Administration of osmotic diuretics, insensible fluid loss, and pituitary gland dysfunction may be responsible for fluid and electrolyte disturbances in patients with TBI. Strict monitoring of intake and output, as well as hemodynamic monitoring, guides the health care team in prescribing adequate fluid replacement. Routine monitoring of serum osmolality is helpful in preventing excessive systemic dehydration when administering osmotic diuretics or hypertonic saline. Surveillance of serum electrolytes allows for early identification and treatment of electrolyte abnormalities.

Disorders of sodium imbalance are common in the patient with TBI (Table 36-4). Hyponatremia most commonly occurs as a result of the syndrome of inappropriate antidiuretic hormone secretion (SIADH), in which antidiuretic hormone (ADH) is released in excessive amounts, resulting in hemodilution.[20] Hemodilution leads to a lower concentration of sodium in the blood. SIADH often is a transient phenomenon that can be treated with fluid restriction.

Cerebral salt-wasting syndrome may also cause hyponatremia. The precise physiologic mechanism of cerebral salt-wasting syndrome is poorly understood but involves a primary loss of sodium and free water through the kidneys. Treatment of this disorder requires fluid and sodium replacement in amounts that equal losses.[20,21]

Diabetes insipidus (DI) is a cause of hypernatremia and hypovolemia that occurs commonly in patients with injury or ischemia in the pituitary gland. Herniation syndrome often causes direct compression of the pituitary gland or compression to the supplying blood vessels. Damage to the pituitary gland prevents or decreases the secretion of ADH. DI is diagnosed by increasing serum sodium level, low urine specific gravity, and increased urine output. Treatment of DI includes aggressive fluid replacement that matches hourly fluid losses and the administration of exogenous ADH (vasopressin). Vasopressin may be given intravenously, subcutaneously, or intranasally, depending on the severity of the disorder.

Managing Cardiovascular Complications

Myocardial stunning and a transient decrease in cardiac function may occur in severe TBI. Inversion of T waves and ST-segment elevation or depression may be noted. Serum cardiac enzyme levels, electrocardiography, and echocardiography may be used to evaluate myocardial function. Hemodynamic monitoring devices, such as arterial and central lines and pulmonary artery catheters, may be used to guide medical therapies during the critical phases of TBI.

Disorders of coagulation are a significant concern in patients with TBI causing the release of large amounts of thromboplastin in response to brain injury. Disseminated intravascular coagulation may result. If hypothermia is

Table 36-4 Disorders of Sodium Imbalance: Comparison of Diabetes Insipidus, the Syndrome of Inappropriate Antidiuretic Hormone Secretion, and Cerebral Salt-Wasting Syndrome

	Diabetes Insipidus	Syndrome of Inappropriate Antidiuretic Hormone Secretion	Cerebral Salt-Wasting Syndrome
Urinary output	Increased	Decreased	Increased
Specific gravity	Decreased	Increased	Decreased
Volume status	Decreased	Mildly increased	Decreased
Serum sodium	Increased	Decreased	Decreased
Treatment	Administration of exogenous vasopressin, fluid replacement	Fluid restriction, judicious sodium replacement	Fluid and sodium replacement

employed, it is important to recognize that coagulopathies may be exacerbated as the body temperature decreases.

Prophylaxis of deep venous thrombosis (DVT) is an essential component in the care of patients with head injuries, who are often immobile for extended periods. Sequential compression devices provide intermittent pulsatile pressure to the lower extremities, increasing venous return and promoting systemic fibrinolysis. Antiembolic stockings, anticoagulant administration, and early mobilization are recommended to prevent DVT and pulmonary emboli.[14]

Managing Pulmonary Complications

Pulmonary complications in the patient with TBI include pneumonia, acute respiratory distress syndrome (ARDS), neurogenic pulmonary edema, and pulmonary embolus. Pulmonary toilet, vigilant oral hygiene, and monitoring of endotracheal tube cuff pressure are necessary to prevent nosocomial pneumonia and mitigate pulmonary complications in patients with head injuries who require prolonged mechanical ventilation (see Chapter 25 for a discussion of the causes and prevention of ventilator-associated pneumonia).

Early mobility is critical in facilitating pulmonary toilet, preventing atelectasis, and preventing pulmonary emboli due to DVT. Early consideration of extubation to reduce the number of days on mechanical ventilation as well as early planning for tracheostomy in patients unable to protect their airway may prevent additional pulmonary complications.[14]

ARDS is a hypoxic lung disease resulting from the activation of the inflammatory cascade, causing leakage of protein-rich fluid from the pulmonary capillaries into the interstitium of the lungs as well as destruction of alveolar cells. There are many causes of ARDS in patients with head injuries, including concomitant pulmonary contusion, aspiration pneumonia, sepsis, and massive blood transfusion. Medical management of ARDS may involve the use of pressure modes of mechanical ventilation to decrease the volume needed to deliver each breath (high volumes have been implicated in furthering alveolar injury); see Chapter 27 for a complete discussion of ARDS management.

Neurogenic pulmonary edema may result from injury to the brainstem, increased ICP, or an increase in sympathetic tone that causes a catecholamine surge at the time of trauma. Neurogenic pulmonary edema often presents as "flash pulmonary edema" because it has a sudden onset. This type of pulmonary edema is thought to be caused by massive vasoconstriction due to an acute increase in ICP causing activation of the sympathetic nervous system. Consequently, there is marked increase in systemic afterload resulting in left ventricular failure. Pulmonary edema resulting from left ventricular failure is exacerbated by an increase in pulmonary capillary permeability, causing further edema.[22] Treatment includes judicious use of low-dose diuretics. The condition is typically self-limiting in patients without cardiac disease.

Multidisciplinary care of the patient with TBI with respect to pulmonary complications requires the involvement of the nursing and the physician teams; the respiratory therapist; the occupational therapist; the physical therapist (for early mobilization); and the speech–language pathologist (to address issues with aspiration).

Managing Nutrition and Maintaining Glycemic Control

Head injury is thought to cause hypermetabolic and hypercatabolic states as well as a decrease in immunocompetency.[23] Morbidity and mortality may significantly increase if nutritional requirements are not met. Indirect calorimetry is useful in determining resting energy expenditure (REE).[23] Indirect calorimetry is performed using a machine (metabolic cart) that interfaces with the ventilator to measure oxygen consumption and carbon dioxide production.

Nutrition in the form of enteral or parenteral nutrition is administered in amounts that meet metabolic needs within 5 to 7 days of the injury.[14,23] Enteral feeding may prevent the translocation of bacteria from the intestines to the bloodstream as well as prevent gastrointestinal ulceration and bleeding.[24] Early nutrition starting within 5 days of injury may reduce mortality and be one of the few treatment options that can directly affect mortality in TBI patients.[23] Current recommendations suggest replacement of 140% of REE in patients who are not paralyzed and 100% of REE in patients who are paralyzed.[14] Recognition of the importance of nutrition and multidisciplinary collaboration with a nutrition support team are essential to optimize patient outcome. Research suggests a detrimental effect of hyperglycemia on morbidity and mortality of patients with TBI; however, specific treatment thresholds have not been established. Hyperglycemia with a blood glucose exceeding 200 mg/dL and hypoglycemia should be avoided in patients with TBI.[14,25,26]

Managing Musculoskeletal and Integumentary Complications

Comprehensive assessment of the musculoskeletal and integumentary systems is necessary to prevent skin breakdown and other complications, such as contractures. Collaboration with other disciplines, such as occupational and physical therapy, is also essential in developing a plan of care to prevent or mitigate the effects of immobility on the skin and musculoskeletal systems. Splinting of the hands and feet in an unresponsive patient is necessary to preserve musculoskeletal function and ensure the best conditions for future rehabilitation. Functional splinting and range-of-motion exercises also help reduce dependent edema in immobile extremities. Frequent turning of patients, even in the critical phase of the illness, is integral in maintaining skin integrity and facilitating pulmonary drainage.

Caring for the Family

Caring for families in crisis, as well as coordinating available services (such as social work and pastoral care), is an important function of the critical care nurse. Bond et al[27] surveyed the needs of family members of patients with severe TBI and found the following four needs:

- The need for specific truthful information
- The need for information to be consistent
- The need to be actively involved in care
- The need to make sense of the entire experience.

BOX 36-4 NURSING INTERVENTIONS

For Sensory Stimulation

Sound

- Explain to the patient what you are going to do.
- Play the patient's favorite television or radio program for 10 to 15 minutes. Alternatively, play a recording of a familiar voice of a friend or family member.
- During the program, do not converse with others in the room or perform other activities of patient care. The goal is to minimize distractions so the patient may learn to attend to the stimulus selectively.
- Another approach is to clap your hands or ring a bell. Do this for 5 to 10 seconds at a time, moving the sound to different locations around the bed.

Sight

- Place a brightly colored object in the patient's view. Present only one object at a time.
- Alternatively, use an object that is familiar, such as a family photo or favorite poster.

Touch

- Stroke the patient's arm or leg with fabrics of various textures. Alternatively, the back of a spoon can simulate smooth texture and a towel rough texture.
- Rubbing lotion over the patient's skin will also stimulate this sense. For some, firm pressure may be better tolerated than very light touch.

Smell

- Hold a container of a pleasing fragrance under the patient's nose. Use a familiar scent, such as perfume, aftershave, cinnamon, or coffee.
- Present this stimulation for very short periods (1 to 3 minutes maximum).
- If a cuffed tracheostomy or endotracheal tube is in place, the patient will not be able to appreciate this stimulation fully.

Critical care nurses have an opportunity to meet all of these specific needs and to change unit culture to meet these needs. Encouraging family members to touch the patient or allowing family members to assist in providing sensory stimulation (Box 36-4) may be helpful and comforting to some family members. Finding opportunities to involve family members in the patient's plan of care may also be therapeutic for the patient and the family. The Ranchos Los Amigos Scale can be used by the critical care nurse to describe the stages of coma as they relate to rehabilitative methods and interventions (Table 36-5). Attention is given to including both spiritual and cultural needs in the plan of care.

A patient with TBI may be discharged to home, a rehabilitation program, or a nursing facility depending on the severity of his or her neurologic deficits. Families must be informed and educated about the expected course of events and potential scenarios for continued care after the acute hospitalization, especially when the patient has severe TBI. Family resources, as well as other support systems and services available to the patient, should be assessed early in all patients with TBI to facilitate a smooth transition into the next stage of care. Social workers and case managers play an integral role in obtaining information and communicating with the patient, the family, and the multidisciplinary team.

▲ Brain Death

A patient's condition may be so severe that brain death is the final outcome. The critical care nurse continues to provide nursing care to the patient as treatment is continued or life support measures are withdrawn.

In the past, the declaration of brain death was controversial with regard to the standardization of tests needed to make the decision and ethical considerations. The Uniform Determination of Death Act was developed in 1981 by the President's Commission for the Study of Ethical Problems in Medicine and Biomedical Behavior Research and adopted by all 50 states. This act states: "An individual, who has sustained either (1) irreversible cessation of circulatory and respiratory functions, or (2) irreversible cessation of all functions of the entire brain, including the brainstem, is dead. A determination of death must be made in accordance with accepted medical standards."[28]

The brain death examination seeks to confirm the following three cardinal findings: coma or unresponsiveness, absence of brainstem reflexes, and apnea.[29] Tests specific for brain death include, but are not limited to, motor testing; evaluation of pupillary responses; evaluation of the oculocephalic reflex ("doll's eyes" phenomenon); evaluation of the oculovestibular reflex (caloric ice-water test); evaluation of the corneal, cough, and gag reflexes; and apnea testing. Electrolyte abnormalities, hypothermia or hyperthermia, severe hypotension, or the presence of medications in amounts that could cause coma must be resolved before brain death testing can be performed. Apnea testing is performed by removing the patient from the ventilator, inspecting the chest for spontaneous respiratory effort while providing supplemental oxygen, and monitoring for an increase in $PaCO_2$. Baseline acid–base balance is established with an arterial blood gas (ABG) measurement prior to removal from the ventilator, and then serial ABG measures are obtained. A $PaCO_2$ greater than 60 mm Hg or an increase in the $PaCO_2$ of 20 mm Hg or more above the patient's baseline $PaCO_2$ is regarded as a positive test, supporting the diagnosis of brain death.[29] The patient is simultaneously observed for spontaneous respiration and hemodynamic instability, which may cause the test to be aborted. An increased $PaCO_2$ is the single strongest stimulus for the initiation of breathing; therefore, the absence of respiratory effort in the presence of severe hypercarbia constitutes strong evidence of brain death. Confirmatory tests for brain death, such as cerebral angiography (to test for the absence of cerebral blood flow), TCD ultrasonography, EEG, BAER, and SSEP, can be used if any doubt exists after a full clinical examination has been completed.

The American Academy of Neurology recommends repeating the clinical evaluation for brain death after 6 hours.[29] Time of death is recorded at the time that brain death is declared. Different institutions specify requirements based on state laws and statutes for physicians declaring brain death. Brain death determination in pediatric patients differs from that in adults because of the increased viability of

Table 36-5 Ranchos Los Amigos Scale

Level	Guidelines for Interacting With Patient
1. **No response** to any stimuli occurs.	• Assume that the patient can understand all that is said. Converse with, not about, the patient.
2. **Generalized response.** Stimulus response is incoherent, limited, and nonpurposeful with random movements or incomprehensible sounds.	• Do not overwhelm the patient with talking. Leave some moments of silence between verbal stimuli.
3. **Localized response.** Stimulus response is specific but inconsistent; patient may withdraw or push away, may make sounds, may follow some simple commands, or may respond to certain family members.	• Manage the environment to provide only one source of stimulation at a time. If talking is taking place, the radio or television should be turned off. • Provide short, random periods of sensory input that are meaningful to the patient. A favorite television program or recording or 30 min of music from the patient's favorite radio station will provide more meaningful stimulation than constant radio accompaniment, which becomes as meaningless as the continual bleep of the cardiac monitor.
4. **Confused–agitated.** Stimulus response is primarily to internal confusion with increased state of activity; behavior may be bizarre or aggressive; patient may attempt to remove tubes or restraints or crawl out of bed; verbalization is incoherent or inappropriate; patient shows minimal awareness of environment and absent short-term memory.	• Be calm and soothing when handling the patient. Approach with gentle touch to decrease the occurrence of defensive emotional and motor reflexes. • Watch for early signs that the patient is becoming agitated (eg, increased movement, vocal loudness, resistance to activity). • When the patient becomes upset, do not try to reason with him or her or "talk him or her out of it." Talking will be an additional external stimulus that the patient cannot handle. • If the patient remains upset, either remove him or her from the situation or remove the situation from him or her.
5. **Confused, inappropriate–nonagitated.** Patient is alert and responds consistently to simple commands; however, patient has a short attention span and is easily distracted; memory is impaired and patient exhibits confusion of past and present events; patient can perform previously learned tasks with maximal structure but is unable to learn new information; may wander off with vague intention of "going home."	• Present the patient with only one task at a time. Allow time to complete it before giving further instructions. • Make sure that you have the patient's attention by placing yourself in view and touching the patient before talking. • If the patient becomes confused or resistant, stop talking. Wait until he or she appears relaxed before continuing with instruction or activity.
6. **Confused–appropriate.** Patient shows goal-directed behavior but still needs external direction; can understand simple directions and reasoning; follows simple directions consistently and requires less supervision for previously learned tasks; has improved past memory depth and detail and basic awareness of self and surroundings.	• Use gestures, demonstrations, and only the most necessary words when giving instructions. • Maintain the same sequence in routine activities and tasks. Describe these routines to the patient and relate them to time of day.
7. **Automatic–appropriate.** Patient is able to complete daily routines in structured environment; has increased awareness of self and surroundings but lacks insight, judgment, and problem-solving ability.	• Supervision is still necessary for continued learning and safety. • Reinforce the patient's memory of routines and schedules with clocks, calendars, and a written log of activities.
8. **Purposeful–appropriate.** Patient is alert, oriented, and able to recall and integrate past and recent events; responds appropriately to environment; still has decreased ability in abstract reasoning, stress tolerance, and judgment in emergencies or unusual situations.	• The patient should be able to function without supervision. • Consideration should be given to job retraining or a return to school.

the immature brain.[30] Specific guidelines for the determination of brain death in children were developed by a federal task force in 1987 and updated in 2011. These guidelines delineate physical examination features unique to pediatric patients as well as specific time frames for observation when brain death is suspected, depending on the age of the child.[30]

The concept of brain death is often confusing for families because death is typically associated with cardiopulmonary death. Therefore, the language used in discussions is very important. Some family members may interpret the term "brain dead" to mean that the rest of the body can continue to live, so care must be taken to assess the understanding and coping behaviors of family members.[31]

The discussion of brain death should be separated in time from conversations regarding the opportunities for organ donation. It is essential to work closely with an organ procurement organization to provide the most complete and accurate information regarding organ donation.

▲ Clinical Applicability Challenges

CASE STUDY

Mr. M. is a 21-year-old male who was transported to the emergency department (ED) after being assaulted. Emergency medical service personnel placed a rigid collar to immobilize his cervical spine. On arrival in the ED, Mr. M. was unresponsive. His vital signs were blood pressure of 116/76; heart rate, 61; respiratory rate, 22 breaths/min; and temperature, 35.8°C orally. Neurological examination showed no movement to noxious stimulation of his upper and lower extremities; pupils were small, sluggishly reactive to light (cranial nerve III); corneal reflex intact in each eye (cranial nerves V and VII); and intact cough and gag reflexes (cranial nerves IX and X). The Glasgow Coma Scale (GCS) score was 5.

Because of Mr. M's depressed level of consciousness and GCS score, he was intubated using rapid-sequence intubation technique and mechanical ventilation was begun. Secondary survey was performed to detect other obvious traumatic injuries and did not reveal additional deformities. An emergency head CT scan was obtained and revealed a left fronto-temporal subdural hematoma, bilateral frontal contusions with shifting of the midline brain structures, and right uncal herniation. Radiographs of the patient's cervical spine were obtained to rule out vertebral fracture. No fractures were revealed nor was there dislocation of the vertebrae.

Based on the patient's clinical neurological examination and CT findings, neurosurgeons took him emergently to the operating room to evacuate the subdural hematoma and performed a left frontotemporal decompressive craniectomy with durotomy and a ventriculostomy (external ventricular drain) was placed to monitor ICP and allow for drainage of cerebrospinal fluid if necessary.

Mr. M. was admitted to the intensive care unit (ICU) postoperatively. His GCS was now 6T (eye opening = 2, best motor response = 3, flexion to pain, best verbal response = 1T). Both pupils were now large and sluggishly reactive to light. An infusion of propofol was initiated at 20 mcg/kg/hour for sedation. ICP readings remained stable in the range of 10–15 mm Hg.

On ICU day 3, Mr. M continued to be comatose and his intracranial pressure rose to 35 mm Hg. Drainage of CSF from the ventriculostomy was performed until the ICP was sustained in the range of 15–20 mm Hg. A head CT revealed an increase in cerebral edema. A dose of mannitol, 0.5 grams/kg was administered and maintenance IV fluids were increased from 100 mL/h to 125 mL/hour in an attempt to prevent systemic dehydration which could cause a decrease in blood pressure leading to vasodilation of cerebral blood vessels and increased ICP. On day 7, the propofol infusion was weaned to off and the patient was no longer requiring frequent drainage of CSF to maintain normal ICP. On day 8, the ventriculostomy was discontinued and on day 10 tracheostomy and gastrostomy tubes were inserted to facilitate prolonged mechanical ventilation and nutrition support. Physical and occupational therapy were consulted to begin the rehabilitation process.

On ICU day 18, his neurologic examination revealed localization to pain, spontaneous eye opening with tracking of his caregivers from side to side.

On ICU day 20, Mr. M. was transferred to a rehabilitation facility specializing in the care of patients with traumatic brain injury. Mr. M. began to follow simple commands, such as showing two fingers, and he was alert and oriented to person and place. Eventually, he was able to have his tracheostomy removed and he was able to continue outpatient physical and occupational therapy to improve motor and cognitive deficits.

1. Based on the radiological findings and your knowledge of the pathophysiology of head injury, explain why Mr. M. has a decreased level of consciousness.

2. Name at least three multisystem complications from having a severe TBI that Mr. M. may experience.

3. Using the description of the patient's neurologic status at the beginning and end of the case study, place the patient into the appropriate level on the Ranchos Los Amigos Scale (see Table 36-5). Name two interventions that could be used when interacting with patients in these categories.

37 Spinal Cord Injury

Janice J. Hoffman and Kathy A. Hausman

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Describe the mechanism of spinal cord injury (SCI).
2. Discuss the various classification systems for spinal cord injuries.
3. Differentiate between the following syndromes: central cord syndrome, Brown-Séquard syndrome, anterior cord syndrome, and posterior cord syndrome.
4. Differentiate between spinal shock, neurogenic shock, and orthostatic hypotension.
5. Perform an assessment of a patient with an SCI.
6. Develop a collaborative plan of care for a patient with an acute SCI.
7. Describe immediate nursing actions when the patient develops autonomic dysreflexia.
8. Explain other typical complications that occur after an SCI.

Spinal cord trauma is often a devastating injury resulting in permanent paralysis and disability. The estimated annual incidence of spinal cord injury (SCI) in the United States is 40 cases per million or approximately 12,000 new cases, and these numbers do not include those individuals who die at the accident scene.[1] According to the National Spinal Cord Injury Database (2009), there are about 262,000 people living with SCI in the United States.

SCI continues to most often affect young adults, but as the age of the general population has increased, so has the average age at injury of these people. From 1973 to 1979, the average was 28.7 years, while since 2005, the average age at injury increased to 40.7 years.[1] Males are overwhelmingly most often affected, composing 80.8% of those with injuries in the national database. An analysis of race/ethnicity reveals that since 2005, 66.2% were Caucasians, 27% were African American, 7.9% were Hispanic, and 2% were Asian.

Motor vehicle accidents are the most common etiology of SCI (41.3%), followed by falls (27.3%), acts of violence (15%), and sports (7.9%).[1] While the life expectancy of persons with SCI has increased over the years, it is still below those without SCI. Leading causes of death in these people include pneumonia, septicemia, pulmonary emboli, and renal failure. The mortality rates are highest during the first year after injury and greater in those with higher level spinal cord injuries.[1]

The average length of stay in acute care settings for patients after SCI is 12 days. They are then usually transferred to a rehabilitation unit/facility, where the average length of stay is 38 days. Most people (87.7%) discharged from rehabilitation settings reside in noninstitutional settings (most often their homes), with only 5% discharged to long-term care facilities. The cost of care differs significantly based upon the level of injury. Estimated first costs for patients with high tetraplegia (quadriplegia) (C1–C4) is $829,843, low tetraplegia (C5–C8) is $535,877, and paraplegia is $303,220; for succeeding years, the estimated annual cost is $148,645, $60,887, and $30,855, respectively.[1]

▲ Classification of Injury

Understanding the anatomy and physiology of the spinal cord is important to correlating the cord damage to the clinical presentation. The spinal cord extends from the base of the brain to approximately the level of the first or second lumbar vertebra. Blood is supplied to the cord by the anterior and posterior spinal arteries. Extending off of the spinal cord are the spinal nerve roots. The spinal cord is enclosed in the vertebral canal, which consists of 33 vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 sacral (fused), and 4 coccygeal (fused). The vertebrae are held in place by ligaments, muscles, and other supporting structures.

Spinal cord injuries can be classified by mechanism, type of vertebral injury, level of injury, or cause. Spinal cord injuries occur as a result of penetrating injury or mechanical forces. Penetrating injuries, which are most often caused by gunshot or stab wounds, damage the spinal cord and cause loss of neurological functioning.

Mechanism of Injury

Mechanical forces that can result in SCI include hyperflexion, hyperextension, axial loading (compression), and rotational forces (Fig. 37-1):

- Hyperflexion, depicted in Figure 37-1A, is caused by a sudden deceleration of the head and neck and is often seen in patients who have sustained trauma from a head-on motor vehicle crash (MVC) or diving accident. The cervical region is most often involved, especially at the C5–C6 level.
- Hyperextension (see Fig. 37-1B) is the most common type of injury and can be caused by a fall, a rear-end MVC, or getting hit in the head (eg, during a boxing match). Hyperextension of the head and neck may cause contusion and ischemia of the spinal cord without vertebral column damage. Whiplash injuries are an example of a hyperextension injury.
- Axial loading, also known as compression (see Fig. 37-1C), typically occurs when a person lands on the feet or buttocks after falling or jumping from a height, or when there is a direct blow to the head. Injury results from vertebral column compression leading to a fracture that causes damage to the spinal cord.
- Rotational injuries result from forces that cause extreme twisting or lateral flexion of the head and neck (see Fig. 37-1D). Fracture or dislocation of vertebrae may also occur.

Type of Vertebral Injury

Mechanical forces can result in fracture or dislocation of vertebrae, or both. If vertebral injury occurs, the type of vertebral injury can be used to describe the person's SCI.

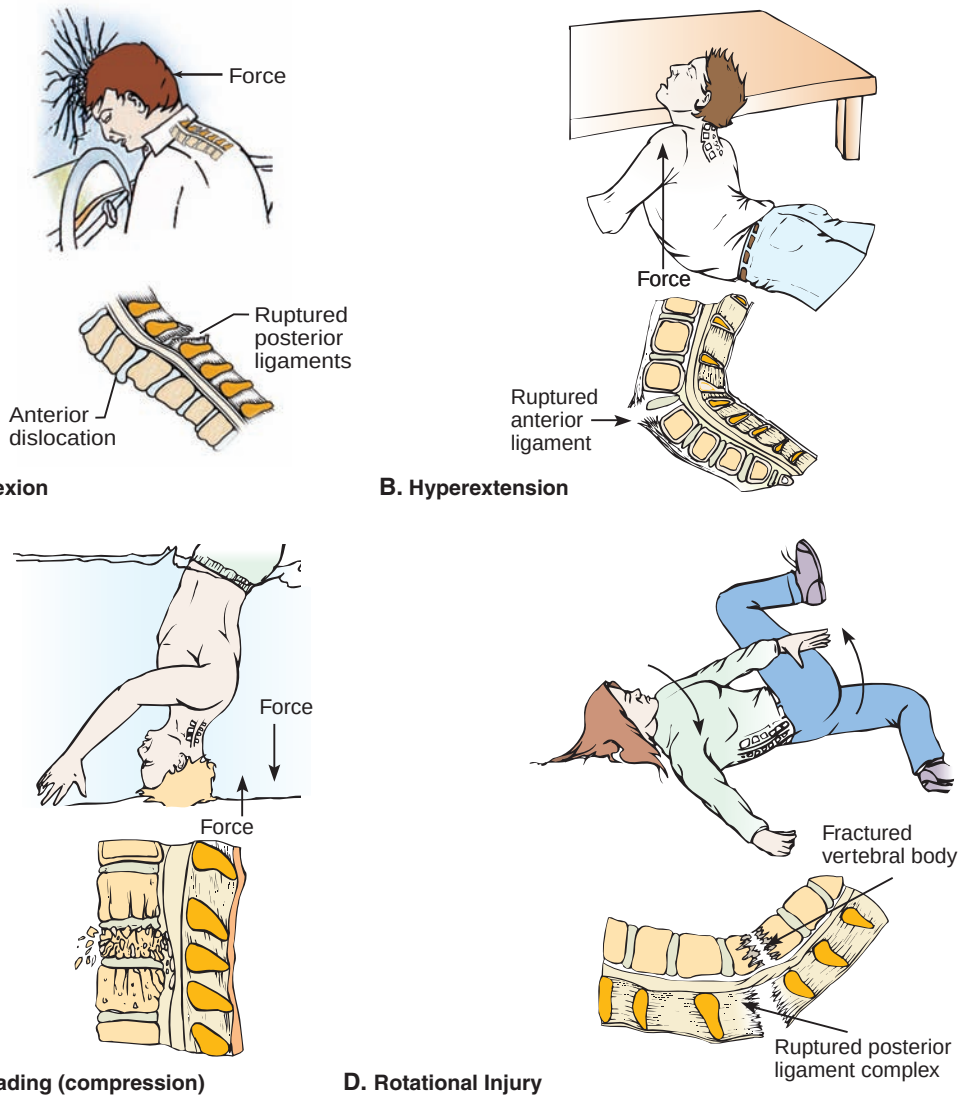

FIGURE 37-1 ▲ Spinal cord injuries can be classified according to the mechanism of injury. **A:** With hyperflexion to the cervical spine, there may be tearing of the posterior ligamentous complex, resulting in anterior dislocation. **B:** Hyperextension injury can result in rupture of the anterior ligament. **C:** Axial loading (compression) of the spine results in fracture and subsequent spinal cord damage. **D:** When rotational force occurs, there is concurrent fracture and tearing of the posterior ligamentous complex. (Adapted from Hickey JV: Clinical Practice of Neurological and Neurosurgical Nursing, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, pp 412–415.)

BOX 37-1 Types of Vertebral Fractures and Dislocations

Fractures

Simple fracture: single fracture; alignment of the vertebrae is intact, and neurological deficits do not occur
Compression fracture: fracture caused by axial loading and hyperflexion
Wedge compression fracture: a stable fracture that involves compression of the vertebral body in the cervical area
Teardrop fracture: an unstable fracture that involves a piece of bone breaking off the vertebra; seen in wedge fractures
Comminuted fracture: the vertebra is shattered into several pieces; bone fragments may be driven into spinal cord

Dislocations

Dislocation: one vertebra overrides another
Subluxation: partial or incomplete dislocation
Fracture–dislocation: fracture and dislocation

Box 37-1 presents definitions of types of fractures and dislocations. A fracture may be considered unstable if the posterior ligaments are torn.

