
Hepatic insufficiency	4
Sepsis	3
Malignant disease	4
Hypotension	3

INTERPRETATION

Score	Survival with CPC Score of 1-2
0-4	83%
5-9	67%
10-14	42%
15-19	23%
20-24	12%

Cardiac Arrest Survival Postresuscitation In hospital (CASPRI) Scorecard	
Predictor	**Points**
25-29	5.2%
30-34	2.1%
35-39	0
≥40	0

Good Outcome Following Attempted Resuscitation (GO FAR) Scorecard[177]

SCORECARD	
Predictor	**Points**
Neurologically intact or with minimal deficits at admission	–15
Major trauma	10
Acute stroke	8
Metastatic or hematologic cancer	7
Septicemia	7
Medical noncardiac diagnosis	7
Hepatic insufficiency	6
Admit from skilled nursing facility	6
Hypotension or hypoperfusion	5
Renal insufficiency or dialysis	4
Respiratory insufficiency	4
Pneumonia	1
Age group (years)	
70-74	2
75-79	5
80-84	6
≥85	11

INTERPRETATION	
Score	**Survival with CPC Score of 1**
≥24	0.8%
14 to 23	2%
–5 to 13	9.2%
–15 to –6	27.8%

CPC, cerebral performance category; PVT, pulseless ventricular tachycardia; VF, ventricular fibrillation.

Data from references 176 and 177.

EVALUATION OF THERAPEUTIC OUTCOMES

To measure the success of resuscitation outcomes, therapeutic outcome monitoring should occur both during the resuscitation attempt and in the postresuscitation phase. The optimal outcome following CPR is an awake, responsive, spontaneously breathing patient. Patients must remain neurologically intact with minimal morbidity

following the resuscitation if it is to be truly classified as a success.

Unfortunately, there are no reliable surrogate markers that can be used at the bedside to gauge the efficacy of CPR and a positive outcome. Nonetheless, heart rate, cardiac rhythm, and blood pressure should be assessed and documented throughout the resuscitation attempt and subsequent to each intervention. Determination of the presence or absence of a pulse is paramount to deciding which interventions may be appropriate. However, clinicians must be cautious to not exceed 10 seconds when checking for a pulse. Palpating a pulse to determine the efficacy of blood flow during CPR has not been shown to be useful.

A specific mean arterial pressure (MAP) that should be targeted remains unknown but avoiding and immediately correcting hypotension (MAP less than 65 mm Hg or systolic blood pressure [SBP] less than 90 mm Hg) is suggested.[37] Other hemodynamic measures remain undefined but coronary perfusion pressure (CPP = aortic diastolic pressure minus right atrial diastolic pressure) and central venous oxygen saturation (ScvO2) correlate with cardiac output and myocardial blood flow. Thresholds that have been identified which are associated with poor achievement of ROSC include less than 15 mm Hg for CPP and less than 30% for $ScvO_2$.[105] Because coronary perfusion pressures are not routinely available during CPR, arterial diastolic pressure can be used as a reasonable surrogate. Arterial diastolic pressure values less than 20 mm Hg are generally considered suboptimal.[105] $ETCO_2$ monitoring is another useful method to assess cardiac output during CPR and has been associated with ROSC. The main determinant for carbon dioxide excretion is the rate of delivery from the peripheral sites (where it is produced) to the lungs. Increasing cardiac output (through effective CPR) will yield higher $ETCO_2$ levels as delivery of carbon dioxide to the lungs increases. Persistently low ETCO2 values (less than 10 mm Hg) during CPR in intubated patients suggest ROSC is unlikely.[36]

ABBREVIATIONS

Chapter 13: Hypertension

Joseph J. Saseen; Eric J. MacLaughlin

INTRODUCTION

KEY CONCEPTS

- 1 The risk of cardiovascular (CV) morbidity and mortality is directly correlated with blood pressure (BP).
- 2 Evidence from clinical trials has shown that antihypertensive drug therapy substantially reduces the risks of CV events and death in patients with high BP.
- 3 Essential hypertension is usually an asymptomatic disease. A diagnosis cannot be made based on only one elevated BP measurement. An elevated value from the average of two or more measurements, present during two or more clinical encounters, is needed to diagnose hypertension.
- 4 The overall goal of treating hypertension is to reduce associated morbidity and mortality from CV events. Antihypertensive drug therapy selection should be based on evidence demonstrating CV event reduction.
- 5 A goal BP of less than 140/90 mm Hg is appropriate for most patients with hypertension.
- 6 The magnitude of BP elevation should be used to guide the determination of the number of antihypertensive agents to start when implementing drug therapy. Most patients with stage 1 hypertension should be initially treated with one drug, with the option of starting treatment with two for some patients. However, most patients presenting with stage 2 hypertension should be initially treated with two drugs.
- 7 Lifestyle modifications should be prescribed to all patients, especially those with prehypertension and hypertension.
- 8 An Angiotensin-converting enzyme inhibitors (ACEi), angiotensin II receptor blocker (ARB), calcium channel blocker (CCB), and thiazide are first-line antihypertensive agents for most patients with hypertension. These first-line options are for patients with hypertension who do not a compelling indication(s) for a specific antihypertensive drug class.
- 9 For most patients with hypertension, treatment with a β-blockers does not reduce CV events as well as has been demonstrated with an ACEi, ARB, CCB, or thiazide.
- 10 Compelling indications are comorbid conditions where specific antihypertensive drug classes have been shown in clinical trials to reduce CV events in patients with the specific comorbidity.
- 11 Patients with diabetes and hypertension should ideally be treated with either an ACEi or an ARB, and

often must be used in combination with one or more other antihypertensive agents to control BP.

- 12 Older patients are often at risk for orthostatic hypotension related to antihypertensive drug therapy. While antihypertensive drug therapy selection should be the same as in younger patients, low initial doses should be used to minimize the risk of orthostatic hypotension.

- 13 Alternative antihypertensive agents should only be used in combination with first-line antihypertensive agents to provide additional BP lowering because they do not have significant evidence demonstrating CV event reduction.

- 14 Initial therapy with the combination of two antihypertensive agents should be used in most patients presenting with stage 2 hypertension. This is also an option for patients presenting with stage 1 hypertension. Most patients require combination therapy to achieve goal BP.

- 15 Patients have resistant hypertension when they fail to achieve goal BP while adherent to a regimen that includes three antihypertensive agents at full doses (one of which includes a diuretic), or when four or more agents are needed to treat hypertension.

- 16 Hypertensive urgency is ideally managed by adjusting maintenance therapy, adding a new antihypertensive, and/or increasing the dose of a current antihypertensive medication. This provides a gradual reduction in BP, which is a safer treatment approach than rapid reductions in BP.

Hypertension is a common disease that is simply defined as persistently elevated arterial blood pressure (BP). Although elevated BP was perceived to be "essential" for adequate perfusion of vital organs during the early and middle 1900s, it is now identified as one of the most significant risk factors for cardiovascular (CV) disease. Increasing awareness and diagnosis of hypertension, and improving control of BP with appropriate treatment are considered critical public health initiatives to reduce CV morbidity and mortality.

The Joint National Committee (JNC) on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure guidelines have been the most prominent evidence-based clinical guideline in the United States for the management of hypertension. The Seventh version of these guidelines, the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC7), was published in 2003 and is the last version that was sponsored by the National Heart Lung and Blood Institute (NHLBI).[1] Other publications, particularly, the 2014 Report From the Panel Members Appointed to the Eighth Joint National Committee (JNC8), the 2014 Guidelines by the American Society of Hypertension/International Society of Hypertension (ASH/ISH), and the 2015 American Heart Association (AHA)/American College of Cardiology (ACC)/ASH Scientific Statement provide additional insight regarding pharmacotherapy for hypertension.[2,3,4] This chapter incorporates relevant components of these documents and additional evidence from clinical trials, with a focus on the pharmacotherapy of hypertension. However, when the ACC/AHA publishes their Guideline on the Management of Hypertension in late 2016, it will represent the most recent evidence-based guideline that should be used in clinical practice.

The National Health and Nutrition Examination Survey and the National Center for Health Statistics regularly assess hypertension in the United States.[5] Data from 2009 to 2012 indicate that approximately 80 million Americans aged 20 years and above have hypertension. Among these patients, 54.1% were at their goal BP, 76.5% were treated, and 82.7% were aware they had hypertension. While these statistics, particularly the control rate, are substantially higher than in the past, there remain many opportunities for clinicians to improve the care of patients with hypertension.

EPIDEMIOLOGY

Approximately one in three adult (age 20 years or older) Americans have elevated BP.[5] The overall incidence is similar between men and women, but varies depending on age. The percentage of men with high BP is higher than that of women before the age of 55 and is similar to that of women between the ages 55 and 64. However, after the age of 64, a much higher percentage of women have high BP than men.[5] Prevalence rates are highest in non-Hispanic blacks (46% in women, 45% in men), followed by non-Hispanic whites (30% in women, 33% in men), and Mexican Americans (30% in both women and men).[3] It is projected that by 2030, over 40% of American adults will have hypertension, which is an increase of 8.4% from 2012.[5]

BP values increase with age, and hypertension (persistently elevated BP values) is very common in the elderly. The lifetime risk of developing hypertension among those 55 years of age and older who are normotensive is 90%.[1] Most patients have prehypertension before they are diagnosed with hypertension, with most diagnoses occurring between the third and fifth decades of life.

ETIOLOGY

In most patients, hypertension results from unknown pathophysiologic etiology (*essential* or *primary hypertension*). This form of hypertension cannot be cured, but it can be controlled. A small percentage of patients have a specific cause of their hypertension (*secondary hypertension*). There are many potential secondary causes that either are concurrent medical conditions or are endogenously induced. If the cause can be identified, hypertension in these patients can be mitigated or potentially be cured.

Essential Hypertension

Over 90% of individuals with high BP have essential hypertension.[1] Numerous mechanisms have been identified that may contribute to the pathogenesis of this form of hypertension, so identifying the exact underlying abnormality is not possible. Genetic factors may play a role in the development of essential hypertension by affecting sodium balance, or other BP regulating pathways. In the future, genetic testing for these traits could lead to alternative approaches to preventing or treating hypertension. However, this is not currently recommended.

Secondary Hypertension

Fewer than 10% of patients have secondary hypertension where either a comorbid disease or a drug (or other product) is responsible for elevating BP (**Table 13-1**).[1,6] In most of these cases, renal dysfunction resulting from severe chronic kidney disease (CKD) or renovascular disease is the most common secondary cause. Certain drugs (or other products), either directly or indirectly, can cause hypertension or exacerbate hypertension by increasing BP. The most common agents are listed in Table 13-1. When a secondary cause is identified, removing the offending agent (when feasible) or treating/correcting the underlying comorbid condition should be the first step in management.

TABLE 13-1 Secondary Causes of Hypertension

Disease	Drugs and Other Products Associated with Hypertension[a]
Chronic kidney disease **Cushing's syndrome** **Coarctation of the aorta**	**Prescription drugs** • Amphetamines (amphetamine, dexmethylphenidate, dextroamphetamine, lisdexamfetamine, methylphenidate, phendimetrazine, phentermine) • Antivascular endothelin growth factor agents (bevacizumab, sorafenib, sunitinib) • Corticosteroids (cortisone, dexamethasone, fludrocortisone, hydrocortisone,

Disease	Drugs and Other Products Associated with Hypertension[a]
	methylprednisolone, prednisolone, prednisone, triamcinolone) • Calcineurin inhibitors (cyclosporine, tacrolimus) • Decongestants (pseudoephedrine, phenylephrine) • Ergot alkaloids (bromocriptine, dihydroergotamine, methysergide) • Erythropoiesis-stimulating agents (erythropoietin, darbepoetin) • Estrogen-containing oral contraceptives • Nonsteroidal anti-inflammatory drugs—cyclooxygenase-2 selective (celecoxib) and nonselective (aspirin [at higher doses], choline magnesium trisalicylate, diclofenac, diflunisal, etodolac, fenoprofen, flurbiprofen, ibuprofen, indomethacin, ketoprofen, ketorolac, meclofenamate, mefenamic acid, meloxicam, nabumetone, naproxen, naproxen sodium, oxaprozin, piroxicam, salsalate, sulindac, tolmetin) • Others: desvenlafaxine, venlafaxine, bupropion
Obstructive sleep apnea **Parathyroid disease** **Pheochromocytoma** **Primary aldosteronism** **Renovascular disease** **Thyroid disease**	Situations: β-blocker or centrally acting α-agonists (when abruptly discontinued); β-blocker without α-blocker first when treating pheochromocytoma; use of a monoamine oxidase inhibitor (isocarboxazid, phenelzine, tranylcypromine) with tryamine-containing foods or certain drugs
	Street drugs and other products • Cocaine and cocaine withdrawal • Ephedra alkaloids (eg, Ma huang), “herbal ecstasy,” other analogues • Nicotine and withdrawal, anabolic steroids, narcotic withdrawal, ergot-containing herbal products, St. John’s wort
	Food substances • Sodium • Ethanol • Licorice

[a]Agents of most clinical importance.

PATHOPHYSIOLOGY

Multiple factors that control BP are potential contributing components in the development of essential hypertension. These include malfunctions in either humoral (ie, the renin–angiotensin–aldosterone system [RAAS]) or vasodepressor mechanisms, abnormal neuronal mechanisms, defects in peripheral autoregulation, and disturbances in sodium, calcium, and natriuretic hormones. Many of these factors are cumulatively affected by the multifaceted RAAS, which ultimately regulates arterial BP. It is probable that no one factor is solely responsible for

essential hypertension.

Arterial BP

Arterial BP is the pressure in the arterial wall measured in millimeters of mercury (mm Hg). The two identified arterial BP values are *systolic BP* (SBP) and *diastolic BP* (DBP). SBP represents the peak value, which is achieved during cardiac contraction. DBP is achieved after contraction when the cardiac chambers are filling, and represents the nadir value. The difference between SBP and DBP is called the *pulse pressure* and is a measure of arterial wall tension. Mean arterial pressure (MAP) is the average pressure throughout the cardiac cycle of contraction. It is sometimes used clinically to represent overall arterial BP, especially in hypertensive emergency. During a cardiac cycle, two-thirds of the time is spent in diastole and one third in systole. Therefore, the MAP is calculated by using the following equation:

$$\mathrm{MAP} = \left(\mathrm{SBP} \times \frac{1}{3}\right) + \left(\mathrm{DBP} \times \frac{2}{3}\right)$$

Arterial BP is hemodynamically generated by the interplay between blood flow and the resistance to blood flow. It is mathematically defined as the product of cardiac output (CO) and total peripheral resistance (TPR) according to the following equation:

BP = CO × TPR

CO is the major determinant of SBP, whereas TPR largely determines DBP. In turn, CO is a function of stroke volume, heart rate, and venous capacitance. **Table 13-2** lists physiologic causes of increased CO and TPR and correlates them to potential mechanisms of pathogenesis.

TABLE 13-2 Potential Mechanisms of Pathogenesis

Blood pressure (BP) is the mathematical product of cardiac output and peripheral resistance. Elevated BP can result from increased cardiac output and/or increased total peripheral resistance.

Increased cardiac output	*Increased cardiac preload:* • Increased fluid volume from excess sodium intake or renal sodium retention *Venous constriction:* • Excess stimulation of the renin–angiotensin–aldosterone system (RAAS) • Sympathetic nervous system overactivity
Increased peripheral resistance	*Functional vascular constriction:* • Excess stimulation of the RAAS • Sympathetic nervous system overactivity • Genetic alterations of cell membranes • Endothelial-derived factors *Structural vascular hypertrophy:* • Excess stimulation of the RAAS

- Sympathetic nervous system overactivity
- Genetic alterations of cell membranes
- Endothelial-derived factors
- Hyperinsulinemia resulting from the metabolic syndrome

Under normal physiologic conditions, arterial BP fluctuates throughout the day following a circadian rhythm. BP decreases to its lowest values during sleep followed by a sharp rise starting a few hours prior to awakening, with the highest values occurring midmorning. BP is also increased acutely during physical activity or emotional stress.

Classification

The classification of BP in adults (age 18 years and older) is based on the average of two or more properly measured BP values from two or more clinical encounters (**Table 13-3**).[1] It includes four categories: normal, prehypertension, stage 1 hypertension, and stage 2 hypertension. Prehypertension is not a disease category, but identifies patients whose BP is likely to increase into the classification of hypertension in the future.

TABLE 13-3 Classification of Blood Pressure in Adults (Age ≥18 Years)[a]

Classification	Systolic Blood Pressure (mm Hg)		Diastolic Blood Pressure (mm Hg)
Normal	<120	and	<80
Prehypertension[b]	120-139	or	80-89
Stage 1 hypertension	140-159	or	90-99
Stage 2 hypertension	≥160	or	≥100

[a]Classification determined based on the average of two or more properly measured seated BP values from two or more clinical encounters. If systolic and diastolic BP values yield different classifications, the highest category is used for the purpose of determining a classification.

[b]For certain patients, BP values within the prehypertension range are considered above goal (see Clinical Presentation "Desired Outcomes: Goal BP Values").

Hypertensive crises are clinical situations where there are extreme BP elevations, typically greater than 180/120 mm Hg. They are categorized as either *hypertensive emergency* or *hypertensive urgency*. Hypertensive emergencies are extreme BP elevations that are accompanied by acute or progressing end-organ damage. Hypertensive urgencies are extreme BP elevations without acute or progressing end-organ injury.

Cardiovascular Risk and Blood Pressure

1 Epidemiologic data demonstrate a strong correlation between BP and CV morbidity and mortality.[7] Risk of stroke, myocardial infarction (MI), angina, heart failure, kidney failure, or early death from a CV causes (all are hypertension-associated complications) is directly correlated with BP. Starting at a BP of 115/75 mm Hg, the risk of CV disease doubles with every 20/10 mm Hg increase.[1] Even patients with prehypertension have an increased risk of CV disease.

2 Treating patients with hypertension with antihypertensive drug therapy provides significant clinical benefits. Evidence from large-scale placebo-controlled clinical trials has shown that the increased risks of CV events and death associated with elevated BP are reduced substantially by antihypertensive therapy.[8,9,10,11] This is discussed

in Treatment section of this chapter.

SBP is a stronger predictor of CV disease than DBP in adults aged 50 years and older; it is the most important clinical BP parameter for most patients.[1] Patients are considered to have *isolated systolic hypertension* when their SBP values are elevated (ie, greater than or equal to 140 mm Hg) and DBP values are not (ie, less than 90 mm Hg, but commonly less than 80 mm Hg). Isolated systolic hypertension is believed to result from pathophysiologic changes in the arterial vasculature consistent with aging. These changes decrease the compliance of the arterial wall and portend an increased risk of CV morbidity and mortality. The elevated pulse pressure (SBP minus DBP) is believed to reflect the extent of atherosclerotic disease in the elderly and is a measure of increased arterial stiffness. Higher pulse pressure values seen in those with isolated systolic hypertension are directly correlated with risk of CV mortality.

Humoral Mechanisms

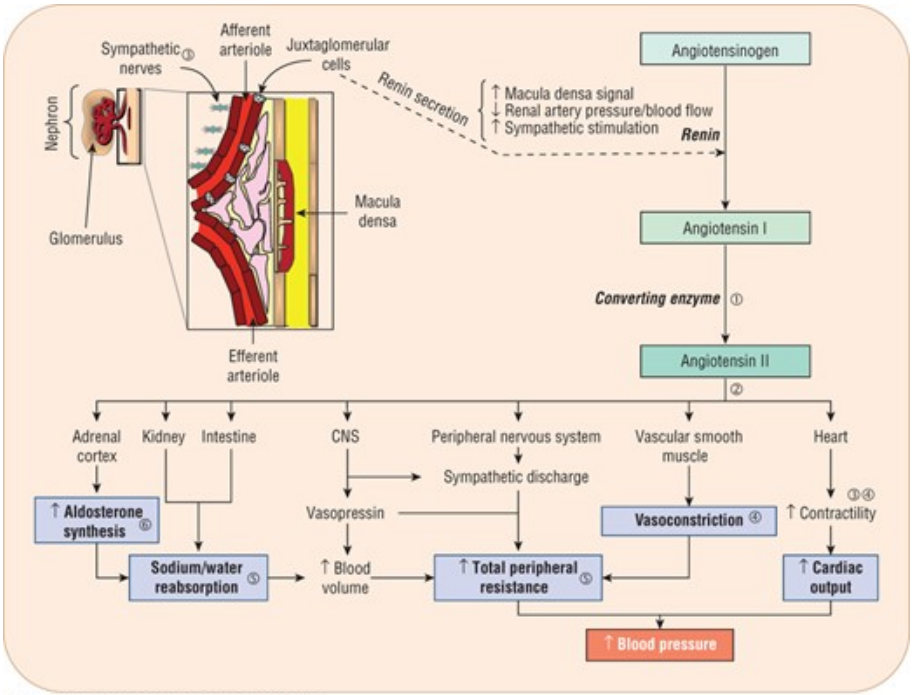
Several humoral abnormalities involving the RAAS, natriuretic hormone, and hyperinsulinemia may be involved in the development of essential hypertension.

The Renin–Angiotensin–Aldosterone System

The RAAS is a complex endogenous system involved with most regulatory components of arterial BP. Activation and regulation is primarily governed by the kidney (**Fig. 13-1**). The RAAS regulates sodium, potassium, and blood volume. Therefore, this system significantly influences vascular tone and sympathetic nervous system activity, and is the most influential contributor to the homeostatic regulation of BP.

FIGURE 13-1

Diagram representing the renin–angiotensin–aldosterone system. The interrelationship between the kidney, angiotensin II, and regulation of blood pressure is depicted. Renin secretion from the juxtaglomerular cells in the afferent arterioles is regulated by three major factors to trigger conversion of angiotensinogen to angiotensin 1. The primary sites of action for major antihypertensive agents are included: ① ACE inhibitor; ② angiotensin II receptor blocker; ③ β-blocker; ④ calcium channel blocker; ⑤ thiazide; ⑥ aldosterone antagonist.



Renin is an enzyme that is stored in the juxtaglomerular cells, which are located in the afferent arterioles of the kidney. The release of renin is modulated by several factors: intrarenal factors (eg, renal perfusion pressure, catecholamines, angiotensin II) and extrarenal factors (eg, sodium, chloride, potassium).

Juxtaglomerular cells function as a baroreceptor-sensing device. Decreased renal artery pressure and kidney blood flow is sensed by these cells and stimulates secretion of renin. The juxtaglomerular apparatus also includes a group of specialized distal tubule cells referred to collectively as the *macula densa*. A decrease in sodium and chloride delivered to the distal tubule stimulates renin release. Catecholamines increase renin release probably by directly stimulating sympathetic nerves on the afferent arterioles that in turn activate the juxtaglomerular cells.

Renin catalyzes the conversion of angiotensinogen to angiotensin I in the blood. Angiotensin I is then converted to angiotensin II by angiotensin-converting enzyme (ACE). After binding to specific receptors (classified as either angiotensin II type 1 [AT_1] or angiotensin II type 2 [AT_2] subtypes), angiotensin II exerts biologic effects in several tissues. The AT_1 receptor is located in brain, kidney, myocardium, peripheral vasculature, and the adrenal glands. These receptors mediate most responses that are critical to CV and kidney function. The AT_2 receptor is located in adrenal medullary tissue, uterus, and brain. Stimulation of the AT_2 receptor does not influence BP regulation.

Circulating angiotensin II can elevate BP through pressor and volume effects. Pressor effects include direct vasoconstriction, stimulation of catecholamine release from the adrenal medulla, and centrally mediated increases in sympathetic nervous system activity. Angiotensin II also stimulates aldosterone synthesis from the adrenal cortex. This leads to sodium and water reabsorption that increases plasma volume, TPR, and ultimately BP. Aldosterone also has a deleterious role in the pathophysiology of other CV diseases (eg, heart failure, MI, and kidney disease) by promoting tissue remodeling leading to myocardial fibrosis and vascular dysfunction. Clearly, any disturbance in the body that leads to activation of the RAAS could explain chronic hypertension.

The heart and brain contain a local RAAS. In the heart, angiotensin II is also generated by angiotensin I convertase (human chymase). This enzyme is not blocked by ACE inhibition. Activation of the myocardial RAAS increases cardiac contractility and stimulates cardiac hypertrophy. In the brain, angiotensin II modulates the production and release of hypothalamic and pituitary hormones, and enhances sympathetic outflow from the medulla oblongata.

Natriuretic Hormone

Natriuretic hormone inhibits sodium and potassium-ATPase and thus interferes with sodium transport across cell membranes. Inherited defects in the kidney's ability to eliminate sodium can cause increased blood volume. A compensatory increase in the concentration of circulating natriuretic hormone theoretically could increase urinary excretion of sodium and water. However, this hormone might block the active transport of sodium out of arteriolar smooth muscle cells. The increased intracellular sodium concentration ultimately would increase vascular tone and BP.

Neuronal Regulation

Central and autonomic nervous systems are intricately involved in the regulation of arterial BP. Many receptors that either enhance or inhibit norepinephrine release are located on the presynaptic surface of sympathetic terminals. The α and β presynaptic receptors play a role in negative and positive feedback to the norepinephrine—containing vesicles. Stimulation of presynaptic α-receptors (α_2) exerts a negative inhibition on norepinephrine release. Stimulation of presynaptic β-receptors facilitates norepinephrine release.

Sympathetic neuronal fibers located on the surface of effector cells innervate the α- and β-receptors. Stimulation of postsynaptic α-receptors (α_1) on arterioles and venules results in vasoconstriction. There are two types of postsynaptic β-receptors: β_1 and β_2. Both are present in all tissues innervated by the sympathetic nervous system. However, in some tissues β_1-receptors predominate (eg, heart), and in other tissues β_2-receptors predominate (eg, bronchioles). Stimulation of β_1-receptors in the heart results in an increase in heart rate (chronotropy) and force of contraction (ionotropy), whereas stimulation of β_2-receptors in the arterioles and venules causes vasodilation.

The baroreceptor reflex system is the major negative feedback mechanism that controls sympathetic activity. Baroreceptors are nerve endings lying in the walls of large arteries, especially in the carotid arteries and aortic arch. Changes in arterial BP rapidly activate baroreceptors that then transmit impulses to the brain stem through the ninth cranial nerve and vagus nerve. In this reflex system, a decrease in arterial BP stimulates baroreceptors, causing reflex vasoconstriction and increased heart rate and force of cardiac contraction. These baroreceptor reflex mechanisms may be less responsive in the elderly and those with diabetes.

Stimulation of certain areas within the central nervous system (eg, nucleus tractus solitarius, vagal nuclei, vasomotor center, and area postrema) can either increase or decrease BP. For example, α_2-adrenergic stimulation within the central nervous system decreases BP through an inhibitory effect on the vasomotor center. However, angiotensin II increases sympathetic outflow from the vasomotor center, which increases BP.

The purpose of these neuronal mechanisms is to regulate BP and maintain homeostasis. Pathologic disturbances in any of the four major components (autonomic nerve fibers, adrenergic receptors, baroreceptors, and central nervous system) could chronically elevate BP. These systems are physiologically interrelated. A defect in one component may alter normal function in another. Therefore, cumulative abnormalities may explain the development of essential hypertension.

Peripheral Autoregulatory Components

Abnormalities in renal or tissue autoregulatory systems could cause hypertension. It is possible that a renal defect in sodium excretion may develop, which can then cause resetting of tissue autoregulatory processes resulting in a higher BP. The kidney usually maintains a normal BP through a volume–pressure adaptive mechanism. When BP drops, the kidneys respond by increasing retention of sodium and water, which leads to plasma volume expansion that increases BP. Conversely, when BP rises above normal, renal sodium and water excretion are increased to reduce plasma volume and CO.

Local autoregulatory processes maintain adequate tissue oxygenation. When tissue oxygen demand is normal to low, the local arteriolar bed remains relatively vasoconstricted. However, increase in metabolic demand triggers arteriolar vasodilation that lowers peripheral vascular resistance (PVR) and increases blood flow and oxygen delivery.

Intrinsic defects in renal adaptive mechanisms could lead to plasma volume expansion and increased blood flow to peripheral tissues, even when BP is normal. Local tissue autoregulatory processes that vasoconstrict would then be activated to offset the increased blood flow. This effect would result in increased PVR and, if sustained, would also result in thickening of the arteriolar walls. This pathophysiologic component is plausible because increased TPR is a common underlying finding in patients with essential hypertension.

Vascular Endothelial Mechanisms

Vascular endothelium and smooth muscle play important roles in regulating blood vessel tone and BP. These regulating functions are mediated by vasoactive substances that are synthesized by endothelial cells. It has been postulated that a deficiency in local synthesis of vasodilating substances (eg, prostacyclin and bradykinin) or excess vasoconstricting substances (eg, angiotensin II and endothelin I) contributes to essential hypertension, atherosclerosis, and other CV diseases.

Nitric oxide is produced in the endothelium, relaxes the vascular epithelium, and is a very potent vasodilator. The nitric oxide system is an important regulator of arterial BP. Patients with hypertension may have an intrinsic nitric oxide deficiency, resulting in inadequate vasodilation.

Electrolytes

Epidemiologic and clinical data have associated excess sodium intake with hypertension. Population-based studies indicate that high-sodium diets are associated with a high prevalence of stroke and hypertension. Conversely, low-sodium diets are associated with a lower prevalence of hypertension. Clinical studies have shown that dietary sodium restriction lowers BP in many (but not all) patients with elevated BP. The exact mechanisms by which excess sodium leads to hypertension are not known.

Alterations in calcium and potassium may also play an important role in the pathogenesis of hypertension. A lack of dietary calcium hypothetically can disturb the balance between intracellular and extracellular calcium, resulting in an increased intracellular calcium concentration and alterations in vascular smooth muscle function. Potassium depletion may increase PVR, but the clinical significance of small serum potassium concentration changes is unclear. While altered calcium and potassium may play a role in the development of hypertension, data demonstrating reduced CV risk with supplementation are very limited.

CLINICAL PRESENTATION

The clinical presentation of hypertension is described in Clinical Presentation “Hypertension”.

CLINICAL PRESENTATION Hypertension General: May Appear Healthy or May Have Additional CV Risk Factors:

- Age (greater than or equal to 55 years for men, greater than or equal to 65 years for women)
- Diabetes (type 1 or type 2)
- Dyslipidemia
- Albuminuria

- Family history of premature CV disease
- Overweight (body mass index [BMI] 27-29.9 kg/m^2) or Obesity (BMI greater than or equal to 30 kg/m^2)
- Physical inactivity
- Tobacco use

Symptoms: Usually none related to elevated BP.

Signs: Previously elevated BP values in the prehypertension or the hypertension category.

Routine laboratory tests: Blood urea nitrogen (BUN)/serum creatinine, fasting lipid panel, fasting blood glucose, serum electrolytes (sodium, potassium), hemoglobin and hematocrit, and spot urine albumin-to-creatinine ratio. May have normal values and still have hypertension. However, some patients may have abnormal values consistent with either additional CV risk factors or hypertension-related damage.

Other tests: 12-Lead electrocardiogram, estimated GFR (using modification of diet in renal disease [MDRD] equation).

Hypertension-related complications: The patient may have a previous medical history or diagnostic findings that indicate the presence of hypertension-associated complications:

- **Brain** (stroke, transient ischemic attack, dementia)
- **Eyes** (retinopathy)
- **Heart** (left ventricular hypertrophy [LVH], angina, prior MI, prior coronary revascularization, heart failure)
- **Kidney** (chronic kidney disease [CKD])
- **Peripheral vasculature** (peripheral arterial disease [PAD])

Diagnostic Considerations

3 Hypertension is called the *silent killer* because most patients do not have symptoms. The primary physical finding is elevated BP. The diagnosis of hypertension cannot be made based on only one elevated BP measurement. The average of two or more measurements taken during two or more clinical encounters is required to diagnose hypertension.[1] This BP average should be used to establish a diagnosis, and then classify the stage of hypertension using Table 13-3.

Measuring BP

The measurement of BP is a common routine medical screening tool that should be conducted at every healthcare encounter.[1]

Cuff Measurement

The most common procedure to measure BP in clinical practice is the indirect measurement of BP using an oscillometric device or sphygmomanometry. The appropriate procedure to indirectly measure BP has been described by the AHA.[12] It is imperative that the measurement equipment (ie, inflation cuff, stethoscope, and manometer) meet national standards to ensure maximum quality and precision with measurement.

The AHA stepwise technique is recommended:

1. Patients should ideally refrain from nicotine and caffeine ingestion for 30 minutes and sit with lower back supported in a chair. Their bare arm should be supported and resting near heart level. Feet should be flat on the floor (with legs not crossed). The measurement environment should be relatively quiet and ideally provide privacy. Measuring BP in a position other than seated (supine or standing position) may be required under special circumstances (eg, suspected orthostatic hypotension, dehydration).
2. Measurement should begin only after a 5-minute period of rest.
3. A properly sized cuff (pediatric, small, regular, large, or extra large) should be used. The inflatable rubber bladder should be at least 80% of arm circumference and a width that is at least 40% of arm circumference.
4. The palpatory method should be used to estimate the SBP:
    a. Place the cuff on the upper arm 2 to 3 cm above the antecubital fossa and attach it to the manometer.
    b. Close the inflation valve and inflate the cuff to 70 mm Hg.

    Palpate the radial pulse with the index and middle fingers of the opposite hand.

    c. Inflate further in increments of 10 mm Hg until the radial pulse can no longer be palpated.
    d. Note the pressure at which the radial pulse is no longer palpated. This is the estimated SBP.
    e. Release the pressure in the cuff by opening the valve.
5. The bell (use the diaphragm only if using the bell is not possible) of the stethoscope should be placed on the skin of the antecubital fossa, directly over where the brachial artery is palpated. The stethoscope earpieces should be inserted appropriately. The valve should be closed, with the cuff then inflated to 30 mm Hg above the estimated SBP from the palpatory method. The valve should then be slightly opened to slowly release pressure at a rate of approximately 2 mm Hg/s.
6. The clinician should listen for Korotkoff sounds with the stethoscope. The first phase of Korotkoff sounds is the initial presence of clear tapping sounds. Note the pressure at the first recognition of these sounds. This is the SBP. As pressure deflates, note the pressure when all sounds disappear, right at the last sound. This is the DBP.
7. Measurements should be rounded to the nearest 2 mm Hg.
8. A second measurement should be obtained after at least 1 minute. If these values differ by more than 5 mm Hg, additional measurements should be obtained.
9. Neither the patient nor the observer should talk during measurement.
10. When first establishing care with a patient, BP should be measured in both arms. If consistent inter-arm differences exist, the arm with the higher value should be used.

Inaccuracies with indirect measurements result from inherent biologic variability of BP, inaccuracies related to suboptimal technique, and the white coat effect.[12] Variations in BP occur with environmental temperature, the time of day and year, meals, physical activity, posture, alcohol, nicotine, and emotions. In the clinic setting, standard BP measurement procedures (eg, appropriate rest period, correct technique, wrong cuff size) are often not followed, which results in poor estimation of true BP. In addition, variations may occur between individuals measuring BP due to differences in hearing or technique. Due to various human factors related to manual measurements of BP,

use of oscillometric devices is generally preferred.

Approximately 15% to 20% of patients have *white coat hypertension*, where BP values rise in a clinical setting but return to normal in nonclinical environments using home or ambulatory BP (ABP) measurements.[12] Interestingly, the rise in BP dissipates gradually after leaving the clinical setting. It may or may not be precipitated by other stresses in the patient's daily life. This is in contrast to *masked hypertension*, where a decrease in BP occurs in the clinical setting.[13] With masked hypertension, home BP is hypertensive, while the in-office BP is normotensive or substantially lower than that at home. This situation may lead to under treatment or lack of treatment for hypertension. Moreover, patients with either white coat or masked hypertension have a high risk of progressing to develop sustained hypertension, which can result in a higher risk of CV events compared with normotensive patients.[14]

Pseudohypertension is a falsely elevated BP measurement. It may be seen in the elderly, those with long-standing diabetes, or those with CKD due to rigid, calcified brachial arteries.[12] In these patients, the true arterial BP when measured directly with intra-arterial measurement (the most accurate measurement of BP) is much lower than that measured using the indirect cuff method. The Osler's maneuver can be used to test for pseudohypertension. In this maneuver, the BP cuff is inflated above peak SBP. If the radial artery remains palpable, the patient has a positive Osler's sign (rigid artery), which may indicate pseudohypertension.

Elderly patients with a wide pulse pressure may have an auscultatory gap that can lead to underestimated SBP or overestimated DBP measurements.[12] In this situation, as the cuff pressure falls from the true SBP value, the Korotkoff sound may disappear (indicating a false DBP measurement), reappear (a false SBP measurement), and then disappear again at the true DBP value. When an auscultatory gap is present, Korotkoff sounds are usually heard when pressure in the cuff first starts to decrease after inflation. This may be eliminated by raising the arm overhead by 30 seconds before bringing it to the proper position and inflating the cuff. This maneuver decreases the intravascular volume and improves inflow thereby allowing Korotkoff sounds to be heard.[12]

Ambulatory and Self-BP Monitoring

Ambulatory BP (ABP) monitoring using an automated device can document BP at frequent time intervals (eg, every 15-30 minutes) throughout a 24-hour period.[12] ABP values are usually lower than clinic-measured values. The definition of hypertension for ABP is greater than or equal to 135/85 mm Hg during the day, greater than or equal to 120/75 mm Hg nighttime (or asleep), and greater than or equal to 130/80 mm Hg over 24 hours.[12] For self-BP monitoring, a BP greater than or equal to 135/85 mm Hg is considered hypertensive. Self-BP measurements are collected by patients, preferably in the morning, using home monitoring devices.

Neither ABP nor self-BP monitoring is required for the routine diagnosis of hypertension. However, these modalities can enhance the ability to identify patients with white coat and masked hypertension.[13] Recommendations from the United States Preventive Services Task Force recommend outside of clinical setting measurements for diagnostic confirmation before starting antihypertensive therapy.[15] ABP and self-BP measurements may also be useful in evaluating and optimizing BP control for patients on antihypertensive drug therapy. ABP monitoring may be helpful for patients with apparent drug resistance, hypotensive symptoms while on antihypertensive therapy, episodic hypertension (eg, white coat hypertension), autonomic dysfunction, and in identifying "nondippers" whose BP does not decrease by greater than 10% during sleep and who may portend increased risk of BP-related complications.[12]

Limitations of ABP and self-BP measurements may prohibit routine use in some patients. These include complexity of use, costs, and lack of prospective outcome data describing normal ranges for these measurements. Although self-monitoring of BP at home is less complicated and less costly than ambulatory monitoring, patients may omit or fabricate readings, or have poor technique (eg, not resting for adequate period of time, improper placement,

wrong cuff size).

Clinical Evaluation

Frequently, the only sign of essential hypertension is elevated BP. The rest of the physical examination may be completely normal. However, a complete medical evaluation (a comprehensive medical history, physical examination, and laboratory and/or diagnostic tests) is recommended after diagnosis to (a) identify secondary causes, (b) identify other CV risk factors or comorbid conditions that may define prognosis and/or guide therapy, and (c) assess for the presence or absence of hypertension-associated complications. All patients with hypertension should have the tests described in Clinical Presentation "Hypertension" measured prior to initiating therapy.[1] For patients without a history of coronary artery disease, noncoronary atherosclerotic vascular disease (ASCVD), left ventricular dysfunction, or diabetes, it is also important to estimate future risk of CV disease and clinical ASCVD. The 10-year risk of clinical ASCVD (defined as coronary death or nonfatal myocardial infarction, or fatal or nonfatal stroke) based on the Pooled Cohort Equations and lifetime risk prediction tools can be found at: *http://tools.acc.org/ASCVD-Risk-Estimator/*

Secondary Causes

The most common secondary causes of hypertension are listed in Table 13-1. A complete medical evaluation should provide clues for identifying secondary hypertension.

Patients with secondary hypertension might have signs or symptoms suggestive of the underlying disorder. Patients with pheochromocytoma may have a history of paroxysmal headaches, sweating, tachycardia, and palpitations. Over half of these patients suffer from episodes of orthostatic hypotension. In primary hyperaldosteronism symptoms related to hypokalemia usually include muscle cramps and muscle weakness. Patients with Cushing's syndrome may complain of weight gain, polyuria, edema, menstrual irregularities, recurrent acne, or muscular weakness and have several classic physical features (eg, moon face, buffalo hump, hirsutism). Patients with coarctation of the aorta may have higher BP in the arms than in legs and diminished or even absent femoral pulses. Patients with renal artery stenosis may have an abdominal systolic–diastolic bruit.

Routine laboratory tests may also help identify secondary hypertension. Baseline hypokalemia may suggest mineralocorticoid-induced hypertension. Protein, red blood cells, and casts in the urine may indicate renovascular disease. Some laboratory tests are used specifically to diagnose secondary hypertension. These include plasma norepinephrine and urinary metanephrine for pheochromocytoma, plasma and urinary aldosterone concentrations for primary hyperaldosteronism, and plasma renin activity, captopril stimulation test, renal vein renin, and renal artery angiography for renovascular disease.

Certain drugs and other products can result in drug-induced hypertension (see Table 13-1). For some patients, the addition of these agents can be the cause of elevated BP or can exacerbate underlying hypertension. Identifying a temporal relationship between starting the suspected agent and developing elevated BP is most suggestive of drug-induced BP elevation.

Natural Course of Disease

Essential hypertension is usually preceded by elevated BP values that are in the prehypertension category. BP values may fluctuate between elevated and normal levels for a period. As the disease progresses, PVR increases, and BP elevation becomes chronic.

Hypertension-Associated Complications

There are several complications that can result as a consequence of high BP in patients with hypertension (see

Clinical Presentation "Hypertension"). CV events (eg, MI, cerebrovascular events, kidney failure) are the primary causes of CV morbidity and mortality in patients with hypertension. The probability of CV events and CV morbidity and mortality in patients with hypertension is directly correlated with the severity of BP elevation.

Hypertension accelerates atherosclerosis and stimulates left ventricular and vascular dysfunction. These pathologic changes are thought to be secondary to both a chronic pressure overload and a variety of nonhemodynamic stimuli. Several nonhemodynamic disturbances have been implicated in these effects (eg, the adrenergic system, RAAS, increased synthesis and secretion of endothelin I, decreased production of prostacyclin and nitric oxide). Atherosclerosis in hypertension is accompanied by the proliferation of smooth muscle cells, lipid infiltration into the vascular endothelium, and enhancement of vascular calcium accumulation.

Cerebrovascular disease is a consequence of hypertension. A neurologic assessment can detect either gross neurologic deficits or a slight hemiparesis with some incoordination and hyperreflexia that are indicative of cerebrovascular disease. Stroke can result from lacunar infarcts caused by thrombotic occlusion of small vessels or intracerebral hemorrhage resulting from ruptured microaneurysms. Transient ischemic attacks secondary to atherosclerotic disease in the carotid arteries can also happen in patients with hypertension.

Retinopathies can occur in hypertension and may manifest as a variety of different findings. A funduscopic examination can detect hypertensive retinopathy, and the result can be categorized according to the Keith-Wagener-Barker retinopathy classification. Retinopathy manifests as arteriolar narrowing, focal arteriolar constrictions, arteriovenous crossing changes (nicking), retinal hemorrhages and exudates, and disk edema. Accelerated arteriosclerosis, a long-term consequence of essential hypertension, can cause nonspecific changes such as increased light reflex, increased tortuosity of vessels, and arteriovenous nicking. Focal arteriolar narrowing, retinal infarcts, and flame-shaped hemorrhages usually are suggestive of an accelerated or malignant phase of hypertension. Papilledema is swelling of the optic disk caused by a breakdown in autoregulation of capillary blood flow in the presence of high pressure. It is usually only present in hypertensive emergencies.

Heart disease is a commonly identified complication of hypertension. A thorough cardiac and pulmonary examination can identify cardiopulmonary abnormalities. Clinical manifestations include LVH, coronary heart disease (angina, prior MI, and prior coronary revascularization), and heart failure. These complications may lead to cardiac arrhythmias, angina, MI, and sudden death. Coronary disease (also called *coronary heart disease*) and associated CV events are the most common causes of death in patients with hypertension.

The kidney damage caused by hypertension is characterized pathologically by hyaline arteriosclerosis, hyperplastic arteriosclerosis, arteriolar hypertrophy, fibrinoid necrosis, and atheroma of the major renal arteries. Glomerular hyperfiltration and intraglomerular hypertension are early stages of hypertensive nephropathy. Albuminuria is followed by a gradual decline in renal function. The primary renal complication in hypertension is nephrosclerosis, which is secondary to arteriosclerosis. Atheromatous disease of a major renal artery may give rise to renal artery stenosis. Although overt kidney failure is an uncommon complication of essential hypertension, it is an important cause of end-stage kidney disease, especially in African Americans, Hispanics, and Native Americans.

The peripheral vasculature is a target organ. Physical examination of the vascular system can detect evidence of atherosclerosis, which may present as arterial bruits (aortic, abdominal, or peripheral), distended veins, diminished or absent peripheral arterial pulses, or lower extremity edema. Peripheral arterial disease (PAD) is a clinical condition that can result from atherosclerosis, which is accelerated in hypertension. Other CV risk factors (eg, smoking) can increase the likelihood of PAD as well as all other complications.

TREATMENT

Overall Goal of Treatment

4 The overall goal of treating hypertension is to reduce associated morbidity and mortality from CV events (eg, coronary events, cerebrovascular events, heart failure, kidney disease). Therefore, the specific selection of antihypertensive drug therapy should be based on evidence demonstrating CV event reduction.

Surrogate Targets—Blood Pressure Goals

5 Treating patients with hypertension to achieve a desired target BP value is a surrogate goal of therapy. Reducing BP to goal does not guarantee prevention of hypertension-associated complications, but is associated with a lower risk. Targeting a goal BP value is how clinicians evaluate response to therapy. It is the primary method used to determine the need for titration and regimen modification.

Most guidelines recommend a goal BP of less than 140/90 mm Hg for the management of hypertension in most patients (Clinical Presentation "Desired Outcomes: Goal BP Values").[1,2,3,4] The American Diabetes Association historically recommended lower BP goals for patients with diabetes, but now recommend a standard goal of less than 140/90 mm Hg for most patients with diabetes.[16] A lower BP goal of less than 130/80 mm Hg may be appropriate for certain patients (eg, younger patients) if achieved without undue treatment burden, but this is simply a therapeutic option. Similarly, the Kidney Disease Improving Global Outcomes (KDIGO) guidelines recommend a BP goal of 140/90 mm Hg for patients with hypertension and CKD (nondialysis), with a lower BP goal of less than 130/80 mm Hg only for those patients who have persistent albuminuria (greater than 30 mg urine albumin excretion per 24 hours or equivalent) as a therapeutic option.[17,18]

CLINICAL PRESENTATION Desired Outcomes: Goal BP Values Most patients, including diabetes and/or CKD and the elderly

- less than 140/90 mm Hg

Frail elderly at high risk for serious adverse effects

- less than 150/90 mm Hg

Certain Patients with lower goals as a therapeutic option (not a standard of care)

- Some patients with diabetes (eg, younger patients), less than 130/80 mm Hg may be an option if achieved without undue treatment burden
- Some patients with CKD (nondialysis) who have persistent urine albumin excretion of greater than 30 mg per 24 hours (or equivalent), less than 130/80 mm Hg may be an option if achieved without undue treatment burden
- Some patients greater than 50 years at increased risk of CV disease (one or more risk factors including clinical or subclinical CVD other than stroke, CKD with eGFR 20-60 mL/min/1.73m^2, 10-year risk of CVD greater than or equal to 15%, greater than or equal to 75 years) but without diabetes, may consider SBP goal less than 120 mm Hg

Until the new ACC/AHA guidelines are available, clinicians should follow the goals listed in Clinical Presentation "Desired Outcomes: Goal BP Values". Of note, the Systolic Blood Pressure Intervention Trial (SPRINT) was recently published that evaluated a BP goal of less than 120 mm Hg versus less than 140 mm Hg in certain high CV risk patients with hypertension, but without diabetes.[19] The study was stopped early after a median follow-up of 3.3 years due to significantly lower risk of the primary composite outcome (MI, other acute coronary syndromes, stroke, heart failure, or death from CV causes) and all-cause mortality in patients treated to the lower BP goal. Although SPRINT has demonstrated a benefit of a lower BP goal, clinicians should be cautious until details of this

clinical trial have been fully interpreted and incorporated into evidence-based guidelines before broadly applying this lower BP goal. Treating patients to lower than normal BP goals may lead to harm. In SPRINT, there was increased risk of adverse events in the more intensive treatment group including hypotension, syncope, electrolyte abnormalities, and acute kidney injury or failure. However, this may be outweighed by the significant benefits. Therefore, waiting until full interpretation and application of SPRINT is recommended.

Evidence Supporting BP Goal of Less Than 140/90 mm Hg in Most Patients

Lower goal DBP values have been evaluated prospectively in the Hypertension Optimal Treatment (HOT) study.[20] In this study, over 18,700 patients were randomized to DBP goals of less than equal to 90, less than equal to 85, less than equal to 80 mm Hg. Although actual DBP values achieved were 85.2, 83.2, and 81.1 mm Hg, respectively, there were no significant differences in risk of major CV events when the three DBP goal groups were compared with each other. Therefore, the HOT data did not demonstrate that lower DBP goals were better than the standard DBP goal of less than 90 mm Hg. However, when the relationship between actual BP values and risk of CV events was evaluated, there was a trend that lower DBP values were better.

A major limitation of the HOT study is the use of DBP goal values. SBP is more directly correlated to CV risk than DBP in most patients with hypertension, especially those above the age of 50. Therefore, data from the HOT study cannot determine the optimal SBP goal value. It is important to note that no J-curve relationship was seen. The *J-curve hypothesis* suggests that lowering BP too much might increase the risk of CV events.[21] This theoretical hypothesis was described many years ago and was originally suggested in observational studies. Therefore, it remains an unproven hypothesis, and may be viewed with particular skepticism considering the recent results of SPRINT.[19]

Additional data are available that suggest lower is better when SBP goal values are targeted. In a recent systematic review and meta-analysis of 19 trials involving 44,989 patients, CV events and renal outcomes were compared between intensive versus less intensive BP-lowering treatment. Compared to less intensive BP-lowering (mean BP 140/81 mm Hg), intensive treatment (mean BP 133/76 mm Hg) was associated with a reduced risk of major CV events, MI, stroke, albuminuria, and retinopathy progression. There was no significant reduction in heart failure, CV death, total mortality, or end-stage kidney disease. The risk of serious adverse events with intensive therapy was low and did not differ significantly compared to less-intensive treatment. However, severe hypotension was more frequent. Therefore, additional evidence is available supporting lower BP goals, particularly for patients at increased CV risk.[22]

Clinical Controversy…

HOW LOW TO GO IN MOST PATIENTS?

A standard BP goal of less than 140/90 mm Hg is recommended for most patients with hypertension. Lower goals were historically recommended in specific patient populations, but now are only a therapeutic option for select patients (eg, younger patients with diabetes, CKD patients that have persistent albuminuria). However, the SPRINT was a prospective randomized trial that compared a standard SBP goal of less than 140 mm Hg to a lower SBP goal of less than 120 mm Hg in high risk patients with hypertension. Patients with a history of diabetes or a history of stroke were excluded. The trial was stopped early due to a significant reduction in CVD events and mortality associated with the lower SBP goal. Until these data are fully interpreted and incorporated into evidence-based treatment guidelines, clinicians should use caution if applying the results of SPRINT widely and should consider using standard BP goals for most patients with hypertension.

Limited Evidence Supporting Lower BP Goals in Diabetes

A BP goal of less than 130/80 mm Hg was historically recommended for patients with diabetes for many years, by multiple organizations. The primary evidence supporting this recommendation was from the HOT study, where the only subgroup to show a lower risk of major CV events in the less than 80 mm Hg group versus the less than 90 mm Hg group was in patients with diabetes (*n* = 1,501).

The NHLBI-sponsored Action to Control Cardiovascular Risk in Diabetes Blood Pressure (ACCORD-BP) study evaluated the benefit of lower BP goals for patients with diabetes.[23] The ACCORD-BP was an open-label, factorial study that randomized 4,733 patients with type 2 diabetes to intensive therapy targeting a SBP of less than 120 mm Hg, or to standard therapy targeting a SBP less than 140 mm Hg for a mean follow-up of 4.7 years. After 1 year, an average of 3.4 medications was needed in the intensive therapy group to attain a mean SBP of 119.3 mm Hg, compared with an average of 2.1 medications in the standard therapy group to attain a mean SBP of 133.5 mm Hg. This difference was generally maintained throughout the study duration. However, there was no significant difference in the annual rate of the primary end point (nonfatal MI, nonfatal stroke, or CV death) between the two groups. The annual incidence of the secondary end point of stroke was lower with the intensive therapy group versus the standard therapy group, and this was the only prespecified end point that was different between the two groups. Reasons for discordant findings of ACCORD-BP compared to SPRINT could be due to study design and lack of power.

Despite consensus guidelines historically recommending a BP goal of less than 130/80 mm Hg for patients with diabetes, evidence supporting this approach over a standard goal of less than 140/90 mm Hg is marginal, and comes at the cost of increased side effects (eg, hypotension, hyperkalemia, bradycardia). While the ACCORD-BP provided additional evidence evaluating BP goals for patients with diabetes, these data do not provide all of the clinical answers that are needed. The ACCORD-BP was open label, and those in the standard group (SBP less than 140 mm Hg) actually had SBP values that were closer to 130 mm Hg than to 140 mm Hg. Based on these data, in 2015 the American Diabetes Association changed their recommendation to a goal BP of less than 140/90 mm Hg for most patients with hypertension and diabetes.[16] The KDIGO guidelines recommend a BP goal of less than 140/90 mm Hg for patients with hypertension and CKD (nondialysis) and a BP goal of less than 130/80 mm Hg only for those patients who have persistently increased urine albumin excretion.[17]

Avoiding Clinical Inertia

Although hypertension is one of the most common medical conditions, BP control rates are poor. *Clinical inertia* in hypertension has been defined as an office visit at which no therapeutic move was made to lower BP in a patient with uncontrolled hypertension.[24] Clinical inertia is not the entire reason why many patients with hypertension do not achieve goal BP values. However, it is certainly a major reason that can be remedied simply through more aggressive treatment with drug therapy. This strategy can include initiating, titrating, or changing drug therapy.

General Approach to Treatment

Most patients should be placed on both lifestyle modifications and drug therapy concurrently after a diagnosis of hypertension. Lifestyle modification alone is appropriate for most patients with prehypertension. However, lifestyle modifications alone may not adequately lower BP in patients who have hypertension. Patients with additional CV risk factors or those with hypertension-associated complications will typically need antihypertensive drug therapy in addition to lifestyle modifications.

6 The choice of initial antihypertensive drug therapy depends on the degree of BP elevation and presence of compelling indications (discussed in the Pharmacotherapy section later). Most patients with stage 1 hypertension should be initially treated with a first-line antihypertensive drug or the combination of two. Combination drug therapy is recommended for patients with more severe BP elevation (stage 2 hypertension), using preferably two first-line antihypertensive drugs. This general approach is outlined in **Fig. 13-2**. There are six compelling

indications where specific antihypertensive drug classes have evidence showing unique benefits in patients with hypertension and the listed compelling indication (**Fig. 13-3**).

FIGURE 13-2

Algorithm for treatment of hypertension. Drug therapy recommendations are graded with strength of recommendation and quality of evidence in brackets. Strength of recommendations: A, B, and C are good, moderate, and poor evidence to support recommendation, respectively. Quality of evidence: (1) evidence from more than one properly randomized controlled trial; (2) evidence from at least one well-designed clinical trial with randomization, from cohort or case-controlled studies, or dramatic results from uncontrolled experiments or subgroup analyses; (3) evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

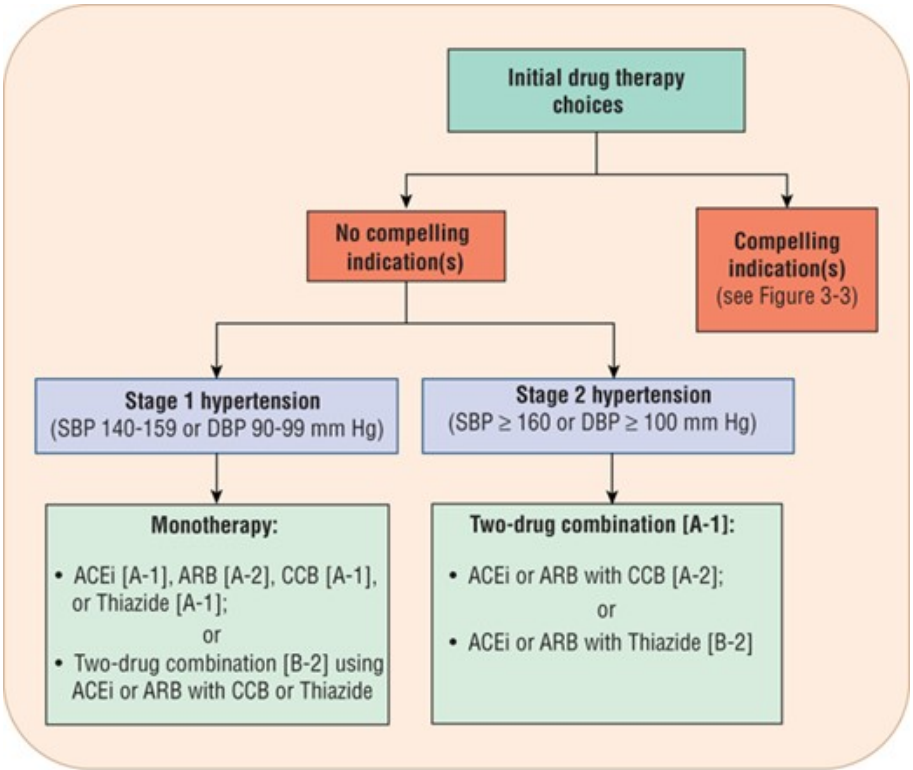


FIGURE 13-3

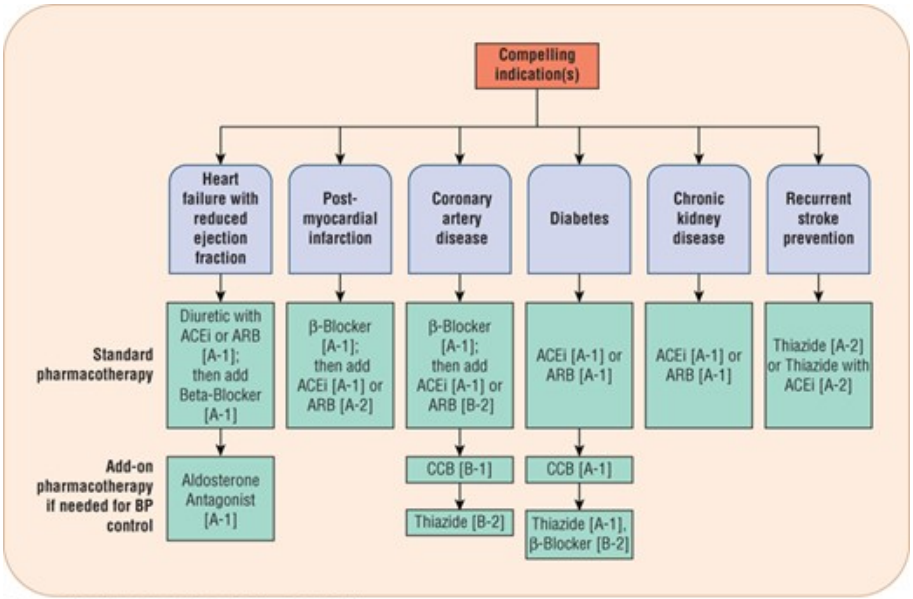
Compelling indications for individual drug classes. Compelling indications for specific drugs are evidenced-based recommendations from outcome studies or existing clinical guidelines. The order of drug therapies serves as a general guidance that should be balanced with clinical judgment and patient response. Add-on pharmacotherapy recommendations are when additional agents are needed to lower BP to goal values. Blood pressure control should be managed concurrently with the compelling indication. Drug therapy recommendations are graded with strength of recommendation and quality of evidence in brackets. Strength of recommendations: A, B, and C are good, moderate, and poor evidence to support recommendation, respectively. Quality of evidence: (1) evidence from more than one properly randomized controlled trial; (2) evidence from at least one well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple time series, or dramatic results from uncontrolled experiments or subgroup analyses; (3) evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.



Nonpharmacologic Therapy

7 All patients with prehypertension and hypertension should be prescribed lifestyle modifications. However, they should never be used as a replacement for antihypertensive drug therapy for patients with hypertension who are not at goal BP, especially in those with additional CV risk factors or hypertension-associated complications. Recommended modifications that have been shown to lower BP are listed in **Table 13-4**.[25] They can provide small to moderate reductions in SBP. Aside from lowering BP in patients with known hypertension, strict adherence with lifestyle modification can decrease the progression to hypertension in patients with prehypertension BP values.

TABLE 13-4 Lifestyle Modifications to Prevent and Manage Hypertension[29]

Modification	Recommendation	Approximate Systolic Blood Pressure Reduction (mm Hg)[a]
Weight loss	Maintain normal body weight (body mass index, 18.5-24.9 kg/m^2)	5-20 per 10-kg weight loss
DASH-type dietary patterns	Consume a diet rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat	8-14
Reduced salt intake	Reduce daily dietary sodium intake as much as possible, ideally to ≈65 mmol/day (1.5 g/day sodium, or 3.8 g/day sodium chloride)	2-8
Aerobic physical activity	3 to 4 sessions/wk, lasting an average of 40 min/session, and involving moderate- to vigorous-intensity physical activity	4-9
Moderation of alcohol intake	Limit consumption to ≤2 drink equivalents per day in men and ≤1 drink equivalent per day in women and lighter-weight persons[b]	2-4

[a]Effects of implementing these modifications are time- and dose-dependent and could be greater for some patients.

[b]One drink equivalent is equal to 1.5 oz (approximately 45 mL) of 80-proof distilled spirits (eg, whiskey), a 5 oz (approximately 150 mL) glass of wine (12%), or 12 oz (approximately 350 mL) of beer.

A sensible dietary program is one that is designed to reduce weight gradually (for overweight and obese patients) and one that restricts sodium intake with only moderate alcohol consumption if one consumes alcohol. Successful implementation of dietary lifestyle modifications by clinicians requires aggressive promotion through patient education, encouragement, and continued reinforcement. The rationale for dietary intervention in hypertension can be explained to patients as follows:

1. Weight loss, as little as 5% to 10% of your body weight, can decrease BP significantly in overweight or obese patients.

2. Diets rich in fruits and vegetables and low in saturated fat have been shown to lower BP in patients with hypertension.

3. Most people experience some BP lowering with sodium restriction.

The Dietary Approaches to Stop Hypertension (DASH) eating plan is a diet that is rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat. It is recommended as a reasonable and feasible diet that has proven to lower BP. Intake of sodium should be minimized as much as possible, ideally to 1.5 g/day, although an interim goal of less than 2.3 g/day may be reasonable considering the difficulty in achieving these low intakes. Patients should be aware of the multiple sources of dietary sodium (eg, processed foods, soups, and table salt) so that they may follow these recommendations. Potassium intake should be encouraged through fruits and vegetables with high content (ideally 4.7 g/day) in those with normal kidney function or without impaired potassium excretion. Excessive alcohol use can either cause or worsen hypertension. Patients with hypertension who drink alcoholic beverages should restrict their daily intake.

Aerobic physical activity consisting of 3 to 4 sessions per week, lasting on average 40 minutes per session, and involving moderate- to vigorous-intensity physical activity should be encouraged when possible. Studies have shown that aerobic physical activity can reduce BP, even in the absence of weight loss. Patients should consult their physicians before starting an exercise program, especially those with hypertension-associated complications.

Cigarette smoking is not a secondary cause of essential hypertension. Therefore, smoking cessation is not a recommended strategy to control BP. Smoking is a major, independent, modifiable risk factor for CV disease. Patients with hypertension who smoke should be counseled regarding the additional health risks that result from smoking. Moreover, the potential benefits that cessation can provide should be explained to encourage cessation.

Pharmacotherapy

8 An ACEi, angiotensin II receptor blocker (ARB), calcium channel blocker (CCB), or thiazide are preferred first-line antihypertensive agents for most patients (**Table 13-5**).[1,2,3,4] These agents should be used to treat the majority of patients with hypertension because of evidence demonstrating CV event reduction. Several have subclasses where significant differences in mechanism of action, clinical use, side effects, or evidence from outcome studies exist. β-Blocker therapy should be reserved to either treat a specific compelling indication or used in combination with one or more of the aforementioned first-line antihypertensive agents for patients without a compelling indication. Other antihypertensive drug classes are considered alternative drug classes that may be used in select patients after first-line agents (**Table 13-6**).

