

## summary page

✚ The five sorting algorithms are :

✚ Cocktail , Comb, Counting, Gnome, Strand

- **Stable Definition :simply** The relative order of items with equal keys is preserved

### → Cocktail (Stable & comparison sort & inplace)

|                             |          |
|-----------------------------|----------|
| Data structure              | Array    |
| Worst case performance      | $O(n^2)$ |
| Best case performance       | $O(n)$   |
| Average case performance    | $O(n^2)$ |
| Worst case space complexity | $O(1)$   |

An example of a list that proves the need for cocktail sort :

A list (2,3,4,5,1), which would only need to go through one pass of cocktail sort to become sorted, but if using an ascending [bubble sort](#) would take four passes.

### → Comb (inplace ,not stable)

|                             |  |
|-----------------------------|--|
| Data structure              | Array  |
| Worst case performance      | $O(n^2)^{[1]}$   |
| Best case performance       | $O(n)$   |
| Average case performance    | $\Omega(n^2/2^p)$ , where $p$ is the number of increments <sup>[1]</sup> |
| Worst case space complexity | $O(1)$   |

The basic idea is to eliminate small values near the end of the list, using a gap ..

**Gap of initially** [input size / shrink factor] shrink factor = 1.3 ,,after testing over 200,000 random lists

---

## → Counting (Stable, only for non negative number)

used as a subroutine in another sorting algorithm, [radix sort](#),

→ takes linear time :

### Time Complexity Analysis

- So the counting sort takes a total time of:  $O(n + k)$
- Counting sort is called stable sort.
  - A sorting algorithm is **stable** when numbers with the same values appear in the output array in the same order as they do in the input array.

---

## → Gnome (inplace & stable)

moving an element to its proper by a series of swaps

|                                    |                  |
|------------------------------------|------------------|
| <b>Data structure</b>              | Array            |
| <b>Worst case performance</b>      | $O(n^2)$         |
| <b>Best case performance</b>       | $O(n)$           |
| <b>Average case performance</b>    | $O(n^2)$         |
| <b>Worst case space complexity</b> | $O(1)$ auxiliary |

## → Strand (not stable, not in place)

The Idea is pulling sorted sublists out of the list to be sorted and merging them with a result array

|                                    |                  |
|------------------------------------|------------------|
| <b>Data structure</b>              | Linked list      |
| <b>Worst case performance</b>      | $O(n^2)$         |
| <b>Best case performance</b>       | $O(n)$           |
| <b>Average case performance</b>    | $O(n^2)$         |
| <b>Worst case space complexity</b> | $O(1)$ auxiliary |