Level of Injury

Spinal cord injuries can also be classified according to the segment of the spinal cord that is affected:

1. Upper cervical (C1–C2) injuries (atlas fractures, atlantoaxial subluxation, odontoid fractures, and hangman's fractures)
2. Lower cervical (C3–C8) injuries
3. Thoracic (T1–T12) injuries
4. Lumbar (L1–L5) injuries
5. Sacral (S1–S5) injuries

The degree of functional recovery depends on the location and extent of the injury. The level of SCI is determined by the effect of the injury on sensory and motor function (Table 37-1). Total loss of voluntary muscle control and sensation below the level of injury suggests that the lesion is complete. Complete lesions involving spinal cord regions C1 to T1 result in tetraplegia (Fig. 37-2). Complete lesions involving spinal cord regions T2 to L1 result in paraplegia (Fig. 37-2). In incomplete injuries, there is some motor or sensory function below the level of injury. The level of sensory loss seen in a person with

Table 37-1 Functional Loss From Spinal Cord Injury (Based on Complete Lesions)

Level of Spinal Injury	Motor Function	Deep Tendon Reflexes	Sensory Function	Respiratory Function	Voluntary Bowel and Bladder Function	Rehabilitative Potential
C1–C4	Tetraplegia: loss of all motor function from the neck down	All lost	Loss of all sensory function in the neck and below (C4 supplies the clavicles)	Loss of involuntary (phrenic) and voluntary (intercostals) respiratory function; ventilatory support and a tracheostomy needed	No bowel or bladder control	May be discharged home on a ventilator with home care
C5	Tetraplegia: loss of all function below the upper shoulders **Intact:** sternomastoids, cervical paraspinal muscles, and the trapezius; can control head	C5, C6 biceps	Loss of sensation below the clavicle and most portions of arms, hands, chest, abdomen, and lower extremities **Intact:** head, shoulders, deltoid, clavicle, portion of forearms (C5 supplies the lateral aspect of the arm)	Phrenic nerve intact, but not intercostal muscles	No bowel or bladder control	Use of extremity-powered devices to achieve some upper limb control Head control facilitates wheelchair (W/C) balance Adaptive tools, held in mouth, for typing and writing Some adaptive tools and use of special computer technology
C6	Tetraplegia: loss of all function below the shoulders and upper arms; lacks elbow, forearm, and hand control **Intact:** deltoid, biceps, and external rotator muscles of shoulders	C5, C6 brachioradialis	Loss of everything listed for a C5 lesion, but greater arm and thumb sensation **Intact:** head, shoulders, arms, palms of hands, and thumbs (C6 supplies the forearm and thumb)	Phrenic nerve intact, but not intercostal muscles	No bowel or bladder control	Needs assistive devices to use arms (may be able to help feed, groom, and dress self) Needs a motorized W/C Dependent for all transfers

(Continued on page 827)

Table 37-1 Functional Loss From Spinal Cord Injury (Based on Complete Lesions) (continued)

Level of Spinal Injury	Motor Function	Deep Tendon Reflexes	Sensory Function	Respiratory Function	Voluntary Bowel and Bladder Function	Rehabilitative Potential
C7	Tetraplegia: loss of motor control to portions of the arms and hands **Intact:** voluntary strength in shoulder depressors, shoulder abductors, internal rotators, and radial wrist extensors	C7, C8 triceps	Loss of sensation below the clavicle and portions of arms and hands **Intact:** head, shoulders, most of arms and hands (C7 supplies the middle finger)	Phrenic nerve intact, but not intercostal muscles	No bowel or bladder function	Can perform some activities of daily living (ADLs) Can use wrist extensor with a special splint to induce finger flexion Can push a W/C with special hand grasps May be able to drive a specially equipped car
C8	Tetraplegia: loss of motor control to portions of the arms and hands **Intact:** some voluntary control of elbow extensors, wrist, finger extension, and finger flexors		Loss of sensation below the chest and in portions of hands **Intact:** sensation to face, shoulders, arms, hands, and part of chest (C8 supplies the little finger)	Phrenic nerve intact, but not intercostal muscles	No bowel or bladder function	Able to push up in the W/C Improved sitting tolerance Can grasp and release hands voluntarily Independent in most ADLs from W/C Independent in use of W/C Can use hands for catheterization and rectal stimulation for bowel movements
T1–T6	Paraplegia: loss of everything below the midchest region, including the trunk muscles **Intact:** control of function to the shoulders, upper chest, arms, and hands		Loss of sensation below the midchest area **Intact:** everything to the midchest region, including the arms and hands (T1 and T2 supply the inner aspect of the arm; T4 supplies the nipple area)	Phrenic nerve functions independently Some impairment of intercostal muscles	No bowel or bladder function	Full control of upper extremities and completely independent in W/C Full-time employment possible Independent in managing urinary drainage and inserting suppositories Able to live in a dwelling without major architectural changes
T6–T12	Paraplegia: loss of motor control below the waist **Intact:** shoulders, arms, hands, and long trunk muscles		Loss of everything below the waist **Intact:** shoulders, chest, arms, and hands (T10 supplies the umbilicus; T12 supplies the groin area)	No interference with respiratory function	No bowel or bladder control	In addition to the previously described capabilities, there is complete abdominal and upper back control. Good sitting balance (allows for greater ease of W/C operation and athletics)
L1–L3	Paraplegia: loss of most control of legs and pelvis **Intact:** shoulders, arms, hands, torso, hip rotation and flexion, and some leg flexion	L2–L4 (knee jerk)	Loss of sensation to the lower abdomen and legs **Intact:** all of the above plus some sensation to the inner and anterior thigh (L3 supplies the knee)	No interference with respiratory function	No bowel or bladder control	Independent for most activities from W/C
L3–L4	Paraplegia: loss of control of portions of lower legs, ankles, and feet **Intact:** all of the above, plus increased knee extension		Loss of sensation to portions of the lower legs, feet, and ankles **Intact:** all of the above, plus sensation to the upper legs	No interference with respiratory function	No bowel or bladder control	Voluntary control of hip extensors; weak abductors Walking with braces possible

(Continued on page 828)

Table 37-1 Functional Loss From Spinal Cord Injury (Based on Complete Lesions) (continued)

Level of Spinal Injury	Motor Function	Deep Tendon Reflexes	Sensory Function	Respiratory Function	Voluntary Bowel and Bladder Function	Rehabilitative Potential
L4 to S5	Paraplegia: incomplete Segmental motor control L4 to S1: abduction and internal rotation of hip, ankle dorsiflexion, and foot inversion L5 to S1: foot eversion L4 to S2: knee flexion S1–S2: plantar flexion (ankle jerk) S2–S5: bowel/bladder control	S1–S2 (ankle jerk)	Lumbar sensory nerves innervate the upper legs and portions of the lower legs L5: medial aspect of foot S1: lateral aspect of foot S2: posterior aspect of calf/thigh Sacral sensory nerves innervate the lower legs, feet, and perineum	No interference with respiratory function	Bowel and bladder control possibly impaired S2–S4 segments control urinary continence S3–S5 segments control bowel continence (perianal muscles)	Can walk with braces or may use W/C Can be relatively independent

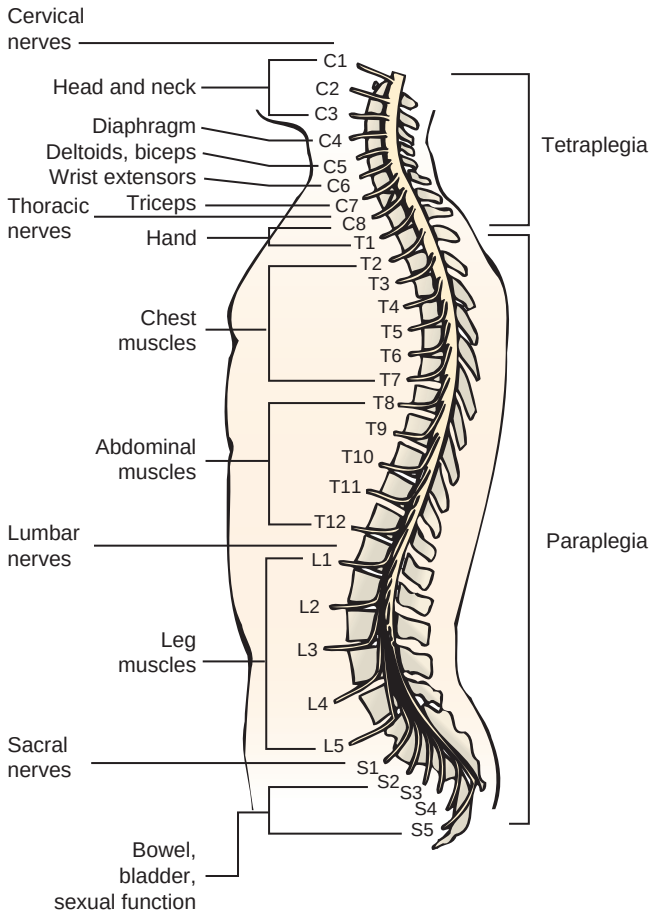

FIGURE 37-2 ▲ The level of spinal cord injury (SCI) relates to functional loss. The higher the SCI, the more motor, sensory, and autonomic functional losses are incurred. (Adapted from Hickey JV: Clinical Practice of Neurological and Neurosurgical Nursing, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 411.)

a complete cord injury follows the corresponding dermatome pathway as shown in Figure 37-3.

Cause of Injury

Spinal cord injuries are also classified according to the cause of injury. Causes of SCI include concussion or jarring injuries, compression of the neural elements by bony fragments or hemorrhage, contusion (bruising) of the spinal cord, and laceration, transection, or blockage of the blood vessels that supply the cord.

Functional Outcome

Spinal cord injuries may be classified as complete or incomplete injuries based upon functional outcome. Injuries that result in total loss of all sensory and motor function below the level of the injury are classified as complete injuries. The clinical presentation depends greatly upon the level of injury; patients with injuries at or above C4 are particularly vulnerable to complete respiratory failure resulting from loss of innervations to both the diaphragm (C2–C4) and the intercostal muscles (T1–T4). Incomplete cord injuries often cause recognizable neurological syndromes that are classified according to the area damaged (Fig. 37-4).

▲ Spinal Cord Syndromes

Central Cord Syndrome

Damage to the spinal cord in central cord syndrome is centrally located. Hyperextension of the cervical spine often is the mechanism of injury, and the damage is greatest to the

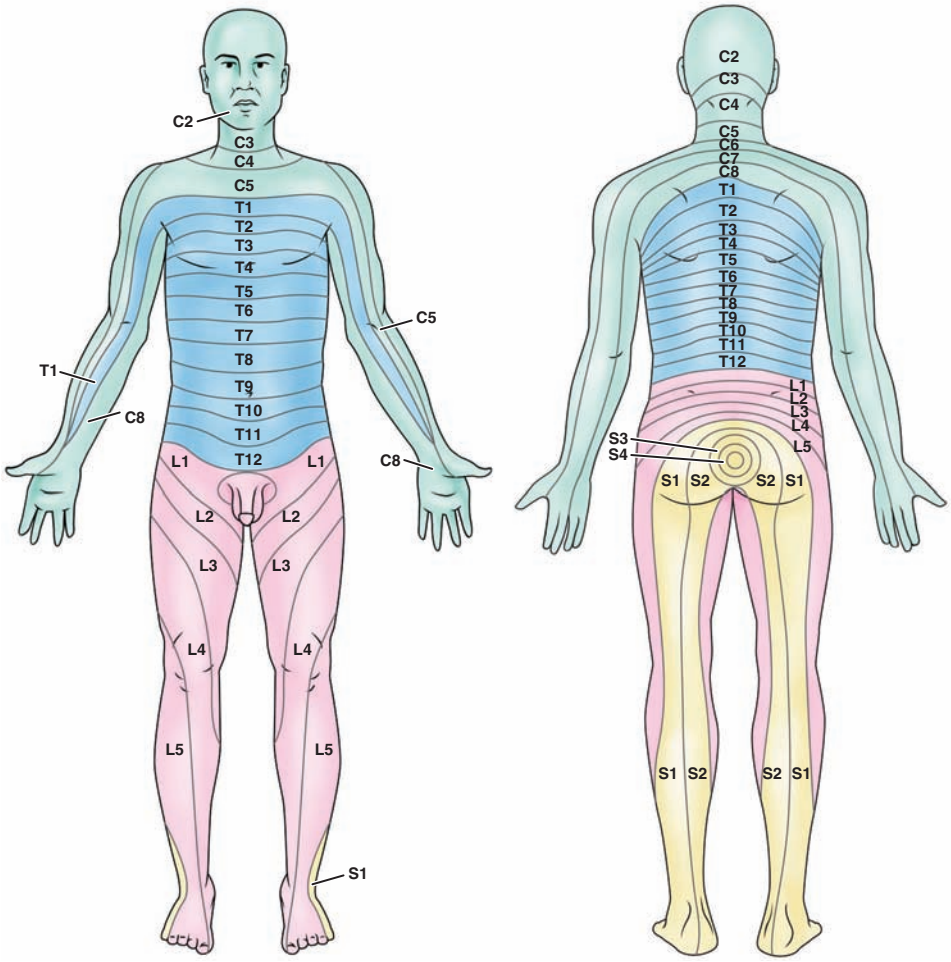

FIGURE 37-3 ▲ A person with complete SCI follows the dermatome pathways for the level of sensory loss. (From Smeltzer SC, Bare BG: Brunner & Suddarth's Textbook of Medical-Surgical Nursing, 12th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 1837.)

cervical tracts supplying the arms.[2] Clinically, the patient may present with paralyzed arms but with no deficit in the legs or bladder (see Fig. 37-4A).

Brown-Séquard Syndrome

The damage in Brown-Séquard syndrome is located on one side of the spinal cord. The clinical presentation is one in which the patient has either increased or decreased cutaneous sensation of pain, temperature, and touch on the same side of the spinal cord at the level of the lesion. Below the level of the lesion on the same side, there is complete motor paralysis. On the patient's opposite side, below the level of the lesion, there is loss of pain, temperature, and touch because the spinothalamic tracts cross soon after entering the cord. The posterior columns are interrupted ipsilaterally (on the same side), but this does not cause a major deficit because some fibers cross instead of running ipsilaterally. Clinically, the patient's limb with the best motor strength has the poorest sensation. Conversely, the limb with the best sensation has the poorest motor strength (see Fig. 37-4B).

Anterior Cord Syndrome

The area of damage in anterior cord syndrome is, as the name suggests, the anterior aspect of the spinal cord. Clinically, the patient usually has complete motor paralysis below the level of injury (corticospinal tracts) and loss of pain, temperature, and touch sensation (spinothalamic tracts), with preservation of light touch, proprioception, and position sense (see Fig. 37-4C).

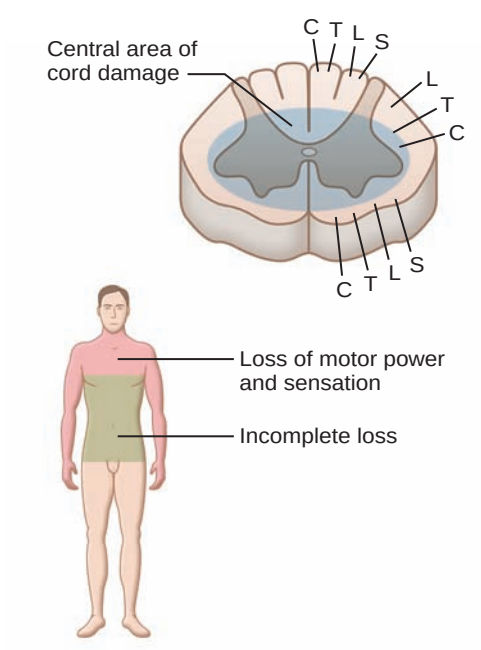
Posterior Cord Syndrome

Posterior cord syndrome is usually the result of a hyperextension injury at the cervical level and is not commonly seen. Position sense, light touch, and vibratory sense are lost below the level of the injury, while motor function and pain and temperature sensation remain intact (Fig. 37-4D).

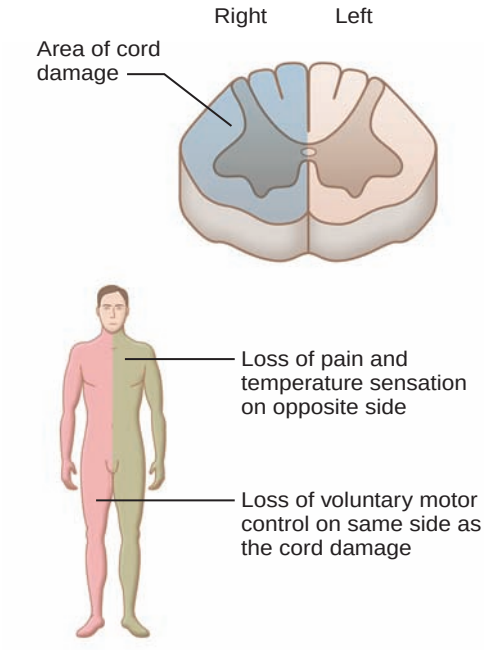
▲ Pathophysiology

Primary Injury

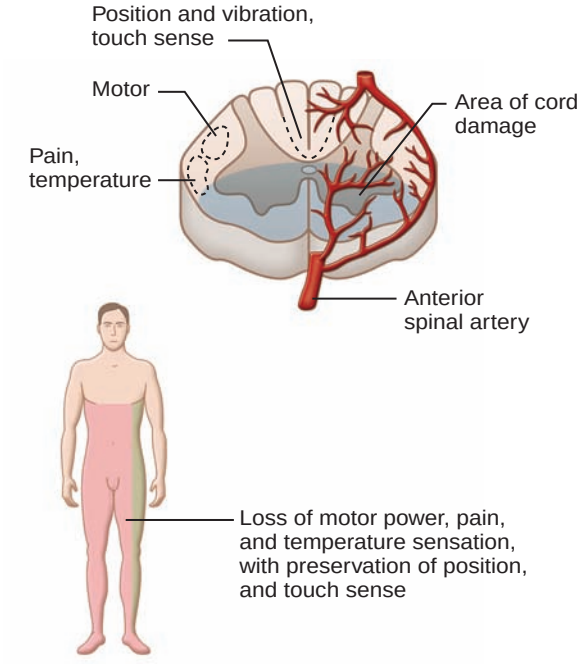
Injury to the spinal cord that occurs at impact is referred to as the primary injury and is most often associated with damage to the vertebral column. The vertebrae may be fractured, dislocated, or compressed leading to concussion, contusion, compression, laceration, or transaction of the spinal cord. The more mobile areas of the vertebral column (such as the cervical area) are most frequently involved.



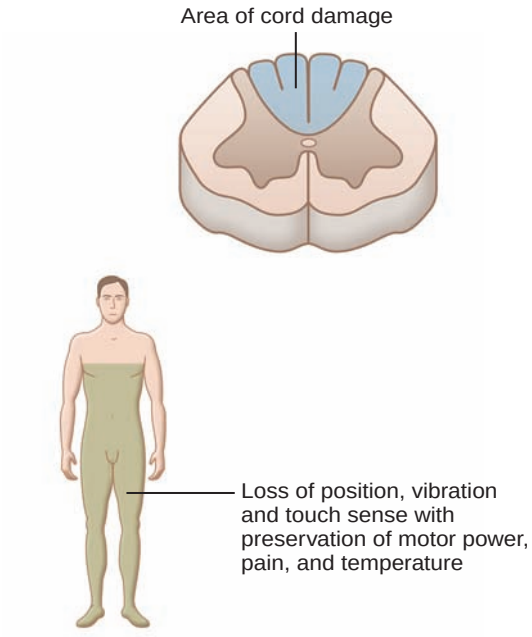
A. Central cord syndrome



B. Brown-Sèquard syndrome



C. Anterior cord syndrome



D. Posterior cord syndrome

FIGURE 37-4 ▲ Selected syndromes related to SCI. C, cervical; L, lumbar; S, sacral; T, thoracic. (Adapted from Hickey JV: Clinical Practice of Neurological and Neurosurgical Nursing, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, pp 424–425.)

Secondary Injury

Equally destructive is the secondary injury or damage to the spinal cord that continues for hours to days after the initial trauma. Complex vascular, inflammatory, and chemical processes result in additional axonal damage and further neurological deficit. Mechanisms of secondary injury include:

- Immune cells, which normally do not enter the spinal cord, engulf the area after an SCI. These immune cells respond as they normally do with inflammation in other parts of the body, resulting in release of regulatory chemicals, some of which are harmful to the spinal cord. Highly reactive oxidizing agents (free radicals) are produced, damaging the cell membrane and disrupting the sodium–potassium pump. Intracellular calcium increases secondary to disruption of sodium–potassium pump leading to release of vasoactive substances (catecholamines, histamine, and prostaglandins). This series of events ultimately leads to decreased blood flow to the spinal cord further exacerbating cord ischemia.

- Hypoperfusion of the spinal cord from microscopic hemorrhage and edema leads to cord ischemia. Ischemic areas develop at the injury site as well as one or two segments above and below the level of injury.
- The release of catecholamines and vasoactive substances (norepinephrine, serotonin, dopamine, and histamine) contributes to decreased circulation and impaired cellular perfusion of the spinal cord.
- The release of excess neurotransmitters leads to overexcitation of the nerve cells. Excitotoxicity allows high levels of calcium to enter the cells, causing further oxidative damage and damage to mitochondria. Excitotoxicity is thought to damage oligodendrocytes (the cells that produce myelin), leading to demyelinated axons that are unable to conduct impulses.

BOX 37-2 Clinical Manifestations of Spinal Shock

- Flaccid paralysis below the level of injury
- Absence of cutaneous and proprioceptive sensation
- Hypotension and bradycardia
- Absence of reflex activity below the level of injury; may cause urinary retention, bowel paralysis, and ileus
- Loss of temperature control; vasodilation and inability to shiver make it difficult for the patient to conserve heat in a cool environment, and the inability to perspire prevents normal cooling in a hot environment

▲ Autonomic Nervous System Dysfunction

Spinal Shock

Spinal shock is a condition that occurs immediately or within several hours of an SCI and is caused by the sudden cessation of impulses from the higher brain centers (Fig. 37-5). Due to a decrease in sympathetic innervation to the vascular system, massive vasodilation occurs that initiates a series of events including decreases in preload and stroke volume. The loss of sympathetic nervous system function, accompanied by unopposed parasympathetic nervous system stimulation to the heart leads to a decrease in heart rate, and also further decreases stroke volume. The vasodilation also leads to a decrease in afterload. Due to the changes in innervation, the patient develops hypotension and bradycardia. Spinal shock is a unique shock state as there is not the reflex tachycardia that usually accompanies the decrease in blood pressure. Characteristics include the loss of motor, sensory, reflex, and autonomic function below the level of the injury, with resultant flaccid paralysis (Box 37-2), and loss of bowel and bladder function also. Additionally, the body's ability to control temperature is lost, and the patient's temperature tends to equilibrate with that of the external environment (poikilothermia).

If the SCI produces an incomplete transection, the suppression of function below the level of injury is temporary, lasting a few days to weeks or months. The duration of spinal shock is variable, depending on the severity of the insult and the presence of other complications. The return of perianal reflex activity signals the end of the period of spinal shock. Reflexes associated with the area surrounding the injured cord return last. The skeletal muscles become spastic, and there is increased muscle tone and exaggerated flexor muscle movement.

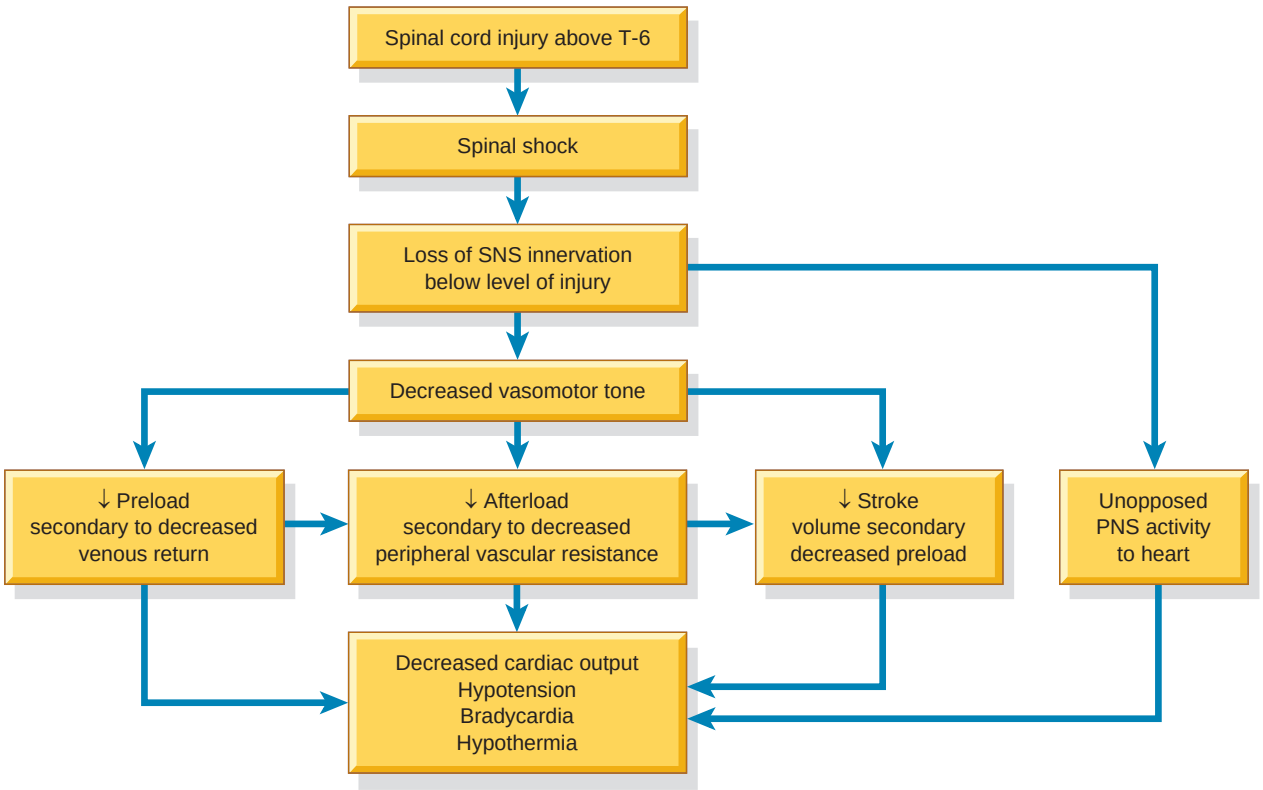


FIGURE 37-5 ▲ Mechanisms involved in spinal shock. PNS, parasympathetic nervous system; SNS, sympathetic nervous system.

Neurogenic Shock

Neurogenic shock, a form of distributive shock, is a condition seen in patients with severe cervical and upper thoracic injuries. It is caused by the loss of sympathetic input to the systemic vasculature of the heart and subsequent decreased peripheral vascular resistance. Signs and symptoms include hypotension, severe bradycardia, and loss of the ability to sweat below the level of injury. The same clinical findings pertaining to disruption of the sympathetic transmissions in spinal shock occur in neurogenic shock.

Orthostatic Hypotension

Orthostatic hypotension may occur in a patient with an SCI because the patient is unable to compensate for changes in position. The vasoconstriction message from the medulla cannot reach the blood vessels because of the cord injury.

▲ Initial Assessment and Management

Prehospital Management

An SCI should be suspected at the scene of an accident when the patient has decreased or absent movement or sensation. An unconscious patient or one with a head injury is treated as though an SCI has occurred until cord injury is ruled out. Because elapsed time from injury significantly affects prognosis, the patient with an SCI is transported as safely and rapidly as possible to a specialized trauma center or a hospital with adequate diagnostic and treatment facilities to handle such trauma. A primary survey performed at the scene of an accident includes a rapid assessment of airway, breathing, and circulation (ABCs). Airway patency is assessed, and the cervical spine is immobilized and stabilized. It is important to remember that a cervical collar increases the level of stability but does not provide complete immobilization, especially in the case of complete ligamentous disruption, in which the collar has a minimal immobilization effect on spinal stability.[3]

In-Hospital Management

After the patient has been admitted to the emergency department, assessment of the patient's airway is a priority. Facial, mandibular, or laryngeal injuries, as well as broken teeth or a swollen tongue, may be a cause of airway obstruction. Based on assessment findings, the emergency department staff promptly initiates appropriate ventilatory support, which may include elective intubation and mechanical ventilation followed by a chest radiograph. Breathing is assessed after an airway is established. Absence of breath sounds or hyperresonance on chest percussion may indicate an open or tension pneumothorax, flail chest, or hemothorax. These injuries require prompt treatment to prevent deterioration in the patient's respiratory status.

Once airway and breathing are stabilized, the circulatory status is assessed. Hypotension generally occurs secondary to volume loss from hemorrhage. Fluid resuscitation is accomplished by infusing intravenous fluids, crystalloids, or blood. Early administration of blood enhances oxygenation and may minimize the secondary ischemic injury to the spinal cord.[4] The clinical staff completes a thorough neurological and orthopedic assessment and assesses the patient for additional injuries, and then the patient is removed from the backboard to minimize the development of pressure injuries. Last, the emergency department team stabilizes the patient before transfer to the intensive care unit (ICU) or a specialized trauma center.