TABLE 13-5 First-Line and Other Common Antihypertensive Agents

Class	Subclass	Drug (Brand Name)	Usual Dose Range (mg/day)	Daily Frequency	Comments
ACEi		Benazepril (Lotensin)	10-40	1 or 2	May cause hyperkalemia in

Class	Subclass	Drug (Brand Name)	Usual Dose Range (mg/day)	Daily Frequency	Comments
					patients with CKD or in those receiving a potassium-sparing diuretic, aldosterone antagonist, ARB, or direct renin inhibitor; can cause acute kidney failure in patients with severe bilateral renal artery stenosis or severe stenosis in artery to solitary kidney; do not use in pregnancy or in patients with a history of angioedema; starting dose should be reduced 50% in patients who are on a thiazide, are volume depleted, or are very elderly due to risks of hypotension
		Captopril (Capoten)	12.5-150	2 or 3	
		Enalapril (Vasotec)	5-40	1 or 2	
		Fosinopril (Monopril)	10-40	1	
		Lisinopril (Prinivil, Zestril)	10-40	1	
		Moexipril (Univasc)	7.5-30	1 or 2	
		Perindopril (Aceon)	4-16	1	
		Quinapril (Accupril)	10-80	1 or 2	
		Ramipril (Altace)	2.5-10	1 or 2	
		Trandolapril (Mavik)	1-4	1	
ARB					May cause hyperkalemia in patients with CKD or in those receiving a potassium-sparing diuretic, aldosterone antagonist, ACEi, or direct renin inhibitor; can cause acute kidney failure in patients with severe bilateral renal artery stenosis or severe stenosis in artery to solitary kidney; do not cause a dry cough like an ACEi may; do not use in pregnancy; starting dose should
		Azilsartan (Edarbi)	40-80	1	
		Candesartan (Atacand)	8-32	1 or 2	
		Eprosartan (Teveten)	600-800	1 or 2	
		Irbesartan (Avapro)	150-300	1	
		Losartan (Cozaar)	50-100	1 or 2	
		Olmesartan (Benicar)	20-40	1	
		Telmisartan (Micardis)	20-80	1	
		Valsartan (Diovan)	80-320	1	

Class	Subclass	Drug (Brand Name)	Usual Dose Range (mg/day)	Daily Frequency	Comments
					be reduced 50% in patients who are on a thiazide, are volume depleted, or are very elderly due to risks of hypotension
Calcium channel blocker	Dihydropyridine	Amlodipine (Norvasc)	2.5-10	1	Short-acting dihydropyridines should be avoided, especially immediate-release nifedipine and nicardipine; dihydropyridines are more potent peripheral vasodilators than nondihydropyridines and may cause more reflex sympathetic discharge (tachycardia), dizziness, headache, flushing, and peripheral edema; have additional benefits in Raynaud's syndrome
		Felodipine (Plendil)	5-20	1	
		Isradipine (DynaCirc)	5-10	2	
		Isradipine SR (DynaCirc SR)	5-20	1	
		Nicardipine sustained release (Cardene SR)	60-120	2	
		Nifedipine long-acting (Adalat CC, Nifedical XL, Procardia XL)	30-90	1	
		Nisoldipine (Sular)	10-40	1	
	Nondihydropyridine	Diltiazem sustained release (Cardizem SR)		2	Extended-release products are preferred for hypertension; these agents reduce heart rate; may produce heart block, especially in combination with β-blockers; these products are not AB rated as interchangeable on an equipotent milligram-per-milligram basis
		Diltiazem sustained release (Cardizem CD, Cartia XT, Dilacor XR, Diltia XT, Tiazac, Taztia XT)	180-360	1	
			120-480	1 (morning or evening)	
		Diltiazem extended release (Cardizem LA)	120-540		
		Verapamil sustained release (Calan SR, Isoptin SR, Verelan)	180-480	1 or 2	
			180-420	1 (in the evening)	
		Verapamil controlled onset, extended release (Covera-HS)	100-400		
		Verapamil chronotherapeutic oral		1 (in the evening)	

Class	Subclass	Drug (Brand Name)	Usual Dose Range (mg/day)	Daily Frequency	Comments
		drug absorption system (Verelan PM)			due to different release mechanisms and different bioavailability parameters; Cardizem LA, Covera-HS, and Verelan PM have delayed drug release for several hours after dosing, when dosed in the evening can provide chronotherapeutic drug delivery starting shortly before patients awake from sleep; nondihydropyridines have additional benefits in patients with atrial tachyarrhythmia
Diuretic	Thiazide	Chlorthalidone (Hygroton) Hydrochlorothiazide (Esidrix, HydroDiuril, Microzide, Oretic) Indapamide (Lozol) Metolazone (Zaroxolyn)	12.5-25 12.5-50 1.25-2.5 2.5-10	1 1 1 1	Hydrochlorothiazide is a “thiazide-type” agent; chlorthalidone, indapamide, and metolazone are “thiazide-like” agents. Dose in the morning to avoid nocturnal diuresis; thiazides are more effective antihypertensives than loop diuretics in most patients; use usual doses to avoid adverse metabolic effects; hydrochlorothiazide, chlorthalidone, and indapamide are preferred; chlorthalidone is

Class	Subclass	Drug (Brand Name)	Usual Dose Range (mg/day)	Daily Frequency	Comments
					approximately 1.5 times as potent as hydrochlorothiazide and has a much longer half-life; have additional benefits in osteoporosis; use with caution in patients with a history of gout
	Loop	Bumetanide (Bumex)	0.5-4	2	Dose in the morning and late afternoon (when twice daily) to avoid nocturnal diuresis; higher doses may be needed for patients with severely decreased GFR or heart failure; preferred over thiazides in patient with concomitant renal dysfunction and resistant hypertension
		Furosemide (Lasix)	20-80	2	
		Torsemide (Demadex)	5-10	1	
	Potassium sparing	Amiloride (Midamor)	5-10	1 or 2	Weak diuretics that are generally used in combination with a thiazide to minimize hypokalemia; do not significantly lower BP unless used with a thiazide; should generally be reserved for patients experiencing diuretic-induced hypokalemia; avoid in patients with CKD (estimated creatinine clearance [CrCl] <30 mL/min [<0.5 mL/s]); may cause hyperkalemia,
		Amiloride/hydrochlorothiazide (Moduretic)	5-10/50-100	1	
		Triamterene (Dyrenium)	50-100	1 or 2	
		Triamterene/hydrochlorothiazide (Dyazide)	37.5-75/25-50	1	

Class	Subclass	Drug (Brand Name)	Usual Dose Range (mg/day)	Daily Frequency	Comments
					especially in combination with an ACEi, ARB, direct renin inhibitor, or potassium supplements
	Aldosterone antagonist	Eplerenone (Inspra)	50-100	1 or 2	Dose in the morning and late afternoon (when twice daily) to avoid nocturnal diuresis; eplerenone contraindicated in patients with an estimated CrCl <50 mL/min (<0.83 mL/s), elevated serum creatinine (>1.8 mg/dL [159 µmol/L] in women, >2 mg/dL [177 µmol/L] in men), and type 2 diabetes with microalbuminuria; spironolactone often used as add-on therapy in resistant hypertension; avoid spironolactone in patients with CKD (estimated CrCl <30 mL/min [<0.5 mL/s]); may cause hyperkalemia, especially in combination with an ACEi, ARB, direct renin inhibitor, or potassium supplements
		Spironolactone (Aldactone)	25-50	1 or 2	
		Spironolactone/hydrochlorothiazide (Aldactazide)	25-50/25-50	1	
β-Blocker	Cardioselective	Atenolol (Tenormin)	25-100	1	Abrupt discontinuation may cause rebound hypertension; inhibit β_1-receptors at low
		Betaxolol (Kerlone)	5-20	1	
		Bisoprolol (Zebeta)	2.5-10	1	

Class	Subclass	Drug (Brand Name)	Usual Dose Range (mg/day)	Daily Frequency	Comments
					to moderate dose, higher doses also block β_2-receptors; may exacerbate asthma when selectivity is lost; have additional benefits in patients with atrial tachyarrhythmia or preoperative hypertension
	Nonselective	Metoprolol tartrate (Lopressor)	100-400	2	
		Metoprolol succinate extended release (Toprol XL)	50-200	1	
		Nadolol (Corgard)	40-120	1	Abrupt discontinuation may cause rebound hypertension; inhibit β_1- and β_2-receptors at all doses; can exacerbate asthma; have additional benefits in patients with essential tremor, migraine headache, portal hypertension, thyrotoxicosis
		Propranolol (Inderal)	160-480	2	
		Propranolol long acting (Inderal LA, Inderal XL, InnoPran XL)	80-320	1	
		Timolol (Blocadren)	10-40	1	
	Intrinsic sympathomimetic activity	Acebutolol (Sectral)	200-800	2	Abrupt discontinuation may cause rebound hypertension; partially stimulate β-receptors while blocking against additional stimulation; no clear advantage for these agents; contraindicated in patients postmyocardial infarction
		Carteolol (Cartrol)	2.5-10	1	
		Pindolol (Visken)	10-60	2	
	Mixed α- and β-blockers	Carvedilol (Coreg)	12.5-50	2	Abrupt discontinuation may cause rebound
		Carvedilol phosphate (Coreg CR)	20-80	1

		Labetalol (Normodyne, Trandate)	200-800	2	hypertension; additional α-blockade produces vasodilation and more orthostatic hypotension
	Cardioselective and vasodilatory	Nebivolol (Bystolic)	5-20	1	Abrupt discontinuation may cause rebound hypertension; additional vasodilation does not result in more orthostatic hypotension

TABLE 13-6 Alternative Antihypertensive Agents

Class	Drug (Brand Name)	Usual Dose Range (mg/day)	Daily Frequency	Comments
α_1-Blocker	Doxazosin (Cardura)	1-8	1	Give first dose at bedtime; patients should rise from sitting or laying down slowly to minimize risk of orthostatic hypotension; additional benefits in men with benign prostatic hyperplasia
	Prazosin (Minipress)	2-20	2 or 3	
	Terazosin (Hytrin)	1-20	1 or 2	
Direct renin inhibitor	Aliskiren (Tekturna)	150-300	1	May cause hyperkalemia in patients with CKD and diabetes or in those receiving a potassium-sparing diuretic, aldosterone antagonist, ACEi, or ARB; may cause acute kidney failure in patients with severe bilateral renal artery stenosis or severe stenosis in artery to solitary kidney; do not use in pregnancy
Central α_2-agonist	Clonidine (Catapres)	0.1-0.8	2	Abrupt discontinuation may cause rebound hypertension; most effective if used with a thiazide to diminish fluid retention; clonidine patch is replaced once per week
	Clonidine patch (Catapres-TTS)	0.1-0.3	1 weekly	
	Methyldopa (Aldomet)	250-1,000	2	
Peripheral adrenergic antagonist	Reserpine (generic only)	0.05-0.25	1	Used in many of the landmark clinical trials; should be used with a thiazide to diminish fluid retention

Class	Drug (Brand Name)	Usual Dose Range (mg/day)	Daily Frequency	Comments
Direct arterial vasodilator	Minoxidil (Loniten)	10-40	1 or 2	Should be used with thiazide and β-blocker to diminish fluid retention and reflex tachycardia
	Hydralazine (Apresoline)	20-100	2 to 4	

Historical Evidence Supporting Thiazide Therapy

Landmark placebo-controlled clinical trials demonstrate that thiazide therapy irrefutably reduces risk of CV morbidity and mortality. The Systolic Hypertension in the Elderly Program (SHEP),[8] Swedish Trial in Old Patients with Hypertension (STOP-Hypertension),[9] and Medical Research Council (MRC)[10] studies showed significant reductions in stroke, MI, all-cause CV disease, and mortality with thiazide-based therapy versus placebo. These trials allowed for β-blockers as add-on therapy for BP control. Agents such as an ACEi, ARB, and CCB were not available at the time of these studies. However, subsequent clinical trials have compared these antihypertensive agents with a thiazide and have demonstrated similar long-term benefits.[26,27,28,29,30,31,32,33]

The Antihypertensive and Lipid Lowering Treatment to Prevent Heart Attack Trial (ALLHAT)

The results of the ALLHAT were the deciding evidence that the JNC7 used to justify thiazide therapy as first-line therapy.[29] It was designed to test the hypothesis that newer antihypertensive agents (an α-blocker, ACEi, or dihydropyridine CCB) would be superior to thiazide-based therapy. The primary objective was to compare the combined end point of fatal CHD and nonfatal MI. Other hypertension-related complications (eg, heart failure, stroke) were evaluated as secondary end points. This was the largest prospective hypertension trial ever conducted and included 42,418 patients aged 55 and older with hypertension and one additional CV risk factor. This double-blind trial randomized patients to chlorthalidone-, amlodipine-, doxazosin-, or lisinopril-based therapy for a mean of 4.9 years.

The doxazosin arm was terminated early when a significantly higher risk of heart failure versus chlorthalidone was observed.[34] The other arms were continued as scheduled and no significant differences in the primary end point was seen between the chlorthalidone and lisinopril or amlodipine treatment groups. However, chlorthalidone had statistically fewer secondary end points than amlodipine (heart failure) and lisinopril (combined CV disease, heart failure, and stroke). The study conclusions were that chlorthalidone-based therapy was superior in preventing one or more major forms of CV disease and was less expensive than amlodipine- or lisinopril-based therapy.

ALLHAT was designed as a superiority study with the hypothesis that amlodipine, doxazosin, and lisinopril would be better than chlorthalidone.[35] It did not prove this hypothesis because the primary end point was no different between chlorthalidone, amlodipine, and lisinopril. Many subgroup analyses of specific populations (eg, black patients, CKD, diabetes) from the ALLHAT have been conducted to assess response in certain unique patient populations.[36,37,38] Surprisingly, none of these analyses demonstrated superior CV event reductions with lisinopril or amlodipine versus chlorthalidone. Overall, thiazides remain unsurpassed in their ability to reduce CV morbidity and mortality in most patients.

The JNC7 guidelines (from 2003) recommend a thiazide as first-line therapy for most patients, and are consistent with the historical treatment of hypertension.[1] Subsequent guidelines and evidence-based recommendations have noted that an ACEi, ARB, or CCB may also be considered for first-line therapy. Contrary to the historical preference to use a thiazide as preferred for treating most patients with hypertension, they are simply one of four first-line

drug therapy options. Figure 13-2 displays the algorithm for the treatment of hypertension and highlights that four drug classes are considered first-line agents for patients without a compelling indication for a specific drug class.

Clinical Controversy…

IS CHLORTHALIDONE SUPERIOR TO HYDROCHLOROTHIAZIDE?

Chlorthalidone (a thiazide-like diuretic) undisputedly reduces CV morbidity and mortality. It was used in the most landmark long-term placebo-controlled trials in hypertension. It is almost twice as potent in lowering BP on a milligram-per-milligram basis as hydrochlorothiazide, which has not been as extensively studied in major long-term hypertension clinical trials and has a much longer half-life. In clinical practice, it is well accepted that CV benefits in hypertension apply to all types of thiazides (considered a class effect). However, it is not definitively known if the clinical benefits of reducing CV morbidity and mortality that have been proven with chlorthalidone can be extrapolated to hydrochlorothiazide.

ACEi, ARB, and CCB as First-Line Agents

Clinical trial data cumulatively demonstrate that ACEi-, CCB-, or ARB-based antihypertensive therapy reduces CV events. These agents may be used for patients without compelling indications as a first-line therapy. The Blood Pressure Lowering Treatment Trialists' Collaboration has evaluated the incidence of major CV events and death among different antihypertensive drug classes from 29 major randomized trials in 162,341 patients.[39] In placebo-controlled trials, the incidences of major CV events were significantly lower with ACEi- and CCB-based regimens versus placebo. Although there were differences in the incidence of certain CV events in some comparisons (eg, stroke was lower with diuretic or CCB-based regiments vs ACEi-based regimens), there were no differences in total major CV events when an ACEi, CCB, or thiazide were compared with each other. In studies evaluating ARB-based therapy to control regimens, the incidence of major CV events was lower with ARB-based therapy. However, the control regimens used in these comparisons included both active antihypertensive drug therapies and placebo.

Data from meta-analyses may not be as influential as data from well-designed, prospective, randomized controlled trials (eg, the ALLHAT). However, they provide clinically useful data that support using ACEi-, CCB-, or ARB-based treatment for hypertension as first-line antihypertensive agents. Clinicians can use meta-analyses data as supporting evidence when selecting a first-line antihypertensive regimen for hypertension in most patients.

Other major consensus guidelines recommend multiple several first-line drug therapy options for treating hypertension in most patients. The 2013 European Society of Hypertension/European Society of Cardiology guidelines and the 2011 UK's National Institute for Health and the Clinical Excellence guidelines list more than one drug therapy option as an acceptable first-line treatment approach.[40,41] The European Society of Hypertension/European Society of Cardiology guidelines are founded on the principle that CV risk reduction is a function of BP control that is largely independent of specific antihypertensives.[40] The UK guidelines stratify patients based on age and race; they recommend an ACEi or ARB first-line for patients under the age of 55, and a CCB first-line for patients age 55 or older or for black patients.[41]

9 ***β*-Blocker Versus First-Line Agents** Clinical trial data cumulatively suggest that treatment with a *β*-blocker may not reduce CV events to the extent that an ACEi, ARB, CCB, or thiazide does. These data are from meta-analyses of clinical trials evaluating *β*-blocker-based therapy for hypertension.[42] Overall, these analyses demonstrated less CV event reduction benefits with *β*-blocker-based antihypertensive therapy compared mostly with ACEi- and CCB-based therapy. Although comparative data with ARB-based therapy are more limited, a similar trend was observed.

Meta-analyses data evaluating *β*-blockers and their ability to reduce CV events have limitations. Most studies that

were included used atenolol as the β-blocker studied. Therefore, it is possible that atenolol is inferior and is the only β-blocker that reduces CV events less than the other first-line antihypertensive drug classes. However, consensus guidelines and expert recommendations do extrapolate these findings to the β-blocker drug class in general.[2,3,4] In the absence of a compelling indication, the 2011 UK guidelines recommend a β-blocker as fourth-line therapy, only after other first-line antihypertensive agents (ACEi or ARB, CCB, thiazide) have been used.[41] These findings also call in question the validity of results from prominent prospective, controlled clinical trials evaluating antihypertensive drug therapy that used β-blocker-based therapy, especially atenolol, as the primary comparator.[28,33] Of note, these studies used once-daily atenolol, which may be inadequate based on the short half-life of this agent.

β-Blocker therapy for patients without compelling indications still has a role in the management of hypertension. It is important for clinicians to remember that β-blocker-based antihypertensive therapy does not increase risk of CV events; β-blocker-based therapy reduces risk of CV events compared with no antihypertensive therapy. Using a β-blocker as a first-line antihypertensive agent is optimal when an ACEi, ARB, CCB, or thiazide cannot be used as the first-line agent. β-Blockers still have an important add-on role after first-line agents to reduce BP in patients with hypertension but without compelling indications.

Many of the clinical trials included in the meta-analyses that suggest β-blocker-based therapy may not reduce CV events as well as these other agents used atenolol dosed once daily.[42] Atenolol has a half-life of 6 to 7 hours and is nearly always dosed once daily, while immediate-release forms of carvedilol and metoprolol have half-lives of 6 to 10 and 3 to 7 hours, respectively, and are dosed at least twice daily.[42] Therefore, it is possible that these findings might only apply to atenolol and also that these findings may be a result of using atenolol once daily instead of twice daily. Based on available evidence, metoprolol succinate or carvedilol are preferred β-blocker if a β-blocker is to be used.

Patients with Compelling Indications

10 Compelling indications represent specific comorbid conditions where evidence from clinical trials supports using specific antihypertensive classes to treat both the compelling indication and hypertension. Drug therapy recommendations typically consist of combination drug therapy (see Fig. 13-3). Data from clinical trials have demonstrated reduction in CV morbidity and/or mortality that justify use for patients with hypertension and with such a compelling indication. Some compelling indications include recommendations that are provided by other national treatment guidelines, or from newer clinical trials, which are complementary to the hypertension guidelines.

Heart Failure with Reduced Ejection Fraction

Five drug classes have compelling indications in heart failure with reduced ejection fraction (HF*r*EF), also known as systolic heart failure or left ventricular dysfunction.[43] The primary physiologic abnormality in this compelling indication is decreased CO resulting from a decrease left ventricular ejection fraction. An evidence-based pharmacotherapy regimen for HF*r*EF, sometimes called guideline-directed medical therapy, consists of three to four drugs: an ACEi or ARB plus diuretic therapy, followed by the addition of an evidence-based β-blocker (ie, bisoprolol, carvedilol, or metoprolol succinate) and possibly an aldosterone receptor antagonist.

Evidence from clinical trials shows that ACEi therapy significantly modifies disease progression by reducing morbidity and mortality. Although HF*r*EF was the primary disease in these studies, ACEi therapy will also control BP in these patients with concomitant hypertension. ARBs are acceptable as an alternative therapy for patients who cannot tolerate an ACEi. An ACEi or ARB should be started with low doses for patients with HF*r*EF, especially those with an acute exacerbation. Heart failure induces a compensatory high-renin condition, and starting an ACEi or ARB under these conditions can cause a pronounced first-dose effect and possible orthostatic hypotension.

Diuretics are also a part of standard pharmacotherapy primarily to control symptoms. They provide symptomatic relief of edema by inducing diuresis. Loop diuretics are often needed, especially for patients with more advanced heart failure and/or CKD. However, some patients with well-controlled heart failure and without significant CKD may be managed with a thiazide.

β-Blocker therapy is appropriate to further modify disease in HF*r*EF and is a component of standard therapy for these patients. For patients on an initial regimen of a thiazide and ACEi or ARB, β-blockers have been shown to reduce CV morbidity and mortality.[43] It is of paramount importance that β-blockers be dosed appropriately due to the risk of inducing an acute exacerbation of heart failure. They must be started in very low doses, doses much lower than that used to treat hypertension, and titrated slowly to high doses based on tolerability. Bisoprolol, carvedilol, and sustained-release metoprolol succinate are the only β-blockers proven to be beneficial in HF*r*EF.

After implementation of a standard three-drug regimen (diuretic, ACEi or ARB, and β-blocker), other agents may be added to further reduce CV morbidity and mortality, and reduce BP if needed. The addition of an aldosterone antagonist can reduce CV morbidity and mortality in HF*r*EF.[43] Spironolactone has been studied in severe HF*r*EF and has shown benefit in addition to diuretic and ACEi therapy. Eplerenone has been studied in patients with symptomatic HF*r*EF within 3 to 14 days after an acute MI in addition to a standard three-drug regimen and in patients with mild left ventricular dysfunction.[43] Spironolactone and eplerenone are similar in their ability to lower risk of CV events in HF*r*EF. For patients self-described as African Americans, the combination of a fixed dose of isosorbide dinitrate and hydralazine to standard three-drug regimen is recommended as an option to improve CV outcomes.[43]

Post-MI β-Blocker (those without intrinsic sympathomimetic activity [ISA]) and ACEi or ARB therapy are recommended in the AHA/American College of Cardiology Foundation and JNC7 guidelines.[1,4,44] β-Blockers decrease cardiac adrenergic stimulation and have been shown in clinical trials to reduce the risk of a subsequent MI or sudden cardiac death. ACEi treatment has been shown to improve cardiac remodeling and cardiac function and to reduce CV events post-MI. These two drug classes, with β-blockers first, are considered the first drugs of choice for patients who have experienced an MI.

Coronary Artery Disease

Chronic stable angina and acute coronary syndrome (unstable angina and acute MI) are forms of coronary artery disease (aka ischemic heart disease).[44,45] These are the most common forms of hypertension-associated complications. This compelling indication is also referred to as high coronary and CV disease risk in the JNC7.[1] β-Blocker therapy has been considered a standard of care for treating patients with coronary artery disease and hypertension. β-Blockers are first-line therapy in chronic stable angina and have the ability to reduce BP and improve ischemic symptoms by decreasing myocardial oxygen consumption and demand. β-Blocker therapy seems to be most effective in reducing the risk of CV events in patients with recent MI and/or ischemic symptoms. However, evidence indicates that the long-term risk of CV events and mortality may not be reduced with β-blocker therapy in patients with very stable coronary artery disease (do not have ischemic symptoms or have a distant history of MI).[46]

Long-acting CCBs (the nondihydropyridine CCBs diltiazem and verapamil) may be considered alternatives to β-blockers or as add-on therapy (dihydropyridine CCBs) in chronic stable angina for patients with ischemic symptoms.[45] The International Verapamil-Trandolapril Study (INVEST) demonstrated no difference in CV risk reduction when β-blocker-based therapy was compared with nondihydropyridine CCB-based therapy in this population.[47] Nonetheless, the preponderance of data is with β-blockers and they remain the therapy of choice.[1,44,45]

For acute coronary syndromes (ST-elevation MI and unstable angina/non-ST-segment MI), first-line therapy should

consist of a β-blocker and ACEi.[48,49] An ARB is a reasonable alternative to an ACEi. This regimen will lower BP, control acute ischemia, and reduce CV risk.

CCBs (especially nondihydropyridine CCBs) and β-blockers provide anti-ischemic effects; they lower BP and reduce myocardial oxygen demand in patients with hypertension and coronary artery disease. However, cardiac stimulation may occur with dihydropyridine CCBs (particularly immediate release formulations) or β-blockers with ISA, making these agents less desirable. Therefore, β-blockers with ISA should be avoided. Nondihydropyridine CCBs should be used as alternatives to β-blockers, and dihydropyridines should be add-on therapy to β-blockers.

Once ischemic symptoms are controlled with β-blocker and/or CCB therapy, other antihypertensive drugs can be added to provide additional CV risk reduction. Clinical trials have demonstrated that the addition of an ACEi further reduces CV events in patients with chronic stable angina.[45] ARB therapy may provide similar benefits but have not been as extensively studied as ACEi therapy.[45] Therefore, in coronary artery disease, an ARB is generally considered an alternative to an ACEi. Thiazides can be added thereafter to provide additional BP lowering and to further reduce CV risk; they do not provide anti-ischemic effects.

Diabetes

The primary cause of mortality in diabetes is CV disease, and hypertension management is a very important risk reduction strategy.[1,16] Five antihypertensive agents have evidence supporting their use in diabetes (see Fig. 13-3). All of these agents have been shown to reduce CV events in patients with diabetes. However, risk reduction may not be equal when comparing these agents.

11 Patients with diabetes and hypertension should ideally be treated with an ACEi or an ARB.[16] Pharmacologically, both of these agents should provide nephroprotection due to vasodilation in the efferent arteriole of the kidney. Moreover, ACEi therapy has overwhelming data demonstrating CV risk reduction in patients with established forms of heart disease. Evidence from clinical studies have demonstrated reductions in both CV risk (mostly with an ACEi) and reduction in risk of progressive kidney dysfunction (mostly with ARBs) in patients with diabetes.[16] There is debate surrounding which agent is better because data support both drug classes. Nonetheless, either drug class should ideally be used to control BP as one of the drugs in the antihypertensive regimen for patients with diabetes, because multiple agents are often needed to attain goal BP values. However, an ACEi should not be used in combination with an ARB as a treatment to control BP in patients with hypertension.

CCBs are the most appropriate add-on agents for BP control for patients with diabetes. Evidence demonstrates that these are the most optimal second agent added to either an ACEi or an ARB. Specifically, in the cohort of patients with diabetes from the Avoiding Cardiovascular Events Through Combination Therapy in Patients Living with Systolic Hypertension (ACCOMPLISH) trial, the combination of an ACEi with a CCB was better at reducing CV events than the combination of an ACEi with a thiazide.[50] The ACCOMPLISH trial is discussed later in this chapter.

A thiazide is recommended add-on therapy to lower BP and provide additional CV risk reduction. A subgroup analysis of patients with diabetes from the ALLHAT trial showed no difference in long-term risk of CV events in the chlorthalidone and lisinopril treatment groups.[37] Therefore, some argue that thiazides, used in low doses, are equally effective for patients with hypertension and diabetes. Nonetheless, the entire body of evidence evaluating pharmacotherapy for patients with hypertension and diabetes supports an ACEi or ARB first-line.[1,16,17]

A β-Blocker, similar to a CCB, is useful add-on therapy for BP control for patients with diabetes. These agents should also be used to treat another compelling indication (eg, post-MI). A β-Blocker (especially a nonselective agent) can possibly mask the signs and symptoms of hypoglycemia in patients with tightly controlled diabetes because most of the symptoms of hypoglycemia (eg, tremor, tachycardia, and palpitations) are mediated through the sympathetic nervous system. Sweating, a cholinergically mediated symptom of hypoglycemia, should still occur

during a hypoglycemic episode despite β-blocker therapy. Patients may also have a delay in hypoglycemia recovery time because compensatory recovery mechanisms need the catecholamine inputs that are antagonized by β-blocker therapy. Finally, unopposed α-receptor stimulation during the acute hypoglycemic recovery phase (due to endogenous epinephrine release intended to reverse hypoglycemia) may result in acutely elevated BP due to vasoconstriction. Despite these potential problems, β-blockers can be safely used for patients with diabetes.

Based on the weight of all evidence, an ACEi or ARB are preferred first-line agents for controlling hypertension in diabetes. The need for combination therapy should be anticipated, and a CCB should be the second agent added. Thiazides, and even β-blockers, are useful evidence-based agents in this population, but are considered add-on therapies to the aforementioned agents.

Chronic Kidney Disease

Patients with hypertension may develop damage to either the renal tissue (parenchyma) or the renal arteries.[18] CKD initially presents as moderately increased albuminuria (urine albumin-to-creatinine ratio 30 to 299 mg/g [3.4-33.8 mg/mmol] on a spot urine sample or greater than or equal to 30 mg albumin in a 24-hour urine collection) that can progress to overt kidney failure. The rate of kidney function deterioration is accelerated when both hypertension and diabetes are present. Once patients have an estimated glomerular filtration rate (GFR) less than 60 mL/min/1.73 m^2 or albuminuria, they have significant CKD and risk of CV disease and progression to severe CKD increases.[1] BP control can slow the decline in kidney function.

In addition to lowering BP, ACEi, and ARB therapy reduces intraglomerular pressure, which can theoretically provide additional benefits by further reducing the decline in kidney function. Using either an ACEi or ARB has been shown to slow progression of CKD in diabetes[16,17] and in those without diabetes.[18,51] It is difficult to differentiate whether the kidney protection benefits are from RAAS blockade versus BP lowering. A meta-analysis failed to demonstrate any unique long-term kidney protective effects of RAAS-blocking drugs compared with other antihypertensive drugs.[52] Moreover, a subgroup analysis of patients from the ALLHAT stratified by different baseline GFR values also did not show a difference in long-term outcomes with chlorthalidone versus lisinopril.[36] Patients may experience a rapid and profound drop in BP or acute kidney failure when given an ACEi or ARB. The potential to produce acute kidney failure is particularly problematic in patients with bilateral renal artery stenosis or a solitary functioning kidney with stenosis. Patients with renal artery stenosis are usually older, and the condition is more common in patients with diabetes or those who smoke. Patients with renal artery stenosis do not always have evidence of kidney disease unless sophisticated tests are performed. Starting with low dosages and evaluating serum creatinine soon after starting the drug can minimize this risk.

Recurrent Stroke Prevention

Ischemic stroke (not hemorrhagic stroke) and transient ischemic attack are complications of hypertension.[52] Achieving goal BP values in patients who have experienced an ischemic stroke is considered a primary modality to reduce risk of a second stroke. A thiazide, either in combination with an ACEi or as monotherapy, is considered an evidence-based antihypertensive regimen for patients with a history of stroke or transient ischemic attack.[1,53,54] ARBs have also been studied in this population.[55,56] Antihypertensive drug therapy should only be implemented after patients have stabilized following an acute cerebrovascular event.

Alternative Drug Treatments

It is sometimes necessary to use other agents such as a direct renin inhibitor, α-blocker, central α_2-agonist, adrenergic inhibitor, and arterial vasodilator in some patients. Although these agents are effective in lowering BP, they either do not have compelling outcome data showing reduced morbidity and mortality in hypertension, or

have poor tolerability and adverse effects that significantly limit their use. Alternative agents are generally reserved for patients with resistant hypertension or as add-on therapy with multiple other first-line antihypertensive agents.

Special Populations

Selection of drug therapy should follow the recommendations provided by established guidelines, which are summarized in Figs. 13-2 and 13-3.[1] These should be maintained as the guiding principles of drug therapy. However, there are some patient populations where the approach to drug therapy may be slightly different, or utilize recommended agents using tailored dosing strategies. In some cases, this is because other agents have unique properties that benefit a coexisting condition, but may not be based on evidence from outcome studies in hypertension.

Hypertension in Older People

Hypertension often presents as isolated systolic hypertension in the elderly.[57] Epidemiologic data indicate that CV morbidity and mortality are more directly correlated to SBP than to DBP for patients aged 50 and older. This population is at high risk for hypertension-associated complications.[1] Although several placebo-controlled trials have specifically demonstrated risk reduction in this form of hypertension, many older people with hypertension are either not treated, or treated but not controlled.

The SHEP was a landmark double-blind, placebo-controlled trial that evaluated chlorthalidone-based treatment (with atenolol or reserpine as add-on therapy) for isolated systolic hypertension.[8] A 36% reduction in total stroke, a 27% reduction in coronary artery disease, and 55% reduction in heart failure were demonstrated versus placebo. The Systolic Hypertension in Europe (Syst-Eur) trial was another placebo-controlled trial that evaluated treatment with a long-acting dihydropyridine CCB.[11] Treatment resulted in a 42% reduction in stroke, 26% reduction in coronary artery disease, and 29% reduction in heart failure. These data clearly demonstrate reductions in CV morbidity and mortality in older patients with isolated systolic hypertension, especially with thiazides and long-acting dihydropyridine CCBs.

The very elderly population (greater than or equal to 80 years of age) were underrepresented in the SHEP and Syst-Eur studies. Historically, this population often was not treated to goal either because of a fear of side effects or because of limited data demonstrating benefit. However, the Hypertension in the Very Elderly Trial (HYVET) provided definitive evidence that antihypertensive drug therapy provides significant clinical benefits in the very elderly.[58] The HYVET was a prospective controlled clinical trial that randomized patients 80 years and older with hypertension to placebo or antihypertensive drug therapy. It was stopped early after a median of only 1.8 years because the incidence of death was 21% higher in placebo-treated patients. Based on these results, hypertension should be treated in the very elderly.

Thiazide or β-blocker therapy has been compared with either an ACEi or CCB in elderly patients with either systolic hypertension, diastolic hypertension, or both in the Swedish Trial in Old Patients with Hypertension-2 (STOP-2) study.[59] In this trial, no significant differences were seen between conventional drugs and either an ACEi or CCB. However, there were significantly fewer MIs and cases of heart failure in the ACEi group compared with the CCB group. These data suggest that overall treatment may be more important than specific antihypertensive agents in this population.

Elderly patients are more sensitive to volume depletion and sympathetic inhibition than younger patients. This may lead to orthostatic hypotension (see next section). In the elderly, this can increase the risk of falls due to the associated dizziness. Centrally acting agents and α_1-blockers should generally be avoided or used with caution in the elderly because they are frequently associated with dizziness and orthostatic hypotension. A thiazide, ACEi, or ARB provides significant benefits and can safely be used in the elderly, but smaller-than-usual initial doses must be

used for initial therapy.

The AHA expert consensus on hypertension in the elderly from 2011,[57] the ASH-ISH guidelines and JNC8 Report[2,3] all recommend higher than standard SBP goals in patients older than 80 years of age. The HYVET trial established that treating hypertension in patients aged 80 years or older with drug therapy to a SBP goal of less than 150 mm Hg was superior to placebo in reducing mortality.[58] However, a pre-specified subgroup analysis of SPRINT evaluated patients age 75 years and older. In this elderly group treatment to a SBP goal of less than 120 mm Hg reduced risk of CV events better than a SBP goal of less than 140 mm Hg. Although there was a slightly higher risk of adverse effects, these data indicated that lower BP goals were better than higher goals. When selecting BP goals in older patients clinicians should evaluate risk versus benefit. Using a higher SBP goal in older patients only seems reasonable when there is either concern for orthostatic hypotension or in frail patients. Absent these factors, standard SBP goals (less than 140 mm Hg) should be considered for elderly patients.

Treatment of hypertension in older patients should follow the same principles outlined for the general care of hypertension. However, lower initial drug doses, and dosage titrations over a longer period of time are usually needed to minimize risks.

12 **Patients at Risk for Orthostatic Hypotension** *Orthostatic hypotension* is a significant drop in BP when standing and can be associated with dizziness and/or fainting. It is defined as a SBP decrease of greater than 20 mm Hg or DBP decrease of greater than 10 mm Hg when changing from supine to standing.[1] The risk of orthostatic hypotension is increased in older patients (especially those with isolated systolic hypotension) and those with long-standing diabetes, severe volume depletion, baroreflex dysfunction, autonomic insufficiency (eg, diabetes), and on concomitant venodilators (α-blockers, mixed α-/β-blockers, nitrates, and phosphodiesterase inhibitors). For patients with these risks factors, antihypertensive agents should be started in low doses, especially a thiazide, ACEi or ARB.

Hypertension in Children and Adolescents

Detecting hypertension in children requires special attention to BP measurement, which is defined as SBP and/or DBP that is greater than 95th percentile for sex, age, and height on at least three occasions.[61] BP between the 90th and 95th percentile, or greater than 120/80 mm Hg in adolescents, is considered prehypertension. Hypertensive children often have a family history of high BP, and many are overweight predisposing them to insulin resistance and associated CV disease. Unlike hypertension in adults, secondary hypertension is more common in children and adolescents. An appropriate workup for secondary causes is required if elevated BP is identified. Kidney disease (eg, pyelonephritis, glomerulonephritis) is the most common cause of secondary hypertension in children. Coarctation of the aorta can also produce secondary hypertension. Medical or surgical management of the underlying disorder usually normalizes BP.

Nonpharmacologic treatment, particularly weight loss in those overweight, is the cornerstone of therapy for essential hypertension in children.[61] The goal is to reduce the BP to less than 95th percentile for sex, age, and height, or less than 90th percentile if concurrent conditions such as CKD, diabetes, or hypertension-associated complications are present. An ACEi, ARB, β-blocker, CCB, and thiazide are all acceptable choices in children and have data supporting their use. An ACEi, ARB, or direct renin inhibitor should all be avoided in sexually active girls due to potential teratogenic effect. As with adults, selection of initial agents should be based on the presence of compelling indications or concurrent conditions that may warrant their use (eg, ACEi or ARB for those with diabetes or CKD).

Pregnancy

Hypertension during pregnancy is a major cause of maternal and neonatal morbidity and mortality.[1] Hypertension

during pregnancy is categorized as preeclampsia-eclampsia, chronic hypertension (of any cause), chronic hypertension superimposed preeclampsia, and gestational hypertension.[62] *Preeclampsia* is defined as hypertension (elevated BP greater than or equal to 140/90 mm Hg on more than two occasions at least 4 hours apart after 20 weeks' gestation or greater than or equal to 160/110 mm Hg confirmed within a short interval) in association with thrombocytopenia, impaired liver function, new development of renal insufficiency, pulmonary edema, or new-onset cerebral or visual disturbances. It can lead to life-threatening complications for both mother and fetus. Eclampsia, the onset of convulsions in preeclampsia, is a medical emergency. Chronic hypertension is hypertension that predates pregnancy; superimposed preeclampsia is chronic hypertension associated with preeclampsia. *Gestational hypertension* is defined as new-onset hypertension arising after 20 weeks of gestation in the absence of proteinuria or other systemic findings (eg, thrombocytopenia, renal insufficiency, pulmonary edema, cerebral, visual disturbances). It is controversial whether treating elevated BP for patients with chronic hypertension in pregnancy is beneficial. However, women with chronic hypertension prior to pregnancy are at increased risk of a number of complications including superimposed preeclampsia, preterm delivery, fetal growth restriction or demise, placental abruption, heart failure, and acute kidney failure. In a recent open, international, multicenter study of 987 women at 14 weeks 0 days to 33 weeks 6 days of gestation with nonproteinuric preexisiting or gestational hypertension, tighter DBP goals (less than 85 mm Hg) was not associated with decreased rates of the primary composite outcome of pregnancy loss or high-level neonatal care for more than 48 hours during the first 28 days. However, severe hypertension (greater than or equal to 160/110 mm Hg) developed less often in patients randomized to the tight control group compared to less-tight control (40.6% vs 27.5%).[63]

Definitive treatment of preeclampsia is delivery. Delivery is indicated if pending or frank eclampsia is present. Otherwise, management consists of restricting activity, bedrest, and close monitoring. Salt restriction, or any other measures that contract blood volume, should not be employed. Antihypertensive agents are used prior to induction of labor if DBP is greater than 105 mm Hg with a target DBP of 95 to 105 mm Hg. Intravenous (IV) hydralazine is most commonly used, and IV labetalol is also effective. Immediate-release oral nifedipine has been used in the past, but is not approved by the FDA for hypertension, and untoward fetal and maternal effects (hypotension with fetal distress) have been reported.

Many agents can be used to treat chronic hypertension in pregnancy (**Table 13-7**). Unfortunately, there are few data regarding the most appropriate therapy in pregnancy. Labetalol, long-acting nifedipine, or methyldopa is recommended as first-line agents due to favorable safety profile.[62] Other β-Blockers (other than atenolol) and CCBs are also reasonable alternatives. An ACEi, ARB, and direct renin inhibitor are known teratogens and are absolutely contraindicated.

TABLE 13-7 Treatment of Chronic Hypertension in Pregnancy

Drug/Class	Comments
Methyldopa	Long-term follow-up data supports safety; *considered a preferred agent*
β-Blocker	Generally safe, but intrauterine growth retardation reported (mostly with atenolol)
Labetalol	Increasingly used over methyldopa because of fewer side effects; *considered a first-line agent*
Clonidine	Limited data available; used mainly in third trimester
CCB	Limited data available; no increase in major teratogenicity with exposure (except immediate-release oral nifedipine should not be used); *long-acting nifedipine considered a preferred agent*
Thiazide	Not first-line agents but probably safe in low doses if started prior to conception for essential hypertension
ACEi, ARB, direct renin inhibitor	Contraindicated; major teratogenicity reported with exposure (fetal toxicity and death)

African Americans

Hypertension affects African American patients at a disproportionately higher rate, and hypertension-associated complications are more prevalent than in other populations.[1,64] Reasons for these differences are not fully understood, but may be related to differences in electrolyte homeostasis, GFR, sodium excretion and transport mechanisms, plasma renin activity, and BP response to plasma volume expansion.

BP-lowering effects of antihypertensive classes vary in African Americans, primarily when used as monotherapy. CCBs and thiazides are most effective at lowering BP in African Americans. When either of these two classes (especially thiazides) are used in combination with a β-blocker, ACEi, or ARB (which are three classes known to be less effective at lowering BP in African Americans), antihypertensive response is significantly increased. This may be due to the low-renin pattern of hypertension in African Americans, which can result in less BP lowering with a β-blocker, ACEi, or ARB when used as monotherapy compared with white patients. Interestingly, African Americans have a higher risk of angioedema and cough from an ACEi compared with whites.[64]

Despite potential differences in antihypertensive effects, drug therapy selection should be based on evidence, no different from what is recommended for the hypertensive population in general. Drug therapies should be used if a compelling indication is present, even if the antihypertensive effect may not be as great as with another drug class (eg, a β-blocker is first-line for BP control in an African American patient who is post-MI).

Other Concomitant Conditions

Most patients with hypertension have some other coexisting conditions that may influence selection or utilization of drug therapy. The influence of concomitant conditions should only be complementary to, and never in replacement of, drug therapy choices indicated by compelling indications. Under some circumstances, these considerations are helpful in deciding on a particular antihypertensive agent when more than one antihypertensive class is recommended to treat a compelling indication. In some cases, an agent should be avoided because it may aggravate a concomitant disorder. In other cases, an antihypertensive can be used to treat hypertension, a compelling indication, and another concomitant condition. These are briefly summarized in Table 13-5.

Pulmonary Disease and Peripheral Arterial Disease

β-Blockers, especially nonselective agents, have been generally avoided for patients with hypertension and reactive airway disease (asthma or chronic obstructive pulmonary disease [COPD] with a reversible obstructive component) due to a fear of inducing bronchospasm.[65] However, cardioselective β-blockers can safely be used in patients with asthma or COPD. Therefore, cardioselective β-blockers should be used to treat a compelling indication (ie, post-MI, coronary disease, or heart failure) for patients with reactive airway disease.

PAD is considered a noncoronary form of ASCVD.[44,65] β-Blockers can theoretically be problematic for patients with PAD due to possible decreased peripheral blood flow secondary to unopposed stimulation of α_1-receptors that results in vasoconstriction. If problematic, this can be mitigated by using a β-blocker that also has α_1-blocking properties (eg, carvedilol). However, β-blockers are not contraindicated in PAD and have not been shown to adversely affect walking capacity.[65]

Metabolic Syndrome

Metabolic syndrome is a cluster of multiple cardiometabolic risk factors.[66] It has been most recently defined as the presence of three of the following five criteria: abdominal obesity (based on waist circumference measurements), elevated triglycerides, low HDL cholesterol, elevated BP (greater than or equal to 130/greater than or equal to 85 mm Hg or receiving drug treatment for high BP), and elevated fasting blood glucose.[66]

Despite the debate regarding whether or not metabolic syndrome is a true “disease” or rather simply a cluster of

risk factors, it is widely accepted that patients with metabolic syndrome have increased risk of developing CV disease and/or type 2 diabetes. Using an ACEi or ARB is associated with the lowest rate of developing new-onset diabetes in patients with hypertension.[67] However, studies specifically evaluating the most effective antihypertensive regimen for patients with metabolic syndrome have not been done. In addition, an ALLHAT subgroup analysis of patients with impaired fasting glucose showed that CV events were reduced more with chlorthalidone compared with lisinopril.[37] Thus, thiazides can be used first-line for patients with metabolic syndrome, similar to an ACEi, ARB, or CCB, but treated patients will have a higher risk of developing elevated fasting glucose.

Erectile Dysfunction

Most antihypertensive agents have been associated with erectile dysfunction in men. However, it is not clear if erectile dysfunction associated with antihypertensive treatment is solely a result of drug therapy or rather a symptom of underlying vascular disease. β-Blockers have traditionally been labeled as agents that significantly cause sexual dysfunction, and many practitioners have avoided prescribing them as a result. However, data supporting this notion are limited. A systematic review of 15 studies involving 35,000 patients assessing β-blocker use for MI, heart failure, and hypertension found only a very slight increased risk for erectile dysfunction.[68] In addition, prospective long-term data from the Treatment of Mild Hypertension Study (TOMHS) and the Veterans Administration Cooperative trial show no difference in the incidence of erectile dysfunction between thiazide and β-blocker versus an ACEi and CCB.[69,70] Centrally acting agents are associated with higher rates of sexual dysfunction and should be avoided in men with erectile dysfunction.

Hypertensive men frequently have atherosclerotic vascular disease, which frequently results in erectile dysfunction. Therefore, erectile dysfunction is associated with chronic arterial changes resulting from elevated BP, and lack of control may increase the risk of erectile dysfunction. These changes are even more pronounced in hypertensive men with diabetes.

Individual Antihypertensive Agents

Angiotensin-converting enzyme inhibitors

An ACEi is a first-line therapy option in most patients with hypertension.[1,2,3,4] The ALLHAT demonstrated less heart failure and stroke with chlorthalidone versus lisinopril.[28] However, another outcome study has demonstrated similar, if not better, outcomes with an ACEi versus hydrochlorothiazide.[31] It is possible that the different thiazides have different abilities to reduce CV events. Nonetheless, most clinicians will agree that if an ACEi is not the first agent used in most patients with hypertension, they should be the second agent used.

ACE facilitates production of angiotensin II that has a major role in arterial BP regulation as depicted in Fig. 13-1. ACE is distributed in many tissues and is present in several different cell types, but its principal location is in endothelial cells. Therefore, the major site for angiotensin II production is in the blood vessels, not the kidney. An ACEi blocks the ACE, thus inhibiting conversion of angiotensin I to angiotensin II. Angiotensin II is a potent vasoconstrictor that stimulates aldosterone secretion, causing an increase in sodium and water reabsorption with accompanying potassium loss. By blocking the ACE, vasodilation and a decrease in aldosterone occur.

An ACEi also blocks degradation of bradykinin and stimulates the synthesis of other vasodilating substances (prostaglandin E_2 and prostacyclin). The observation that an ACEi lowers BP in patients with normal plasma renin activity suggests that bradykinin and perhaps tissue production of ACE are important in the pathogenesis of hypertension. Increased bradykinin enhances the BP-lowering effects of an ACEi, but also is responsible for the side effect of a dry cough. An ACEi may effectively prevent or regress LVH by reducing direct stimulation by angiotensin II on myocardial cells.

There are many evidence-based uses for an ACEi (see Fig. 13-3). An ACEi reduces CV morbidity and mortality in patients with HF*r*EF and decrease progression of CKD. They should be first-line as disease-modifying therapy in all of these patients unless absolutely contraindicated. An ACEi (or ARB in certain patients) is first-line for patients with diabetes and hypertension because of demonstrated CV disease and kidney benefits. A regimen including an ACEi with a thiazide is considered first-line in recurrent stroke prevention based on benefits demonstrated from the PROGRESS trial showing reduced risk of secondary stroke.[30] In combination with β-blocker therapy, evidence shows that an ACEi further reduce CV risk in coronary disease and in patients post-MI.[44,45,48,49] These benefits of an ACEi occur in patients with atherosclerotic vascular disease even in the absence of left ventricular dysfunction and have the potential to reduce the development of new-onset type 2 diabetes.[71]

Most agents can be dosed once daily in hypertension (see Table 13-5). In some patients, especially when higher doses are used, twice-daily dosing is needed to maintain 24-hour effects with enalapril, benazepril, moexipril, quinapril, and ramipril.

ACEi therapy is generally well tolerated.[72] They decrease aldosterone and can increase potassium serum concentrations. While this increase is usually small, hyperkalemia is possible. Patients with CKD or those on concomitant potassium supplements, potassium-sparing diuretics, ARBs, or a direct renin inhibitor are at risk for hyperkalemia. Judicious monitoring of serum potassium and creatinine values within 4 weeks of starting or increasing the dose of an ACEi can often identify these abnormalities early before they evolve into serious adverse events.

The most worrisome adverse effect of ACEi therapy is acute kidney failure. This serious adverse effect is rare, occurring in less than 1% of patients. Preexisting kidney disease increases the risk of this side effect. Bilateral renal artery stenosis or unilateral stenosis of a solitary functioning kidney renders patients dependent on the vasoconstrictive effect of angiotensin II on the efferent arteriole of the kidney, thus explaining why these patients are particularly susceptible to acute kidney failure from an ACEi. Slow titration of the ACEi dose and judicious kidney function monitoring can minimize risk and allow for early detection of those with renal artery stenosis.

It is important to note that GFR does decrease somewhat in patients when started on an ACEi or ARB.[73] This is attributed to the inhibition of angiotensin II vasoconstriction on the efferent arteriole. This decrease in GFR often increases serum creatinine, and small increases should be anticipated when monitoring patients on an ACEi. Either modest elevations of less than or equal to 35% (for baseline creatinine values less than or equal to 3 mg/dL [265 µmol/L]) or absolute increases less than 1 mg/dL (88 µmol/L) do not warrant changes. If larger increases occur, ACEi therapy should be stopped or the dose reduced.

Angioedema is a serious potential complication of ACEi therapy. It occurs in less than 1% of the population, and it is more likely in African Americans and smokers. Symptoms include lip and tongue swelling and possibly difficulty breathing. Drug withdrawal is appropriate for treating patients with angioedema. However, angioedema associated with laryngeal edema and/or pulmonary symptoms occasionally occurs and requires additional treatment with icatibant, fresh frozen plasma, and/or emergent intubations to support respiration. A history of angioedema, even if not from an ACEi, precludes use of another ACEi (it is a contraindication). Cross-reactivity between an ACEi and an ARB does not appear to be a significant concern. The Telmisartan Randomized Assessment Study in ACE-Intolerant Subjects with Cardiovascular Disease (TRANSCEND) trial enrolled 75 patients with a history of ACEi–induced angioedema, and randomized these patients to either placebo or ARB therapy.[74] There were no cases of repeat angioedema among these patients. These data suggest the cross-reactivity is very low. Hence, an ARB can be used in a patient with a history of ACEi-induced angioedema when it is needed. However, clinicians should monitor for repeat occurrences, since idiopathic angioedema may still occur.

A persistent dry cough develops in up to 20% of patients treated with an ACEi. It is pharmacologically explained by the inhibition of bradykinin breakdown. This cough does not cause respiratory illness but is annoying to patients

and can compromise adherence. It should be clearly differentiated from a wet cough due to pulmonary edema, which may be a sign of uncontrolled heart failure versus an ACEi-induced cough.

An ACEi, as well as an ARB or direct renin inhibitor, are absolutely contraindicated in pregnancy. Female patients of childbearing age should be counseled regarding effective forms of birth control as ACEi therapy has been associated with major congenital malformations when exposed in the first trimester and fetopathy (group of conditions that includes renal failure, renal dysplasia, hypotension, oligohydramnios, pulmonary hypotension, hypocalvaria, and death) has occurred when exposed in the second and third trimesters. Similar to a thiazide, an ACEi can increase lithium serum concentrations in patients on lithium therapy. Concurrent use of an ACEi with a potassium-sparing diuretic (including aldosterone antagonists), potassium supplements, an ARB, or a direct renin inhibitor may result in hyperkalemia.

Starting doses of an ACEi should be low, with even lower doses for patients at risk for orthostatic hypotension or severe renal dysfunction (eg, elderly, CKD). Acute hypotension may occur at the onset of ACEi therapy. Patients who are sodium or volume depleted, in a heart failure exacerbation, very elderly, or on concurrent vasodilators or thiazide therapy are at high risk for this effect. It is important to start with half the normal dose of an ACEi for all patients with these risk factors and to use slow dose titration.

ARB

Angiotensin II is generated by two enzymatic pathways: the RAAS, which involves ACE, and an alternative pathway that uses other enzymes such as chymase (aka "tissue ACE"). An ACEi inhibits only the effects of angiotensin II produced through the RAAS, whereas ARBs inhibit angiotensin II from all pathways. It is unclear how these differences affect tissue concentrations of ACE. An ACEi only partially blocks the effects of angiotensin II, although the clinical significance of this is not known.

Angiotensin II receptor blocker therapy directly blocks the AT_1 receptor that mediates the known effects of angiotensin II in humans: vasoconstriction, aldosterone release, sympathetic activation, antidiuretic hormone release, and constriction of the efferent arterioles of the glomerulus. They do not block the AT_2 receptor. Therefore, beneficial effects of AT_2 receptor stimulation (vasodilation, tissue repair, and inhibition of cell growth) remain intact when ARBs are used. Unlike an ACEi, an ARB does not block the breakdown of bradykinin. Therefore, some of the beneficial effects of bradykinin, such as vasodilation, regression of myocyte hypertrophy and fibrosis, and increased levels of tissue plasminogen activator, are not present with ARB therapy.

An ARB is a first-line therapy option in most patients with hypertension.[1,2,3,4] ARB therapy has been directly compared with ACEi therapy in the management of hypertension.[75] The Ongoing Telmisartan Alone and in Combination with Ramipril Global End Point Trial (ON-TARGET) was a double-blind trial that randomized 25,620 patients with hypertension to ACEi-based therapy, ARB-based therapy, or the combination of an ACEi with an ARB. The primary end point was a composite end point of CV death or hospitalization for heart failure. After a median follow-up of 56 months, there was no difference in the primary end point between any of the three treatment groups. Therefore, these data establish that the CV event-lowering benefits of ARB therapy are similar to ACEi therapy in hypertension. Moreover, the combination of an ACEi with an ARB had no additional CV event lowering but was associated with a higher risk of side effects (renal dysfunction, hypotension). Therefore, there is no reason to use an ACEi with an ARB for the management of hypertension.

For patients with type 2 diabetes and nephropathy, progression of nephropathy has been shown to be significantly reduced with ARB therapy.[16] Some benefits appear to be independent of BP lowering, suggesting that the pharmacologic effects of ARBs on the efferent arteriole may result in attenuated progression of kidney disease. For patients with HF*r*EF, ARB therapy has been shown to reduce risk of hospitalization for heart failure when used as an alternative therapy in ACEi-intolerant patients.[43]

Angiotensin II receptor blockers have been compared head-to-head with CCBs. The Morbidity and Mortality After Stroke: Eprosartan Versus Nitrendipine in Secondary Prevention (MOSES) trial demonstrated that eprosartan reduced the risk of recurrent stroke greater than nitrendipine in patients with a past medical history of cerebrovascular disease.[55] Using nitrendipine was a reasonable comparator because the Syst-Eur had already demonstrated that nitrendipine reduces the occurrence of CV events, particularly stroke, in older patients with isolated systolic hypertension compared with placebo.[11] These data support the common notion that ARBs may have cerebroprotective effects that may explain CV event reductions. Another outcome study, the Valsartan Antihypertensive Long-Term Use Evaluation (VALUE) trial, showed that valsartan-based therapy is equivalent to amlodipine-based therapy for the primary composite outcome of first CV event in patients with hypertension and additional CV risk factors.[32] However, occurrence of certain components of the primary end point (stroke and MI) and new-onset type 2 diabetes was lower in the valsartan group. Although patients treated with amlodipine had slightly lower mean BP values than valsartan-treated patients, there was no difference in the primary end point.

The addition of a CCB or thiazide to an ARB significantly increases antihypertensive efficacy. Similar to an ACEi, most ARBs have long enough half-lives to allow for once-daily dosing. However, candesartan, eprosartan, losartan, and valsartan have the shortest half-lives and may require twice-daily dosing for sustained BP lowering.

Angiotensin II receptor blocker therapy has the lowest incidence of side effects compared with other antihypertensive agents.[72] Because ARBs do not affect bradykinin, they do not illicit a dry cough like an ACEi. While these drugs have been referred to as an "ACEi without the cough," pharmacologic differences highlight that they could have very different effects on vascular smooth muscle and myocardial tissue that can correlate to different effects when compared with an ACEi. Regardless, their first-line role for patients with hypertension is well established, and they are reasonable alternatives for patients requiring an ACEi but who experience an intolerable cough.

Like an ACEi, an ARB may cause renal insufficiency, hyperkalemia, and orthostatic hypotension. The same precautions that apply to ACEi therapy for patients with suspected bilateral renal artery stenosis, those on drugs that can raise potassium, and those on drugs that increase risk of hypotension apply to ARBs. As discussed in ACEi, ARB, or CCB as First-Line Agents above, patients with a history of ACEi angioedema can be treated with an ARB when needed.[74] An ARB should not be used in pregnancy.

CCB

CCB therapy, including both dihydropyridine and nondihydropyridine types, are first-line therapy and are very effective antihypertensive agents.[1,2,3,4] They also have compelling indications in coronary artery disease and diabetes. However, with these compelling indications, they are in addition to, or instead of, other first-line antihypertensive drug classes.

Contraction of cardiac and smooth muscle cells requires an increase in free intracellular calcium concentrations from the extracellular fluid. When cardiac or vascular smooth muscle is stimulated, voltage-sensitive channels in the cell membrane are opened, allowing calcium to enter the cells. The influx of extracellular calcium into the cell releases stored calcium from the sarcoplasmic reticulum. As intracellular free calcium concentration increases, it binds to a protein, calmodulin, which then activates myosin kinase enabling myosin to interact with actin to induce contraction. CCBs work by inhibiting influx of calcium across the cell membrane. There are two types of voltage-gated calcium channels: a high-voltage channel (L-type) and a low-voltage channel (T-type). Currently available CCBs only block the L-type channel, which leads to coronary and peripheral vasodilation.

The two subclasses, dihydropyridines and nondihydropyridines (see Table 13-5), are pharmacologically very different from each other. Antihypertensive effectiveness is similar with both subclasses, but they differ somewhat in other pharmacodynamic effects. Nondihydropyridines (verapamil and diltiazem) decrease heart rate and slow

atrioventricular nodal conduction. Similar to a β-blocker, these drugs may also treat supraventricular tachyarrhythmias (eg, atrial fibrillation). Verapamil produces negative inotropic and chronotropic effects that are responsible for its propensity to precipitate or cause systolic heart failure in high-risk patients. Diltiazem also has these effects but to a lesser extent than verapamil. All CCBs (except amlodipine and felodipine) have negative inotropic effects. Dihydropyridines may cause a baroreceptor-mediated reflex tachycardia because of their potent peripheral vasodilating effects. This effect appears to be more pronounced with the first-generation dihydropyridines (eg, nifedipine) and is significantly diminished with the newer agents (eg, amlodipine) and when given in sustained-release dosage forms. Dihydropyridines do not alter conduction through the atrioventricular node and thus are not effective agents in supraventricular tachyarrhythmias.

Dihydropyridine CCB

The dihydropyridine CCBs have been extensively studied. In ALLHAT there was no difference in the primary outcome between chlorthalidone and amlodipine, and only the secondary outcome of heart failure was higher with amlodipine.[29] A subgroup analysis of ALLHAT directly compared amlodipine with lisinopril and demonstrated that there was no difference in the primary outcome.[76] However, amlodipine was superior to lisinopril for BP control in blacks, and for stroke reduction in blacks and in women. There was a lower risk of heart failure in the lisinopril group. As discussed previously, the VALUE study also showed no difference between valsartan and amlodipine in the primary outcome of first CV event in high-risk patients.[32]

Dihydropyridine CCBs are very effective in older patients with isolated systolic hypertension. The placebo-controlled Syst-Eur trial demonstrated that a long-acting dihydropyridine CCB reduced the risk of CV events markedly in isolated systolic hypertension.[11] A long-acting dihydropyridine CCB should be strongly considered as preferred add-on therapy when a thiazide is not controlling BP in a patient with isolated systolic hypertension and no other compelling indications.

Among dihydropyridines, short-acting nifedipine may rarely cause an increase in the frequency, intensity, and duration of angina in association with acute hypotension. This effect is most likely due to a reflex sympathetic stimulation and is likely obviated by using sustained-release formulations of nifedipine. For this reason, all other dihydropyridines have an intrinsically long half-life or are sustained-release formulations. Immediate-release nifedipine has been associated with an increased incidence of adverse CV effects, is not approved for treatment of hypertension, and should not be used to treat hypertension. Other side effects with dihydropyridines include dizziness, flushing, headache, gingival hyperplasia, peripheral edema, mood changes, and various GI complaints. Side effects due to vasodilation such as dizziness, flushing, headache, and peripheral edema occur more frequently with all dihydropyridines than with the nondihydropyridines (ie, verapamil, diltiazem) because they are less potent vasodilators.

Nondihydropyridine CCB

Diltiazem and verapamil can cause cardiac conduction abnormalities such as bradycardia or atrioventricular block. These problems occur mostly with high doses or when used for patients with preexisting abnormalities in the cardiac conduction system. Heart failure has been reported in otherwise healthy patients due to negative inotropic effects. Both drugs can cause anorexia, nausea, peripheral edema, and hypotension. Verapamil causes constipation in about 7% of patients. This side effect also occurs with diltiazem, but to a lesser extent.

Verapamil and to a lesser extent diltiazem can cause drug interactions due to their ability to inhibit the cytochrome P450 3A4 isoenzyme system. This inhibition can increase serum concentrations of other drugs that are metabolized by this isoenzyme system (eg, cyclosporine, digoxin, lovastatin, simvastatin, tacrolimus, theophylline). Verapamil and diltiazem should be given very cautiously with a β-blocker because there is an increased risk of heart block with these combinations. When a CCB is needed in combination with a β-blocker for BP lowering, a dihydropyridine should be selected because it will not increase risk of heart block. The hepatic metabolism of

CCBs, especially felodipine, nicardipine, nifedipine, and nisoldipine, may be inhibited by ingesting large quantities of grapefruit juice (eg, greater than or equal to 1 quart daily).

Many different formulations of verapamil and diltiazem are currently available (see Table 13-5). Although certain sustained-release verapamil and diltiazem products contain the same active drug (eg, Calan SR and Verelan), they are usually not AB rated by the FDA as interchangeable on a milligram-per-milligram basis due to different biopharmaceutical release mechanisms. However, the clinical significance of these differences is likely negligible.