The administration of high-dose methylprednisolone (Solu-Medrol) in the emergency department remains controversial. The drug reduces swelling and helps minimize secondary injury by reversing the intracellular accumulation of calcium, reducing the risk for cord degeneration and ischemia. However, steroid use has been associated with severe pneumonia and sepsis. The physician determines whether to prescribe methylprednisolone based on assessment of the patient, past medical history, and diagnostic testing.[5]

Physical Examination

RESPIRATORY ASSESSMENT. The nurse assesses and records the patient's respiratory rate and arterial oxygen saturation (by pulse oximetry). Clinical manifestations other than those associated with concomitant injuries may include hypoventilation or respiratory failure. The risk for hypoventilation results from loss of innervation to both the diaphragm (C2–C4) and the intercostal muscles (T1–T4) and is a priority assessment in patients with high cervical injuries. Spinal cord edema can act like an ascending lesion and may compromise function of the diaphragm with injuries to C5 or C6. Assessment of tidal volume and vital capacity and auscultation of breath sounds are vital to determining early clinical manifestations of respiratory compromise.

The patient with an SCI may have additional respiratory compromise because of preexisting pulmonary disease or coexistent chest, laryngeal, tracheal, or esophageal injuries. Major cranial nerves and surrounding arteries and veins may also be injured. Pulmonary collapse or consolidation from retained secretions or aspiration of vomitus may directly affect alveolar ventilation. Pulmonary edema may also result from incorrect management of intravenous fluids. Because paralytic ileus and gastric dilation may increase the pressure on the diaphragm and cause further respiratory compromise, insertion of a nasogastric tube may be indicated.

CARDIOVASCULAR ASSESSMENT. The trauma team immediately places the patient on a cardiac monitor, obtains vital signs, and completes a cardiovascular assessment. Hypotension and bradycardia may be due to neurogenic shock or hemorrhagic shock. Causes of hemorrhagic shock (manifested by hypotension, tachycardia, and cold, clammy skin) include intrathoracic, intra-abdominal, or retroperitoneal injury or pelvic or long bone fractures. Examination of the patient determines whether other injuries are present. The rate of intravenous infusion is adjusted based on the patient's presenting signs and symptoms and past medical history. Insertion of an indwelling Foley catheter allows for accurate monitoring of the fluid status. Chest injury often accompanies thoracic spinal cord trauma, and it is important to examine the chest, head, and abdomen for evidence of concomitant injuries. If neurogenic shock is suspected, the patient will demonstrate bradycardia, in contrast to the tachycardia associated with hypovolemia, due to loss of autonomic innervation.

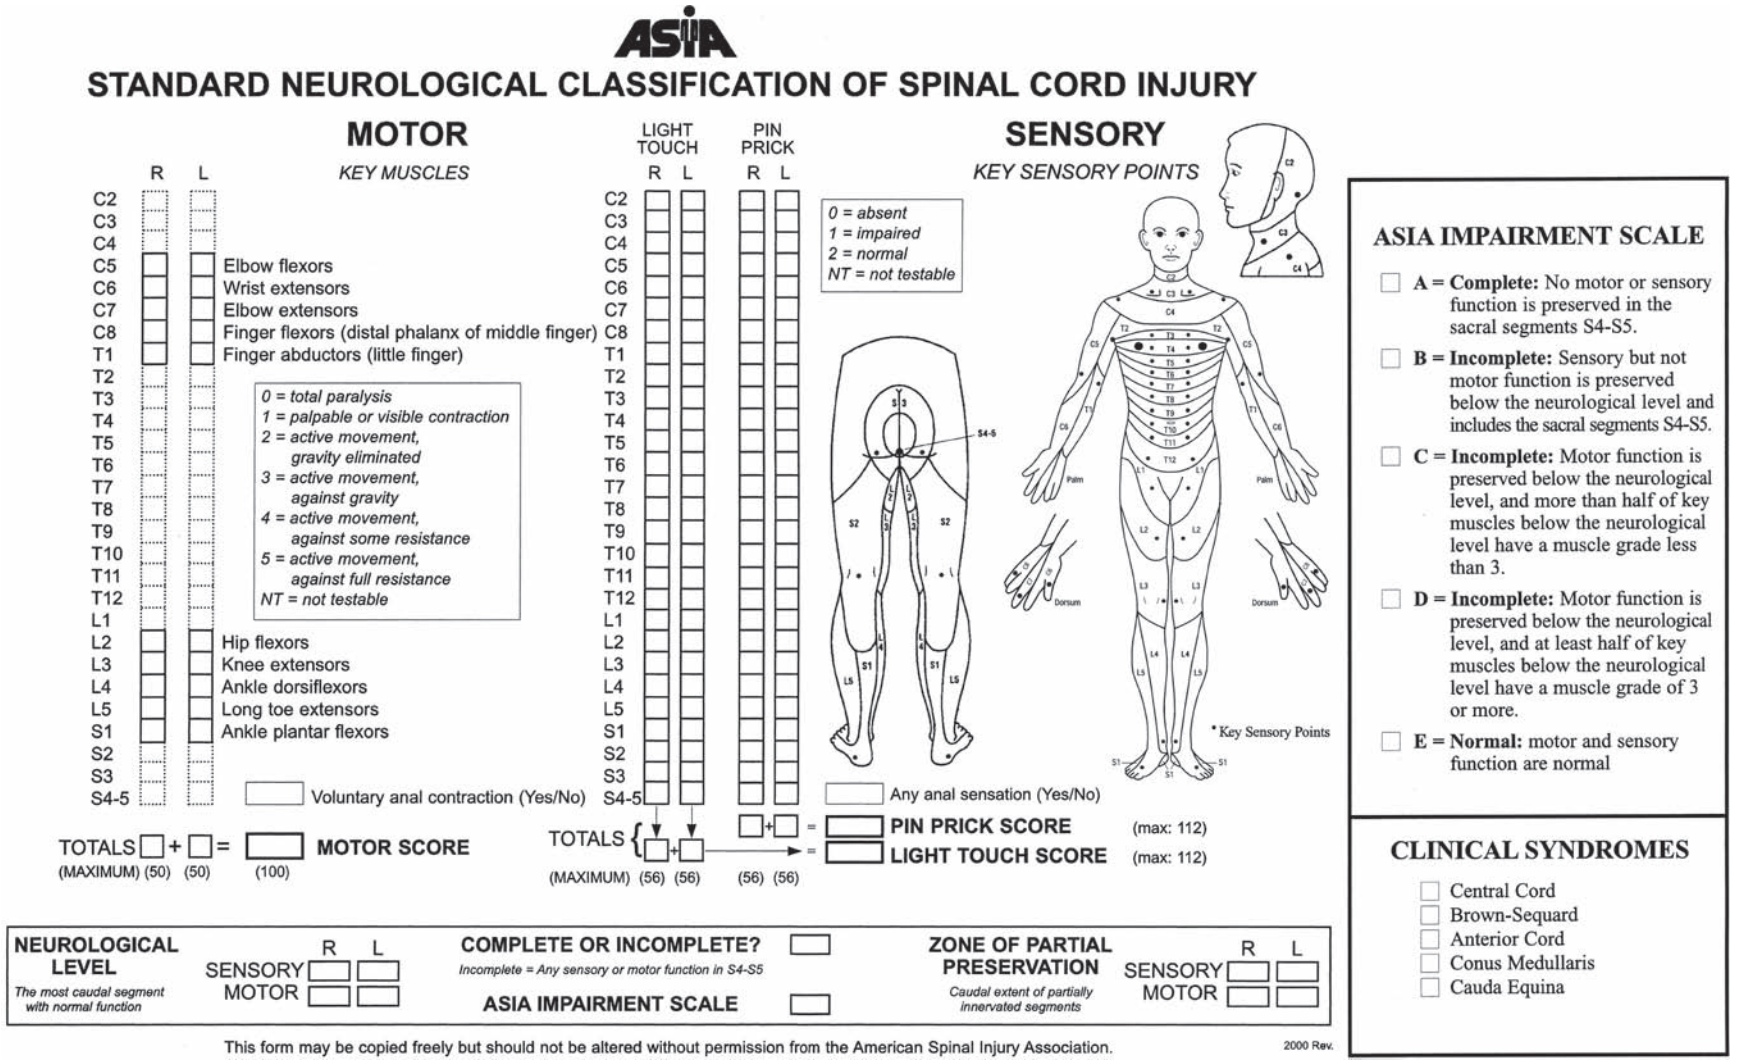

FIGURE 37-6 ▲ This Standard Neurological Classification of SCI flow sheet defines key motor and sensory impairments and clinical syndromes and also includes a functional assessment scale. Motor movement of the major muscle groups is scored on a scale of 0 to 5, with 0 indicating total paralysis and 5 indicating active movement against full resistance or normal movement. Sensation testing is done starting at the area of absent or decreased sensation and proceeding to the area of normal sensation, following the sensory distribution of the skin dermatomes. Each spinal cord segment is tested for sensation and is scored as 0 for absent, 1 for impaired, or 2 for normal. (Courtesy of the American Spinal Injury Association.)

NEUROLOGICAL ASSESSMENT. Frequent assessment of neurological status determines the extent of the SCI and allows for early recognition of changes in level of consciousness that may occur secondary to traumatic brain injury. The trauma team uses the Glasgow Coma Scale (GCS) or other standardized tools to determine patient's level of consciousness. Most SCI centers use a specialized flow sheet, such as the Standard Neurological Classification of Spinal Cord Injury flow sheet, to assess and document the patient's level of functioning (Fig. 37-6). Cranial nerve testing is necessary, particularly if the cause of the injury was penetrating trauma or involved a head injury. For a further discussion of the care of patients with a head injury, see Chapter 36.

During the early assessment of the patient, a digital rectal examination is important to determine whether the injury is incomplete or complete. The lesion is incomplete if the patient can feel the palpating finger or can contract the perianal muscles around the finger voluntarily. Sensation may be present in the absence of voluntary motor activity. Sensation seldom is absent when voluntary perianal muscle contraction is present. In either case, the prognosis for further motor and sensory return is good. Preservation of sacral function might be the only finding that indicates an incomplete lesion, and significant neurological recovery may occur in the patient with an incomplete cord injury. Rectal tone by itself, without the presence of voluntary perianal muscle contraction or rectal sensation, is not evidence of an incomplete cord injury.

BOWEL AND BLADDER ASSESSMENT. Incontinence of urine and possibly feces may have occurred at the scene of the accident. To prevent the bladder from becoming distended secondary to an atonic bladder, insertion of an indwelling urinary catheter is indicated. There may be an imbalance between parasympathetic and sympathetic innervation to the bowel and therefore a loss of voluntary control.

DIAGNOSTIC STUDIES. Once the patient is stabilized, definitive diagnostic tests may be completed safely. The diagnostic workup consists of radiographs of the spine, chest, and other structures as clinically indicated. A computed tomography (CT) scan provides additional information concerning bony structures and fractures. Soft tissue injury is more easily diagnosed with magnetic resonance imaging (MRI). Typical laboratory tests ordered include a complete blood count, electrolytes, glucose, blood urea nitrogen, creatinine, blood type and crossmatch, arterial blood gases, and coagulation studies.

Although rare, the incidence of missed spinal fractures is usually less than 2% with CT.[6] Consequences of a missed injury include chronic pain, deformity, and a delayed injury to the spinal cord or adjacent nerve root. The factors most associated with a missed injury are high-energy trauma, older age, closed head injury, and insufficient imaging. Ideally, flexion–extension views or an MRI is necessary in patients with altered mental status and in those who complain of pain, even when plain radiographs and CT are negative.

When the patient is in the critical care or acute care environment, a physician often orders a somatosensory evoked potential test (see Chapter 33). This test measures the ability of the spinal cord to transmit impulses along the neural pathways to the higher centers in the brain and is used in determining treatment. In this test, a peripheral nerve in the arm or leg below the level of injury is stimulated, and the neurological response (evoked potential) is recorded. If the injury is complete, there is no response. In incomplete injuries, varying responses occur.

▲ Ongoing Assessment and Management

Box 37-3 presents examples of nursing diagnoses and collaborative problems for the patient with SCI. Based on the assessment data, the interdisciplinary team develops an individual treatment plan (Box 37-4), and management is based on the type and severity of injury. Collaboration with all health care disciplines is necessary to enable the patient to achieve the fullest potential after injury. The initial goals are to realign or stabilize the spine to prevent further neurological deterioration, to prevent complications, and to initiate prompt interventions to treat any complications that do occur.

Realignment and Stabilization of the Spine

The trauma team carefully evaluates the patient to determine the most effective treatment based on the type and cause of injury. The surgeon must balance the risks of surgery against the possible benefits associated with eventual patient outcome.[7]

Medical Management

Regardless of the treatment approach, medical management of the patient is an important cornerstone of initial treatment.[8] Closed reduction of a cervical fracture often involves skeletal traction. Cervical traction is used when the fracture is unstable or if subluxation has occurred. Gardner-Wells, Vinke, or Crutchfield tongs are common forms of cervical traction; however, because of the complications that accompany prolonged immobility, long-term traction with tongs

BOX 37-3 EXAMPLES OF NURSING DIAGNOSES

For the Patient With Spinal Cord Injury

- Ineffective Airway Clearance
- Impaired Gas Exchange
- Ineffective Breathing Pattern
- Decreased Cardiac Output
- Risk for Ineffective Peripheral Tissue Perfusion
- Risk for Deficient Fluid Volume
- Acute Pain
- Imbalanced Nutrition: Less Than Body Requirements
- Risk for Impaired Skin Integrity
- Risk for Autonomic Dysreflexia
- Ineffective Thermoregulation
- Impaired Physical Mobility
- Impaired Urinary Elimination
- Bowel Incontinence
- Anxiety
- Disturbed Body Image
- Ineffective Coping
- Compromised Family Coping
- Risk for Infection
- Bathing Self-Care Deficit
- Toileting Self-Care Deficit
- Feeding Self-Care Deficit
- Sexual Dysfunction, Ineffective Sexuality Pattern

BOX 37–4 COLLABORATIVE CARE GUIDE for the Patient With Spinal Cord Injury

Outcomes	Interventions
Oxygenation/Ventilation	
Arterial blood gas values will be within normal limits. No evidence of atelectasis is demonstrated.	• Assess need for mechanical ventilation. • Provide routine pulmonary toilet, including: Airway suctioning Chest percussion, couth and deep breathing Incentive spirometer, nebulizer treatment • Turn frequently. • Mobilize out of bed to chair. • Apply abdominal binder when out of bed. • Consult pulmonologist as needed. • Obtain pulmonary function tests.
Circulation/Perfusion	
There will be no evidence of neurogenic (spinal) shock (T10 injuries and higher). Blood pressure (BP) will be adequate to maintain vital organ function. There will be no development of deep venous thrombosis (DVT) or pulmonary embolism.	• Monitor for bradycardia, vasodilation, and hypotension. • Assess for dysrhythmias. • Prepare to administer intravascular volume, vasopressors, and positive chronotropic agents. • Begin DVT prophylaxis on admission (eg, external compression device, low-dose heparin). • Measure calf and thigh circumference daily and at same location; report increase. • Apply elastic bandage/wraps to lower extremities before mobilizing out of bed.
There will be no evidence of orthostatic hypotension.	• Monitor for orthostatic hypotension when raising head of bed and getting out of bed. • Consult cardiology department as needed.
Neurological	
There will be no evidence of deterioration in neurological status.	• Perform neurological check and spinal cord function checks every 2–4 h. • Monitor for deterioration in neurological status and report to the physician or nurse practitioner. • Monitor for and prevent complications. • Provide patient and family education concerning injury, effects of injury, and rehabilitation.
Fluids/Electrolytes	
Serum electrolytes will be within normal limits. Fluid balance will be maintained as evidenced by stable weight, absence of edema, normal skin turgor.	• Monitor laboratory studies as indicated by patient condition. • Assess for dehydration. • Administer mineral/electrolyte replacement as ordered. • Monitor gastrointestinal and insensible fluid loss. • Make accurate daily fluid intake and output measurements. • Weigh weekly. • Monitor results of laboratory studies, particularly albumin and electrolyte levels.
Mobility/Safety	
Joint range of motion will be maintained and contractures prevented. Skin integrity will be maintained under or around stabilization devices (eg, cervical collar, Yale brace, halo vest).	• Position in correct alignment. • Consult with wound care specialist to determine correct type of bed. • Begin range-of-motion exercises early after admission. • Use high-top tennis shoes, moon boots, extremity splints routinely. • Consult with physical and occupational therapists. • Maintain splint, brace, and adaptive device schedule; check for pressure ulcers every 4 h or more often if indicated. • Monitor skin or pin sites of stabilization devices. • Use meticulous skin care/pin care under or around stabilization devices.

(Continued on page 836)

BOX 37–4 *COLLABORATIVE CARE GUIDE for the Patient With Spinal Cord Injury (continued)*

Outcomes	Interventions
Skin Integrity	
Skin will remain intact.	• Consult with wound care specialist to determine correct type of bed. • Reposition at least every 2 h while patient is in bed. • Position patient to prevent pressure on bony prominences. • Use upright, straight-backed chair when patient is out of bed (not a reclining chair). Use felt pad on chair seat. • Reposition/shift weight every hour when patient is sitting upright. • Use Braden scale to monitor risk for skin breakdown.
Nutrition	
Protein, carbohydrate, fat, and calorie intake will meet minimal daily requirements.	• Consult dietitian. • Encourage fluids, high-fiber diet. • Monitor fluid intake and output, calorie count. • Administer parenteral and enteral nutrition as appropriate. • Assist with feeding/feed as needed.
Comfort/Pain	
Pain will be <"4" on visual analog scale.	• Assess and differentiate pain from anxiety or stress response. • Administer appropriate analgesic or sedative to relieve pain and monitor patient response. • Use nonpharmacological pain relief techniques (eg, distraction, music, relaxation therapies).
Psychosocial	
Patient will adapt to loss of motor and sensory function.	• Provide emotional support by: Encouraging ventilation of sadness, fears, and the like. Arranging for social services, clergy, neuropsychologist, or support groups to see patient.
Therapeutic strategies will be used to cope with anxiety and chronic pain syndrome.	• Provide information and counseling regarding: Personal resources Nonpharmacological pain management techniques Stress management strategies Appropriate use of prescribed pharmacological agents
Integration will be made into prior social role.	• Provide patient/family counseling regarding: Stages of grief Sexual function and management techniques Social services and community resources
Teaching/Discharge Planning	
Patient will adapt to loss of bowel/bladder control. Patient will participate in bowel and bladder program.	• Teach patient/family: Bowel program and training Dietary habits to maintain bowel function Bladder training/intermittent catheterization Prevention of and signs/symptoms of autonomic dysreflexia
Complications of immobility will be prevented.	• Teach patient/family: Positioning to prevent skin breakdown Physical therapy exercises Pulmonary toilet
Patient will be placed in appropriate postacute setting.	• Consult rehabilitation/discharge planner/social services early after admission to initiate placement arrangements.

is seldom used, especially since the advent of the halo vest (Fig. 37-7). Boxes 37-5 and 37-6 present collaborative care guides for the patient in cervical traction and for the patient in a halo vest, respectively.

A halo device, Miami J, or Aspen collar is used for cervical immobilization. Immobilization devices for cervical and thoracic injuries may involve the use of a metal and plastic (Minerva) brace. Thoracolumbar–sacral orthosis may be accomplished using a fiberglass and plastic canvas corset or Jewett brace. Each of these devices is fitted to the patient to provide support and stabilization of the spine. Surgical stabilization may also be necessary. Bed rest is the recommended treatment for sacral and coccygeal injuries.

Surgical Management

The goal of surgical management is to stabilize and support the spine. Emergency surgery may be necessary to remove bone fragments, a hematoma, or a penetrating object, such as a bullet. If the patient's motor status continues to decline, a laminectomy (removal of a portion of the vertebral column) may be performed to allow for swelling of the spinal cord secondary to edema. Rod placement, laminectomy and fusion,

FIGURE 37-7 ▲ A lightweight fleece-lined vest with a halo may be used to stabilize the cervical vertebrae. Note that the vest comes in various sizes and does not need to be removed for magnetic resonance imaging studies. (Courtesy of Bremer Medical, Inc., Dawin Road, Jacksonville, FL).

BOX 37–5 *COLLABORATIVE CARE GUIDE for the Patient in Cervical Traction*

Outcomes	Interventions
Equipment Management	
The orthopedic frame will remain intact. Tongs will not slip. Traction weights will hang freely. There will not be any extension of cord injury secondary to slippage of the traction apparatus.	• Check the orthopedic frame and traction daily to ensure that nuts and bolts are secure. • Check tongs daily to be sure that they are secure. • Be sure that traction weights are hanging freely and not resting on the floor or frame. (Releasing the traction is dangerous because cord injury could be extended.)
Oxygenation/Ventilation	
Airway patency will be maintained. The patient will not aspirate. The patient will not develop a respiratory infection.	• Have suction available to maintain a patent airway. • Provide respiratory care. • Provide for deep breathing, assistive coughing, and incentive spirometer exercises every 1–2 h
Circulation/Perfusion	
Air boots and thigh-high elastic hose (antiembolism stockings) will be worn at all times. Vital signs will be maintained within normal limits. The patient will be observed for DVT and pulmonary emboli.	• Maintain antiembolism stockings and sequential compression boots. • If the patient is receiving heparin, observe for signs and symptoms of bleeding. • Monitor for DVT and pulmonary emboli. (May be receiving minidoses of subcutaneous heparin every 12 h, if not contraindicated.)
Mobility/Safety	
The patient will be free from pain. Contractures will not develop. Strategies will be used to manage spasticity if it occurs.	• Provide comfort measures. • Provide range-of-motion exercises four times per day. • Position the patient in proper body alignment. • Reposition the patient frequently. • Stretch the patient's heel cord with exercises.

(Continued on page 838)

BOX 37-5 COLLABORATIVE CARE GUIDE for the Patient in Cervical Traction (continued)

Outcomes	Interventions
Skin Integrity	
The pin site will remain free of infection. Skin integrity will be maintained. The vertebral column will be maintained in a neutral position and in proper alignment.	• Inspect tong sites, and clean and dress daily as ordered (may be referred to as "pin care"). • Turn the patient every 2 h from side to back to other side using a triple log-roll technique as described below if a patient is on a regular hospital bed: Nurse #1 stands behind the head of the bed and places hands firmly on the patient's head and neck, maintaining the head and neck in a neutral position; the head and neck are turned as a unit. Nurse #2 stands at the patient's side and moves the patient's shoulders. Nurse #3 stands at the patient's side and moves the patient's hips and legs. Plan ahead, identifying desired position and pillow placement *before* moving the patient. When all three nurses are ready, turn the patient as a log on the count of three. Leave the patient positioned in the middle of the bed (if not, he or she will be uncomfortable); use pillows to support the patient's body in alignment. Nurse #1 should hold the head and neck until the patient is supported adequately (if traction slips, manual traction can be supplied by Nurse #1).
Nutrition	
A diet high in protein and carbohydrates, which includes a fluid intake of up to 3,000 mL, will be provided. Aspiration will be prevented.	• Encourage an adequate diet. • Ask the dietitian to see the patient. • Provide for adequate fluid intake up to 3,000 mL daily. • Encourage the patient to take small portions of food into the mouth and chew well to prevent aspiration. • Keep suction equipment handy.
Elimination	
Pattern of bowel evacuation every 1 to 2 days will be established. Intake will be 3,000 mL unless contraindicated. Postvoid residuals will be <100 mL. Strict aseptic technique will be used for catheter protocols.	• Institute a bowel retraining program. • Auscultate the abdomen for bowel sounds. • Record the frequency and consistency of stool. • Monitor intake and output. • Force fluids. • If an intermittent catheterization protocol is initiated, use aseptic technique. • If the patient is voiding on his or her own, monitor postvoid residuals.
Psychosocial	
The patient's mental health will be supported. Social interaction and diversion will be provided based on the patient's ability to participate. A positive body image will be supported. Necessary information will be provided. Sexual function and SCI are discussed with the patient when he or she is ready.	• Provide for social interaction and diversion based on the patient's functional level. • Reinforce a positive self-image. • Allow the patient to participate in decision making as much as possible. • Provide for patient teaching. • Provide information about sexual function.

BOX 37-6 COLLABORATIVE CARE GUIDE for the Patient in a Halo Vest

Outcomes	Interventions
Equipment Management	
The patient will be comfortable and without signs of skin irritation. Proper body alignment will be maintained.	• Check the pins on the halo ring to be sure they are secure and tight. • Check the edges of the fiberglass vest for comfort and fit by inserting the small finger or index finger between the vest and the patient's skin. If the vest is too tight, skin breakdown, edema, and possible nerve injury can occur. • The vest should be supported while the patient is in bed. • Place a rubber cork over the tips of the halo device to diminish magnification of sound if the pin is bumped.
Oxygenation/Ventilation	
The patient will not develop a respiratory infection.	• Provide for deep-breathing exercises at least four times daily.
Circulation/Perfusion	
Risk for thrombus or embolus formation will be decreased.	• Apply thigh-high elastic hose to the legs to improve blood return to the heart. • Observe the legs for development of thrombophlebitis or DVT.
Mobility/Safety	
The patient will maintain muscle tone. The patient will ambulate in a safe manner to the best of his or her ability.	• If the patient's neurological function is intact, he or she will be able to ambulate in the halo vest. • Start to assess the patient's tolerance of the upright position by having him or her sit on the edge of the bed ("dangle"). Check vital signs. (Orthostatic hypotension may be a problem to overcome in the early stages.) • Teach the patient to compensate for lost head and neck movement by making increased use of eye movement to scan the area. • Accompany patients when ambulating because they are more accident prone owing to a displaced center of gravity, a tendency for loss of balance, and decreased peripheral vision. • Consider the patient's use of a walker for ambulation as a means of support and greater safety.
Skin Integrity	
The patient will maintain skin integrity. The patient will maintain proper body alignment without injuries. Early signs of skin irritation or breakdown will be detected.	• Inspect and cleanse the pin site once or twice daily, as prescribed, to prevent infection. • Turn the patient in bed every 2 h by means of the triple log-roll technique to prevent the development of hypostatic pneumonia, atelectasis, and skin breakdown. • Provide sponge pads to prevent pressure on prominent body areas, such as the forehead and shoulder, while the patient is in bed. • Inspect under the vest, and keep all areas of skin dry.
Elimination	
Pattern of bowel elimination every 1 to 2 days will be established. Intake will be 3,000 mL unless contraindicated; postvoid residuals will be <100 mL.	• Institute a bowel retraining program. • Monitor intake and output.
Comfort/Pain Control	
The patient will be comfortable, with pain controlled.	• Administer mild analgesics to control headache and discomfort, which are common, around the pin site. • Provide a soft diet because many patients have jaw pain if they attempt to chew.
Psychosocial	
The patient's emotional well-being will be supported.	• Help the patient adjust to the distorted body image that the halo device can create. • Encourage self-care as much as possible.
Teaching/Discharge Planning	
The patient will be provided the necessary information to ensure competent home care. The patient will use equipment in a safe manner.	• If the patient is to go home with the halo vest, begin a patient and family teaching plan using a booklet or other printed material. Review any written material prepared by the manufacturer for accuracy before giving it to the patient or family.

EVIDENCE-BASED PRACTICE HIGHLIGHT 37-1

Timing Decompressive Surgery for Acute Spinal Cord Injury

A systematic review of literature with a prospective survey was conducted to seek expert opinion regarding the timing of decompressive surgery for patients with acute spinal cord injury (SCI). The lack of consistent practices related to timing of this surgery in this patient population results in wide variability in clinical practice. The methods of this study included a systematic review of the literature related to the optimal timing of decompressive surgery, and the development of a 20-question survey. Data were collected from neurosurgical and orthopedic spine surgeons across the world, with a total of 971 responses. More than 80% of the respondents reported a preference for decompression within 24 hours. Additionally, in complete cervical spinal cord injuries, 46.2% of the surgeons would decompress within 6 hours, and 72.9% would decompress within 6 hours in patients with incomplete injury. Findings of this study found that the majority of spine surgeons recommend decompression of the spine within 24 hours of acute injury, and early surgical decompression should be considered in patients with most spinal cord injuries.

From Fehlings MG, Rabin D, Sears W, et al: Current practice in the timing of surgical intervention in spinal cord injury. Spine 35(21Suppl):A166–A173, 2010.

and anterior fusion are types of surgical stabilization. Bone for fusion usually comes from the iliac crest, tibia, or ribs, or may be retrieved through a tissue bank. See Evidence-Based Practice Highlight 37-1 for information about the timing of decompression surgery.

Postoperatively, the nurse monitors the patient's neurological status at least every hour for the first 24 hours and then every 4 hours. Any indication of deterioration in neurological status is reported immediately to the physician. A major complication of surgery is postoperative infection. This is especially true in older patients and in those with preexisting comorbidities or with open wounds, injuries to the thoracolumbar spine, or complete injuries.[9] The causative organisms are typically Gram-positive organisms, although other concurrent organisms may include *Enterococcus faecalis*, *Enterobacter cloacae*, *Pseudomonas* species, *Klebsiella* species, and *Escherichia coli*.

Prevention of Respiratory Problems

Patients with an SCI, especially injuries above T6, are at risk for respiratory problems, such as ineffective airway clearance, ineffective breathing patterns, and impaired gas exchange. The degree of respiratory compromise is determined primarily by the level of the injury, although not entirely. For example, a 28-year-old patient with C5 tetraplegia with no lung disease may have better ventilation than a 65-year-old patient with C8 tetraplegia with a long history of smoking and chronic obstructive pulmonary disease.

Normally, ventilation is accomplished through a complex interaction between muscles of the chest, the abdominal wall, and the diaphragm. An SCI above T6 results in paralysis of the inspiratory and expiratory muscles. Dysfunction of the intercostal and accessory muscles decreases ventilation and predisposes the patient to atelectasis. Dysfunction of the abdominal muscles and expiratory intercostal muscles diminishes the patient's ability to generate a cough to clear secretions. The intercostal muscles also normally provide support to the lateral chest wall. When the intercostals are impaired, this part of the chest wall collapses during inspiration as the abdomen expands. This breathing pattern is easily discernible and results in ineffective ventilation.