Two sustained-release verapamil products (Covera-HS and Verelan PM) and one diltiazem product (Cardizem LA) are chronotherapeutically designed to target the circadian BP rhythm. These agents are primarily dosed in the evening (with the exception of Cardizem LA, which may be dosed in the morning or evening) so that drug is released during the early morning hours when BP first starts to increase. The rationale behind chronotherapy in hypertension is that blunting the early morning BP surge may result in greater reductions in CV events than conventional dosing of regular antihypertensive products in the morning. However, evidence from the Controlled Onset Verapamil Investigation of Cardiovascular End-Points (CONVINCE) trial showed that chronotherapeutic verapamil was similar to, but not better than, a thiazide-β-blocker-based regimen with respect to CV events.[27]

Thiazide and other Diuretics

There are four subclasses of diuretics that are used in the treatment of hypertension: thiazides, loops, potassium-sparing agents, and aldosterone antagonists (see Table 13-5).[77] A thiazide is the preferred type of diuretic for hypertension and is considered a first-line therapy option in most patients with hypertension.[1,2,3,4] The best available evidence justifying this recommendation is from the ALLHAT.[29] Moreover, when combination therapy is needed in hypertension to control BP, a thiazide as an add-on agent, but not necessarily the second agent, is very effective in lowering BP.

Loops are more potent agents for inducing diuresis, but they are not ideal antihypertensive agents unless relief of edema is also needed. In general, loops are sometimes needed over a thiazide for hypertension in patients with CKD when estimated GFR is less than 30 mL/min/1.73 m^2, especially when edema is present.[77] However, many patients with an estimated GFR of less than 30 mL/min/1.73 m^2 but not on dialysis will still have antihypertensive effects with thiazides. This is especially true with chlorthalidone.[77]

Potassium-sparing diuretics are very weak antihypertensive agents when used alone and provide minimal additive effect when used in combination with a thiazide or loop diuretic. Their primary use is in combination with another diuretic to counteract the potassium-wasting properties of the other diuretic agent. Aldosterone antagonists (spironolactone and eplerenone) may be technically considered potassium-sparing agents but are more potent as antihypertensives. However, they are viewed as an independent class due to evidence supporting compelling indications.

The exact hypotensive mechanism of action of diuretics is not known, but has been well hypothesized. The drop in BP seen when diuretics are first started is caused by an initial diuresis. Diuresis causes reductions in plasma and stroke volume, which decreases CO and BP. This initial drop in CO causes a compensatory increase in PVR. With chronic diuretic therapy, extracellular fluid and plasma volume return to near pretreatment values. However, PVR decreases to values that are lower than the pretreatment baseline. This reduction in PVR is responsible for chronic antihypertensive effects.

With thiazide therapy additional actions may further explain their antihypertensive effects. They mobilize sodium and water from arteriolar walls. This effect would lessen the amount of physical encroachment on the lumen of the vessel created by excessive accumulation of intracellular fluid. As the diameter of the lumen relaxes and increases, there is less resistance to the flow of blood and PVR further drops. High dietary sodium intake can blunt this effect

and a low salt intake can enhance this effect. Thiazides are also postulated to cause direct relaxation of vascular smooth muscle.

Diuretics should ideally be dosed in the morning if given once daily and in the morning and late afternoon when dosed twice daily to minimize risk of nocturnal diuresis. However, with chronic use, thiazides, potassium-sparing diuretics, and aldosterone antagonists rarely cause a pronounced diuresis.

The major pharmacokinetic differences between the various thiazides are serum half-life and duration of diuretic effect. The clinical relevance of these differences is unknown because the serum half-life of most antihypertensive agents does not correlate with the hypotensive duration of action. Moreover, diuretics lower BP primarily through extrarenal mechanisms. Hydrochlorothiazide and particularly chlorthalidone are the two most frequently used thiazides in landmark clinical trials that have demonstrated reduced morbidity and mortality. Hydrochlorothiazide is considered a "thiazide-type" agent while chlorthalidone is a "thiazide-like" agent. These agents are not equipotent on a milligram-per-milligram basis; chlorthalidone is 1.5 to 2 times more potent than hydrochlorothiazide.[77] This has been attributed to a longer half-life (45-60 hours vs 8-15 hours) and longer duration of effect (48-72 hours vs 16-24 hours) with chlorthalidone.

A thiazide is very effective in lowering BP when used in combination with most other antihypertensives. This additive response is explained by two independent pharmacodynamic effects. First, when two drugs cause the same overall pharmacologic effect (BP lowering) through different mechanisms of action, their combination usually results in an additive or synergistic effect. This is especially relevant when a β-blocker or ACEi/ARB is indicated in an African American, but does not elicit sufficient antihypertensive effect. Adding a thiazide in this situation can often significantly lower BP. Second, a compensatory increase in sodium and fluid retention may be seen with antihypertensive agents. This problem is counteracted with the concurrent use of a thiazide.

Side effects of a thiazide include hypokalemia, hypomagnesemia, hypercalcemia, hyperuricemia, hyperglycemia, dyslipidemia, and sexual dysfunction. Many of these side effects were identified when high doses of thiazides were used in the past (eg, hydrochlorothiazide 100-200 mg/day). Current guidelines recommend dosing hydrochlorothiazide or chlorthalidone to 12.5 to 25 mg/day, which markedly reduces the risk for most metabolic side effects. However, the most effective antihypertensive dose of hydrochlorothiazide is 50 mg daily, although many clinicians are dissuaded from this higher dose due to potential higher risk of hypokalemia.[78] Loop diuretics may cause the same side effects. although the effect on serum lipids and glucose is not as significant, hypokalemia is more pronounced, and hypocalcemia may occur.

Hypokalemia and hypomagnesemia may cause muscle fatigue or cramps. However, serious cardiac arrhythmias can occur in patients with severe hypokalemia and hypomagnesemia. Patients at greatest risk include those with LVH, coronary disease, post-MI, a history of arrhythmia, or concurrently receiving digoxin. Low-dose therapy (ie, 25 mg hydrochlorothiazide or 12.5 mg chlorthalidone daily) causes small electrolyte disturbances. However, the most effective doses of these two thiazides are hydrochlorothiazide 50 mg daily and chlorthalidone 25 mg daily. Efforts should be made to keep potassium in the therapeutic range by careful monitoring, especially if these higher doses are used.

Thiazide-induced hyperuricemia can precipitate gout. This side effect may be especially problematic for patients with a previous history of gout and is more common with thiazides. However, acute gout is unlikely in patients with no previous history of gout. If gout does occur in a patient who requires thiazide therapy, allopurinol can be given to prevent gout and will not compromise the antihypertensive effects of the thiazide. High doses of thiazide and loop diuretics may increase fasting glucose and serum cholesterol values. These effects, however, usually are transient and often inconsequential.[79]

Potassium-sparing diuretics can cause hyperkalemia, especially in patients with CKD or diabetes and in patients receiving concurrent treatment with an ACEi, ARB, direct renin inhibitor, or potassium supplements. Hyperkalemia

is especially problematic for the newest aldosterone antagonist eplerenone. This agent is a very selective aldosterone antagonist, and its propensity to cause hyperkalemia is greater than with the other potassium-sparing agents and even spironolactone. Due to this increased risk of hyperkalemia, eplerenone is contraindicated for patients with impaired kidney function or type 2 diabetes with proteinuria (see Table 13-5). While spironolactone may cause gynecomastia in up to 10% of patients, this occurs rarely with eplerenone.

A thiazide can be used safely with most other agents. However, concurrent administration with lithium may result in increased lithium serum concentrations and can predispose patients to lithium toxicity.

β-Blocker

A *β*-blocker has been used in several large outcome trials in hypertension. However, in most of these trials, a thiazide was the first-line agent with a *β*-blocker added for additional BP lowering. Moreover, as previously discussed, for patients with hypertension but without compelling indications, other first-line agents (ie, ACEi, ARB, CCB, thiazide) should be used as the initial first-line agent before a *β*-blocker. This recommendation is based on meta-analyses that suggest *β*-blocker-based therapy may not reduce CV events as well as these other agents when used as the initial drug to treat patients with hypertension and without a compelling indication for a *β*-blocker.[42]

A *β*-blocker is only considered an appropriate first-line agent to treat specific compelling indications (eg, post-MI, coronary artery disease, HF*r*EF). Numerous trials have shown a reduced risk of CV events when *β*-blockers are used following an MI, during an acute coronary syndrome, or in patients with chronic stable angina with ischemic symptoms. Although once contraindicated in heart failure, studies have shown that bisoprolol, carvedilol, and metoprolol succinate reduce mortality in patients with HF*r*EF who are treated with a diuretic and ACEi.

Several mechanisms of action have been proposed for *β*-blockers, but none of them alone has been shown to be consistently associated with a reduction in arterial BP. *β*-Blocker therapy has negative chronotropic and inotropic effects that reduce CO, which explains some of the antihypertensive effect. However, CO falls equally for patients treated with a *β*-blocker regardless of BP lowering. Additionally, *β*-blockers with ISA do not reduce CO, yet they lower BP and decrease peripheral resistance.

β-Adrenoceptors are also located on the surface membranes of juxtaglomerular cells, and a *β*-blocker inhibits these receptors and thus the release of renin. However, there is a weak association between plasma renin and antihypertensive efficacy of *β*-blocker therapy. Some patients with low plasma renin concentrations do respond to *β*-blocker therapy. Therefore, additional mechanisms likely also account for the antihypertensive effect of a *β*-blocker. However, the ability of a *β*-blocker to reduce plasma renin and thus angiotensin II concentrations may play a major role in their ability to reduce CV risk.

There are important pharmacodynamic and pharmacokinetic differences among *β*-blockers, but all agents provide a similar degree of BP lowering. There are three pharmacodynamic properties of *β*-blocker therapy that differentiate this class: cardioselectivity, ISA, and membrane-stabilizing effects. *β*-Blocker agents that possess a greater affinity for β_1-receptors than for β_2-receptors are *cardioselective*.

β_1-Adrenoceptors and β_2-adrenoceptors are distributed throughout the body, but they concentrate differently in certain organs and tissues. There is a preponderance of β_1-receptors in the heart and kidney, and a preponderance of β_2-receptors in the lungs, liver, pancreas, and arteriolar smooth muscle. β_1-Receptor stimulation increases heart rate, contractility, and renin release. β_2-Receptor stimulation results in bronchodilation and vasodilation. Cardioselective *β*-blocker therapy is not likely to provoke bronchospasm and vasoconstriction. Insulin secretion and glycogenolysis are mediated by β_2-receptors. Blocking β_2-receptors may reduce these processes and increase blood glucose or blunt recovery from hypoglycemia.

Cardioselective *β*-blockers (eg, atenolol, bisoprolol, metoprolol, and nebivolol) have clinically significant

advantages over nonselective agents (eg, propranolol and nadolol), and are preferred when using a β-blocker to treat hypertension. Cardioselective agents are safer than nonselective agents for patients with asthma or diabetes who have a compelling indication for a β-blocker. However, cardioselectivity is a dose-dependent phenomenon; at higher doses, cardioselective agents lose their relative selectivity for β_1-receptors and block β_2-receptors as effectively as they block β_1-receptors. The dose at which cardioselectivity is lost varies from patient to patient.

Some β-blockers (eg, acebutolol, pindolol) have ISA and act as partial β-receptor agonists. When they bind to the β-receptor, they stimulate it, but far less than a pure β-agonist. If sympathetic tone is low, as it is during resting states, β-receptors are partially stimulated by ISA β-blockers. Therefore, resting heart rate, CO, and peripheral blood flow are not reduced when these types of β-blockers are used. Theoretically, ISA agents would appear to have advantages over a non-ISA β-blocker in certain patients with heart failure or sinus bradycardia. Unfortunately, they do not appear to reduce CV events as well as other β-blockers. In fact, they may increase CV risk post-MI or in those with coronary artery disease. Thus, agents with ISA are rarely needed.

All β-blockers exert a *membrane-stabilizing action* on cardiac cells when large doses are given. This activity is needed when β-blockers are used as an antiarrhythmic agent.

Pharmacokinetic differences among β-blockers relate to first-pass metabolism, route of elimination, degree of lipophilicity, and serum half-lives. Propranolol and metoprolol undergo extensive first-pass metabolism, so the dose needed to attain β-blockade with either drug varies from patient to patient. Atenolol and nadolol are renally excreted. The dose of these agents may need to be reduced for patients with moderate-to-severe CKD.

β-Blockers, especially those with high lipophilic properties, penetrate the central nervous system and may cause other effects. Propranolol is the most lipophilic drug and atenolol is the least lipophilic. Therefore, higher brain concentrations of propranolol compared with atenolol are seen after equivalent doses are given. It is thought that higher lipophilicity is associated with more central nervous system side effects (dizziness and drowsiness). However, the lipophilic properties can provide better effects for non-CV conditions such as migraine headache prevention, essential tremor, and thyrotoxicosis. BP lowering is equal among β-blockers regardless of lipophilicity.

Most side effects of β-blocker therapy are extensions of their ability to antagonize β-adrenoceptors. β-Blockade in the myocardium can be associated with bradycardia, atrioventricular conduction abnormalities (eg, second- or third-degree heart block), and the development of acute heart failure. The decrease in heart rate may benefit certain patients with atrial arrhythmias (atrial fibrillation and atrial flutter) and hypertension by both providing rate control and BP lowering. β-Blocker therapy usually only produce heart failure if used in high initial doses for patients with preexisting left ventricular dysfunction or if started in these patients during an acute heart failure exacerbation. Blocking β_2-receptors in arteriolar smooth muscle may cause cold extremities and may aggravate intermittent claudication or Raynaud's phenomenon as a result of decreased peripheral blood flow. In addition, there is an increase of sympathetic tone during periods of hypoglycemia in patients with diabetes that may result in a significant increase in BP because of unopposed α-receptor-mediated vasoconstriction.

Abrupt cessation of β-blocker therapy can produce unstable angina, MI, or even death in patients with coronary disease. Abrupt cessation may also lead to rebound hypertension (a sudden increase in BP to or above pretreatment values). To avoid this, β-blockers should always be tapered gradually over 1 to 2 weeks before eventually discontinuing the drug. This acute withdrawal syndrome is believed to be secondary to progression of underlying coronary disease, hypersensitivity of β-adrenergic receptors due to upregulation, and increased physical activity after withdrawal of a drug that decreases myocardial oxygen requirements. For patients without coronary disease, abrupt discontinuation may present as tachycardia, sweating, and generalized malaise in addition to increased BP.

Like a thiazide, β-blocker therapy has been shown to increase serum cholesterol and glucose values, but these effects are transient and of little clinical significance. For patients with diabetes, the reduction in CV events was as

great with β-blocker therapy as with an ACEi in the United Kingdom Prospective Diabetes Study (UKPDS)[80] and far superior to placebo in the SHEP trial.[8] In the Glycemic Effects in Diabetes Mellitus: Carvedilol–Metoprolol Comparison in Hypertensives (GEMINI) trial, patients with diabetes and hypertension who were randomized to metoprolol tartrate had an increase in hemoglobin A1C values, while patients randomized to carvedilol did not.[81] This suggests that mixed α- and β-blocking effects of carvedilol may be preferential to metoprolol for patients with uncontrolled diabetes. However, differences in hemoglobin A1C values were small.

Nebivolol is considered a third-generation β-blocker. Similar to carvedilol and labetalol, this β-blocker results in vasodilation. However, carvedilol and labetalol cause vasodilation because of their ability to block α_1-receptors, while nebivolol causes vasodilation through release of nitric oxide. The long-term clinical benefits of the nitric oxide effects seen with nebivolol are currently unknown, but this might explain a lower risk of β-blocker-associated fatigue, erectile dysfunction, and metabolic side effects (eg, hyperglycemia) with this agent.

Alternative Agents

The primary role of an alternative antihypertensive agent is to provide additional BP lowering in patients who are already treated with combination therapy consisting of first-line antihypertensive.

α_1-Blocker

Prazosin, terazosin, and doxazosin are selective α_1-receptor blockers. They work in the peripheral vasculature and inhibit the uptake of catecholamines in smooth muscle cells resulting in vasodilation and BP lowering.

Doxazosin was one of the original treatment arms of the ALLHAT. However, it was stopped prematurely when statistically more secondary end points of stroke, heart failure, and CV events were seen with doxazosin compared with chlorthalidone.[34] There were no differences in the primary end point of fatal coronary heart disease and nonfatal MI. These data suggest that thiazides are superior to α_1-blockers in preventing CV events in patients with hypertension. Therefore, α_1-blockers are alternative agents that should be used in combination with first-line antihypertensive agents.

An α_1-blocker can provide symptomatic benefits in men with benign prostatic hypertrophy. These agents block postsynaptic α_1-adrenergic receptors located on the prostate capsule, causing relaxation and decreased resistance to urinary outflow. However, when used to lower BP, they should only be in addition to other first-line antihypertensive agents.

A potentially severe side effect of an α_1-blocker is a “first-dose” phenomenon that is characterized by transient dizziness or faintness, palpitations, and even syncope within 1 to 3 hours of the first dose. This adverse reaction can also happen after dose increases. These episodes are accompanied by orthostatic hypotension and can be obviated by taking the first dose and subsequent first increased doses at bedtime. Because orthostatic hypotension and dizziness may persist with chronic administration, these agents should be used very cautiously in elderly patients, as they may increase the risk of falls. Even though antihypertensive effects are achieved through a peripheral α_1-receptor antagonism, these agents cross the blood–brain barrier and may cause central nervous system side effects such as lassitude, vivid dreams, and depression. α_1-Blocker therapy also may cause priapism. Sodium and water retention can occur with higher doses, and sometimes even with chronic administration of low doses. Therefore, these agents are most effective when given in combination with a thiazide to maintain antihypertensive efficacy and minimize potential edema.

Aliskiren

Aliskiren is the only agent that is a direct renin inhibitor. This drug blocks the RAAS at its point of activation, which

results in reduced plasma renin activity and BP lowering. It has a 24-hour half-life, is primarily eliminated through biliary excretion unchanged, and provides 24-hour antihypertensive effects with once-daily dosing.

The role of this drug class in the management of hypertension is very limited. Aliskiren is approved as monotherapy or in combination therapy. Since aliskiren is a RAAS blocker, it should not be used in combination with an ACEi or an ARB because of a higher risk of serious adverse effects without providing additional reduction in CV events.[82]

Many of the cautions and adverse effects seen with an ACEi or ARB applies to aliskiren. Aliskiren should never be used in pregnancy due to the known teratogenic effects of using other drugs that block the RAAS system. Angioedema has also been reported in patients treated with aliskiren. Increases in serum creatinine and serum potassium values have been observed. The mechanisms of these adverse effects are likely similar to those with an ACEi or ARB. It is reasonable to utilize similar monitoring strategies by measuring serum creatinine and serum potassium in patients treated with aliskiren.

Central α_2-Agonist

Clonidine, guanabenz, guanfacine, and methyldopa lower BP primarily by stimulating α_2-adrenergic receptors in the brain. This stimulation reduces sympathetic outflow from the vasomotor center in the brain and increases vagal tone. It is also believed that peripheral stimulation of presynaptic α_2-receptors may further reduce sympathetic tone. Reduced sympathetic activity together with enhanced parasympathetic activity can decrease heart rate, CO, TPR, plasma renin activity, and baroreceptor reflexes. Clonidine is often used in resistant hypertension, and methyldopa is commonly used for pregnancy-induced hypertension.

Chronic use of a centrally acting α_2-agonist results in sodium and water retention, which is most prominent with methyldopa. Low doses of clonidine (and guanfacine or guanabenz) can be used to treat hypertension without the addition of a thiazide. However, methyldopa should be given in combination with a thiazide to avoid the blunting of antihypertensive effect that happens with prolonged use when used to treat chronic hypertension (not necessary in pregnancy-induced hypertension). Sedation and dry mouth are common anticholinergic side effects that typically improve with chronic use of low doses, but they are more troublesome in the elderly. As with other centrally acting antihypertensives, depression can occur, especially with high doses. The incidence of orthostatic hypotension and dizziness is higher than with other antihypertensive agents, so they should be used very cautiously in the elderly. Lastly, clonidine has a relatively high incidence of anticholinergic side effects (sedation, dry mouth, constipation, urinary retention, and blurred vision). Thus, it should generally be avoided for chronic antihypertensive therapy in the elderly.

Abrupt cessation of a central α_2-agonist may lead to rebound hypertension. This effect is thought to be secondary to a compensatory increase in norepinephrine release after abrupt discontinuation. In addition, other effects such as nervousness, agitation, headache, and tremor can also occur, which may be exacerbated by concomitant β-blocker use, particularly with clonidine. Thus, if clonidine is to be discontinued, it should be tapered. For patients who are receiving concomitant β-blocker therapy, the β-blocker should be gradually discontinued first several days before gradual discontinuation of clonidine.

Methyldopa can cause hepatitis or hemolytic anemia, although this is rare. Transient elevations in serum hepatic transaminases are occasionally seen with methyldopa therapy but are clinically irrelevant unless they are greater than three times the upper limit or normal. Methyldopa should be quickly discontinued if persistent increases in serum hepatic transaminases or alkaline phosphatase are detected because this may indicate the onset of fulminant life-threatening hepatitis. A Coombs-positive hemolytic anemia occurs in less than 1% of patients receiving methyldopa, although 20% exhibit a positive direct Coombs test without anemia. For these reasons, methyldopa has limited use in routine management of hypertension, except in pregnancy.

Reserpine

Reserpine lowers BP by depleting norepinephrine from sympathetic nerve endings and blocking transport of norepinephrine into its storage granules. Norepinephrine release into the synapse following nerve stimulation is reduced and results in reduced sympathetic tone, PVR, and BP. Reserpine also depletes catecholamines in the brain and the myocardium, which may lead to sedation, depression, and decreased CO.

Reserpine can cause significant sodium and water retention; therefore, it should be given in combination with a thiazide. Reserpine's strong inhibition of sympathetic activity results in increased parasympathetic activity, which explains why side effects such as nasal stuffiness, increased gastric acid secretion, diarrhea, and bradycardia can occur. Depression, which is a consequence of central nervous system depletion of catecholamines and serotonin, has been reported with high dose therapy. However, when reserpine is dosed between 0.05 and 0.25 mg daily (recommended doses), the rate of depression is equal to that seen with a β-blocker, thiazide, or placebo.[8]

Reserpine was used as a third-line agent in many of the landmark clinical trials that have documented the benefit in treating hypertension, including the Veterans Administration Cooperative trials and the SHEP trial.[8] An analysis of the SHEP data found that reserpine was well tolerated and that the combination of a thiazide and reserpine is effective in reducing CV events.

Direct Arterial Vasodilator

Hydralazine and minoxidil directly relax arteriolar smooth muscle resulting in vasodilation and BP lowering. They exert little to no venous vasodilation. Both agents cause potent reductions in perfusion pressure that activate baroreceptor reflexes. Activation of baroreceptors results in a compensatory increase in sympathetic outflow, which leads to an increase in heart rate, CO, and renin release. Consequently, tachyphylaxis can develop resulting in a loss of hypotensive effect with continued use. This compensatory baroreceptor response can be counteracted by concurrent use of a β-blocker.

All patients receiving hydralazine or minoxidil long-term for hypertension should first receive both a thiazide and a β-blocker. Direct arterial vasodilators can precipitate angina in patients with underlying coronary disease unless the baroreceptor reflex mechanism is blocked with a β-blocker. Nondihydropyridine CCBs (diltiazem and verapamil) can be used as an alternative to β-blockers in these patients, but a β-blocker is preferred. The side effect of sodium and water retention is significant but is minimized by using a thiazide concomitantly.

One side effect unique to hydralazine is a dose-dependent drug-induced lupus-like syndrome. Hydralazine is eliminated by hepatic *N*-acetyltransferase. This enzyme displays genetic polymorphism, and "slow acetylators" are especially prone to develop drug-induced lupus with hydralazine. This syndrome is more common in women and is reversible on discontinuation. Drug-induced lupus may be avoided by using less than 200 mg of hydralazine daily. Because of side effects, hydralazine has limited clinical use for chronic management of hypertension. However, it is especially useful for patients with severe CKD and in kidney failure on hemodialysis. Hydralazine, when used in combination with isosorbide dinitrate, has been shown to reduce the risk of CV events in black patients with HF*r*EF when added to a standard regimen of a thiazide, ACEi or ARB, and evidence-based β-blocker therapy.[43]

Minoxidil is a more potent vasodilator than hydralazine. Therefore, the compensatory increases in heart rate, CO, renin release, and sodium retention are even more dramatic. Due to significant water retention, a loop diuretic is often a more effective antihypertensive than a thiazide in patients treated with minoxidil. A troublesome side effect of minoxidil is hypertrichosis (hirsutism), presenting as increased hair growth on the face, arms, back, and chest. Hypertrichosis usually ceases when the drug is discontinued. Other minoxidil side effects include pericardial effusion and a nonspecific T-wave change on the electrocardiogram. Minoxidil is reserved for very difficult-to-control hypertension and for patients requiring hydralazine that experience drug-induced lupus.

Pharmacoeconomic Considerations

The cost of effectively treating hypertension is substantial. It is projected that the direct and indirect costs of treating hypertension will rise from $4.64 billion in 2011 to $274 billion in 2030.[5] However, these costs are offset by savings that would be realized by reducing CV morbidity and mortality. Cost related to treating CV events (eg, MI, end-stage kidney failure) can drastically increase healthcare costs.

Antihypertensive drug costs are a major portion of the total cost of hypertensive care. First-line drug classes (ie, ACEi, ARB, CCB, and thiazide) are predominantly generic. Using these agents to treat hypertension results in lower drug acquisition costs. There are even multiple generic fixed-dose combinations of these agents.

It is crucial to identify ways to control the cost of care without increasing the morbidity and mortality associated with uncontrolled hypertension. Using evidence-based pharmacotherapy will save costs. An ACEi, ARB, CCB, and thiazide are all first-line treatment options in most patients without compelling indications, and most are very inexpensive. Just utilizing generic agents, either as monotherapy or in combination, is appropriate under most circumstances in hypertension management. Brand name drugs may also be used when needed. However, considerations to implement once-daily options and fixed-dose combination options that are economical should be considered.

Team-Based Collaborative Care

Team-based care for patients with cardiovascular disease is highly recommended in the comprehensive care of patients.[83] A collaborative approach to management of hypertension is a proven strategy that improves goal BP attainment rates.[84,85] These patient care models are interprofessional and utilize physicians, pharmacists, nurses, and other healthcare professionals.

With the advent of healthcare reform, collaborative team-based approaches to chronic diseases are viewed as high-quality and cost-effective improvement modalities. Within these models, pharmacists have been proven to be an effective component of team-based models both in ambulatory clinic settings[84] and in community pharmacist settings.[86] In addition to optimizing selection and implementation of antihypertensive drug therapy, clinical interventions by pharmacists have been proven to reduce the risk of adverse drug events and medication errors in ambulatory patients with CV disease.[87] Clinical pharmacists have a substantial effect in a wide variety of roles in clinical settings, largely through optimization of drug use, avoidance of adverse drug events, and transitional care activities focusing on medication reconciliation and patient education.[88]

EVALUATION OF THERAPEUTIC OUTCOMES

Monitoring the Pharmacotherapy Plan

Routine ongoing monitoring to assess the desired effects of antihypertensive therapy (efficacy, including BP goal attainment), the undesired adverse side effects (toxicity), and disease progression is needed in all patients treated with antihypertensive drug therapy.

Efficacy

The most important strategy to prevent CV morbidity and mortality in hypertension is BP control to goal values (Clinical Presentation "Desired Outcomes: Goal BP Values"). Routine goal BP values should be attained in elderly patients and in those with isolated systolic hypertension, but actual BP lowering can occur at a gradual pace over a period of several months to avoid orthostatic hypotension. Modifying other CV risk factors (eg, smoking,

dyslipidemia, diabetes) is also important.

Clinic-based BP monitoring remains the standard for managing hypertension. BP response should be evaluated 2 to 4 weeks after initiating or making changes in therapy. With some agents, monitoring BP 4 to 6 weeks later may better represent steady-state BP values (eg, thiazide, reserpine). Once goal BP values are attained, assuming no signs or symptoms of acute end-organ damage are present, BP monitoring can be done every 3 to 6 months. More frequent evaluations are required for patients with a history of poor control, nonadherence, progressive end-organ damage, or symptoms of adverse drug effects.

Self-measurements of BP or automated ABP monitoring can be useful clinically to establish effective 24-hour control. This type of monitoring may become the standard of care in the future because evolving data have demonstrated significant benefits of using these types of measurements to both diagnose hypertension[89,90] and optimize the use of antihypertensive drug therapy. Currently, ABP monitoring is used in select situations such as suspected white coat hypertension.[13] If patients are measuring their BP at home, it is important that they measure during the early morning hours for most days and then at different times of the day on alternative days of the week and use appropriate technique (e.g., proper cuff size, seated position, resting, etc.). It is also of paramount importance that clinicians remember self-BP and ABP measurements are lower than clinic BP measurements.[13] Goal BP values should be lowered accordingly when clinicians use self-BP or ABP measurements to monitor and/or adjust antihypertensive pharmacotherapy.

Toxicity

Patients should be monitored routinely for adverse drug effects. The most common side effects associated with each class of antihypertensive agents were discussed in Individual Antihypertensive Agents above, and laboratory parameters for first-line agents are listed in **Table 13-8**. Laboratory monitoring should typically occur 2 to 4 weeks after starting a new agent or dose increase, and then every 6 to 12 months in stable patients. Additional monitoring may be needed for other concomitant diseases if present (eg, diabetes, dyslipidemia, gout). Moreover, patients treated with an aldosterone antagonist (eplerenone or spironolactone) should have potassium concentrations and kidney function assessed within 3 days of initiation and again at 1 week to detect potential hyperkalemia. The occurrence of an adverse drug event may require dosage reduction or substitution with an alternative antihypertensive agent.

TABLE 13-8 Select Monitoring for Antihypertensive Pharmacotherapy

Class	Parameters
Aldosterone antagonist	BP; BUN/serum creatinine; serum potassium
ACEi	BP; BUN/serum creatinine; serum potassium
ARB	BP; BUN/serum creatinine; serum potassium
Calcium channel blocker	BP; heart rate
Thiazide	BP; BUN/serum creatinine; serum electrolytes (potassium, magnesium, sodium); uric acid (for thiazides)
β-Blocker	BP; heart rate

Disease Progression

Patients should be monitored for signs and symptoms of progressive hypertension-associated complications. A careful history for ischemic chest pain (or pressure), palpitations, dizziness, dyspnea, orthopnea, headache, sudden change in vision, one-sided weakness, slurred speech, and loss of balance should be taken to assess the presence

of CV and cerebrovascular hypertensive complications. Other clinical monitoring parameters that may be used to assess hypertension-associated complications include funduscopic changes on eye examination, LVH on electrocardiogram, proteinuria, and changes in kidney function. These parameters should be monitored periodically because any sign of deterioration requires immediate assessment and follow-up.

Adherence and Persistence

Nonadherence and lack of persistence with hypertension treatment is a major problem in the United States and is associated with significant increases in costs due to development of complications. Since hypertension is a relatively asymptomatic disease, poor adherence is frequent, particularly in patients newly treated. It has been estimated that only 50% of patients with newly diagnosed hypertension are continuing treatment at 1 year.[91] It has also been demonstrated that long-term risk of CV events is significantly reduced when newly diagnosed patients are adherent with their antihypertensive drug therapy.[92] Therefore, it is imperative to assess patient adherence on a regular basis.

The American Society of Hypertension has outlined four global practical considerations and recommendations for adherence in patients with hypertension.[93] These include: (a) focus on clinical outcomes (eg, following national guidelines, simplifying drug regimens, encouraging self-monitoring of BP), (b) empowering informed, activated patients (eg, problem-solving and behavior change interventions, urge the use of pill boxes, help patients develop a system for refilling prescriptions), (c) implement a team approach (eg, implementing collaborative models of care, using office practice policies and procedures to improve BP control), and (d) advocating for health policy reform (eg, elevate medication adherence as a critical healthcare issue, structure/finance healthcare that stimulates behavioral aspects).

Identification of nonadherence should be followed up with appropriate patient education, counseling, and intervention. Once-daily regimens are preferred in most patients to improve adherence. Although some may believe that aggressive treatment may negatively impact quality of life and thus adherence, several studies have found that most patients actually feel better once their BP is controlled. Patients on antihypertensive therapy should be questioned periodically about changes in their general health perception, energy level, physical functioning, and overall satisfaction with treatment. Lifestyle modifications should always be recommended to provide additional BP lowering and other potential health benefits. Persistence with lifestyle modifications should be continually encouraged for patients engaging in such endeavors.

Combination Therapy

14 Initial therapy with a combination of two antihypertensive drugs is highly recommended for patients with stage 2 hypertension and is an option for treating patients with stage 1 hypertension.[94] Using a fixed-dose combination product is an option for these types of patients and has been shown to improve adherence.[95] Initial two-drug combination therapy may also be appropriate for patients with multiple compelling indications for different antihypertensive agents. Moreover, combination therapy is often needed to control BP in patients who are already treated with drug therapy because most patients require two or more agents.[1,40,94]

The Avoiding Cardiovascular Events Through Combination Therapy for Patients Living with Systolic Hypertension Trial

Long-term safety and efficacy of initial two-drug therapy for hypertension has been evaluated in the ACCOMPLISH trial.[96] This was a prospective, randomized, double-blind trial in 11,506 patients with hypertension and other CV risk factors. All of these patients either had stage 2 hypertension or were on antihypertensive drug therapy on enrollment. Patients were randomized to receive either benazepril with hydrochlorothiazide or benazepril with amlodipine as initial drug therapy. Treatment was titrated to a goal BP of less than 140/90 mm Hg for most

patients and less than 130/80 mm Hg for patients with diabetes or CKD.

The trial was terminated early after a mean of 36 months because the incidence of CV events was 20% lower in the benazepril with amlodipine group compared with the benazepril with hydrochlorothiazide group. What is most important for clinical practice is that this trial established that initial two-drug therapy, as is recommended in JNC and AHA guidelines, was safe and highly effective in lowering BP. Mean BP measurements were 132/73 and 133/74 mm Hg in the benazepril with amlodipine and the benazepril with hydrochlorothiazide groups, respectively. However, rates of attaining a BP of less than 140/90 mm Hg were 75.4% and 72.4% (benazepril with amlodipine and benazepril with hydrochlorothiazide, respectively). These goal attainment rates are higher than in any other long-term prospective study and are higher than what is seen in clinical practice.

The ACCOMPLISH trial established initial two-drug antihypertensive therapy as an evidence-based strategy to treat hypertension. Clinicians should consider this study as justification for implementing initial two-drug therapy antihypertensive regimens in appropriate patients. Moreover, The ACCOMPLISH trial demonstrated that the combination of an ACEi with a dihydropyridine CCB was more effective in reducing risk of CV events than the combination of an ACEi with a thiazide. However, thiazides are very effective at lowering BP, especially when used in combination with other agents, and hydrochlorothiazide is available in many fixed-dose combination products.

Optimal Use of Combination Therapy

Clinicians should anticipate the need for combination drugs to control BP in most patients. Using low-dose combinations also provides greater reductions in BP compared with high doses of single agents, with fewer drug-related side effects.[72] Contrary to popular myth, appropriately increasing the number of antihypertensive medications to attain goal BP values does not increase the risk of adverse effects. The American Society of Hypertension has recommended three categories of combination therapy (see Clinical Presentation "Recommendations for Combination Therapy").[94] Preferred combinations are ideal for lowering BP, have complementary mechanisms of action, and use first-line drugs that have been shown to lower risk of CV events. Acceptable combinations may not provide all of the benefits that preferred combinations do, and may have additive side effect profiles. Less effective combinations are limited in their overall benefits, and should only be used when absolutely necessary.

Clinical Presentation Recommendations for Combination Therapy Preferred

- ACEi/CCB
- ARB/CCB
- ACEi/thiazide
- ARB/thiazide

Acceptable

- β-Blocker/thiazide
- CCB (dihydropyridine)/β-blocker
- CCB/thiazide
- Thiazide/potassium-sparing diuretic

Less Effective

- ACEi/β-blocker
- ARB/β-blocker
- CCB (nondihydropyridine)/β-blocker
- Centrally acting agent/β-blocker

Some combinations are not effective long-term in treating hypertension. As previously discussed, the ON-TARGET demonstrated that the use of an ACEi with an ARB in the management of hypertension resulted in no additional reduction in incidence of CV events.[75] Moreover, this combination resulted in a higher risk of adverse events which was also demonstrated in other trials. These same effects are seen when aliskiren is used in combination with an ARB.[82] These combinations (using two RAAS blockers together) should not be used for the purpose of managing hypertension. Other combinations such as a thiazide with a potassium-sparing diuretic, both of which appear to have overlapping mechanisms of action, should be implemented primarily to minimize side effects. The combination of two CCBs, a dihydropyridine with a nondihydropyridine, can provide additional BP lowering but has limited use in the routine management of most patients with hypertension.[97] Under no circumstance should two drugs from the exact same class of medications be used to treat hypertension.

Fixed-Dose Combination Products

Many fixed-dose combination products are commercially available, and some are generic (**Table 13-9**). Most of these products contain a thiazide and have multiple dose strengths available. Individual dose titration is more complicated with fixed-dose combination products, but this strategy can reduce the number of daily tablets/capsules and can simplify regimens to improve adherence by decreasing pill burden.[94,95] This alone may increase the likelihood of achieving or maintaining goal BP values. Depending on the product, some may be less expensive to patients and to health systems. Nonadherence rates are 24% lower when fixed-dose combination products are used to treat hypertension compared with using free drug components (separate pills) to treat hypertension.[95]

TABLE 13-9 Fixed-Dose Combination Products

Combination	Drugs (Brand Name)	Strengths (mg/mg)	Daily Frequency
ACEi with CCB	Amlodipine/benazepril (Lotrel)	2.5/10, 5/10, 10/20	1
	Enalapril/felodipine (Lexxel)	5/5	1
	Trandolapril/verapamil (Tarka)	2/180, 1/240, 2/240, 4/240	1 or 2
ARB with CCB	Amlodipine/olmesartan (Azor)	5/20, 10/20, 5/40, 10/40	1
	Telmisartan/amlodipine (Twynsta)	40/5, 40/10, 80/5, 80/10	1
	Valsartan/amlodipine (Exforge)	5/160, 10/160, 5/320, 10/320	1
ACEi with a thiazide	Benazepril/hydrochlorothiazide (Lotensin HCT)	5/6.25, 10/12.5, 20/12.5, 20/25	1
	Captopril/hydrochlorothiazide (Capozide)	25/15, 25/25, 50/15, 50/25	1 to 3
	Enalapril/hydrochlorothiazide (Vaseretic)	5/12.5, 10/25	1
	Fosinopril/hydrochlorothiazide (Monopril HCT)	10/12.5, 20/25	1
	Lisinopril/hydrochlorothiazide (Prinizide, Zestoretic)	10/12.5, 20/12.5, 20/25	1
	Moexipril/hydrochlorothiazide (Uniretic)	7.5/12.5, 15/25	1 or 2

Combination	Drugs (Brand Name)	Strengths (mg/mg)	Daily Frequency
	Quinapril/hydrochlorothiazide (Accuretic)	10/12.5, 20/12.5, 20/25	1
ARB with a thiazide	Azilsartan/chlorthalidone (Edarbyclor)	40/12.5, 40/25	1
	Candesartan/hydrochlorothiazide (Atacand HCT)	16/12.5, 32/12.5	1
	Eprosartan/hydrochlorothiazide (Teveten HCT)	600/12.5, 600/25	1
	Irbesartan/hydrochlorothiazide (Avalide)	75/12.5, 150/12.5, 300/12.5	1
	Losartan/hydrochlorothiazide (Hyzaar)	50/12.5, 100/25	1
	Olmesartan/hydrochlorothiazide (Benicar HCT)	20/12.5, 40/12.5, 40/25	1
	Telmisartan/hydrochlorothiazide (Micardis HCT)	40/12.5, 80/12.5	1
	Valsartan/hydrochlorothiazide (Diovan HCT)	80/12.5, 160/12.5	1
β-Blocker with a thiazide	Atenolol/chlorthalidone (Tenoretic)	50/25, 100/25	1
	Bisoprolol/hydrochlorothiazide (Ziac)	2.5/6.25, 5/6.25, 10/6.25	1
	Metoprolol succinate/hydrochlorothiazide (Dutoprol)	25/12.5, 50/12.5, 100/12.5 mg	1
	Propranolol/hydrochlorothiazide (Inderide)	40/25, 80/25	2
	Propranolol LA/hydrochlorothiazide (Inderide LA)	80/50, 120/50, 160/50	1
	Metoprolol/hydrochlorothiazide (Lopressor HCT)	50/25, 100/25	1 or 2
	Nadolol/bendroflumethiazide (Corzide)	40/5, 80/5	1
	Timolol/hydrochlorothiazide (Timolide)	10/25	1 or 2
Direct renin inhibitor with thiazide	Aliskiren/hydrochlorothiazide (Tekturna HCT)	150/12.5, 150/25, 300/12.5, 300/25	1
Direct renin inhibitor with CCB	Aliskiren/amlodipine (Tekamlo)	100/5, 150/10, 300/5, 300/10	1
ARB with CCB with a thiazide	Amlodipine/valsartan/hydrochlorothiazide (Exforge HCT)	5/160/12.5, 5/160/25, 10/160/12.5, 10/160/25, 10/320/25	1
	Olmesartan/amlodipine/hydrochlorothiazide (Tribenzor)	20/5/12.5, 40/5/12.5, 40/5/25, 40/10/12.5, 40/10/25	1
Direct renin inhibitor with CCB with a thiazide	Aliskiren/amlodipine/hydrochlorothiazide (Amturnide)	150/5/12.5, 300/5/12.5, 300/5/25, 300/10/12.5, 300/10/25	1

Resistant Hypertension

15 Patients with resistant hypertension are those who fail to achieve goal BP with the use of three or more antihypertensive drugs.[98] This includes patients who are adhering to full doses of an appropriate three-drug regimen that includes a diuretic, but also includes patients who are controlled but require the use of four or more

medications.[98] It has been estimated that 12% of patients with hypertension fall under this definition.[5] Patients with newly diagnosed hypertension or who are not treated with drug therapy should not be considered to have resistant hypertension. Difficult-to-control hypertension is persistently elevated BP despite treatment with two or three drugs that does not meet the criteria for resistant hypertension (eg, maximum doses that include a diuretic).

Several causes of resistant hypertension are listed in **Table 13-10**. Volume overload is a common cause, thus highlighting the importance of diuretic therapy in the management of hypertension. Pseudoresistance should also be ruled out by assuring adherence with prescribed therapy and possibly use of home BP measurements (by using a self-monitoring device or 24-hour ABP monitor).[98] Patients should be closely evaluated to see if any of these causes can be reversed.

TABLE 13-10 Causes of Resistant Hypertension

Improper BP measurement

Volume overload:

- Excess sodium intake
- Volume retention from kidney disease
- Inadequate diuretic therapy

Drug induced or other causes:

- Nonadherence
- Inadequate antihypertensive doses
- Use of agents listed in Table 13-1

Associated conditions:

- Obesity, excess alcohol intake, obstructive sleep apnea
- Secondary hypertension

Treatment of patients with resistant hypertension should ultimately follow the principle of drug therapy selection from the JNC and AHA guidelines. Compelling indications, if present, should guide selection assuming these patients are on a thiazide or other type of diuretic. However, there are treatment philosophies that are germane to the management of resistant hypertension: (a) assuring adequate diuretic therapy, (b) appropriate use of combination therapies, and (c) using alternative antihypertensive agents when needed.

Assuring Appropriate Diuretic Therapy

Diuretics have a large role in the pharmacotherapy of resistant hypertension. Thiazides are the mainstay of treatment, but chlorthalidone (thiazide-like) should be preferentially used instead of hydrochlorothiazide, especially for patients with resistant hypertension, because it is more potent on a milligram-per-milligram basis.[77,98] Clinicians should identify that chlorthalidone therapy, like all thiazides, has dose-dependent metabolic side effects (hypokalemia and hyperglycemia) and that appropriate monitoring should be implemented. However, it does not seem as though side effects are more common with chlorthalidone versus hydrochlorothiazide. Though less commonly used, indapamide (similar to chlorthalidone as "thiazide like") is also a more potent antihypertensive agent than hydrochlorothiazide at commonly prescribed doses, and evidence does not

demonstrate a higher risk of metabolic side effects.[99]

An aldosterone antagonist (eg, spironolactone) is highly effective as an add-on agent.[98] Data indicate that many patients with resistant hypertension have some degree of underlying hyperaldosteronism, emphasizing the role of adding an aldosterone antagonist. Spironolactone has been compared to an α-blocker and a β-blocker as add-on therapy in resistant hypertension in the Prevention And Treatment of Hypertension With Algorithm-based therapY-2 (PATHWAY-2) study.[100] Spironolactone was the most effective add-on drug for the treatment of resistant hypertension in this trial, reinforcing the important role of aldosterone antagonism in managing resistant hypertension.

Clinicians may consider using a loop diuretic, even in place of a thiazide, for patients with resistant hypertension who have very compromised kidney function (estimated GFR less than 30 mL/min/1.73m^2). Torsemide can be dosed once daily while furosemide must be dosed twice daily or three times daily.

Hypertensive Urgencies and Emergencies

Both hypertensive urgencies and emergencies are characterized by the presence of very elevated BP, typically greater than 180/120 mm Hg.[1] However, the need for urgent or emergent antihypertensive therapy must be determined based on the presence of acute or immediately progressing end-organ injury, not elevated BP alone. Urgencies are not associated with acute or immediately progressing end-organ injury, while emergencies are. Examples of acute end-organ injury include encephalopathy, intracranial hemorrhage, acute left ventricular failure with pulmonary edema, dissecting aortic aneurysm, unstable angina, and eclampsia or severe hypertension during pregnancy.

Hypertensive Urgency

16 A common error with hypertensive urgency is overly aggressive antihypertensive therapy. This treatment has likely been perpetrated by the classification terminology "urgency." Hypertensive urgencies are ideally managed by adjusting maintenance therapy, by adding a new antihypertensive, and/or by increasing the dose of a present medication. This is the preferred approach to these patients as it provides a more gradual reduction in BP. Very rapid reductions in BP to goal values should be discouraged due to potential risks. Because autoregulation of blood flow in patients with hypertension occurs at a much higher range of pressure than in normotensive persons, the inherent risks of reducing BP too precipitously include cerebrovascular accidents, MI, and acute kidney failure. Hypertensive urgency requires BP reductions with oral antihypertensive agents to stage 1 over a period of several hours to days. All patients with hypertensive urgency should be reevaluated within and no later than 7 days (preferably after 1 to 3 days).

Acute administration of a short-acting oral antihypertensive (eg, captopril, clonidine, labetalol) followed by careful observation for several hours to assure a gradual reduction in BP is an option for hypertensive urgency. However, there are no data supporting this approach as being absolutely needed. Oral captopril is one of the agents of choice and can be used in doses of 25 to 50 mg at 1- to 2-hour intervals. The onset of action of oral captopril is 15 to 30 minutes, and a marked fall in BP is unlikely to occur if no hypotensive response is observed within 30 to 60 minutes. For patients with hypertensive rebound following withdrawal of clonidine, 0.2 mg can be given initially, followed by 0.2 mg hourly until the DBP falls below 110 mm Hg or a total of 0.7 mg clonidine has been administered. A single dose may be all that is necessary. Labetalol can be given in a dose of 200 to 400 mg, followed by additional doses every 2 to 3 hours.

Oral or sublingual immediate-release nifedipine has been used for acute BP lowering in the past but is potentially dangerous. This approach produces a rapid reduction in BP. Immediate-release nifedipine should never be used for hypertensive urgencies due to risk of causing severe adverse events (eg, MI, stroke).

Hypertensive Emergency

Hypertensive emergencies are those rare situations that require immediate BP reduction to limit new or progressing end-organ damage (see Classification under Arterial BP above). Hypertensive emergencies require parenteral therapy, at least initially, with one of the agents listed in **Table 13-11**. The goal in hypertensive emergencies is not to lower BP to less than 140/90 mm Hg; rather, the initial target is a reduction in MAP of up to 25% within minutes to hours. If the patient is then stable, DBP can be reduced to 100 to 110 mm Hg within the next 2 to 6 hours. Precipitous drops in BP may lead to end-organ ischemia or infarction. If patients tolerate this reduction well, additional gradual reductions toward goal BP values can be attempted after 24 to 48 hours. The exception to this guideline is for patients with an acute ischemic stroke where maintaining an elevated BP is needed for a longer period of time.

TABLE 13-11 Parenteral Antihypertensive Agents for Hypertensive Emergency

Drug	Dose	Onset (minutes)	Duration (minutes)	Adverse Effects	Special Indications
Clevidipine	1-2 mg/h (32 mg/h maximum)	2-4	5-15	Headache, nausea, tachycardia, hypertriglyceridemia	Most hypertensive emergencies except acute heart failure; caution with coronary ischemia; contraindicated in soy or egg allergy, defective lipid metabolism, and severe aortic stenosis
Enalaprilat	1.25-5 mg IV every 6 hours	15-30	360-720	Precipitous fall in pressure in high-renin states; variable response	Acute left ventricular failure; avoid in acute myocardial infarction, eclampsia
Esmolol hydrochloride	250-500 mcg/kg/min IV bolus, and then 50-100 mcg/kg/min IV infusion; may repeat bolus after 5 minutes or increase infusion to 300 mcg/min	1-2	10-20	Hypotension, nausea, asthma, first-degree heart block, heart failure	Aortic dissection; perioperative; avoid in patients already on β-blocker, bradycardic, or decompensated heart failure
Fenoldopam mesylate	0.1-0.3 mcg/kg/min IV infusion	<5	30	Tachycardia, headache, nausea, flushing	Most hypertensive emergencies; caution with glaucoma
Hydralazine hydrochloride	12-20 mg IV	10-20	60-240	Tachycardia, flushing, headache vomiting, aggravation of angina	Eclampsia
	10-50 mg intramuscular	20-30	240-360		
Labetalol hydrochloride	20-80 mg IV bolus every 10 minutes; 0.5-2 mg/min IV infusion	5-10	180-360	Vomiting, scalp tingling, bronchoconstriction, dizziness, nausea, heart block, orthostatic hypotension	Most hypertensive emergencies except acute heart failure or heart block

Drug	Dose	Onset (minutes)	Duration (minutes)	Adverse Effects	Special Indications
Nicardipine hydrochloride	5-15 mg/h IV	5-10	15-30, may exceed 240	Tachycardia, headache, flushing, local phlebitis	Most hypertensive emergencies except acute heart failure; caution with coronary ischemia
Nitroglycerin	5-100 mcg/min IV infusion	2-5	5-10	Headache, vomiting, methemoglobinemia, tolerance with prolonged use	Coronary ischemia
Sodium nitroprusside	0.25-10 mcg/kg/min IV infusion (requires special delivery system)	Immediate	1-2	Nausea, vomiting, muscle twitching, sweating, thiocyanate and cyanide intoxication	Most hypertensive emergencies; caution with high intracranial pressure, azotemia, or in chronic kidney disease

The clinical situation should dictate which IV medication is used to treat hypertensive emergencies. Regardless, therapy should be provided in a hospital or emergency room setting with intraarticular BP monitoring. Table 13-11 lists special indications for agents that can be used.

Nitroprusside is widely considered the agent of choice for most cases, but it can be problematic for patients with CKD. It is a direct-acting vasodilator that decreases PVR but does not increase CO unless left ventricular failure is present. Nitroprusside can be given to treat most hypertensive emergencies, but in aortic dissection, propranolol should be given first to prevent reflex sympathetic activation. Nitroprusside is metabolized to cyanide and then to thiocyanate, which is eliminated by the kidneys. Therefore, serum thiocyanate levels should be monitored when infusions are continued longer than 72 hours. Nitroprusside should be discontinued if the concentration exceeds 12 mg/dL (approximately 2 mmol/L). The risk of thiocyanate accumulation and toxicity is increased for patients with impaired kidney function. The use of nitroprusside is limited by a recent and significant increase in the cost of this agent.

IV nitroglycerin dilates both arterioles and venous capacitance vessels, thereby reducing both cardiac afterload and cardiac preload, which can decrease myocardial oxygen demand. It also dilates collateral coronary blood vessels and improves perfusion to ischemic myocardium. These properties make IV nitroglycerin ideal for the management of hypertensive emergency in the presence of myocardial ischemia. IV nitroglycerin is associated with tolerance when used over 24 to 48 hours and can cause severe headache.

Fenoldopam, nicardipine, and clevidipine are newer and more expensive agents. Fenoldopam is a dopamine-1 agonist. It can improve renal blood flow and may be especially useful for patients with kidney insufficiency. Nicardipine and clevidipine are dihydropyridine CCBs that provide arterial vasodilation and can treat cardiac ischemia similar to nitroglycerin, but they may provide more predictable reductions in BP.

The hypotensive response of hydralazine is less predictable than with other parenteral agents. Therefore, its major role is in the treatment of eclampsia or hypertensive encephalopathy associated with renal insufficiency.

CONCLUSION

Hypertension is a very common medical condition in the United States. Treatment of patients with hypertension should include both lifestyle modifications and pharmacotherapy. Evidence from outcome-based clinical trials has definitively demonstrated that treating hypertension reduces the risk of CV events and subsequently reduces morbidity and mortality. Moreover, evidence evaluating individual drug classes has resulted in an evidence-based

approach to selecting pharmacotherapy in an individual patient. An ACEi, ARB, CCB, and thiazide are all first-line agents. Data suggest that using a β-blocker first-line to treat patients with hypertension, without the presence of a compelling indication, may not be as beneficial in reducing risk of CV events compared with ACEi-, ARB-, CCB-, or thiazide-based therapy. Therefore, they are not first-line therapy options unless an appropriate compelling indication is present.

Patients should be treated to a goal BP value. In addition to selecting the most appropriate agent, attaining a goal BP is also of paramount importance to ensure maximum reduction in risk for CV events is provided. A BP goal of less than 140/90 mm Hg is recommended for most patients with hypertension and some patients are candidates for lower goal values. Most patients with hypertension require more than one drug to attain goal BP values; therefore, combination therapy should be anticipated. Future evidence-based guidelines from the AHA (expected in 2016) will provide additional recommendations for the treatment of hypertension.

Optimizing hypertension management can be achieved many ways. Team-based approaches to implement care and attain goal BP values are effective. Judicious use of cost-effective treatments and fixed-dose combination products should always be considered to improve sustainability of treatment. Lastly, interventions to reinforce adherence and lifestyle modifications are needed for comprehensive management of hypertension.

Chapter 14: Chronic Heart Failure

Robert B. Parker; Jean M. Nappi; Larisa H. Cavallari

INTRODUCTION

KEY CONCEPTS

- 1 Heart failure (HF) is a progressive clinical syndrome that can result from any changes in cardiac structure or function that impair the ability of the ventricle to fill with or eject blood. HF may be caused by an abnormality in systolic function, diastolic function, or both. The leading causes of HF are coronary artery disease and hypertension. The primary manifestations of the syndrome are dyspnea, fatigue, and fluid retention.

- 2 In heart failure with reduced ejection fraction (HFrEF) there is a decrease in cardiac output, resulting in activation of a number of compensatory responses that attempt to maintain adequate cardiac output. These responses include activation of the sympathetic nervous system (SNS) and the renin–angiotensin–aldosterone system (RAAS), resulting in vasoconstriction and sodium and water retention as well as ventricular hypertrophy/remodeling. These compensatory mechanisms are responsible for the symptoms of HFrEF and contribute to disease progression.

- 3 Our current understanding of HFrEF pathophysiology is best described by the neurohormonal model. Activation of endogenous neurohormones including norepinephrine (NE), angiotensin II, aldosterone, vasopressin, and numerous proinflammatory cytokines plays an important role in ventricular remodeling and the subsequent progression of HF. Importantly, pharmacotherapy targeted at antagonizing this neurohormonal activation has slowed the progression of HFrEF and improved survival.

- 4 Most patients with HFrEF should be routinely treated with guideline directed medical therapy (GDMT) that includes an angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) and a β-blocker. Selected patients should also receive loop diuretics, hydralazine/nitrates, or aldosterone antagonists. The benefits of these medications on slowing HF progression, reducing morbidity and mortality, and/or improving symptoms are clearly established.

- 5 In patients with HFrEF, ACE inhibitors improve survival, slow disease progression, reduce hospitalizations, and improve quality of life. The doses for these agents should be targeted at those shown in clinical trials to improve survival. When ACE inhibitors are contraindicated or not tolerated, an ARB or the combination of hydralazine and isosorbide dinitrate is a reasonable alternative. Patients with asymptomatic left ventricular dysfunction and/or a previous myocardial infarction (MI) (Stage B of

the American College of Cardiology [ACC]/American Heart Association [AHA] classification scheme) should also receive ACE inhibitors, with the goal of preventing symptomatic HF and reducing mortality.

- 6 The β-blockers carvedilol, metoprolol succinate, and bisoprolol have been shown to prolong survival, decrease hospitalizations and need for transplantation, and cause "reverse remodeling" of the left ventricle. These agents are recommended for all patients with HFrEF unless contraindicated. Therapy must be instituted at low doses, with slow upward titration to the target dose.

- 7 Although chronic loop diuretic therapy frequently is used in patients with either HFrEF or HFpEF, it is not mandatory. Diuretic therapy along with sodium restriction is required only in those patients with peripheral edema and/or pulmonary congestion. Many patients will need continued diuretic therapy to maintain euvolemia after fluid overload is resolved.

- 8 Aldosterone antagonists reduce mortality in patients with HFrEF and New York Heart Association (NYHA) class II to IV symptoms and thus should be strongly considered in these patients provided that potassium and renal function can be carefully monitored. Aldosterone antagonists should also be considered soon after MI in patients with left ventricular dysfunction and either HF or diabetes and may be considered to reduce the risk of hospitalization in patients with HFpEF.

- 9 The combination of hydralazine and nitrates improves the composite end point of mortality, hospitalizations for HF, and quality of life in African Americans receiving standard therapy for HFrEF. Current guidelines recommend the addition of hydralazine and nitrates to self-described African Americans with HFrEF and moderate to severe symptoms that are receiving GDMT with ACE inhibitors and β-blockers. Hydralazine and a nitrate might be reasonable in patients unable to tolerate either an ACE inhibitor or ARB because of renal insufficiency, hyperkalemia, or possibly hypotension.

- 10 Digoxin does not improve survival in patients with HFrEF but does provide symptomatic benefits. Digoxin doses should be adjusted to achieve plasma concentrations of 0.5 to 0.9 ng/mL (0.6-1.2 nmol/L); higher plasma concentrations are not associated with additional benefits but may be associated with increased risk of toxicity.

- 11 Treatment of heart failure with preserved ejection fraction (HFpEF) should be targeted at symptom reduction, causal clinical disease, and underlying basic mechanisms. Patients with HFpEF may be treated differently than those with HFrEF.

1 2 Heart failure (HF) is a progressive clinical syndrome that can result from any abnormality in cardiac structure or function that impairs the ability of the ventricle to fill with or eject blood.[1] HF may be caused by an abnormality in systolic function, diastolic function, or both. Making the distinction is important because the treatment of HF may be quite different depending on whether the predominant mechanism of the disorder is systolic or diastolic dysfunction. HF is the final common pathway for numerous cardiac disorders including those affecting the pericardium, heart valves, and myocardium. Diseases that adversely affect ventricular diastole (filling), ventricular systole (contraction), or both can lead to HF.

For many years it was believed that reduced myocardial contractility, or systolic dysfunction (ie, reduced left ventricular ejection fraction [LVEF]), now referred to as heart failure with reduced ejection fraction (HFrEF), was the sole disturbance in cardiac function responsible for HF. However, it is now recognized that large

numbers of patients with the HF syndrome have relatively normal systolic function (ie, normal LVEF). This is now referred to as HF with preserved LVEF (HFpEF) and is believed to be primarily due to diastolic dysfunction of the heart.[1] Recent estimates suggest approximately 50% of patients with HF have preserved LVEF with disturbances in relaxation (lusitropic) properties of the heart, or diastolic dysfunction.[1,2] However, regardless of the etiology of HF, the underlying pathophysiologic process and principal clinical manifestations (fatigue, dyspnea, and often volume overload) are similar and appear to be independent of the initial cause. Historically, this disorder was commonly referred to as *congestive HF*; the preferred nomenclature is now *HF* since a patient may have the clinical syndrome of HF without having symptoms of congestion. This chapter will focus on treatment of patients with chronic HF from reduced as well as preserved LVEF. Chapter e5 will discuss the treatment of acute decompensated HF.

EPIDEMIOLOGY

Heart failure is an epidemic public health problem in the United States.[3] Nearly 6 million Americans have HF with over 800,000 new cases diagnosed each year.[3] Unlike most other cardiovascular diseases, the incidence and prevalence of HF are increasing and are expected to continue to increase over the next few decades as the population ages. A large majority of patients with HF are elderly, with multiple comorbid conditions that influence morbidity and mortality.[3] Improved survival after myocardial infarction (MI) is thought to be a likely contributor to the increased incidence and prevalence of HF.[4] Annual hospital discharges for HF now total over 1 million, and HF remains the most common hospital discharge diagnosis in individuals over age 65.[3] The disorder also has a tremendous economic impact, with this expected to increase markedly as the baby-boom generation ages. Current estimates suggest annual expenditures for HF of over $30 billion, with the majority of these costs spent on hospitalized patients.[3] Thus, HF is a major medical problem, with substantial economic impact that is expected to become even more significant as the population ages.

Despite prodigious advances in our understanding of the etiology, pathophysiology, and pharmacotherapy of HF, the prognosis for patients with this disorder remains grim. Although the mortality rates have declined over the last 50 years, the overall 5-year survival remains approximately 50% for all patients with a diagnosis of HF, with mortality increasing with symptom severity.[1,3] Death is classified as sudden in about 40% of patients, implicating serious ventricular arrhythmias as the underlying cause.[1] Factors affecting the prognosis of patients with HF include, but are not limited to, age, gender, LVEF, renal function, natriuretic peptide plasma concentrations, diabetes, metabolic syndrome, extent of underlying coronary artery disease, blood pressure (BP), HF etiology, and drug or device therapy. Recent models incorporating these and other factors enable clinicians to develop reliable estimates of an individual patient's prognosis.[1]

ETIOLOGY

1 2 Heart failure can result from any disorder that affects the ability of the heart to contract (systolic function) and/or relax (diastolic dysfunction); common causes of HF are shown in **Table 14-1**.[5] HF with reduced systolic function (ie, reduced LVEF) is the classic, more familiar form of the disorder and is now referred to as heart failure with reduced ejection fraction (HFrEF). Current estimates indicate up to 50% of patients with HF have preserved left ventricular systolic function with presumed diastolic dysfunction, now termed *heart failure with preserved ejection fraction* (HFpEF).[2,6] In contrast to HFrEF that is often caused by previous MI, patients with HFpEF typically are elderly, female, and obese, and have hypertension (HTN),

atrial fibrillation, or diabetes.[2,6] Recent data indicate that survival is similar in patients with HFrEF or HFpEF.[1,2]

TABLE 14-1 Causes of Heart failure

Systolic dysfunction (decreased contractility)

- Reduction in muscle mass (eg, myocardial infarction)
- Dilated cardiomyopathies
- Ventricular hypertrophy
    - Pressure overload (eg, systemic or pulmonary hypertension, aortic or pulmonic valve stenosis)
    - Volume overload (eg, valvular regurgitation, shunts, high-output states)

Diastolic dysfunction (restriction in ventricular filling)

- Increased ventricular stiffness
    - Ventricular hypertrophy (eg, hypertrophic cardiomyopathy, other previous examples)
    - Infiltrative myocardial diseases (eg, amyloidosis, sarcoidosis, endomyocardial fibrosis)
    - Myocardial ischemia and infarction
- Mitral or tricuspid valve stenosis
- Pericardial disease (eg, pericarditis, pericardial tamponade)

Data from Mann DL. Management of patients with heart failure with reduced ejection fraction. In: Mann DL, Zipes DP, Libby P, Bonow RO, Braunwald E, eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 10th ed. Philadelphia, PA: Elsevier; 2015:512-546.

1 Coronary artery disease is the most common cause of HFrEF, accounting for nearly 70% of cases.[5] MI leads to reduction in muscle mass due to death of affected myocardial cells. The degree to which contractility is impaired depends on the size of the infarction. To attempt to maintain cardiac output (CO), the surviving myocardium undergoes a compensatory remodeling, thus beginning the maladaptive process that initiates the HF syndrome and leads to further injury to the heart. This is discussed in greater detail in Pathophysiology section of this chapter later. Myocardial ischemia and infarction also affect the diastolic properties of the heart by increasing ventricular stiffness and slowing ventricular relaxation. Thus, MI frequently results in systolic and diastolic dysfunction.

Impaired systolic function is a cardinal feature of dilated cardiomyopathies. Although the cause of reduced contractility frequently is unknown, abnormalities such as interstitial fibrosis, cellular infiltrates, cellular hypertrophy, and myocardial cell degeneration are seen commonly on histologic examination. Inherited forms of dilated as well as hypertrophic cardiomyopathies may also occur.[1,5]

Pressure or volume overload causes ventricular hypertrophy, which attempts to return contractility to a near-normal state. If the pressure or volume overload persists, the remodeling process results in alterations

in the geometry of the hypertrophied myocardial cells and is accompanied by increased collagen deposition in the extracellular matrix. Thus, both systolic and diastolic functions may be impaired.[7] Examples of pressure overload include systemic or pulmonary HTN and aortic or pulmonic valve stenosis.

HTN remains an important cause and/or contributor to both HFrEF and HFpEF in many patients, particularly women, the elderly, and African Americans.[1,5] The role of HTN should not be underestimated because it is an important risk factor for ischemic heart disease and thus is also present in a high percentage of the patients with coronary artery disease. HF is a largely preventable disorder such that appropriate management of lifestyle risk factors (eg, HTN, coronary heart disease, smoking, obesity, physical activity, diabetes, etc.) is key to minimize the risk of HF development.

PATHOPHYSIOLOGY

Normal Cardiac Function

To understand the pathophysiologic processes in HF, a basic understanding of normal cardiac function is necessary. CO is defined as the volume of blood ejected per unit time (L/min) and is the product of heart rate (HR) and stroke volume (SV):

$$CO = HR \times SV$$

The relationship between CO and mean arterial pressure (MAP) is given as follows:

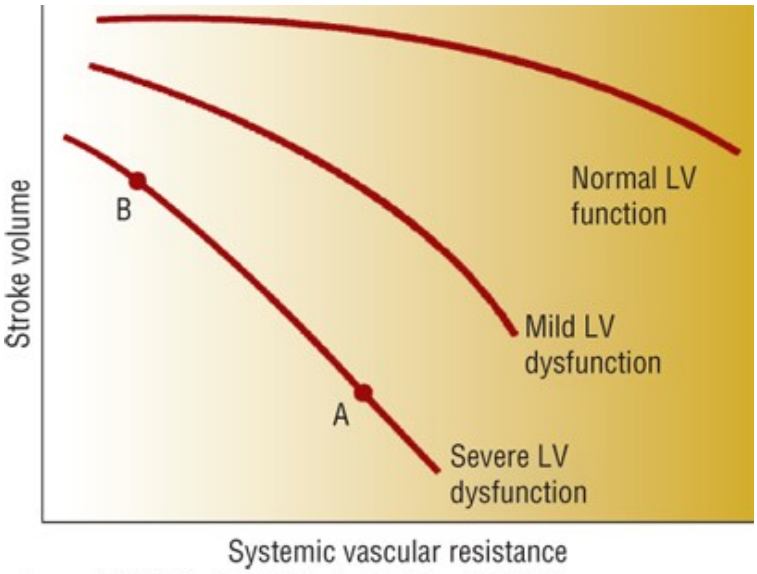
$$MAP = CO \times \text{systemic vascular resistance (SVR)}$$

Heart rate is controlled by the autonomic nervous system. SV, or the volume of blood ejected during systole, depends on preload, afterload, and contractility.[7] As defined by the Frank–Starling mechanism, the ability of the heart to alter the force of contraction depends on changes in preload. As myocardial sarcomere length is stretched, the number of cross-bridges between thick and thin myofilaments increases, resulting in an increase in the force of contraction. The length of the sarcomere is determined primarily by the volume of blood in the ventricle; therefore, left ventricular end-diastolic volume (LVEDV) is the primary determinant of preload. In normal hearts, the preload response is the primary compensatory mechanism such that a small increase in end-diastolic volume results in a large increase in CO. Because of the relationship between pressure and volume in the heart, left ventricular end-diastolic pressure (LVEDP) is often used in the clinical setting to estimate preload. The hemodynamic measurement used to clinically estimate LVEDP is the pulmonary capillary wedge pressure (PCWP), also known as the pulmonary artery occlusion pressure (PAOP). Afterload is a more complex physiologic concept that can be viewed pragmatically as the sum of forces preventing active forward ejection of blood by the ventricle. Major components of afterload are ejection impedance, wall tension, and regional wall geometry. In patients with left ventricular systolic dysfunction, an inverse relationship exists between afterload (estimated clinically by SVR) and SV such that increasing afterload causes a decrease in SV (**Fig. 14-1**). Contractility is the intrinsic property of cardiac muscle describing fiber shortening and tension development.

FIGURE 14-1

Relationship between stroke volume and systemic vascular resistance. In an individual with normal left ventricular (LV) function, increasing systemic vascular resistance has little effect on stroke volume. As the

extent of LV dysfunction increases, the negative, inverse relationship between stroke volume and systemic vascular resistance becomes more important (B to A).



Heart Failure with Preserved Ejection Fraction

Heart failure with preserved ejection fraction can be defined as a condition in which myocardial relaxation and filling are impaired and incomplete. The ventricle is unable to accept an adequate volume of blood from the venous system, does not fill at low pressure, and/or is unable to maintain normal SV. In its most severe form, HFpEF results in overt symptoms of HF. In modest HFpEF, symptoms of dyspnea and fatigue occur only during stress or activity, when HR and end-diastolic volume increase. In its mildest form, HFpEF can be manifested as a slow or delayed pattern of relaxation and filling with little or no elevation in diastolic pressure and few or no cardiac symptoms. The congestive symptoms that occur with HFpEF are a manifestation of increased pulmonary venous pressures. HFpEF is caused by impaired myocardial relaxation and/or increased diastolic stiffness. When HF is caused by a predominant abnormality in diastolic function, the ventricular chamber is not enlarged, and EF may be normal or even elevated.[2,8] **Figure 14-2** shows the pressure–volume relationship in a patient with normal versus abnormal diastolic function. Changes in the myocardium are associated with a shift upward and to the left of the pressure–volume curve, so that for any increase in LV volume, diastolic pressure rises to a much greater level than normally would occur. Clinically, patients present with reduced exercise tolerance and dyspnea when they have elevated LV diastolic pressures. Patients with HFpEF have a predominant abnormality in diastolic function, whereas patients with HFrEF have a predominant abnormality in systolic function of the LV.

FIGURE 14-2

Diastolic pressure–volume relationship in a normal patient (*right trace*) and a patient with diastolic dysfunction (*left trace*).

Recent data suggest that HFpEF may also be associated with abnormalities in endothelial and ventricular reserve function. During physical exertion, CO increases through integrated enhancements in venous return, contractility, HR, and peripheral vasodilation. The vasodilation that normally occurs during exercise is impaired in HFpEF. Pulmonary HTN is also a common finding. Abnormalities in each of these components of normal exercise reserve function have been identified in HFpEF and all may contribute to pathophysiology in individual patients.[2,8]

Compensatory Mechanisms in HFrEF

2 HFrEF is a progressive disorder initiated by any event that impairs the ability of the heart to contract and sometimes relax resulting in a decrease in CO. The index event may have an acute onset, as with MI, or the onset may be slow, as with long-standing HTN. Regardless of the index event, a decrease in CO results in activation of compensatory responses to maintain the circulation.[7,9] These compensatory responses include: (a) tachycardia and increased contractility through sympathetic nervous system (SNS) activation, (b) the Frank–Starling mechanism, whereby an increase in preload results in an increase in SV, (c) vasoconstriction, and (d) ventricular hypertrophy and remodeling. Compensatory responses evolved to provide short-term support to maintain circulatory homeostasis after acute reductions in BP or renal perfusion. However, the persistent decline in CO in HF triggers long-term activation of these compensatory responses resulting in the complex functional, structural, biochemical, and molecular changes important for the development and progression of HF. The beneficial and detrimental effects of these compensatory responses are described later and are summarized in **Table 14-2**.

TABLE 14-2 Beneficial and Detrimental Effects of the Compensatory Responses in Heart Failure

Compensatory Response	Beneficial Effects of Compensation	Detrimental Effects of Compensation
Increased preload (through Na^+ and retention)	Optimize stroke volume via Frank–Starling mechanism	Pulmonary and systemic congestion and edema formation Increased MVO_2

Compensatory Response	Beneficial Effects of Compensation	Detrimental Effects of Compensation
Vasoconstriction	Maintain BP in face of reduced CO	Increased MVO_2
	Shunt blood from nonessential organs to brain and heart	Increased afterload decreases stroke volume and further activates the compensatory responses
Tachycardia and increased contractility (due to SNS activation)	Helps maintain CO	Increased MVO_2
		Shortened diastolic filling time β_1-receptor down-regulation, decreased receptor sensitivity
		Precipitation of ventricular arrhythmias
		Increased risk of myocardial cell death
Ventricular hypertrophy and remodeling	Helps maintain CO	Diastolic dysfunction
	Reduces myocardial wall stress	Systolic dysfunction
	Decreases MVO_2	Increased risk of myocardial cell death
		Increased risk of myocardial ischemia
		Increased arrhythmia risk
		Fibrosis

SNS, sympathetic nervous system; BP, blood pressure; MVO_2, myocardial oxygen demand; CO, cardiac output.

Tachycardia and Increased Contractility

The increase in HR and contractility that rapidly occurs in response to a drop in CO is primarily due to release of norepinephrine (NE) from adrenergic nerve terminals, although parasympathetic nervous system activity is also diminished.[9] Loss of atrial contribution to ventricular filling also can occur (atrial fibrillation, ventricular tachycardia), reducing ventricular performance even more. Because ionized calcium is sequestered into the sarcoplasmic reticulum and pumped out of the cell during diastole, the shortened diastolic time with increases in HR also results in a higher average intracellular calcium concentration during diastole, increasing actin–myosin interaction, augmenting the active resistance to fibril stretch, and reducing lusitropy. Conversely, the higher average calcium concentration translates into greater filament interaction during systole, generating more tension.[7] Increasing HR also increases myocardial oxygen demand. If ischemia is induced or worsened, both diastolic and systolic functions may become impaired, and SV can drop precipitously. In addition, polymorphisms in genes coding for adrenergic receptors (eg, β_1- and α_{2c}-receptors) and their signaling pathways may affect the risk for development of HF and alter the response to endogenous NE.[9,10]

Fluid Retention and Increased Preload

Augmentation of preload is another compensatory response that is rapidly activated in response to decreased CO. Renal perfusion in HF is reduced due to both depressed CO and redistribution of blood away from nonvital organs. The kidney interprets the reduced perfusion as an ineffective blood volume, resulting in activation of the renin–angiotensin–aldosterone system (RAAS) in an attempt to maintain BP and increase renal sodium and water retention. Reduced renal perfusion and increased sympathetic tone also stimulate renin release from juxtaglomerular cells in the kidney. As shown in **Fig. 14-3**, renin is responsible for conversion of angiotensinogen to angiotensin I. Angiotensin I is converted to angiotensin II by angiotensin-converting enzyme (ACE). Angiotensin II may also be generated via non-ACE-dependent pathways. Angiotensin II stimulates aldosterone release from the adrenal gland, thereby providing an additional mechanism for renal sodium and water retention. As intravascular volume increases secondary to sodium and water retention, left ventricular volume and pressure (preload) increase, sarcomeres are stretched, and the force of contraction is enhanced.[7] While the preload response is the primary compensatory mechanism in normal hearts, the chronically failing heart usually has exhausted its preload reserve.[7] As shown in **Fig. 14-4**, increases in preload will increase SV only to a certain point. Once the flat portion of the curve is reached, further increases in preload will only lead to pulmonary or systemic congestion, a detrimental result.[7] Figure 14-4 also shows that the curve is flatter in patients with left ventricular dysfunction. Consequently, a given increase in preload in a patient with HF will produce a smaller increment in SV than in an individual with normal ventricular function.

FIGURE 14-3

Physiology of the renin–angiotensin–aldosterone system. Renin produces angiotensin I from angiotensinogen. Angiotensin I is cleaved to angiotensin II by angiotensin-converting enzyme (ACE). Angiotensin II has a number of physiologic actions that are detrimental in heart failure. Note that angiotensin II can be produced in a number of tissues, including the heart, independent of ACE activity. ACE is also responsible for the breakdown of bradykinin. Inhibition of ACE results in accumulation of bradykinin that, in turn, enhances the production of vasodilatory prostaglandins.

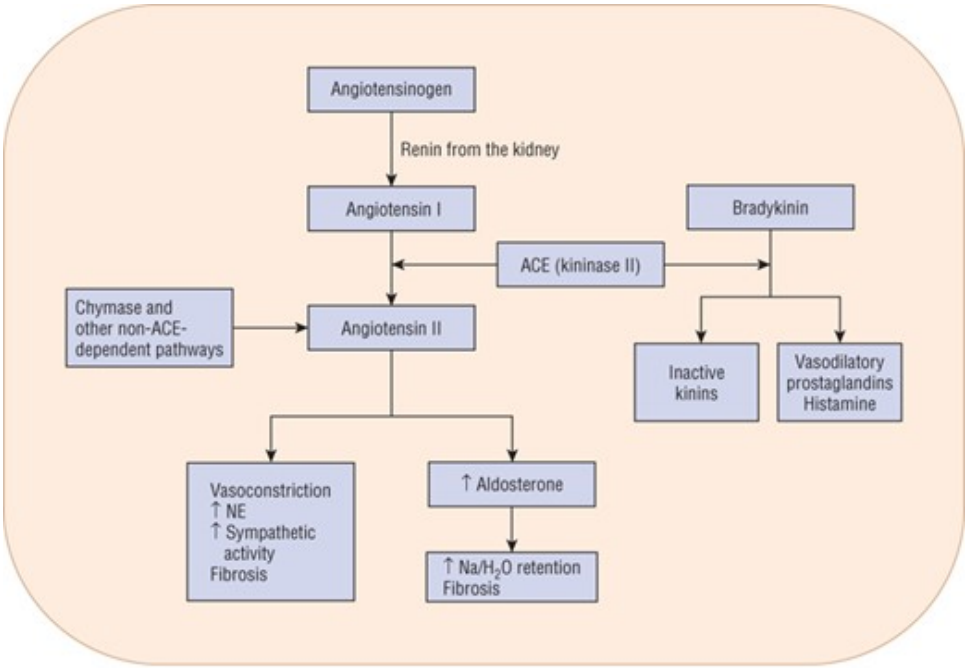

FIGURE 14-4

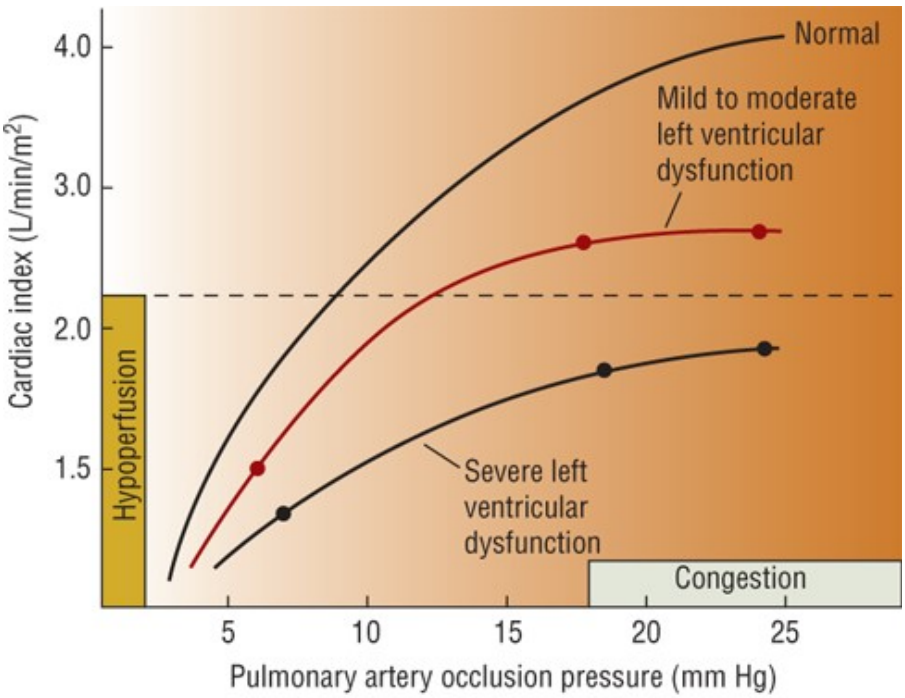
Relationship between cardiac output (shown as cardiac index which is CO/BSA) and preload (shown as pulmonary artery occlusion pressure).



Vasoconstriction and Increased Afterload

Vasoconstriction occurs in patients with HFrEF to help redistribute blood flow away from nonessential

organs to coronary and cerebral circulations to support BP, which may be reduced secondary to a decrease in CO (MAP = CO × SVR).[7] A number of neurohormones likely contribute to the vasoconstriction, including NE, angiotensin II, endothelin-1 (ET-1), neuropeptide Y, urotensin II, and arginine vasopressin (AVP).[7,9] Vasoconstriction impedes forward ejection of blood from the ventricle, further depressing CO and heightening the compensatory responses. The failing ventricle is exquisitely sensitive to changes in afterload (see Fig. 14-1). Thus, increases in afterload often potentiate a vicious cycle of continued worsening and downward spiraling of the HF state.

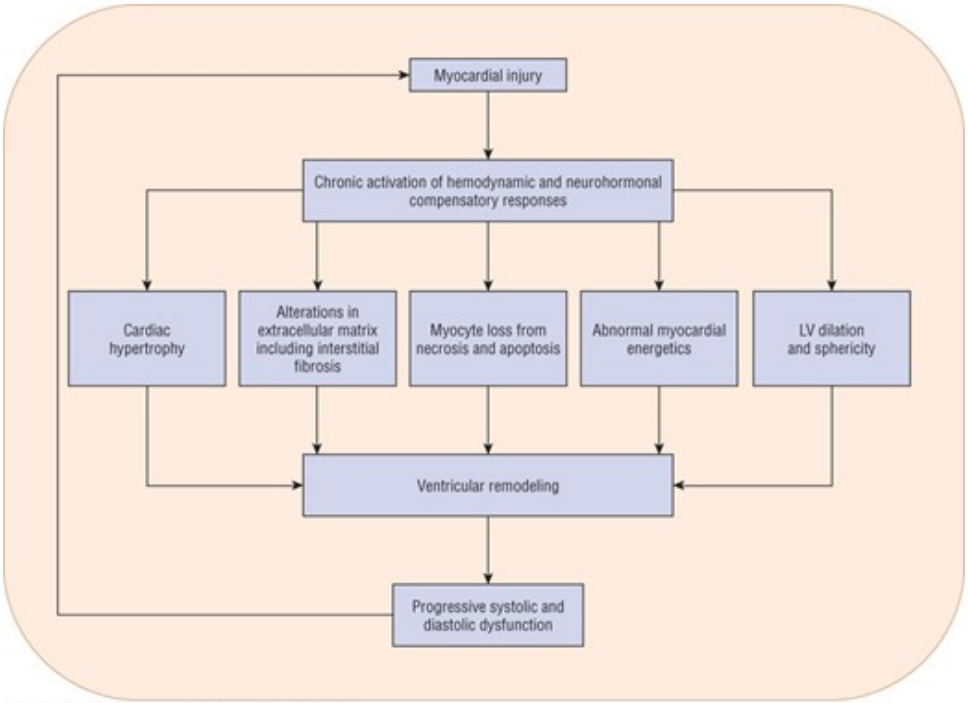
Ventricular Hypertrophy and Remodeling

3 While the signs and symptoms of HF are closely associated with the items described earlier, the progression of HF appears to be independent of the patient's hemodynamic status. It is now recognized that left ventricular hypertrophy and remodeling are key components in the pathogenesis of progressive myocardial failure.[7] *Ventricular hypertrophy* is a term used to describe an increase in ventricular muscle mass. *Cardiac or ventricular remodeling* is a broader term describing changes in both myocardial cells and extracellular matrix that result in changes in the size, shape, structure, and function of the heart.[11] These progressive changes in ventricular structure and function ultimately result in a change in shape of the left ventricle from an ellipse to a sphere. This change in ventricular size and shape serves to further depress the mechanical performance of the heart, increases regurgitant flow through the mitral valve, and, in turn, fuels the continued progression of remodeling. Ventricular hypertrophy and remodeling can occur in association with any condition that causes myocardial injury.[11] The onset of the remodeling process precedes the development of HF symptoms.

Cardiac remodeling is a complex process that affects the heart at the molecular and cellular levels.[7,11] Key elements in the process are shown in **Fig. 14-5**. Collectively, these events result in progressive changes in myocardial structure and function such as cardiac hypertrophy, myocyte loss, and alterations in the extracellular matrix. The progression of the remodeling process leads to reductions in myocardial systolic and/or diastolic function that, in turn, results in further myocardial injury, perpetuating the remodeling process and the decline in left ventricular performance. Angiotensin II, NE, ET, aldosterone, vasopressin, and numerous inflammatory cytokines, as well as substances under investigation, that are activated both systemically and locally in the heart and vasculature play an important role in initiating the signal transduction cascade responsible for ventricular remodeling. Although these mediators produce harmful effects on the heart, their increased circulating and tissue concentrations are also toxic to other organs and serve as an important reminder that HF is a systemic as well as a cardiac disorder.[7,9,11]

FIGURE 14-5

Key components of the pathophysiology of cardiac remodeling. Myocardial injury (eg, myocardial infarction) results in the activation of a number of hemodynamic and neurohormonal compensatory responses in an attempt to maintain circulatory homeostasis. Chronic activation of the neurohormonal systems results in a cascade of events that affect the myocardium at the molecular and cellular levels. These events lead to the changes in ventricular size, shape, structure, and function known as ventricular remodeling. The alterations in ventricular function result in further deterioration in cardiac systolic and diastolic functions that further promotes the remodeling process.



Pressure overload (and probably hormonal activation) associated with HTN produces a concentric hypertrophy (increase in the ventricular wall thickness without chamber enlargement), that is often found in HFpEF.[8] Conversely, eccentric left ventricular hypertrophy (myocyte lengthening with increased chamber size with minimal increase in wall thickness) characterizes the hypertrophy seen in patients with systolic dysfunction or previous MI. As the myocytes undergo change, so do various components of the extracellular matrix. For example, collagen degradation may lead to myocyte slippage, fibroblast proliferation, and increased fibrillar collagen synthesis, resulting in fibrosis and stiffening of the entire myocardium. Thus, a number of important ventricular changes that occur with remodeling include alterations in the geometry of the heart from an elliptical to a spherical shape, increases in ventricular mass (from myocyte hypertrophy), and changes in ventricular composition (especially the extracellular matrix) and volumes, all of which contribute to the impaired cardiac function. If the event producing cardiac injury is acute (eg, MI), the ventricular remodeling process begins immediately. However, it is the progressive nature of this process that results in continual worsening of the HF state, and thus is now the major focus for identification of therapeutic targets. In fact, HF pharmacotherapy associated with decreased mortality, and/or slowing the progression of the disease, produces these effects largely by slowing or reversing ventricular remodeling, a process often referred to as *reverse remodeling*.

The Neurohormonal Model of Heart Failure and Therapeutic Insights It Provides

2 3 Over the years, several different paradigms have guided our understanding of the pathophysiology and treatment of HF.[7] The early paradigm is often called the *cardiorenal model*, where the problem was viewed as excess sodium and water retention, and diuretic therapy was the main therapeutic approach. Next, the *cardiocirculatory model* focused on impaired CO (viewed as being due to both reduced pumping capacity of the heart and systemic vasoconstriction). Treatment strategies here focused on positive inotropes and, later, vasodilators, as the primary therapies to overcome reduced CO. While the therapeutic approaches associated with these paradigms provided some symptomatic benefits, they did little to slow progression of the disease. In fact, the detrimental effects of positive inotropic drugs on survival highlighted

the inadequacy of the cardiocirculatory model to explain the progressive nature of HF.

Balanced (arterial and venous) vasodilation with ACE inhibitors was the basis for initial clinical trials with these agents. Subsequent discovery that ACE inhibitors provided benefits beyond their vasodilating effects, followed by the positive results with β-adrenergic receptor blockers and aldosterone antagonists, led to the current paradigm used to describe HF pathogenesis: the *neurohormonal model*.[7] This model recognizes an initiating event (eg, MI, long-standing HTN) that leads to decreased CO and begins the "HF state." The problem then moves beyond the heart, and it becomes a systemic disease whose progression is mediated largely by neurohormones and autocrine/paracrine factors that drive myocyte injury, oxidative stress, inflammation, and extracellular matrix remodeling. While the former paradigms still guide us to some extent in the symptomatic management of the disease (eg, diuretics and digoxin), it is the latter paradigm that helps us understand disease progression and, more important, the ways to slow disease progression. In the sections that follow, key neurohormones and autocrine/paracrine factors, sometimes now collectively termed *biomarkers*, are described with respect to their role in HF and its progression. The benefits of current and investigational drug therapies can be better understood through a solid understanding of the neurohormones they regulate/affect. Although the neurohormonal model provides a logical framework for our current understanding of HF progression and the role of various medications in attenuating this progression, it must be emphasized that this model does not completely explain HF progression. For example, drug therapies that target the neurohormonal perturbations in HF usually only slow the progressive nature of the disorder rather than completely stop it. Ongoing research will likely identify additional targets for drug therapy.

Angiotensin II

Of the neurohormones and autocrine/paracrine factors that play an important role in HFrEF pathophysiology, angiotensin II is probably the best understood.[7,12] Although circulating angiotensin II produced from ACE activity is the most familiar route for generation of angiotensin II, recent evidence indicates that this hormone is synthesized directly in the myocardium through non-ACE-dependent pathways and also contributes to HF pathophysiology.

Angiotensin II has multiple actions that contribute to its detrimental effects in HF. It is a potent vasoconstrictor mediated by binding to the angiotensin type 1 (AT1) receptor in the vasculature and it also causes release of AVP and ET-1. Angiotensin II facilitates release of NE from adrenergic nerve terminals, heightening SNS activation. It promotes sodium retention through direct effects on the renal tubules and by stimulating aldosterone release. Its vasoconstriction of the efferent glomerular arteriole helps to maintain renal perfusion pressure in patients with severe HF or impaired renal function. Finally, angiotensin II, and many of the neurohormones released in response to angiotensin II, plays a central role in stimulating ventricular hypertrophy, remodeling, myocyte apoptosis, oxidative stress, inflammation, and alterations in the myocardial extracellular matrix. Clinical data suggest that attenuating angiotensin II-mediated effects contributes substantially to the benefits of ACE inhibitor-treated and angiotensin receptor blocker (ARB)-treated patients with HFrEF.[12,13] The favorable effects of ACE inhibitors and ARBs on hemodynamics, symptoms, hospitalizations, and survival highlight the importance of angiotensin II in HF pathophysiology.

Norepinephrine

As described earlier in this chapter, NE plays a central role in the tachycardia, vasoconstriction, and increased contractility and plasma renin activity in HFrEF.[9] Plasma NE concentrations are elevated in

correlation with the degree of HF, and patients with the highest plasma NE concentrations have the poorest prognosis.[14] Excessive SNS activation causes downregulation of β_1-receptors, with a subsequent loss of sensitivity to receptor stimulation. Excess catecholamines increase the risk of arrhythmias and can cause myocardial cell loss by stimulating both necrosis and apoptosis. Finally, NE contributes to ventricular hypertrophy and remodeling. The detrimental effects of SNS activation are further highlighted by the clinical trials of chronic therapy with β-agonists, phosphodiesterase inhibitors, or other drugs that cause SNS activation, since these agents are uniformly associated with increased mortality. Conversely, β-blockers, ACE inhibitors, and digoxin all help to decrease SNS activation, through various mechanisms, and are beneficial in HF. Thus, it is clear that NE plays a critical role in the pathophysiology of the HF state.

Aldosterone

Aldosterone-mediated sodium retention and its key role in volume overload and edema have long been recognized as important components of the HF syndrome.[15] Circulating aldosterone is increased in HF due to stimulation of its synthesis and release from the adrenal cortex by angiotensin II and due to decreased hepatic clearance from reduced hepatic perfusion. Recent studies demonstrate direct effects of aldosterone on the heart that may be even more important than sodium retention in HF pathophysiology. Chief among these is the ability of aldosterone to produce interstitial cardiac fibrosis through increased collagen deposition in the extracellular matrix of the heart. By increasing the stiffness of the myocardium, cardiac fibrosis may decrease systolic function and impair diastolic function. Current research shows that extra-adrenal production of aldosterone in the heart, kidneys, and vascular smooth muscle also contributes to the progressive nature of HF through target organ fibrosis and vascular remodeling. Induction of a systemic proinflammatory state, increased oxidative stress, wasting of soft tissues and bone, secondary hyperparathyroidism, and mineral/micronutrient dyshomeostasis are other important pathologic actions of aldosterone that directly contribute to ventricular remodeling and HF progression.[16] Aldosterone also may increase the risk of ventricular arrhythmias through a number of mechanisms, including creation of reentrant circuits as a result of fibrosis, inhibition of cardiac NE reuptake, depletion of intracellular potassium and magnesium, and impairment of parasympathetic traffic. Other detrimental effects of aldosterone include insulin resistance and endothelial and baroreceptor dysfunction. Clinical trials with the aldosterone antagonists spironolactone[17] and eplerenone[18,19] showing significant reductions in morbidity and mortality in patients with HFrEF provide compelling evidence of the important role of aldosterone in the initiation and progression of this syndrome. Although not studied as extensively as in HFrEF, aldosterone antagonists also show benefit in patients with HFpEF.[20,21]

Natriuretic Peptides

The natriuretic peptide family has three members, atrial natriuretic peptide (ANP), B-type natriuretic peptide (BNP), and C-type natriuretic peptide (CNP).[22] Of these, BNP is the most useful in the diagnosis and management of HF.[22] BNP and its related biologically inactive peptide, NT-proBNP, are synthesized and released from the ventricle in response to pressure or volume overload. BNP or NT-proBNP plasma concentrations are elevated in patients with HF functioning to increase natriuresis and diuresis and attenuate activation of the RAAS and SNS. The important role of these peptides in HF pathophysiology is supported by the recent clinical trial showing that neprilysin-mediated inhibition of natriuretic peptide breakdown improves outcomes in patients with HFrEF.[23]

The development of easily performed commercial assays for BNP and NT-proBNP, resulted in widespread

interest in the role of these peptides as a biomarker for prognostic, diagnostic, and therapeutic use. In patients with chronic HFrEF, the degree of elevation in BNP concentrations is closely associated with increased mortality, risk of sudden death, symptoms, and hospital readmission.[22] Accurate diagnosis of acute decompensated HF in acute care settings is often difficult since many of the symptoms (eg, dyspnea) mimic those of other disorders such as pulmonary disease or obesity. The most well-established clinical application of BNP testing is in the urgent care setting where the BNP or NT-proBNP assay is useful when combined with clinical evaluation for differentiating dyspnea secondary to either HFrEF or HFpEF from other causes.[1]

Much interest has focused on the benefits of serial measurement of BNP as a target to guide drug therapy, primarily diuretics. Recent studies evaluating this approach have not shown consistent improvement in long-term outcomes compared with standard medical therapy, particularly in patients with HFpEF.[22,24,25,26] As a result, current guidelines reflect this uncertainty and do not support the routine use of serial measurement of BNP in the management of chronic HF.[1]

Arginine Vasopressin

AVP is a pituitary peptide hormone that regulates renal water excretion and plasma osmolality.[7] Plasma concentrations of AVP are elevated in patients with HF, supporting its role in the pathophysiology of this disorder. The physiologic effects of AVP are mediated through the V_{1a}, V_{1b}, and V_2 receptors. Stimulation of these receptors by increased circulating AVP results in several maladaptive responses including: (a) increased renal free water reabsorption in the face of plasma hypoosmolality resulting in volume overload and hyponatremia; (b) increased arterial vasoconstriction that contributes to reduced CO; and (c) stimulation of remodeling by cardiac hypertrophy and extracellular matrix collagen deposition.

Given the importance of AVP in HF, recent efforts have focused on the development of AVP antagonist drugs for treatment of acute and chronic HF. By blocking the AVP receptor, these agents primarily increase free water excretion (ie, an "aquaretic" effect). Although clinical trials with the AVP antagonists, tolvaptan, and conivaptain demonstrate improvements in acute symptoms and increases in serum sodium and urine output without affecting HR, BP, renal function, or other electrolytes, no improvements in morbidity and mortality were seen.[27]

Factors Precipitating/Exacerbating Heart Failure

Although significant advances have been made in treatment, symptom exacerbation, to the point that hospitalization is required, is a common and growing problem in patients with chronic HF. Hospitalization for HF exacerbation consumes large amounts of healthcare dollars and significantly impairs the patient's quality of life; thus, there is great interest in identifying and then remedying factors that increase the risk of decompensation. Appropriate therapy can often maintain patients in a "compensated" state, indicating that they are relatively symptom-free. However, there are many aggravating or precipitating factors that may cause a previously compensated patient to develop worsened symptoms necessitating hospitalization. Often, these precipitating factors are reversible or treatable, such that a thorough evaluation for their presence is imperative.

Cardiac events are a frequent cause of worsening HF.[1] Myocardial ischemia and infarction are potentially reversible causes that must be carefully considered since nearly 70% of patients with HF patients have coronary artery disease. Revascularization should be considered in appropriate patients. Atrial fibrillation

occurs in up to 10% to 50% of patients with HF and is associated with increased morbidity and mortality.[28,29] It can exacerbate HF through rapid ventricular response and loss of atrial contribution to ventricular filling. Conversely, HF can precipitate atrial fibrillation by increasing atrial distension from ventricular volume overload. Control of ventricular response, maintenance of sinus rhythm in appropriate patients, and prevention of thromboembolism are important elements in the treatment of patients with concomitant HF and atrial fibrillation. Uncontrolled HTN is also an important contributing factor and should be treated according to current guidelines.[1]

Noncardiac events are also associated with HF decompensation. Pulmonary infections frequently cause worsening HF. Many of these events would be preventable with more widespread use of the pneumococcal and influenza vaccines. Pulmonary embolus, diabetes, worsening renal function, hypothyroidism, and hyperthyroidism should also be considered.

Nonadherence with prescribed HF medications or with dietary recommendations (eg, sodium intake and fluid restriction) is also a common cause of HF exacerbation.[1,30] Recent estimates indicate that nonadherence is an important contributor to poor outcomes and that socioeconomically disadvantaged patients appear to be disproportionately affected.

A number of drugs can precipitate or exacerbate HF by one or more of the following mechanisms: (a) negative inotropic effects; (b) direct cardiotoxicity; or (c) increased sodium and/or water retention (**Table 14-3**).[31,32] The resulting symptoms are typically those associated with volume overload, but in more severe cases hypoperfusion may also be present. Nonsteroidal antiinflammatory drugs (NSAIDs) are increasingly recognized for their ability to exacerbate HF and increase risk of hospitalization and mortality through volume retention, decreased renal function, and increased BP.[31,33]

TABLE 14-3 Drugs that May Precipitate or Exacerbate Heart Failure

Negative Inotropic Effect
Antiarrhythmics (eg, disopyramide, flecainide, propafenone)
Beta-blockers (eg, propranolol, metoprolol, carvedilol)
Calcium channel blockers (eg, verapamil, diltiazem)
Itraconazole
Cardiotoxic
Doxorubicin
Epirubicin
Daunomycin
Cyclophosphamide
Trastuzumab
Bevacizumab
Mitoxantrone

Ifosfamide

Mitomycin

Lapatinib

Sunitinib

Imatinib

Ethanol

Amphetamines (eg, cocaine, methamphetamine)

Sodium and Water Retention

NSAIDs

COX-2inhibitors

Rosiglitazone and pioglitazone

Glucocorticoids

Androgens and estrogens

Salicylates (high dose)

Sodium-containing drugs (eg, carbenicillin disodium, ticarcillin disodium)

Uncertain Mechanism

Adalimumab

Dronedarone

Etanercept

Infliximab

What should be evident is that many of the precipitating factors are preventable, particularly through appropriate healthcare professional intervention. Specifically, patient education and counseling by a pharmacist should be able to identify and address inadequate HF therapy, detect medication nonadherence, and administration of drugs or the presence of drug–drug interactions that may worsen HF (see Table 14-3).[34,35] A careful medication history is an important aspect of evaluating the cause(s) of HF exacerbation. Discontinuation of medications known to exacerbate HF may help prevent hospitalizations. Use of medications such as antiarrhythmic agents, particularly disopyramide, dronedarone, and flecainide, and nondihydropyridine calcium channel blockers are important precipitants of exacerbations. The widespread use of NSAIDs, particularly the nonprescription agents that many patients perceive as having a low risk of adverse effects, is also problematic and should be discouraged. Thus, many of the factors precipitating HF exacerbations are amenable to pharmacist intervention. Attention to these factors may make important contributions to reducing the risk of adverse cardiovascular outcomes and improving the patient's quality of life.

CLINICAL PRESENTATION

CLINICAL PRESENTATION Heart Failure General

Patient presentation may range from asymptomatic to cardiogenic shock.

Symptoms

Dyspnea, particularly on exertion

Orthopnea

Paroxysmal nocturnal dyspnea

Exercise intolerance

Tachypnea

Cough

Fatigue

Nocturia

Hemoptysis

Abdominal pain

Anorexia

Nausea

Bloating

Poor appetite, early satiety

Ascites

Mental status changes

Weight gain or loss

Signs

Pulmonary rales

Pulmonary edema

S_3 gallop, mitral regurgitant murmur

Cool extremities

Pleural effusion

Cheyne-Stokes respiration

Tachycardia

Narrow pulse pressure

Cardiomegaly

Peripheral edema

Jugular venous distention

Hepatojugular reflux

Hepatomegaly

Venous stasis changes

Lateral displacement of apical impulse

Cachexia

Laboratory tests

BNP > 100 pg/mL

NT-proBNP > 300 pg/mL

Electrocardiogram may be normal or it could show numerous abnormalities including acute ST-T wave changes from myocardial ischemia, atrial fibrillation, bradycardia, left ventricular hypertrophy

Serum creatinine: It may be increased due to hypoperfusion. Preexisting renal dysfunction can contribute to volume overload

Complete blood count useful to determine if heart failure due to reduced oxygen carrying capacity

Chest X-ray: Useful for detection of cardiac enlargement, pulmonary edema, and pleural effusions

Echocardiogram: Used to assess LV size, valve function, pericardial effusion, wall motion abnormalities, and ejection fraction

Hyponatremia: serum sodium < 130 mEq/L is associated with reduced survival and may indicate worsening volume overload and/or disease progression

Signs and Symptoms

[2][11] The primary manifestations of both HFrEF and HFpEF are dyspnea and fatigue, which lead to exercise intolerance, and fluid overload, which can result in peripheral edema and pulmonary congestion.[1,36] The presence of these signs and symptoms may vary considerably from patient to patient such that some patients have dyspnea but no signs of fluid retention, whereas others may have marked volume overload with few complaints of dyspnea or fatigue. However, many patients have both dyspnea and volume overload. Clinicians should remember that symptom severity often does not correlate with the degree of LV

dysfunction. Patients with a low LVEF (less than 20%-25%) may be asymptomatic, whereas those with preserved LVEF may have significant symptoms. It is also important to note that symptoms can vary considerably over time in a given patient, even in the absence of changes in ventricular function or medications.

Systemic congestion is associated with a number of signs and symptoms. Jugular venous distension (JVD) is the simplest and most reliable sign of fluid overload. Examination of the right internal jugular vein with the patient at a 45 degree angle is the preferred method for assessing JVD. The presence of JVD more than 4 cm above the sternal angle suggests systemic venous congestion. In patients with mild systemic congestion, JVD may be absent at rest, but application of pressure to the abdomen will cause an elevation of JVD (hepatojugular reflux).

Peripheral edema is a cardinal finding in HF. Edema usually occurs in dependent parts of the body, and thus is seen as ankle or pedal edema in ambulatory patients, although it may be manifested as sacral edema in bedridden patients. Adults typically have a 10-lb (4.5-kg) fluid weight gain before trace peripheral edema is evident; therefore, patients with acute decompensated HF may have no clinical evidence of systemic congestion except weight gain. Body weight is thus an excellent short-term end point for evaluating fluid status. Nonfluid weight gain and loss of muscle mass due to cardiac cachexia are potential confounders for long-term use of weight as a marker for fluid status. Hepatomegaly and ascites are other signs of systemic congestion.

Patients with HFrEF may exhibit signs and symptoms of low CO alone or in addition to volume overload. The primary complaint associated with hypoperfusion is fatigue. Poor appetite or early satiety may be due to limited perfusion of the GI tract. Conversely, patients with such GI complaints may simply be experiencing gut edema. Objective indicators of low CO include worsening renal function, cool extremities, altered mental status, resting tachycardia, and narrow pulse pressure.

Diagnosis

No single test is available to confirm the diagnosis of HF—it is a clinical syndrome associated with specific signs and symptoms.[1,36] Because HF can be caused or worsened by multiple cardiac and noncardiac disorders, some of which may be treatable or reversible, accurate diagnosis is essential for development of therapeutic strategies. HF is often initially suspected in a patient based on symptoms. However, signs and symptoms lack sensitivity for diagnosing HF since they are frequently found with many other disorders. Even in patients with known HF, there is poor correlation between the presence or severity of symptoms and the hemodynamic abnormality. With few exceptions, HFpEF cannot be distinguished from HFrEF on the basis of the history, physical examination, chest x-ray, and ECG alone.[37] Patients with HFpEF are often elderly, hypertensive women.[37]

A complete history and physical examination targeted at identifying cardiac or noncardiac disorders or behaviors that may cause or hasten HF development or progression are essential in the initial patient evaluation. However, the physical examination cannot distinguish between HFrEF and HFpEF. A careful medication history should also be obtained with a focus on use of ethanol, tobacco, illicit drugs (eg, cocaine or methamphetamine), vitamins and supplements (including herbal or "natural" supplements), NSAIDs, and antineoplastic agents (anthracyclines, cyclophosphamide, trastuzumab, and imatinib).

Particular attention should be paid to cardiovascular risk factors and to other disorders that can cause or exacerbate HF such as HTN, diabetes, atrial fibrillation, dyslipidemia, tobacco use, sleep-disordered

breathing, and thyroid disease. Since coronary artery disease is the cause of HF in many patients, evaluation of the possibility of coronary disease is essential, especially in men. If coronary artery disease is detected, appropriate revascularization procedures may then be considered. The patient's volume status should be documented by assessing the body weight, JVD, and presence or absence of pulmonary congestion and peripheral edema. Laboratory testing may assist in identification of disorders that cause or worsen HF. The initial evaluation should include a complete blood count, serum electrolytes (including calcium and magnesium), assessment of renal and hepatic function, urinalysis, lipid profile, hemoglobin A1C, thyroid function tests, chest x-ray, and 12-lead ECG. There are no specific ECG abnormalities associated with HF, but findings may help detect coronary artery disease or conduction abnormalities that could affect prognosis and guide treatment decisions. Measurement of BNP or NT-proBNP may also assist in differentiating dyspnea caused by HF from other causes.

Although the history, physical examination, and laboratory tests provide important insight into the underlying cause of HF, the echocardiogram is the single most useful test in the evaluation of the patient. The echocardiogram is used to assess abnormalities in cardiac structure and function and should include evaluation of the pericardium, myocardium, and heart valves, and quantification of the LVEF to determine if systolic or diastolic dysfunction is present.

TREATMENT

Of Chronic Heart Failure

Desired Outcomes

The goals of therapy in management of chronic HF are to improve the patient's quality of life, relieve or reduce symptoms, prevent or minimize hospitalizations, slow progression of the disease, and prolong survival. Pharmacotherapy plays a key role in achieving these goals.[1] In addition, identification of risk factors for HF development and recognition of its progressive nature have led to increased emphasis on preventing the development of this disorder. With this in mind, the American College of Cardiology (ACC)/American Heart Association (AHA) guidelines for the evaluation and management of HF utilize a staging system that not only recognizes the evolution and progression of the disorder but also emphasizes risk factor modification and preventive treatment strategies (**Fig. 14-6**).[1] The four stages of this system differ from the NYHA functional classification (**Table 14-4**) with which most clinicians are familiar. The NYHA system is primarily intended to classify symptoms according to the clinician's subjective evaluation and does not recognize preventive measures or the progression of the disorder. A patient's symptoms can change frequently over a short period of time due to changes in medications, diet, intercurrent illnesses, etc. For example, a patient with ACC/AHA Stage C HF with NYHA class IV symptoms such as marked volume overload could rapidly improve to class I to II with aggressive diuretic therapy. Despite these limitations, this system can be useful for monitoring patients and is widely used in HF studies. In contrast, and consistent with the progressive nature of HF, a patient's ACC/AHA HF stage could not improve (eg, go from Stage C to Stage B) even though the patient's symptoms could fluctuate from NYHA class IV to I.

FIGURE 14-6

ACC/AHA heart failure staging system. (*Adapted from Yancy CW, Jessup M, Bozkurt B, et al. 2013 ACCF/AHA guideline for the management of heart failure: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol*

2013;62:e147-239.)

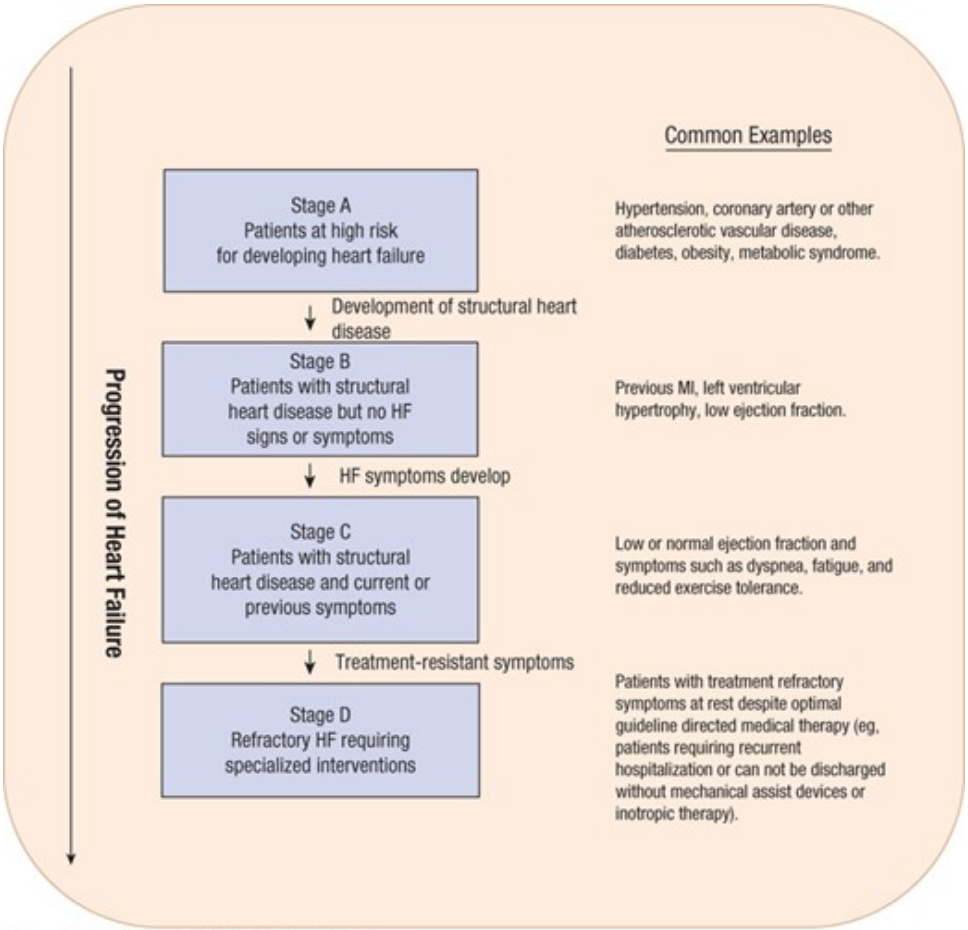


TABLE 14-4 New York Heart Association Functional Classification

Functional class

I. Patients with cardiac disease but without limitations of physical activity. Ordinary physical activity does not cause undue fatigue, dyspnea, or palpitation.

II. Patients with cardiac disease that results in slight limitations of physical activity. Ordinary physical activity results in fatigue, palpitation, dyspnea, or angina.

III. Patients with cardiac disease that results in marked limitation of physical activity. Although patients are comfortable at rest, less than ordinary activity will lead to symptoms.

IV. Patients with cardiac disease that results in an inability to carry on physical activity without discomfort. Symptoms of congestive heart failure are present even at rest. With any physical activity, increased discomfort is experienced.

The general principles used to guide the treatment of HFrEF are based on numerous large, randomized, double-blind, multicenter trials. Until recently, no such randomized trials had been performed in patients with HFpEF. Consequently, the guidelines for the management of HFpEF are based primarily on clinical investigations in relatively small groups of patients, clinical experience, and concepts based on the

knowledge and understanding of the pathophysiology of the disease process. The treatment regimen outlined in **Table 14-5** applies to patients with HFpEF who have clear manifestations of congestion either at rest or with exertion. Whether treatment of asymptomatic diastolic dysfunction confers any benefit has not been demonstrated.

TABLE 14-5 Targeted Approach to Treatment of HFpEF

Symptom-targeted treatment	Rationale	Agent
Decrease pulmonary venous pressure	Reduce left ventricular volume	Diuretics, nitrates, salt restriction
Decrease myocardial oxygen consumption	Reduce heart rate	β-blockers, diltiazem, verapamil, ACE inhibitors, ARBs, calcium channel blockers
	Control blood pressure	
Maintain atrial contraction	Restore and/or maintain sinus rhythm	Cardioversion of atrial fibrillation
Improve exercise tolerance	As above	Use positive inotropic agents with caution
Disease-targeted treatment		
Prevent/treat myocardial ischemia		β-blockers, diltiazem, verapamil, nitrates
Prevent/regress ventricular hypertrophy		Antihypertensive therapy
Mechanism-targeted treatment		
Modify myocardial and extramyocardial mechanisms		Possibly ACE inhibitors or ARBs, diuretics, spironolactone
Modify intracellular and extracellular mechanisms		Possibly ACE inhibitors or ARBs, spironolactone

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; HFpEF, heart failure with preserved ejection fraction.

General Measures

The complexity of the HF syndrome necessitates a comprehensive approach to management that includes accurate diagnosis, identification and treatment of risk factors, elimination or minimization of precipitating factors, appropriate pharmacologic and nonpharmacologic therapy, and close monitoring and followup.

The first step in management of chronic HF is to determine the etiology (see Table 14-1) and/or any precipitating factors. Appropriate treatment of underlying disorders (eg, hyperthyroidism, valvular heart disease) may obviate the need for specific HF treatment. Revascularization or anti-ischemic therapy in patients with coronary disease may reduce HF symptoms. Drugs that aggravate HF (see Table 14-3) should be discontinued if possible.

Restriction of physical activity reduces cardiac workload and is recommended for virtually all patients with acute congestive symptoms. However, once the patient's symptoms have stabilized and excess fluid is removed, restrictions on physical activity are discouraged. Exercise training may improve functional status, quality of life, and yield trends toward reduced hospitalizations and death from cardiovascular causes and is supported by current guidelines to improve functional status.[1,38]

Restriction of dietary sodium and fluid intake is an important lifestyle intervention for both HFrEF and HFpEF. Mild (less than 3 g/day) to moderate (less than 2 g/day) sodium restriction, in conjunction with daily measurement of weight, should be implemented to minimize volume retention and allow use of lower and safer diuretic doses. The typical American diet contains 8 to 10 g of sodium per day, so most patients would need to reduce their intake by over 50%. Patients should avoid adding salt to prepared foods and eliminate foods high in sodium (eg, salt-cured meats, salted snack foods, pickles, soups, delicatessen meats, and processed foods). In patients with hyponatremia (serum Na less than 130 mEq/L [less than 130 mmol/L]) or those with persistent volume retention despite high diuretic doses and sodium restriction, daily fluid intake should be limited to 2 L/day from all sources. However, both sodium and fluid restriction must be done with care in patients with HFpEF. Excessive restriction can lead to hypotension, low-output state, and/or renal insufficiency. Daily weights may help to assess volume status. Dietary and lifestyle factors that decrease the risk of development of CAD and HTN should be encouraged. Although guidelines indicate sodium restriction is reasonable to minimize congestion, proven benefits on clinical outcomes are lacking and some data suggest sodium restriction is associated with worse outcomes in patients with HFrEF.[39]

Other important general measures include patient and family counseling on the signs and symptoms of HF, detailed written instructions on the importance of appropriate medication use and compliance, activity level, diet, discharge medications, weight monitoring, continuity of care, and the need for close monitoring and followup to reinforce compliance and minimize the risk of HF exacerbations and subsequent hospitalization. These activities are now referred to as self-care and constitute an important means to improve such important outcomes as hospitalization and quality of life.[40]

General Approach to Treatment

4 The ACC/AHA treatment guidelines are organized around the four identified stages of HF, and the treatment recommendations are summarized in **Figs. 14-7** and **14-8**.[1] Clinicians are reminded that, in addition to the ACC/AHA, other cardiology professional societies publish guidelines for evaluation and treatment of HF including the Heart Failure Society of America (HFSA) and the European Society of Cardiology (ESC).[41,42] Although minor differences exist between the recommendations in these guidelines, they are in general agreement in their overall approach to evaluation and treatment of HF. In addition to chronic HFrEF, these guidelines now also provide thorough discussions of acute decompensated HF and management of patients with comorbid diseases often encountered in this population.

FIGURE 14-7

Treatment algorithm for patients with ACC/AHA Stage A and B heart failure. (*Adapted from Yancy CW, Jessup M, Bozkurt B, et al. 2013 ACCF/AHA guideline for the management of heart failure: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2013;62:e147-239.*)

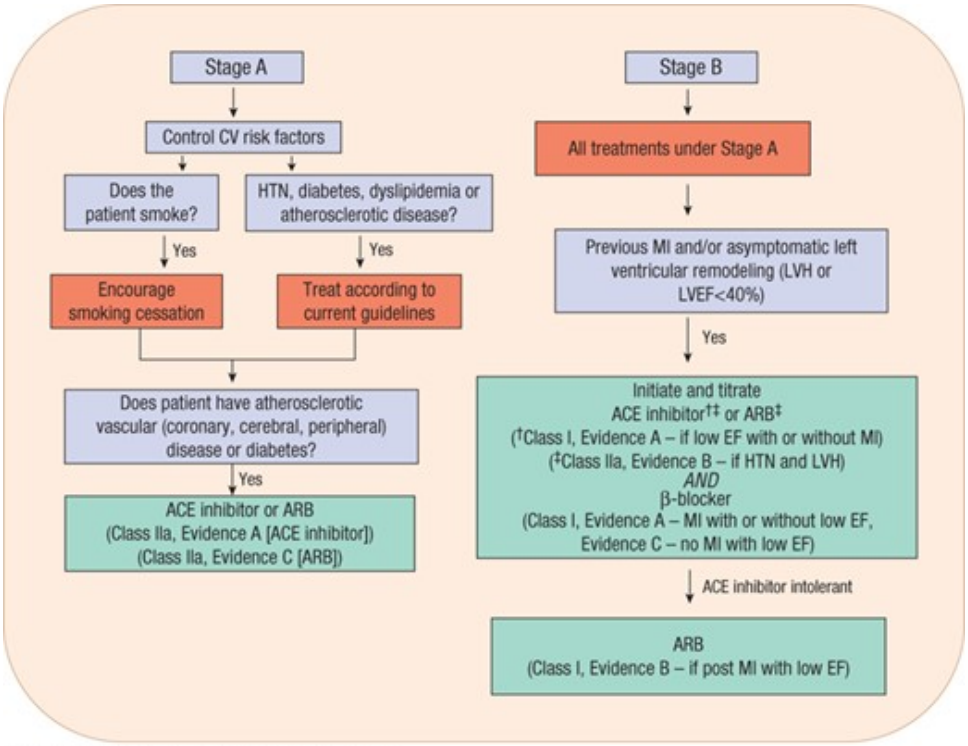

FIGURE 14-8

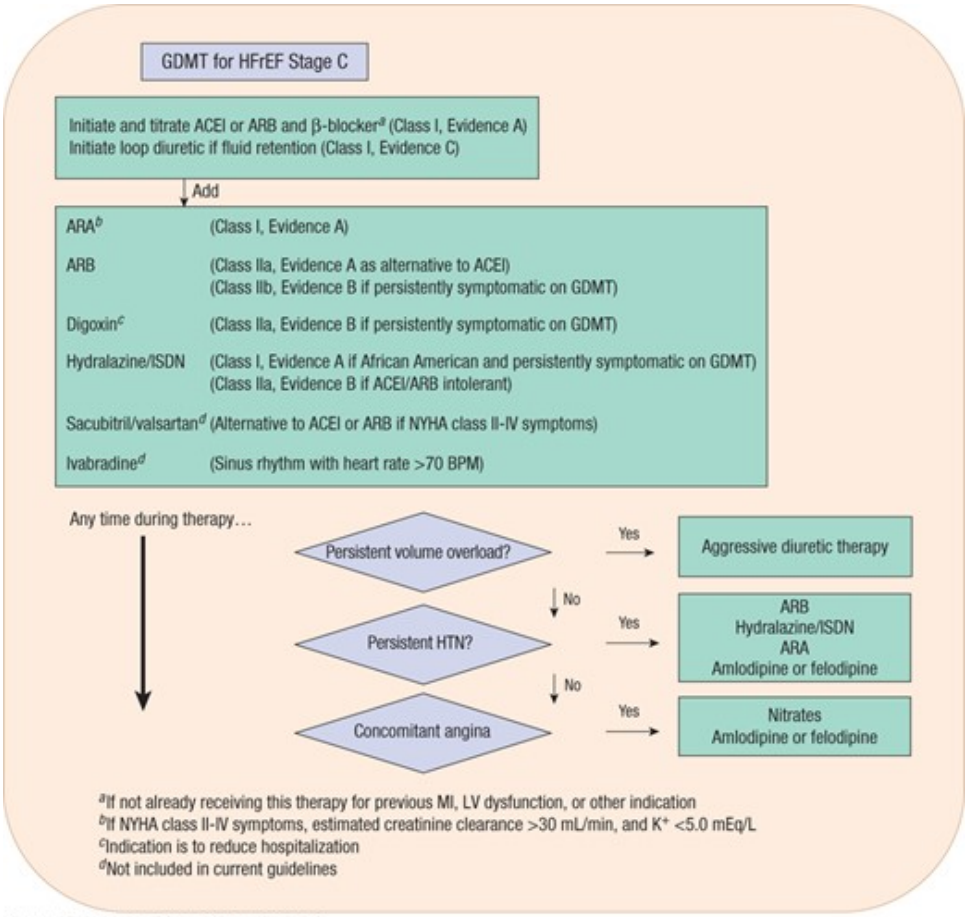
Guideline-directed treatment algorithm for patients with ACC/AHA Stage C heart failure with reduced ejection fraction. (*Adapted from Yancy CW, Jessup M, Bozkurt B, et al. 2013 ACCF/AHA guideline for the management of heart failure: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2013;62:e147-239.*)



Heart Failure with Preserved Ejection Fraction

Less information on the treatment of HFpEF is available. This relative paucity of evidence is reflected in guidelines for the diagnosis and management of HFpEF published by the ACC/AHA, the ESC, and the HFSA.[1,41,42] In general, all three guidelines recommend treating comorbid conditions by controlling HR and BP, alleviating causes of myocardial ischemia, reducing volume, and restoring and maintaining sinus rhythm in patients with atrial fibrillation. **Table 14-6** summarizes the therapeutic recommendations.

TABLE 14-6 Pharmacotherapy for Heart Failure with Preserved Ejection Fraction

Recommendations

Diuretics

- A loop or a thiazide diuretic should be considered for patients with volume overload. However, with more severe volume overload or inadequate response to a thiazide, a loop diuretic should be implemented. Caution is warranted not to lower preload excessively, which may reduce stroke volume and cardiac output.

ACE inhibitors

- ACE inhibitors may be considered in all patients.
- ACE inhibitors should be considered in all patients who have symptomatic atherosclerotic

cardiovascular disease or diabetes and one additional risk factor.

Angiotensin receptor blockers

- Angiotensin receptor blockers may be considered in all patients.
- In patients who are intolerant of ACE inhibitors, an angiotensin receptor blocker can be considered an alternative.

Aldosterone antagonists

- Aldosterone antagonists can be considered to reduce the risk of hospitalization in patients that do not have contraindications or are at risk for hyperkalemia.

***β*-Blockers**

- *β*-blockers should be considered in patients with one or more of the following conditions:
- Myocardial infarction
- Hypertension
- Atrial fibrillation requiring ventricular rate control

Calcium channel blockers

- In patients with atrial fibrillation warranting ventricular rate control who either are intolerant to or have not responded to a *β*-blocker, diltiazem or verapamil should be considered.
- A nondihydropyridine or dihydropyridine calcium channel blocker can be considered for symptom-limiting angina.
- A nondihydropyridine or dihydropyridine calcium channel blocker can be considered for hypertension.

ACE, angiotensin-converting enzyme.

A recent study showing that use of guideline directed medical therapy (GDMT) improves mortality in patients with HFrEF reinforces the importance for clinicians to be familiar with these recommendations.[43] However, clinicians should also remember that these are only *guidelines* and that evaluation and treatment should be individualized for each patient.

As the management of HF has become increasingly complex, the development of disease management programs that use multidisciplinary teams has been studied extensively. These programs utilize several broad approaches including HF specialty clinics, home-based interventions, structured telephone support, and close patient followup. Most are multidisciplinary and may include physicians, advanced practice nurses, dieticians, and pharmacists. In general, the programs focus on optimization of drug and nondrug therapy, patient and family education and counseling, exercise and dietary advice, intense followup by telephone or home visits, improving adherence to medications and lifestyle recommendations, encouragement of

self-care, and early recognition of and management of volume overload.[1] Such programs have typically focused on patients with more severe HF who are at high risk for hospital admission. In general, multidisciplinary disease management programs improve quality of life and reduce HF and all-cause hospitalizations and costs, although these benefits are not consistently demonstrated in all studies. Pharmacists can play an important role in the multidisciplinary team management of HF taking on such responsibilities as medication evaluation and therapeutic recommendations, improved use of GDMT, patient education, and followup telephone monitoring to reduce hospitalizations for HF, evaluation of adverse drug events, and medication errors.[34,44]

Treatment of Stage A Heart Failure

Patients in Stage A do not have structural heart disease or HF symptoms but are at high risk for developing HF because of the presence of risk factors (see Fig. 14-7). The emphasis here is on risk factor identification and modification to prevent the development of structural heart disease and subsequent HF. Commonly encountered risk factors include HTN, dyslipidemia, diabetes, obesity, metabolic syndrome, smoking, and coronary artery disease. Although each of these disorders individually increases risk, they frequently coexist in many patients and act synergistically to foster the development of both HFrEF and HFpEF.Effective blood pressure control reduces the risk of developing HF by approximately 50%; thus, current HTN treatment guidelines should be followed.[1] Obesity, diabetes, and metabolic syndrome also importantly contribute to the risk of developing HF although it remains unclear whether controlling these risk factors reduces the risk of developing HF.[45,46,47] Appropriate management of coronary disease and its associated risk factors is also important. Although treatment must be individualized, ACE inhibitors or ARBs and statins are recommended for HF prevention in patients with multiple vascular risk factors.[1]

Treatment of Stage B Heart Failure

Patients in Stage B have structural heart disease, but do not have HF symptoms (see Fig. 14-7). This group includes patients with left ventricular hypertrophy, recent or remote MI, valvular disease, or LVEF less than 40%. These individuals are at risk for developing HF, and treatment is targeted at minimizing additional injury and preventing or slowing the remodeling process. In addition to the treatment measures outlined in Stage A, ACE inhibitors or ARBs and β-blockers are important components of therapy. All patients with a reduced LVEF should receive an ACE inhibitor or ARB and a β-blocker to prevent development of HF, whether or not they have had an MI.[1] Patients with a previous MI and reduced LVEF should also receive an ACE inhibitor or ARB, evidence-based β-blockers, and a statin.[1]

Treatment of Stage C HF

4 5 6 7 8 9 10 11 Patients with structural heart disease and previous or current symptoms are classified in Stage C and include both HFrEF and HFpEF. In addition to treatments in Stages A and B, patients with HFrEF in Stage C should be routinely treated with GDMT that includes an ACE inhibitor or ARB and an evidence-based β-blocker (see Fig 14-8).[1] The benefits of these medications on slowing HF progression, reducing morbidity and mortality, and improving symptoms are clearly established. Loop diuretics, aldosterone antagonists, and hydralazine–isosorbide dinitrate (ISDN) are also routinely used in these patients. Digoxin can also be considered in selected patients, as can two newly approved medications, ivabradine and sacubitril/valsartan. Nonpharmacologic therapy with devices such as an implantable cardioverter-defibrillator (ICD) or cardiac resynchronization therapy (CRT) with a biventricular pacemaker is

also indicated in certain patients with HFrEF in Stage C (see Nonpharmacologic Therapy). Other general measures noted earlier are also important as is careful followup and patient education to reinforce dietary and medication compliance to prevent clinical deterioration and reduce hospitalization.[1,48]

Dozens of trials evaluated pharmacotherapy in patients with HFrEF, but few focused on patients with HFpEF. In fact, most published HF studies specifically excluded patients with preserved EF. The results of some clinical trials for treatment of HFpEF as well as ongoing studies are summarized in **Table 14-7**. Phosphodiesterase inhibitors, ranolazine, interleukin-1 blockade, and cardiac resynchronization therapy are some of the other strategies being investigated in this patient population.