Respiratory complications are the leading cause of death in the acute and chronic phases of SCI, especially among tetraplegic patients. The nurse and respiratory therapist auscultate breath sounds and measure respiratory parameters (eg, tidal volume and vital capacity) frequently. Respiratory failure is anticipated if the patient's vital capacity is less than 15 to 20 mL/kg and the respiratory rate is greater than 30 breaths/min. Other interventions include measuring oxygenation via pulse oximetry. If the value is less than 85 mm Hg or if the arterial carbon dioxide tension ($PaCO_2$) is above 45 mm Hg, intubation may be required. Other interventions include providing oxygen per nasal cannula and ensuring that the patient is well hydrated.

Kinetic therapy involves placing the patient on a special bed that rotates a minimum of 40 degrees on a continuous basis. This stabilizes the spine and the continuous slow rotation prevents pulmonary complications.

The nurse encourages the patient to take deep breaths and to use an incentive spirometer every 2 hours, or more frequently if tolerated. For example, if the patient has a TV or radio in the room, every time there is a commercial, the patient can take four to five deep breaths or use the incentive spirometer independently or with the assistance of the nurse or a family member. Assisting the patient with the quad coughing technique may help clear airways more effectively despite weakness or loss of the respiratory muscles that produce the automatic cough reflex. The quad coughing technique involves compressing the sides of the patient's chest (if patient is on his or her side or abdomen) or the diaphragm (if the patient is supine) during exhalation. This technique often is most helpful after postural drainage or vibration of the chest.

Suctioning may be necessary if the patient's airway cannot be cleared effectively with other techniques. Nurses should remember that suctioning (or nasogastric tube insertion) might trigger an abnormal vasovagal response, resulting in bradycardia.

When turning a patient to the prone position on a Stryker frame, the nurse needs to remain at the bedside for the first few turns to evaluate the patient's respiratory tolerance of the turn. Patients with high-level tetraplegia can experience respiratory arrest in the prone position because movement of the diaphragm is compromised. When the patient is in the prone position, bradycardia is also common.

Restoration of Hemodynamic Stability

The management of arterial oxygenation and blood pressure (BP) support are critical in optimizing the potential for neurological recovery. Continuous hemodynamic monitoring is essential to measure cardiac output and systemic perfusion. Insertion of a pulmonary artery catheter and central venous line may be necessary if this was not done in the emergency department. It is important to maintain mean arterial pressure between 85 and 90 mm Hg for the first week after injury. The systolic BP should be above 90 mm Hg. The patient is at risk for cardiovascular compromise because of disruption in the autonomic nervous system. Bradycardia, hypotension, and dysrhythmias may occur. Hypotension and tachycardia may indicate hemorrhage from intra-abdominal bleeding or bleeding around fracture sites. Sequential compression devices, antiembolism stockings, or an abdominal binder may be used to promote venous return.

Left ventricular dysfunction may occur secondary to release of β-endorphins. Cardiac enzymes should be obtained if there are electrocardiographic changes. Dysrhythmias and heart block may occur. It is necessary to address adequate tissue perfusion to the spinal cord and other vital organs, such as the kidneys. Careful intravenous fluid replacement provides hydration without fluid overload. Vasopressors may not be necessary to maintain BP during spinal shock, but when the BP is not high enough to sustain vital organ perfusion, usually low-dose dopamine is useful. Bradycardia also may not need treatment, but if necessary, atropine may be used to speed up the heart rate. A transcutaneous or transvenous pacemaker may be essential if the patient remains bradycardic despite atropine.

Neurological Management

While in the ICU, the patient requires neurological assessment every hour until stable, then every 4 hours. The patient's motor and sensory states warrant particular attention. If there is any deterioration in the patient's condition, the frequency of assessment increases, and the nurse notifies the physician or nurse practitioner.

Depending on the patient's motor function, an adapted nurse call system may be necessary. Useful devices include low-pressure, voice-controlled, and sip-and-puff straw-like call systems. Other communication systems can be developed in conjunction with the speech language pathologist for the patient on a mechanical ventilator.

Pain Management

It is not unusual for the patient to complain of pain, frequently severe pain. The source of the pain may be neuropathic, musculoskeletal, central, or visceral. Abnormal sensation may occur at the level of the lesion in injuries causing diverse nerve root damage, such as occurs with gunshot or knife wounds. Pain resulting from either the SCI, surgery, or both is treated aggressively following institutional protocol and within the pain management standards of the institution.

Medication Administration

Medications used in treating the patient with SCI are listed in Table 37-2. Nurses administering medications to patients with spinal cord injuries must take into account several special considerations. Subcutaneous and intramuscular injections are not absorbed well because of the lack of muscle tone. Sterile abscesses may result, causing autonomic dysreflexia or an increase in spasms. Injection sites are the deltoid area, the anterior thigh, and the abdominal area. Rotation of injection sites is necessary, and the volume injected should not exceed 1 mL at any one site.

Nurses often start peripheral intravenous lines, but the intravenous site of choice is the subclavian vein. In this area of high blood flow, there is less chance of thrombosis secondary to vasomotor paralysis, especially during spinal shock. For this reason, the veins of the lower extremities should never be used for intravenous administration.

Thermoregulation

Ineffective thermoregulation is a common problem seen in patients with spinal cord injuries above the thoracolumbar area. Interruption of the sympathetic nervous system prevents the thalamic thermoregulatory mechanisms. As a result, the patient fails to sweat to get rid of body heat, and there is an absence of vasoconstriction, resulting in an inability to shiver to increase body heat. The degree of thermal control and dysfunction is directly proportional to the extent of body area with loss of thermal regulation. Hence, a tetraplegic patient has more difficulty with thermoregulation than a paraplegic patient.

Hypothermia is usually managed by using warmed blankets. The room temperature is adjusted to maintain patient comfort. Electric heating blankets or hot water bottles may present a danger for body parts with no sensation. An attempt is made to stabilize the patient's temperature above 96.5°F (35.8°C). Ideally, the patient is placed in a private room so that the room temperature does not adversely affect the other patient in the room. Over the long term, thermal control can be facilitated by use of clothing appropriate for the weather conditions.

Nutrition

The possibility of inadequate nutrition is of significant concern during the acute phase of injury and must not go unnoticed while the focus is on hemodynamic stability. Negative nitrogen balance contributes to skin breakdown, poor wound healing, and lack of energy for rehabilitative efforts. Along with other required blood work, a serum albumin test is necessary. A value less than 3.5 g/dL and/or total lymphocyte count less than 1,500 to 2,000/mm^2 is indicative of clinical malnutrition. A dietary consult should be obtained as early as possible. Caloric requirements are calculated to ensure adequate, but not excessive, nutritional support. If the patient must remain nothing by mouth (NPO) for more than a few days, total parenteral nutrition should be initiated.

Patients with spinal cord injuries often have increased energy needs secondary to metabolic stress response. This

Table 37-2 Drugs Used in the Treatment of the Patient With a Spinal Cord Injury

Drug	Description	Administration
Drugs to Minimize Injury		
Methylprednisolone	Synthetic adrenal corticosteroid used as an anti-inflammatory agent	Loading dose: 30 mg/kg IV over 15 min Pause for 45 min; infuse normal saline solution or other IV fluid Maintenance dose: 5.4 mg/kg/h IV for 23 h if loading dose given within 3 h of injury Loading dose must be given within 8 h of injury. Maintenance dose must begin within 1 h of loading dose.
Drugs for Cardiovascular Stabilization		
Atropine	Anticholinergic used to treat symptomatic bradycardia	Dosage: 0.4–1.0 mg IV slowly; maximum dose 2 mg
Dobutamine (Dobutrex)	β-Adrenergic agent that enhances myocardial contractility, stroke volume, and cardiac output; improves perfusion to the spinal cord	Dosage 2.5–10 mcg/kg/min up to maximum dosage of 30 mcg/kg/min; usually given for a total of 72 h if needed
Dopamine (Intropin)	α- and β-Adrenergic agent used to treat hypotension related to neurogenic shock	Dosage: 3–5 mcg/kg/min; increase gradually at 10- to 30-min intervals up to 20–50 mcg/kg/min until optimum blood pressure (BP) achieved Start the older adult on lower doses; use with caution if the patient is on a monoamine oxidase inhibitor
Phenylephrine (Neosynephrine)	α-Adrenergic agent used to treat hypotension related to neurogenic shock	Dosage: 0.1–0.5 mg; may administer every 10–15 min as needed. Do not exceed initial dose.
Drugs for Paralytic Ileus and Stress Ulcers		
Proton pump inhibitors (lansoprazole, omeprazole, pantoprazole)	Suppress gastric acid secretion; used to prevent or treat gastric ulcers	Dosage: dependent on medication prescribed
Histamine blockers (cimetidine, famotidine, nizantine, ranitidine hydrochloride)	Inhibit histamine action at H_2 receptor sites; used to treat and prevent ulcers and gastric reflux	Dosage: dependent on medication prescribed
Drugs for Autonomic Hyperreflexia		
Nitroglycerin	Organic nitrate used if systolic BP rises above 140 mm Hg	Dosage: 1 inch of nitroglycerin paste placed above the level of injury
Nifedipine (Procardia)	Calcium channel blocker used to decrease systemic vascular resistance and BP	Dosage: 10–20 mg orally every 20–30 min if necessary
Hydralazine, trimethaphan, diazoxide	Antihypertensive agents	Dosage: dependent on medication prescribed Trimethaphan: dilute per hospital protocol (usually 500 mg in 500 mL D_5W); usual dose 0.5–1 mg/min Hydralazine: 25 mg orally four times daily or 10–20 mg IV every 4–6 h Diazoxide: 1–3 mg/kg, up to 150 mg, IV; repeat at 5- to 15-min intervals if needed
Drugs for Skeletal Muscle Spasm		
Dantrolene (Dantrium)	Skeletal muscle relaxant used to treat spasticity	Dosage: initial dose 25 mg/d; may increase to 25–100 mg twice or thrice a day. Max dose is 400 mg/d
Baclofen (Lioresal)	Skeletal muscle relaxant used to treat spasticity	Dosage: initially 5 mg three times a day for 3 d, then 10 mg three times a day for 3 d, then 20 mg three times a day for 3 d; then titrated to response Max daily dose is 80 mg/d.
Tizanidine hydrochloride (Zanaflex)	Central-acting skeletal muscle relaxant used to treat acute and intermittent increased muscle tone associated with spasticity	Dosage: initially 4 mg; gradually increase to 8 mg every 6–8 h for a maximum dose of 36 mg/24 h
Investigational Drugs		
Fampridine-SR ("4-AP," "4-aminopyridine")	This drug has been approved by FDA for patients with multiple sclerosis; however, evidence for use in patients with acute SCI is inconclusive.	

can lead to a severe catabolic state and malnutrition. It is not unusual to see a significant weight loss within the first few days of injury. Total parental nutrition or enteral feedings are instituted until the patient is able to start on an oral diet. The patient's intake and output are strictly monitored.

Ensuring adequate nutrition is a collaborative problem involving the patient, family, dietitian, occupational therapist (OT), and nurse. The dietitian meets with the patient and family to identify the foods the patient enjoys and develops a menu that incorporates patient preference into the required dietary plan. Family members learn what foods they can bring from home to include in the patient's prescribed diet. The OT assesses the patient's need for assistive devices to use during mealtimes and teaches the patient and family how to use the adapted silverware. The nurse reinforces the information provided by the dietitian and OT. The nurse may teach family and friends how to assist the patient with meals and about the importance of allowing the patient as much independence as possible at mealtime. It is necessary to encourage fluid and a high-roughage diet, unless contraindicated. Before meals, the nurse assists the patient with mouth care and ensures that the patient has not been incontinent.

Mobilization and Skin Care

Rehabilitation begins in the critical care unit and is a collaborative effort involving the patient, physician, physical therapist (PT), OT, nurse, and the patient's family. Initially, the nurse assists the patient with range-of-motion exercises. When the patient is stable, family members may be taught to assist the patient with these exercises. Based on their assessment findings, the PT and OT develop an individualized treatment plan to begin mobilization of the patient.

Positioning is not simply based on the usual every-2-hour turn schedule. Development of proper positioning protocols occurs in conjunction with the physical and OT to maximize range of motion and prevent joint contractures. When turning the patient, the nurse places a pillow under the patient's head but not under the forearms. When the patient is on his or her side, most of the upper body weight should be over the scapula that rests on the bed. Flexing of the hips and knees allows the patient to remain on the side with minimal support. The nurse places pillows and foam cushions between the knees and against the back.

Pressure is a common cause of structural damage to a muscle and its peripheral nerve supply. Preventing skin breakdown is a priority for the nurse in the critical care unit. There is a definite time–pressure relationship in the development of pressure ulcers. Microscopic tissue changes secondary to local ischemia occur in less than 30 minutes. Pressure interferes with arteriolar and capillary blood flow. When the pressure is prolonged, there is definite damage to superficial circulation and tissue. The damage may be associated with congestion and induration of the area or blistering and loss of the superficial epidermal layers of the skin. As the pressure continues, the deeper skin layers are lost, leading to necrosis and ulceration. Serous drainage from such ulceration can constitute a continuous protein loss of as much as 50 g/d. Prolongation of the pressure results in deep penetrating necrosis of the skin, subcutaneous tissue, fascia, and muscle. The destruction may progress to gangrene of the underlying bony structure. Pressure necrosis can begin from within the tissue over a bony prominence, where the body weight is greatest per square inch.

A turn schedule for the patient is important, even if the patient has not had stabilizing surgery. It may take three staff members to accomplish this safely, particularly in the patient with a cervical injury. One person stabilizes the neck, and the other two flex the hips, knees, and ankles and hold the feet flat on the bed surface while turning the patient's trunk. To maintain alignment, the nurse uses foam wedges, pillows, or air-filled rolls. Turning occurs a minimum of every 2 hours. Use of an air or egg-crate mattress does not preclude the need to turn. The nurse checks the condition of the skin before and after the position change, paying particular attention to the patient's earlobes, back of head, elbows, inner aspects of the knees, heels, and sacral area. The posterior thigh and ischial tuberosities are prone to skin breakdown from prolonged lying on the back with the head of bed elevated or when sitting in a chair. The nurse documents any change in skin integrity, notifies the wound care specialist, and implements a plan of care. Numerous kinetic beds and air beds are available for patient comfort, preventing skin breakdown and treating complications of immobility.

Together with the PT and the OT, the nurse develops a plan to prevent foot drop. Initially, the heels are placed in "bunny boots." Frequently, high-top sneakers/basketball shoes are worn. It is important to ensure that the boots or shoes are the correct size, to check for signs of skin breakdown, and to ensure that the patient's feet are dry. It is necessary to develop an "on and off" schedule with the PT. When the boots or shoes are off, the nurse pays careful attention to foot positioning and assesses for pressure ulcers.

The OT determines the need for splints or braces for the patient's wrists and hands. The nurse must assess the patient's skin frequently to identify pressure areas early. If necessary, the splints are modified to prevent skin breakdown.

Urinary Management

Acute tubular necrosis may occur within 48 hours of injury as a result of hypotension. An indwelling urinary catheter is necessary to allow for hourly measurement of urinary output during this phase, with the goal of keeping it at least 30 mL/h. The nurse closely monitors fluid and electrolyte balance. Removal of the indwelling catheter as soon as spinal shock has resolved reduces the risk for infection.

The long-range objective of bladder management, regardless of the level of the injury, is to achieve a means whereby the bladder consistently empties, the urine is sterile, and the patient remains continent. The ultimate goal is to have the patient catheter free, with consistent low residual urine checks, no urinary tract infection, and no evidence of damage to the upper urinary tract structures.

One method of bladder management involves intermittent catheterization, and it may begin in the early recovery phase after spinal shock is resolved. The purpose of this program is to exercise the detrusor muscle, again with the goal of keeping the patient catheter free. The advantage of this method is that no irritant remains in the bladder; consequently, the risk for urinary tract infection, periurethral abscess, and epididymitis is reduced.

Bowel Management

Before the initiation of a bowel program, it is necessary to perform a systematic, comprehensive evaluation of the type of cord injury, bowel function, impairment, and possible problems. This includes an abdominal assessment, a rectal examination, and evaluation of anal sphincter tone. In addition, the anocutaneous reflex (contraction of the anal sphincter secondary to cutaneous stimulation) and bulbocavernosus reflex (also referred to as the penile reflex; compression or tapping on the dorsum of the glans penis, which leads to contraction of the bulbocavernosus muscle at the tip of the penis) warrant assessment to determine whether the patient has upper motor neuron or lower motor neuron dysfunction. Equally important, a bowel program must consider the ability of the patient and care givers to carry out the planned interventions at discharge.

Simple steps can prevent constipation and begin progress toward bowel continence. It is necessary to maintain appropriate intake, either through intravenous or oral fluids and diet. The nurse records bowel movements in an area that is easily accessible for review and administers stool softeners daily. Development of a consistent schedule for the bowel program is warranted. The timing of the program is usually after meals to coincide with peristalsis that occurs after meals to move food through the gastrointestinal tract. Rectal stimulation may be necessary to trigger defecation.

Psychological Support

As soon as the patient is medically stable, the nurse begins to focus on the psychosocial issues that are of concern to the patient and family. Questions often asked of the nurse include the following: Am I going to die? Will I walk or use my arms again? What is going to happen to me? There are no easy answers to these questions. It can be difficult for patients and family members to accept this uncertainty. Most patients are accustomed to receiving treatment for illnesses or conditions that have a predictable course of treatment and outcome. For example, antibiotics are prescribed for 10 days and the infection clears up, or surgery is performed and we are discharged home and able to return to our normal activities within an expected timeframe.

Answer questions to the best of your knowledge. Never predict the future, tell stories about patients who made a complete recovery, or ignore a question or a concern. Listen to the patient and the family. Let the patient and family talk about their fears and anxieties. Detailed patient education in a critical care unit is not generally appropriate. However, providing information the patient and family need to know while they are being cared for in the critical care unit is important. Focus on the patient care issues that present each day and on the patient's abilities. Do not minimize the patient's disabilities. Refer questions to other members of the health care team as appropriate. If indicated, ask for an order for a psychiatric consult.

Incorporate the use of technology to help the patient stay connected with family and friends. For example, place a "hands free" telephone in the room. Use a laptop computer and web cam if wireless internet is available. Explore other enhancements that may be on the patient's personal laptop that will enable continued support with others and provide a means for helping pass the long days in the critical care unit.

Psychological transition from the loss of previous physical abilities to the current state is unique to each person. Feelings of grief, loss, anger, and frustration are common. Certain emotions are characteristic after an SCI, whatever names are given to the stages of grief (Box 37-7). The rate at which a person works through this process varies, and no stage is static. A person can move back and forth between stages. The emotions felt and displayed by someone with an SCI are no different from the emotions felt by everyone at one time or another, and recognition of that fact may help promote empathy with the patient.

All staff members should have an understanding of the types of feelings and reactions the patient with an SCI may exhibit. They can share this process of recovery with family members in helping them to support the injured person and participate in recovery. It is necessary to provide psychological support for family members, who no doubt have many concerns, such as finances, role changes, and long-term prognosis. It is important to be supportive of them and help them and the patient with coping strategies.

Addressing Concerns About Sexuality

After an SCI, patients have concerns about their ability to function sexually, although they may not verbalize this issue immediately. Critical care nurses probably will not deal with this problem specifically, but it is important to have some knowledge of the functional potential of the patient to begin to manage the patient's fears and concerns in this area. By avoiding discussion of this important issue, professionals validate the patient's fear that there can be no sex after an SCI, which is certainly not true.

Male Sexuality

Many men with an SCI believe that their total sexuality is tied to erection and ejaculation. There are three general types of erection in men: psychogenic, reflexogenic, and spontaneous. A psychogenic erection can result from sexual thoughts. The area of the cord responsible for this type of erection is between T11 and L2. Therefore, if the lesion is above this level, the message from the brain cannot get through the damaged area.

Reflexogenic erections are a direct result of stimulation to the penis. Some patients may get this type of erection when changing their catheter or pulling the pubic hairs. The length of time the erection can be maintained is variable; therefore, its usefulness for sexual activity is variable. Reflexogenic erections are better with higher cervical and thoracic lesions. Damage to lumbar and sacral regions may destroy the reflex arc.

The third type of erection is spontaneous. This may occur when the bladder is full, and it comes from some internal stimulation. How long the spontaneous erection lasts will determine its usefulness for sexual activity. The ability to achieve a reflexogenic or spontaneous erection comes from nerves in the S2, S3, and S4 segments of the spinal cord.

BOX 37-7 Stages of Grief in a Patient With a Spinal Cord Injury

Stage	Description	Implications for the Nurse
1. Shock and disbelief	During this phase, the patient does not request an explanation of what has happened. The patient is overwhelmed by the injury. There may be more concern with whether he or she will live than with whether he or she will walk again. This period may result in extreme dependence on the staff members.	The nurse may feel that the patient does not understand the ramifications of the injury. The nurse may identify with the feelings of being overwhelmed because he or she is often overwhelmed with the acute medical management of this catastrophic illness.
2. Denial	The process of denial is an escape mechanism. Usually, the whole disability is not denied, but particular aspects of it are. For instance, the patient may say he or she cannot walk now but will be able to in 6 months. Bargaining, instead of being a separate stage, can be considered a form of denial. Bargains with God may be in the form of offering Him the legs if He will just return function of the arms.	The nurse often finds it difficult to deal with patients in this stage. A helpful approach is to focus on the present problems. This is not the stage to discuss long-term changes, such as ordering a wheelchair or making modifications to the home. More appropriate matters to deal with would be skin care and range-of-motion exercises.
3. Reaction	During this stage, instead of denying the impact of the injury, the patient expresses this impact. There may be severe depression and loss of motivation and involvement. Previous hobbies or interests lose their meaning. There is great helplessness during this period, and there may be suicidal statements.	The nurse can help at this stage by listening to the patient as feelings are verbalized. The nurse should avoid setting up failure situations, which could happen if he or she pushes the patient too fast. It is important to note that both the sudden absence of muscular activity and sensations in the patient with an SCI and the mental state of helplessness appear to alter central nervous system metabolism. Depression coincides with a fall in a brain metabolite excreted in the urine as tryptamine. Thus, it is important for the nurse to understand that depression in some patients with SCI might have a metabolic basis and that a trial of pharmacological therapy might be beneficial.
4. Mobilization	Problem-solving behavior is seen during this stage. The patient is looking toward the future and wants to learn about self-care. In fact, the patient may become very possessive of the therapist or nurse and resent the time spent with other patients. This is a time of sharing and planning between patient and staff.	
5. Coping	Some authorities think that patients do not accept the disability *per se* but instead learn to cope with it. Disability still is an inconvenience, but it is no longer the center of the patient's life. Life is again meaningful to the patient, and the patient is again involved with others.	

Female Sexuality

In 50% of women with an SCI, the menstrual pattern is interrupted for approximately 6 months after injury but then is reestablished. Women are able to become pregnant and seem to have no increase in rate of miscarriage. There are potential complications for the pregnant woman, such as urinary tract infection, pressure sores, and anemia, but with careful medical attention, complications usually can be avoided or minimized.

Labor may be painless, or the woman may experience other signs that indicate labor is occurring (eg, abdominal or leg spasms, back pain, difficulty breathing). Autonomic dysreflexia is a complication of labor in women with injuries above T4 to T6 and should be anticipated so that it can be controlled. Women may breastfeed if they wish.

▲ Complications

Autonomic Dysreflexia

Autonomic dysreflexia, or hyperreflexia, is a syndrome that sometimes occurs after the acute phase in patients with a spinal cord lesion at T7 or above. Autonomic dysreflexia constitutes a medical emergency. The syndrome presents quickly and can precipitate a seizure or stroke. Death can occur if the cause is not relieved.

Triggering conditions include bladder or intestinal distention, spasticity, pressure ulcers, or stimulation of the skin below the level of the injury. In men, ejaculation can initiate the reflex, and in pregnant women, strong

BOX 37-8 Precipitating Factors in Autonomic Dysreflexia

- Bladder distention or urinary tract infection
- Bladder or kidney stones
- Distended bowel
- Pressure areas or decubitus ulcers
- Thrombophlebitis
- Acute abdominal problems (eg, ulcers, gastritis)
- Pulmonary emboli
- Menstruation
- Second stage of labor
- Constrictive clothing
- Heterotopic bone
- Pain
- Sexual activity; ejaculation by a man
- Manipulation or instrumentation of bladder or bowel
- Spasticity
- Exposure to hot or cold stimuli

uterine contractions can elicit it. Box 37-8 lists potential precipitating factors.

These stimuli produce a sympathetic discharge that causes a reflex vasoconstriction of the blood vessels in the skin and splanchnic bed below the level of the injury. The vasoconstriction produces extreme hypertension and a throbbing headache. Vasoconstriction of the splanchnic bed distends the baroreceptors in the carotid sinus and aortic arch. These baroreceptors in turn stimulate the vagus nerve, producing a bradycardia, in an attempt to lower the BP. The body also attempts to reduce the hypertension by superficial vasodilation of vessels above the SCI. As a result, there is flushing, blurred vision, and nasal congestion. Because the SCI interrupts transmission of the vasodilation message below the level of the injury, the vasoconstriction continues below the level of the injury until the stimulus is identified and interrupted. The vasoconstriction results in pallor below the injury, whereas flushing occurs above the injury. Box 37-9 summarizes the signs and symptoms of autonomic dysreflexia.

When autonomic dysreflexia is recognized, there are several things the nurse can do quickly to relieve the patient's condition. The nurse can elevate the head of the bed and make frequent checks of BP. In addition, he or she quickly checks the bladder drainage system for kinks in the tubing. The urine collection bag should not be overly full. Some protocols for checking the patency of the urinary drainage system include irrigating the catheter with 10 to 30 mL of irrigating solution.

BOX 37-9 *PATIENT SAFETY*

Signs and Symptoms of Autonomic Dysreflexia

- Paroxysmal hypertension
- Pounding headache
- Blurred vision
- Bradycardia
- Profuse sweating above the level of the injury
- Flushing or splotching of the face and neck
- Piloerection
- Nasal congestion
- Nausea
- Pupil dilation

Absolutely no more than that amount is used because the addition of the fluid may aggravate the massive sympathetic outflow already present. If the symptoms persist, the catheter is changed so that the bladder can empty. Foley catheter placement may be necessary for patients on a bladder management program and those who have not voided in the past 4 to 6 hours.

If the urinary system does not appear to be the cause of the stimulus, it is necessary to check the patient for bowel impaction. Removal of the impaction should not occur until the symptoms subside. Rectal application of dibucaine or lidocaine ointment anesthetizes the area until symptoms subside. If the patient's BP does not return to normal, sublingual nifedipine (Procardia) may be very effective. A sympathetic ganglionic blocking agent, such as atropine sulfate, guanethidine sulfate (Ismelin), reserpine, or methyldopa (Aldomet), may be useful. Hydralazine (Apresoline) and diazoxide (Hyperstat) also may help. Box 37-10 presents nursing intervention guidelines for managing autonomic dysreflexia.

Pulmonary Complications

Pulmonary complications are the most common cause of death in people with SCI, both in the acute and chronic phases. These pulmonary complications are especially prevalent in people injured above T10. If there is concomitant chest trauma or preexisting pulmonary disease, a history of smoking, or older age, there is higher risk for these complications.

Atelectasis and Pneumonia

Atelectasis is possible in any immobilized patient. Early mobilization, ensuring the airways are clear of secretions, and bronchial hygiene may be useful in minimizing or preventing atelectasis. Pneumonia may also result from hypoventilation and an inability to keep the airways clear. Adequate hydration helps keep secretions liquefied for ease of removal, and bronchoscopy may be necessary to remove mucous plugs. Supplemental oxygen administration is used to treat hypoxia. Ventilator-dependent patients need exquisite pulmonary care (see Chapter 25).

Deep Venous Thrombosis and Pulmonary Embolus

The Virchow triad for venous thrombosis—venous stasis, vein injury, and hypercoagulability—is found in the patient with an SCI. As a result, the patient is at increased risk for deep venous thrombosis (DVT) and pulmonary embolus. In addition to swelling and pain, obstruction to venous return can lead to compartment syndrome and limb ischemia. Although it is infrequent, hypovolemic shock can occur if enough blood and interstitial fluid pool in the extremity.[10] (If the thrombus breaks off, pulmonary emboli can obstruct venous return and lead to cardiovascular collapse and death.) Patients particularly at risk for a fat embolus are those with long bone fractures. Signs of chest or neck petechiae and low-grade fever may be early indications.

Leg veins should not be used as sites from which to draw blood, lest the trauma to the vessel wall enhance platelet aggregation and clot formation. It is important to encourage smokers to quit because nicotine causes vasoconstriction, thereby slowing blood flow through the periphery.

There is some controversy about the effectiveness of serial leg measurements in monitoring for DVT. A standard measurement protocol is necessary, and all staff should follow

BOX 37-10 NURSING INTERVENTIONS

For Managing Autonomic Dysreflexia

1. Elevate the head of bed.
2. Apply BP cuff, and check BP every 1 to 2 minutes.
   - If BP is above 180/90 mm Hg, proceed to step 5.
   - If BP is below 180/90 mm Hg, proceed as follows.
3. Quickly insert bladder catheter or check bladder drainage system in place to detect possible obstruction.
   - Check to make sure plug or clamp is not in catheter or on tubing.
   - Check for kinks in catheter or drainage tubing.
   - Check inlet to leg bag to make sure it is not corroded.
   - Check to make sure leg bag is not overfull.
   - If none of these are evident, proceed to step 4.
4. Determine whether catheter is plugged by irrigating the bladder slowly with no more than 30 mL of irrigation solution. Use of more solution may increase the massive sympathetic outflow already present. If symptoms have not subsided, proceed to step 5.
5. Change the catheter and empty the bladder.
6. When you are sure the bladder is empty and if BP is:
   - Above 180/90 mm Hg, call physician immediately.
   - Below 180/90 mm Hg, proceed as follows: Give sublingual nifedipine (Procardia) if protocol calls for it. Give atropine according to physician's order. If BP rises or fails to subside, call physician immediately. Guanethidine monosulfate (Ismelin), hydralazine (Apresoline), or inhaled amyl nitrate may then be ordered by the physician. Dibenzylene may be used for chronic dysreflexia.
7. Ideally, this procedure requires three people: one to check the BP, one to check the drainage system, and one to notify the physician.

If bladder overdistention does not seem to be the cause of the dysreflexia,

- Check for bowel impaction. Do not attempt to remove it, if present. Apply Nupercainal ointment or Xylocaine jelly to the rectum and anal area. As the area is anesthetized, the BP should fall. After the BP is again stable, using a generous amount of anesthetizing ointment or jelly, manually remove impaction.
- Change the patient's position. Pressure areas may be the source of dysreflexia.

it. For example, use a special measuring tape rather than a sewing tape, mark the area where the tape is placed, and use running averages.

Treatment of DVT and pulmonary embolus includes heparin infusion, insertion of an intravenous vena cava filter, or dissolving the clot with thrombolytic agents. Measures to prevent DVT may include the administration of low–molecular-weight heparin and the use of antiembolism stockings. Other modalities include sequential compression devices, passive range-of-motion exercises, and early mobilization. In addition, a kinetic bed can be useful; this device works by keeping the patient in continuous motion.

Paralytic Ileus and Stress Ulcers

Early medical management for paralytic ileus and stress ulcers includes NPO, particularly for cervical spinal cord–injured patients. Nasogastric tube placement with intermittent suction is useful in treating the paralytic ileus that frequently accompanies SCI. Nasogastric tube placement also decreases the risk for aspiration and reduces abdominal distention. As soon as bowel sounds are present, safe stimulation of peristalsis may be facilitated with stool softeners, mild laxatives, or suppositories. It is important to avoid enemas, other than the oil-retention type, because the risk for intestinal perforation is high.

Patients with cervical injuries are more likely to experience gastrointestinal bleeding as a result of stress ulcers. Medical treatment includes histamine-2 (H_2) receptor blockers, proton pump inhibitors, antacids, or a combination of the three.

Heterotropic Ossification

Calcification around a joint, especially the hip joint, may occur within 12 weeks of injury. Clinical manifestations include limited range of motion, swelling of the affected joint, and an elevated alkaline phosphatase level. Pain may or may not be present. The treatment goal is to prevent further damage and progression. Additional treatment includes irradiation, nonsteroidal anti-inflammatory drugs, and disodium etidronate.

Spasticity

Spasticity develops after recovery from the period of spinal shock and affects the flexor muscles of the arms and the extensor muscles of the legs. An interdisciplinary approach is the hallmark of treatment. A physical therapy consult is warranted to develop an exercise, stretching, and positioning program for the patient. A variety of medications such as baclofen, dantrolene sodium, diazepam, and clonidine may be useful.

▲ Research in the Treatment of Spinal Cord Injuries

Progress in clinical investigations may contribute to the treatment of SCI.

- Stem cell research holds promise for a number of neurological disorders, including spinal cord regeneration. Some studies have advanced to phase I clinical trials.
- Medications are under investigation to identify drugs that may be useful in the treatment of the primary and secondary effects of the cord injury itself. Other studies are focusing on the development of medications to treat complications such as spasticity or neuropathic pain. Other research is focusing on designing DNA vaccines for the treatment of axonal degeneration and demyelination. The goal is to improve motor function.
- Medical devices and assistive devices continue to be developed and older tools improved to enable the person with an SCI to function at the maximal level possible. With the increased numbers of military personnel suffering spinal cord injuries, this area will continue to expand.
- The use of systemic hypothermia is being investigated as an intervention during the acute phases of SCI.

▲ Patient Teaching and Discharge Planning

The nurse plays an integral role in working with the patient and family in finding a rehabilitation program that has a program specific for spinal cord–injured patients. Usually, the patient is discharged to a rehabilitation setting to learn the skills needed for activities of daily living and, when possible, independent living. The nurse helps the family find a rehabilitation program specifically for patients with SCI. When searching for an appropriate rehabilitation program, the family should obtain answers to the following questions:

1. How many patients with SCI are treated in the program each year?
2. What is the average age of the patients in the program?
3. Does the treatment plan identify both long-term and short-term goals?
4. Will the patient be assigned an experienced case manager to coordinate the transition between the rehabilitation center and home?
5. How much time is spent teaching the patient and family about sexuality, bowel and bladder care, and other activities of daily living?

The family should also ask if the staff has specialized training in SCI. Rehabilitation therapies should be available for a minimum of 3 hours per day. There should be activities or programs for the patients on weekends and in the evenings. Most importantly, the facility should have 24-hour staffing with registered nurses and respiratory therapists. Box 37-11 offers a teaching guide for a person living with an SCI.

BOX 37–11 TEACHING GUIDE *Living With a Spinal Cord Injury*

Respiratory Management
- Cough and deep-breathe routinely.
- Drink plenty of fluids, unless contraindicated.
- Use postural drainage or chest physiotherapy.
- Because you are at risk for pneumonia, be careful around anyone with a cold and get an annual influenza vaccination.

Nutritional Management
- Eat a well-balanced diet that includes protein (lean meat, dairy foods, legumes), fresh fruits, vegetables, and liquids.
- Maintain ideal body weight.

Skin Management
- You and your helper should check your skin twice a day. Look for redness, bruises or scrapes, blisters, and rashes. Pay particular attention to bony areas. Check your groin for rashes and reddened areas.
- Keep your skin clean and dry, especially in areas where skin touches skin (eg, between the toes, underneath the breasts). Do not use antimicrobial or harsh soaps. Apply moisturizing lotion. Avoid lotions or creams that dry the skin.
- Check your feet whenever you wear new shoes. Check for ingrown toenails. Keep your nails trimmed and filed smooth and have calluses treated by a podiatrist.
- Use the wheelchair and cushion prescribed by your PT.
- Change positions frequently to relieve pressure on bony areas.
- Be sure you are not sitting or lying on anything. Avoid putting objects in your pockets.
- Check to be sure braces, leg bags, and other adaptive equipment are not too tight.
- When in bed, use padding over bony areas. Use a firm mattress. If possible, sleep on your stomach.
- Notify your health care provider of any skin breakdown.

Urinary Tract Management
- Follow the bladder program developed by the rehabilitation team.
- Drink plenty of fluids unless contraindicated.
- If you have a Foley catheter, keep it free of kinks and change it as directed by your health care provider.
- Watch for signs and symptoms of urinary tract infection (eg, cloudy urine with a foul odor, sediment in the urine).

Bowel Management
- Follow the bowel program developed by your rehabilitation team. Avoid the regular use of laxatives. Schedule sufficient time to complete the required activities. Notify your health care provider if you have not had a bowel movement in 3 or 4 days.
- Drink plenty of fluids, unless contraindicated.
- Monitor your diet to see what foods cause constipation and diarrhea.
- Prevent constipation through diet and fluid intake and medications as needed.
- Avoid foods that cause gas, such as beans, corn, and apples.
- Be aware of the potential for the development of autonomic dysreflexia during your bowel program.

Home Environment Management
- Arrange for representatives from physical and occupational therapy to evaluate the patient's home for the following:
  Wheelchair accessibility
  Clearance for maneuvering a wheelchair within the home
  Necessary adaptations to the bedroom, bathroom, and kitchen
  Smoke and fire alarms
- Obtain needed equipment for home care, depending on patient's level of injury. Be sure the equipment is delivered before the patient leaves the rehabilitation facility. Also be sure that the patient and his or her family members know how to operate the equipment.
- Make arrangements for home health care, physical therapy, occupational therapy, and job training or vocational rehabilitation, as necessary.
- Notify the electric company if there will be lifesaving equipment in the home, such as a respirator.
- Carry out patient and family education
- Locate community support groups.

Complications

Autonomic Dysreflexia
- This complication occurs in patients with injury at T5 or above.
- The most common cause is overfilling of the bladder. Other causes include constipation or gas, skin irritations, pressure sores, wounds, and ingrown toenails.
- Autonomic dysreflexia can be a life-threatening emergency. You or a helper must take immediate action to correct this problem.
- Signs and symptoms include a severe headache, nasal congestion, goose pimples, and restlessness.
- Be sure your head is up. If you are sitting in a chair, stay there; if you are in bed, get your head elevated.
- If you have an indwelling catheter:
  Check for kinks along the tubing.
  Empty the Foley bag; if there is no drainage, the Foley may be obstructed—change the Foley.
  Check the catheter and drainage bag for deposits.
  Check urine for color.

(Continued on page 849)

BOX 37–11 TEACHING GUIDE *Living With a Spinal Cord Injury* (continued)

- If you are on intermittent catheterization, catheterize yourself.
- If the problem is related to the bowel, perform a digital stimulation and empty the bowel.
- If it is not related to a bladder or bowel problem, check for a pressure sore, ingrown toenail, or possible bone fracture.
- If none of the above actions relieve the signs and symptoms, get emergency medical treatment.

Deep Venous Thrombosis

- Prevention is important.
- Signs and symptoms include leg swelling, chest pain, and cough.
- Call your health care provider immediately if signs or symptoms develop.

Hypothermia and Hyperthermia

- To prevent hyperthermia:
  Drink lots of fluids.
  Dress according to the temperature you will be in.
  Watch for signs and symptoms of hyperthermia.
  Use sun block.
- To prevent hypothermia:
- Dress appropriately for the weather.
- Watch for signs and symptoms of hypothermia and frostbite.

Heterotopic Ossification

- Check for development of abnormal bone in soft tissue, usually around the hip or knee.
- Signs and symptoms include a change in range of motion, decreased ability to perform activities of daily living, swelling, warmth, redness over the hip or knee, spasticity, and fever.
- Notify your health care provider immediately if any of these signs or symptoms develop.

Medication-Related Complications

- Select a pharmacy that will keep your medication profile on record, including any allergies you may have.
- Be sure the pharmacy has a system to check for and identify drug and food interactions.
- Have all of your prescriptions filled at the same pharmacy.
- Follow the directions on the label.
- Take all the medication that is ordered.
- Keep a current list of all medications.
- Know the important side effects of the medication; if any occur, notify your health care provider.

Pain

- Prevention of other problems such as pressure ulcers, stress ulcers, and infections is important.
- Maintain your activity program, range-of-motion exercises, and a healthy diet.
- Notify your health care provider of the type of pain you are experiencing.
- Medications and stress reduction techniques may be used.

Orthostatic Hypotension

- Know that this is a drop in BP when you first sit up.
- Wear elastic hose or an abdominal support.
- Sit up slowly.
- If you experience orthostatic hypotension while you are sitting up, ask someone to tilt your wheelchair back until your head is parallel to the floor.
- Be sure to drink plenty of fluids.

Spasticity

- Prevention is crucial. Watch for and immediately treat skin problems such as an ingrown toenail. Prevent pressure ulcers. Maintain your bowel and bladder program.
- Notify your health care provider if spasticity develops.

▲ Clinical Applicability Challenges

CASE STUDY

D.C. is a 24-year-old college student who was admitted to the Neuroscience Critical Care Unit 2 days ago secondary to injuries suffered when the bicycle he was riding was hit by an automobile. When paramedics arrived at the scene of the accident, D.C. had minimal spontaneous breathing and was unconscious. After stabilizing his neck and removing his helmet, the paramedics intubated him in the field and placed him on a spinal board. Two peripheral IV lines were started with normal saline solution. His pulse rate was 80 beats/min and BP was 90/60 mm Hg. Other than moderate abrasions on his lower arms, D.C. had no other obvious areas of injury or overt bleeding.

Upon arrival to the emergency department, D.C. began to open his eyes and attempted to talk around his endotracheal tube. The trauma staff explained where he was and began a more comprehensive neurological examination. D.C. had no voluntary movement of his arms or legs. He was able to shrug his shoulders, and he opened his eyes spontaneously. He had some sensation intact in the neck area and on the top of his shoulders. When tested, he had no perianal reflex activity, suggesting that he was in spinal shock. Radiographic evaluation and computed tomography (CT) scan demonstrated fracture at the C4–C5 level, with moderate spinal cord edema. There were no findings of head trauma on the CT scan. A loading dose of methylprednisolone (Solu-Medrol) was administered, followed by a continuous IV infusion for 23 hours.

(continued on page 850)

CASE STUDY *(Continued)*

D.C. was admitted to the critical care unit, where he was placed in a halo fixation device to realign the cervical vertebrae and stabilize the fracture. During the first 24 hours after admission, BP control was problematic as D.C. demonstrated signs of neurogenic shock, including decreased BP with bradycardia. In addition to IV fluids, he was also started on a continuous infusion of dopamine at 3 mcg/kg/min to maintain a mean arterial pressure of 85 to 90 mm Hg. Atropine was to be administered if the bradycardia became symptomatic.

Currently, 2 days after the injury, D.C. is alert and oriented to person and place but unable to talk because of oral intubation with a 7.5 endotracheal tube. He is on a mechanical ventilator, as he is still unable to initiate sufficient respiratory effort. Physical assessment reveals flaccid paralysis below the level of the injury. He is able to shrug his shoulders and discriminate between sharp and dull sensations at the corresponding level of his injury. Two peripheral IV lines are in place with normal saline solution infusing at 75 mL/h. He also has a nasogastric tube connected to low intermittent suction; a Foley catheter draining clear, yellow urine; and sequential pressure devices on both legs.

Nursing interventions include monitoring vital signs every 1 to 2 hours with complete motor and sensory evaluations every 4 hours. The nurses who are caring for D.C. continue vigilant monitoring of his respiratory status. He is repositioned (turned) every 2 hours, and the outputs of his Foley catheter and nasogastric tube are measured and recorded every 4 hours. Every effort is made to prevent complications of immobility, both in the critical care and acute care units. After consulting physical and occupational therapy, D.C.'s health care team initiates a treatment plan. Once he is past the acute phase of his injury, plans will be made to transfer him to a rehabilitation facility for further recovery and adaptation to his injury.

1. Correlate D.C.'s clinical presentation to his C4–C5 level of injury.
2. When D.C. questions (via word board or some other method of communication) whether he will require mechanical ventilation for the rest of his life, what is the nurse's best response?
3. What is the significance of loss of perianal reflex activity immediately after the spinal cord injury?

PART 9

GASTROINTESTINAL SYSTEM

38

Anatomy and Physiology of the Gastrointestinal System

Allison G. Steele and Valerie K. Sabol

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Describe the processes of ingestion, digestion, absorption, and elimination.
2. Define the functions of the major structures of the gastrointestinal system.
3. Explain digestion and absorption of carbohydrates, proteins, fats, vitamins, and minerals.
4. Describe bile production, secretion, and excretion.
5. Discuss the processes involved in emesis and defecation.

The gastrointestinal system consists of the gastrointestinal tract and the accessory glandular organs that empty their contents into the gastrointestinal tract. The major structures of the gastrointestinal tract are the mouth, pharynx, esophagus, stomach, small intestine (duodenum, jejunum, ileum), and large intestine (colon, rectum, anus). The accessory glandular organs include the salivary glands, liver, gallbladder, and pancreas.

The primary physiological functions of the gastrointestinal system are to take in nutrients for cell maintenance and growth and to eliminate waste. Cell maintenance and growth are accomplished through the processes of ingestion (taking in food), motility (mixing and propelling food through the gastrointestinal tract), digestion (breaking down food), and absorption (movement of food particles into the bloodstream). Elimination is the process by which waste is eliminated from the body.

Gastrointestinal function is regulated and coordinated by the autonomic nervous system (ANS) and a variety of peptides, which are further classified as endocrines (hormones), paracrines, and neurocrines. Endocrines are released in the general circulation and reach all tissues. Endocrine cells release paracrines, which target specific tissues. Neurocrines, or neurotransmitters, diffuse across a synaptic gap and can stimulate or inhibit the release of endocrines and paracrines.

▲ Structure of the Gastrointestinal System

Macroscopic Anatomy of the Gastrointestinal System

The gastrointestinal system is composed of the gastrointestinal tract (also called the alimentary canal), a hollow tube about 8 m (25 ft) long that begins at the mouth and ends at the anus (Fig. 38-1). The accessory glands (eg, salivary glands) and organs (eg, liver and pancreas) release secretory products into the gastrointestinal tract.

The oral cavity opens into the pharynx, a structure that allows the passage of nutrients and air. The anterior pharynx, divided into the oropharynx and nasopharynx, connects the oral and nasal cavities. The posteroinferior end of the pharynx (at about the level of the sixth cervical vertebra) connects to the esophagus and larynx. The epiglottis, a thin

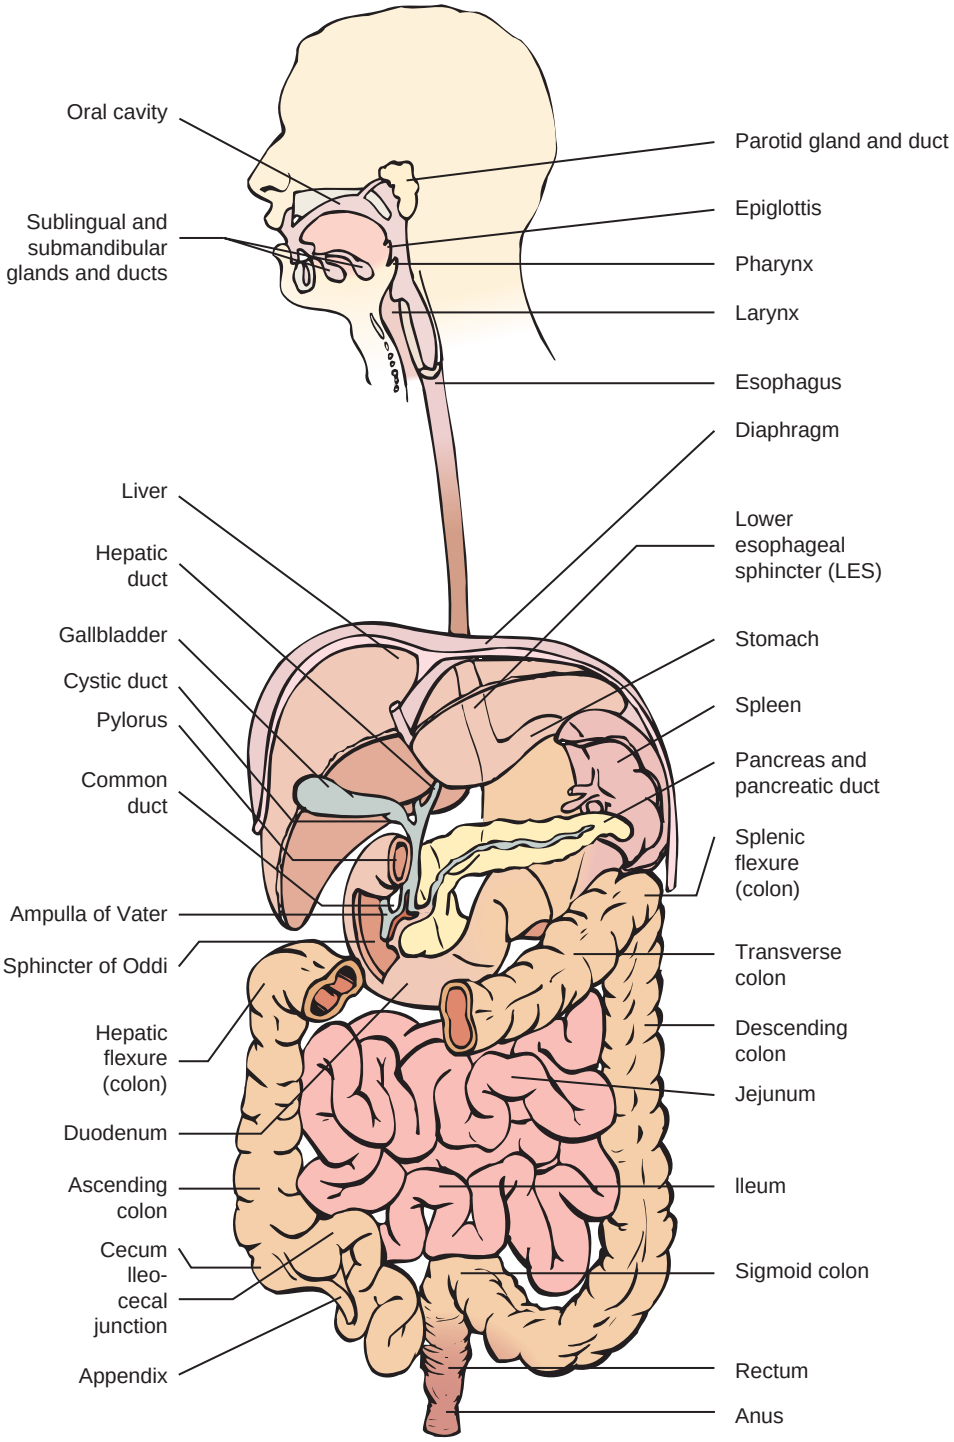

FIGURE 38-1 ▲ The gastrointestinal tract.

cartilaginous flap covered by soft tissue, reflexively covers the larynx during swallowing and prevents the passage of food and water into the trachea.

The esophagus, a 25-cm (10-inch) collapsible tube, connects the pharynx to the stomach at the cardiac orifice (Fig. 38-2). The esophagus is posterior to the trachea, in the posterior mediastinum, and crosses through the diaphragm. Its main function is to deliver food to the stomach. Two muscular rings, the upper and lower esophageal sphincters, border the esophagus. The upper esophageal sphincter (UES) prevents aspiration and swallowing of excessive air. The lower esophageal sphincter (LES), a muscular ring at the gastroesophageal junction, prevents reflux of gastric contents into the esophagus. The esophageal lumen, a central hollow tube through which food passes, is surrounded by four layers of tissue (see Microscopic Anatomy of the Gastrointestinal System section for more details). From the lumen outward, these layers are the mucosa, submucosa, muscularis propria, and serosa (Fig. 38-3).

The stomach is a flask-shaped organ that lies in the upper abdomen below the diaphragm (Fig. 38-4). The main

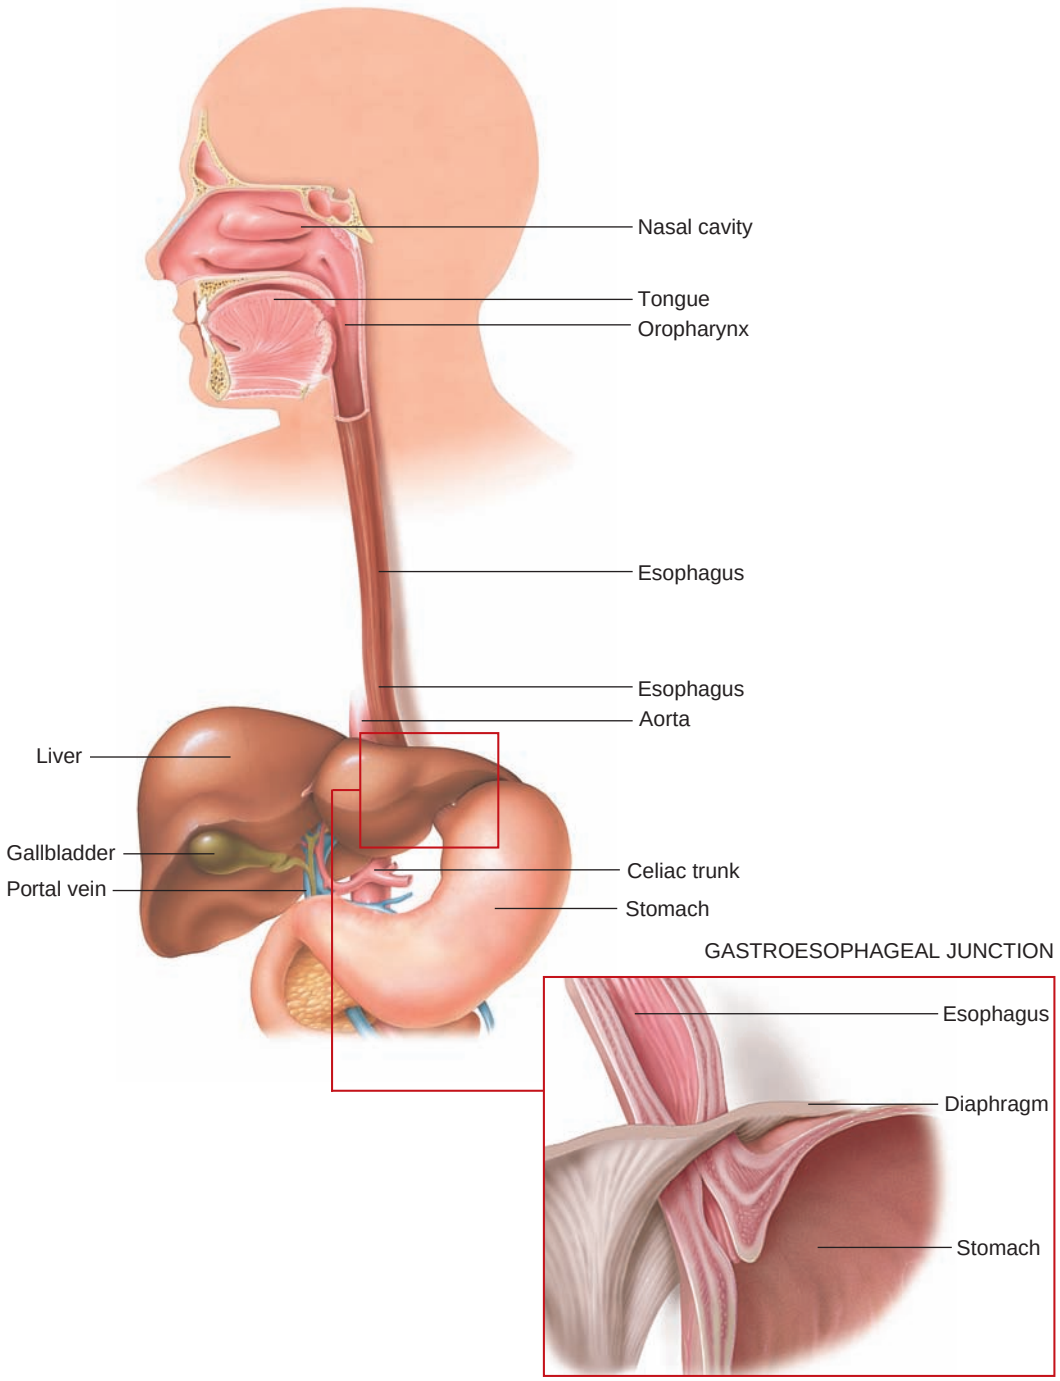

FIGURE 38-2 ▲ Gastroesophageal junction. (From Anatomical Chart Company: Atlas of Human Anatomy. Springhouse, PA: Springhouse, 2001, p 203.)

function of the stomach is storage; it acts as a reservoir for chewed food. The stomach also mixes ingested food with gastric secretions to form a semisolid liquid called chyme and regulates the release of chyme into the duodenum at a controlled rate. The esophagus joins the stomach at the cardia of the stomach. The cells of the cardia secrete mucus that helps protect the esophagus from the acidic secretions of the stomach. The dome-shaped fundus, located to the left of the cardia, acts as a reservoir. The body and the fundus have coarse folds called rugae that allow for expansion of the stomach. Gastric pits, which contain the acid-secreting cells of the stomach, are located mainly in the body of the stomach. The antrum, the most distal area of the stomach, is the site of G cells, which secrete gastrin. The antrum narrows into the pyloric channel, or pylorus, ending in the gastroduodenal junction at the pyloric sphincter. The pyloric sphincter, a muscular structure between the stomach and the duodenum, minimizes intestinal reflux.

Most digestion and absorption take place in the small intestine. The duodenum, the first 25 to 30 cm (10 to 12 inch) of the small intestine, begins at the pylorus. The common bile duct opens into the duodenum at the duodenal papilla through the

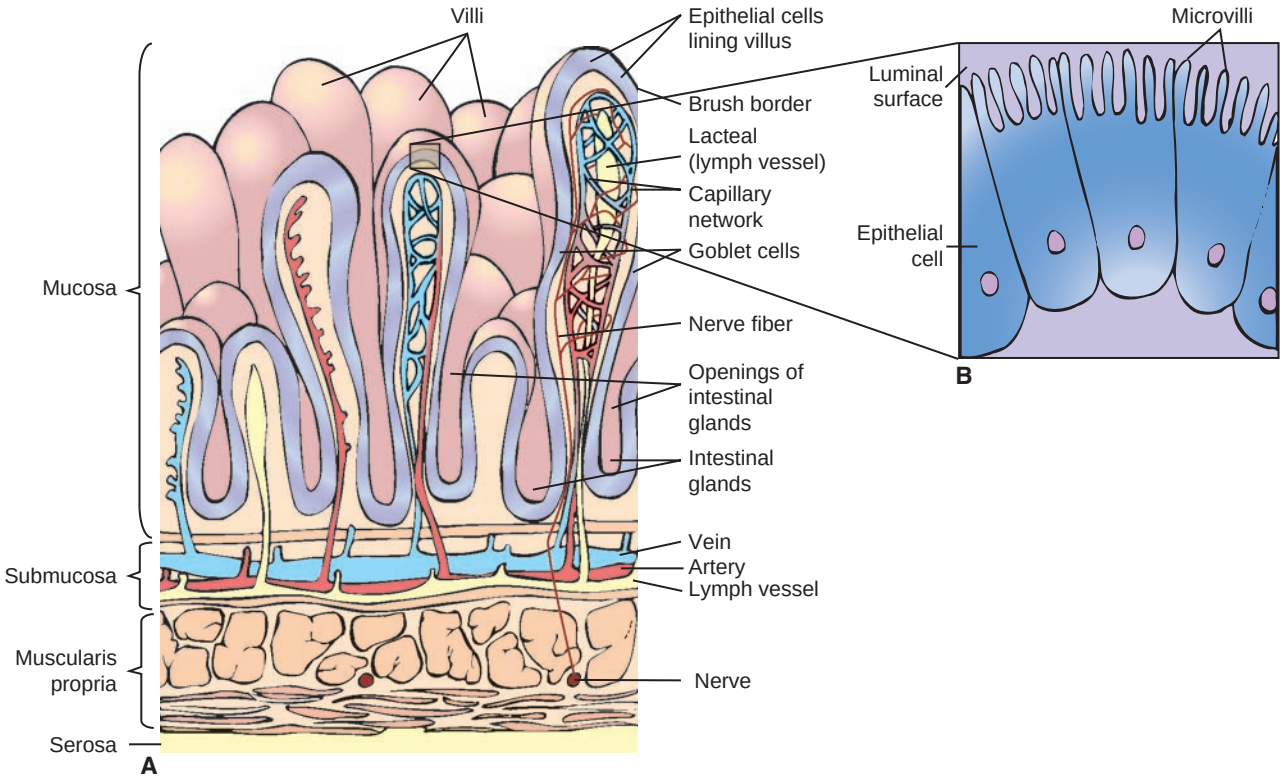

FIGURE 38-3 ▲ **A:** Layers of tissue in the gastrointestinal tract. **B:** Microvilli on the luminal surface of intestinal epithelial cells.

ampulla of Vater. The next 2.6 m (8.5 ft) of the small intestine is the jejunum. The ileum, the last 1.1 m (3.6 ft) of the small intestine, connects to the colon (cecum) at the ileocecal valve. The ileocecal valve prevents reflux of colonic contents into the ileum.