TABLE 14-7 Completed and Ongoing Large Clinical Trials for HFpEF

Trial (No. of Patients)	Treatment	Inclusion Criteria	Primary End Point	Results
DIG Ancillary Study (n = 988)[109]	Digoxin vs placebo for a mean of 37 months. Patients received ACE inhibitor (86%) and diuretics (85%)	EF >45%, NYHA II–IV, normal sinus rhythm	Composite of HF hospitalization or HF mortality	No significant difference was found in the primary end point between treatment groups (HR = 0.82, P = 0.136). Digoxin had no effect on all-cause mortality or cause-specific mortality or on all-cause or CV hospitalization. Compared with placebo, digoxin use was associated with a trend toward a reduction in HF hospitalizations (HR = 0.79, P = 0.094) and an increase in unstable angina admissions (HR = 1.37, P = 0.061).
CHARM-Preserved[68] (n = 3,023)	Candesartan vs placebo for a mean of 36.6 months. Patients continued their background HF medications: ACE inhibitor (19%), β-blocker (55%), diuretics (75%), spironolactone (11%)	EF >40%, NYHA II–IV, ≥1 hospitalization for CV reason	Composite of CV mortality or HF hospitalization	No significant difference was found in the primary end point between treatment groups (adjusted HR = 0.86, P = 0.051) or in CV deaths (adjusted HR = 0.95, P = 0.635). Compared with placebo, candesartan use was associated with fewer HF admissions (P = 0.047), lower incidence of new diabetes (HR = 0.60, P = 0.005), and a reduction in the composite of CV death, hospitalization for HF, MI, and stroke (adjusted HR = 0.86, P = 0.037).
PEP-CHF[159] (n = 850)	Perindopril vs placebo for a mean of 2.1 years	Clinical criteria for HF, EF ≥40%, age ≥70 years	Composite of total mortality and HF hospitalization	No significant difference was found in the primary end point between treatment groups (HR = 0.69, P = 0.055; HR = 0.70, P =

Trial (No. of Patients)	Treatment	Inclusion Criteria	Primary End Point	Results
				0.545). In a subgroup analysis, patients ≤75 years of age (HR = 0.29, *P* = 0.035) and with a history of MI (HR = 0.38, *P* = 0.004) showed a reduction in the primary end point. Compared with placebo, perindopril use at 1 year was associated with fewer unplanned hospital admissions (HR = 0.63, *P* = 0.033), greater improvements in exercise tolerance (*P* = 0.011), and improvement in NYHA class (*P* = 0.030).
I-Preserve[69] (*n* = 4,128)	Irbesartan vs placebo for 2 years. ACE inhibitor can be used for any indication other than HTN	Clinical criteria for HF or hospitalized within 6 months for HF, age ≥60 years, NYHA II–IV, EF ≥45%	Composite of all-cause mortality or CV hospitalization	No significant difference was found in the primary end point between treatment groups (HR = 0. 95, *P* = 0.35), overall death rates (HR = 1.00, *P* = 0.98), or CV hospitalization rate (HR = 0.95, *P* = 0.44).
SENIORS[160] (*n* = 2,111)	Nebivolol vs placebo for 21 months	Clinical criteria for HF with either documented heart failure hospitalization with 1 year or documented EF ≤35% within 6 months, age ≥70 years	All-cause mortality or cardiovascular hospitalization	In the study, 1,359 patients (64%) had an EF ≤35% (mean 28.7%), and 752 (36%) had an EF >35% (mean 49.2%). In patients with EF >35%, the HR for nebivolol vs placebo for the primary end point was 0.81 (*P* = 0.104). No significant difference existed between groups (EF ≤35% vs EF >35%, *P* = 0.720).
TOPCAT[21] (*n* = 3,345)	Spironolactone vs placebo for 2 years	Clinical criteria for HF, age ≥50 years, EF ≥45%, ≥1 hospitalization for HF, controlled SBP	CV mortality, aborted cardiac arrest, HF hospitalization	With a mean follow-up of 3.3 years, the primary outcome occurred in 18.6% of the spironolactone group and 20.4% in the placebo group (HR 0.89; *P* = 0.14).Only hospitalizations were significantly reduced by 17%. A posthoc analysis showed a significant benefit in the primary outcome in those patients enrolled in the Americas as compared to those enrolled in Russia and Georgia.

Trial (No. of Patients)	Treatment	Inclusion Criteria	Primary End Point	Results
PARAGON-HF (*n* = 4,300)	Sacubitril/valsartan vs valsartan	NYHA class II–IV with EF >45%	Composite of CV death and total HF hospitalization	Estimated completion 2019. https://clinicaltrials.gov/ct2/show/NCT01920711

Treatment of Stage D HFrEF

Stage D HF includes patients receiving maximally tolerated GDMT that have persistent symptoms. This is often referred to as advanced, refractory, or end-stage HF. These patients often undergo recurrent hospitalizations or cannot be discharged from the hospital without special interventions, have a poor quality of life, and are at high risk for morbidity and mortality. These individuals have the most advanced form of HF and should be referred to HF management programs so that specialized therapies including mechanical circulatory support, continuous IV positive inotropic therapy, and cardiac transplantation can be considered in addition to standard treatments outlined in Stages A to C.[1,49] Discussions with the patient and family members regarding prognosis, patient priorities for minimizing symptoms versus prolonging survival, options for additional treatments, and end-of-life and hospice care should be initiated. Several excellent resources are available that address these issues.[49,50,51]

Management of volume status can be challenging in these patients.[1,27] Restriction of sodium and fluid intake may be beneficial. High doses of diuretics, combination therapy with a loop and thiazide diuretic, or mechanical methods of fluid removal such as ultrafiltration may be required. Patients in Stage D may be less tolerant to ACE inhibitors (hypotension, worsening renal insufficiency) and β-blockers (worsening HF) as high levels of neurohormonal activation maintain circulatory homeostasis. Initiation of therapy with low doses, slow upward dose titration, and close monitoring for signs and symptoms of intolerance are essential in this group of patients. The approach to treatment of patients with Stage D HF is discussed in more detail in Chapter 15.

Nonpharmacologic Therapy

Sudden cardiac death, primarily due to ventricular tachycardia and fibrillation, is responsible for 40% to 50% of the mortality in patients with HFrF. Patients in the earlier stages of the disorder with milder symptoms are more likely to die from sudden death, whereas death from pump failure is more frequent in those with advanced HF. Many of these patients have complex and frequent ventricular ectopy, although it remains unknown whether these ectopic beats contribute to the risk of malignant arrhythmias or merely serve as markers for individuals at higher risk for sudden death. Although class I antiarrhythmic agents can suppress ventricular ectopy, empiric treatment with them adversely affects survival.[52] Drugs that attenuate disease progression such as β-blockers and aldosterone antagonists reduce the risk of sudden death.

Implantation of an ICD prevents sudden cardiac death and is an effective primary prevention to reduce the risk of mortality in selected patients with HFrEF.[1] Current guidelines recommend use of an ICD for primary prevention in patients receiving GDMT with NYHA class II–III symptoms with a LVEF less than or equal to 35% that are expected to live for at least one year.[1] In patients with NYHA class I symptoms and a LVEF less

than or equal to 30%, an ICD is also recommended for primary prevention if life expectancy exceeds 1 year.[1] An ICD is also indicated for secondary prevention in survivors of sudden cardiac death as these patients are at high risk for recurrent arrhythmias.[1]

Delayed electrical activation of the left ventricle, characterized on the ECG by a QRS duration that exceeds 120 milliseconds, occurs in approximately one third of patients with moderate to severe HFrEF. Since the left and right ventricles normally activate simultaneously, this delay results in asynchronous contraction of the ventricles, which contributes to the hemodynamic abnormalities of HF. Implantation of a specialized biventricular pacemaker to restore synchronous activation of the ventricles improves ventricular function and hemodynamics and is associated with reverse remodeling and increased LVEF. As a result, use of CRT is associated with improvements in exercise capacity, NYHA symptom classification, quality of life, hospitalizations, and mortality in patients with HRrEF.[1,53] Current guidelines recommend CRT in patients receiving GDMT that have NYHA class II–III or ambulatory class IV symptoms and with a QRS duration greater than or equal to 150 milliseconds and LVEF less than or equal to 35%.[1] CRT can also be considered in selected patients with QRS durations of 120 to 149 milliseconds. Combined CRT and ICD devices are available and are frequently used if the patient meets the indications for both devices.

In patients with stage D HFrEF receiving GDMT, the use of mechanical circulatory support with a ventricular assist device (VAD) can be considered in certain patients.[1] Although the criteria for use of these devices continue to rapidly evolve, they are frequently used to bridge patients to cardiac transplant or as destination therapy in patients ineligible for transplant and their use in these settings is associated with better survival and improved functional capacity.[1,54]

Pharmacologic Therapy of HFpEF

11 With a few notable exceptions, many of the drugs used to treat HFrEF are the same as those for treatment of HFpEF. However, the rationale for their use, the pathophysiologic process that is being altered by the drug, and the dosing regimen may be entirely different depending on whether the patient has HFrEF or HFpEF. For example, β-blockers are recommended for the treatment of both HFrEF and HFpEF. In HFpEF, however, β-blockers are used to decrease HR, increase diastolic duration, and modify the hemodynamic response to exercise. In HFrEF, β-blockers are used in the long term to increase the inotropic state and modify LV remodeling. Diuretics also are used in the treatment of both HFrEF and HFpEF. However, the doses of diuretics used to treat HFpEF are, in general, much smaller than those used to treat HFrEF. Antagonists of the RAAS are useful in lowering BP and reducing LVH. Some drugs, however, are used to treat either HFrEF or HFpEF, but not both. Calcium channel blockers such as diltiazem, amlodipine, and verapamil have little utility in the treatment of HFrEF. In contrast, each of these drugs has been proposed as being useful in the treatment of HFpEF.

Drug Therapies for Routine Use in Guideline Directed Medical Therapy for Patients with Stage C HFrEF

4 5 6 7 8 9 10 A treatment algorithm for management of patients with Stage C HFrEF is shown in Fig. 14-8. In general, these patients should receive combined therapy with an ACE inhibitor or ARB and a β-blocker, plus a diuretic if there is evidence of fluid retention. Other therapies including an aldosterone antagonist or the combination of hydralazine-nitrates should also be considered in selected patients.[1] Initiation of digoxin therapy can be considered to decrease hospitalizations in patients with HFrEF that remain symptomatic despite GDMT or added during intial treatment of patients with severe symptoms

while GDMT is started.[1] Drug dosing and monitoring are summarized in **Tables 14-8** and **14-9**.

TABLE 14-8 Drug Dosing Table

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Comments
Loop Diuretics					
Furosemide	Lasix®	20-40 mg once or twice daily	20-160 mg once or twice daily	Cl_{cr} 20-50 mL/min: 160 mg once or twice daily Cl_{cr}<20 mL/min: 400 mg daily	Single doses exceeding those listed are unlikely to elicit additional response
Bumetanide	Bumex®	0.5-1.0 mg once or twice daily	1-2 mg once or twice daily	Cl_{Cr} 20-50 mL/min: 2 mg once or twice daily Cl_{cr}<20 mL/min: 8-10 mg daily	Single doses exceeding those listed are unlikely to elicit additional response
Torsemide	Demadex®	10-20 mg once daily	10-80 mg once daily	Cl_{Cr} 20-50 mL/min: 40 mg once daily Cl_{cr}<20 mL/min: 200 mg daily	Single doses exceeding those listed are unlikely to elicit additional response
ACE Inhibitors					
Captopril	Capoten®	6.25 mg three times daily	50 mg three times daily*		
Enalapril	Vasotec®	2.5 mg twice daily	10-20 mg twice daily*		
Lisinopril	Zestril®, Prinivil®	2.5-5.0 mg once daily	20-40 mg once daily*		
Quinapril	Accupril®	5 mg twice daily	20-40 mg twice daily		
Ramipril	Altace®	1.25-2.5 mg	5 mg twice daily*		
Fosinopril	Monopril®	5-10 mg once daily	40 mg once daily		Undergoes both hepatic and renal elimination
Trandolapril	Mavik®	0.5-1.0 mg once daily	4 mg once daily*		Undergoes both hepatic and renal elimination
Perindopril	Aceon®	2 mg once daily	8-16 mg once daily		Undergoes both hepatic and renal elimination

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Comments
Angiotensin Receptor Blockers					
Candesartan	Atacand®	4 mg once daily	32 mg once daily*		
Valsartan	Diovan®	20-40 mg twice daily	160 mg twice daily*		
Losartan	Cozaar®	25-50 mg once daily	150 mg once daily*		
Beta-Blockers					
Bisoprolol	Zebeta®	1.25 mg once daily	10 mg once daily*		
Carvedilol	Coreg®	3.125 mg twice daily	25 mg twice daily*	Target dose for patients weighing >85 kg is 50 mg twice daily	Should be taken with food
Carvedilol phosphate	Coreg CR®	10 mg once daily	80 mg once daily		Should be taken with food
Metoprolol succinate CR/XL	Toprol-XL®	12.5-25 mg once daily	200 mg once daily*		
Aldosterone Antagonists					
Spironolactone	Aldactone®	eGFR ≥50 mL/min/1.73m^2: 12.5-25 mg once daily	25-50 mg once daily*	eGFR 30-49 mL/min/1.73m^2: 12.5 mg once daily or every other day	The risk of hyperkalemia increases if serum creatinine is >1.6 mg/dL. Avoid if baseline potassium is ≥5 mEq/L
Eplerenone	Inspra®	eGFR ≥50 mL/min/1.73m^2: 25 mg once daily	50 mg once daily*	eGFR 30-49 mL/min/1.73m^2: 25 mg every other day	The risk of hyperkalemia increases if serum creatinine is >1.6 mg/dL. Avoid if baseline potassium is ≥5 mEq/L
Other					
Hydralazine-Isosorbide Dinitrate	Bidil®	Hydralazine 37.5 mg three times daily	Hydralazine 75 mg three times daily* Isosorbide		Indicated in conjunction with standard heart

Drug	Brand Name	Initial Dose	Usual Range	Special Population Dose	Comments
		Isosorbide dinitrate 20 mg three times daily	dinitrate 40 mg three times daily*		failure therapy to improve survival and reduce hospitalizations in self-identified African-American patients
Digoxin	Lanoxin®	0.125-0.25 mg once daily	0.125-0.25 mg once daily	Reduce dose in elderly, patients with low lean body mass, and patients with impaired renal function	Target plasma concentration range is 0.5-0.9 ng/mL. Does not improve survival in patients with HFrEF
Ivabradine	Corlanor®	5 mg twice daily	5-7.5 mg twice daily	Avoid if resting heart rate <60 BPM before treatment	Indicated to reduce the risk of hospitalization in patients with HFrEF with a resting heart rate ≥70 BPM receiving maximally tolerated beta-blocker doses Take with meals
Sacubitril/valsartan	Entresto®	49/51 mg sacubitril/valsartan twice daily	97/103 mg sacubitril/valsartan twice daily*	For patients taking a low dose of or not taking an ACE inhibitor or ARB or if eGFR is <30 mL/min/1.73m^2, the starting dose is 24/26 mg sacubitril/valsartan twice daily	Discontinue ACE inhibitors at least 36 hours before initiating sacubitril/valsartn treatment

*Regimens proven in large clinical trials to reduce mortality.

TABLE 14-9 Drug Monitoring

Drug Class	Adverse Effect	Monitoring Parameters	Comments
ACE inhibitors	Angioedema, cough, hyperkalemia, hypotension, renal dysfunction	BP, electrolytes, BUN, and creatinine	Contraindicated in patients with bilateral renal artery stenosis, history of angioedema, or pregnancy. Assess BP, BUN, creatinine, and electrolytes at baseline and 1-2 weeks after initiation or increase in dose. Goal is target dose from clinical trials or highest tolerated.
ARBs	Hyperkalemia, hypotension, renal dysfunction	BP, electrolytes, BUN, and creatinine	Contraindicated in patients with bilateral renal artery stenosis or pregnancy. Assess BP, BUN, creatinine, and electrolytes at baseline and 1-2 weeks after initiation or increase in dose. Use with caution in patients with a history of ACE inhibitor-associated angioedema. Goal is target dose from clinical trials or highest tolerated.
Sacubitril/valsartan	Angioedema, hyperkalemia, hypotension, dizziness, renal dysfunction	BP, electrolytes, BUN, and creatinine	Contraindicated in patients with a history of angioedema associated with ACE inhibitor or ARB therapy or in pregnancy. Assess BP, BUN, creatinine, and electrolytes at baseline and 1-2 weeks after initiation or dose increase. Start with a low dose and double the dose every 2-4 weeks as tolerated based on BP, serum potassium, and renal function. Goal is target dose from clinical trials or highest tolerated.
Aldosterone antagonists	Gynecomastia/breast tenderness/menstrual irregularities (spironolactone), hyperkalemia, worsening renal function	BP, electrolytes, BUN, and creatinine	Assess BP, BUN, creatinine, and electrolytes at baseline. Check potassium 3 days and 1 week after initiation and then monthly for the first 3 months. Change to eplerenone if gynecomastia develops with spironolactone.
β-blockers	Bradycardia, heart block, bronchospasm, hypotension, worsening HF	BP, HR, ECG, signs and symptoms of worsening HF, blood glucose	Start with low dose and titrate upward no more often than every 2 weeks as tolerated based on BP, HR, and symptoms. Goal is target dose from clinical trials or highest tolerated.

Drug Class	Adverse Effect	Monitoring Parameters	Comments
			Patients may feel worse before they feel better.
Digoxin	GI and CNS adverse effects, brady- and tachyarrhythmias See table 11	electrolytes, BUN, creatinine, ECG, serum digoxin concentration	Target serum digoxin concentration 0.5-0.9 ng/mL.
Ivabradine	Bradycardia, hypertension, atrial fibrillation, luminous phenomena (phosphenes, transiently enhanced brightness in a portion of the visual field)	BP, HR, ECG	Start with 5 mg twice daily and after 2 weeks adjust dose to achieve a resting HR 50-60 BPM. Only use in patients in sinus rhythm.
Diuretics	Hypovolemia, hypotension, hyponatremia, hypokalemia, hypomagnesemia, hyperuricemia, renal dysfunction, thirst	BP, electrolytes, BUN, creatinine, glucose, uric acid, changes in weight, JVD	Dose should be adjusted based on volume status, renal function, electrolytes, and BP. Reassess these parameters 1-2 weeks after dose changes. Goal is lowest dose that maintains euvolemia.
Hydralazine	Hypotension, headache, rash, arthralgia, lupus, tachycardia	BP, HR	
Nitrates	Hypotension, headache, lightheadedness	BP, HR	

Diuretics

7 The compensatory mechanisms in HF stimulate excessive sodium and water retention, often leading to pulmonary and systemic congestion.[55,56] Diuretic therapy, in addition to sodium restriction, is recommended in all patients with clinical evidence of fluid retention. Once fluid overload has been resolved, many patients require chronic diuretic therapy to maintain euvolemia. Among the drugs used to manage HF, diuretics are the most rapid in producing symptomatic benefits. However, diuretics do not prolong survival or (with the possible exception of torsemide) alter disease progression, and therefore are not considered mandatory therapy. Thus, patients who do not have fluid retention would not require diuretic therapy.

The primary goal of diuretic therapy is to reduce symptoms associated with fluid retention, improve exercise tolerance and quality of life, and reduce hospitalizations from HF. Diuretics accomplish this by decreasing pulmonary and peripheral edema through reduction of preload. Although preload is a determinant of CO, the Frank–Starling curve (see Fig. 14-4) shows that patients with congestive symptoms have reached the flat portion of the curve. A reduction in preload improves symptoms but has little effect on the patient's SV or CO until the steep portion of the curve is reached. However, diuretic therapy must be used judiciously because overdiuresis can lead to a reduction in CO, renal perfusion, and symptoms of volume depletion.

Diuretic therapy is usually initiated in low doses in the outpatient setting, with dosage adjustments based on symptom assessment and daily body weight. Change in body weight is a sensitive marker of fluid retention or loss, and it is recommended that patients monitor their status by taking daily morning body weights. Patients who gain 1 lb/day for several consecutive days or 3 to 5 lb (1.4-2.3 kg) in a week should contact their healthcare provider for instructions (which often will be to increase the diuretic dose temporarily). Such action often will allow patients to prevent a decompensation that requires hospitalization. One study demonstrated a significant reduction in emergency department visits with a protocol that directed patients to self-adjust their diuretic dose based on changes in HF symptoms and daily body weight.[57] Hypotension or worsening renal function (eg, increases in serum creatinine) may be indicative of volume depletion and necessitates a reduction in the diuretic dose. Assessing volume status is particularly important before ACE inhibitor or β-blocker initiation or dose uptitration as overdiuresis may predispose patients to hypotension and other adverse effects with increases in ACE inhibitor or β-blocker doses.

11 In patients with HFpEF, diuretic treatment should be initiated at low doses in order to avoid hypotension and fatigue. Hypotension can be a significant problem in the treatment of HFpEF because these patients have a very steep LV diastolic pressure–volume curve such that a small change in volume causes a large change in filling pressure and CO. After the acute treatment of HFpEF has been completed, long-term treatment should include small to moderate oral doses of diuretics (furosemide 20-40 mg/day, chlorthalidone 25-100 mg, or hydrochlorothiazide 12.5-25 mg/day).

Thiazide Diuretics

Thiazide diuretics such as hydrochlorothiazide block sodium reabsorption in the distal convoluted tubule (approximately 5%-8% of filtered sodium). The thiazides therefore are relatively weak diuretics and infrequently are used alone in HF. However, thiazides or the thiazide-like diuretic metolazone can be used in combination with loop diuretics to promote a very effective diuresis. In addition, thiazide diuretics may be preferred in patients with only mild fluid retention and elevated BP because of their more persistent antihypertensive effects compared with loop diuretics.

Loop Diuretics

Loop diuretics are usually necessary to restore and maintain euvolemia in HF. They act by inhibiting a Na–K–2Cl transporter in the thick ascending limb of the loop of Henle, where 20% to 25% of filtered sodium normally is reabsorbed. Because loop diuretics are highly bound to plasma proteins, they are not highly filtered at the glomerulus. They reach the tubular lumen by active transport via the organic acid transport pathway. Competitors for this pathway (probenecid or organic by-products of uremia) can inhibit delivery of loop diuretics to their site of action and decrease effectiveness. Loop diuretics also induce a prostaglandin-mediated increase in renal blood flow, which contributes to their natriuretic effect. Coadministration of NSAIDs, including cyclooxygenase-2 (COX-2) inhibitors, blocks this prostaglandin-mediated effect and can diminish diuretic efficacy. Excessive dietary sodium intake may also reduce the efficacy of loop diuretics. Unlike thiazides, loop diuretics maintain their effectiveness in the presence of impaired renal function, although higher doses may be necessary to obtain adequate delivery of the drug to the site of action.

ACE Inhibitors

5 ACE inhibitors are a key component of the pharmacotherapy of patients with HFrEF.[1] By blocking the conversion of angiotensin I to angiotensin II by ACE, the production of angiotensin II and, in turn,

aldosterone is decreased, but not completely eliminated.[13] This decrease in angiotensin II and aldosterone attenuates many of the deleterious effects of these neurohormones that drive HF progression including ventricular remodeling, myocardial fibrosis, myocyte apoptosis, cardiac hypertrophy, NE release, vasoconstriction, and sodium and water retention.[13] The endogenous vasodilator bradykinin, which is inactivated by ACE, is also increased by ACE inhibitors along with the release of vasodilatory prostaglandins and histamine.[16] The precise contribution of the effects of ACE inhibitors on bradykinin and vasodilatory prostaglandins is unclear. However, the persistence of clinical benefits with ACE inhibitors despite the fact that angiotensin II and aldosterone levels return to pretreatment levels in some patients suggests these are potentially important effects.[13]

Numerous placebo-controlled clinical trials in both symptomatic and asymptomatic patients with reduced LVEF have documented the favorable effects of ACE inhibitor therapy on symptoms, NYHA functional classification, clinical status, heart failure progression, hospitalizations, and quality of life.[13] Importantly, ACE inhibitors improve survival by 20% to 30% compared with placebo and these benefits are maintained with continued therapy.[13] The benefits of ACE inhibitor therapy are independent of the etiology of HF (ischemic vs nonischemic) and are greatest in patients with the most severe symptoms.[13] As efficacy has been demonstrated with numerous agents, the improved outcomes are likely a "class effect" of ACE inhibitors.[1,13]

The most common cause of HFrEF is ischemic heart disease, where MI results in loss of myocytes, followed by ventricular dilation and remodeling. Captopril, ramipril, and trandolapril all benefit post-MI patients whether therapy is initiated early or late after the infarct.[13] Collectively, these studies indicate that ACE inhibitors administered after MI improve overall survival, decrease development of severe HF, and reduce reinfarction and HF hospitalization rates.[13] The effects are most pronounced in higher-risk patients, such as those with symptomatic HF or reduced LVEF, with 20% to 30% reductions in mortality reported in these patients.[13] Post-MI patients without HF symptoms or reduced LVEF (Stage B) should also receive ACE inhibitors to prevent the development of HF and to reduce mortality.[1,13]

The use of ACE inhibitors in patients with chronic kidney disease is particularly relevant since it is a common co-morbidity in patients with HF and is associated with an increased risk of mortality.[58] In spite of the perceived risks, ACE inhibitors are effective in patients with chronic kidney disease and HFrEF.[59,60] Since many patients have concomitant disorders (eg, HTN, previous MI) that also may be favorably affected by ACE inhibitors, chronic kidney disease should not be an absolute contraindication to ACE inhibitor use in patients with reduced LVEF. However, these patients should be monitored carefully for the development of worsening renal function and/or hyperkalemia with special attention to risk factors associated with this complication of ACE inhibitor therapy.[1,60]

An important practical consideration is determining the proper dose of an ACE inhibitor. Despite the overwhelming benefit demonstrated with these agents, they remain underused and underdosed.[61] Also, for patients receiving an ACE inhibitor at hospital discharge, use significantly decreases over time and patients not prescribed ACE inhibitors at discharge were unlikely to have therapy initiated in the outpatient setting.[61] Common reasons cited for underuse or underdosing are concerns about safety and adverse reactions to ACE inhibitors, especially in patients with chronic kidney disease or low blood pressure. Clinical trials establishing the efficacy of these agents titrated drug doses to a predetermined target rather than according to therapeutic response. Although data on the dose-dependent effects of ACE inhibitors in patients with HF are limited, higher doses may reduce the risk of hospitalization, but not mortality, compared with lower doses.[62] In many positive trials of other HF therapies (eg, β-blockers, aldosterone

antagonists), intermediate ACE inhibitor doses were generally used as background therapy. These results emphasize that clinicians should attempt to use ACE inhibitor doses proven beneficial in clinical trials, but if these doses are not tolerated, lower doses can be used with the knowledge that it is unlikely that there are differences in mortality between the high and low doses. Also, initiation of β-blocker therapy should not be delayed until target ACE inhibitor doses are achieved since the addition of a β-blocker is proven to reduce mortality, whereas that is not the case with increasing ACE inhibitor doses.

In summary, the evidence that ACE inhibitors improve symptoms, slow disease progression, and decrease mortality in patients with HFrEF is unequivocal. As a result, current guidelines recommend that all patients with HFrEF, regardless of whether or not symptoms are present, should receive ACE inhibitors, unless there are contraindications.[1] The clear benefit of ACE inhibitors is also evident by the selection of these agents as a key performance measure by the Joint Commission and Centers for Medicare and Medicaid Services (CMS). This measure states that patients with left ventricular systolic dysfunction discharged from the hospital should receive ACE inhibitors unless there is documentation in the medical record of an absolute contraindication or drug intolerance.

Angiotensin II Receptor Blockers

5 The crucial role of the RAAS in HF development and progression is well established as are the benefits of inhibiting this system with ACE inhibitors. ACE inhibitors decrease angiotensin II production in the short term, but these agents do not completely suppress generation of this hormone and angiotensin II can be formed in a number of tissues, including the heart, through non-ACE-dependent pathways (eg, chymase, cathepsin, and kallikrein).[7,13] By blocking the angiotensin II receptor subtype, AT1, ARBs attenuate the deleterious effects of angiotensin II on ventricular remodeling, regardless of the site of origin of the hormone. Since ARBs do not inhibit the ACE enzyme, these agents do not affect bradykinin, which is linked to ACE inhibitor cough and angioedema.

Although a number of ARBs are currently available, candesartan, losartan, or valsartan are recommended by the guidelines as the efficacy of these agents has been demonstrated in clinical trials.[1] In these studies, ARBs reduced mortality and hospitalizations and improved symptoms.[63]

A comparison of high-dose (150 mg) versus low-dose (50 mg) losartan treatment showed that higher doses slightly (~10%) reduced the primary end point of death or hospital admission for HF.[64] Significant increases in renal insufficiency, hyperkalemia, and hypotension were also associated with the higher dose. These findings point out the importance of titrating the doses of these medications to the targets achieved in clinical trials.

Combination therapy with an ACEI inhibitor and an ARB remains controversial. The addition of candesartan to ACE inhibitor and β-blocker therapy produced incremental reductions in cardiovascular death and hospitalizations for HF, but did not improve overall survival.[65] A meta-analysis showed that combination therapy is associated with increased risk of medication discontinuation due to adverse effects, hyperkalemia, renal insufficiency, and hypotension.[66] Collectively, these results suggest the addition of an ARB to optimal HF therapy (ACE inhibitors, β-blockers, diuretics, etc.) offers, at best, marginal benefits with increased risk of adverse effects. Current guidelines recommend the addition of an ARB can be considered in patients with HFrEF who remain symptomatic despite treatment with an ACE inhibitor and a β-blocker if an aldosterone antagonist cannot be used. Addition of an aldosterone antagonist is preferred over an ARB as this combination improves survival in patients with HFrEF.[17,18,19]

Although ACE inhibitors remain first-line therapy in patients with Stage C HFrEF, the current guidelines recommend the use of ARBs in patients who are unable to tolerate (usually due to cough) ACE inhibitors.[1] Caution should be exercised when ARBs are used in patients with angioedema from ACE inhibitors as some cross-reactivity is reported.[67] ARBs are not an alternative in patients with hypotension, hyperkalemia, or renal insufficiency secondary to ACE inhibitors because they are as likely to cause these adverse effects. Also, the combined use of ACE inhibitors, ARBs, and aldosterone antagonists is not recommended because of the increased risk of renal dysfunction and hyperkalemia.[1] The specific drugs and doses proven to be effective in clinical trials should be used (see Table 14-8).

11 The role of ARBs in the treatment of HFpEF is less clear. The CHARM-Preserved trial was the first large prospective study to demonstrate some benefit (reduction in hospitalizations for HF) of an ARB in patients with HFpEF receiving standard background treatment, although no improvement in cardiovascular death was observed.[68] Adverse effects of candesartan in this study were frequent; 22% of candesartan-treated patients discontinued therapy because of hypotension, increased serum creatinine, or hyperkalemia. In the Irbesartan in Heart Failure with Preserved EF (I-PRESERVE) trial, Irbesartan was compared with placebo in over 4,000 patients with symptoms of HF and a LVEF of at least 45%.[69] There was no significant difference between Irbesartan and placebo with regard to death or hospitalization for cardiovascular causes. No benefit was seen in quality-of-life measures. There was a high discontinuation rate of the study drug in this trial (33%), as well as a high rate of postrandomization initiation of ACE inhibitors (20%) and spironolactone (10%), which may have contributed to the outcome in this trial.

β-Blockers

6 There is overwhelming evidence from multiple randomized, placebo-controlled clinical trials that *β*-blockers reduce morbidity and mortality in patients with HFrEF. As such, the ACC/AHA guidelines on the management of HF recommend that *β*-blockers should be used in all stable patients with HF and a reduced left ventricular EF in the absence of contraindications or a clear history of *β*-blocker intolerance.[1] Patients should receive a *β*-blocker even if their symptoms are mild or well controlled with diuretic and ACE inhibitor therapy. Importantly, it is not essential that ACE inhibitor doses be optimized before a *β*-blocker is started because the addition of a *β*-blocker is likely to be of greater benefit than an increase in ACE inhibitor dose.[1] *β*-Blockers are also recommended for asymptomatic patients with a reduced left ventricular EF (Stage B) to decrease the risk of progression to HF.

β-Blockers have been studied in over 20,000 patients with HFrEF in placebo-controlled trials. Three *β*-blockers have been shown to significantly reduce mortality compared with placebo: carvedilol, metoprolol succinate (CR/XL), and bisoprolol. Each was studied in a large population with the primary end point of mortality. Carvedilol was the first *β*-blocker shown to improve survival in HF. In the United States Carvedilol Heart Failure Study, 1,094 patients were randomized to carvedilol or placebo in addition to standard therapy, including an ACE inhibitor, digoxin, and diuretic.[70] The study was stopped early because of a 65% reduction in the risk of death with carvedilol. Nearly 4,000 patients were randomized to metoprolol succinate (Toprol-XL®) or placebo in the Metoprolol CR/XL Randomised Intervention Trial in Congestive Heart Failure (MERIT-HF), the largest *β*-blocker mortality trial to date.[71] This trial was also stopped early because of a significant survival benefit with *β*-blockade. Specifically, metoprolol was associated with a 34% reduction in total mortality, a 41% reduction in sudden death, and a 49% reduction in death from worsening HF. Bisoprolol was studied in over 2,600 patients enrolled in the Cardiac Insufficiency Bisoprolol Study II

(CIBIS II).[72] The study was also stopped prematurely because of a 34% reduction in total mortality with bisoprolol compared with placebo. Bisoprolol was also associated with a 44% reduction in sudden death and a 26% reduction in death due to worsening HF. Multiple posthoc subgroup analyses of data from the MERIT-HF and CIBIS II trials suggest that the benefits of β-blockade occur regardless of HF etiology or disease severity.

The majority of participants in MERIT-HF and CIBIS II had either NYHA class II or class III HFrEF. The efficacy and safety of β-blockers in patients with class IV HF were examined in the Carvedilol, Prospective, Randomized, Cumulative Survival (COPERNICUS) trial.[73] This trial randomized nearly 2,300 clinically stable patients who had symptoms at rest or with minimal exertion to carvedilol or placebo. Like the other studies, COPERNICUS was stopped prematurely after carvedilol produced a 35% relative reduction in mortality. Carvedilol was well tolerated in this population, with fewer participants receiving carvedilol compared with placebo requiring permanent discontinuation of study medication.

Data supporting the use of β-blockers in asymptomatic patients with left ventricular systolic dysfunction (Stage B) come from a study of carvedilol in post-MI patients with a decreased left ventricular EF.[74] While the primary end point of all-cause mortality or hospital admission for cardiovascular problems was similar in the carvedilol and placebo groups, carvedilol significantly reduced all-cause mortality alone compared with placebo. Cardiovascular mortality and nonfatal MI were also lower among carvedilol-treated patients.

In addition to improving survival, β-blockers have been shown to improve multiple other end points. All the large clinical trials demonstrated 15% to 20% reductions in all-cause hospitalization and 25% to 35% reductions in hospitalizations for worsening HF with β-blocker therapy.[72,75,76] Studies have also shown consistent improvements in left ventricular systolic function with β-blockers, with increases in LVEF of 5 to 10 units (eg, from an EF of 20%-25% or 30%) after several weeks to months of therapy. β-Blockers have also been shown to decrease ventricular mass, improve the sphericity of the ventricle, and reduce systolic and diastolic volumes (left ventricular end-systolic volume and LVEDV).[77] These effects are often collectively called *reverse remodeling*, referring to the fact that they return the heart toward more normal size, shape, and function.

The effects of β-blockers on symptoms and exercise tolerance varied among studies. Many studies showed improvements in NYHA functional class, patient symptom scores or quality-of-life assessments (such as the Minnesota Living with Heart Failure Questionnaire), and exercise performance, as assessed by the 6-minute walk test.[75,76] Other investigators found significant reductions in mortality with β-blockers but no significant improvement in symptoms.[78] As such, it is important to educate patients that β-blocker therapy is expected to positively influence disease progression and survival even if there is little to no symptomatic improvement.

Most participants in β-blocker trials were on ACE inhibitors at baseline since the benefits of ACE inhibitors were proven prior to β-blocker trials. Whether the strategy of starting a β-blocker prior to an ACE inhibitor is safe and effective was addressed in CIBIS III, in which patients with mild to moderate symptoms were randomized to initial therapy with either bisoprolol or enalapril.[79] Rates of death or hospitalization were similar with the two strategies. However, the trial failed to satisfy the prespecified statistical criterion for noninferiority of initial therapy with a β-blocker compared with an ACE inhibitor. In the absence of more compelling evidence, ACE inhibitors should be started first in most patients. Initiating a β-blocker first may be advantageous for patients with evidence of excessive SNS activity (eg, tachycardia) and may also be appropriate for patients whose renal function or potassium concentrations preclude starting an ACE

inhibitor (or ARB) at that time. However, the risk for decompensation during β-blocker initiation may be greater in the absence of preexisting ACE inhibitor therapy, and careful monitoring is essential.

β-Blockers antagonize the detrimental effects of the SNS described earlier in the chapter. To this end, potential mechanisms to explain the favorable effects of β-blockers in HF include antiarrhythmic effects, attenuating or reversing ventricular remodeling, decreasing myocyte death from catecholamine-induced necrosis or apoptosis, preventing fetal gene expression, improving left ventricular systolic function, decreasing HR and ventricular wall stress thereby reducing myocardial oxygen demand, and inhibiting plasma renin release.[1]

Components that are critical for successful β-blocker therapy include appropriate patient selection, drug initiation and titration, and patient education. β-Blockers should be initiated in stable patients who have no or minimal evidence of fluid overload.[1] While β-blockers are typically started in the outpatient setting, there are data indicating that initiation of a β-blocker prior to discharge in patients who are hospitalized for decompensated HF increases β-blocker usage compared with outpatient initiation without increasing the risk of serious adverse effects.[76] However, β-blockers should not be started in patients who are hospitalized in the intensive care unit or recently required IV inotropic support. In unstable patients, other HF therapy should be optimized and then β-blocker therapy reevaluated once stability is achieved.

Initiation of a β-blocker at normal doses in patients with HF may lead to symptomatic worsening or acute decompensation owing to the drug's negative inotropic effect. For this reason, β-blockers are listed as drugs that may exacerbate or worsen HF (see Table 14-3). To minimize the likelihood for acute decompensation, β-blockers should be started in very low doses with slow upward dose titration and close monitoring. β-Blocker doses should be doubled no more often than every 2 weeks, as tolerated, until the target or maximally tolerated dose is reached. According to current guidelines, target doses are those associated with reductions in mortality in placebo-controlled clinical trials.[1] The starting and target doses achieved in clinical trials are described in Table 14-8. Data with both metoprolol and carvedilol suggest that HR may serve as a guide to the degree of β-blockade and that lower β-blocker doses might be considered reasonable if the reduction in HR indicates a good response to β-blocker therapy.[81] In fact, it remains uncertain whether β-blocker dose or the degree of HR reduction is the optimal end point to guide dose titration and predict survival.

A meta-analysis of 23 randomized trials involving over 19,000 patients receiving β-blockers for HF compared HR reduction and β-blocker dose as predictors of survival.[81] Overall, β-blocker treatment was associated with a 24% mortality reduction. However, trials with the largest decrease in HR (median 15 beats per minute) reported a 36% reduction in mortality, whereas trials with the smallest HR reduction (median 8 beats/min) showed only a 9% mortality reduction. Greater magnitude of HR reduction was significantly associated with greater improvement in survival. On the other hand, in contrast to findings from other investigators,[82] no relationship between β-blocker dose and magnitude of mortality decrease was found. The results from this study suggest that the degree of β-blocker-mediated reduction in resting HR, but not β-blocker dose, is associated with the magnitude of improved survival. However, the analysis is limited by its retrospective design, inability to account for other factors affecting HR (eg, vagal activity, β-receptor pharmacogenomics), and reliance on resting HR as a surrogate marker for extent of β-blockade. Although resting HR is routinely used clinically to evaluate extent of β-blockade, it is not as accurate as inhibition of exercise HR. Whether magnitude of resting HR reduction or achievement of clinical trial doses is the optimal surrogate marker for improved outcomes with β-blockers in HF remains uncertain and may only be definitively determined by prospective trials.

Of note, the smallest commercially available tablet of bisoprolol is a scored 5-mg tablet. Since the recommended starting dose of 1.25 mg/day is not readily available, bisoprolol is the least commonly used of the three agents and, in fact, is not approved by the FDA for use in HF. Thus, therapy is generally limited to either carvedilol or metoprolol succinate, and there is no compelling evidence that one drug is superior to the other. A controlled-release formulation of carvedilol (carvedilol CR) that allows once-daily dosing is available, and pharmacokinetic studies demonstrate similar degrees of drug exposure with the controlled- and immediate-release formations of the drug.[79]

Good communication between the patient and healthcare provider(s) is particularly important for successful therapy. Patients should understand that dose uptitration is a long, gradual process and that achieving the target dose is important to maximize the benefits of therapy. Patients should also be aware that response to therapy may be delayed and that HF symptoms may actually worsen during the initiation period. In the event of worsening symptoms, patients who understand the potential benefits of long-term β-blocker therapy may be more likely to continue treatment.

In summary, the data provide clear evidence that β-blockers slow disease progression, decrease hospitalizations, and improve survival in HFrEF. β-Blockers have also been shown to improve quality of life in many patients with HF, although this is not a universal finding. Based on these data, β-blockers are recommended as standard therapy for all patients with HFrEF, regardless of the severity of their symptoms. Clinical trial experience shows that target β-blocker doses can be achieved in the majority of patients provided that appropriate initiation, titration, and education are implemented.

11 In patients with HFpEF, β-blockers may help to lower and maintain low pulmonary venous pressures by decreasing HR and increasing the duration of diastole. Tachycardia is poorly tolerated in patients with HFpEF for several reasons. First, rapid HRs cause an increase in myocardial oxygen demand and a decrease in coronary perfusion time. This can promote ischemia even in the absence of epicardial CAD. Second, incomplete relaxation between cardiac cycles may result an increase in diastolic pressure relative to volume. Third, a rapid rate reduces diastolic filling time and ventricular filling. Thus, many clinicians use β-blockers (and nondihydropyridine calcium channel blockers) to prevent excessive tachycardia and produce a relative bradycardia in patients with diastolic dysfunction. However, excessive bradycardia can result in a fall of CO despite an increase in LV filling.[2] Such considerations underscore the need for individualizing therapeutic interventions that affect HR. In general, it is not necessary to start at an extremely low dose and titrate the β-blocker in a slow, progressive fashion in HFpEF as it is in HFrEF. However, because older patients have numerous comorbidities, and take many concomitant medications, it is prudent to start with a moderate dose of β-blockers. A meta-analysis examining the effects of β-blocker therapy on clinical outcomes in patients with HFpEF found lower all-cause mortality (relative risk 0.81, $p<0.001$) but no significant reduction for HF hospitalizations in observational studies.[84] These findings were not replicated in two small randomized trials; however those studies were underpowered and many patients were lost to followup.

Aldosterone Antagonists

8 Spironolactone and eplerenone are aldosterone antagonists that work by blocking the mineralocorticoid receptor, the target site for aldosterone, and, thus, they are also referred to as mineralocorticoid receptor antagonists. In the kidney, aldosterone antagonists inhibit sodium reabsorption and potassium excretion. While the diuretic effects with low doses of aldosterone antagonists are minimal, the potassium-sparing effects can have significant consequences as discussed later. In the heart, aldosterone antagonists inhibit cardiac extracellular matrix and collagen deposition, thereby attenuating cardiac fibrosis and ventricular

remodeling.[81] Aldosterone antagonists also attenuate the systemic proinflammatory state, atherogenesis, and oxidative stress caused by aldosterone. In addition, there is evidence that aldosterone antagonists may attenuate aldosterone-induced calcium excretion and reductions in bone mineral density and protect against fractures in HF.[82] While spironolactone historically has been viewed as a diuretic, this is believed to contribute little to its benefits in HF, in part, because the doses used have minimal diuretic effect.[17] Thus, as with ACE inhibitors and β-blockers, the data on aldosterone antagonists also support the neurohormonal model of HF.

Three large, randomized controlled trials have evaluated low-dose aldosterone antagonism in patients with either HF or post-MI and left ventricular dysfunction. All three trials excluded patients with significant renal dysfunction (eg, serum creatinine above 2.5 mg/dL [221 µmol/L]) and elevated serum potassium (eg, above 5 mEq/L [5 mmol/L]) at baseline.

The RALES trial randomized over 1,600 patients with current or recent NYHA class IV HFrEF to aldosterone blockade with spironolactone 25 mg/day or placebo.[17] Patients were also treated with standard therapy, usually including an ACE inhibitor, loop diuretic, and digoxin. Those with a serum creatinine concentration above 2.5 mg/dL (221 µmol/L) or a serum potassium concentration above 5 mEq/L (5 mmol/L) was excluded. The study was stopped prematurely after an average followup of 24 months because of a significant 30% reduction in the primary end point of total mortality with spironolactone. Spironolactone reduced mortality due to both progressive HF and sudden cardiac death. It also produced a 35% reduction in hospitalizations for worsening HF and significant symptomatic improvement, as assessed by changes in NYHA functional class. The low dose of spironolactone was well tolerated in RALES. The most common adverse effect was gynecomastia, which occurred in 10% of men on spironolactone compared with 1% of men on placebo, and led to treatment discontinuation in 2% of patients. There were statistically (but not clinically) significant increases in serum creatinine (by 0.05-0.10 mg/dL) and potassium concentrations (by 0.30 mEq/L) with spironolactone. The incidence of serious hyperkalemia (greater than 6 mEq/L) was minimal and did not differ between spironolactone- and placebo-treated groups.

The EPHESUS trial evaluated the effect of selective antagonism of the mineralocorticoid receptor with eplerenone in patients with left ventricular dysfunction after MI.[18] To be eligible for study participation, patients had to have evidence of either HF or diabetes. Over 6,600 patients were randomized within 3 to 14 days of MI to eplerenone, titrated to 50 mg/day, or placebo in addition to standard therapy, which usually included an ACE inhibitor, β-blocker, aspirin, and diuretics. Treatment with eplerenone was associated with a significant 15% relative reduction in the risk for death from any cause and a 15% reduction in the risk of hospitalization from HF. Serious hyperkalemia occurred in 5.5% of eplerenone-treated patients and 3.9% of placebo-treated patients.

Most recently, the EMPHASIS-HF trial demonstrated significant improvements in clinical outcomes with aldosterone antagonism in mild HFrEF.[19] Over 2,700 patients with NYHA class II HF and a LVEF of 35% or less were randomized to eplerenone up to 50 mg/day (mean dose of 39 mg/day) or placebo, in addition to receiving treatment with an ACE inhibitor or ARB and β-blocker. Eligible patients were hospitalized for a cardiovascular reason within 6 months of study entry or had a plasma BNP of at least 250 pg/mL (72 pmol/L) or an N-terminal proBNP of at least 500 pg/mL (59 pmol/L) in men and 750 pg/mL (89 pmol/L) in women. The trial was stopped prematurely after a median followup of 21 months because of a significant benefit with eplerenone. Eplerenone treatment reduced the primary end point of cardiovascular death or HF hospitalization by 37%, all-cause and cardiovascular mortality by 24%, and hospitalization for HF by 42%. A posthoc analysis of the data also showed a reduction in the incidence of new-onset atrial fibrillation or

flutter with eplerenone. The rate of serum potassium greater than 5.5 mEq/L (5.5 mmol/L) was 11.8% in the eplerenone group and 7.2% with placebo.

The TOPCAT trial examined the effect of spironolactone in patients with HFpEF.[21] TOPCAT randomized 3,445 patients with symptomatic heart failure and an ejection fraction of 45% or greater to spironolactone up to 45 mg/day (mean dose of 25 mg/day) or placebo. As an additional criterion for inclusion, patients had to either have a hospitalization within 1 year in which heart failure management was a major component or a BNP of at least 100 pg/mL (or N-terminal proBNP of at least 360 pg/mL) within 60 days of study entry. The primary outcome was the composite of death from cardiovascular causes, aborted cardiac arrest, or hospitalization for heart failure. After a mean follow-up of 3.3 years, there was no difference in the primary outcome or in the secondary outcomes of all-cause mortality, hospitalization for any reason, myocardial infarction, or stroke between groups. However, there was a significant 17% reduction in the risk for hospitalization for heart failure with spironolactone compared to placebo. There was a higher rate of hyperkalemia (serum potassium greater than or equal to 5.5 mEq/L) in the spironolactone group, but the incidence of serious side effects was similar between groups. Prespecified subgroup analysis showed a benefit with spironolactone among those enrolled on the basis of an elevated natriuretic peptide level, but not in those enrolled on the basis of the hospitalization criterion. There also appeared to be a difference in outcomes by region of enrollment. Approximately 51% of patients were enrolled from the Americans (United States, Canada, Argentina, and Brazil), and the remainder were enrolled from Eastern Europe (Russia and the Republic of Georgia). Posthoc analysis showed a greater reduction in the primary outcome with spironolactone among patients from the Americans, but not in those from Eastern Europe.[20] While the prespecified test for interaction between region and study arm was not significant, differences in baseline characteristics by region and the lower event rate overall in patients from Eastern Europe, confound the interpretation of the study results.

Current guidelines recommend adding a low-dose aldosterone antagonist to standard therapy to improve symptoms, reduce the risk of HF hospitalization, and increase survival in select patients provided that potassium and renal function can be carefully monitored.[1] Based on the clinical trial data low-dose aldosterone antagonists are appropriate for two groups of patients: those with mild to moderately severe HFrEF (NYHA class II-IV) who are receiving standard therapy and those with left ventricular dysfunction and either acute HF or diabetes early after MI.[1,85] Among patients with mild HFrEF (NYHA class II), aldosterone antagonists should be considered in those with a prior hospitalization for cardiovascular reasons or an elevated plasma BNP or N-terminal proBNP level. An aldosterone antagonist may be preferred over an ARB in patients with persisting symptoms despite ACE inhibitor and β-blocker therapy provided that serum potassium and renal function are acceptable.[1,85] Current guidelines were published prior to the completion of TOPCAT, and there are no clear guidelines on aldosterone antagonist use for patients with HFpEF or others who fall outside the populations studied in these clinical trials. On the basis of findings from TOPCAT, it may be reasonable to add an aldosterone antagonist to decrease risk for hospitalization for heart failure in patients with HFpEF, especially if plasma natriuretic peptide levels are elevated.

Despite the clear benefits of aldosterone antagonists in patients with mild to severe HFrEF, registry data show that only one third of patients meeting guideline criteria for an aldosterone antagonist actually receive one.[87] The low use of aldosterone antagonists is likely due in large part to safety concerns. The clinical trial data suggest that aldosterone antagonists in HF are associated with minimal risk when used appropriately (eg, in those with adequate renal function and with close laboratory monitoring). However, shortly after publication of RALES, an observational study of approximately 1.3 million elderly patients in the Ontario Drug Benefit Program found that the increase in the spironolactone prescription rate following the

publication of RALES was accompanied by nearly threefold increases in the rate of hospital admissions and the rate of death related to hyperkalemia.[88] In addition, small case series showed that 25% to 35% of patients treated outside the controlled clinical trial setting developed hyperkalemia (greater than 5 mEq/L [greater than 5 mmol/L]) and that 10% to 12% developed serious hyperkalemia.[89]

Potential factors contributing to the high incidence of hyperkalemia in clinical practice include the initiation of aldosterone antagonists in patients with impaired renal function or high potassium concentrations and the failure to decrease or stop potassium supplements when starting aldosterone antagonists. Other risk factors for hyperkalemia include diabetes, inadequate laboratory monitoring, high potassium intake, and concomitant use of both ACE inhibitors and ARBs or NSAIDs. The ACC/AHA recommended strategies to minimize the risk for hyperkalemia with aldosterone antagonists in HF.[1] These strategies are summarized in **Table 14-10**. Chief among these recommendations is to avoid aldosterone antagonists in patients with renal dysfunction or elevated serum potassium. It is important to emphasize here that serum creatinine may overestimate renal function in the elderly and in patients with decreased muscle mass, in whom creatinine clearance should serve as a guide for the appropriateness of aldosterone antagonist therapy. The risk for hyperkalemia is dose dependent, and the morbidity and mortality reductions with aldosterone antagonists in clinical trials occurred at low doses (ie, spironolactone 25 mg/day and eplerenone 50 mg/day). Therefore, the doses of aldosterone antagonists should be limited to those associated with beneficial effects in order to decrease the risk for hyperkalemia. Initiation of every-other-day dosing is appropriate for patients with marginal renal function or who are otherwise at high risk for hyperkalemia. Spironolactone also interacts with androgen and progesterone receptors, which may lead to gynecomastia, impotence, and menstrual irregularities in some patients. Such adverse effects are less frequent with eplerenone owing to its low affinity for the progesterone and androgen receptors.

TABLE 14-10 Recommended Strategies for Reducing the Risk for Hyperkalemia with Aldosterone Antagonists

- Avoid starting aldosterone antagonists in patients with any of the following:
    - Serum creatinine concentration >2.0 in women or >2.5 mg/dL in men or a creatinine clearance <30 mL/min/1.73 m^2
    - Recent worsening of renal function
    - Serum potassium concentration >5.0 mEq/L
    - History of severe hyperkalemia
- Start with low doses (12.5 mg/day for spironolactone and 25 mg/day for eplerenone) especially in the elderly and in those with diabetes or a creatinine clearance <50 mL/min/1.73 m^2.
- Decrease or discontinue potassium supplements when starting an aldosterone antagonist.
- Avoid concomitant use of NSAIDs or COX-2 inhibitors.
- Avoid concomitant use of high-dose ACE inhibitors or ARBs.
- Avoid triple therapy with an ACE inhibitor, ARB, and aldosterone antagonist.

- Monitor serum potassium concentrations and renal function within 3 days and 1 week after the initiation or dose titration of an aldosterone antagonist or any other medication that could affect potassium homeostasis. Thereafter, potassium concentrations and renal function should be monitored monthly for the first 3 months, and then every 3 months.
- If potassium exceeds 5.5 mg/dL at any point during therapy, discontinue any potassium supplementation or, in the absence of potassium supplements, reduce or stop aldosterone antagonist therapy.
- Counsel patients to:
    - Limit intake of high potassium-containing foods and salt substitutes.
    - Avoid the use of over-the-counter NSAIDs.
    - Temporarily discontinue aldosterone antagonist therapy if diarrhea develops or diuretic therapy is interrupted.

Adapted from Yancy CW, Jessup M, Bozkurt B, et al. 2013 ACCF/AHA guideline for the management of heart failure: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2013;62:e147-239.

Only 10% of RALES participants were taking β-blockers at baseline since the benefits of β-blockers in HF were not appreciated fully at the time the trial began.[17] β-Blockers inhibit plasma renin release and may provide additional suppression of the RAAS when used with ACE inhibitors. Thus, there has been some speculation about whether spironolactone will provide further benefit in patients receiving both ACE inhibitors and β-blockers. However, data from EPHESUS and EMPHASIS provide some clarity to this issue, since the majority of EPHESUS participants were on β-blockers at baseline, and the trial still demonstrated significant reductions in mortality with the addition of eplerenone.[18,19]

Drug Therapies to Consider for Selected Patients with HFrEF

Nitrates and Hydralazine

9 Nitrates and hydralazine were originally combined in the treatment of HFrEF because of their complementary hemodynamic actions. Nitrates, by serving as nitric oxide donors, activate guanylate cyclase to increase cyclic guanosine monophosphate (cGMP) in vascular smooth muscle resulting in venodilation and decreased preload. Hydralazine is a direct-acting arterial vasodilator causing a decrease in SVR and resultant increases in SV and CO (see Fig. 14-1). However, the beneficial effects of hydralazine and nitrates extend beyond their hemodynamic actions and are likely related to attenuating the biochemical processes driving HF progression.[90]

The efficacy of the combination of hydralazine and ISDN has been evaluated in three large, randomized clinical trials. The first trial predated the use of ACE inhibitors and β-blockers and found that the combination of hydralazine and isosorbide dinitrate reduced mortality compared with placebo in patients receiving diuretics and digoxin.[91] A subsequent study demonstrated that an ACE inhibitor improved survival compared to this combination.[92] Posthoc analysis of these trials suggested that the combination of

hydralazine and ISDN was more effective in African Americans, and led to examining the efficacy of adding the combination to standard therapy in the African-American Heart Failure Trial (A-HeFT).[90] This study enrolled self-identified African Americans with NYHA class III or IV HFrEF receiving standard therapy and compared outcomes in patients randomized to the fixed-dose combination of hydralazine/Isosorbide dinitrate (BiDil®) or placebo.[93] The trial was terminated early because of a significant 43% reduction in all-cause mortality in patients receiving hydralazine/isosorbide compared with placebo. Based on these results, BiDil® was approved by the FDA to treat HFrEF in African Americans.

The mechanism for the beneficial effects of hydralazine/ISDN remains uncertain but is most likely related to normalization of the increased oxidative stress and reduced nitric oxide signaling that contributes to HF progression. By serving as a nitric oxide donor, nitrates increase nitric oxide bioavailability and hydralazine reduces oxidative stress.[90,91] Nitric oxide attenuates myocardial remodeling and may play a protective role in HF. African Americans may have less nitric oxide availability compared with non-African Americans, and, thus, may derive particular benefit from therapy that enhances nitric oxide bioavailability. Whether the benefits of adding hydralazine/ISDN to standard therapy extend to non-African Americans remains to be prospectively evaluated.

Guidelines recommend the addition of hydralazine/ISDN to self-described African Americans with HFrEF and NYHA class III–IV symptoms treated with ACE inhibitors and β-blockers.[1] Hydralazine/ISDN can also be useful in patients unable to tolerate either an ACE inhibitor or ARB because of renal insufficiency, hyperkalemia, or possibly hypotension.[1]

Several potential obstacles limit the use of hydralazine/ISDN.[90] The first is the need for frequent dosing, with the fixed-dose combination administered three times daily. Second, adverse effects are common with hydralazine/ISDN, with nearly 30% of patients reporting dizziness, as well as headache and GI distress, all occurring more frequently than with placebo.[91,93] A third potential obstacle is the high cost of the BiDil® fixed-dose combination product compared with that of the individual generic drugs purchased separately. Because of the high cost, many clinicians use generic hydralazine and ISDN as separate agents, rather than the combination product. Although the generic and brand name products are not bioequivalent as determined in healthy volunteer studies, it is unknown if these pharmacokinetic differences impact clinical outcomes.[90]

HFpEF

In contrast to the beneficial effects of hydralazine/ISDN in patients with HFrEF, the effects in patients with HFpEF are less clear. Nitrates are frequently used in patients with HFpEF to improve exercise tolerance although their actual benefits are poorly understood. A recent study determined the effect of increasing doses of isosorbide mononitrate (30-120 mg daily) on exercise tolerance in 110 patients with HFpEF.[94] These investigators found that compared to placebo, a dose-dependent reduction in activity levels was found in patients receiving isosorbide mononitrate.[94] In addition, isosorbibe mononitrate did not improve quality of life or plasma NT-proBNP concentrations. Adverse events, including worsening HF and presyncope/syncope, were more frequent in the isosorbide mononitrate treatment arm. These findings suggest that in the absence of another indication for nitrate therapy (eg, angina), nitrates provide limited benefits to patients with HFpEF.

Angiotensin II Receptor Blocker/Neprilysin Inhibitor (ARNI)

The first angiotensin receptor/neprilysin inhibitor approved for the treatment of patients with HFrEF is valsartan/sacubitril. It is a crystalline complex composed of the ARB valsartan and sacubitril, a neprilysin inhibitor prodrug. After ingestion, sacubitril dissociates from the complex and is cleaved into its active form LBQ657, which inhibits the action of neprilysin that degrades natriuretic peptides (NPs) and bradykinin.[95]

Natriuretic pepetides are beneficial because they cause vasodilation, increase glomerular filtration, natriuresis, and diuresis. Neprilysin is a neutral endopeptidase, which is one of the enzymes that breaks down the body's endogenous NPs. By inhibiting neprilysin, LBQ657 promotes vasodilation through a different mechanism than the ARB.[95]

BNP and NT-proBNP plasma concentrations are elevated in the setting of worsening heart failure and have been used to evaluate and monitor the volume status of patients with HF. If patients are receiving sacubitril/valsartan, BNP concentrations will be "falsely elevated" and cannot be used in monitoring patients. However, NT-proBNP is not a substrate for neprilysin, therefore it may be used in monitoring.

The PARADIGM-HF study tested the hypothesis that treatment with an ARNI (sacubitril/valsartan) would be superior to ACE inhibition.[23] In this study, 8,442 patients with NYHA Class II–IV heart failure and an ejection fraction less than 40% were randomized to a target dose of sacubitril/valsartan 200 mg (97 mg/103 mg) twice daily or enalapril 10 mg twice daily. The primary outcome of the trial was a composite of death from cardiovascular causes or first hospitalization for heart failure. There was a statistically significant 20% relative risk reduction in the primary outcome for patients receiving sacubitril/valsartan (21.8%) compared to enalapril (26.5%). A similar reduction was seen in each component of the primary endpoint. Death from any cause was also significantly reduced in the sacubitril/valsartan treated patients. The trial was ended after a median of 27 months of follow-up. Twenty-one patients would need to treated for the duration of the study in order to prevent one primary event.[23]

The majority of patients in PARADIGM-HF were white (66%) males (78%) with NYHA class II symptoms (70%). At the time of randomization 80% of patients were taking diuretics, 93% β-blockers, 55% aldosterone antagonists, and 30% digitalis. A small number of patients in each group had an ICD (15%) or cardiac resynchronization therapy (7%). Hypotension occurred more frequently in patients randomized to sacubitril/valsartan compared to enalapril. However, more patients receiving enalapril experienced cough and hyperkalemia greater than 6.0 mEq/L. Angioedema was rare in either treatment group.

HFpEF

Sacubitril/valsartan was studied in the phase II PARAMOUNT trial, where NT-proBNP levels were significantly reduced after 12 weeks of therapy when compared to valsartan alone.[96] This trial formed the basis of the larger phase III study PARAGON, which is intended to enroll over 4,000 patients with a preserved EF.