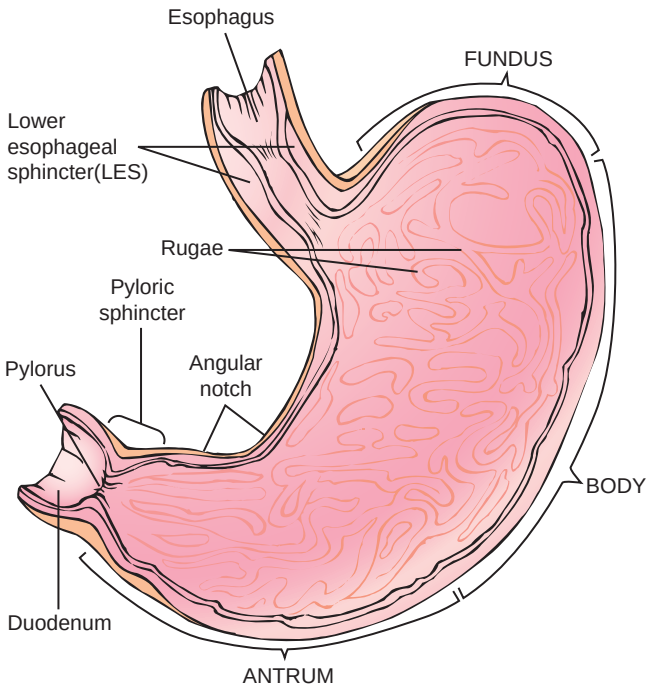

FIGURE 38-4 ▲ Anatomy of the stomach.

Traditionally, the colon is considered to have six sections. The *cecum* is the most proximal section and is the location of the ileocecal valve. The *vermiform appendix*, a blind-ended 2.5- to 20-cm (1- to 8-inch) tube, protrudes posteriorly from the cecum. The *ascending colon* extends superiorly from the cecum to the hepatic flexure. The *transverse colon* lies between the hepatic and splenic flexures. The *descending* colon extends from the splenic flexure to the level of the iliac crest. At the iliac crest, the colon becomes the sigmoid colon. The *sigmoid colon* continues downward to the pelvic floor as the rectum. The last 2.5 cm (1 inch) or so of the rectum, the anal canal, passes between the levator ani muscles of the pelvic floor and opens to the exterior body surface as the anal orifice. Two sphincters, which work to provide fecal continence, guard this orifice: an internal sphincter composed of smooth muscle and an external sphincter composed of skeletal muscle. The colon, although not necessary for life, is responsible for the reabsorption of electrolytes and fluid, thus allowing the body to maintain fluid and electrolyte balance with less fluid intake.

Microscopic Anatomy of the Gastrointestinal System

The microscopic structure of the gastrointestinal tract varies depending on location but possesses common features that are independent of the location.

Mucosa

The mucosa is composed of three layers: the epithelium, the lamina propria, and the muscularis mucosae. A single

layer of epithelial cells lines the mucosa. The tight junctions between the epithelial cells act as a barrier to bacteria and other large molecules. In the small intestine, this layer is more convoluted and possesses finger-like projections called villi (see Fig. 38-3). Such structural modifications dramatically increase the surface area of the small intestine, thereby facilitating absorption. The lamina propria, a layer of connective tissue, contains capillaries and lymph vessels. The muscularis mucosae, the innermost layer, is composed of two layers of smooth muscle. The mucosa contains cells that produce gastrointestinal secretions and cells that are sensitive to chemical and mechanical stimuli.

Submucosa

The submucosa contains blood vessels, nerve networks, and connective tissue. The submucosa of the small intestine contains aggregates of lymphatic tissue (Peyer's patches), which are especially numerous in the ileum. Specialized mucosal cells that lie superiorly to the patches of lymphatic tissue in the small intestine absorb viral and bacterial antigens. These specialized cells sensitize the lymphatic cells to antigens and manufacture and secrete antibodies of immunoglobulin class A (IgA). The antibodies protect the body from the antigen the next time (or times) it enters the small intestine.

Muscularis Propria

The muscularis propria consists of two layers of smooth muscle, an inner circular muscle layer and an outer longitudinal layer. The two smooth muscle layers function in the two major types of gastrointestinal motility: propulsive motion and mixing movements. The stomach has an additional layer of smooth muscle to facilitate its food-mixing movements.

Serosa

The serosa, or adventitia, is the outermost layer of the gastrointestinal tract. The serosa is continuous with the mesentery and forms part of the visceral peritoneum.

Innervation

The gastrointestinal tract is innervated by the ANS. The ANS can be divided into the extrinsic nervous system and the intrinsic (enteric) nervous system.

Extrinsic Nervous System

The extrinsic nervous system is further divided into parasympathetic and sympathetic branches. Parasympathetic stimulation increases gastrointestinal activity through sensory and motor fibers to promote motility, relax sphincters, and promote secretion. Activation of the sympathetic nerves usually inhibits the motor and secretory activities of the gastrointestinal system.

Parasympathetic Branch

The parasympathetic innervation of the gastrointestinal tract is primarily through the vagus and pelvic nerves. The vagal nerve (cranial nerve X) innervates the esophagus, stomach, pancreas, gallbladder, small intestine, cecum, and proximal colon. Vagal efferents synapse onto neurons in the myenteric plexus, or Auerbach plexus, which lies between the circular and longitudinal layers of smooth muscle cells in the muscularis propria. Postganglionic fibers then synapse with secretory and smooth muscle cells.

Vagal afferent (sensory) fibers originate in the esophagus, stomach, small intestine, and possibly the large intestine. The cell bodies are located in the nodose ganglion (in the neck) and join the vagus high in the neck. Afferent fibers relay information about pain and distention to the brain and spinal cord.

The pelvic nerve, issuing from spinal routes S2 to S4, carries parasympathetic afferent and efferent fibers to innervate the rectum and descending colon. For sacral efferents, the cell bodies are located in the spinal cord. Afferent cell bodies are in the corresponding dorsal root ganglia.

Sympathetic Branch

Sympathetic efferent fibers exit the spinal cord and synapse on ganglia near the spinal cord. Then, long postganglionic fibers travel to the gut and synapse on blood vessels, myenteric plexus ganglia, and secretory cells. The esophagus receives dense sympathetic innervation. Sympathetic fibers to the stomach and duodenum exit T6 to T9, synapse in the celiac ganglion, and then travel along the celiac artery. Sympathetic fibers exiting at T9 and T10 synapse in the superior mesenteric ganglion and then travel with the celiac artery to the large and small intestine. Fibers terminate on enteric neurons and blood vessels; a few fibers innervate the muscle layers.

Intrinsic (Enteric) Nervous System

The intrinsic, more commonly known enteric nervous system (ENS), coordinates gastrointestinal motility and secretion. The ENS is grouped into several nerve plexuses, with the myenteric and submucosal plexuses being the most prominent. The nerves in these plexuses receive input from receptors in the gastrointestinal tract and from the ENS. When integrated into the intrinsic system, this input helps coordinate function. Peripheral fibers innervate the voluntary muscles responsible for chewing, swallowing, and defecating.

The ENS is a complex network embedded in the wall of the gastrointestinal tract from the pharynx to the anus. It includes enteric neurons and the processes of afferent and efferent extrinsic neurons. There are two main ganglionic plexuses containing the cell bodies of enteric neurons. The outer plexus, the myenteric, or Auberbach's plexus lies between the longitudinal and circular muscle layers. The inner plexus, the submucosal plexus, or Meissner plexus lies between the circular muscle and the mucosa. The myenteric plexus mainly controls gastrointestinal movement, and the submusocal plexus mainly controls gastrointestinal secretion and blood flow.

The ENS can function on its own, independent of the extrinsic nerves, although stimulation by the parasympathetic or sympathetic nerves can further activate or stimulate its function.

Nerves in the ENS are characterized by both their function and by the neurotransmitters they contain. These include acetylcholine, norepinephrine, serotonin, and dopamine. In addition, many GI hormones have been identified in the nerves of the ENS where they act as neurotransmitters, and in the brain where they influence autonomic outflow. These include substance P, vasoactive intestinal polypeptide, gastric inhibitory peptide (GIP), and opioid peptides. There is evidence

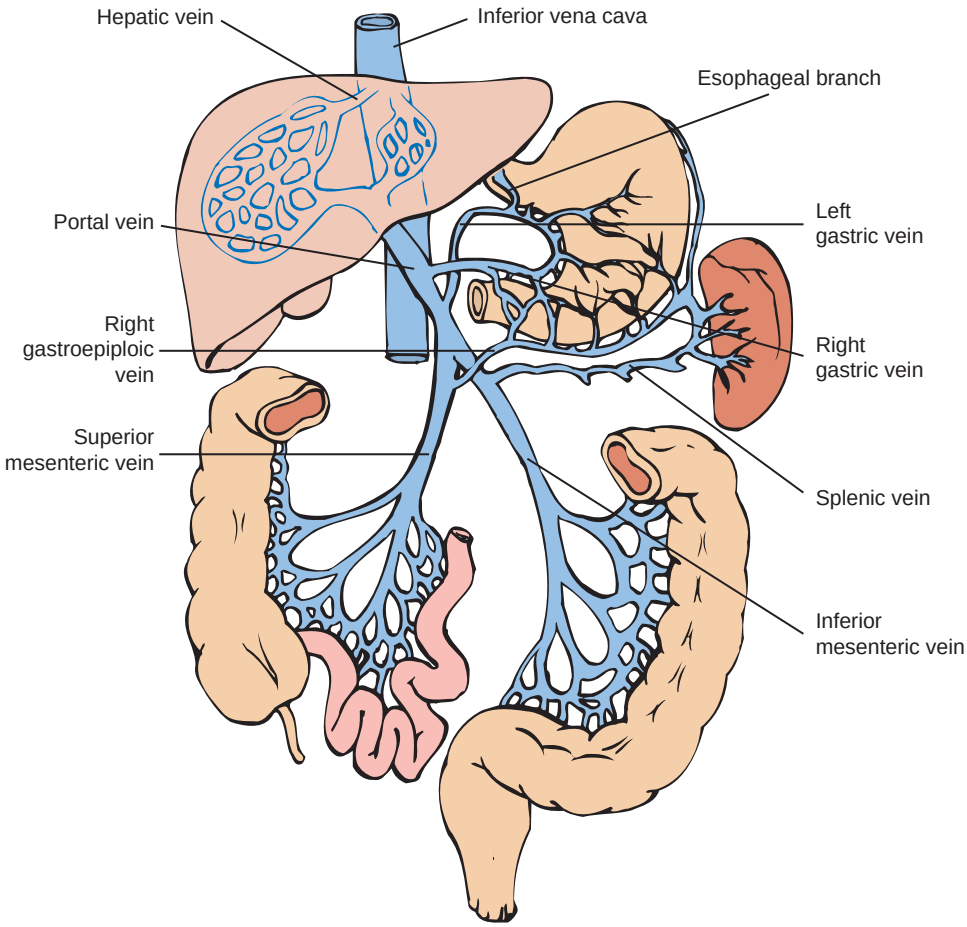

FIGURE 38-5 ▲ Portal circulation. Blood from the gastrointestinal tract, spleen, and pancreas travels to the liver by way of the portal vein before moving into the inferior vena cava for return to the heart.

that these neuropeptides participate in the control of all gastrointestinal functions (secretion, motility, and absorption).

Circulation

Blood supply to the gastrointestinal tract and spleen is called the splanchnic circulation. The gastrointestinal system receives about one fourth of the resting cardiac output, more than any other organ system. When circulation is impaired (as in shock), perfusion to the splanchnic bed is shunted to the systemic circulation. Because splanchnic organs normally extract only about 20% of the oxygen from the perfusing blood, splanchnic perfusion can be reduced without compromising the organs. However, a severe reduction in splanchnic perfusion can damage the mucosal lining of the gut.

The esophageal artery branches from the thoracic aorta and perfuses the esophagus. Three branches of the abdominal aortic artery perfuse the gastrointestinal organs:

- The celiac axis (consisting of the left gastric artery, the common hepatic artery, and the splenic artery) perfuses the lower esophagus, stomach, duodenum, gallbladder, and liver.
- The superior mesenteric artery perfuses the small intestine to transverse colon.
- The inferior mesenteric artery perfuses the descending colon, sigmoid colon, and rectum.

The areas of perfusion overlap, providing some protection against ischemia.

Venous drainage of the stomach and small and large intestines is primarily through the portal vein to the liver. The blood supply from the lower rectum and the lower esophagus bypasses the portal system. Blood from the rectum drains into the inferior vena cava through the rectal veins, which empty into the external iliac vein. Blood from the esophagus drains through the hemiazygos and azygos veins into the inferior vena cava.

The blood supply of the liver is unique. The liver receives its blood supply from both venous and arterial sources. The venous blood is supplied by the portal vein, which drains most of the blood from the gastrointestinal tract (Fig. 38-5). The portal vein forms behind the spleen at the confluence of the superior mesenteric and splenic veins and leads to the liver. The arterial supply is by the common hepatic artery, which branches from the celiac trunk near the aorta and then perfuses the liver. Both sets of vessels form capillaries and then drain into the hepatic vein, which in turn feeds into the inferior vena cava.

▲ Function of the Gastrointestinal System

The main function of the gastrointestinal tract is to break down nutrients into a form of usable energy. Food is ingested in the form of macromolecules that cannot be absorbed. These macromolecules are converted into usable forms of energy by mixing with digestive enzymes and secretions as

they move through the gastrointestinal tract. These processes will be discussed in relationship to the various parts of the gastrointestinal tract and the secretions and motility that make digestion possible.

Oropharynx

Secretions

The salivary glands of the oropharynx produce saliva. There are three pairs of salivary glands: the submaxillary glands, the sublingual glands, and the parotid glands. These glands are drained by ducts into the mouth. Saliva is composed of mucus (a lubricant that facilitates swallowing), lingual lipase (a fat-digesting enzyme secreted by tongue glands), salivary amylase (an enzyme that breaks down starch), and class A (IgA) antibodies (which provide a first line of defense against bacteria, viruses, and bacteriostatic and carcinogenic chemicals; Table 38-1). A moist oral cavity also facilitates speech. The pH of saliva is 7; saliva contains bicarbonate, which allows it to neutralize acid substances that enter the oral cavity, including regurgitated gastric acid. Lingual lipase

Table 38-1 Major Gastrointestinal Secretions

Location	Daily Volume	Composition (and Action)
Mouth	1,000–2,000 mL	Amylase (carbohydrate digestion) Lipase (fat digestion) Immunoglobulins Mucus Water, electrolytes
Esophagus	300–800 mL	Mucus
Stomach	2,000 mL	Intrinsic factor (vitamin B_{12} absorption) Hydrochloric acid (activates pepsinogen) Pepsinogen (protein digestion) Mucus Water, electrolytes Gastrin (stimulates hydrochloric acid release; trophic effects on mucosa, especially in stomach)
Pancreas	1,200–1,800 mL	Enzymes • Amylase (carbohydrate digestion) • Trypsinogen (protein digestion) • Chymotrypsin (protein digestion) • Elastase (protein digestion) • Carboxypeptidase (protein digestion) • Lipase (fat digestion) • Colipase (fat digestion) • Esterase (cholesterol digestion) • Phospholipase (phospholipid digestion) • Nucleases (RNA and DNA digestion) Bicarbonate (protects luminal wall by neutralizing acid) Water, electrolytes
Liver	500–1,000 mL	Bile salts (emulsify fats) Bilirubin (excretory end product of hemoglobin breakdown) Water, electrolytes
Small intestine	3,000–4,000 mL	Enzymes • Enterokinase (activates trypsinogen) • Lipase (fat digestion) • Enteropeptidase (protein digestion) • Peptidase (protein digestion) • Nucleases (RNA and DNA digestion) • Maltase (carbohydrate digestion) • Lactase (carbohydrate digestion) • Sucrase (carbohydrate digestion) Mucus Bicarbonate Water, electrolytes CCK into blood (stimulates pancreatic secretion and gallbladder contraction) Glucose-dependent insulinotropic peptide into blood (stimulates insulin release and gastric motility, secretion) Gastrin (stimulates gastric acid secretion)
Large intestine	Variable	Mucus

digests about 30% of the dietary fat in the stomach. The salivary glands secrete about one half of the digestive amylase used in digestion; the rest is secreted by the pancreas.

Saliva production is elicited by multiple stimuli, including the sight, smell, or thought of food, and by the pleasant taste or smooth texture of food in the mouth. Rough, bad-tasting, unpleasant-smelling foods reduce salivary gland secretions. Stimuli are received by the two salivary centers in the medulla of the brainstem, which then send impulses to the salivary glands through the seventh and ninth cranial nerves (parasympathetic fibers) and the first and second thoracic nerves (sympathetic fibers). Parasympathetic stimulation, or the administration of drugs that mimic stimulation (cholinergics) or enhance it (neostigmine), promotes copious secretion of watery saliva. Sympathetic stimulation or sympathomimetic drug administration produces a scanty output of thick saliva. Cholinergic blockers (eg, atropine) also inhibit salivation.

Motility

In the mouth, chewing mechanically breaks down food into smaller particles. This produces a bolus of food held together and lubricated by saliva that can then be propelled into the stomach by the process of swallowing. Swallowing is a complex process that has several phases (Fig. 38-6). During the oral phase, the tongue propels the food or fluid bolus to the posterior pharynx. This is a voluntary process. During the involuntary pharyngeal phase, the presence of food or fluid in the pharynx stimulates pharyngeal sensory receptors that initiate impulses through cranial nerve V (the trigeminal nerve) to the swallowing center in the medulla. Sensory impulses reflexively trigger the outflow of impulses down motor fibers in cranial nerve IX (the glossopharyngeal nerve) and cranial nerve X (the vagus nerve) to pharyngeal and laryngeal structures. This causes the following coordinated events, which propel the solid or fluid substance into the esophagus:

1. The soft palate elevates and retracts, sealing off the nasopharynx to prevent regurgitation.
2. The vocal cords close, and the epiglottis closes over the larynx to prevent aspiration.
3. The UES relaxes.
4. The larynx pulls up and increases the opening of the esophagus and UES.
5. The pharyngeal muscles contract, propelling food or fluid into the opened esophagus.

During this phase, respiration is reflexively inhibited. Damage to sensory or motor fibers (in cranial nerves V, IX, or X) or to the swallowing center in the brainstem weakens or eliminates the ability to swallow or causes poorly coordinated swallowing, wherein food or fluid enters the nasopharynx or larynx, or both.

Esophagus

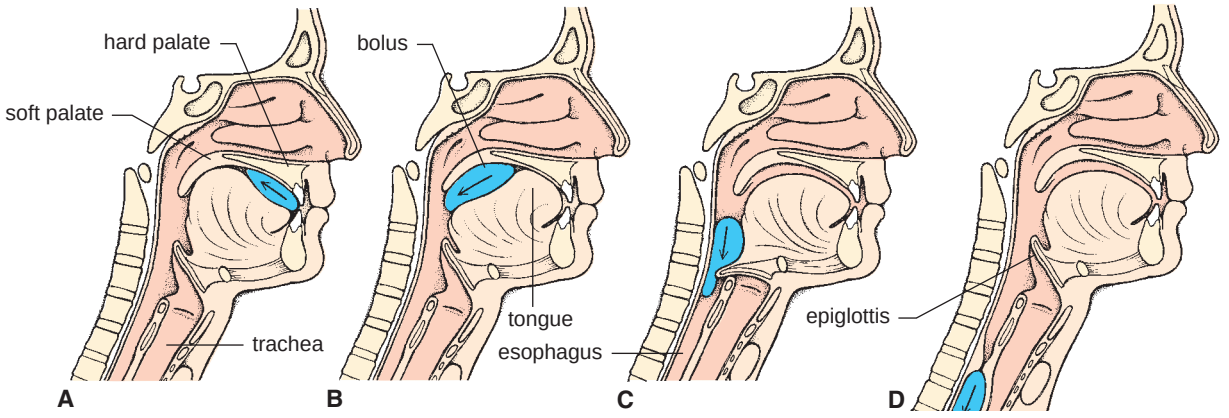
Secretions

Esophageal mucosal cells secrete mucus (see Table 38-1, p. 857). The mucus protects the esophageal lining from damage by gastric secretions or food and acts as a lubricant to facilitate the passage of food.

Motility

The esophageal phase of swallowing begins once food or fluid enters the esophagus (Fig. 38-7). Swallowing-induced contractions of the esophagus are called primary peristalsis. The wave of peristalsis causes the LES to relax, thereby allowing food to enter the stomach. If primary peristalsis cannot clear the esophagus, food or fluid distends the esophagus. This distention stimulates stretch receptors that reflexively promote relaxation of the esophageal muscles ahead of the area of distention as well as contraction of the esophageal muscles in and behind it. This propels the food or fluid ahead into the newly relaxed area, which then becomes distended. This is called secondary peristalsis. The peristalsis reflex repeatedly recurs until the food or fluid arrives at the LES.

The tone of the LES can be altered by a variety of agents (Table 38-2). Some people suffer from a hypertrophic LES, which impedes esophageal emptying (and can lead to overdistention of the lower esophagus), whereas others have an incompetent LES, which results in repeated episodes of gastric reflux (which can lead to lower esophageal strictures).



swallowing: (A) bolus is pushed back; (B) nasopharynx closes; (C) epiglottis closes the trachea; (D) bolus is moved down the esophagus

FIGURE 38-6 ▲ Swallowing. Passage of bolus of food from the mouth through the pharynx.

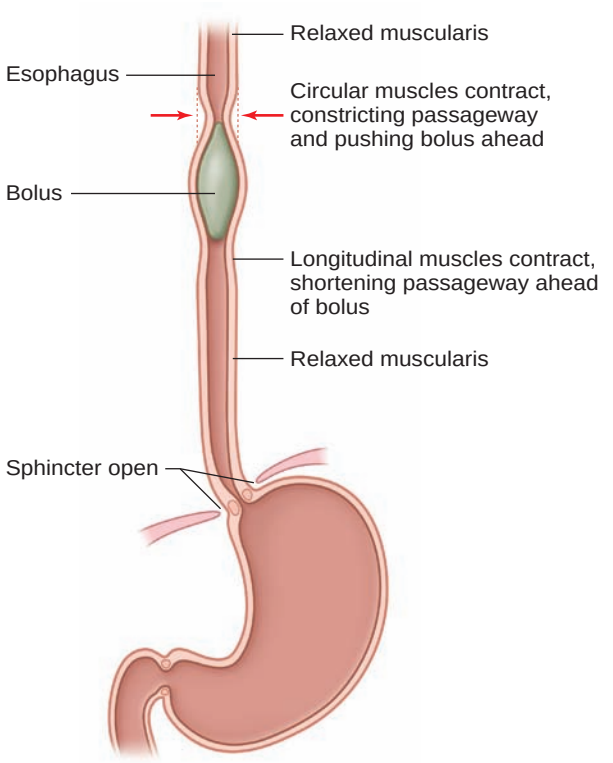


FIGURE 38-7 ▲ Movement of a bolus of food through the esophagus by a peristaltic contraction.

Stomach

Secretions

The major secretions of the stomach are hydrochloric acid, intrinsic factor, pepsinogen, gastrin, and mucus (see Table 38-1, p. 857). The oxyntic glands contain parietal cells that secrete hydrochloric acid and intrinsic factor. Hydrochloric acid converts pepsinogen, which is secreted by the chief cells of the stomach, to pepsin, a proteolytic enzyme. The hydrochloric acid provides an ideal pH for the activity of pepsin; together, hydrochloric acid and pepsin begin the digestion of protein. The chemical action of hydrochloric acid also breaks down food molecules and helps protect the gastrointestinal tract from bacterial invasion. Intrinsic factor is necessary for the absorption of vitamin B_{12} in the small intestine.

G cells, located in the gastric antrum, secrete the hormone gastrin, which promotes the secretion by the chief and parietal cells and promotes the growth of the gastric mucosa (Table 38-3). Overproduction of gastrin, a condition known as Zollinger-Ellison syndrome, results in gastric hypersecretion and peptic ulceration.

Gastric mucosal cells continuously secrete a thin coat of mucus. Mucus, a lubricant, works together with bicarbonate to neutralize acid, protecting the stomach wall from damage. This barrier can be disrupted by a variety of agents, including bile salts, alcohol, aspirin, nonsteroidal anti-inflammatory drugs, and infection with *Helicobacter pylori*.

Table 38-2 Factors Influencing Lower Esophageal Sphincter Tone

Increased Tone	Decreased Tone
Food substances:	Food substances:
Protein	Fats
Drugs:	Coffee
Metoclopramide	Chocolate
Some prostaglandins (F_2)	Alcohol
	Peppermint
	Tomato products
	Citrus juices
	Carbonated beverages
	CCK
	Progesterone (as in pregnancy)
	Somatostatin
	Dopamine
	Some prostaglandins (E_2, A_2)
	Cigarette smoking

Factors Affecting Gastric Secretions

The gastric parietal cells contain receptors for acetylcholine, histamine, and gastrin. Stimulation of these receptors prompts the parietal cells to secrete hydrochloric acid. Hydrochloric acid secretion is inhibited by chemicals that block the histamine receptors (eg, H_2-receptor antagonists) or the acetylcholine receptors (eg, atropine). Proton pump inhibitors inhibit the H^+/K^+-adenosine triphosphatase (ATPase) enzyme pathway, the final common step in the acid secretory pathway. Some prostaglandins also inhibit hydrochloric acid secretion.

Factors that stimulate gastric secretions include alcohol, caffeine, and hypoglycemia. The first two factors act directly by way of gastric chemoreceptors and the intramural nerve plexuses in the stomach wall. Hypoglycemia acts by way of the brainstem and vagal fibers.

Control of Gastric Secretions

Gastric secretions are regulated in three phases: the cephalic phase, the gastric phase, and the intestinal phase (Table 38-4). These phases are controlled by neural and hormonal mechanisms.

In the cephalic phase, the sight, smell, taste, or thought of food stimulates brainstem centers, reflexively prompting parasympathetic (vagal) stimulation of salivation, pancreatic secretion, bile release, and gastric secretions of pepsinogen and hydrochloric acid by the chief and parietal cells, respectively. Sympathetic stimulation can alter the cephalic phase response. This is the mechanism by which emotions can influence gastrointestinal secretions. Fear, anger, and depression decrease secretions.

During the gastric phase, distention of the stomach by food stimulates stretch receptors in the stomach wall. Chemicals, mainly proteins, stimulate chemoreceptors in the mucosa. The stretch receptors and chemoreceptors in turn activate neurons in the submucosal plexus, which then stimulate neurons in the myenteric plexus, which in turn stimulate secretion by the parietal and chief cells. Proteins in the chyme also directly promote gastrin secretion by G cells; the gastrin provides an additional stimulus for parietal and chief cell secretion.

Table 38-3 Hormones Controlling Secretion and Motility

Hormone	Source	Stimulation of Release	Major Function
Gastrin	Stomach, small intestine	Gastric distention, presence of partially digested protein near pylorus	Stimulates • Gastric acid secretion • Gastric intrinsic factor secretion • Gastric motility • Intestinal motility • Mucosal growth • Pancreatic growth • Pancreatic insulin release • Lower esophageal tone
Secretin	Small intestine	Acid entering small intestine	Stimulates • Pancreatic bicarbonate secretion • Pancreatic enzyme secretion • Pancreatic growth • Gastric pepsin secretion • Bile bicarbonate secretion • Gallbladder contraction Inhibits • Gastric emptying • Gastric motility • Intestinal motility
CCK	Small intestine	Fatty acids and amino acids in small intestine	Stimulates • Gastric acid secretion • Gastric motility • Intestinal motility • Colonic motility • Gallbladder contraction and sphincter of Oddi relaxation (thus increasing bile flow into small intestine) • Pancreatic bicarbonate secretion • Pancreatic enzyme release • Pancreatic growth Inhibits • Lower esophageal tone • Gastric emptying
GIP	Small intestine	Fatty acids and lipids in small intestine	Stimulates • Insulin release • Intestinal motility Inhibits • Gastric acid secretion • Gastric emptying • Gastric motility
Motilin	Small intestine	Acid and fat in small intestine	Stimulates • Gastric motility • Intestinal motility

A combination of events eventually brings the gastric phase to a halt: the stretch receptors and chemoreceptors in the wall of the stomach become refractory to stimulation, the acidity of the chyme inhibits further gastrin secretion, and GIP decreases hydrochloric acid secretion and gastric motility.