Ivabradine

Ivabradine has been recently approved to reduce hospitalizations in patients with HFrEF. This agent has a unique pharmacology as it blocks the I_f current in the sinoatrial node that is responsible for controlling the heart rate.[97,98] By blocking this current, ivabradine slows the spontaneous depolarization of the sinus node resulting in a dose-dependent slowing of the heart rate. Ivabradine's effects are specific to the I_f current and this agent does not affect BP, myocardial contractility, or AV conduction.[97,98]

Elevated resting heart rate (greater than 70-80 BPM) is emerging as an important independent risk factor for

adverse outcomes in patients with HF and is associated with increased hospital admissions, disease progression, and mortality.[99,100] Increased sympathetic nervous system activity is the likely cause of the heart rate increase but how this affects prognosis remains uncertain. Potential deleterious effects of elevated heart rate include increased myocardial oxygen demand, decreased oxygen supply, and tachycardia-induced cardiomyopathy.[97,100] The beneficial effects of β-blockers are more closely related to the degree of heart rate reduction than the dose of the β-blocker, further supporting the link between elevated heart rate and outcomes.[97,100] New approaches to address increased heart rate in these patients are needed because, for a variety of reasons, β-blockers are frequently underdosed in clinical practice.[97]

To determine the impact of heart rate lowering on clinical outcomes, the SHIFT trial examined the effect of ivabradine treatment in over 6,500 patients with an EF less than or equal to 35% and NYHA class II–III symptoms in sinus rhythm with a baseline heart rate greater than or equal to 70 BPM that were receiving standard background HF treatment (over 90% of the patients were taking β-blockers).[101] Patients were randomized to receive ivabradine 5 mg twice daily or placebo and the ivabradine dose could be increased to 7.5 twice daily if the patient's if the resting heart rate was greater than 60 BPM after 2 weeks of treatment with the lower dose. The primary composite endpoint of cardiovascular death or hospital admission for worsening HF was significantly reduced by 18% in the ivabradine treatment group compared to placebo ($p<0.0001$). The primary endpoint was largely driven by reduced hospitalizations for worsening HF and ivabradine did not affect overall or cardiovascular mortality. Ivabradine reduced resting heart rate by approximately 11 BPM compared to placebo. The most common adverse effects associated with ivabradine were bradycardia, atrial fibrillation, and visual disturbances.

Digoxin

10 In 1785, William Withering was the first to report extensively on the use of foxglove or *Digitalis purpurea* for the treatment of dropsy (ie, edema). Although digitalis glycosides have been in clinical use for more than 200 years, not until the 1920s were they clearly demonstrated to have a positive inotropic effect on the heart. Furthermore, it was not until the late 1980s that clinical trials were conducted to critically evaluate the role of digoxin in the therapy of chronic HF. The view of digoxin has also shifted over the past decade. While it was historically considered useful in HF because of its positive inotropic effects, it now seems clear that its real benefits in HF are related to its neurohormonal modulating activity.[102,103]

Clinical trials have shown that digoxin improves cardiac function, quality of life, exercise tolerance, and HF symptoms in patients with HFrEF.[104,105,106] However, these studies involved small numbers of patients followed for short time periods. Although these trials demonstrated hemodynamic and symptomatic improvement in HF patients receiving digoxin, an unresolved issue was the unknown effect of digoxin on mortality. This was of particular concern given the increased mortality seen with other positive inotropic drugs, and finally led to the Digitalis Investigation Group (DIG) trial to determine the effects of digoxin on survival in patients with HF in sinus rhythm.

The DIG trial was a double-blind, randomized, placebo-controlled trial with the primary end point of all-cause mortality.[107] Patients (n=6,800) with HF symptoms, a LVEF of 45% or less, and normal sinus rhythm were eligible for the main DIG trial and were randomized to receive digoxin or placebo for a mean followup period of 37 months. Most patients received background therapy with diuretics and ACE inhibitors. Digoxin serum concentrations of 0.5 to 2 ng/mL (0.6-2.6 nmol/L) were targeted, with a mean serum digoxin concentration (SDC) of 0.8 ng/mL (1 nmol/L) achieved at 12 months. No significant differences in all-cause

mortality were found between patients receiving digoxin and placebo. A trend toward lower mortality due to worsening HF was observed in the digoxin group, although this was offset by a trend toward an increased mortality from other cardiovascular causes (presumably arrhythmias) in patients receiving digoxin. Importantly, digoxin reduced hospitalizations for worsening HF by 28% compared with placebo ($P<0.001$). Therefore, DIG is the first trial to show that a positive inotropic agent does not increase mortality and actually decreases morbidity in patients with HFrEF. On the other hand, among an additional 988 patients with a LVEF greater than 45% (HFpEF) who were enrolled in an ancillary DIG trial, there was no apparent benefit of digoxin on hospitalizations or mortality during the 37-month followup period.[108]

The PROVED and RADIANCE trials investigated the effect of digoxin withdrawal in patients with chronic HF and normal sinus rhythm and further defined the role of digoxin in this setting.[105,106] Both of these trials were short-term (12-week), prospective, randomized, and placebo-controlled and were conducted prior to the use of β-blockers. Together, data from these trials suggested that digoxin produces important symptomatic benefits and that digoxin withdrawal results in worsening HF, decreased exercise capacity, and a reduction in ejection fraction. A posthoc analysis of the DIG trial data supports findings that discontinuation of digoxin may be detrimental. Specifically, among patients treated with digoxin prior to enrollment in the DIG trial, those assigned to the placebo arm (ie, those discontinuing digoxin therapy) had an increased risk of all-cause hospitalization and HF-related hospitalization compared with patients assigned to the digoxin arm (ie, those continuing digoxin therapy).[106]

Retrospective analyses of the combined PROVED/RADIANCE database[110] and the DIG trial database[111] suggest that the clinical benefits of digoxin are achieved at lower SDCs, with no additional benefit with higher concentrations. In particular, analysis of digoxin-treated patients in the PROVED and RADIANCE trials showed similar clinical outcomes among those with a SDC between 0.5 and 0.9 ng/mL (between 0.6 and 1.2 nmol/L) as those with higher serum concentrations.[110] While the DIG trial showed no reduction in mortality in the study population overall, a comprehensive analysis of the DIG trial database found that lower SDCs were associated with decreased mortality, whereas higher concentrations were not.[111] Specifically, compared with placebo, SDCs of 0.5 to 0.9 ng/mL (0.6-1.2 nmol/L) 1 month after digoxin initiation were associated with lower mortality, all-cause hospitalizations, and HF hospitalizations. Serum concentrations greater than or equal to 1 ng/mL (1.3 nmol/L) were associated with lower HF hospitalizations with no effect on mortality. A digoxin dose of 0.125 mg daily or less was predictive of SDCs of 0.4 to 0.9 ng/mL (0.5-1.2 nmol/L). While an initial, well-publicized study suggested that digoxin might be harmful in women,[109] subsequent analyses show no increased risks with digoxin in women, particularly with SDCs less than 1 ng/mL (1.3 nmol/L).[111,113]

Based on the available data, for most patients, the target SDC should be 0.5 to 0.9 ng/mL (0.6-1.2 nmol/L). This more conservative target would also be expected to decrease the risk of adverse effects from digoxin toxicity and evidence indicates this is indeed the case[114] whereas other data show no change in ED admissions for digoxin toxicity.[115] In most patients with normal renal function, this serum concentration range can be achieved with a daily dose of 0.125 mg. Patients with decreased renal function or low body weight, the elderly, or those receiving interacting drugs (eg, amiodarone) should receive 0.125 mg daily or every other day. Routine measuring of SDCs is not necessary in the absence of suspected digoxin toxicity, worsening renal function, institution of an interacting drug, or other conditions that may significantly affect SDC. In patients with atrial fibrillation and a rapid ventricular response, the historic practice of increasing digoxin doses (and concentrations) until rate control is achieved is no longer recommended. Digoxin alone is often ineffective to control ventricular response in patients with atrial fibrillation and increasing the dose

only increases the risk of toxicity. Digoxin combined with a β-blocker or amiodarone is superior to either agent alone for controlling ventricular response in patients with atrial fibrillation and HF.[1] Therefore, target SDCs are the same regardless of whether the patient is in sinus rhythm or atrial fibrillation. Several equations and nomograms have been proposed to estimate digoxin maintenance doses based on estimated renal function for a particular patient and population pharmacokinetic parameters. These methods are extensively reviewed elsewhere.[116] More recently, based on posthoc analyses from the DIG, PROVED, and RADIANCE trials, investigators developed a digoxin dosing nomogram that targets a lower digoxin plasma concentration.[117] In the absence of supraventricular tachyarrhythmias, a loading dose is not indicated because digoxin is a mild inotropic agent that will produce gradual effects over several hours, even after loading.

The DIG trial was conducted prior to the proven benefits and widespread use of β-blockers in HF, and, thus, recent observational studies have reexamined digoxin in the context of contemporary HF therapy and shown either neutral or detrimental effects of the drug on mortality.[118,119] Based on the totality of data, digoxin is not considered a first line agent in HF but a trial may be considered in conjunction with GDMT including ACE inhibitors, β-blockers, and diuretics in patients with symptomatic HFrEF to improve symptoms and reduce hospitalizations.[1] Digoxin may also be considered to help control ventricular response rate in patients with HFrEF and supraventricular arrhythmias, although β-blockers are generally more effective rate control agents, especially during exercise. In the absence of digoxin toxicity or serious adverse effects, digoxin should be continued in most patients. Digoxin withdrawal may be considered for asymptomatic patients who have significant improvement in systolic function with optimal ACE inhibitor and β-blocker treatment.[120]

There is no established role for digoxin in HFpEF when patients are in normal sinus rhythm. Digoxin may be of benefit in patients with concomitant HFpEF and atrial fibrillation.[121]

Calcium Channel Blockers

11 Calcium channel blockers can provide symptom-targeted treatment in patients with HFpEF by decreasing HR and increasing exercise tolerance. They can also provide disease-targeted therapy by treating HTN and coronary artery disease. However, the beneficial effect of these agents on exercise tolerance is not always paralleled by improved LV diastolic function or increased relaxation rate. Nonetheless, a number of small clinical trials have shown that the use of these agents results in both short- and long-term improvement in exercise capacity in patients with HFpEF.[41]

Of the calcium channel blockers, the nondihydropyridines (verapamil and diltiazem) are the most effective because they lower heart rate in addition to lowering BP. Nondihydropyridines are also frequently used to treat the co-morbidities of hypertension and atrial fibrillation in patients with HFpEF. Sustained-release nifedipine, because of its strong vasodilator properties, tends to cause hypotension, reflex tachycardia, and peripheral edema. These characteristics make it less useful in HFpEF. Amlodipine may be effective because it reduces BP. Initial daily doses are verapamil 120 to 240 mg, diltiazem 90 to 120 mg, and amlodipine 2.5 mg.

Heart block is a contraindication for the nondihydropyridines. The most common adverse effects are bradycardia and heart block (for the nondihydropyridines). Peripheral edema and headache also are common. Nondihydropyridines exacerbate the bradycardic effects of β-blockers, and verapamil raises digoxin serum concentrations by 70%. Diltiazem increases cyclosporine, tacrolimus, and sirolimus serum concentrations. Generic formulations, but not necessarily generic equivalents to the original brand names,

are available for some of the calcium channel blockers.

Treatment of Concomitant Disorders

HF is often accompanied by other disorders whose natural history or therapy may affect morbidity, mortality, and treatment approach. Optimal management of these concomitant disorders in the context of the patient's HF is an important consideration in the overall careof the patient.

Hypertension

Although ischemic heart disease has replaced HTN as the most common cause of HF, still nearly two thirds of patients with HF have current or a previous history of HTN.[1] HTN can contribute directly to the development of both HFrEF and HFpEF as well as indirectly by increasing the risk of coronary artery disease. Effective treatment of HTN reduces the risk of developing HF, especially in patients with diabetes.[1] Pharmacotherapy of HTN in patients with HFrEF should initially involve agents that can treat both disorders such as ACE inhibitors or ARBs, β-blockers, and diuretics. Target levels of BP should be consistent with current guidelines.[122] If control of HTN is not achieved after optimizing treatment with these agents, the addition of an ARB, aldosterone antagonist, ISDN/hydralazine, or a second-generation calcium channel blocker such as amlodipine (or possibly felodipine) should be considered. Medications that should be avoided in patients with HFrEF include the calcium channel blockers with negative inotropic effects (eg, verapamil, diltiazem) and direct-acting vasodilators (eg, minoxidil) that cause sodium retention.

In patients with HFpEF, both verapamil and diltiazem can be safely used. However, clinicians should remember that HFpEF is associated with HTN and aging, making it a common diagnosis in elderly women. Because these women often are frail and have low muscle mass, their creatinine clearance and renal function may be compromised. Special care must be taken when selecting and titrating doses of drugs such as diuretics, ACE inhibitors, and ARBs and close attention paid to monitoring serum creatinine and electrolytes.

Angina

Coronary artery disease is the most common etiology of HFrEF. Appropriate management of coronary disease and its risk factors is thus an important strategy for the prevention and treatment of HF. Coronary revascularization should be strongly considered in patients with both HF and angina.[1] Pharmacotherapy of angina in patients with HF should utilize drugs that can effectively treat both disorders. Nitrates and β-blockers are effective antianginals and are the preferred agents for patients with both disorders since they may improve hemodynamics and clinical outcomes. It should be noted that the antianginal effectiveness of these agents may be significantly limited if fluid retention is not controlled with diuretics.

Similar to their use in HTN, both amlodipine and felodipine appear to be safe to use in this setting. Optimization of other treatments for secondary prevention of coronary and other atherosclerotic vascular disease should also be considered.[123] Statins have not been shown to improve outcomes in patients with HFrEF and are only recommended if other indications for their use are present (eg, post-MI).[1]

Atrial Fibrillation

Atrial fibrillation is the most frequently encountered arrhythmia and it is commonly found in patients with

HF (both HFrEF and HFpEF), affecting 5% to 50% of patients with the prevalence increasing in parallel to the severity of HF.[1,124] The high incidence of atrial fibrillation in these patients is not surprising since each disorder predisposes to the other and they share many risk factors including coronary artery disease, diabetes, obesity, and HTN. The presence of atrial fibrillation in patients with HF is associated with a worse long-term prognosis.[29,124] Detrimental effects of these disorders include increased risk of thromboembolism, a reduction in CO due to loss of the atrial contribution to ventricular filling, and hemodynamic compromise from the rapid ventricular response. Moreover, HF exacerbations and atrial fibrillation are closely linked and it is often difficult to determine which disorder caused the other. For example, worsening HF results in volume overload, which, in turn, causes atrial distension and increases the risk of atrial fibrillation. Similarly, atrial fibrillation with a rapid ventricular response can reduce CO and lead to HF exacerbation. Thus, optimal management according to established guidelines is required with careful attention paid to control of ventricular response, symptoms, and anticoagulation for stroke prevention.[121]

Digoxin is frequently used to slow ventricular response in patients with HF and atrial fibrillation. However, it is more effective at rest than with exercise and it does not affect the progression of HF. In addition, the potential for digoxin to increase mortality in patients with atrial fibrillation is a growing concern.[125,126] β-Blockers are more effective than digoxin and have the added benefits of improving morbidity and mortality in patients with HFrEF. Combination therapy with digoxin and a β-blocker may be more effective for rate control than either agent used alone. Calcium channel blockers with negative inotropic effects such as verapamil or diltiazem should be avoided in patients with HFrEF but are effective in patients with HFpEF.

There appear to be no differences in outcomes between the rhythm (restoration and maintenance of sinus rhythm) and rate control approaches to atrial fibrillation in patients with HF.[121,124] Rhythm control is often reserved for patients in whom the rate cannot be controlled or who remain symptomatic. In general, amiodarone is the preferred agent if the rhythm control approach is taken. Although it has many noncardiac toxicities, amiodarone does not have cardiodepressant or significant proarrhythmic effects and appears to be safe in HFrEF. Dofetilide also appears to be safe and effective in this population.[1,121] Class I antiarrhythmics should be avoided. Because of the limited efficacy and potential for serious adverse effects with antiarrhythmic drugs, there is growing interest in the use of catheter ablation for restoring sinus rhythm in these patients.[1]

Diabetes

Diabetes is a common comorbid condition in patients with HF, present in 25% to 40% of patients with HF.[45] As an important risk factor for coronary artery disease, diabetes directly contributes to the development of HF. Importantly, diabetes is also a risk factor for developing HF, particularly in women, independent of coronary artery disease or HTN.[45] Diabetes is associated with more rapid HF progression and is a significant predictor of mortality and hospitalizations in patients with HF.[45]

Pharmacotherapy of diabetes in patients with HF should be targeted to control hyperglycemia according to current guidelines, although it remains uncertain if this approach reduces the risk of HF development.[1,46] The optimal approach to the treatment of diabetes in this population remains uncertain as many clinical trials of diabetes medications excluded patients with moderate to severe HF. Some medications used to treat diabetes can have important adverse effects in patients with HF. Because the thiazolidinediones (TZDs; pioglitazone and rosiglitazone) are associated with fluid retention, these medications should not be used in patients with NYHA class II–IV HF.[1] TZDs should be discontinued in patients developing symptoms related

to volume overload. Use of metformin in patients with HF has been contraindicated because of the purported risk of lactic acidosis. However, a growing body of data demonstrates that not only is metformin safe in HF, but it is also associated with improved morbidity and mortality.[46,127] Nevertheless,careful monitoring of volume status and renal function is still needed when metformin is used in these patients. The use of the dipeptidylpeptidase-4 (DPP-4) inhibitors in patients with HF remains controversial with clinical trials showing association of some of these agents with increased risk of developing HF whereas other studies show no increased risk.[46,128]

Drug Class Information

Diuretics

7 Loop diuretics, as described earlier, represent the typical diuretic therapy for patients with HF due to their potency and, as such, are the only diuretics discussed here.[55,129] There are currently three loop diuretics available that are used routinely: furosemide, bumetanide, and torsemide. They share many similarities in their pharmacodynamics, with their differences being largely pharmacokinetic in nature. Relevant information on the loop diuretics is shown in Tables 14-8 and 14-9. Following oral administration, the peak effect with all the agents occurs in 30 to 90 minutes, with duration of 4 to 8 hours (longer for torsemide). Following IV administration, the diuretic effect begins within minutes. All three drugs are highly (greater than 95%) bound to serum albumin and enter the nephron by active secretion in the proximal tubule. The magnitude of effect is determined by the peak concentration achieved in the nephron, and there is a threshold concentration that must be achieved before any diuresis is seen.

The biggest difference between the agents is bioavailability. Bioavailability of bumetanide and torsemide is essentially complete (80%-100%), whereas furosemide bioavailability exhibits marked intrapatient and interpatient variability. Furosemide bioavailability ranges from 10% to 100%, with an average of 50%. Thus, if bioequivalent IV and oral doses are desired, oral furosemide doses should be approximately double that of the IV dose, whereas IV and oral doses are the same for torsemide and bumetanide. Coadministration of furosemide and bumetanide with food can decrease bioavailability significantly, whereas food has no effect on bioavailability of torsemide. The intra-abdominal congestion that can occur in HF also may slow the rate (and thus decrease the peak concentration) of furosemide, which can reduce the diuretic's efficacy. Thus, furosemide is most problematic with respect to rate and extent of absorption and the factors that influence it, whereas torsemide has the least variable bioavailability.

Data suggest that these differences in bioavailability and variability may have clinical implications. For example, several studies have suggested that torsemide is absorbed reliably and is associated with better outcomes than the more variably absorbed furosemide.[130] There is also some evidence that torsemide may modulate neurohormonal levels resulting in attenuation of cardiac remodeling.[131] Torsemide is preferred in patients with persistent fluid retention despite high doses of other loop diuretics. And while the costs of torsemide exceed those of furosemide, pharmacoeconomic analyses suggest that the costs of care are similar or less with torsemide.[132] These data require confirmation in controlled, double-blind clinical trials but provide preliminary evidence that the more reliably absorbed loop diuretics with potential neurohormonal modulating effects may be superior to furosemide.

Heart failure is one of the disease states in which the maximal response to loop diuretics is reduced. This is believed to result from a decrease in the rate of diuretic absorption and/or increased proximal or distal tubule reabsorption of sodium, possibly due to increased activity of the Na–K–2Cl transporter.[56] As a

consequence, loop diuretics exhibit a ceiling effect in HF, meaning that once the ceiling dose is reached, no additional diuretic response is achieved by increasing the dose. Thus, when this dose is reached, additional diuresis can be achieved by giving the drug more often (twice daily or occasionally three times daily) or by giving combination diuretic therapy. Multiple daily dosing achieves a more sustained diuresis throughout the day. When dosed two or three times daily, the first dose is usually given first thing in the morning and the final dose in late afternoon/early evening. The appropriate chronic dose of a loop diuretic is that which maintains the patient at a stable dry weight without symptoms of dyspnea. Ranges of doses of loop diuretics and recommended ceiling doses are shown in Table 14-8.

Diuretics cause a variety of metabolic abnormalities, with severity related to the potency of the diuretic. The reader is referred to Chapter e3 for a detailed discussion on the adverse effects of diuretic therapy. Hypokalemia is the most common metabolic disturbance with thiazide and loop diuretics, which in HF patients may be exacerbated by hyperaldosteronism. Hypokalemia increases the risk for ventricular arrhythmias in HF and is especially worrisome in patients receiving digoxin. It is often accompanied by hypomagnesemia. Since adequate magnesium is necessary for entry of potassium into the cell, co-supplementation with both magnesium and potassium may be necessary to correct the hypokalemia. Concomitant ACE inhibitor (or ARB) and/or aldosterone antagonist therapy may help to minimize diuretic-induced hypokalemia because these drugs tend to increase serum potassium concentration through their inhibitory effect on aldosterone secretion. Nonetheless, the serum potassium concentration should be monitored closely in HF patients and supplemented appropriately when needed. In addition to metabolic abnormalities, a posthoc analysis of the DIG trial suggested that chronic diuretic use was associated with increased risk of mortality and hospitalization.[133] These findings must be interpreted with caution because this trial was not designed to evaluate outcomes associated with diuretic therapy. However, they do serve to remind clinicians of the importance of appropriate patient selection and monitoring when using diuretic therapy.

ACE Inhibitors

5 A number of ACE inhibitors are currently available; those commonly used in the treatment of patients with HF are summarized in Table 14-8. Although ACE inhibitors vary in their chemical structure (eg, sulfhydryl vs non-sulfhydryl-containing agents) and tissue affinity, the major differences in the ACE inhibitors are not in these pharmacologic properties but in their pharmacokinetic properties.[13] To date all ACE inhibitors studied improve symptoms and mortality in patients with HFrEF.[13] However, it seems most prudent to use those agents documented to reduce morbidity and mortality because the dose required for these end points has been determined.[1]

To minimize the risk of hypotension and renal insufficiency, ACE inhibitor therapy should be started with low doses followed by gradual titration as tolerated to the target doses.[1] Asymptomatic hypotension should not be considered a contraindication to starting therapy with an ACE inhibitor, although initiation or dose increases in patients with systolic blood pressures less than 90 to 100 mm Hg should be done cautiously. Renal function and serum potassium should be evaluated at baseline and within 1 to 2 weeks after therapy is started with subsequent periodic assessments. In the outpatient setting, clinicians should wait at least 2 weeks between dose increases and renal function and potassium should be checked 1 to 2 weeks after each increase. After titration of the drug to the target dose, most patients tolerate chronic therapy with few complications. Although symptoms may improve within a few days of initiating therapy, it may take weeks to months before the full benefits are apparent. Even if symptoms do not improve, long-term ACE inhibitor

therapy should be continued to reduce the risk of mortality and hospitalization. Careful attention to appropriate doses of diuretics is important since fluid overload may blunt the beneficial effects of ACE inhibitors and overdiuresis increases the risk of hypotension and renal insufficiency.

Since ACE inhibitors were the first agents to show improvements in survival and were frequently used as background therapy in clinical trials of other medications, they are often used as the initial therapy in patients with HF. However, initiation of β-blocker therapy should not be delayed while the ACE inhibitor is titrated to the target dose since low-intermediate ACE inhibitor doses are equally effective as higher doses for improving symptoms and survival.[1,62] Also, in β-blocker clinical trials, most patients were receiving background therapy with low-intermediate ACE inhibitor doses. Thus, in most patients, ACE inhibitors should be the initial therapy but it is important to remember that even a small dose of ACE inhibitor is better than no ACE inhibitor and that the greatest benefit is seen when these agents are combined with a β-blocker.

Adverse Effects

The primary adverse effects of ACE inhibitors are secondary to their major pharmacologic effects of suppressing angiotensin II and increasing bradykinin. The most common adverse effects with these agents are hypotension and functional renal insufficiency resulting from the drug-related reductions in angiotensin II. ACE inhibitors reduce BP in nearly all patients, with hypotension becoming problematic when symptoms such as dizziness, light-headedness, blurred vision, presyncope, or syncope are observed. Hypotension occurs most frequently soon after therapy is started or after an increase in dose, although it may occur at any time during treatment. Risk factors for hypotension include hyponatremia (serum sodium less than 130 mEq/L [less than 130 mmol/L]), hypovolemia, and overdiuresis. The risk of hypotension may be minimized by initiating therapy with lower ACE inhibitor doses and/or temporarily withholding or reducing the dose of diuretic, and liberalizing salt and fluid intake.[1] An often overlooked solution to hypotension is to space the administration times of vasoactive medications (eg, diuretics and β-blockers) throughout the day so that these medications are not all administered at or near the same time. Also, if the patient is receiving other vasodilating drugs (eg, nitrates, amlodipine), the need for these medications or at least the feasibility of dose reduction should be considered. Many patients who experience symptomatic hypotension early in therapy are still good candidates for long-term treatment if risk factors for low BP are addressed.

Functional renal insufficiency causes increases in serum creatinine and blood urea nitrogen (BUN). As CO and renal blood flow decline, renal perfusion is maintained by the vasoconstrictor effect of angiotensin II on the efferent arteriole. Patients most dependent on this system for maintenance of renal perfusion (and therefore most likely to develop functional renal insufficiency with ACE inhibitors) are those with severe HF, hypotension, hyponatremia, volume depletion, bilateral renal artery stenosis, and concomitant use of NSAIDs.[134] Sodium depletion, usually secondary to diuretic therapy, is the most important factor in the development of functional renal insufficiency with ACE inhibitor therapy. Renal insufficiency therefore can be minimized in some cases by reduction in diuretic dosage or liberalization of sodium intake. Increases in serum creatinine of 10% to 20% from baseline are commonly observed after initiation of ACE inhibitor therapy. In some patients, the serum creatinine will return to baseline levels without a reduction in ACE inhibitor dose.[134] Increases in serum creatinine of greater than 0.5 mg/dL if the baseline creatinine is less than 2 mg/dL or of greater than 1 mg/dL if the creatinine is greater than 2 mg/dL should prompt clinicians to reduce the dose of ACE inhibitors or reconsider ACE therapy and evaluate potential causes for the abrupt decline in renal function.[134] The safety and efficacy of ACE inhibitors in patients with baseline serum creatinine greater than 2.5 mg/dL (greater than 221 µmol/L) is uncertain as these patients were usually

excluded from clinical trials. Caution should also be exercised when using ACE inhibitors in such patients. Since renal dysfunction with ACE inhibitors is secondary to alterations in renal hemodynamics, it is almost always reversible on discontinuation of the drug.[134]

Careful dose titration can minimize the risks of hypotension and transient worsening of renal function. Thus, usual initial doses should be about one fourth the final target dose with slow upward dose titration based on BP and serum creatinine. In certain patients, especially those hospitalized patients who seem at high risk for hypotension or worsening of renal function, it also may be advisable to initiate therapy with a short-acting agent such as captopril. This will help minimize the duration of these adverse effects should they occur. Once stabilized on captopril, the patient can then be switched to an agent given once daily.

Hyperkalemia with ACE inhibitor therapy can occur and is due to the reduced feedback of angiotensin II to stimulate aldosterone release. Hyperkalemia is most likely to occur in patients with renal insufficiency, in elderly patients, and in those taking concomitant potassium supplements, potassium-containing salt substitutes, or potassium-sparing diuretic therapy (including an aldosterone antagonist), especially if they have diabetes.[134] The more widespread use of aldosterone antagonists (eg, spironolactone) in patients with HF may increase the risk of hyperkalemia. Recent evidence shows that concomitant use of trimethoprim-sulfamethoxazole with either ACE inhibitors or ARBs increases the risk of hyperkalemia and sudden cardiac death.[135,136] The likely mechanism of this interaction is trimethoprim-induced reduction in renal potassium excretion as this agent is structurally similar to the potassium-sparing diuretic amiloride.[135]

ACE inhibitors are also associated with other important adverse effects. A dry, hacking cough is the most common reason for discontinuation of ACE inhibitors, and this adverse effect occurs with a similar frequency with all the agents.[1] Up to 15% to 20% of patients treated with ACE inhibitors will develop cough.[137] The cough is usually nonproductive, occurs within the first few months of therapy, resolves within 1 to 2 weeks of drug discontinuation, and reappears with rechallenge. Cough occurs in up to 40% of patients with HF, independent of ACE inhibitor use; therefore, it is important to rule out other potential causes of cough, such as pulmonary congestion. Because cough is a bradykinin-mediated effect, replacement of ACE inhibitor therapy with an ARB would be reasonable. Angioedema is a rare, occurring in less than 1% of patients receiving an ACE inhibitor, but potentially life-threatening complication that is also due to bradykinin accumulation. It occurs more frequently in African Americans, women, and patients with HF than in other populations.[138,139] Approximately 50% of patients develop angioedema within the first 90 days of therapy, but it can occur years after treatment was started.[139] Use of ACE inhibitors is contraindicated in patients with a history of angioedema. Extreme caution should be exercised if ARBs are used as an alternative therapy in patients with ACE inhibitor-induced angioedema, as cross-reactivity is reported.[1,138] ACE inhibitors are contraindicated during the second and third trimesters of pregnancy due to the increased risk of fetal renal failure, intrauterine growth retardation, and other congenital defects. An analysis of a Medicaid database of nearly 30,000 patients suggests that first-trimester use of ACE inhibitors should also be avoided as the risk of major congenital defects was increased 2.7-fold in infants exposed to these agents during the first trimester.[140]

Angiotensin II Receptor Blockers

5 Although ACE inhibitors remain the agents of first choice to treat HFrEF, ARBs are now the recommended alternatives in patients who are unable to tolerate an ACE inhibitor.[1] Although numerous ARBs are currently available, only three agents, candesartan, valsartan, and losartan, are recommended in

the treatment guidelines.[1] The efficacy of these agents is supported by clinical trial data that document a target dose associated with improved survival and other important outcomes in patients with decreased EF.[1] ARBs are also alternatives to ACE inhibitors in patients with Stage A or B HF.[1]

The clinical use of ARBs is also similar to that of ACE inhibitors. Therapy should be initiated at low doses and then titrated to target doses (see Table 14-8).[1] Blood pressure, renal function, and serum potassium should be evaluated within 1 to 2 weeks after initiation of therapy and after increases in dose and these end points used to guide subsequent dose changes. It is not necessary to reach target doses before adding a β-blocker, although incremental benefits may be associated with higher doses of ARBs.[64]

Adverse Effects

The ARBs have a low incidence of adverse effects. Since they do not affect bradykinin, they are not associated with cough and have a lower risk of angioedema than ACE inhibitors.[137] However, because of reports of recurrences of angioedema after ARB administration to patients with a history of ACE inhibitor-related angioedema, ARBs should be used with extreme caution in any patient with a history of angioedema as cross-reactivity may occur.[67]

The major adverse effects are related to suppression of the RAAS. The incidence and risk factors for developing hypotension, decreases in renal function, and hyperkalemia with the ARBs are similar to those with ACE inhibitors.[1] Thus, ARBs are not alternatives in patients who develop these complications from ACE inhibitors. Careful monitoring is required when an ARB is used with another inhibitor of the RAAS (eg, ACE inhibitor or aldosterone antagonist) as this combination increases the risk of these adverse effects. Similar to the ACE inhibitors, the ARBs are contraindicated in the second and third trimesters of pregnancy and should be avoided in the first trimester because of increased risk of fetal/neonatal morbidity and mortality. Neither candesartan nor valsartan is metabolized by the cytochrome P450 system, so no pharmacokinetic drug–drug interactions with these agents are expected.

Angiotensin II Receptor Blocker/Neprilysin Inhibitor (ARNI)

Deterimental effects of the activation of the SNS and RAAS are managed through the use of β-blockers, aldosterone antagonists, and either ACE inhibitors or ARBs. The combination of sacubitril/valsartan affects the RAAS and inhibits neprilysin. This two-pronged approach showed significant benefit in reducing mortality and hospitalizations in patients with HFrEF when compared to enalapril and is currently being studied in patients with HFpEF.[23]

The natriuretic peptides ANP and BNP cause vasodilation, natriuresis, and diuresis. In addition, they inhibit renin secretion, aldosterone production and attenuate ventricular hypertrophy and fibrosis.[141] When HF is present there are elevations in ANP, BNP and its inactive precursor NT-pro-BNP. Another structurally unrelated peptide called *adrenomedullin* (ADM) has similar vasodilatory and natriuretic properties. Neprilysin breaks down the natriuretic peptides ANP and BNP as well as ADM, bradykinin, and several other substances.[95,141] Inhibition of neprilysin as a therapeutic target has been of interest for several decades.

Omipatrilat was an ACE inhibitor neprilysin inhibitor that was abandoned due to an unacceptable rate of angioedema. Sacubitril/valsartan was designed to lessen the risk of angioedema by using an ARB instead of an ACE inhibitor and inhibiting only one of the enzymes that breaks down bradykinin. Neprilysin is also involved in the clearance of amyloid-β from the brain and CSF. Administration of sacubitril/valsartan is

associated with increased levels of amyloid A $\beta_{1\text{-}38}$;however the clinical relevance of this finding is unknown.

The half-lives of valsartan and LBQ657, the active component of sacubitril, are similar at 10 to 12 hours.[142] Both components are highly protein bound. The valsartan component of the combination product is 40% to 60% more bioavailable than conventional valsartan tablets. Thus, the 24 mg sacubitril/26 mg valsartan tablet is equivalent to 40 mg of valsartan.[142] The initial starting dose for most patients being treated for HFrEF is 49/51 mg sacubitril/valsartan twice daily and titrated to the target dose of 97/103 mg sacubitril/valsartan twice daily after 2 to 4 weeks. A reduced dose of 24/26 mg sacubitril/valsartan is available for patients taking a low dose of either an ACE inhibitor or an ARB prior to initiation, those with severe renal dysfunction (eGFR less than 30 mL/min/1.73 m^2) and those with moderate hepatic impairment (Child-Pugh B). Sacubitril/valsartan should be avoided in patients with severe hepatic impairment (Child-Pugh C).

Adverse Effects

The most common adverse reactions and risk factors for their development are similar to those with ACE inhibitors or ARBs and include hypotension, dizziness, hyperkalemia, worsening renal function, and cough. Angioedema occurred more frequently with sacubitril/valsartan compared to enalapril (0.5% vs 0.2%, respectively).[23] The risk of angioedema is 4-fold higher in African-American patients.[142] Sacubitril/valsartan is contraindicated in patients with history of angioedema associated with an ACE inhibitor or ARB. Sacubitril/valsartan is also contraindicated in pregnancy and should not be used concurrently with ACE inhibitors or other ARBs. ACE inhibitors should be discontinued 36 hours prior to initiating sacubitril/valsartan. This agent should also be avoided with aliskiren in patients with diabetes.

β-Blockers

6 Metoprolol succinate, carvedilol, and bisoprolol are the only *β*-blockers shown to reduce mortality in large trials in patients with HFrEF. Metoprolol and bisoprolol selectively block the β_1-receptor, while carvedilol blocks the β_1-, β_2-, and α_1-receptors and also possesses antioxidant effects. While there is no clear evidence that these pharmacologic differences result in differences in efficacy among agents, they may aid in selection of a specific agent. For example, carvedilol is expected to have greater antihypertensive effects than the other agents because of its *α*-receptor blocking properties and may be preferred in patients with poorly controlled BP. Conversely, metoprolol or bisoprolol may be preferred in patients with low BP or dizziness and in patients with significant airway disease. Bisoprolol is eliminated approximately 50% by the kidneys, whereas metoprolol and carvedilol are essentially completely metabolized and undergo extensive hepatic first-pass metabolism.

There is fairly strong evidence that benefits of *β*-blockers in HFrEF are not a class effect. Specifically, in a study powered for mortality reduction, there was no difference in survival between the nonselective *β*-blocker bucindolol and placebo.[143] While there has been considerable debate over why bucindolol failed to provide a survival benefit, it may be related to the drug's ancillary properties or differences among *β*-blocker trials in the characteristics of study participants. Additional data suggest that bucindolol's effects on survival might be genotype specific, as described in Personalized Pharmacotherapy. In the absence of bucindolol's approval for HF, *β*-blocker use should be confined to one of the agents with proven survival benefits, especially given the diversity among *β*-blockers in their receptor sensitivities and ancillary properties.

There has been much debate over whether one *β*-blocker is superior to another. Specifically, it has been

hypothesized that nonselective blockade with carvedilol might produce greater benefits than β_1-selective blockade. This hypothesis is based on observations that the β_1-receptor is downregulated, and the β_2- and α_1-receptors account for a larger proportion of total cardiac adrenergic receptors in the failing heart. Only one trial with a mortality end point has provided a head-to-head comparison of carvedilol and a β_1-selective blocker. The Carvedilol Or Metoprolol European Trial (COMET) compared carvedilol 25 mg twice daily and immediate-release metoprolol 50 mg twice daily and found a significant 17% lower mortality rate in patients treated with carvedilol.[144] However, concerns regarding the formulation and dose of metoprolol used in COMET limit the conclusions that can be drawn from these findings. Specifically, the study used the immediate-release formulation of metoprolol (metoprolol tartrate), not the sustained-release formation (metoprolol succinate) shown to reduce mortality. The efficacy of the immediate-release formulation in reducing mortality in HF has not been proven. Metoprolol succinate provides more consistent plasma concentrations over a 24-hour period and appears to provide more favorable effects on HR variability, autonomic balance, and BP, suggesting that this formulation might be superior to immediate-release metoprolol.[145] The target dose of metoprolol also differed between COMET and MERIT-HF. The target dose in COMET was 100 mg/day (50 mg twice daily), whereas the target dose of metoprolol in MERIT-HF was 200 mg/day. Many question whether the degree of β-blockade achieved in COMET with immediate-release metoprolol 50 mg twice daily is comparable to that achieved with metoprolol succinate 200 mg/day in MERIT-HF or carvedilol 25 mg twice daily in COMET. More recent data from heart failure registries suggest that metoprolol succinate and carvedilol are similarly effective.[146,147] While some clinicians may still argue the superiority of carvedilol, it seems clear that what is most important is that one of the three β-blockers proven to reduce mortality is used.

Adverse Effects

Possible adverse effects with β-blocker use in HF include bradycardia or heart block, hypotension, fatigue, impaired glycemic control in diabetic patients, bronchospasm in patients with asthma, and worsening HF. Clinicians should monitor vital signs and carefully assess for signs and symptoms of worsening HF during β-blocker initiation and uptitration. Hypotension is more common with carvedilol due to its α_1-receptor blocking properties. Bradycardia and hypotension generally are asymptomatic and require no intervention; however, β-blocker dose reduction is warranted in symptomatic patients. Fatigue usually resolves after several weeks of therapy, but sometimes requires dose reduction. In diabetic patients, β-blockers may worsen glucose tolerance and can mask the tachycardia and tremor (but not sweating) that accompany hypoglycemia. In addition, nonselective agents such as carvedilol may prolong insulin-induced hypoglycemia and slow recovery from a hypoglycemic episode. Despite this, there is evidence that carvedilol produces better glycemic control in diabetic patients compared with immediate-release metoprolol and may improve insulin sensitivity.[147] Furthermore, posthoc analysis of HF trials shows that β-blockers are well tolerated and significantly reduce morbidity and mortality in patients with diabetes and HFrEF.[149] Thus, while β-blockers should be used cautiously in patients with recurrent hypoglycemia, concerns of masking symptoms of hypoglycemia or worsening glycemic control should not preclude β-blocker use in patients with diabetes. Patients with diabetes should be warned of these potential adverse effects, and blood glucose monitored with initiation, adjustment, and discontinuation of β-blocker therapy. Adjustment of hypoglycemic therapy may be necessary with concomitant β-blocker use in diabetics.

Uptitration should be avoided if the patient experiences signs of worsening HF, including volume overload and poor perfusion. Fluid overload may be asymptomatic and manifest solely as an increase in body weight. Mild fluid overload may be managed by intensifying diuretic therapy. Once the patient has been stabilized,

dose titration may continue as tolerated until the target or highest tolerated dose is reached. Despite their negative inotropic effects, continuing β-blocker therapy during hospitalization for acute decompensated HF appears to neither worsen symptoms nor delay clinical improvement. In fact, β-blocker withdrawal may increase the risk for mortality after hospital discharge.[150] Further, stopping β-blocker therapy during acute decompensation may lead to lower chronic β-blocker use due to failure to reinstitute β-blocker therapy once the patient has stabilized.[151] Guidelines recommend continuing β-blocker therapy during hospitalization for HF whenever possible.[1]

Absolute contraindications to β-blocker use include uncontrolled bronchospastic disease, symptomatic bradycardia, advanced heart block without a pacemaker, and acute decompensated HF. However, β-blockers may be tried with caution in patients with asymptomatic bradycardia, COPD, or well-controlled asthma. Particular caution is warranted in patients with marked bradycardia (less than 55 beats/min) or hypotension (systolic BP less than 80 mm Hg).

Ivabradine

Ivabradine reduces heart rate by selective inhibition of the I_f current responsible for controlling the depolarization rate of the sinus node.[97,98] Ivabradine does not affect AV conduction, blood pressure, or myocardial contractility.[97,98] Thus, ivabradine specifically targets the high resting heart rate that is associated with increased risk of adverse outcomes in this patient population.[99] This novel agent was recently approved for the treatment of patients with HFrEF in sinus rhythm with a heart rate greater than or equal to 70 beats/min that are receiving maximally tolerated treatment with β-blockers or have contraindications to β-blockers. Ivabradine is not included in current ACC/AHA HFrEF treatment guidelines as it was approved after publication of these guidelines.[1]

Ivabradine is extensively metabolized by intestinal and hepatic CYP3A4 resulting in an oral bioavailability of 40%.[98] The elimination half-life is approximately 6 hours and the drug's clearance is not affected by impaired renal function.[98] Ivabradine does not affect the metabolism of concomitantly administered medications. However, ivabradine pharmacokinetics are affected by other drugs that inhibit or induce CYP3A4.[98] Co-administration with strong CYP3A4 inhibitors (eg, itraconazole, macrolide antibiotics, HIV protease inhibitors) is contraindicated because of the large increase in exposure and potential for bradycardia or other conduction abnormalities. Moderate CYP3A4 inhibitors (eg, verapamil, diltiazem, grapefruit juice) and inducers (eg, St. John's wort, rifampin, phenytoin) should be avoided as well. Because QT interval prolongation can be increased by slower heart rates, ivabradine should be used cautiously, if at all, with other agents known to prolong the QT interval.

The starting dose of ivabradine in most patients is 5 mg twice daily with meals. After 2 weeks of treatment, resting heart rate should be evaluated and if between 50 and 60 beats/min, the dose should be continued. If the heart rate is greater than 60 beats/min, the dose can be increased to the maximum of 7.5 mg twice daily. If at any point, the heart rate is less than 50 beats/min or if the patient has symptomatic bradycardia, the dose should be reduced by 2.5 mg twice daily. In this case, if the patient is receiving only 2.5 mg twice daily, then ivabradine should be discontinued.

Adverse Effects

Consistent with its mechanism of action, ivabradine's most common adverse effect is bradycardia, occurring in approximately 10% of patients, although it rarely leads to drug discontinuation.[101] Effects on vision are

found in 3% of patients, primarily manifesting as phosphenes (transient brightness in portions of the visual field).[98,101] These often resolve with continued therapy. Also, atrial fibrillation occurred more frequently in patients receiving ivabradine.[98,101]

Digoxin

10 Digoxin exerts its positive inotropic effect by binding to sodium- and potassium-activated adenosine triphosphatase (Na,K-ATPase or sodium pump). Inhibition of Na,K-ATPase decreases outward transport of sodium and leads to increased intracellular sodium concentrations. Higher intracellular sodium concentrations favor calcium entry and reduce calcium extrusion from the cell through effects on the sodium–calcium exchanger. The result is increased storage of intracellular calcium in the sarcoplasmic reticulum and, with each action potential, a greater release of calcium to activate contractile elements. Digoxin also has beneficial neurohormonal actions. These effects occur at low plasma concentrations, where little inotropic effect is seen, and are independent of inotropic activity. Unlike other positive inotropes that increase intracellular cyclic adenosine monophosphate (cAMP), digoxin attenuates the excessive SNS activation present in HF patients. Although the precise mechanism is unknown, a digoxin-mediated reduction in central sympathetic outflow and improvement in impaired baroreceptor function appear to play an important role. Because mortality and progression of HF are linked to the extent of SNS activation, these sympatho inhibitory effects may be an important component of the clinical response to the drug. Chronic HF is also marked by autonomic dysfunction, most notably suppression of the parasympathetic (vagal) system. Digoxin increases parasympathetic activity in HF patients and leads to a decrease in HR, thus enhancing diastolic filling. The vagal effects also result in slowed conduction and prolongation of AV node refractoriness, thus slowing the ventricular response in patients with atrial fibrillation. Because atrial fibrillation is a common complication of HF, the combined positive inotropic, neurohormonal, and negative chronotropic effects of digoxin can be particularly beneficial for such patients. The overall response to digoxin is usually an increase in cardiac index and a decrease in PCWP with relatively little change in arterial BP.[103,120]

Pharmacokinetics

Numerous studies of digoxin pharmacokinetics have been published and are summarized in **Table 14-11**. Digoxin has a large volume of distribution and is extensively bound to various tissues, most notably to Na,K-ATPase in skeletal and cardiac muscles. Because it does not distribute appreciably to body fat, loading doses of digoxin (when necessary) should be calculated based on estimates of lean body weight. There is a long "distribution phase" after administration of oral or IV digoxin, resulting in a lag time before maximum pharmacologic response is observed (see Table 14-11). Transiently elevated SDCs during the distribution phase are not associated with increased therapeutic or adverse effects, although they can mislead the clinician who is unaware of the timing of blood sampling relative to the previous digoxin dose. Consequently, blood samples for measurement of SDCs should be collected at least 6 hours and preferably 12 hours or more after the last dose.

TABLE 14-11 Clinical Pharmacokinetics of Digoxin

Oral bioavailability	
Tablets	0.5-0.9 (0.65)[a]
Elixir	0.75-0.85 (0.80)
Capsules	0.9-1.0 (0.95)

Onset of action	
Oral	1.5-6 h
Intravenous	15-30 min
Peak effect	
Oral	4-6 h
Intravenous	1.5-4 h
Terminal half-life	
Normal renal function	36 h
Anuric patients	5 d
Volume of distribution at steady state	7.3 L/kg
Fraction unbound in plasma	0.75-0.80
Fraction excreted unchanged in urine	0.65-0.70

[a]Range and mean value in parentheses.

Data from Schentag JJ, Bang AJ, Kozinski-Tober JL. In: Burton ME, Shaw LM, Schentag JJ, Evans WE, eds. *Applied Pharmacokinetics and Pharmacodynamics: Principles of Therapeutic Drug Monitoring*, 4th ed. Baltimore, MD: Lippincott Williams and Wilkins, 2006:410-439.

In patients with normal renal function, 60% to 80% of a dose of digoxin is eliminated unchanged in urine via glomerular filtration and tubular secretion. The terminal half-life of digoxin is approximately 1.5 days in subjects with normal renal function but approximately 5 days in anuric patients (see Table 14-11). Recent evidence indicates that the drug efflux transporter P-glycoprotein (P-gp) plays an important role in the bioavailability, renal and nonrenal clearance, and drug interactions with digoxin. Clinically important pharmacokinetic/pharmacodynamic drug interactions are summarized in **Table 14-12**. An extensive review of the pharmacokinetics and pharmacodynamics of digoxin is available.[116]

TABLE 14-12 Selected Digoxin Drug Interactions

Drugs	Mechanism/Effect	Suggested Clinical MGT
Amiodarone, dronedarone	Inhibits P-glycoprotein resulting in decrease in renal and nonrenal clearance; can increase SDC by 70%-100%	Monitor SDC and adverse effects; anticipate the need to reduce the dose by 30%-50%
Antacids	Concurrent administration may decrease digoxin bioavailability by 20%-35%	Space doses at least 2 h apart or avoid concurrent use if possible
Cholestyramine, colestipol	Bind digoxin in gut and decrease bioavailability 20%-35%; may also decrease enterohepatic recycling	Space doses at least 2 h apart or avoid concurrent use if possible
Cyclosporine	Inhibits P-glycoprotein resulting in decreased clearance	Monitor SDC and adverse effects; anticipate the need to reduce the dose
Diuretics	Thiazides or loop diuretics may cause hypokalemia and hypomagnesemia, thereby increasing the risk of digitalis toxicity	Monitor and replace electrolytes if necessary

Drugs	Mechanism/Effect	Suggested Clinical MGT
Erythromycin, clarithromycin, tetracycline	Alter gut bacterial flora; bioavailability and SDC increase 40%-100% in about 10% of patients who extensively metabolize digoxin in the gut, may also be due to inhibition of P-glycoprotein by macrolides	Monitor SDC and anticipate the need to reduce the dose; avoid concurrent use if possible
Ketoconazole, itraconazole	Decrease in renal and nonrenal clearance by inhibition of P-glycoprotein; SDC may increase by 50%-100%	Monitor SDC and anticipate the need to reduce the dose by 50%
Kaolin-pectin	Large dose (30-60 mL) may decrease digoxin bioavailability by about 60%	Space doses at least 2 h apart or avoid concurrent use if possible
Metoclopramide	Increase in gut mobility may decrease bioavailability of slow dissolving tablets; unknown significance	Effect is minimized by administration of digoxin capsules
Neomycin, sulfasalazine	Decrease in bioavailability by 20%-25%	Space doses at least 2 h apart or avoid concurrent use if possible
Propafenone	Decrease in renal clearance; SDC may increase 30%-40%	Monitor SDC and anticipate the need to reduce the dose
Ranolazine	Inhibits P-glycoprotein; SDC may increase 50%	Monitor SDC
Ritonavir, telaprevir	Inhibits P-glycoprotein and may increase SDC	Monitor SDC and anticipate the need to reduce the dose
Quinidine	Inhibits P-glycoprotein resulting in decrease in renal and nonrenal clearance; also displacement of digoxin from tissue binding sites with decrease in the volume of distribution; SDC generally increases about twofold	Monitor SDC and adverse effects; anticipate the need to reduce dose by 50%
Spironolactone	Decrease in renal and nonrenal clearance; also interference with some digoxin assays thus increasing apparent SDC	Monitor SDC and anticipate the need to reduce dose; check assay for interference
Verapamil	Inhibits P-glycoprotein resulting in decrease in renal and nonrenal clearance, SDC may increase 70%-100%	Monitor SDC and anticipate the need to reduce the dose by 50%; consider using another calcium channel blocker

SDC, serum digoxin concentration.

Adverse Effects

Digoxin can produce a variety of cardiac and noncardiac adverse effects, but it is usually well tolerated by most patients (**Table 14-13**).[103,120] Noncardiac adverse effects frequently involve the CNS or GI systems but also may be nonspecific (eg, fatigue or weakness). Cardiac manifestations include numerous different arrhythmias caused by the drug's multiple electrophysiologic effects (see Table 14-13). Cardiac arrhythmias may be the first evidence of toxicity in a patient (before any noncardiac symptoms occur). Rhythm disturbances are of particular concern because patients with chronic HF are already at increased risk for

sudden cardiac death, presumably due to ventricular arrhythmias. Patients at increased risk of toxicity include those with impaired renal function, decreased lean body mass, the elderly, and those taking interacting drugs. Hypokalemia, hypomagnesemia, and hypercalcemia will predispose patients to cardiac manifestations of digoxin toxicity. Thus, concomitant therapy with diuretics may lead to electrolyte abnormalities and increase the likelihood of cardiac arrhythmias. Similarly, hypothyroidism, myocardial ischemia, and acidosis will also increase the risk of cardiac adverse effects. Although digoxin toxicity is commonly associated with plasma concentrations greater than 2 ng/mL (2.6 nmol/L), toxicity may occur at lower concentrations and clinicians should remember that digoxin toxicity is based on the presence of symptoms rather than a specific plasma concentration.[116] Usual treatment of digoxin toxicity includes drug withdrawal or dose reduction and treatment of cardiac arrhythmias and electrolyte abnormalities. In patients with life-threatening digoxin toxicity, purified digoxin-specific Fab antibody fragments should be administered. SDCs will not be reliable until the antidote has been eliminated from the body.[117]

TABLE 14-13 Signs and Symptoms of Digoxin Toxicity

Noncardiac (mostly CNS) adverse effects
Anorexia, nausea, vomiting, abdominal pain
Visual disturbances
Halos, photophobia, problems with color perception (ie, red-green or yellow-green vision), scotoma
Fatigue, weakness, dizziness, headache, neuralgia, confusion, delirium, psychosis
Cardiac adverse effects[a,b]
Ventricular arrhythmias
Premature ventricular depolarizations, bigeminy, trigeminy, ventricular tachycardia, ventricular fibrillation
Atrioventricular (A-V) block
First degree, second degree (Mobitz type I), third degree
A-V junctional escape rhythms, junctional tachycardia
Atrial arrhythmias with slowed A-V conduction or A-V block
Particularly paroxysmal atrial tachycardia with A-V block
Sinus bradycardia

[a]Some adverse effects may be difficult to distinguish from the signs/symptoms of heart failure.

[b]Digoxin toxicity has been associated with almost every known rhythm abnormality (only the more common manifestations are listed).

Data from Eichorn EJ, Gheorghiade M. *Prog Cardiovasc Dis* 2002;44:251-266.

Personalized Pharmacotherapy

Pharmacogenetics holds promise for future personalized HF therapy. Most HF pharmacogenetic research has focused on genetic association responses to β-blockers. For example, there is evidence that the β_1-adrenergic receptor (*ADRB1*) Arg389Gly polymorphism is associated with improvement in left ventricular EF with β-blockers.[152] Further, the Arg389Gly variant was associated with clinical outcomes with bucindolol, the only β-blocker among those studied in large, randomized, multicenter HF trials that did not significantly improve outcomes.[143] The trial with bucindolol was unique in that it included a large number of African American patients. A subgroup analysis showed survival improvement with bucindolol in whites, but not African Americans. African Americans have a higher frequency of the *ADRB1* 389Gly allele and the α_{2c}-adrenergic receptor (*ADRA2C*) Del322-325 variant, both of which are associated with a lack of improvement in HF outcomes with bucindolol.[153] In contrast, the nonvariant*ADRB1* and *ADRA2C* genotypes, which occur more often among whites, were associated with a reduced risk for hospitalization and death with bucindolol. The manufacturer of bucindolol sought FDA approval of the drug for patients with the more favorable response genotype; however, their efforts were unsuccessful.

Clinical Controversy…

Current treatment guidelines recommend that, in the absence of contraindications, all patients with HFrEF should receive an ACE inhibitor or ARB to improve survival and morbidity. Compared to enalapril, the recently approved combination product sacubitril/valsartan (neprilysin inhibitor/ARB) significantly reduced the risk of cardiovascular mortality and heart failure hospitalization in patients with HFrEF. Based on these new findings, the optimal initial approach to RAAS inhibition in these patients remains to be determined.

Both metoprolol and carvedilol are also substrates for the cytochrome P450 2D6 enzyme, which is known to be polymorphic. A total of 7% of the white population and 1% to 2% of the Asian-American and African-American populations who are CYP2D6 poor metabolizers would be expected to have higher plasma concentrations than anticipated at the usual doses of carvedilol and metoprolol. However, given that β-blockers have a wide therapeutic index, it is unclear whether CYP2D6 phenotype significantly impacts hemodynamic and clinical effects.

There is also preliminary evidence of genetic determinants of outcomes with hydralazine/ISDN. Specifically, the endothelial nitric oxide synthase-3 (NOS3) Glu298Asp polymorphism was associated with the effects of hydralazine/ISDN on the composite end point of survival, hospitalization, and quality of life, with greater improvement with the Glu298Glu genotype.[154] A separate analysis focused on the gene for corin, a protein expressed in cardiomyocytes that cleaves pro-ANP and proBNP into active natriuretic peptides. The corin Gln568Pro variant leads to a dysfunctional protein and was associated with an increased risk for death or HF hospitalization in the A-HeFT population.[155] However, no detrimental effect of the 568Pro variant was observed among patients treated with hydralazine/ISDN, suggesting that the drug combination attenuates the adverse consequences of the 568Pro allele. Both the NOS3 Glu298Glu genotype and corin 568Pro variant occur predominately in persons of African descent, potentially explaining why hydralazine/ISDN is especially effective in African Americans.

Clinical Controversy…

Elevated resting heart rate in patients with HFrEF is associated with increased risk of adverse outcomes. The recently approved novel agent ivabradine reduces heart rate by selective inhibiton of the I_f current in the sinus node. This agent reduces the risk of hospitalization in patients with HFrEF in sinus rhythm that are receiving GDMT. Digoxin also decreases the risk of hospitalization in this patient population. In patients in

sinus rhythm with a heart rate ≥70 BPM with persistent symptoms despite optimal GDMT, it remains uncertain whether adding ivabradine or digoxin is the best approach.

EVALUATION OF THERAPEUTIC OUTCOMES

Although mortality is an important end point, it does not give a complete measure of the overall impact of this disorder because many patients are hospitalized repeatedly for HF exacerbations and continue to survive, albeit with a significantly reduced quality of life. Thus, some of the more important therapeutic outcomes in HF management, such as prolonged survival or prevention or slowing of the progression of HF, cannot be quantified in an individual patient. However, after appropriate diagnostic evaluation to determine the etiology of HF, ongoing clinical assessment of patients typically focuses on evaluation of three general areas: (a) functional capacity, (b) volume status, and (c) laboratory monitoring.

The evaluation of functional capacity should focus on the presence and severity of symptoms the patient experiences during activities of daily living and how his or her symptoms affect these activities. Questions directed toward the patient's ability to perform specific activities may be more informative than general questions about what symptoms the patient may be experiencing. For example, patients should be asked if they could exercise, climb stairs, get dressed without stopping, check the mail, go shopping, or clean the house. Another important component of assessment of functional capacity is to ask patients what activities they would like to do but are now unable to perform.

Assessment of volume status is a vital component of the ongoing care of patients with HF. This evaluation provides the clinician important information about the adequacy of diuretic therapy. Since the cardinal signs and symptoms of HF are caused by excess fluid retention, the efficacy of diuretic treatment is readily evaluated by the disappearance of these signs and symptoms. The physical examination is the primary method for the evaluation of fluid retention, and specific attention should be focused on the patient's body weight, extent of JVD, presence of hepatojugular reflux, presence and severity of pulmonary congestion, and peripheral edema. Specifically, in a patient with pulmonary congestion, monitoring is indicated for resolution of rales and pulmonary edema and improvement or resolution of DOE, orthopnea, and PND. For patients with systemic congestion, a decrease or disappearance of peripheral edema, JVD, and hepatojugular reflux is sought. Other therapeutic outcomes include an improvement in exercise tolerance and fatigue, decreased nocturia, and a decrease in HR. Clinicians also will want to monitor BP and ensure that the patient does not develop symptomatic hypotension as a result of drug therapy. Body weight is a sensitive short-term marker of fluid loss or retention, and patients should be counseled to weigh themselves daily, reporting changes to their healthcare provider so that adjustments can be made in diuretic doses. Patients and healthcare providers should be aware that HF progression may be slowed even though symptoms have not resolved.

Routine monitoring of serum electrolytes and renal function is required in patients with HF. Assessment of serum potassium and magnesium is especially important because hypokalemia and hypomagnesemia are common adverse effects of diuretic therapy and are associated with an increased risk of arrhythmias and digoxin toxicity (hypokalemia). Serum potassium monitoring is also required because of the risk of hyperkalemia associated with ACE inhibitors, ARBs, and aldosterone antagonists. A serum potassium greater than or equal to 4mEq/L (greater than or equal to 4 mmol/L) should be maintained with some evidence suggesting it should be greater than or equal to 4.5 mEq/L (greater than or equal to 4.5 mmol/L).[156] Assessment of renal function (BUN and serum creatinine) is also an important end point for monitoring diuretic and ACE inhibitor therapy. Common causes of worsening renal function in patients with HF include

overdiuresis, adverse effects of ACE inhibitor or ARB therapy, and hypoperfusion.

Most of these therapeutic end points are incorporated into the ACC/AHA performance measures outlined in **Table 14-14**.[157]

TABLE 14-14 ACC/AHA Clinical Performance Measures for Adults with HFrEF

Performance Measure	Recommendation
Inpatient Measures	
Evaluation of left ventricular systolic function[a]	Echocardiogram with Doppler flow studies is the most useful test as it enables clinicians to determine the presence of pericardial, myocardial, or valvular abnormalities. Patients with LVEF < 40% should be considered for specific therapy (eg, ACE inhibitors, *β*-blockers). *Class I recommendation, Level of Evidence C.*
ACE inhibitors or ARBs for patients with left ventricular systolic dysfunction[a]	Patients with a LVEF < 40% or moderate or severe systolic dysfunction should receive an ACE inhibitor or ARB unless contraindications are present or there is a history of intolerance to both drugs. ACE inhibitors: *Class I recommendation, Level of Evidence A.* ARBs: *Class 1, Level of Evidence A.*
Beta-blocker therapy for patients with left ventricular systolic dysfunction	All patients with stable heart failure and LVEF 40% should receive treatment with one of the three beta-blockers proven to reduce mortality unless contraindicated. *Class I recommendation, Level of Evidence A.*
Postdischarge follow-up appointment	At the time of hospital discharge, patients should receive an appointment for a follow-up visit to occur within 7-10 days of discharge.
Outpatient Measures	
Evaluation of left ventricular systolic function	Echocardiogram with Doppler flow studies is the most useful test as it enables clinicians to determine the presence of pericardial, myocardial, or valvular abnormalities. Patients with LVEF < 40% should be considered for specific therapy (eg, ACE inhibitors, *β*-blockers). *Class I recommendation, Level of Evidence C.*
Symptom and activity assessment	Both initial and ongoing quantitative assessment of symptom type, severity, duration, and their impact on the patient's functional capacity should be performed. This can be accomplished using the NYHA functional classification or other established evaluation instruments (eg, Minnesota Living with Heart Failure Questionnaire). *Class I recommendation, Level of Evidence C.*
Beta-blocker therapy for patients with left ventricular systolic dysfunction	All patients with stable heart failure and decreased LVEF should receive treatment with one of the three beta-blockers proven to reduce mortality unless contraindicated. *Class I recommendation, Level of Evidence A.*
ACE inhibitors or ARBs for patients with left ventricular systolic dysfunction	Patients with a LVEF < 40% or moderate or severe systolic dysfunction should receive an ACE inhibitor or ARB unless contraindications are present or there is a history of intolerance to both drugs. ACE inhibitors: *Class I recommendation, Level of Evidence A.* ARBs: *Class 1, Level of Evidence A.*

ABBREVIATIONS

Favorite Table | Download (.pdf) | Print

ACC	American College of Cardiology
ACE	angiotensin converting enzyme
AHA	American Heart Association
ANP	atrial natriuretic peptide
ARB	angiotensin receptor blocker
AVP	arginine vasopressin
BNP	B-type natriuretic peptide
BP	blood pressure
BPM	beats per minute
BUN	blood urea nitrogen
cAMP	cyclic adenosine monophosphate
CNP	C-type natriuretic peptide
CO	cardiac output
COX-2	cyclooxygenase-2
CRT	cardiac resynchronization therapy
ET	endothelin
GDMT	guideline-directed medical therapy
HF	heart failure
HFpEF	heart failure with preserved ejection fraction
HFrEF	heart failure with reduced ejection fraction
HFSA	Heart Failure Society of America
HR	heart rate
HTN	hypertension
ICD	implantable cardioverter-defibrillator
JVD	jugular venous distension
LVAD	left ventricular assist device
LVEDV	left ventricular end diastolic volume
LVEDP	left ventricular end diastolic pressure
LVEF	left ventricular ejection fraction
MI	myocardial infarction
NE	norepinephrine
NSAID	non-steroidal anti-inflammatory drug
NYHA	New York Heart Association
PCWP	pulmonary capillary wedge pressure

P-gp	P-glycoprotein
RAAS	renin-angiotensin-aldosterone system
SDC	serum digoxin concentration
SNS	sympathetic nervous system
SVR	systemic vascular resistance
TZD	thiazolidinedione

Chapter 15: Acute Decompensated Heart Failure

Jo E. Rodgers; Brent N. Reed

INTRODUCTION

KEY CONCEPTS

- 1 Patients presenting to the hospital with acute decompensated heart failure (ADHF) can be categorized into four hemodynamic subsets based on volume status (euvolemic or “dry” vs volume overloaded or “wet”) and cardiac output (adequate cardiac output or “warm” vs hypoperfusion or “cold”). Patients may be warm and dry, warm and wet, cold and dry, or cold and wet.
- 2 While invasive hemodynamic monitoring using a pulmonary artery (PA) catheter does not alter outcomes in a broad population of ADHF patients, it may be considered in those who are refractory to initial therapy, whose volume status is unclear, or in those with clinically significant hypotension (ie, systolic blood pressure <80 mm Hg) or worsening renal function despite standard therapy.
- 3 Key hemodynamic parameters monitored with a PA catheter include pulmonary capillary wedge pressure (PCWP; reflecting fluid status or “preload”), cardiac output or cardiac index (CI; reflecting the innate contractility of the heart), and systemic vascular resistance (SVR; reflecting vascular tone or “afterload”). Although a normal PCWP (6-12 mm Hg) is desirable in healthy patients, higher ventricular filling pressures (15-18 mm Hg) are often necessary in patients with heart failure (HF).
- 4 Treatment goals for ADHF include relief of congestive symptoms, restoration of systemic tissue perfusion via improved cardiac output, and minimization of further cardiac damage and other adverse effects.
- 5 Optimizing oral chronic HF therapy in the setting of ADHF may assist with improving cardiac output, relieving congestion, and preventing hospital readmission.
- 6 Pharmacologic therapies used in the management of ADHF can be broadly classified according to whether they improve volume overload and/or low cardiac output. No therapy studied to date has conclusively been shown to reduce mortality and several may potentially worsen outcomes.