The intestinal phase begins after chyme reaches the duodenum. The acidity of the chyme stimulates duodenal mucosal cells to release secretin into the bloodstream; proteins and fat trigger the release of cholecystokinin (CCK) into the blood from similar cells, and glucose and fat stimulate the secretion of GIP. Secretin and CCK cause pancreatic secretion and release of gallbladder contents into the duodenum. GIP stimulates the release of insulin from the islets of Langerhans and decreases gastric motility and secretions (see Table 38-3). Stretch receptors in the duodenum trigger peristalsis so that chyme is degraded, mixed with enzymes and diluents, and moved past the highly absorbent small intestinal lumen. If the chyme is less acidic, gastrin is released. Under neural control, motilin is another hormone that is cyclically released during fasting. Motilin stimulates stomach and small intestine motility.

Motility

The passage of food from the esophagus into the stomach reflexively initiates receptive relaxation. After the stomach has filled with food, peristaltic contractions mix the food and propel gastric contents toward the pylorus, where small

Table 38-4 Phases of Gastric Secretion

Phase	Stimulus to Secretion	Effect
Cephalic (neuronal)	Sight, smell, taste of food initiates central nervous system impulse mediated by vagus nerve	Gastric effects: Hydrochloric acid (from parietal cells) Pepsinogen (from chief cells) Mucus secretion Other effects: Salivation Pancreatic secretion Bile release
Gastric (neuronal and hormonal)	Food in antrum initiates central nervous system impulse mediated by vagus nerve	Gastrin release Hydrochloric acid release Pepsinogen release
Intestinal (hormonal)	Chyme in small intestine	pH of chyme <2: release of secretin, gastric inhibitory polypeptide, CCK (decreases gastric acid secretion) pH of chyme >3: release of gastrin (increases gastric acid secretion)

amounts enter the duodenum. The pyloric sphincter plays a minor role in gastric emptying; its main function is to prevent duodenal reflux. The bile acids in the chyme that reenters the stomach through duodenal reflux damage the chemical barrier that coats the surfaces of gastric mucosal cells. Mild peristaltic contractions that persist after the stomach has completely emptied are called hunger contractions; however, they play no role in appetite regulation. Gastric emptying can be retarded by vagotomy; by the presence of fats, proteins, or hydrochloric acid in the duodenal chyme; by duodenal distention; and by intestinal hormones.

Emesis, or vomiting, is the regurgitation of food from the stomach through the mouth. During vomiting, the abdominal muscles and diaphragm contract, and the LES relaxes, allowing reflux of gastric content into the esophagus and propulsion of gastric contents out of the mouth. The reflex elevation of the palate prevents expulsion through the nasopharynx. Respiratory inhibition and closure of the glottis prevent pulmonary aspiration. In addition, irritation of the small intestine (by materials in the chyme, by inflammation, or by a disease process) can cause reverse peristalsis. These movements move chyme toward the pyloric valve. If strong enough to force open the pylorus, intestinal contents may be vomited. When yellow bile from the duodenum is exposed to acid in the stomach, the interaction turns the vomitus green. Occasionally, vomiting of intestinal contents can be so rapid that the vomitus contains yellow bile. When blood is exposed to acid in the stomach, the exposure results in a brownish-black "coffee-ground" emesis. If the rapidity of vomiting does not allow sufficient time for this interaction between acid and blood to occur, blood in the vomitus has its normal red color (hematemesis).

Pancreas

The pancreas is composed of both exocrine and endocrine tissue. The islets of Langerhans, endocrine tissue scattered throughout the pancreas, secrete insulin, glucagon, and pancreatic polypeptide hormones, which aid in the digestive process. The exocrine pancreas is composed of acinar cells, which are arranged in lobules. The acinar cells empty secretions into an internal pancreatic ductal system (Fig. 38-8). These internal ducts drain into progressively larger ducts that terminate in the duct of Wirsung, the main pancreatic duct. This pancreatic duct then joins the common bile duct to form a shared short duct called the ampulla of Vater. This ampulla, carrying bile and pancreatic secretions, opens into the duodenum. A smooth muscle ring, the sphincter of Oddi, encircles the ampulla. Because of the anatomical arrangements between the common bile duct and the duct of Wirsung, a gallstone that obstructs the ampulla of Vater can obstruct the normal flow of bile and pancreatic secretions. (Such obstruction, although rare, can lead to a stasis of pancreatic secretion, resulting in acute pancreatitis.) Some people have a second external pancreatic duct (duct of Santorini) that opens into the duodenum near the pylorus.

The exocrine acinar cells secrete both a watery alkaline bicarbonate solution and enzymes (see Table 38-1, p. 857). The large amount of water secreted by the pancreas is instrumental in diluting chyme before absorption. In addition, the bicarbonate neutralizes the highly acidic chyme from the stomach. The pancreatic enzymes digest proteins (trypsin, chymotrypsin, elastase, and carboxypeptidase), fats (lipase, colipase, and esterase), phospholipase and nucleic acids (nucleases), and starch (amylase). Although pancreatic enzymes require a pH close to neutrality for optimal activity, they are capable of nearly completing the digestion of food in the absence of all other digestive secretions.

Pancreatic enzymes are secreted from the pancreas in their inactive forms. Trypsin inhibitor prevents the premature activation of trypsinogen into its active form, trypsin. Once the pancreatic secretions arrive in the duodenum, trypsinogen is activated by an intestinal mucosal enzyme, enterokinase, into its active form, trypsin. Trypsin then activates the other pancreatic enzymes.

Regulation of pancreatic secretion occurs by neural and hormonal means. Vagal stimulation results in the secretion of pancreatic enzymes. Hormonal regulation occurs as a result of duodenal mucosal responses to chyme and is discussed later.

Gallbladder

In the duodenum, chyme mixed with pancreatic secretions is watery. The fat in chyme is not water soluble and

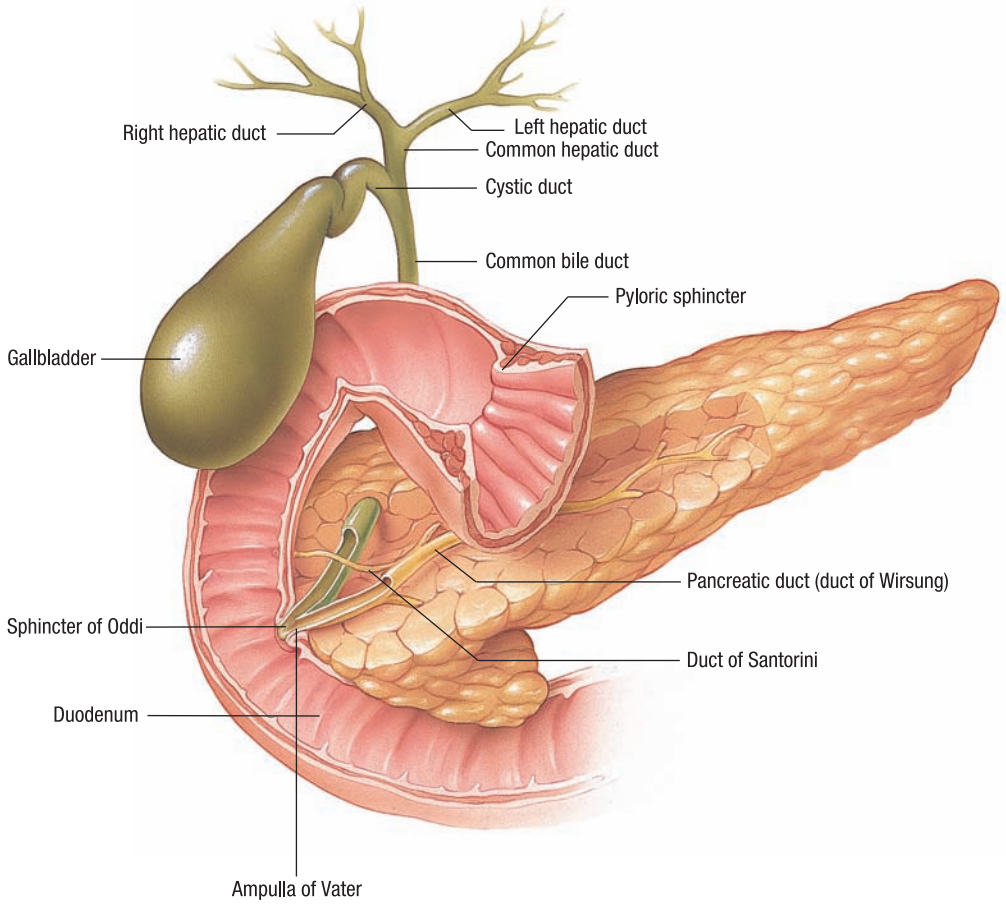

FIGURE 38-8 ▲ Biliary system. (From Anatomical Chart Company: Atlas of Human Anatomy. Springhouse, PA: Springhouse, 2001, p 217.)

requires a solvent enzyme mixture from the liver to render it absorbable by intestinal cells. Hepatocytes, among many other metabolic functions, make bile. Bile is a mixture of bile salts, cholesterol, bilirubin, and acids suspended in water. This solution emulsifies the fat in chyme, breaking the fat into small globules that can be absorbed across the intestinal lumen. The action of bile ionizes fat-soluble vitamins into absorbable forms. Bile also suspends cholesterol, triglycerides, and multiple-density lipoproteins in the bloodstream, thus preventing precipitation and deposition of these molecules in the vasculature until they can be catabolized.

Bile is stored and concentrated in the gallbladder. Gallbladder secretion is greatest during the intestinal phase of digestion. This activity is stimulated by CCK, which is secreted by the intestinal mucosa when fatty acids or amino acids are present. CCK causes gallbladder contraction and relaxation of the sphincter of Oddi, allowing the release of bile into the duodenum to mix with chyme.

Small Intestine

Secretions

In the duodenum, chyme mixes with pancreatic digestive enzymes, alkaline substances, water, mucus, and bile. When the mucosa of the small intestine is exposed to acid in the chyme, secretin is released. Secretin stimulates bicarbonate release by cells that line the bile ducts. The intestinal enzymes secretin, CCK, and enterokinase are added to this mixture, along with mucus, bicarbonate, and water. The small intestine secretes 3 to 4 L a day of alkaline secretions. These intestinal secretions help maintain the liquidity of chyme and can dilute noxious agents.

Motility

The small intestine has two types of characteristic movements, propulsive and mixing. The intramural plexuses initiate and coordinate these movements, but the movements can be enhanced or retarded by extrinsic autonomic stimulation, as discussed previously. Propulsive movements propel food forward, allowing for digestion and absorption. This peristalsis is stimulated by distention. During mixing movement, localized concentric contractions of the intestinal wall called segmentation promote mixing of food particles. These segments have the appearance of linked sausages. Repetition of this process continually kneads the chyme, which increases the exposure of the molecules to the absorptive surfaces of the intestinal mucosa.

Emptying of the small intestine into the colon occurs in the same way as gastric emptying. Peristaltic waves build pressure in the ileum behind the ileocecal valve and push the

chyme through the valve into the colon. The ileocecal valve then prevents backflow. Ileal emptying can be retarded by intramural reflexes, which are initiated by a full (distended) colon.

Absorption

The major functions of the small intestine are absorption and digestion, which are facilitated by secretions from the pancreas, liver, and gallbladder. The mucosal layer of the small intestine has many folds (valvulae conniventes) covered with numerous finger-like projections (villi) and microvilli, which dramatically increase the absorptive surface area of the small intestine.

CARBOHYDRATES. The three major sources of carbohydrates in the human diet are sucrose, lactose, and starch. The breakdown of carbohydrates begins in the mouth when food mixes with salivary amylase during chewing. The digestion continues in the duodenum. Conversion to simple sugars continues in the small intestine by intestinal enzymes. Both active and passive transport are used to absorb sugars across the intestinal lumen into the bloodstream.

PROTEINS. Protein degradation is initiated in the stomach through the actions of hydrochloric acid and pepsin. However, in the absence of pepsin and hydrochloric acid, the small intestine is capable of fully digesting all available protein. Most digestion occurs in the duodenum and jejunum by proteolytic pancreatic enzymes. Polypeptides in the small intestine are degraded into peptide fragments and amino acids by trypsin, chymotrypsin, and carboxypeptidase. Amino acids are absorbed into the blood by active and passive diffusion.

FATS. Triglycerides, lipids, and phospholipids are first degraded in the small intestine. Bile salts, in a process called emulsification, facilitate the creation of small droplets of fats from larger globules. Pancreatic enzymes then degrade the fats into fatty acid chains and monoglycerides. These smaller molecules form into even smaller globules, called micelles. Fatty acids and monosaccharides are transported across the intestinal mucosa from a micelle passively, leaving bile behind.

In the submucosa, free fatty acids are passed into the blood directly, if small enough. If too large for direct passive diffusion, the free fatty acid is reorganized into a triglyceride, coupled with lipoproteins and cholesterol, and passed into the lymph fluid as chylomicron.

The bile left behind in the intestine after absorption of fats from a micelle is reabsorbed in the ileum. If bile salts enter the colon, they decrease the reabsorption of sodium and water, thereby increasing the liquidity of the undigested food residues in the colon. Most fat is absorbed by the time chyme reaches the middle of the jejunum.

VITAMINS, MINERALS, AND WATER. Most vitamins, whether fat or water soluble, diffuse across the intestinal mucosa and submucosa into the blood. Fat-soluble vitamin B_{12} couples with intrinsic factor, forming a larger molecule. In this form, vitamin B_{12} is absorbed in the ileum.

Minerals and electrolytes vary in their absorption. Sodium and iron require active transport, whereas other minerals and electrolytes diffuse passively. Iron is primarily absorbed in the duodenum.

Water is absorbed passively throughout the stomach and small and large intestines. The gastrointestinal tract is highly permeable, in both directions, to water. If a hypertonic solution enters the duodenum, osmosis occurs within the lumen. The converse is also true: a hypotonic chyme in the stomach and duodenum causes extremely rapid movement of water into the bloodstream.

Large Intestine

Secretion

The goblet cells of the colonic mucosa secrete mucus, which lubricates the passage of chyme (see Table 38-1, p. 857). The production of mucus is stimulated by irritation and by cholinergic activation.

Motility

Colonic movements include mixing and peristaltic movements. These operate as described for the small intestine. A third movement, unique to the colon, is mass movement. This consists of simultaneous contractions of colonic smooth muscle over large portions of the descending and sigmoid portions of the colon. Mass movement rapidly moves the undigested food residue (feces) from these areas into the rectum.

Humans cannot digest the cellulose, hemicellulose, or lignin in plant tissues. These plant materials form a large portion of the undigested food residue. They are usually termed vegetable fiber or dietary bulk. These fibers attract and hold water, creating a larger, softer stool. Low quantities of bulk result in a relatively inactive colon, leading to bowel movements that are relatively infrequent and feces that are relatively small, dry, and difficult to pass. Epidemiological reports suggest that high-fiber diets are associated with a decreased incidence of diverticulitis and colon cancer.

Filling of the rectum triggers the defecation reflex by stimulating stretch receptors in the rectal wall. Stimulation of the stretch receptors causes sensory (afferent) nerve fibers to transmit impulses to the lower spinal cord. Because of anatomical arrangements of neurons in this part of the cord, these afferent impulses reflexively cause nerve impulses to travel out of the cord along parasympathetic motor fibers that innervate the smooth muscles of the descending and sigmoid colon, the rectum, and the internal anal sphincter. The afferent impulses also reflexively cause nerve impulses to be sent out of the cord along somatic motor neurons that innervate the skeletal muscle of the external anal sphincter. The total effect of these events is to produce coordinated expulsive contractions of the colon and rectum, relaxation (opening) of the sphincters, and expulsion of feces from the anus.

The urge to defecate begins after the pressure within the rectum reaches 18 mm Hg. After intrarectal pressure reaches 55 mm Hg, reflex bowel evacuation occurs. This defecation reflex is inhibited in a continent person by descending neuronal impulses from higher brain centers that inhibit the actions of the somatic motor neurons that innervate the external sphincter. Such inhibition keeps the

external anal sphincter closed, thereby averting inappropriate defecation. After a few minutes, the defecation reflex subsides, but it usually becomes active again a few hours later. Defecation is a spinal cord reflex that does not require intact pathways between the sacral cord and the brain. In the early posttraumatic phase of spinal shock, the reflex does not work. After cord shock is ended, reflex defecation occurs once again, but voluntary inhibition is not possible (neurogenic bowel).

Absorption

In the large intestine, most of the water and potassium are absorbed from the chyme. This produces a semisolid residue of undigested food (feces) that can be eliminated from the body. Diarrhea can reduce the transit time for chyme, thereby limiting such potassium and water reabsorption. This can result in hypokalemia and dehydration. Diarrhea can be caused by materials that hold water in the chyme (eg, magnesium sulfate), resulting in semiliquid stool.

At birth the colon is sterile, but large colonic bacterial populations become established soon afterward. Some of these organisms produce vitamin K and a number of B vitamins. Other bacteria produce ammonia, which is absorbed. Normally, ammonia is removed from the blood once it reaches the liver. However, in people with seriously impaired liver function or with collateral circulatory routes that bypass the liver (usually the result of portal hypertension), ammonia can remain in the circulation and lead to hepatic encephalopathy.

Liver

The liver lies in the right upper quadrant of the abdomen. It has two lobes (right and left) and lies just below the diaphragm, with its greatest portion located on the right side of the body. Its superior (rounded) surface fits into the curve of the diaphragm and is in contact with the anterior wall of the abdominal cavity. The inferior surface is molded over the stomach, the duodenum, the pancreas, the hepatic flexure of the colon, the right kidney, and the right adrenal gland.

The liver is covered with a thin layer of peritoneum over a thin fibrous coat called Glisson's capsule. This fibrous capsule encases and partitions the liver, sending inward fibrous sheets that divide the liver into functional units called lobules. Each lobule consists of sheets of hepatocytes organized around a core cluster of vessels called the portal triad (Fig. 38-9). The portal triad includes the two sets of afferent vessels (portal vein and hepatic artery) and a small bile duct. The afferent vessels lead to the liver sinusoids, which drain into the efferent hepatic vein, lying at the periphery of each lobule.

The lobule measures approximately 1.5 mm in diameter and 8 mm in length. Each lobe of the liver contains between 50,000 and 100,000 lobules. Rows of hepatocytes radiate from a central venule like spokes of a wheel. Branches of the hepatic artery and the hepatic portal vein lie at the periphery of the wheel. Blood from these branches is poured into open channels (hepatic sinuses) that run between alternate rows of hepatocytes. Kupffer's cells, specialized white cells of the reticuloendothelial system, phagocytize bacteria, debris, and

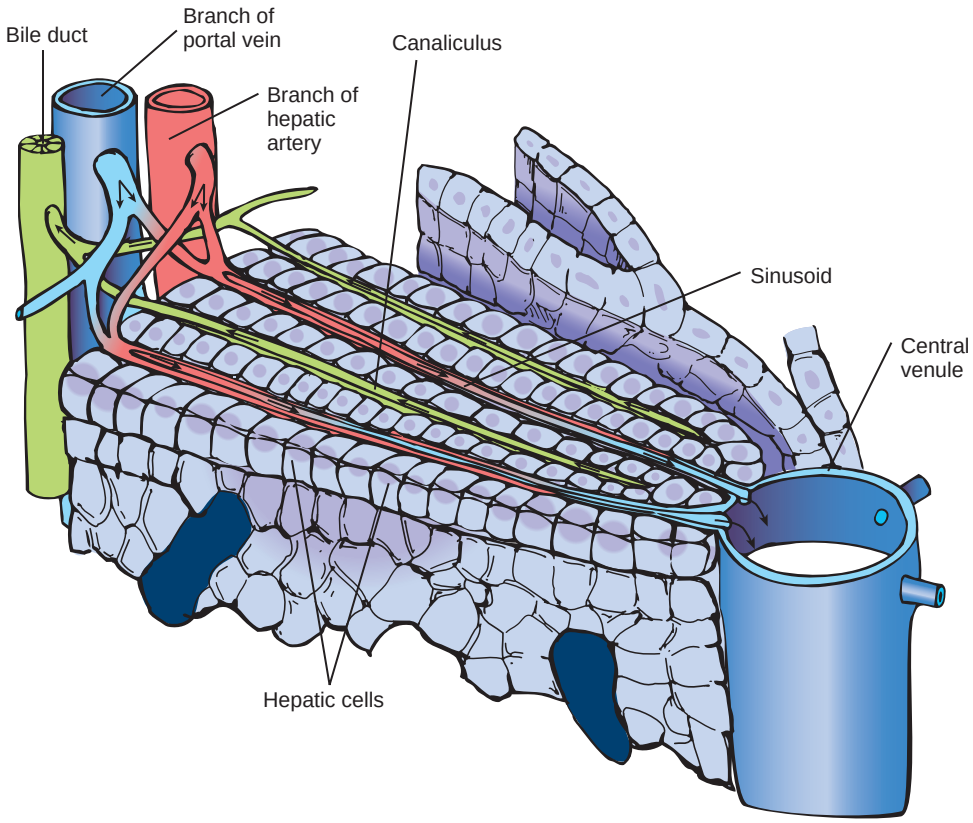

FIGURE 38-9 ▲ A section of the liver lobule showing the location of the hepatic veins, hepatic cells, liver sinusoids, and branches of the portal vein and hepatic artery.

other foreign matter in the sinus blood. The sinuses drain into the central venule, which in turn carries blood to the hepatic vein.

Blind-ended bile canaliculi arise between the other rows of hepatocytes. They carry newly secreted bile to larger ducts located at the periphery. These smaller ducts eventually drain into the common bile duct. Bile that is leaving the liver is concentrated and stored in the gallbladder. Fluid and electrolyte reabsorption in the gallbladder can increase the concentration of bile salts, cholesterol, and bilirubin 12-fold.

The gallbladder has a maximum capacity of 50 mL and can hold a 24-hour output of bile (600 mL) from the liver. The intestinal hormone CCK (secreted by the duodenal mucosa) and vagus nerve activity stimulate gallbladder contraction as a part of food digestion, particularly lipids. CCK and local reflexes initiated by duodenal peristalsis open the sphincter of Oddi. These events permit an outflow of bile down the common bile duct into the duodenum.

The common bile duct and the main duct from the pancreas usually unite just before the duct enters the lumen of the duodenum. There is often a dilation of the tube after this junction (the ampulla of Vater). The opening of the common bile duct in the duodenum is about 8 to 10 cm from the pylorus.

The liver cells perform many vital functions, as described in the sections that follow and summarized in Table 38-5.

Carbohydrate Metabolism

The liver participates in carbohydrate metabolism. The liver and skeletal muscle are the two primary sites of glycogen storage. Serum glucose levels are maintained by hepatic glycostatic function, involving two mechanisms. When plasma glucose levels are high, hepatocytes remove glucose from the plasma. Some of this glucose is then stored in the liver as glycogen. If plasma glucose levels decline, hepatocytes convert the glycogen back into glucose through a process called glycogenolysis, and the glucose is released into the bloodstream. Although many body tissues have the requisite cellular enzymes for glycogenolysis, hepatocytes are one of the few cell types that can release this intracellular glucose into the bloodstream. Hepatocytes do not simply respond directly to plasma glucose. These glycostatic functions are mediated by several hormones; some (eg, insulin) promote hepatic glucose uptake, and others (eg, glucagon, growth hormone, and epinephrine) stimulate glycogenolysis and the release of glucose from liver cells.

The liver does not contain enough glycogen reserves to be able to buffer plasma glucose during prolonged fasting or severe exercise. During these times, low plasma glucose levels stimulate the secretion of one or more hormones (glucagon, glucocorticoids, or thyroxine) that trigger the biochemical conversion of intracellular fatty and amino acids into glucose (gluconeogenesis), which the liver cell can then release into the bloodstream or store as glycogen. Only hepatocytes

Table 38-5 Hepatic Function

General Category	Specific Description
Carbohydrate metabolism	Glycogenesis (conversion of glucose to glycogen) Glycogenolysis (breakdown of glycogen to glucose) Gluconeogenesis (formation of glucose from amino acids or fatty acids)
Protein metabolism	Synthesis of nonessential amino acids Synthesis of plasma proteins (albumin, prealbumin, transferrin, clotting factors, complement factors; not γ-globulin or immunoglobulins) Urea formation from NH_3 (NH_3 formed by deamination of amino acids in liver and by action of colonic bacteria on proteins)
Lipid and lipoprotein metabolism	Synthesis of lipoproteins Breakdown of triglycerides into fatty acids and glycerol Formation of ketone bodies Synthesis of fatty acids from amino acids and glucose Synthesis and breakdown of cholesterol
Bile acid synthesis and excretion	Bile formation (containing bile salts, bile pigments [bilirubin, biliverdin]), cholesterol Bile excretion
Storage	Glucose (as glycogen) Vitamins (A, D, E, K, B_1, B_2, B_{12}, folic acid) Fatty acids Minerals (Fe, Cu) Amino acids (as albumin, β-globulins)
Biotransformation, detoxification, excretion of endogenous and exogenous compounds	Inactivation of drugs and excretion of the breakdown products Clearance of procoagulants, activated clotting factors, byproducts of coagulation
Removal of pathogens	Clearance of microorganisms by macrophages
Steroid catabolism	Conjugation and excretion of gonadal steroids Conjugation and excretion of adrenal steroids (cortisol, aldosterone)

possess the enzyme that is critical for gluconeogenesis. Glycogen storage is important for other functions of liver cells. A glycogen-rich hepatocyte conjugates bilirubin at a faster rate and is more resistant to toxins and infectious agents.

Protein Metabolism

The liver plays an essential role in the metabolism of proteins. The amino acids that result from the breakdown of proteins are deaminated to form ammonia by the liver and then converted to urea. The liver also synthesizes plasma proteins, including albumins, globulins, fibrinogens, plasma lipoproteins, and other proteins involved in clotting. The albumins maintain normal plasma oncotic pressure. A fall in this pressure leads to edema (both systemic and pulmonary) and contributes to ascites. The globulins bind thyroid and adrenal hormones. Bound, the hormones are inactive. Decreased hepatic protein levels can lead to a clinical excess of these hormones.

Lipid and Lipoprotein Metabolism

The liver contributes to adipose stores through the metabolism of triglycerides, fatty acids, and cholesterol. During fasting, triglycerides from adipose tissue are catabolized by the liver into fatty acids and glycerols. The free fatty acids in prolonged fasting are further catabolized into acetyl coenzyme A and then into ketone bodies. Ketone bodies provide an energy source for some (nonneuronal) tissues.

Bile Acid Synthesis and Excretion

Hepatocytes make bile, which contains water, bile salts, cholesterol, bilirubin, gluconate, and inorganic acids. Bile salts aid digestion by emulsifying dietary fats and fostering their absorption and the absorption of fat-soluble vitamins through the intestinal mucosa. They also prevent the cholesterol in the bile from precipitating out of solution and forming calculi. More than 90% of the daily output of bile is reabsorbed for recycling by an active transport process of the ileal mucosa.

Another hepatic function is elimination of bilirubin from the body. Old or defective erythrocytes are phagocytosed by large reticuloendothelial cells that line the large veins and the sinuses of the liver and spleen. These phagocytes degrade the hemoglobin of these cells into biliverdin, iron, and globulin molecules. The last two components are recycled by the body and used for future erythropoiesis. The biliverdin is almost immediately converted to free bilirubin. Because free bilirubin is an insoluble compound, it is transported bound to plasma albumin molecules. The hepatocytes convert this insoluble bilirubin into a soluble (and thus excretable) form by conjugating it with glucuronic acid to form bilirubin gluconate. This soluble form of bilirubin is then added to the bile and is eliminated from the body by the feces. Bilirubin gluconate gives the bile its normal golden yellow color. Organisms in the intestine convert most of the bilirubin gluconate into a darker brown compound, urobilinogen, which gives the feces its natural brown color. Because it is soluble in water, urobilinogen can also be absorbed from the colon back into the bloodstream and can be excreted by the kidneys. Excess plasma levels of either conjugated (direct) or unconjugated (indirect) bilirubin produce jaundice. Excess unconjugated bilirubin can cross the immature or damaged blood–brain barrier and bind with the basal ganglia, resulting in kernicterus.

Storage

Fat-soluble vitamins and many minerals are stored in the liver. These vitamins and minerals are released under the influence of hormones and serum concentrations of inorganic elements.

Biotransformation

Hepatocytes possess a mixed-function oxidase (MFO) system of enzymes that degrade certain drugs, including alcohol, benzodiazepines, tranquilizers, phenobarbital, phenytoin, and sodium warfarin, among others. This system operates in addition to other intracellular systems that also degrade some of these drugs. Its clinical significance lies in the nature of the drugs that this system catabolizes and in the fact that MFO system activity can be either inhibited or augmented (induced) by these same drugs, depending on when they are taken.

Administration of two MFO system–catabolized drugs within a few hours of one another or together causes each agent to act competitively, slowing down the degradation of the other. For example, simultaneous ingestion of diazepam (Valium) and alcohol can result in slower degradation of each drug. The outcome is higher blood levels of both chemicals for a longer time after administration.