- 7 Intravenous (IV) loop diuretics are considered first-line therapy for the management of ADHF associated with volume overload refractory to orally administered diuretics. Administration as a bolus or continuous infusion appears to be equally efficacious and safe when selected as initial therapy, although high-dose loop diuretic therapy (ie, up to 2.5-times the oral regimen prior to admission) is associated with greater volume removal. The addition of a thiazide-type diuretic may be considered in patients with diuretic resistance. If patients continue to be refractory to, or experience worsening renal function with diuretic therapy, IV vasodilators and/or inotropes may be indicated. Placement of a PA catheter may be helpful in guiding therapy in such patients.

- 8 Intravenous vasodilators may be added to diuretics for rapid resolution of congestive symptoms, especially in patients with acute pulmonary edema or severe hypertension. Such therapy may also be considered in patients who fail to respond to aggressive treatment with diuretics. Vasodilators should be avoided in patients with symptomatic hypotension or reduced left ventricular filling pressure. Frequent blood pressure monitoring is necessary to ensure their safe use.

- 9 Vasopressin antagonists such as tolvaptan may be considered in patients with severe euvolemic or hypervolemic hyponatremia. Therapy should only be initiated in a hospital setting to allow for monitoring of volume status and serum sodium concentrations, as rapid correction of serum sodium may result in adverse neurological sequelae.

- 10 Ultrafiltration may be considered in patients with diuretic resistance or those with worsening renal impairment despite IV vasodilator and/or inotrope therapy.

- 11 In the absence of hypotension (systolic blood pressure <90 mm Hg or symptomatic hypotension), IV vasodilators should be considered prior to IV inotropes in patients with ADHF and evidence of low cardiac output.

- 12 Intravenous inotropes are recommended for maintaining systemic perfusion and end-organ function in hypotensive patients with evidence of severe left ventricular dysfunction and low cardiac output. Inotropic therapy may also be considered in patients who do not tolerate or respond to IV vasodilators or in patients with worsening renal function despite standard therapy, but should be avoided in patients with reduced left ventricular filling pressures. Patients receiving IV inotropes should be monitored continuously for arrhythmias.

- 13 Temporary mechanical circulatory support (MCS) is indicated in select patients with severe ADHF or those with advanced HF who are refractory to pharmacologic therapy. The intra-aortic balloon pump (IABP) is the most common type of temporary MCS but provides the least amount of hemodynamic support. Other types of temporary MCS include ventricular assist devices (VADs) and extracorporeal membrane oxygenation (ECMO).

- 14 Cardiac transplantation remains the only definitive therapy for advanced HF. Given the extended wait time for identifying suitable donors, implantation of a durable VAD may be considered for patients who are eligible for cardiac transplantation (ie, “bridge to transplant” or BTT) or in whom transplantation is not an option (ie, “destination therapy” or DT).

An estimated 5.7 million American adults have heart failure (HF) and projections indicate another 3 million will develop HF by 2030, a 50% increase in prevalence from prior estimates.[1,2] Despite survival from HF having improved over time, 5-year mortality remains 50%.[1] In addition, the growing number of patients living with HF has led to substantial increases in hospitalization rates. Recent data indicate that over 1 million patients are hospitalized for HF annually, contributing to significant increases in morbidity and mortality and adding substantial burden to the healthcare system.[1,3] Hospitalization for HF has been independently associated with increases in subsequent hospitalization as well as decreased survival.[3,4] The cost of HF is projected to approach $70 billion by 2030, an increase thought to be driven primarily by the costs of acute care.[2]

The clinical course of HF manifests as periods of relative stability with increasingly frequent episodes of decompensation as the disease progresses.[5] Several terms have been used to characterize worsening HF requiring hospitalization. Patients with persistent symptoms or advanced HF requiring specialized interventions (eg, surgery) despite guideline-directed medical therapy (GDMT) are classified as Stage D according to the American College of Cardiology Foundation/American Heart Association (ACCF/AHA) system.[6] Due to the presence of HF symptoms with minimal activity or at rest, these patients are also typically classified as New York Heart Association (NYHA) class III or IV, respectively. The terms *acute decompensated heart failure* (ADHF) or *exacerbation of heart failure* refer to those patients with new or worsening signs or symptoms of HF (often as a result of volume overload and/or low cardiac output [CO]) requiring medical intervention such as an emergency department visit or hospitalization. The term *acute heart failure* may be misleading as it more often refers to patients with a sudden onset of HF signs or symptoms following previously normal cardiac function (eg, following myocardial infarction [MI]). This chapter focuses on the management of patients with ADHF, which may include those with heart failure with reduced ejection fraction (HFrEF) or heart failure with preserved ejection fraction (HFpEF).

Despite the considerable morbidity and mortality associated with ADHF, few randomized controlled trials have been conducted in this patient population. For those studies that have been published, the heterogeneity of patients enrolled often limits clinical application. Nonetheless, a comprehensive update to the clinical practice guidelines for HF was issued by ACCF/AHA in 2013, including sections specifically focused on the management of advanced HF and ADHF (Sections 7.4 and 8.1-8.9, respectively); these will be referenced where relevant throughout the remainder of this chapter.[6]

ETIOLOGY AND PATHOPHYSIOLOGY

The underlying etiology of ADHF varies and is often multifactorial. *De novo* HF may occur due to left ventricular dysfunction following a large MI or sudden elevation in blood pressure; such cases represent approximately 25% of admissions.[7] However, the majority of hospitalizations for ADHF (70%) are comprised of patients experiencing an acute worsening of chronic HF;[7] readers are referred to (Chapter 14) for a more detailed discussion of the pathophysiology of chronic HF. Patients can become refractory to oral therapies and decompensate after even a relatively mild insult (eg, dietary indiscretion, nonsteroidal anti-inflammatory drug use), medication nonadherence, or concurrent noncardiac illness (eg, infection). New or worsening cardiac processes, such as MI, atrial or ventricular arrhythmias, hypertensive crises, myocarditis, or acute valvular insufficiency, may also produce ADHF in an otherwise stable patient. Emerging evidence indicates that exacerbations of chronic HFrEF and HFpEF occur in

approximately equal numbers.[6] A minority of patients (5%) present with progressive worsening of CO and refractoriness to therapy due to advanced left ventricular systolic dysfunction.[7]

Several studies have provided a better understanding of the prognostic factors associated with ADHF. Data from the Acute Decompensated Heart Failure National Registry (ADHERE) found blood urea nitrogen (BUN) greater than or equal to 43 mg/dL to be the best individual predictor of in-hospital mortality, followed by systolic blood pressure less than 115 mm Hg and serum creatinine greater than or equal to 2.75 mg/dL. Using these three parameters, patients may be classified as low, intermediate, high, and very high risk, with in-hospital mortalities of 2%, 6%, 13%, and 20%, respectively.[8] Hyponatremia, elevations in troponin I, ischemic etiology, and poor functional capacity are also negative prognostic factors.[3] In the Organized Program to Initiate Lifesaving Treatment in Hospitalized Patients with Heart Failure (OPTIMIZE-HF) Registry, low blood pressure and poor renal function were found to be negative prognostic markers for subsequent readmission or death.[9] Use of GDMT at discharge as well as coronary angiography or implantable cardioverter-defibrillator placement during hospitalization were associated with improved prognosis, suggesting that optimal management during hospitalization can yield beneficial effects on subsequent prognosis.[9]

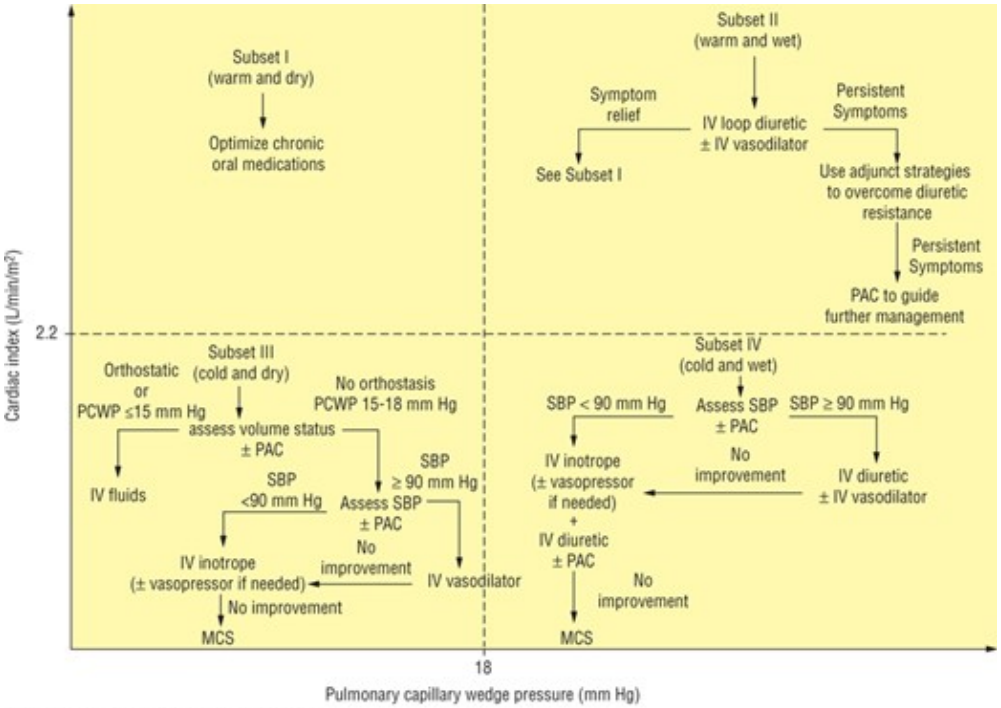
CLINICAL PRESENTATION

A careful history and physical examination are key components of an ADHF diagnosis. The history should focus on potential etiologies of ADHF, the presence of precipitating factors, onset, duration, and severity of symptoms, and a careful medication history. Hemodynamic status should also be ascertained in order to guide initial therapy. Patients presenting with ADHF may be categorized into one of four hemodynamic subsets based on volume status (euvolemic or "dry" vs volume overloaded or "wet") and CO (adequate CO or "warm" vs hypoperfusion or "cold"). The corresponding subsets are warm and dry (subset I), warm and wet (subset II), cold and dry (subset III), or cold and wet (subset IV) **(Fig. 15-1)**. The term *cardiogenic shock* may also be used to describe patients in subsets III and IV who present with low blood pressure and evidence of tissue hypoperfusion. In addition to guiding therapeutic decision-making, these four hemodynamic profiles are also predictive of clinical outcomes. Compared to dry-warm patients, patients in the wet-warm and wet-cold subsets have a 2-fold and 2.5-fold greater risk of death at 1 year, respectively.[10]

FIGURE 15-1

General management algorithm for acute decompensated heart failure based on clinical presentation.

Patients may be categorized into a hemodynamic subset based on signs and symptoms or invasive hemodynamic monitoring. Adjunct strategies for overcoming diuretic resistance include increasing the dose of loop diuretic; switching to a continuous infusion; adding a diuretic with an alternative mechanism of action, an IV vasodilator, or an IV inotrope; and in select patients, ultrafiltration or a vasopressin antagonist. (IV, intravenous; MCS, mechanical circulatory support; PAC, pulmonary artery catheter; PCWP, pulmonary capillary wedge pressure; SBP, systolic blood pressure.)



Although hemodynamic status can be determined in a majority of patients based on signs and symptoms, a small subset of patients may require invasive hemodynamic monitoring to guide therapy. In this latter population, measurement of the pulmonary capillary wedge pressure (PCWP) and cardiac index (CI) may be used to categorize patients by volume status and CO, respectively. A PCWP greater than 18 mm Hg often reflects volume overload and is used to distinguish "wet" from "dry" subsets, whereas a CI less than 2.2 mL/min/m^2 is often used to distinguish "cold" from "warm" subsets; use of these invasive hemodynamic parameters will be discussed in further detail later in this chapter.

Hospitalization for ADHF should be considered based on the clinical findings listed in **(Table 15-1)**. Most patients do not require admission to an intensive care unit and may be admitted to a monitored unit or general medical floor. If a patient experiences hemodynamic instability necessitating frequent monitoring of vital signs, invasive hemodynamic monitoring, or rapid titration of IV medications (with concurrent monitoring), admission to an intensive care unit may be required to ensure optimal outcomes.

TABLE 15-1 Indications for Hospitalization in Patients Presenting with ADHF

Presenting Features	Clinical Findings
Evidence of fluid overload	• Weight gain > 10 kg (consider if >5 kg) • Symptoms of congestion (eg, dyspnea on exertion or at rest, orthopnea, PND, and early satiety*) • Signs of congestion (eg, tachypnea + oxygen saturation < 90%, JVD, crackles, hepatomegaly, and lower extremity edema)

Presenting Features	Clinical Findings
Evidence of low cardiac output	• Extreme fatigue • Hypotension, narrow pulse pressure • Cool extremities
Evidence of organ hypoperfusion	• Worsening renal or hepatic function • Altered mental status
Concomitant cardiovascular diseases that could compromise hemodynamic status	• Uncontrolled hypertension • Myocardial ischemia or infarction • Valvular disease • Arrhythmia (eg, atrial fibrillation with rapid ventricular response, ventricular tachycardia, and repeated ICD shocks)
Other conditions that could compromise hemodynamic status	• Severe electrolyte deficiency (potassium and magnesium) • Acute exacerbation of pulmonary disease (eg, asthma, COPD, or pulmonary embolus) • Infection such as pneumonia or urosepsis • Symptomatic hypothyroidism or hyperthyroidism • Use of medications with negative inotropic effects (eg, nondihydropyridine calcium antagonists) • Use of medications that promote fluid retention (eg, NSAIDs, steroids, thiazolidinediones, and pregabalin)

Abbreviations: COPD, chronic obstructive pulmonary disease; ICD, implantable cardioverter defibrillator; JVD, jugular venous distension; NSAIDs, nonsteroidal anti-inflammatory agents; PND, paroxysmal nocturnal dyspnea.

*Early satiety may also be a symptom of low cardiac output.

Signs and Symptoms

Important elements of the physical examination include assessment of vital signs and weight, cardiac auscultation for heart sounds and murmurs, pulmonary auscultation for crackles, presence and severity of peripheral edema, and evidence of end-organ dysfunction. The most common presentation of ADHF is severe volume overload. Symptoms consistent with pulmonary congestion include orthopnea and dyspnea with minimal exertion, and those associated with systemic congestion include gastrointestinal (GI) discomfort, ascites, and peripheral edema. Orthopnea is the symptom that best correlates with elevated pulmonary pressure, whereas jugular venous pressure is the most reliable sign of volume status, warranting evaluation at admission as well as throughout the acute hospitalization as an indicator of diuretic efficacy.[10] An S3 gallop, suggestive of increased volume in the left ventricle, has high diagnostic specificity for ADHF.[10] Other physical findings, such as pulmonary crackles and lower extremity edema, have low specificity and sensitivity for the diagnosis of ADHF.

Signs and symptoms of low CO are often nonspecific and may include generalized fatigue, cool extremities, and pallor. Manifestations of impaired end-organ perfusion may also be present, such as altered mental status (decreased perfusion to the central nervous system) or decreased urine output (decreased renal perfusion). Hypotension and narrow pulse pressure may also suggest low CO. GI symptoms, such as poor appetite, nausea, and early satiety, may be a sign of poor perfusion to the GI tract, abdominal congestion, or both. Many patients will present with signs and symptoms of both wet and cold subsets; in these patients, symptoms of low CO may not be obvious until congestion has been optimally treated.

Laboratory Findings

Plasma B-type natriuretic peptide (BNP) and N-terminal pro-BNP concentrations are positively correlated with the degree of left ventricular dysfunction and HF, and are now frequently used to assist in the differential diagnosis of dyspnea (HF vs asthma, chronic obstructive pulmonary disease, or infection). A low BNP concentration, often defined as less than 100 pg/mL (ng/L; 29 pmol/L), has a 96% predictive value for excluding HF as an underlying etiology for dyspnea. In addition, an elevated BNP concentration prior to discharge is associated with an increased risk of poor long-term outcomes. However, some limitations exist. For example, any disease process that increases right heart pressures will elevate BNP, such as pulmonary emboli, chronic obstructive lung disease, and pulmonary arterial hypertension. In addition, BNP concentrations may be mildly increased with advanced age, female gender, and renal dysfunction, and lower in the setting of obesity.[10] Although the role of BNP in HF remains an area of ongoing research, guidelines currently recommend obtaining a BNP or NT-proBNP in order to assist with clinical decision-making when the diagnosis of ADHF is uncertain and for determining the prognosis or severity of disease.[6]

A number of other laboratory tests should also be obtained to identify precipitating factors for ADHF (eg, thyroid function tests, complete blood count to assess for infection). In particular, cardiac enzymes should be obtained to exclude the presence of myocardial ischemia. Routine serum chemistries (eg, serum creatinine, liver function tests) should also be obtained to assess end-organ perfusion. Profound volume overload may also contribute to aberrations in serum markers of end-organ function due to venous congestion. Other helpful laboratory tests include markers of peripheral tissue perfusion, such as venous oxygenation saturation and serum lactate concentrations.

Invasive Hemodynamic Monitoring

2 Invasive hemodynamic monitoring should be reserved for select patients with ADHF. Invasive hemodynamic monitoring is usually performed with a flow-directed pulmonary artery (PA) catheter (also known as Swan-Ganz catheter) placed percutaneously into a central vein and advanced through the right side of the heart and into the PA. This process may also be referred to as right heart catheterization (in contrast to left heart catheterization, which is often used to visualize the coronary arteries). In a clinical trial assessing routine PA catheter use in patients with ADHF, no impact on survival was observed, although those with a clear indication for its use (eg, titration of IV inotropes) were excluded.[11] Based on these results, the routine use of invasive hemodynamic monitoring in patients with ADHF is not currently recommended.[6] However, it often provides important information in patients whose clinical status is unclear or complicated, or as a guide for titrating rapidly acting medications (eg, IV vasodilators). As a consequence, invasive hemodynamic monitoring should be considered in patients who are refractory to initial therapy, those in whom volume status is unclear, or those who have clinically significant hypotension (eg, systolic blood pressure <80 mm Hg) or worsening renal function despite appropriate initial therapy. Hemodynamic assessment is also required in patients being evaluated for mechanical circulatory support (MCS) or cardiac transplantation; in the latter case, adequate reversal of pulmonary hypertension in response to vasodilator challenge must be documented before listing for transplant. Finally, documentation of an adequate hemodynamic response to IV inotropic therapy is often necessary in order to obtain approval for reimbursement for chronic outpatient inotropic therapy.[6]

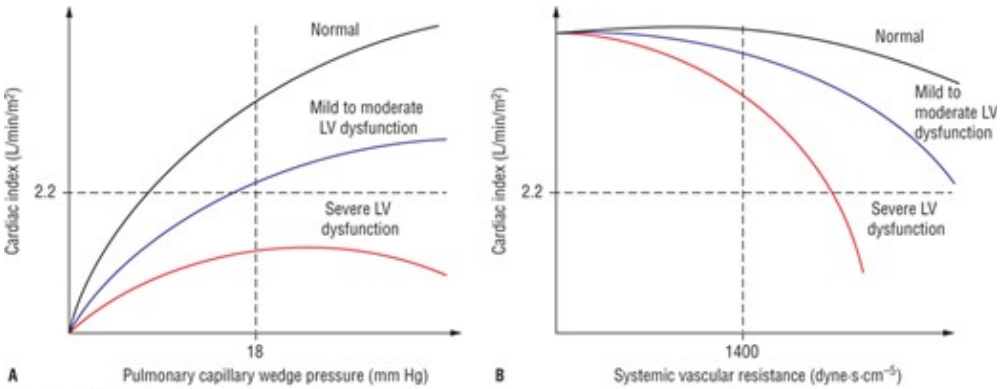
3 Several important hemodynamic parameters can be obtained from a PA catheter. Inflation of a balloon proximal to the end port allows the catheter to be "wedged" inside a pulmonary capillary, yielding the PCWP. In the absence of an intracardiac shunt, mitral valve disease, or severe pulmonary disease, the PCWP may be used to estimate left ventricular end-diastolic pressure, or "preload." Preload refers to the stretch incurred by cardiac myocytes in response to increased volumetric pressure. Thus, PCWP can be a useful marker of volume status; elevated PCWP is often indicative of volume overload whereas reduced PCWP indicates dehydration or inadequate ventricular filling pressure. The relationship between preload (or PCWP) and CO is described by the Frank-Starling mechanism, which is depicted in **Fig. 15-2A**. Due to the much flatter curve observed in patients with HF, increases in preload do not confer the same improvements in CO observed in patients with normal cardiac function. As a consequence, higher pressures (ie, 15-18 mm Hg, compared to a normal range of 6-12 mm Hg) are often required in patients with HF in order to optimize CO. Excess preload (PCWP >18 mm Hg) manifests as signs and symptoms of congestion. Fortunately, PCWP can be lowered to 15 to 18 mm Hg with relatively little decrease in CO due to the flatter shape of the Frank-Starling curve in HF. Extreme elevations in PCWP (representing profound volume overload) are also thought to worsen cardiac function, although a mechanism for this phenomenon is not clearly understood.

FIGURE 15-2

Hemodynamic alterations in heart failure.

Figure A is an illustration of the relationship between cardiac output (displayed as cardiac index, which is cardiac output normalized for body surface area) and preload (displayed as pulmonary capillary wedge pressure) according to severity of left ventricular function. Figure B is an illustration of the corresponding

relationship between cardiac output and afterload (displayed as systemic vascular resistance). (LV, left ventricular.)



A PA catheter may also be used to determine CO, or the volume of blood being pumped by the heart (particularly by the left ventricle) over a unit of time. CO is often normalized for body surface area to yield CI, which allows measurements to be made without regard to body size. Using parameters derived from the PA catheter, CO is calculated based on one of two methods. The thermodilution method for determining CO is performed by releasing cooled fluid from a proximal port on the PA catheter and measuring the resulting change in temperature at a downstream thermistor over a period of time. In the Fick method, blood flow is calculated using the difference between arterial and venous oxygen concentration, oxygen-carrying capacity of hemoglobin, and a population constant for oxygen consumption over time. The preferred method for determining CO varies by clinician, although the presence of certain comorbid conditions (eg, valvular abnormalities and pulmonary disease) may make one method more or less accurate in an individual patient.

The systemic vascular resistance (SVR) can also be calculated using parameters measured by the PA catheter, including CO, mean arterial pressure (MAP), and central venous pressure (CVP). Also referred to as total peripheral resistance or arterial impedance, SVR reflects "afterload," or the total sum of forces impeding ejection of blood from the left ventricle. Vasoconstriction (ie, decreased diameter of arterial vessel lumen) increases vascular resistance, whereas vasodilation decreases it. Although SVR is inversely related to CO, patients with normal left ventricular function can often withstand relatively high elevations in SVR, as shown in **Fig. 15-2B**. However, in patients with HF, even a moderately elevated SVR can compromise left ventricular performance. Elevated SVR is common in untreated HF and generally responsive to oral or IV vasodilators. Conversely, a reduction in resistance is consistent with vasodilatory shock (eg, sepsis) and is routinely managed with IV vasopressor therapy (see Chapter 23).

A PA catheter can also be used to measure pulmonary vascular resistance (PVR), which represents the impedance of blood flow from the right ventricle to the pulmonary circulation. Pulmonary hypertension and pulmonary edema are two common causes of elevated PVR. As described previously, patients with elevated pulmonary pressure must have proven reversibility (in response to vasodilator challenge) prior to being listed for heart transplantation. Otherwise, if elevations in PVR are irreversible, isolated right ventricular failure is likely to occur immediately following heart transplantation. Just as SVR is calculated using MAP, PVR is calculated using the mean PA pressure, which incorporates the PA systolic and diastolic pressures. The PA diastolic pressure may also be useful if the PA catheter fails to wedge (making it impossible to obtain PCWP). If the PCWP and PA diastolic pressure have been correlated prior to the

failure to wedge, then the PA diastolic pressure may be followed as a surrogate marker of volume status. Normal values for the aforementioned hemodynamic parameters are listed in **Table 15-2**.

TABLE 15-2 Normal Hemodynamic Values

Central Venous (Right Atrial) Pressure, mean, CVP	<5 mm Hg
Right Ventricular Pressure (Systolic/Diastolic)	25/0 mm Hg
Pulmonary Artery Pressure (Systolic/Diastolic), PAS/PAD	25/10 mm Hg
Pulmonary Arterial Pressure, mean, PAP	<18 mm Hg
Pulmonary Capillary Wedge Pressure, PCWP	<12 mm Hg
Systemic Arterial Pressure (Systolic/Diastolic), SBP/DBP	120/80 mm Hg
Mean Arterial Pressure, MAP = (DBP+[1/3 (SBP-DBP])	70-110 mm Hg
Cardiac Output, CO	4-6 L/min
Cardiac Index, CI = CO/BSA	2.8-4.2 L/min/m^2
Systemic Vascular Resistance, SVR = ([MAP–CVP]*80)/(CO)	900-1,400 dyne·sec·cm^{-5}
Pulmonary Vascular Resistance, PVR = ([PAP–CVP]*80)/(CO)	150-250 dyne·sec·cm^{-5}
Arterial Oxygen Saturation	90%-94%
Mixed Venous Oxygen Saturation	60%-80%

Abbreviation: BSA, body surface area.

TREATMENT

Desired Outcomes

4 The overall goals of therapy in ADHF are to provide symptomatic relief while optimizing volume status and CO so that a patient can be discharged in a stable compensated state on oral drug therapy. Although IV diuretic, vasodilator, and inotropic therapy can be very effective at achieving these goals, their efficacy must be balanced against the potential for serious adverse effects. All patients should also be evaluated for precipitating factors of ADHF, including arrhythmias, hypertension, myocardial ischemia or infarction, anemia, and thyroid disorders. Patients who may benefit from coronary revascularization should also be identified. Medications (including noncardiac medications) that may worsen cardiac function should also be evaluated. Prior to discharge, optimization of chronic oral therapy and patient education are critical to preventing rehospitalization. When available and appropriate, patients should be referred to an HF disease management program.[6]

General Approach to Treatment

An important step in the management of ADHF is to first assess medications being taken prior to admission and determine whether adjustment or discontinuation is required. If fluid retention is evident on physical examination, aggressive diuresis should be pursued. Although increasing the dose of oral diuretic therapy may be effective in some cases, the use of IV diuretics is often necessary.[5] In the absence of cardiogenic shock or symptomatic hypotension, every effort should be made to continue all

GDMT for HF. β-blocker therapy may be temporarily held or dose-reduced if recent initiation or up-titration is responsible for acute decompensation. Otherwise, β-blocker discontinuation is discouraged as it has been associated with worse outcomes in patients with ADHF.[12,13] Appropriateness of initiating β-blockers prior to discharge will be discussed later in this chapter.

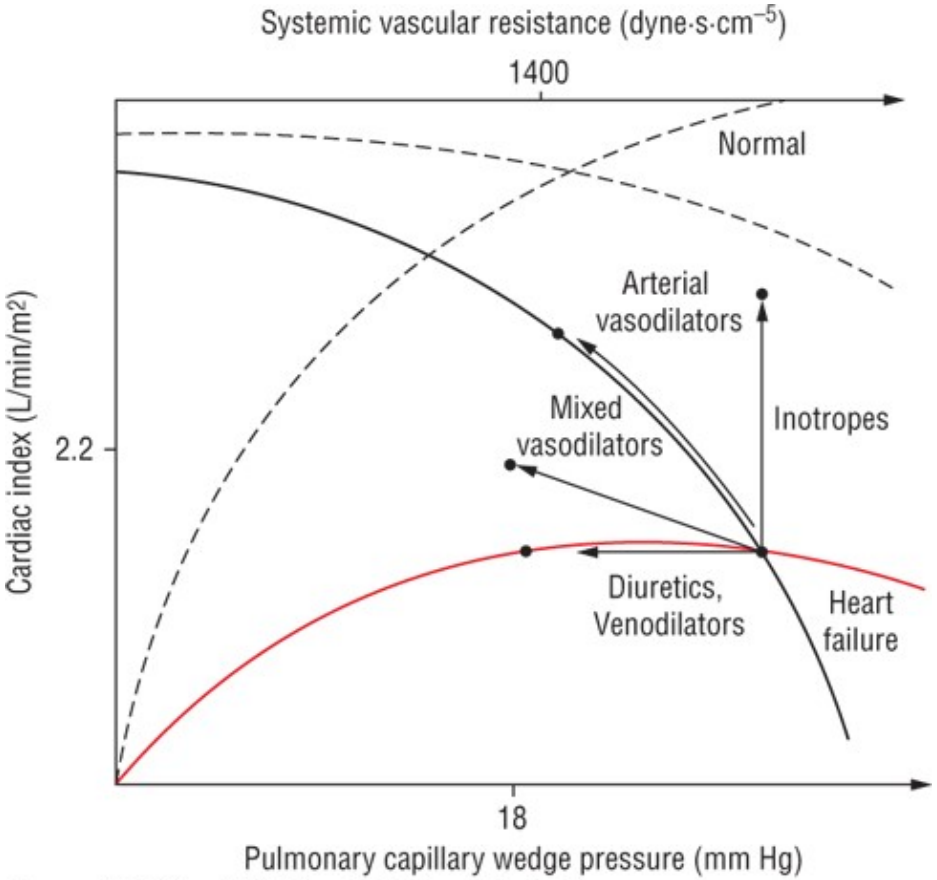
Select GDMT may also need to be temporarily held in the setting of renal dysfunction, especially if oliguria or hyperkalemia is present (eg, ACE inhibitors, angiotensin receptor blockers, neprilysin inhibitors, aldosterone antagonists). Therapies that may cause worsening renal function (eg, ACE inhibitor) should only be initiated or up-titrated cautiously during aggressive volume removal with IV diuretic therapy. Additionally, serum potassium concentrations should be monitored closely as IV diuretic therapy is transitioned to oral diuretic therapy, especially if an aldosterone antagonist has been initiated during the hospital stay; this ensures therapy can be tolerated on the intended oral diuretic dose prescribed at discharge. Most patients may continue to receive digoxin at doses targeting a trough serum concentration of 0.5 to 1 ng/mL.[6] Discontinuation of digoxin is generally discouraged as an association between withdrawal of therapy and worsening HF has been well-documented.[14,15] Digoxin should only be discontinued if serum concentrations cannot be safely maintained within the desirable range.

6 The acute management of ADHF is based primarily on hemodynamic status. The hemodynamic subsets described previously were first proposed for patients with left ventricular dysfunction following acute MI but are also applicable to patients with ADHF due to other causes.[16] Two general approaches exist for determining hemodynamic status. One is to use simple clinical parameters (eg, signs and symptoms, blood pressure, and organ function) and the other is to use these in conjunction with invasive hemodynamic monitoring. A management algorithm based on hemodynamic subset is depicted in Fig. 15-1. The hemodynamic effects exerted by pharmacologic therapies used in the management of ADHF are illustrated in **Fig. 15-3**.

FIGURE 15-3

Hemodynamic effects of pharmacologic therapy in acute decompensated heart failure.

Pharmacologic agents used in the management of acute decompensated heart failure exert important effects on cardiovascular hemodynamics. Although diuretics and venodilators reduce preload, this does not substantially reduce cardiac output in heart failure due to a flatter Frank-Starling curve. Arterial vasodilators reduce afterload, producing an increase in cardiac output as a consequence of improved left ventricular performance. Vasodilators with effects on both venous and arterial tissue may reduce both preload and afterload. Inotropes improve contractility directly, although some agents (eg, milrinone) may exert salutary effects on afterload via vasodilation.



Subset I (Warm and Dry)

Patients in subset I generally do not have signs and symptoms of volume overload or hypoperfusion and usually have CI and PCWP values within appropriate ranges. Patients in this subset have the lowest risk of mortality and do not require immediate intervention other than optimization of GDMT for HF. Patients with significant left ventricular dysfunction may still present in subset I because normal compensatory mechanisms and/or drug therapy may at least partially correct an otherwise abnormal hemodynamic profile.

Subset II (Warm and Wet)

Patients in subset II are likely to present with signs and symptoms of congestion (eg, orthopnea and peripheral edema) due to increased hydrostatic pressure in the pulmonary and systemic circulation, but without evidence of peripheral hypoperfusion. As a consequence, they often have adequate CO but a PCWP greater than 18 mm Hg. The primary goal of therapy in these patients is to relieve symptoms of congestion by lowering PCWP without reducing CO, increasing heart rate, or provoking neurohormonal activation.

Intravenous agents that reduce preload via diuresis and/or direct venodilation (eg, loop diuretics) are the most appropriate initial therapy for patients presenting in subset II. Despite a very rapid onset, the time required for significant improvement in oxygenation with IV loop diuretics may take several hours in

select patients. Thus, IV vasodilators with effects on primarily the venous vasculature (eg, nitroglycerin) may be utilized for rapid venodilation (see Fig. 15-3), which can aid in acutely improving hypoxia. IV vasodilators should especially be considered in patients with acute pulmonary edema or severe hypertension but avoided in patients with symptomatic hypotension. Continuous blood pressure monitoring should be performed during IV vasodilator use. If symptomatic hypotension occurs with vasodilator therapy, the dose should be reduced or the agent discontinued. Resistance to loop diuretics may occur, requiring dose escalation or addition of thiazide-type diuretics. If patients fail to respond to the above therapies or experience worsening renal function, IV inotropic therapy (with or without PA catheter insertion) should be considered.

Patients in subset II should also be placed on a sodium restriction (<2 g daily). In patients with moderate hyponatremia (<130 mEq/L), fluid restriction (<2 L daily) should be considered, and in patients with worsening or severe hyponatremia (<125 mEq/L), stricter fluid restriction may be necessary.[6] Arginine vasopressin (AVP) antagonists may also be considered for severe euvolemic or hypervolemic hyponatremia, particularly if symptoms emerge. Finally, supplemental oxygen should be administered as needed for hypoxemia.

Subset III (Cold and Dry)

Patients in subset III present with evidence of peripheral hypoperfusion (eg, weakness, decreased urine output, and weak pulses) but no signs or symptoms of congestion. They often present with a CI of less than 2.2 L/min/m^2 but no abnormal elevation in PCWP. The mortality rate of patients in subset III is higher than that of patients with adequate perfusion.[16] Although the treatment goal is to alleviate signs and symptoms of hypoperfusion by increasing CI and perfusion to essential organs, therapy may differ based on initial presentation. If evidence of hypovolemia exists (eg, orthostatic hypotension) or PCWP is below 15 mm Hg, IV fluids should be administered to provide a more optimal left ventricular filling pressure (ie, 15-18 mm Hg), consequently improving CI (see Fig. 15-1). As this presentation most often occurs in the setting of overly aggressive diuresis, diuretic therapy should be withheld and fluid restriction liberalized; these interventions alone may obviate the need for IV fluids.

When only mild left ventricular dysfunction is present, IV fluid administration may be all that is necessary to achieve a CI above 2.2 L/min/m^2). However, in patients with more advanced HF, IV positive inotropic agents (eg, dobutamine and milrinone) and/or IV arterial vasodilators (eg, nitroprusside or nesiritide) may be necessary to achieve adequate CI (see Fig. 15-3). As with vasodilators, IV inotrope administration requires frequent blood pressure monitoring as well as continuous monitoring for arrhythmias. If arrhythmias occur, dose reduction or discontinuation of inotropic therapy should be performed. IV inotropes should also be avoided in patients with low left ventricular filling pressure. In general, inotropic should be reserved for patients with evidence of severely low CO who are not candidates for IV vasodilators (ie, hypotension). They may also be used to “bridge” patients to MCS or heart transplantation, or as palliative therapy to improve functional status and quality of life in patients who are ineligible for definitive therapies.

Subset IV (Cold and Wet)

Patients in subset IV present with signs and symptoms of both volume overload and peripheral

hypoperfusion, and often have a CI of less than 2.2 L/min/m^2 and a PCWP exceeding 18 mm Hg. This subset is characterized by the worst prognosis of all four and represents the most common hemodynamic profile for patients with end-stage HF. Given the severity of HF, patients in subset IV cannot maintain adequate CI despite elevated left ventricular filling pressure and increased myocardial fiber stretch. Treatment goals for these patients include alleviation of signs and symptoms associated with congestion and hypoperfusion by increasing CI to above 2.2 L/min/m^2 and reducing PCWP to 15 to 18 mm Hg while maintaining adequate MAP. Therapy often involves a combination of agents used in subsets II and III (ie, combination of IV diuretic plus vasodilator or inotrope). These targets may be difficult to achieve and often necessitate careful monitoring and individualization of drug therapy. In the presence of significant hypotension and low MAP, vasodilators should be avoided. In some cases, even the vasodilating effects of inotropic therapy may compromise MAP, requiring that combined inotrope and vasopressor therapy (eg, dobutamine plus norepinephrine) or an inotrope with vasopressor activity (eg, dopamine) be used to achieve adequate end-organ perfusion. Once peripheral perfusion has been restored, therapy can then be adjusted to obtain the desired clinical response (see Fig. 15-1).

PHARMACOLOGIC MANAGEMENT OF VOLUME OVERLOAD

Although IV loop diuretics are the mainstay of therapy for volume overload in ADHF, several additional therapies may be used in conjunction with loop diuretics in select patients. Until recently, an understanding of the appropriate management of volume overload had not substantially improved due to a dearth of clinical trial data in this population. However, several recent trials have expanded our understanding of both agent selection as well as method of administration, although many questions remain.

Diuretics

7 IV loop diuretics, including furosemide, bumetanide, and torsemide, are used commonly in the management of ADHF **(Table 15-3)**, and furosemide remains the most widely studied and used in this setting. Current guidelines recommend the use of loop diuretics as first-line therapy for patients with ADHF and volume overload, and that they typically be administered IV.[6] Bolus administration reduces preload within 5 to 15 minutes by functional venodilation and later (>20 minutes) via sodium and water excretion, thereby improving pulmonary congestion. However, an acute reduction in venous return may severely compromise effective preload in patients with significant diastolic dysfunction, intravascular depletion, or those in whom CI is significantly dependent on adequate filling pressure (ie, preload-dependent). This reduction in preload may cause reflex neurohormonal activation (ie, elevation of renin, norepinephrine, and AVP), resulting in arteriolar and coronary vasoconstriction, tachycardia, and increased myocardial oxygen consumption. Unlike arterial vasodilators and positive inotropic agents, diuretics do not cause an upward shift in the Frank-Starling curve or significantly increase CO in most patients (see Table 15-3 and Fig. 15-3). In fact, excessive preload reduction (ie, PCWP of <15 mm Hg) can lead to a decline in CO (see Fig. 15-3). Although counterintuitive, patients with excessive fluid overload may initially present with compromised CO, which may improve with diuresis once PCWP approaches the normal range (see Fig. 15-3); this may explain why renal function occasionally improves in the setting of diuresis. Alternatively, the kidneys may simply be responsive to a reduction in venous congestion, similar to the improvement observed when an obstruction is removed in postrenal acute kidney injury.

TABLE 15-3 Diuretics Commonly Utilized for the Management of ADHF

	Furosemide	Bumetanide	Torsemide	Metolazone	Hydrochlorothiazide	Chlorothiazide
Mechanism	Loop diuretic	Loop diuretic	Loop diuretic	Thiazide-type diuretic	Thiazide-type diuretic	Thiazide-type diuretic
Oral Bioavailability	10%-100% (mean 50%)	80%-90%	80%-100%	40%-65%	65%-75%	N/A
Dose Equivalence (IV)	20-40 mg	0.5-1 mg	10-20 mg	N/A	N/A	N/A
Usual Intermittent Dose (maximum)	40-160 mg IV once to three times daily (200 mg/dose)	0.5-4 mg IV once to three times daily (5 mg/dose)	IV no longer available	2.5-5 mg PO once daily (20 mg/day)	25-50 mg PO once daily (100 mg/day)	500 mg-1 g IV once or twice daily (2 g/day)
Usual Continuous Infusion Dose (maximum)	5-20 mg/hr (40 mg/hr)	0.5-2 mg/hr (4 mg/hr)	IV no longer available	N/A	N/A	N/A
Onset of action (Peak effect)	30-60 min PO, 5 mins IV (2 hrs)	30-60 min PO, 2-3 mins IV (1-2 hrs)	1 hr PO (1-2 hrs)	2-3 hrs (6-8 hrs)	2 hrs (4 hrs)	2 hrs (3-6 hrs)
Duration of action	4-6 hrs	4-6 hrs	18-24 hrs	12-24 hrs	5-15 hrs	6-12 hrs

Abbreviations: CrCl, creatinine clearance; IV, intravenous; N/A, not applicable; PO, oral.

Despite relative overload of total body fluid, intravascular volume depletion may occur in the setting of rapid diuresis due to a delay in the migration of fluid from the interstitial space back into the systemic vasculature. Most patients tolerate a two liter per day net negative diuresis. However, some patients with advanced HF will only tolerate a one liter per day net negative diuresis. Patients who are malnourished due to the early satiety commonly observed in advanced HF (as a consequence of abdominal edema and/or reduced perfusion to the GI tract) may be especially sensitive to rapid shifts in intravascular volume, as decreased oncotic pressure resulting from hypoalbuminemia decreases the rate at which fluid can effectively migrate from the interstitial space into the intravascular space. Due to these and other factors, diuretic therapy must be highly individualized in order to obtain the desired improvement in congestive symptoms while avoiding a reduction in CO, symptomatic hypotension, or worsening renal function. Electrolyte depletion should also be monitored closely, especially when high doses or combination diuretic therapy is utilized.

Adjunct Diuretics

Occasionally patients respond less optimally to escalating doses of loop diuretics, a phenomenon known as diuretic resistance. HF is the most common clinical setting in which this phenomenon is observed and multiple retrospective analyses suggest that diuretics, especially aggressive administration, may be associated with dose-dependent increases in mortality.[17] Evidence also suggests that high doses are associated with renal dysfunction in ADHF, which only further exacerbates diuretic resistance.[18,19] As a consequence, the need for increased exposure to diuretics in the setting of resistance warrants concern.

The mechanisms responsible for diuretic resistance in patients with HF are thought to be both pharmacokinetic and pharmacodynamic in nature.[20] The oral bioavailability of furosemide is relatively unchanged in patients with HF as long as GI perfusion has not been compromised, but the rate of absorption is prolonged by approximately twofold and peak concentrations are reduced by approximately half. Because loop diuretics have a sigmoidal-shaped concentration-response curve, prolonged absorption may result in concentrations that fail to reach the threshold necessary for producing effective diuresis. Resistance is also observed with IV administration, suggesting an equally important pharmacodynamic contribution to this phenomenon. The decreased responsiveness in patients with HF may be explained in part by compensatory reabsorption in the distal convoluted tubule in response to the high concentrations of sodium resulting from blocked reabsorption in the loop of Henle. Over time, the distal tubule may also undergo hypertrophy, thereby enhancing its ability to reabsorb sodium. Finally, neurohormonal activation, impaired CO, reduced renal perfusion, and decreased drug delivery to the kidney may also contribute to resistance.

Several strategies may be employed to overcome diuretic resistance. Current guidelines recommend one of two pharmacologic options in patients who do not initially respond to diuretic therapy: increased doses of loop diuretics or addition of an alternative diuretic with a different mechanism of action (eg, thiazide-type diuretics).[6] First, higher doses of loop diuretics are more likely to achieve concentrations near the top of the concentration-response curve. Although higher doses produce greater diuresis, these effects are not associated with improved long-term outcomes and must be weighed against the risk for transient worsening of renal function.[21] Importantly, guidelines emphasize higher doses may be administered as either an IV bolus or continuous infusion.[6] The use of continuous infusion loop diuretics has been considered another approach for overcoming diuretic resistance. Several small studies suggest a greater natriuretic effect with no difference in metabolic adverse effects when continuous infusion furosemide is compared to the same total daily dose given by IV bolus.[22,23] In contrast, a prospective randomized trial of 308 patients with ADHF compared low and high-dose furosemide administered as a continuous infusion or intermittent IV bolus every 12 hours; although differences were observed in the comparison of low and high-dose furosemide, no differences in relief of symptoms, urine output, weight loss, or long-term outcomes were observed between continuous infusion or intermittent IV bolus administration.[21] Importantly, the trial only evaluated the selection of initial diuretic therapy and did not specifically enroll patients with diuretic resistance, thus the role of continuous infusion diuretics in this population remains unknown.

A second strategy for overcoming diuretic resistance is to add a second diuretic with a different mechanism of action. Combining a loop diuretic with a distal tubule blocker such as oral metolazone, oral hydrochlorothiazide, or IV chlorothiazide (see Table 15-3) can produce a synergistic diuretic effect.

Inhibition of sodium reabsorption in the loop of Henle increases sodium delivery to (and reabsorption in) the distal convoluted tubule, which can be subsequently blocked by a thiazide-type diuretic. The combination of a loop and thiazide-type diuretic should generally be reserved for hospitalized patients, as profound diuresis with severe electrolyte and intravascular volume depletion may occur. If used in the outpatient setting, very low doses or infrequent administration (eg, one to three times weekly) of a thiazide-type diuretic should be recommended. Patients should also receive close follow-up (eg, weight, vital signs, serum potassium, and assessment for orthostatic hypotension) to avoid serious adverse events.

Non-pharmacologic strategies for managing diuretic resistance include further limiting sodium and fluid beyond routinely recommended restrictions previously described (ie, less than 1 g and less than 1 L per day, respectively).

Vasodilators

IV vasodilators may also be helpful in select patients with refractory volume overload. The most commonly used IV vasodilators in ADHF are sodium nitroprusside, nitroglycerin, and nesiritide, and each can be classified according to its most prominent site of action (ie, arterial or venous circulation) **(Table 15-4)**. As described in the section on patients in subset II, venodilators act as preload reducers by increasing venous capacitance, thus reducing symptoms of pulmonary congestion in patients with high ventricular filling pressures. Arterial vasodilators act as impedance-reducing agents, thereby reducing afterload and causing a reflexive increase in CO, which may promote diuresis via improved renal perfusion. Mixed vasodilators act on both resistance and capacitance vessels, reducing congestive symptoms while increasing CO. Nitroglycerin and nesiritide will be the focus of this section, as data to support their use for refractory congestive symptoms is the most robust. Because sodium nitroprusside demonstrates several unique properties that make it a reasonable consideration in patients with low CO, it will be discussed later in this chapter.

TABLE 15-4 Vasodilators Commonly Utilized for the Management of ADHF[a]

Drug (Vasodilatory effect)	Onset, Half-life	Elimination	Dose	HR	MAP	PCWP	CO	SVR
Nitroglycerin (venous > arterial)	Immediate, <4 mins	Inactive metabolites in urine	10-20 mcg/min and titrate 10-20 mcg/min q10-20 mins, max 200 mcg/kg/min	0/↑	0/↓	↓	0/↑	0/↓
Nitroprusside (venous = arterial)	Immediate, 2 mins	Cyanide (hepatic), thiocyanate (renal)	0.1-0.2 mcg/ kg/min, titrate 0.1-0.2 mcg/kg/min q10-20 mins,	0/↑	0/↓	↓	↑	↓

Drug (Vasodilatory effect)	Onset, Half-life	Elimination	Dose	HR	MAP	PCWP	CO	SVR
			max 3 mcg/kg/min					
			0.01 mcg/kg/min, titrate					
Nesiritide (venous = arterial, natriuresis)	15 mins, 20 mins	Natriuretic peptide receptor C (no renal/ hepatic adjustment)	0.005 mcg/kg/min q3 hrs, max 0.03 mcg/kg/min (IVB dose generally avoided)	0	0/↓	↓	↑	↓
Furosemide (venous only)	1 hr (PO)/ 5 mins (IV), 2 hrs	Urine	Variable[b]	0	0/↓	↓	0	0
Enalaprilat (arterial > venous)	N/A/ 11 hrs	Urine	1.25-2.5 mg q6-8h	0	0/↓	↓	↑	↓

Abbreviations: ↑, increase; ↓, decrease; 0, no change; HR, heart rate; MAP, mean arterial pressure; PCWP, pulmonary capillary wedge pressure; CI, continuous infusion; CO, cardiac output; IVB, intravenous bolus; SVR, systemic vascular resistance.

[a]See text for a more detailed description of the interpatient variability in response.

[b]Intravenous bolus administered <0.4 mg/min.

Nitroglycerin

Intravenous nitroglycerin is often preferred for preload reduction in patients with ADHF, especially those with evidence of pulmonary congestion. Because of its short half-life (1-3 minutes), IV nitroglycerin is administered by continuous infusion. Its major hemodynamic effects are reductions in preload and PCWP via functional venodilation and mild arterial vasodilation that is particularly evident in patients with HF and elevated SVR or when given in doses approaching 200 mcg/min (see Table 15-4). In higher doses, nitroglycerin displays potent coronary vasodilating properties, exerting beneficial effects on myocardial oxygen demand and supply and making it the vasodilator of choice for patients with severe HF and ischemic heart disease.

Nitroglycerin should be initiated at a dose of 5 to 10 mcg/min (0.1 mcg/kg/min) and increased every 5 to 10 minutes as tolerated. Hypotension and an excessive decrease in PCWP are important dose-limiting side effects. Maintenance doses usually vary from 35 to 200 mcg/min (0.5-3 mcg/kg/min). While

tolerance to the hemodynamic effects of nitroglycerin may develop over 12 to 72 hours of continuous administration, some patients experience a sustained response. Like sodium nitroprusside, nitroglycerin should not be used in the presence of elevated intracranial pressure because it may worsen cerebral edema in this setting.

In contrast to sodium nitroprusside, one prospective randomized controlled trial has evaluated nitroglycerin in patients with ADHF. This study compared nitroglycerin to placebo as well as nesiritide and will be discussed in the following section.[24]

Nesiritide

Nesiritide is a recombinant form of BNP, which is secreted by the myocardium in response to volume overload. Exogenous administration of nesiritide mimics the vasodilatory and natriuretic actions of BNP by stimulating natriuretic peptide receptor A, leading to increased concentrations of cyclic guanosine monophosphate (cGMP) in target tissues. Nesiritide produces dose-dependent venous and arterial vasodilation; increases CO, natriuresis, and diuresis; decreases cardiac filling pressures; and impairs activation of the sympathetic nervous system and renin-angiotensin-aldosterone system. In contrast to nitroglycerin or dobutamine, tolerance does not develop to the pharmacologic actions of nesiritide. It also does not affect cyclic adenosine monophosphate (cAMP) or β-receptors, mechanisms thought to contribute to the myocardial toxicity associated with inotropes (eg, proarrhythmia). Nesiritide is eliminated by several metabolic pathways, including natriuretic peptide receptor C located on target tissues, proteolytic cleavage by neutral endopeptidase, and renal filtration. At 18 minutes, its elimination half-life is considerably longer than that of other IV vasoactive agents.

In a randomized, double-blind trial comparing nesiritide to nitroglycerin or placebo in patients with ADHF and dyspnea, nesiritide improved the incidence of dyspnea at 3 hours when compared to placebo but failed to demonstrate a significant difference compared to nitroglycerin.[24] In the subset of patients who received PA catheterization (permitted at the discretion of the investigators), nesiritide reduced PCWP at 3 hours when compared to both placebo and nitroglycerin. Two meta-analyses raised concern for an increased risk of adverse events with nesiritide, including an increased risk of worsening renal function and mortality.[25,26,27] In a large prospective randomized controlled trial designed to address these concerns, 7,141 patients hospitalized for ADHF were randomized to receive nesiritide at 0.01 mcg/kg/min (with an optional 2 mcg/kg IV bolus) or placebo for up to 7 days.[28] Nesiritide did not increase mortality nor worsen renal function. Rehospitalization for HF at 30 days was also not affected by the use of nesiritide, nor was patient self-assessment of dyspnea symptoms after 6 hours and 24 hours of treatment. In a more recent trial assessing the role of low-dose nesiritide (0.005 mcg/kg/min) added to IV loop diuretics in patients with ADHF and renal impairment, no improvements in urine output, congestive symptoms, or renal function were observed.[29] Despite the lower dose utilized in the trial, rates of hypotension were still higher in patients randomized to nesiritide.

Taken altogether, these trials indicate a limited role for nesiritide beyond the relief of congestive symptoms in patients with acute dyspnea. As a consequence, the use of nesiritide in the contemporary management of patients with ADHF has declined due to marginal improvements in clinical outcomes and its higher cost compared to other IV vasodilators.

Vasopressin Antagonists

Physiologic fluid balance depends on relative concentrations of sodium and water. An abnormally low serum sodium concentration, or *hyponatremia*, is commonly defined as less than 125 mmol/L and can be classified as hypovolemic, euvolemic (urine sodium <30 mmol/L), or hypervolemic (urine sodium >30 mmol/L) in nature. HF is most commonly associated with hypervolemic hyponatremia, although excess diuretic administration may result in hypovolemic hyponatremia. Other causes of hyponatremia include syndrome of inappropriate diuretic hormone (SIADH), cirrhosis with ascites, and medications.

Hyponatremia is often characterized by inappropriately elevated concentrations of AVP, or antidiuretic hormone. In the setting of HF, reduced CO leads to excess stimulation of arterial baroreceptors, which in turn enhances AVP secretion and consequently, net water retention. While the prevalence of hyponatremia in patients with HF varies by definition, as many as 1 in 5 patients hospitalized for acute HF present with serum sodium concentrations less than 136 mmol/L.[30] Furthermore, the presence of hyponatremia has been associated with increased mortality in this population.[31]

While many cases of hyponatremia are mild, asymptomatic, and self-limited, prompt diagnosis and management is critical for the less common but life-threatening presentation, which may include lethargy, confusion, respiratory arrest, cerebral edema, seizures, coma, or death. Treatment is specific to the underlying etiology, as well as duration and severity of symptoms. Strategies for managing hyponatremia include removal of the underlying cause, fluid restriction, isotonic or hypertonic saline administration, or administration of diuretics, vasopressin antagonists, or other therapies. Importantly, while neurological sequelae may occur if treatment is not initiated promptly, overly rapid correction of hyponatremia (>12 mmol/L per 24 hours) may be just as detrimental.

9 The two currently available vasopressin receptor antagonists, tolvaptan and conivaptan, inhibit one or two AVP receptors, V_{1A} or V_2. Stimulation of V_{1A} receptors, which are present in vascular smooth muscle and myocardium, results in vasoconstriction as well as myocyte hypertrophy, coronary vasoconstriction, and positive inotropic effects. V_2 receptors are located in the renal tubules where they regulate water reabsorption. Tolvaptan selectively binds to and inhibits the V_2 receptor, whereas conivaptan nonselectively inhibits both V_{1A} and V_2 receptors. Tolvaptan is orally bioavailable and indicated for the management of hypervolemic and euvolemic hyponatremia in patients with SIADH, cirrhosis, or HF. Tolvaptan is typically initiated at 15 mg daily and then titrated to 30 mg or 60 mg as needed for resolution of hyponatremia. Importantly, tolvaptan is a substrate of cytochrome P450 3A4 and is contraindicated with potent inhibitors of this enzyme. Conivaptan is an IV agent indicated for hypervolemic and euvolemic hyponatremia resulting from a variety of causes; however, because it is not indicated in patients with HF, conivaptan will not be discussed in further detail here. Patients receiving vasopressin antagonists must be monitored closely to avoid an overly rapid rise in serum sodium, which may result in hypotension or hypovolemia, requiring that therapy be discontinued. Therapy may be restarted at a lower dose if hyponatremia recurs or persists and/or adverse effects resolve.

The role of vasopressin antagonists in the long-term management of HF remains unclear at this time. In a trial comprised entirely of hospitalized patients with NYHA class III-IV HF, tolvaptan was associated with significant improvement in hyponatremia compared to placebo.[32,32] Additionally, patients receiving tolvaptan experienced an improvement in diuresis and symptoms of congestion. However, the study failed to demonstrate an improvement in global clinical status at discharge or a reduction in 2-year all-cause mortality, cardiovascular mortality, or HF rehospitalization.

Overall, tolvaptan is well tolerated; common side effects include dry mouth, thirst, urinary frequency, constipation, and hyperglycemia. While tolvaptan is orally available, therapy in clinical trials was initiated in the inpatient setting, where serum sodium and volume status could be closely monitored. Because of the adverse consequences of rapid changes in serum sodium concentrations or fluid balance, caution should be exerted when initiating therapy.

Ultrafiltration

Renal impairment is common among patients with ADHF, and advanced forms may warrant the use of renal replacement therapy (eg, hemodialysis).[10] Ultrafiltration has emerged as another strategy for rapid fluid removal, where salt and water may be eliminated at rates of up to 500 mL/h. Ultrafiltration reduces PCWP and increases diuresis without adversely affecting hemodynamics. Potential candidates for ultrafiltration include patients demonstrating diuretic resistance, renal impairment following diuretic administration, or continued renal impairment despite inotropic therapy. Complications of ultrafiltration include those associated with central venous access (eg, infection), rapid volume removal, and intravascular depletion, although electrolyte depletion is generally less significant compared to other modalities.

Small studies suggest that ultrafiltration represents an effective strategy for fluid removal in HF patients and that early initiation prior to IV diuretics reduces hospital length of stay and readmission rates. In a study comparing early ultrafiltration to IV diuretics in patients with ADHF and evidence of fluid overload, ultrafiltration resulted in greater weight loss at 48 hours (5 kg vs 3.1 kg) as well as net fluid loss (4.6 L vs 3.3 L), although no differences in dyspnea scores were observed.[33] Several additional endpoints were improved among patients in the ultrafiltration group, including the incidence and duration of rehospitalization and incidence of unscheduled office or emergency department visits at 90 days. Although these results were promising, a more recent study challenged these findings.[34] Patients with ADHF, worsened renal function, and persistent congestion were randomized to a strategy of stepped pharmacologic therapy or ultrafiltration. Ultrafiltration was inferior to pharmacologic therapy with respect to the bivariate endpoint of change from baseline in serum creatinine and body weight at 96 hours, primarily due worsening renal function in the ultrafiltration group. There was also no significant difference in weight loss and more patients in the ultrafiltration group experienced a serious adverse event. Subsequently, use of ultrafiltration has received greater scrutiny and ongoing trials are attempting to determine its role in managing volume overload.

Inotropes

Resistance to diuretic therapy may also result from worsening renal perfusion due to low CO. As a consequence, IV inotropes or arterial vasodilators may improve diuresis by improving central hemodynamics. However, given the adverse effect profile of IV inotropes, therapy should generally be reserved for patients not responding to other modalities or those with clear evidence of low CO (discussed in detail later in this chapter).

Administration of low doses of dopamine (ie, 2-5 mcg/kg/min) to enhance diuresis was once common practice, but evidence to support its use remains controversial, as most studies indicate minimal if any improvement in diuresis.[35] Despite an initial prospective randomized trial suggesting dopamine offered

renal protection during aggressive diuresis, more recent investigations assessing low doses in conjunction with IV loop diuretics demonstrated no improvements in urine output, renal protection, or symptom relief, but with increased rates of tachycardia.[29,36,37] Given evidence of β-mediated effects at lower infusion rates, dopamine may not provide any advantages over a traditional inotrope when used in this setting.

MANAGEMENT OF LOW CARDIAC OUTPUT

Patients in subsets III and IV ("cold" subsets) require prompt correction of low CO in order to restore peripheral tissue perfusion and preserve end-organ function. The two most common pharmacologic strategies for improving CO in ADHF are the IV vasodilators and inotropes. Due to the risks associated with IV inotrope therapy, IV vasodilators are preferred although hypotension often precludes their use in many patients with advanced HF.

Importantly, these agents rarely, if ever, produce a single cardiovascular action. Even when intended for a specific purpose (eg, positive inotropic effects), other cardiovascular effects (tachycardia, vasodilation, or vasoconstriction) may either add to the therapeutic effect of the drug, or cause adverse effects that negate or even outweigh its intended therapeutic benefit. How an individual patient will respond to an intervention is often difficult to anticipate. For this reason, hemodynamic monitoring with a PA catheter may be useful.

Vasodilators

11 Current guidelines focus on the role of vasodilators in improving refractory congestive symptoms,[6] but they may also be helpful for restoring CO in select patients. Activation of the sympathetic nervous system, renin–angiotensin–aldosterone system, and other neurohormonal mediators are characteristic features of both acute and chronic HF. Peripheral vasoconstriction and increased SVR often results, leading to a severe decline in stroke volume and thus CO. In these patients, IV vasodilators may be used to reduce arterial impedance, leading to improved left ventricular performance. However, for patients in whom SVR is already low, including those receiving GDMT with vasodilating effects (eg, ACE inhibitors) or those with advanced HF, hypotension may preclude the use of IV vasodilators. Additionally, their use has not been extensively studied in patients with HFpEF. Agents with venodilating effects should be used with caution in this latter population, as a sudden drop in preload may further compromise defects in ventricular filling.

As described previously, vasodilators are commonly classified according to their most prominent site of action (ie, arterial or venous circulation) (see Table 15-4; Fig. 15-3). Recall that in the setting of volume overload, agents with venodilatory effects are selected to reduce preload and filling pressures. However, in states of low CO, arterial vasodilators are selected to reduce afterload, resulting in a reflexive increase in CO. In the setting of both volume overload and low CO, mixed vasodilators (ie, sodium nitroprusside and nesiritide), which act on both resistance and capacitance vessels, may be selected to reduce congestive symptoms while simultaneously increasing CO. The following section will focus on the use of sodium nitroprusside, as other vasodilators have been discussed previously.

Sodium Nitroprusside

Sodium nitroprusside increases synthesis of nitric oxide in vascular smooth muscle, resulting in balanced arterial and venous vasodilation. As a result, it increases CI and decreases venous pressure to a similar degree as dobutamine and milrinone despite having no direct inotropic activity; however, greater decreases in PCWP, SVR, and blood pressure are generally observed. MAP may remain fairly constant due to reflexive improvements in stroke volume and CO but can decrease based on the extent of arterial smooth muscle relaxation. Patients with normal left ventricular function do not experience an increase in stroke volume when SVR falls because the normal ventricle is fairly insensitive to changes in afterload. Consequently, these patients may experience a significant decrease in blood pressure in response to arterial vasodilators. These differences explain why sodium nitroprusside is a potent antihypertensive agent in patients without HF but causes less hypotension and reflex tachycardia in the presence of left ventricular dysfunction (see Fig. 15-2B). Nonetheless, hypotension remains an important dose-limiting effect of sodium nitroprusside and its use should be primarily reserved for patients with elevated SVR. Close monitoring of therapy is warranted, as even modest increases in heart rate can have adverse consequences in patients with underlying ischemic heart disease and/or resting tachycardia.

Sodium nitroprusside is an effective strategy for short-term management of patients with severe HF across a variety of settings (eg, acute MI, valvular regurgitation, postcoronary bypass surgery, and ADHF). Generally, sodium nitroprusside does not worsen, and may even improve, the balance between myocardial oxygen demand and supply by lowering both left ventricular wall tension (thus reducing oxygen demand) and end-diastolic pressure (thereby increasing subendocardial blood flow). However, an excessive decrease in systemic arterial pressure may reduce coronary perfusion and worsen ischemia due to coronary steal.

Sodium nitroprusside has a rapid onset of action but its effects last less than 10 minutes, necessitating administration by continuous IV infusion. This method of administration also allows precise dose-titration based on clinical and hemodynamic response. As with other vasodilators used in ADHF, sodium nitroprusside should be initiated at low doses (0.1-0.2 mcg/kg/min) to avoid excessive hypotension and increased by small increments (0.1-0.2 mcg/kg/min) every 5 to 10 minutes as tolerated. Effective doses usually range from 0.5 to 3 mcg/kg/min. A rebound phenomenon, which may be due to reflex neurohormonal activation during sodium nitroprusside therapy, has been reported following abrupt withdrawal in patients with HF. Therefore, therapy should be tapered slowly when transitioning patients to oral medications. If renal perfusion pressure is compromised by sodium nitroprusside administration, salt and water retention may contribute to volume expansion and tachyphylaxis, although this is typically only observed in patients with chronic hypertension, baseline azotemia, or when augmentation of CO during therapy is minimal. Sodium nitroprusside should be avoided in the presence of elevated intracranial pressure as it may worsen cerebral edema in this setting. Given the potent pulmonary vasodilatory effects of sodium nitroprusside as well as its short half-life, it is frequently used to determine reversibility of pulmonary hypertension in patients being evaluated for heart transplantation.

Following IV administration, sodium nitroprusside interacts with hemoglobin to release cyanide, which undergoes hepatic conversion to thiocyanate before it is eliminated renally. As a consequence, sodium nitroprusside can cause cyanide and thiocyanate toxicity, but these effects are unlikely when doses less than 3 mcg/kg/min are administered for less than 3 days, except in patients with significant renal impairment (ie, serum creatinine concentration >3 mg/dL).

Unfortunately, no prospective randomized controlled trials have investigated the use of sodium nitroprusside in patients with ADHF. However, in one of the many retrospective studies in this population, patients with a reduced CI (ie, ≤2 L/min/m^2) treated with sodium nitroprusside (n = 78) experienced a reduction in all-cause mortality (P = 0.005) compared to patients who did not receive sodium nitroprusside (n = 97).[38] At baseline, patients receiving nitroprusside tended to have higher MAP, increased cardiac filling pressures, and lower CI, but the observed improvements in mortality remained even after including only those patients who had initial MAP less than or equal to 85 mm Hg (P = 0.0001).

Inotropes

12 Although IV inotropes can improve peripheral hypoperfusion by directly enhancing cardiac contractility, their association with adverse outcomes necessitates that they be reserved for select patients with refractory ADHF. Current guidelines recommend that inotrope therapy be considered only as a temporizing measure for maintaining end-organ perfusion in patients with cardiogenic shock or evidence of severely depressed CO and low systolic blood pressure (ie, ineligible for IV vasodilators) until definitive therapy can be initiated, as a "bridge" for those with advanced HF who are eligible for MCS or cardiac transplantation, or for palliation of symptoms in patients with advanced HF who are not eligible for MCS or cardiac transplantation.[6] Much of the concern regarding use of IV inotrope therapy in patients with ADHF is based on data from the ADHERE Registry (n = 15,230), which compared in-hospital mortality among patients receiving IV nitroglycerin, nesiritide, or the inotropes milrinone or dobutamine.[39] After adjusting for baseline parameters known to predict in-hospital mortality, both dobutamine- and milrinone-treated patients experienced higher in-hospital mortality compared to those receiving either nitroglycerin or nesiritide (P < 0.005). In-hospital mortality was higher among patients receiving dobutamine compared to milrinone (P = 0.027), and no difference in in-hospital mortality was observed between nitroglycerin- and nesiritide-treated patients (P = 0.58). Only one randomized controlled trial has prospectively evaluated the use of IV inotropic therapy as a strategy for improving clinical outcomes in patients with ADHF but no evidence of hypoperfusion. In 949 patients with ADHF randomized to a 48-hour infusion of milrinone or placebo, no difference in length of stay was observed and adverse events were more common in the milrinone group, including sustained hypotension requiring intervention (10.7% vs 3.2%; P < 0.001) and new onset of atrial fibrillation or flutter (4.6% vs 1.5%; P = 0.004).[40]

Select populations with advanced HF may require placement of an indwelling IV catheter for continuous outpatient administration of inotropic therapy. This approach may be used to "bridge" patients awaiting durable MCS or cardiac transplantation, or as a palliative approach to facilitate discharge in patients who are not candidates for these advanced therapies but also cannot be weaned from inotropic support. Therapy in this latter group should only be considered after multiple unsuccessful attempts have been made to maximize oral therapy and discontinue IV inotropes. Although this strategy may be effective for symptom palliation, the risk of mortality is likely increased.

The two IV inotropic agents most commonly used for the management of ADHF are dobutamine and milrinone. Although both drugs increase intracellular concentrations of cAMP, they do so by different mechanisms. Dobutamine activates adenylate cyclase through direct stimulation of β-adrenergic receptors, thus catalyzing the conversion of adenosine triphosphate to cAMP, whereas milrinone reduces

degradation of cAMP by inhibiting phosphodiesterase type 3. Increased intracellular cAMP enhances phospholipase (and subsequently phosphorylase) activity, increasing the rate and extent of calcium influx during systole and thus enhancing contractility. Additionally, cAMP enhances reuptake of calcium by the sarcoplasmic reticulum during diastole, improving active relaxation. Comparisons between dobutamine and milrinone indicate that the two agents generally produce similar hemodynamic effects, although dobutamine is usually associated with more pronounced increases in heart rate. Differences in the pharmacologic effects of the two agents may confer advantages or disadvantages in an individual patient; these and other clinical considerations for their use in the management of ADHF will be reviewed in the sections to follow.

Digoxin has a limited role in hemodynamically unstable patients due to its limited inotropic effects. In patients who take digoxin as chronic therapy, discontinuation or dose-adjustment during an acute decompensation is generally unnecessary unless changes in renal function increase the risk of toxicity. As discussed previously in this chapter, discontinuation should be discouraged in the absence of toxicity given the potential for digoxin withdrawal.[14,15]

Dobutamine

The receptor activities of dobutamine and other adrenergic agonists are summarized in **Table 15-5**. Dobutamine, a synthetic catecholamine, is a β_1- and β_2-receptor agonist with some α_1-agonist effects. Unlike dopamine, dobutamine does not result in the release of norepinephrine from nerve terminals. Consequently, the positive inotropic effects of dobutamine are attributed to its effects on β_1-receptors. Stimulation of cardiac β_1-receptors by dobutamine does not generally produce a significant change in heart rate, thus explaining its more modest chronotropic effects compared with dopamine. Modest peripheral β_2-receptor-mediated vasodilation tends to offset minor α_1-receptor-mediated vasoconstriction. In addition, the increase in CO often results in a reflexive decline in SVR. As a consequence, the net hemodynamic effect of dobutamine, particularly at low doses, is usually vasodilation.

TABLE 15-5 Inotropes Commonly Utilized for the Management ADHF[a]

Drug	Onset, Half-life	Dose	Receptor Affinity ($\alpha_1/\beta_1/\beta_2/DA_1$)	HR	MAP	PCWP	CO	SVR

[a]See text for a more detailed description of the dose-dependent hemodynamic effects.

The effects of dobutamine are observed within minutes but its peak effects may take up to 10 minutes to occur given an elimination half-life of 2 minutes. Initial doses of 2.5 to 5 mcg/kg/min may be increased progressively to 20 mcg/kg/min based on clinical and hemodynamic responses. CI is increased due to inotropic stimulation, arterial vasodilation, and a variable increase in heart rate. Because of offsetting changes in arteriolar resistance and CI, dobutamine usually causes relatively little change in MAP, unlike the more consistent increases observed with dopamine. The vasodilating action of dobutamine usually reduces PCWP, making it particularly useful in the presence of low CI and an elevated left ventricular filling pressure; conversely, these effects may be detrimental in the presence of a reduced filling pressure. Although its impact on heart rate is variable, the major adverse effects of dobutamine are tachycardia and ventricular arrhythmias. Potentially detrimental increases in oxygen consumption have also been observed. While concerns exist regarding the attenuation of its effects during prolonged administration, changes in receptor expression require that dobutamine be slowly tapered rather than abruptly discontinued.

Milrinone

Milrinone is a bipyridine derivative that inhibits phosphodiesterase III, an enzyme responsible for the breakdown of cAMP to adenosine monophosphate (AMP). Milrinone has supplanted the use of its prototype amrinone due to less frequent occurrence of thrombocytopenia. Because both inotropic and vasodilating effects contribute to its therapeutic effects in ADHF, milrinone is often referred to as an inodilator. The relative balance of these pharmacologic effects may vary with dose and underlying cardiovascular pathology.

During IV administration, milrinone produces an increase in stroke volume (and therefore CO) with minimal change in heart rate (see Table 15-5). Despite an increase in CI, MAP may remain constant due to a concomitant decrease in arteriolar resistance. However, the vasodilating effects of milrinone may predominate, leading to a decrease in blood pressure and reflex tachycardia. Like dobutamine, milrinone lowers PCWP by venodilation and thus is particularly useful in patients with a low CI and an elevated left ventricular filling pressure. Such a reduction in preload, however, can be hazardous for patients without excessive filling pressure (especially those in subset III), thus blunting the improvement in CO produced by the positive inotropic and arterial dilating actions of milrinone. Furthermore, milrinone should be

used cautiously in severely hypotensive patients because it does not increase, and may even decrease, arterial blood pressure.

Milrinone has a longer elimination half-life than other vasoactive agents. In healthy subjects, the half-life of milrinone is about 1 hour but may be as long as 3 to 6 hours in patients with renal dysfunction. The long elimination half-life of milrinone presents several disadvantages in this patient population, including the inability to perform minute-to-minute titrations based on hemodynamic changes and persistence of adverse effects (eg, arrhythmias or hypotension) following drug discontinuation. Although a loading dose is still listed in the product labeling for milrinone (50 mcg/kg administered over 10 minutes), this practice is uncommon due to an increased risk of hypotension. Most patients are started on a maintenance infusion of 0.1 to 0.3 mcg/kg/min (up to 0.75 mcg/kg/min), although lower initial doses may be considered. Milrinone is excreted unchanged in the urine, and thus, its infusion rate should be decreased by 50% to 70% in patients with significant renal impairment.

The most notable adverse effects associated with milrinone are arrhythmia, hypotension, and thrombocytopenia. Although the incidence of thrombocytopenia is rare, patients should still have platelet counts measured before and during therapy.

Inotrope Selection

Although inotrope selection is often clinician-dependent, certain characteristics may make one agent more ideal in an individual patient. Dobutamine should be considered when a significant decrease in MAP might further compromise hemodynamic function, as this is more common with the initiation of milrinone. Selection of an inotropic drug should also take into account whether patients are receiving chronic β-blocker therapy and whether a β_1-selective agent (eg, metoprolol succinate) or mixed α, β-blocking agent (eg, carvedilol) is used. Traditionally, milrinone has been advocated in patients who are receiving chronic β-blocker therapy because its inotropic effects do not involve β-receptor stimulation. However, this is not supported by evidence. In fact, the hemodynamic effects of dobutamine may persist in the presence of β-blocker therapy, particularly with β_1-selective agents as a result of β-receptor upregulation or selective activation of β_2-receptors by dobutamine.[41] Similar effects are not observed in the presence of carvedilol, which may inhibit the hemodynamic benefits of dobutamine entirely.[41] Concomitant β-blocker therapy may augment the hemodynamic effects of milrinone based on studies with a structurally similar phosphodiesterase inhibitor, enoximone.[41]

The combination of dobutamine and milrinone is likely to produce additive effects on CO and PCWP, suggesting that this regimen may be considered in patients who have dose-limiting adverse effects with either drug class. However, whether this combination provides a therapeutic advantage over the combined use of a positive inotrope and a traditional vasodilator (eg, sodium nitroprusside) is unclear.

Agents with Combined Inotropic and Vasopressor Activity

Although therapies that can increase SVR are generally avoided in ADHF, agents with combined inotropic and vasopressor activity, such as norepinephrine or dopamine, may be required in select scenarios where marked systemic hypotension may preclude the use of traditional IV inotropes (eg, septic shock, refractory cardiogenic shock). Alternatively, these agents may be used in combination with traditional inotropes so that adjustments can be made to each agent independently in order to achieve

the desired hemodynamic response. Although these strategies are common in clinical practice, minimal data exist to support their use.

Norepinephrine is an endogenous catecholamine that exerts its hemodynamic effects via direct stimulation of α_1- and β_1-adrenergic receptors. Its effects on β_1-adrenergic receptors in myocardial tissue are thought to confer improvements in CO as a result of increases in heart rate and cardiac contractility. However, despite having similar affinity for α_1- and β_1-adrenergic receptors, enhanced vasoconstriction via activation of peripheral α_1-receptors appears to be the predominant hemodynamic effect observed clinically. The limited impact of norepinephrine on CO may be due to its lack of affinity for β_2-receptors, which would both enhance cardiac contractility as well as balance its effects on α_1-receptors in vascular smooth muscle. In contrast with dopamine, the affinity of norepinephrine for adrenergic receptors does not appreciably differ based on dose.

Dopamine is an endogenous precursor of norepinephrine and exerts its effects by directly stimulating adrenergic receptors as well as causing release of norepinephrine from adrenergic nerve terminals. Dopamine produces dose-dependent hemodynamic effects as a result of its relative affinity for α_1-, β_1-, β_2-, and D_1- (vascular dopaminergic) receptors (see Table 15-5).

The positive inotropic effects of dopamine are mediated primarily by β_1-receptors and become more prominent at doses of 2 to 5 mcg/kg/min. CI is increased because of an increase in stroke volume and a variable increase in heart rate, which is also partially dose-dependent. Minimal changes in SVR occur, presumably because neither vasodilation (D_1- and β_2-receptor-mediated) nor vasoconstriction (α_1-receptor-mediated) predominates. However, at doses between 5 and 10 mcg/kg/min, chronotropy and α_1-receptor-mediated vasoconstriction become more prominent. MAP is usually raised as a result of increases in both CI and SVR (see Table 15-5).

The vasoconstriction observed with higher doses of norepinephrine and dopamine may limit improvements in CI by concomitantly increasing afterload and preload. As a consequence, they should generally be reserved for patients with low CO and low systolic blood pressure despite adequate ventricular filling pressures, or as an adjunct to inotrope therapy when hypotension precludes the use of inotrope therapy alone. At higher doses, agents with vasopressor activity may alter several parameters that increase myocardial oxygen demand (eg, increased heart rate, contractility, and systolic pressure) and potentially decrease myocardial blood flow (eg, coronary vasoconstriction and increased wall tension), which may worsen ischemia in patients with coronary artery disease. As with dobutamine and milrinone, arrhythmogenesis is also more common at higher doses, although this risk appears to be greater with dopamine than with norepinephrine.[42]

Temporary Mechanical Circulatory Support

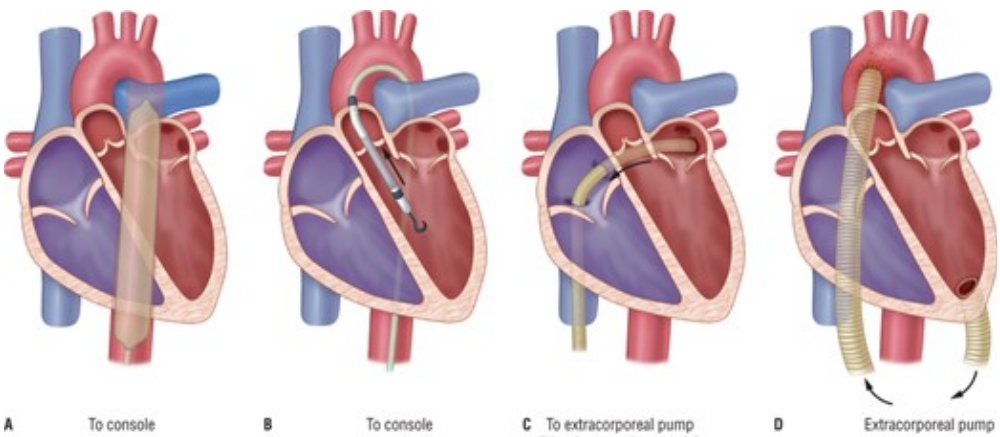
13 For patients with refractory ADHF, temporary MCS may be considered for hemodynamic stabilization until the underlying etiology of cardiac dysfunction resolves or has been corrected ("bridge to recovery") or until evaluation for definitive therapy (eg, durable MCS or cardiac transplantation) can be completed ("bridge to decision").[6] Due to the invasive nature of MCS and its potential complications, therapy should be reserved for patients who are refractory to maximally tolerated pharmacologic therapy. IV vasodilators and inotropic agents may also be used in conjunction with temporary MCS to maximize

hemodynamic and clinical benefits or to facilitate device removal. Regardless of the modality selected, systemic anticoagulation is required to prevent device thrombosis. Temporary MCS should generally be avoided in patients with irreversible advanced HF and no plan for definitive management, those with contraindications to anticoagulation therapy, and those with comorbid conditions or anatomical abnormalities that preclude device implantation. The three most common modalities of temporary MCS are the intra-aortic balloon pump (IABP), ventricular assist device (VAD), and extracorporeal membrane oxygenation (ECMO) **(Fig. 15-4)**. Unique features, contraindications, and complications of each type of device will be discussed in the sections to follow.

FIGURE 15-4

Common types of temporary mechanical circulatory support.

As shown in Figure A, an intra-aortic balloon pump (IABP) is advanced into the descending aorta where it inflates during diastole (shown), displacing blood and improving coronary filling. During systole (not shown), the IABP deflates, producing a vacuum-like effect that reduces peripheral resistance. An example of an Impella percutaneous ventricular assist device (VAD) is illustrated in Figure B. An Impella device is advanced through the aortic valve, where blood is transferred from the left ventricle to the aorta by an axial flow pump. Figure C is an illustration of the TandemHeart device, which is inserted percutaneously into a large peripheral vein and advanced across the intra-atrial septum. Blood is removed from the left atrium and propelled by an extracorporeal centrifugal flow pump back into the systemic circulation (not shown). The cannulae of a CentriMag VAD are shown in Figure D. An inflow cannula is surgically inserted into the apex of the left ventricle, where blood is transferred to an extracorporeal centrifugal flow pump (not shown), where it is returned to the systemic circulation via an outflow cannula surgically inserted into the aorta. In extracorporeal membrane oxygenation (ECMO) (not shown), the inflow and outflow cannulae are inserted into peripheral vessels.



Intra-aortic Balloon Pump

An IABP consists of a polyethylene balloon mounted on a catheter that is inserted percutaneously into the femoral artery and advanced into the descending thoracic aorta (see Fig. 15-4A). During counterpulsation, the balloon is synchronized with the electrocardiogram (or alternatively, changes in pressure) so that it inflates during diastole and displaces blood to the proximal aorta, thus increasing

diastolic pressure and coronary perfusion. The balloon deflates just prior to the opening of the aortic valve during systole, which causes a sudden "vacuum-like" decrease in aortic pressure, allowing the left ventricle to pump against reduced arterial impedance. Although the IABP is the most commonly employed modality of temporary MCS due to its ease of use, it only provides an estimated 1.0 L/min of CO. As a consequence, the primary benefits of an IABP are enhanced coronary perfusion, increased myocardial oxygen supply, and reduced myocardial oxygen demand. It may be particularly useful for patients with myocardial ischemia complicated by cardiogenic shock, although it has not been shown to improve mortality in this setting.[43] Systemic anticoagulation is generally recommended although cases of IABP use without anticoagulation have been reported.[44] Complications of the IABP include vascular injury, thrombocytopenia, and renal impairment due to obstruction of the splanchnic circulation by balloon malposition. Use should be avoided in patients with severe peripheral vascular disease.

Ventricular Assist Devices

A VAD provides hemodynamic support by assisting and, in some cases, replacing the pumping functions of the right and/or left ventricles. Compared to an IABP, temporary VADs confer greater hemodynamic improvements but no differences in long-term survival.[45] A left ventricular assist device (LVAD) propels blood from the left ventricle or left atrium to the ascending aorta whereas a right VAD propels blood from the right ventricle or right atrium to the PA. A right VAD may be used alone or in conjunction with an LVAD; this latter configuration is known as a biventricular assist device. All VADs are preload-dependent, meaning that adequate intra-ventricular filling pressure (ie, volume) is required to optimize blood flow. As with the native ventricle in HF, VADs are also afterload-sensitive, meaning that excess peripheral resistance can impair blood flow. Complications of VAD implantation include bleeding, infections, and risks associated with the specific implantation technique. In addition, the devices can cause thrombosis, renal and hepatic dysfunction, and arrhythmias. Right ventricular failure is a unique complication of LVAD implantation as a result of increased venous return, persistently elevated pulmonary pressures, and changes in right ventricular geometry.

Percutaneous VADs include the Impella series (Abiomed, Danvers, MA) and TandemHeart (CardiacAssist, Pittsburgh, PA). Impella devices are inserted percutaneously into a large peripheral artery and advanced in a retrograde fashion across the aortic valve, where blood is advanced from the left ventricle to the ascending aorta via axial flow (see Fig. 15-4B). The amount of CO augmented by the Impella device depends on model; the Impella 2.5 and 5.0 models supply 2.5 L and 5.0 L/min of flow, respectively. Hemolysis is a common complication of Impella use due to the axial flow facilitated by the device. The TandemHeart device consists of an inflow cannula placed percutaneously into a large peripheral vein and advanced transseptally into the left atrium (see Fig. 15-4C). Blood is withdrawn from the left atrium by an extracorporeal pump and propelled via an outflow cannula placed percutaneously into a large artery. Up to 5.0 L/min of flow can be provided by the TandemHeart. Due to its placement across the intra-atrial septum, perforation and shunt formation are potential complications with this device.

The most common surgically implanted temporary VAD is the CentriMag (Thoractec Corp., Pleasanton, CA), which can provide right, left, or biventricular support and up to 10.0 L/min of CO. The CentriMag device consists of a centrifugal flow extracorporeal pump and surgically placed inflow and outflow cannulae supporting the affected ventricle (see Fig. 15-4D). Given the surgical technique required for placement of the CentriMag device, tissue injury is its most common complication.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation may be venoarterial or venovenous in nature. In venoarterial ECMO, deoxygenated blood is transported from the venous circulation to an extracorporeal oxygenator and centrifugal flow pump and returned as oxygenated blood to the arterial circulation. In contrast, venovenous ECMO consists of only extracorporeal oxygenation; hemodynamic support is provided by native cardiac function. As a consequence, venoarterial ECMO is more common in the management of refractory ADHF, where up to 8 L/min of cardiac support can be provided. Complications of ECMO include bleeding, infections, and organ dysfunction. Serum drug concentrations can also be significantly impacted as a result of increased volume of distribution, decreased elimination due to hepatic and/or renal impairment, and sequestration of drugs in the ECMO circuit.

ADVANCED THERAPIES

No consensus definition exists for advanced HF, or the stage at which patients should be considered for definitive therapies such as durable MCS and heart transplantation. Nonetheless, evaluation for these advanced therapies is commonly initiated during an admission for ADHF, particularly if hospitalization is accompanied by severe symptoms at rest, intolerance of GDMT, decline in organ function, refractory arrhythmias, or an inability to be successfully weaned from inotropic or temporary MCS support. Because of the complexity of care, potential risks, and resource implications of durable MCS and heart transplantation, patients with advanced HF must undergo a rigorous interdisciplinary evaluation before becoming eligible candidates. Components of this evaluation commonly include past medical, surgical, and psychosocial history, medication and adverse event history, adherence to medications and medical care, comorbid conditions, risks for postoperative complications, and health insurance coverage. Relative contraindications to the use of advanced therapies include excess perioperative risk, irreversible pulmonary hypertension, inability to manage postoperative care (eg, medication therapy, monitoring), and concurrent survival-limiting diseases (eg, malignancy).

Durable Mechanical Circulatory Support

The most common indications for durable MCS are temporary device implantation in patients awaiting heart transplantation who are unlikely to survive the duration of time required for identifying a suitable donor (“bridge to transplantation”) and permanent device implantation in patients who are ineligible for heart transplantation due to advanced age or comorbid conditions (“destination therapy”). Although far less common than with temporary MCS, durable VADs may be implanted in patients who are likely to become eligible transplant candidates (“bridge to decision”) but evaluation is incomplete or has been delayed until certain requirements can be satisfied (eg, smoking cessation). Durable MCS is almost exclusively comprised of LVAD implantation, although select patients may remain hospitalized with right VAD or biventricular support while awaiting transplantation.

Durable LVADs are implanted by inserting an inflow cannula into the apex of the left ventricle, which is connected to an intracorporeal pumping unit; blood is returned to the systemic circulation via an outflow cannula inserted into the aorta. Whereas previous devices provided hemodynamic support via pulsatile flow, newer-generation devices utilize a continuous flow mechanism, allowing them to be smaller in size, less subject to deterioration over time, and conferring an improvement in event-free

survival.[46] Research suggests that prolonged unloading of the left ventricle with an LVAD in combination with drug therapy can produce sustained recovery in LV function, amelioration of symptoms, and in some cases, device explantation.[47] The two continuous flow LVADs currently approved for use in the United States are the axial flow HeartMate II LVAD (Thoratec Corp., Pleasanton, CA) and centrifugal flow HeartWare Ventricular Assist Device (HVAD) (HeartWare, Inc; Framingham, MA). Both devices are capable of providing up to 10 L/min of CO. For complete heart replacement therapy, total artificial heart systems continue to be investigated, although size and embolic complications limit widespread use.

Complications following durable LVAD placement are similar as those described for temporary devices. Device malfunction may occur with long-term use but has become rare with advances in technology. The most perplexing challenge in the care of LVAD patients remains identifying a chronic antithrombotic regimen that balances the risk of device thrombosis and bleeding. Antithrombotic regimens most often include a vitamin K antagonist and antiplatelet agent, although the goal international normalized ratio (INR) range and antiplatelet agents selected (eg, aspirin, dipyridamole, clopidogrel) may vary significantly by center. Suspected pump thrombosis should be promptly evaluated, although no consensus exists on an appropriate treatment strategy (eg, enhanced antiplatelet or anticoagulant therapy, thrombolysis, or pump exchange).[48]

Heart Transplantation

14 Orthotopic heart transplantation remains the optimal management strategy for patients with irreversible advanced HF, as 10-year survival rates approach 60% among patients transplanted after 2001.[49] Unfortunately, the shortage of acceptable donor hearts has prolonged waiting times and many patients succumb to their disease prior to transplantation. Another significant percentage of patients are deemed ineligible for heart transplantation because of age, concurrent illnesses, psychosocial factors, or other reasons. The shortage of donor hearts has prompted the development of new surgical strategies, including ventricular aneurysm resection, mitral valve repair, and myocardial cell transplantation, which have resulted in variable degrees of improvement. Further development of these and other techniques may offer additional options in patients who are not eligible for VAD implantation or heart transplantation. For a more detailed discussion of heart transplantation, see Chapter 89.

EVALUATION OF THERAPEUTIC OUTCOMES

Daily monitoring to assess the efficacy of drug therapy is critical to assuring optimal outcomes and should include weight, strict fluid intake and output, and HF signs and symptoms (**Table 15-6**). Foley catheter placement is not recommended unless close monitoring of urine output is not otherwise possible. As for safety endpoints, monitoring for electrolyte depletion, symptomatic hypotension, and renal dysfunction should be assessed frequently. While many of the above parameters may be monitored daily, some will need to be monitored more frequently as dictated by patient clinical status. Vital signs should be assessed multiple times throughout the day at a frequency that is appropriate for the patient's degree of stability. Orthostatic blood pressure should be assessed at least once daily.

TABLE 15-6 Monitoring Recommendations for Patients Hospitalized with ADHF

Parameter	Frequency	Notes

Parameter	Frequency	Notes
		Assess after voiding in the morning
Weight	Daily	Utilize same scale each day, if possible
		Account for increase or decrease in food intake
Fluid balance	Daily*	Strict intake and output
Vital Signs	More than daily	Blood pressure and heart rate including signs/symptoms of orthostatic hypotension, rhythm (continuous)
Signs of congestion and/or low output	Daily*	Jugular venous distension, crackles, hepatomegaly, splenomegaly, hepatojugular reflux, ascites, lower extremity edema, hypotension, narrow pulse pressures, cool extremities, altered mental status, worsening renal or hepatic function
Symptoms of congestion and/or low output	Daily*	Dyspnea on exertion or at rest, orthopnea, paroxysmal nocturnal dyspnea, nausea/vomiting, early satiety, fatigue, lightheadedness, chest pain, palpitations
Electrolytes	Daily*	Potassium, magnesium, sodium
Renal function	Daily*	Blood urea nitrogen and serum creatinine including ratio to assess volume status (ie, over-diuresis)
Hepatic function	Variable*	Alk Phos and GGT primarily for fluid overload, AST and ALT primarily for hypoperfusion
BNP, NT-proBNP	Admission, Discharge	Admission for diagnosis, discharge for prognosis
		Troponin and other cardiac enzymes if myocardial strain
Other	Variable	Arterial blood gas if hypoxic
		Lactate if hypoperfusion present

Alk Phos, alkaline phosphatase; AST, aspartate aminotransferase; ALT, alanine aminotransferase; GGT, gamma-glutamyltransferase.

*Daily unless change in clinical status warrants more frequent assessment.

Patients with ADHF may have critically reduced CO, usually with low arterial blood pressure and systemic hypoperfusion resulting in organ system dysfunction (ie, cardiogenic shock). They may also have pulmonary edema with hypoxemia, respiratory acidosis, and markedly increased work of breathing. With cardiopulmonary support, response to interventions should be assessed promptly to allow for timely adjustments in treatment. Continuous monitoring of ECG, continuous pulse oximetry, urine flow, and automated blood pressure recordings are standards of care for critically ill patients with cardiopulmonary decompensation. Peripheral or femoral arterial catheters may be utilized for continuous and accurate assessment of arterial pressure.

Preparation for Discharge

Patients should not be discharged until optimal volume status is achieved and the patient is successfully transitioned from an IV to an oral diuretic regimen, GDMT is stable, and IV inotropes and vasodilators have been discontinued for at least 24 hours. If relevant, smoking cessation must be addressed to avoid delay in consideration for advanced therapies. The following should be documented in the medical record: left ventricular ejection fraction and ACE inhibitor and beta blocker use (for patients with reduced LVEF) or intolerance to such.[50]

Prior to discharge, patients and caregivers should be counseled on dietary sodium restriction as well as monitoring body weight daily and parameters for when to titrate diuretics or call a healthcare provider for further instruction (eg, two pound weight gain in 24 hours). Medication changes (initiation, discontinuation, dose change) should be clearly conveyed verbally and in writing and financial coverage for all medication assured. The importance of dietary and medication adherence should be emphasized. Appropriate follow-up should be scheduled including an appointment at 7-10 days post discharge including a nurse visit or phone call at 3 days for select patients. Pertinent follow-up labs (eg, potassium, serum creatinine) should also be scheduled including medication related labs (eg, INR for warfarin, serum digoxin concentration). All patients should be considered for referral to a formal disease management program.

Multidisciplinary disease management programs and other specialized interventions involving pharmacists have been associated with a wide range of benefits including reduced HF readmissions.[51] A recent systematic review of multidisciplinary teams involving a pharmacist showed reductions in all-cause and HF hospitalizations.[52] The American Heart Association recently published a statement describing transitional care interventions acknowledging that of the transition of care programs for patients with HF (n = 20), 75% used a collaborative, multidisciplinary team that included pharmacists.[53]

Clinical Controversy…

1. For patients with volume overload, administration of loop diuretic therapy as an IV bolus or continuous infusion appears to be similarly efficacious and safe when selected as initial therapy; however, the optimal strategy for facilitating volume removal in patients with diuretic resistance remains unknown. Higher doses (ie, 2.5-times the previous oral dose) of IV loop diuretic are more effective than lower doses (ie, equivalent to previous oral dose) but may also produce higher rates of transient renal dysfunction. The following controversies remain unaddressed: the role of adding a diuretic with an alternative mechanism of action (ie, thiazide-type diuretic), which alternative diuretic is most optimal (eg, metolazone, hydrochlorothiazide), and how adjunct diuretics compare to other treatment modalities, such as IV vasodilators or ultrafiltration.

2. For patients with low CO, appropriate selection of IV inotropes in the setting of chronic oral beta blockers is unclear. Theoretically milrinone should be the agent of choice for patients receiving beta blockade; however, many patients will not tolerate its potent vasodilatory effects. In addition, small studies suggest that the inotropic effects of dobutamine may be retained with select beta blockers. Furthermore, optimal dosing of beta blocker in the setting of low output (eg, maintain current dose vs dose reduction) has not been addressed, although complete discontinuation should generally be avoided. Additional investigation in this area is warranted.

3. In Chapter 14, several new therapies for the management of patients with stable chronic HF were

discussed.

Unfortunately, trials evaluating these therapies enrolled very few patients with advanced HF and none with ADHF. As a consequence, it is currently unclear if these new therapies would exert beneficial effects in patients with ADHF or, perhaps more importantly, if they are safe. Additional research is warranted on the use of these agents in the ADHF population.

4. Evolving data continue to support the role of MCS as a bridge to transplantation or DT. However, additional research to define optimal candidates, determine timelines for implantation, and minimize complications is warranted. Another area lacking sufficient data is the appropriate management of medications in patients receiving ECMO.

CONCLUSION

Several recent clinical trials have addressed many controversies in the management of ADHF, including the appropriate dosing of diuretics and use of vasodilators and vasopressors (eg, dopamine) in patients with volume overload. Still, many unanswered questions remain, including inotrope selection in low CO and optimal use of GDMT in the setting of ADHF. Many advances in MCS have extended the lives of patients awaiting transplant; however, limited evidence exists to guide management of this patient population, including how to avoid and manage complications associated with these devices. Finally, ideal management of patients with ADHF includes optimization of GDMT, optimal communication with patients, caregivers, and other healthcare providers with each care transition, and outpatient follow-up with a collaborative, multidisciplinary team.

Chapter 16: Stable Ischemic Heart Disease

Paul P. Dobesh

INTRODUCTION

KEY CONCEPTS

- 1 Stable ischemic heart disease (SIHD), if primary, is caused by an obstructive atherosclerotic plaque in one or more epicardial coronary vessels in which increases in myocardial demand in the setting of this fixed decrease in myocardial oxygen supply produces myocardial ischemia.
- 2 Some patients with SIHD also have a component of vasospasm that requires a slightly different pharmacologic approach.
- 3 Chest pain from exertion is the cardinal symptom of myocardial ischemia in patients with SIHD.
- 4 Assessment of successful treatment of angina includes not only reducing the number of episodes and increasing the amount of exertion needed to precipitate an episode, but also allowing patients to participate in activity that provides a high-level quality of life.
- 5 Revascularization can provide a survival advantage compared to medical therapy in patients with more extensive atherosclerotic disease.
- 6 In patients with less extensive atherosclerotic disease, percutaneous coronary intervention (PCI) has not demonstrated a clear advantage over guideline-directed medical therapy (GDMT) in patients with SIHD.
- 7 Aspirin and angiotensin converting enzyme (ACE) inhibitors play an important role preventing adverse cardiovascular events in patients with SIHD.
- 8 Management of modifiable atherosclerotic risk factors is key to improving the quantity of life in patients with SIHD.
- 9 β-blockers are typically regarded as first-line therapy in the management and control of

episodes of angina in patients with SIHD

- 10 Calcium channel blockers (CCBs) and chronic long-acting nitrates are often used as additional therapy for the control of episodes of angina in patients with SIHD.
- 11 All patients with SIHD should receive sublingual nitroglycerin (SL NTG) for acute attacks, along with proper education of their use.
- 12 Ranolazine provides a reduction in episodes of angina by blocking excess accumulation of sodium, and consequentially calcium in the myocyte, without impacting heart rate (HR) or blood pressure (BP).

Coronary artery disease (CAD) is the leading etiology of ischemic heart disease, and is typically the result atherosclerotic plaque in the epicardial vessels. The process of atherosclerosis begins early in life, with fatty steaks being present in many people in their teenage years or early twenties. These plaques grow over decades and start to become pathologic in a person's fifth decade of life and beyond. Besides CAD, atherosclerosis also manifest in other major vascular beds leading to cerebrovascular disease (stroke) and peripheral arterial disease. Ischemic heart disease may present as a medical emergency as an acute coronary syndrome (ACS), which includes unstable angina, non-ST-segment myocardial infarction (MI), or ST-segment elevation MI. It may also present as chronic stable exertional angina or ischemia without clinical symptoms (silent ischemia). Less common causes of stable IHD (SIHD) include microvascular angina, which is due to atherosclerosis in endocardial instead of epicardial vessels. Microvascular angina is more common in women and those with metabolic syndrome. Coronary vasospasm, also known as variant or Prinzmetal's angina, represents a form of SIHD that does not involve atherosclerotic plaque development. This chapter focuses on patients with SIHD. Inappropriate, insufficient, or untreated SIHD can not only lead to MI and cardiac death, but also the development of heart failure, arrhythmias, and valvular disease. Guidelines for the diagnosis and management of SIHD have been published by the American College of Cardiology (ACC) and American Heart Association (AHA), as well as the European Society of Cardiology.[1,2]

EPIDEMIOLOGY

According to AHA statistics in 2013, and estimated 85.6 million Americans had at least one form of cardiovascular disease (CVD), with more than 50% being 60 years of age or older.[3] Despite a reduction in mortality of slightly over 30% between 2001 and 2011, CVD remains the largest cause of death in men and women in the United States.[4] In 2011, CVD was listed as the main cause of death in 30.8% of the 2,596,993 deaths, or approximately 1 in every 3 deaths in the United States.[3] This calculates to approximately 2200 deaths per day or 1 death every 40 seconds. The overall death rate of CVD is 222.9 per 100,000 population, but varies based on gender and ethnicity. The death rate is 270.6 for white males, 356.7 for black males, 183.8 for white females, and 246.6 for black females. Estimated direct and indirect cost of CVD in 2012 was over $316 billion, with a projected direct medical cost of approximately $918 billion by 2030.[3] If all forms of CVD were eliminated, the

predicted increase in life expectancy in the United States could rise by almost 7 years. CVD is not just a problem in the United Sates or "Western" cultures. Death due to CVD accounted for 17.3 million deaths per year (30%), making CVD the leading global cause of death, with numbers expecting to climb to almost 24 million deaths by 2030.[3] In 2010, the global cost of CVD was estimated at $863 billion, which is expected to climb to $1044 billion by 2030.

Among patients with CAD, the total number of patients with SIHD is difficult to determine. Statistics from the AHA estimate that approximately 8.2 million Americans have angina pectoris.[3] Stable angina pectoris is the initial manifestation of ischemic heart disease in approximately one-half of all patients who eventually have an MI. Using these numbers, along with estimates based on patients surviving MI, it is predicted that approximately 15.5 million Americans have coronary heart disease (CHD). These 15.5 million patients would receive treatment strategies that are similar to that for patients with SIHD as described in this chapter. In the United States, CHD is the underlying cause of death in approximately 1 in over 7 deaths, accounting for almost 400,000 deaths in 2013. The risk of mortality is greatest for black men, followed by white men, black females, and white females.[3] The 5 states with the lowest mortality from CHD are Minnesota, Hawaii, Utah, Oregon, and Colorado, with rates ranging from 65.6 to 72.8 per 100,000 populations.[3] The 5 states with the highest mortality from CHD are Oklahoma, Tennessee, New York, Arkansas, and Michigan, with rates being almost double those in the 5 states with the lowest mortality from CHD (130.8-149.8 per 100,000).[3] Estimated direct and indirect cost of CHD was $204 billion in 2010, with costs expected to double[This is a different figure that listed above] by 2030.[3] For countries reporting data, the United States ranks 10th for CHD death rates for males aged 35 to 74 years and 9th for females of the same age.[3] For both males and females, Ukraine, Russian Federation, Romania, and Hungary have the highest CHD death rates, with South Korea, Japan, and France having the lowest.[3]

Prognosis of patients with SIHD will be dependent on the extent of atherosclerotic disease, the presence of left ventricular (LV) dysfunction, as well as the presence of other comorbidities.[2] The severity of angina symptoms may also be used to determine prognosis as well.[5] In a study of 8,908 Veterans Administration patients with CAD, the risk of death increased with the self-reported degree of physical limitation due to angina.[6] It is thought that the degree of physical limitation may simply reflect the extent of underlying atherosclerotic disease. Besides the high mortality, morbidity is also considerable in patients with SIHD. Most of these patients will eventually need hospitalization for episodes of an ACS. These patients often have a reduced quality of life due to their inability to conduct activities of daily living without chest pain.[7,8] There is also a significant amount of lost time from work and lost productivity that can have a large indirect cost to patients and society. Data from the Bypass Angioplasty Revascularization Investigation (BARI) suggest that approximately 15% to 20% of patients rate their own health as fair or poor despite revascularization, and 30% of patients are never able to return to work.[9]

ETIOLOGY AND PATHOPHYSIOLOGY

1 Angina pectoris is typically a result of an imbalance between myocardial oxygen supply and

myocardial oxygen demand (MVO_2). The process of maintaining adequate coronary blood flow to meet the metabolic demands of the myocytes is complex with multiple factors influencing both sides of the supply/demand equation.

The foundation pathophysiology of patients with SIHD is driven by an increase in myocardial oxygen demand (MVO_2) in the setting of a fixed decrease in myocardial oxygen supply.[10] The etiology of the fixed decrease in supply is long-standing, well developed atherosclerotic plaque. These plaques grow over several decades with the extensiveness and rate of growth determined by risk factors such as smoking, dyslipidemia, hypertension (HTN), diabetes mellitus (DM), and genetics (family history). The process and development of atherosclerosis is covered in detail in Chapter 17. The atherosclerotic plaques producing episodes of angina in patients with SIHD are not ones that rupture and produce rapid flow limiting thrombus as in the setting of an ACS.[11,12] In SIHD, the atherosclerotic plaques are more stable, have a reduced lipid core, and a firmer calcified covering. Since their geometry does not typically change acutely, they provide a relatively fixed decrease in myocardial oxygen supply.

Determinants of Myocardial Oxygen Demand

The major determinates of MVO_2 include heart rate (HR), myocardial contractility, and intramyocardial wall tension. A 2-fold increase in any of these individual determinates of MVO_2 requires an approximate 50% increase of coronary flow to maintain the myocardial supply—demand balance. Intramyocardial wall tension is the leading contributor to increased MVO_2 and is directly related to the radius or size of the ventricular cavity and blood pressure (BP), but indirectly related to the ventricular muscle mass. The larger the size of the ventricular cavity, the more energy or myocardial work is needed to begin myocardial contraction (systole). During early systole, myocardial work increases to a peak when the pressure in the LV becomes greater than the pressure outside the aortic valve. Once that occurs, the aortic valve is pushed open and blood is ejected into the systemic circulation. The higher the BP outside the aortic valve, the more MVO_2 needed per cardiac cycle. Increased ventricular muscle mass should make myocardial work easier and reduce MVO_2, for example as in an athlete's heart. Unfortunately, it is more common that the LV hypertrophy that occurs creates dysfunction myocytes that do not improve MVO_2. This type of LV hypertrophy also can worsen the supply/demand balance since blood vessel development (supply) is less than that of native myocardium.

The rate-pressure product, or double product, is a common noninvasive measure of MVO_2, which is the product of the HR and systolic BP. However, any change in contractility or volume loading of the LV is not considered by the double product. The increase in MVO_2 requirements commonly stems from release of norepinephrine by adrenergic nerve endings in the myocardium and vascular bed as part of the physiologic response to exertion, emotion, or mental stress. The rate of increase of MVO_2, or the rate at which a task is carried out, can be as important as the total amount of MVO_2. Hurrying is particularly likely to precipitate angina, as are efforts involving motion of the hands over the head. Mental and emotional stress may also precipitate angina, presumably by increasing adrenergic tone, and reduced vagal activity. Sexual activity may also precipitate angina due to the combination of physical exertion and emotional stimulation. Other precipitates of angina include physical exertion

after a heavy meal and excessive metabolic demands imposed by chills, fever, thyrotoxicosis, tachycardia from any cause, exposure to cold, and hypoglycemia. Anger can also produce constriction of coronary arteries with preexisting narrowing, without necessarily directly affecting O_2 demand.

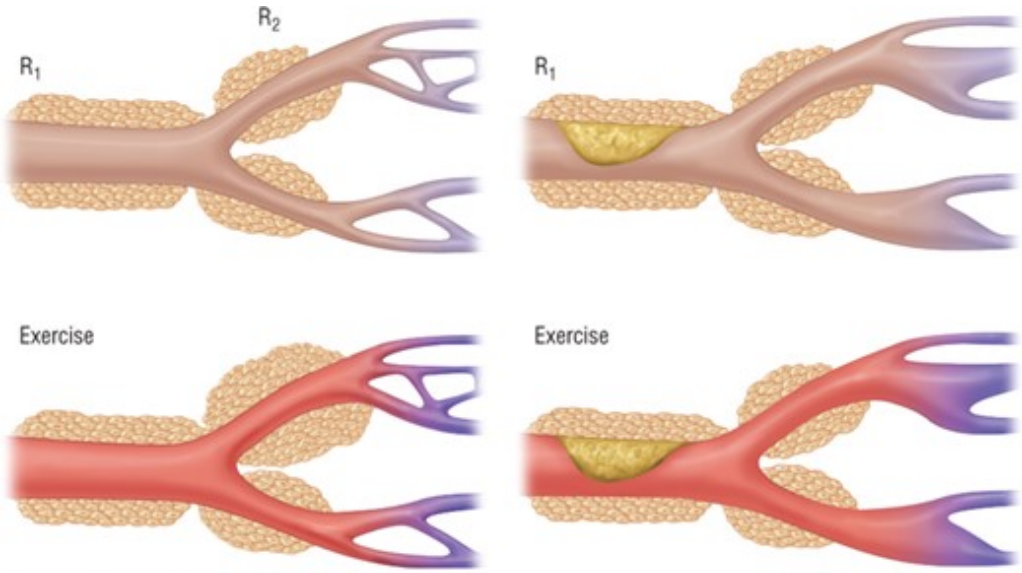
Determinates of Myocardial Oxygen Supply

Coronary Blood Flow

Meeting the metabolic demands of the myocardium is centered on the ability to maintain adequate coronary blood flow and coronary arterial pressure. Resting coronary blood flow under normal conditions averages 0.7 to 1.0 mL/min/g of myocardium.[13] The coronary vasculature is made up of larger epicardial vessels, also referred to as R_1 or conductance vessels, and smaller endocardial vessels, also referred to as R_2 or resistance vessels (**Fig. 16-1**).[14] Resistance to coronary blood flow is the sum of the resistance in the R_1 and R_2 vessels. The larger epicardial vessels typically offer little resistance to blood flow and are able to accommodate large increases in coronary flow without producing any significant drops in pressure. Therefore, these vessels mainly serve a conduit function. Most resistance to flow in normal coronary arteries is provided by the smaller endocardial (R_2) vessels. These vessels will contract and dilate to maintain blood flow based on the metabolic demands of the myocardium. When a person is at rest or not exerting themselves, and MVO_2 is low, the endocardial vessels with constrict since the need for blood flow is low. When this person undergoes physical exertion or emotional stress, the MVO_2 increases, and the endocardial vessels will dilate to increase myocardial oxygen supply in proportion to the increase in MVO_2 (see Fig. 16-1). This process in which the resistance vessels constrict and dilate based on MVO_2 is known as autoregulation.[13,14] Through autoregulation, coronary blood flow can increase 4- to 5-fold over that in normal resting conditions.[13] This increase in coronary flow above resting conditions is termed coronary flow reserve.

FIGURE 16-1

The coronary circulation with large epicardial conductance vessels (R_1) that offer little intrinsic resistance to myocardial blood flow and intramyocardial resistance arterioles (R_2). Resistance to flow equals $R_1 + R_2$ and R_2 resistance is normally much greater than R_1; hence flow is equal to the driving pressure across the coronary bed divided by the resistance in R_2. Dilation in R_2 normally occurs in response to exercise or increased myocardial oxygen demand. When an atherosclerotic lesion narrows the conductance vessel, the arterioles dilate under resting conditions to prevent ischemia. However, with stress, the vasodilator reserve becomes limited.



Coronary atherosclerotic plaque development typically occurs in the larger epicardial vessels. As these plaques continue to grow and cause luminal narrowing of the vessel, the vessel is transformed from one that originally provides minimal resistance into one that now provides considerable resistance to blood flow. This continues to a point where the epicardial artery resistance becomes dominate. Through autoregulation, this increase in resistance in the R_1 or conductance vessels is offset by vasodilation in the R_2 or resistance vessels to maintain flow.[14]

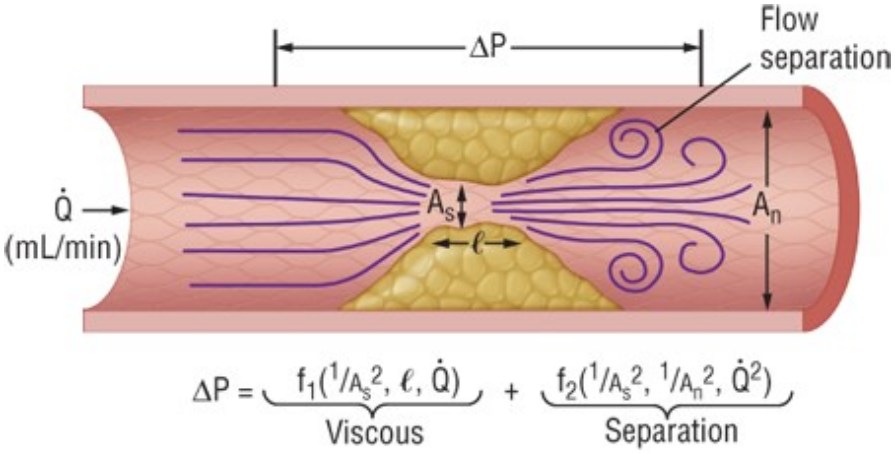
The amount of luminal diameter occupied by the atherosclerotic plaque is the major determine of the drop in pressure after the stenosis. The Bernoulli principle helps explain the fluid mechanics of a stenosis and the relationship between stenosis severity, pressure drop, and flow (**Fig. 16-2**).[15] The total pressure drop (and therefore flow) across a stenosis is governed by three hydrodynamic factors; viscous losses, separation losses, and turbulence, with turbulence representing a minor component of pressure loss. The most important determinant of stenosis resistance for any given level of flow is the minimum stenosis cross-sectional area.[16] Because resistance is inversely proportional to the square of the cross-sectional area, small dynamic changes in luminal area caused by atherosclerotic plaque size, thrombus creation, or vasospasm leads to major changes in the stenosis pressure-flow relation and reduce maximal perfusion during vasodilation.[16] Separation losses determine the steepness of the stenosis pressure-flow relation and become increasingly important as stenosis severity and/or flow rate increases. Stenosis length and changes in cross-sectional area distal to the stenosis are relatively minor determinates of resistance for most coronary lesions.

FIGURE 16-2

Fluid mechanics of a stenosis. The pressure drop across a stenosis can be predicted by the Bernouli equation. It is inversely related to the minimum stenosis cross-sectional area and varies with the square of the flow rate as stenosis severity increases.

(A_n, area of the normal segment; A_s, area of the stenosis; f_1, viscous coefficient; f_2, separation

coefficient; L, stenosis length; μ, viscosity of blood; ρ, density of blood; ΔP, pressure drop; Q, flow.)



Coronary plaques that occupy less than 50% to 70% of the vessel luminal diameter rarely produce ischemia or angina.[14] As the intensity of exercise increases, the endocardial vessels dilate and resistance to flow decreases, leading to a proportional increase in myocardial blood flow so that there is not flow deficit or ischemia. Therefore, since these smaller plaques do not produce symptoms, the patient and clinician typically have no idea that they are there. Since small plaques have a rich lipid core and thin fibrous cap, they are more prone to rupture and acute thrombus production, making them quite dangerous and lethal (see Chapter 17).[11,12]

Once the epicardial vessel is significantly narrowed to 70% or more of the luminal diameter, the endocardial vessels dilate to maintain baseline coronary resistance at normal levels.[13,14] Therefore, much of the coronary flow reserve has been utilized and even low levels of exercise exhaust the remaining reserve. Further increments in exercise intensity can no longer be accompanied by further decreased in endocardial (R_2) resistance, and no further increments in flow can occur once autoregulation has reached its ceiling. This results in a flow deficit, causing myocardial ischemia and often angina. Therefore, the amount of exertion a patient can endure is largely based on the extent of vessel stenosis and the remaining coronary flow reserve. The endocardial flow reserve is completely exhausted at rest when the epicardial stenosis severity exceeds 90%, which is also referred to as a critical stenosis.

Heart Rate and Systole

Increasing HR not only increases MVO_2, but also has an impact on reducing myocardial oxygen supply. While most tissues and organs are perfused during systole, the heart is the only organ that is perfused during diastole. There are two physiologic explanations for this difference.[17] First, pressure created in the ventricles during systole creates in increase in pressure in the distal coronary circulation well above that of the typical coronary perfusion pressure (50-60 mm Hg). Since coronary flow must go from higher to lower pressure, only during diastole does the pressures drop to allow downstream flow and myocardial oxygen supply. Second, the simple physical compression force of

the myocardium that occurs during systole literally squeezes the downstream vessels closed preventing blood flow. During diastole, the myocytes relax and the downstream vessels open allowing coronary blood flow and myocardial oxygen delivery. During a typical cardiac cycle with a normal resting HR, the myocardial spends twice as much time in diastole compared to systole. When HR increases, time spend in diastole is reduced with little change in time spend in systole. During times of exertion and increased HR, the ratio to time spent in diastole to systole can be reduced from 2:1 to 1:1. This reduced time in diastole produces a reduced time for myocardial perfusion, and therefore, reduced total myocardial oxygen supply.[17]

Oxygen Extraction and Oxygen Carrying Capacity

Two additional determinants to myocardial oxygen supply are myocardial oxygen extraction and oxygen carrying capacity. Compared to most other vascular beds, myocardial oxygen extraction is near maximum at rest; nearly 60% to 80% of arterial oxygen content.[18] Coronary venous oxygen tension can only decrease from 25 mm Hg to a minimum of approximately 15 mm Hg. Therefore, during exertion, the ability to increase oxygen delivery to myocytes is limited through increasing the amount of oxygen extracted from the arterial blood.

Arterial oxygen content is equal to the product of the hemoglobin concentration and oxygen saturation. Small amounts of oxygen are also directly dissolved in plasma, but this does not contribute a measurable amount to myocardial oxygen supply. Consequently, patients with anemia (low hemoglobin) or hypoxia (low oxygen saturation) would have a reduction in their oxygen carrying capacity. The impact of anemia is thought to impact total oxygen carrying capacity to a greater degree than hypoxia unless the oxygen saturation falls below 50%. This explains why patients with IHD may receive transfusions if hemoglobin concentrations fall below 10 mg/dL, and patients without IHD are allowed to go as low as 6 to 8 mg/dL. Most patients have an arterial oxygen saturation of 95% to 100%, with little ability to improve. Therefore, during times of exertion and ischemia, there is little opportunity to improve myocardial oxygen supply through myocardial oxygen extraction or oxygen carrying capacity, leaving increased myocardial blood flow as the main mechanism for increasing myocardial oxygen supply.

Coronary Collateral Circulation

Most animals have some native collateral vessels from birth, though the extent can vary widely between species.[19] In the setting of SIHD, these native collateral vessels mature in a process termed arteriogenesis. As coronary stenosis exceeds 70%, resting distal pressure consistently falls due to maximized autoregulation. This extent of stenosis also contributes to episodes of exertion-induced ischemia. The ischemic episodes lead to the production of growth factors such as vascular endothelial growth factor and basic fibroblast growth factor through stimulation of nitric oxide synthase. The combination of physical forces of altered coronary pressure, growth factors, and endogenous vasodilators (eg, nitrous oxide and prostacyclin) change native collateral vessels of approximately 200 µm in existing epicardial anastomoses into mature vessels that can reach 1 to 2 mm in diameter.[20] While most functional collateral flow develops from the process of arteriogenesis, collateral perfusion can also occur from sprouting of new vessels in a process termed angiogenesis. The process of

angiogenesis is also driven by physical forces and growth factors, but produces smaller, capillary-like vessels from preexisting coronary vessels. These vessels may provide collateral flow when they develop in the border between ischemic and nonischemic regions of the myocardium.[21] Capillary angiogenesis may also occur within the ischemic region and can reduce the intercapillary distance for oxygen delivery.

Investigation into pharmacologic mechanisms to improve collateral vessel development has been largely disappointing. While chronic nitrates may assist in development of collateral vessels, the use of growth factors and vasodilators have not produced the expected results. Due to the variability in collateral vessel development across different species, the use of animal models for study has significant limitations.[19]

Additional Factors Impacting Coronary Flow

While atherosclerotic coronary stenosis is the leading etiology in the development of SIHD and angina, there are a number of additional pathophysiologic mechanisms that are also occurring in these patients that contribute to disease onset and progression. These additional mechanisms include endothelial dysfunction, microvascular dysfunction, vasospasm, platelet activation and coagulation, as well as inflammation.[10,22] Endothelial dysfunction is manifested as a reduction in nitric oxide mediated vasodilation. This can be due to impairment in nitric oxide synthesis or availability. Reduced vasodilator response may lead to the development of ischemia at lower levels of exertion. There can also be impairment in how the microvascular response to endogenous vasodilators and vasoconstrictors, with reduced and exaggerated responses, respectively.[10] While atherosclerotic obstructive stenosis typically occurs in epicardial vessels, microvascular obstructions can also occasionally occur. Patients without epicardial stenosis, but presenting with demand driven ischemia, are classified as having cardiac syndrome X.[23]

Patients with an ACS event have ruptured atherosclerotic plaque with significant platelet accumulation and coagulation response producing an acute reduction in myocardial oxygen supply.[11,12] While this is not the pathophysiology of ischemia in patients with SIHD, there can be smaller plaques (30%-50% stenosis) that rupture that produce a fairly reserved platelet and coagulation response that does not produce an acute substantial reduction in myocardial oxygen supply. Instead, the process is arrested with an approximate 70% to 80% stenosis and reendothealialization.[11] Therefore, there is now a plaque that will lead to maximized flow reserve and exertion-driven ischemia that appears more sudden than the typically slowly accumulation plaque in most settings of SIHD. Finally, inflammation also plays a role in the pathophysiology of SIHD. In this setting, macrophages and T lymphocytes produce and secrete cytokines, chemokines, and growth factors that activate endothelial cells, increase vasoreactivity, and proliferation of vascular smooth muscle cells.[10,22] C-reactive protein, a marker of inflammation, has been shown to be elevated in patients with SIHD and correlates to adverse CV events. Statin therapy targeted at patients with elevated C-reactive protein and normal cholesterol levels has demonstrated a reduction in CV events.[24] While an obstructive atherosclerotic plaque contributes to ischemia and angina in patients with SIHD, the pathophysiology involves multiple mechanisms and the potential for multiple

therapeutic targets.

Coronary Vasospasm and Prinzmetal's Angina

2 Most patients with SIHD have an obstructive coronary stenosis and exertion-induced ischemia. Since the size of the obstructive lesion does not change acutely, the amount of exertion needed to induce ischemia and angina is fairly predictable for an individual patient. For example, the patient knows when they work in the garden for 20 minutes or walk 5 blocks at a certain pace, before developing chest pain. Patients with this pattern of chest pain development are described as having a fixed angina threshold. Some patients can have what is described as having variable-threshold angina. In these patients the amount of exertion leading to chest pain may differ from day to day. An example would be the patient who could walk six blocks before experiencing angina yesterday, but today can only walk three blocks before becoming symptomatic. These patients also have an obstructing atherosclerotic plaque leading to a fixed decrease in supply, but they also have a reduction in myocardial oxygen supply due to transient vasospasm superimposed at the site of the obstructing plaque.[14,25] The vasospasm at or distal to the location of atherosclerotic plaque is typically induced by endothelial damage induced by the atherosclerotic plaque. Damaged endothelial cells produce less vasodilator substances such as endothelium-derived relaxing factor (EDRF), while also having an increased response to vasoconstrictors in response to exercise.[25] Patient symptoms will differ depending on the extent of the underlying fixed obstruction and the degree of dynamic change in coronary arterial tone. While the fixed obstruction is usually sufficient to produce symptoms with exertion, episodes of transient vasospasm superimposed on the obstruction significantly reduce myocardial blood flow leading to ischemia. The changing pattern of ischemia in these patients reflects a variable amount of vasospasm under certain conditions. Angina episodes are typically more common in the morning hours due to the circadian release of vasoconstrictors. Exposure to cold temperature, emotion, and mental stress has also been reported to lower the angina threshold in patients with variable threshold angina.

Patients may also have variant angina, also referred to as Prinzmetal's angina. Patients with variant angina typically have a different etiology of ischemia and angina compared to most patients with SIHD. Patients with variant angina usually do not have a coronary flow-obstructing atherosclerotic plaque, but instead have a significant reduction in myocardial oxygen supply due to substantial vasospasm in epicardial vessels.[25] The mechanism of this vasospasm is due to a reduced production of vasodilators, as well as an exaggerated response to endogenous vasoconstrictors. Patients with Prinzmetal's angina also have a different presentation compared to patients with SIHD and an obstructive coronary plaque. Patients with Prinzmetal's angina typically present with chest pain at rest, occur early in the morning, in younger patients, and have ST-segment elevation.[25]

CLINICAL PRESENTATION

A thorough patient history is key to the clinical assessment of a patient with SIHD. Exertional chest pain is the classical main presenting symptom of patients with SIHD. Since the differential diagnosis of "chest" pain is fairly broad (**Table 16-1**), it is important to determine if symptoms are due to a

cardiac or noncardiac pathology. The description of a patient's chest pain also can be helpful in determining if a patient's pain is more likely to be due to SIHD or ACS. A commonly used method for incorporating the important aspects of the chest pain story is the PQRST mnemonic (**Table 16-2**).

TABLE 16-1 Differential Diagnosis of Episodic Chest Pain Resembling Angina Pectoris

	Duration	Quality	Provocation	Relief	Location	Comment
Effort angina	5-15 minutes	Visceral (pressure)	During effort or emotion	Rest, NTG	Substernal, radiates	First episode vivid
Rest angina	5-15 minutes	Visceral (pressure)	Spontaneous (with exercise?)	NTG	Substernal, radiates	Often nocturnal
Mitral prolapse	Minutes to hours	Superficial (rarely visceral)	Spontaneous (no pattern)	Time	Left anterior	No pattern, variable
Esophageal reflux	10 minutes to 1 hour	Visceral	Spontaneous, cold liquids, exercise, lying down	Foods, antacids, H_2 blockers, proton pump inhibitors, NTG	Substernal, radiates	Mimics angina
Peptic ulcer	Hours	Visceral, burning	Lack of food, "acid" foods	Foods, antacids, H_2 blockers, proton pump inhibitors	Epigastric, substernal	
Biliary disease	Hours	Visceral (wax and wane)	Spontaneous, food	Time, analgesia	Epigastric, radiates	Colic
Cervical disk	Variable (gradually subsides)	Superficial	Spontaneous, food	Time, analgesia	Arm, neck	Not relieved by rest
Hyperventilation	2-3 minutes	Visceral	Emotion, tachypnea	Stimulus removed	Substernal	Facial paraesthesia
Musculoskeletal	Variable	Superficial	Movement, palpation	Time, analgesia	Multiple	Tenderness
Pulmonary	30 minutes	Visceral (pressure)	Often spontaneous	Rest, time bronchodilator	Substernal	Dyspneic

NTG, nitroglycerin.

TABLE 16-2 PQRST Approach to Assessment of a Patient's Chest Pain

Factor	Presentation in Stable Ischemic Heart Disease
Precipitating factors	Typically brought on by some level of exercise or exertion
Palliative measures	Relieved by rest with or without a sublingual nitroglycerin in 5 to 10 minutes
Quality of the pain	Described as a squeezing, heaviness, or tightness

Factor	Presentation in Stable Ischemic Heart Disease
Region	Substernal
Radiation	Left or right arm, back, down into the abdomen, up into the neck
Severity	While pain is subjective, those who have pain report a 5 or higher on a 10-point scale
Temporal pattern (timing)	Pain last less than 20 minutes and usually relieved in 5 to 10 minutes

[3] The typical chest pain description of a patient with SIHD includes chest pain that is precipitated by exertion, such as walking, gardening, sexual activity, or some activities of daily living such as showering, cleaning house, or doing laundry. In this setting, the exertion produces an increase in MVO_2 that exceeds what can be provided by the fixed decrease in myocardial oxygen supply from the obstructive atherosclerotic plaque. Typically the most effective palliative measure is rest or the use of sublingual nitroglycerin (SL NTG). As the patient rests for a few minutes, the patient's HR and BP comes down to the level that can be met by the patient's reduced supply, reestablishing a balance between myocardial oxygen supply and demand, and the chest pain is relieved. Use of SL NTG also allows for relieve by acutely increasing myocardial oxygen supply through vasodilation of epicardial vessels and a reduction in preload.