The repeated administration of one MFO system–catabolized drug for several days causes the MFO system to enlarge physically and to possess more enzymes. This is called induction. Once induced, the MFO system degrades drugs more rapidly (including the drug that initiated the induction). If administration of a second MFO system–catabolized drug is begun after MFO system induction, a larger dose of this drug is required to produce a given effect. For example, induction of the MFO system by diazepam increases the dosage of warfarin needed to produce a given therapeutic effect. Other drugs are degraded by various hepatic systems.

Steroid Catabolism

The liver cells degrade steroid hormones, thereby preventing excess serum levels of estrogen, testosterone, progesterone, aldosterone, and glucocorticosteroids.

▲ Clinical Applicability Challenges

SHORT ANSWER QUESTIONS

1. Mr. K. is a 59-year-old male with a history of oropharyngeal cancer treated with radiation therapy which resulted in xerostomia. Discuss the role of saliva. Xerostomia may put Mr. K. at risk for what potential problems?

2. Mrs. C. complains of diarrhea after a cholecystectomy. Discuss how this surgery could contribute to her diarrhea.

3. Ms. Z. complains of an unintentional weight loss of 25 pounds over the past 2 months. She was subsequently diagnosed with a malabsorption deficiency. Which nutrient deficiencies would you expect and why?

39 Patient Assessment: Gastrointestinal System

JoAnn Coleman

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Explain the nursing role in assessing the critical care patient with gastrointestinal (GI) compromise.
2. Discuss important health history components that provide information about GI system status.
3. Describe a systematic approach for conducting a complete GI physical examination.
4. Discuss the importance of referred pain patterns in an abdominal assessment.
5. Differentiate between normal and abnormal findings detected on physical assessment of the GI system.
6. Identify the data used to make judgments about nutrition and metabolism in a critical care patient.
7. Discuss appropriate studies and procedures used to diagnose GI disorders.

The gastrointestinal (GI) system is a long tube with glands and accessory organs (salivary glands, liver, gallbladder, and pancreas). The GI tract begins at the mouth; extends through the pharynx, esophagus, stomach, small intestine, colon, and rectum; and ends at the anus. It is an unsterile system filled with bacteria and other flora. These organisms can cause superinfection from antibiotic therapy, and they can infect other systems when an organ of the GI tract ruptures. A malfunction along the GI tract can produce a variety of metabolic effects, which eventually may be life threatening.

Assessment of the GI system in a critically ill patient provides essential information. Early identification and treatment of GI disorders is necessary and serves as a foundation for developing a holistic plan of care for the patient. Ongoing assessment of the GI system in the critical care patient may help identify new complications. The ability to complete a comprehensive assessment of the GI system depends on the status of the patient. In an intensive care environment, the dynamic nature of the patient may dictate a more focused assessment of the patient. The nurse must be perceptive in obtaining information and timely in soliciting critical information. For example, a ventilated patient cannot converse in an intensive care area, and neither can a comprehensive assessment of the GI system be obtained nor would it be necessary at that time.

When a patient is critically ill, assessment of the GI system helps determine whether assessment findings relate to the current clinical problem or herald a new complication. The nurse correlates and integrates presenting GI signs and symptoms, whether they are isolated entities or related to another underlying problem: Is the bright red blood in the stool a result of GI bleeding or from external bleeding hemorrhoids? Is the abdominal pain due to recent bowel surgery or to a distended stomach? The nurse must be aware of the patient's changing metabolic state and nutritional status because this information may directly affect other health outcomes, such as length of stay, morbidity, and even mortality.[1]

▲ History

Unless emergency conditions require immediate action to preserve life, an assessment of the GI system begins with the history. A thorough and accurate history greatly enhances the assessment process. The patient's history provides information that can lay the foundation and set the direction for the rest of the assessment.

The history is the major subjective data source about a patient's health status and provides insight into actual or potential health problems. It guides the physical assessment. The history organizes pertinent physiological, psychological, cultural, and psychosocial information as it relates to the patient's current health status and accounts for factors such as lifestyle, family relationships, and cultural influences.[2] Box 39-1 lists elements for a comprehensive GI health history.

The initial presentation of the patient in the intensive care area determines how quickly the history will be obtained

BOX 39-1 HEALTH HISTORY for Gastrointestinal Assessment

Chief Complaint
- Patient's description of the problem

History of the Present Illness
- Complete analysis of the following signs and symptoms (using the NOPQRST format; see Box 17-1, p. 207):
- Abdominal pain
- Anorexia
- Indigestion (heartburn)
- Dysphagia
- Eructation
- Nausea
- Vomiting
- Hematemesis
- Fever and chills
- Jaundice
- Pruritus
- Diarrhea
- Constipation
- Flatulence
- Bleeding
- Hemorrhoids
- Melena
- Change in appetite
- Recent weight gain or weight loss
- Mouth lesions
- Anal discomfort
- Fecal incontinence
- Change in abdominal girth

Past Health History
- Relevant childhood illnesses and immunizations: hepatitis, influenza, pneumococcal, meningococcal
- Past acute and chronic medical problems: treatments and hospitalizations—diabetes, cancer, inflammatory bowel disease (Crohn's disease, ulcerative colitis, irritable bowel syndrome, diverticulitis), peptic ulcer, gallstones, polyps, pancreatitis, hepatitis or cirrhosis of the liver, previous GI bleeding, cancers or tumors of the GI tract, spinal cord injury; for women, episiotomy or fourth-degree laceration during delivery
- Risk factors: age, heredity, gender, race, tobacco use, physical inactivity, obesity, diabetes mellitus, tattoos, exposure to infectious diseases—hepatitis and influenza
- Past surgeries: previous GI surgeries (mouth, pharyngeal, esophageal, stomach, small intestine, colon, gallbladder, liver, gallbladder, pancreas), abdominal surgeries or trauma
- Past diagnostic tests and interventions: upper endoscopy, colonoscopy, upper GI, barium enema, rectal manometry
- Medications (prescription drugs, over-the-counter drugs, vitamins, herbs, and supplements): aspirin, steroids, anticoagulants, nonsteroidal anti-inflammatory drugs, laxatives, stool softeners
- Allergies and reactions to medications, foods, contrast dye, latex or other materials
- Transfusions, including type and date

Family History
- Health status or cause of death of parents and siblings: inflammatory bowel disease, Hirschsprung's disease, aganglionic megacolon, malabsorption syndrome, cystic fibrosis, celiac disease, gallbladder disease, Peutz-Jeghers syndrome, familial adenomatous polyposis, familial Mediterranean fever, any cancers of the GI tract

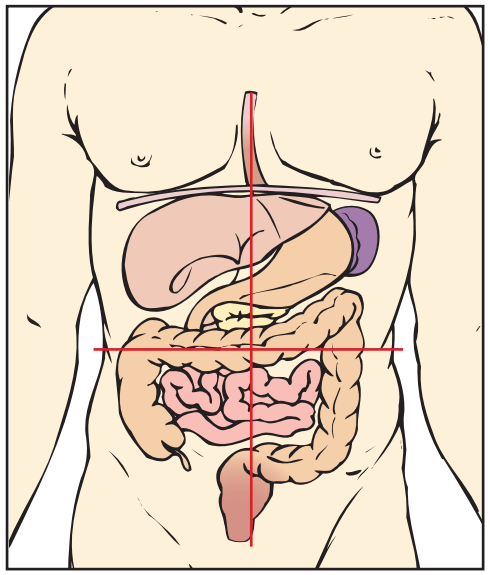
Personal and Social History
- Tobacco, alcohol, and substance use
- Family composition
- Occupation and work environment
- Living environment, water source
- Diet: food intolerances, taste sensations, coffee intake, special diet
- Oral hygiene: dental status, pattern of dental care, dentures, braces, bridges, crowns, caries
- Bowel habits
- Sleep patterns
- Exercise
- Cultural beliefs
- Spiritual/religious beliefs
- Coping patterns and social support systems
- Leisure activities
- Sexual activity
- Recent stressful events: physical or psychological
- Recent travel, overseas military duty

Review of Other Systems
- HEENT: visual changes, headaches, tinnitus, vertigo, epistaxis, sore throat, mouth lesions, swollen glands, lymphadenopathy
- Respiratory: shortness of breath, dyspnea, cough, sputum, lung disease, recurrent infections
- Cardiovascular: chest pain, palpitations, orthopnea, edema, hypertension, congestive heart failure, dysrhythmia, angina, valvular disease
- Genitourinary: incontinence, erectile dysfunction, dysuria, frequency, nocturia
- Musculoskeletal: pain, weakness, varicose veins, change in sensation
- Neurological: transient ischemic attacks, stroke, change in level of consciousness, syncope, seizures, cerebrovascular disease

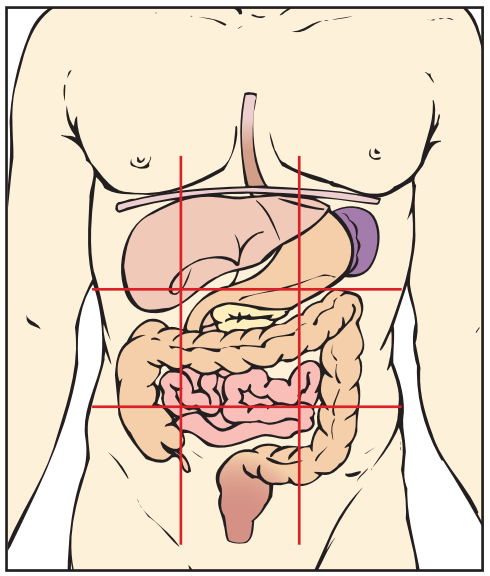
as well as the focus of the interview. If the patient is in acute distress, the history must focus on obtaining answers to pertinent questions about the patient's chief complaint and precipitating events. Information may be more readily obtained from family members or friends. The nurse can obtain a more thorough history from a patient in no obvious distress by focusing on the patient's current symptoms, medical history, and family history. Information that is fixed and needs to be obtained only once includes data about personal health, preexisting GI conditions, previous GI or abdominal surgeries or injuries, and hospitalizations. The critical care nurse must also consider the present nutritional status of the patient, the projected length of illness, and its impact on future nutritional needs or adjustments.[3]

The GI assessment may change over the course of the illness. The data gathered during the initial history may have focused on the pressing issues facing the patient at that time, but these issues can change in a short or protracted amount of time. The critical care nurse must be vigilant, and he or she must maintain data and incorporate additional information to provide individualized and holistic nursing care as the status of the patient continually evolves.

Because pain is often the chief complaint of patients presenting with abdominal disorders, it must be dealt with in detail.[4] A thorough assessment of pain must include details about the onset, progression, migration, character, localization, radiation, and duration of the pain, as well as information about factors that exacerbate or alleviate the pain.



Right upper quadrant (RUQ)	Left upper quadrant (LUQ)
Liver and gallbladder Pylorus Duodenum Head of pancreas Hepatic flexure of colon Portions of ascending and transverse colon	Left liver lobe Stomach Body and tail of pancreas Splenic flexure of colon Portions of transverse and descending colon
Right lower quadrant (RLQ)	**Left lower quadrant (LLQ)**
Cecum and appendix Portion of ascending colon	Sigmoid colon Portion of descending colon



Right hypochondriac	Epigastric	Left hypochondriac
Right liver lobe Gallbladder	Pyloric end of stomach Duodenum Pancreas Portion of liver	Stomach Tail of pancreas Splenic flexure of colon
Right lumbar	**Umbilical**	**Left lumbar**
Ascending colon Portions of duodenum and jejunum	Omentum Mesentery Lower part of duodenum Jejunum and ileum	Descending colon Portions of jejunum and ileum
Right inguinal	**Suprapubic or hypogastric**	**Left inguinal**
Cecum Appendix Lower end of ileum	Ileum	Sigmoid colon

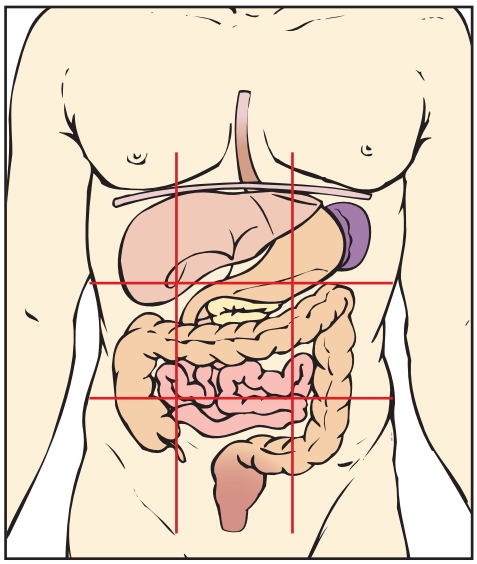
FIGURE 39-1 ▲ To aid accurate abdominal assessment and documentation of findings, the nurse can mentally divide the patient's abdomen into regions. **A:** The quadrant method. **B:** The nine regions method.

To help understand the potential origin, location, and radiation of the pain, the nurse mentally divides the abdomen into regions using either the quadrant method or the nine regions method (Fig. 39-1). Figure 39-2 summarizes common causes of pain by location.

With many GI problems, the pain is referred, which makes diagnosis especially difficult. Referred pain is pain felt at a site different from that of the involved organ. Pain results because nerves that supply an organ also supply the body surface.[4] Figure 39-3 identifies common sites of referred abdominal pain.

▲ Physical Examination

The physical examination helps establish baseline information about the physical dimensions of the patient's present situation. The physical assessment begins by observing the



Right hypochondriac	Epigastric	Left hypochondriac
Cholecystitis/ cholangitis Hepatitis Metastatic disease to the liver Pleurisy, lower lobe pneumonia, or pneumothorax Congestive hepatomegaly Pyelonephritis Renal colic Duodenal ulcer	Duodenal or gastric ulcer Duodenitis or gastritis Pancreatitis Myocardial infarction or angina Pericarditis Gastroenteritis Mesenteric embolus or thrombus Small bowel obstruction	Pleurisy, lower lobe pneumonia, or pneumothorax Myocardial infarction or angina Pericarditis Pyelonephritis Renal colic Splenic injury
Right lumbar	**Umbilical**	**Left lumbar**
Pancreatitis Pyelonephritis Renal colic Colon obstruction/ gangrene	Appendicitis Small bowel obstruction Rectus sheath hematoma Gastroenteritis Umbilical hernia Abdominal aortic aneurysm Aortic dissection Mesenteric embolus or thrombus	Pancreatitis Pyelonephritis Renal colic Sigmoid diverticulitis Colon obstruction/ gangrene

Meckel's diverticulum Appendicitis Cecal perforation Groin hernia Colon obstruction/ gangrene Ectopic pregnancy Spigelian hernia Regional enteritis	Rectus sheath hematoma Salpingitis Ectopic pregnancy Tubo-ovarian torsion Mittelschmerz Regional enteritis Endometriosis Abdominal aortic aneurysm	Sigmoid diverticulitis Groin hernia Colon obstruction/ gangrene Ectopic pregnancy Spigelian hernia Regional enteritis

FIGURE 39-2 ▲ Common causes of pain by location.

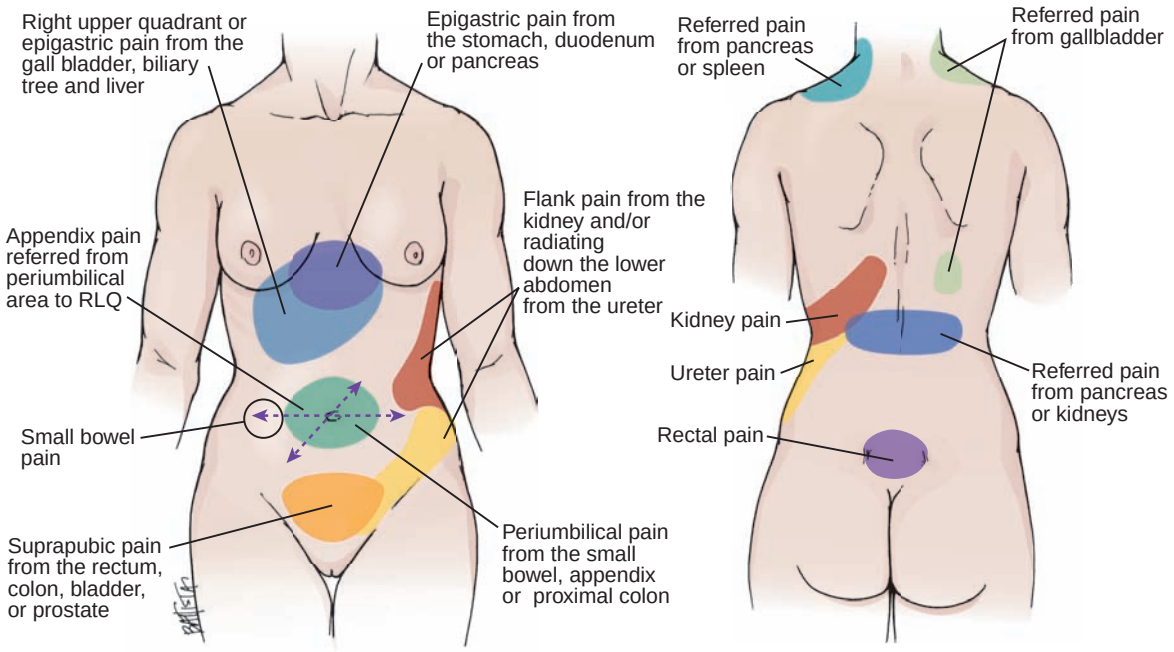

FIGURE 39-3 ▲ Mechanisms and sources of abdominal pain. Abdominal pain may be described as visceral, parietal, or referred. (From Weber J, Kelley J: Health Assessment in Nursing, 4th ed. Philadelphia, PA: Wolters Kluwer Health, 2010, p 418.)

patient's overall appearance. Motor activity, body position, gait, hair (pattern, loss), skin color (jaundice, cyanosis, pallor) and quality (edema), facial expression, level of consciousness, and signs of depression, anxiety, confusion, or irritability are noted. It is important to note that changes in fluid and electrolyte balance, severe infection, drug toxicity, and hepatic disease may cause a change in behavior, such as confusion, lethargy, or agitation. Next, a focused examination of the GI system is necessary. A focused examination of the GI system includes evaluation of the oral cavity and throat, abdomen, and rectum. Assessment of the abdomen includes assessment of the liver, gallbladder, and pancreas.[3]

Oral Cavity and Throat

Adequate nutrition is related to good dental health and the general condition of the mouth. Any disorders of the upper GI tract (lips, mouth, teeth, pharynx, and esophagus) can prevent adequate nutritional intake. Changes in the oral cavity may influence the type and amount of food ingested and the extent to which food is properly mixed with salivary enzymes. Esophageal problems can also adversely affect food and fluid intake, jeopardizing a patient's health.

Examination of the oral cavity includes inspection and palpation using a good light source, a tongue depressor, an examining glove, and a mask (Fig. 39-4). The nurse should explain the procedure to the patient. The patient assumes a comfortable position that facilitates examination. Sitting upright is the best position for this part of the examination.

Inspection of the lips and jaws for abnormal color, texture, lesions, symmetry, and swellings is essential. Palpation of the temporomandibular joints for mobility, tenderness, and crepitus is also warranted. The nurse retracts the lips to allow adequate visualization. It is necessary to inspect dentures for fit and to remove them for the oral examination. The nurse should use a good light source to inspect all structures inside the mouth and the buccal mucosa (see Fig. 39-4). The nurse identifies missing, broken, loose, and decayed teeth while noting redness, pallor, white patches, plaques, ulcers, petechiae, bleeding, and masses. A pool of saliva under the tongue helps assess hydration. Palpation of the parotid and submaxillary ducts is necessary. The nurse palpates suspect areas with a gloved finger to determine tenderness or induration. The patient sticks out his or her tongue while the nurse checks for symmetry of movement, swelling, lesions, and any abnormal coating. While depressing the tongue with a tongue blade, the nurse observes the movement of the soft palate and uvula as the patient says "ah." These structures should rise symmetrically. This is a good time to inspect the hard and soft palates, uvula, tonsils, pillars, and posterior pharynx (Fig. 39-5). Note decreased or absent gag reflex, which suggests possible neurological dysfunction and increases the patient's risk for aspiration. Deviation of the uvula to one side when the patient says "ah" may indicate pathology of cranial nerve IX (the glossopharyngeal nerve) or cranial nerve X (the vagus nerve).[4] Unusual breath odors may indicate serious GI disease, such as esophageal cancer. Fecal breath odor may be caused by a bowel obstruction or hepatic failure; a fruity breath odor may be the result of diabetic or starvation ketoacidosis. Table 39-1 reviews oral assessment, normal and abnormal findings, and possible causes of abnormal findings.

Examination of the oral cavity in an intubated patient is very important, even though the tube may hinder vision during the assessment. The condition of the mouth of a critically ill patient can change rapidly, and the nurse must conduct a periodic assessment to initiate treatment and intervene to prevent complications. It is necessary to assess the presence of any secretions, oral odor, or changes in odors coming from the oral cavity promptly. Studies have indicated that microbial colonization of the oropharynx and dental plaque are associated with pneumonia in patients who are receiving mechanical ventilation.[5]

Evidence now shows that implementing the use of appropriate tools at the bedside, a comprehensive oral care protocol, and staff compliance with the protocol can reduce the rate of ventilator-associated pneumonia (VAP) and associated costs.[6–8] The economic burden from VAP is associated with increased hospital costs, longer duration of hospital stay, and a higher number of services affected.[9]

The patient with a nasogastric, orogastric, or long tube for intestinal decompression warrants close observation because these tubes prevent the lower esophageal sphincter

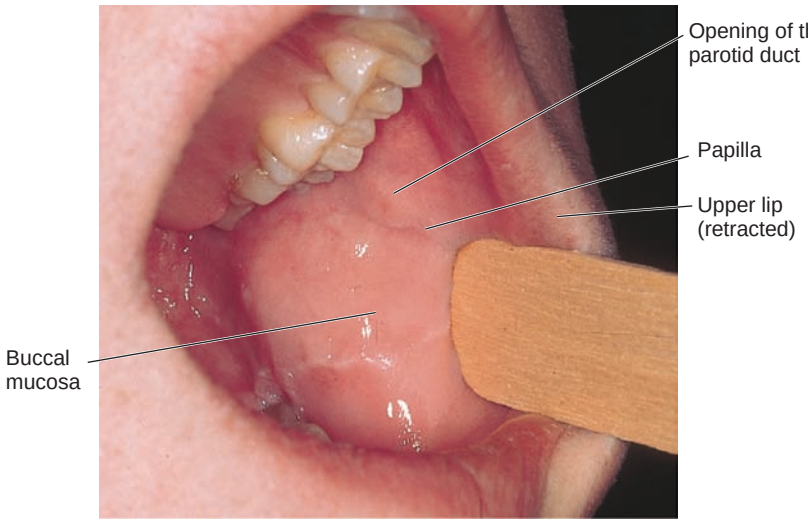

FIGURE 39-4 ▲ Examination of the oral cavity. (From Bickley L: Bates' Guide to Physical Examination and History Taking, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 234.)

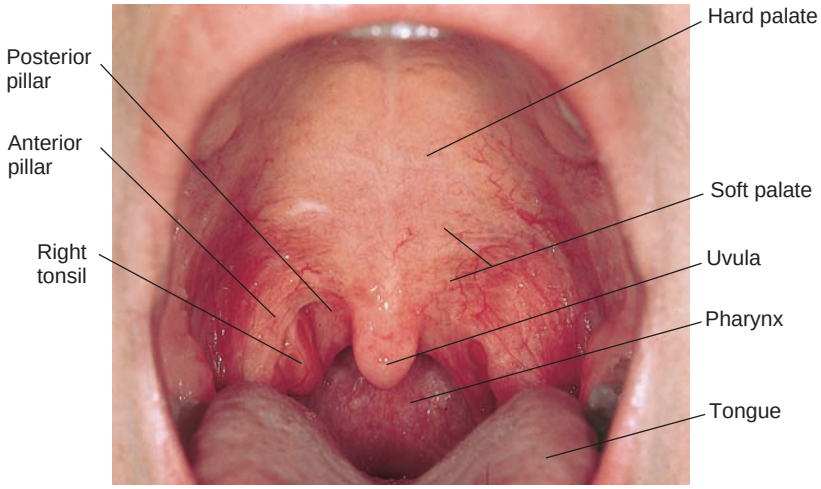

FIGURE 39-5 ▲ Structures of the mouth. (From Bickley L: Bates' Guide to Physical Examination and History Taking, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 233.)

Table 39-1 Oral Assessment

Structure	Normal	Abnormal Findings	Possible Cause
Lips	Smooth, pink, and moist	Dry or cracked	Febrile illness
		Asymmetrical, cracked, fissured, or bleeding	Cheilitis
		Cyanotic	Cold or hypoxia
		Cracks at corner of lips	Possible vitamin B deficiency or poor hygiene
Tongue	Pink, moist with papillae present	Coated or loss of papilla and a shiny appearance (with or without redness); blistered or cracked; altered taste	Infection
		Deviation to one side	Cranial nerve XII (hypoglossal nerve) problem
		Nodules or ulcers on base of tongue	Cancerous lesion
Saliva	Watery	Thick, ropy, or absent	
Mucous membranes	Pink and moist	Reddened without ulcerations	Infection
		Ulcerations with or without bleeding	Poor nutrition
		Inflammation	Ill-fitting dentures
		Leukoplakia on buccal membrane	Precancerous lesion
		Cyanosis	Hypoxia
		Pale mucosa	Anemia
		Small areas of white scar tissue	Chronic irritation from friction of irregular tooth surfaces or biting when chewing
		Inflamed or painful Stensen's duct opening	Parotid gland infection
Gingiva	Pink, stippled, and firm	Edematous with or without redness; spontaneous bleeding or bleeding with pressure; soreness	Gingivitis
Teeth or dentures	Clean without debris	Plaque or debris in between teeth; plaque or debris along gum line or denture-bearing area	
		Toothache, tooth abscess	
		Misfit of dental appliances	
		Absent or broken teeth, cavities	
		Malocclusion, worn or flattened tooth edges	Bruxism
Voice	Normal	Deeper or raspy; difficulty talking or painful to talk	Vocal cord paralysis
Throat/swallowing	Normal	Some pain on swallowing or unable to swallow; sore throat	Cancerous lesion
Glands	Nonpalpable	Inflammation and lumps	Stones or cysts

from closing completely. Gastric reflux or even reflux into the oropharynx may occur, which can cause erosive damage to the esophagus as well as a noxious odor in the mouth. Delayed gastric emptying may also exacerbate the reflux.

Abdomen

The patient's comfort should be preserved as the nurse performs the abdominal examination (Table 39-2). The patient should empty his or her bladder before the examination, or this may be facilitated by an indwelling urinary catheter. A supine position with arms down and knees slightly bent is preferred because this position relieves tension on the abdominal wall. Draping exposes the abdomen and protects the patient's modesty.[3] This is the ideal situation for performing an abdominal examination, but it may not always be possible in a critically ill patient. The nurse must assess the circumstances and prioritize for the individual patient at that time. If the patient is experiencing any or severe pain, reevaluation of the need for an examination may be warranted. Likewise, if the procedure increases discomfort or intensity of pain, the examiner stops.

The order of the abdominal examination is inspection, auscultation, percussion, and palpation. Auscultation precedes percussion and palpation because the latter can alter the frequency and quality of bowel sounds. Likewise, if the painful area is palpated first, the patient may tense the abdominal muscles, making assessment difficult or impossible.

The abdomen is usually divided into four quadrants by imaginary lines crossing at the umbilicus: right upper, right lower, left upper, and left lower quadrants. Another way to view the abdomen is to divide it into nine sections. Figure 39-1 on page 870 shows the abdominal organs and their relationship to these two methods of identifying abdominal landmarks. Figure 39-3 on page 871 shows common causes of pain by location.

Inspection

The examination begins with the nurse standing at the foot of the patient's bed and inspecting for symmetry of the abdomen, visible masses, and pulsations. The nurse inspects the skin of the abdomen for tense, shiny skin, any areas of discoloration, rashes, striae (lines resulting from rapid or prolonged skin stretching), ecchymoses, petechiae (small red or purple spots caused by hemorrhage), lesions, scars, and prominent or dilated veins. Then the nurse moves to the patient's side and assumes a position to obtain an eye-level view across the abdomen. Size; shape; asymmetry; movements from respirations, peristalsis, and vascular pulsations; and exaggerated movement are noteworthy. It is necessary to inspect the umbilicus for position, contour, and color (Fig. 39-6). Pulsation of the aorta is normally apparent in the epigastric area. In a thin person, the femoral pulses may be visible. When ascites or abdominal bleeding is suspected, the nurse should measure the abdominal girth.[4] Measure abdominal girth at the same time of day, ideally in the morning just after voiding,

Table 39-2 Abnormal Abdominal Findings

Finding	Characteristic	Possible Cause
Abdominal contour	Concave (scaphoid)	Malnutrition
	Distention	Tumor; excessive fluid (ascites, perforation); gas accumulation; severe malnutrition
Skin abnormalities	Bulging around old scar	Incisional hernia
	Striae	Obesity; pregnancy; abdominal tumor; Cushing's syndrome (purple striae)
	Pink or blue	Recently developed striae
	White or silver	Older striae
	Tense, glistening	Ascites
	Dilated, tortuous veins	Inferior vena cava obstruction
Umbilicus	Everted	Increased intra-abdominal pressure
	Bluish ecchymosis surrounding umbilicus (Cullen's sign)	Intra-abdominal bleeding; pancreatitis; ectopic pregnancy
	Palpable nodule bulging (Sister Mary Joseph nodule)	May indicate metastasis from pelvic or gastrointestinal (GI) cancer
Peristaltic wave	Strong	Intestinal obstruction
Abdominal aortic pulsations	Obvious and pronounced	Increased intra-abdominal pressure (from tumor or ascites)
Murphy's sign	Sharp pain that stops respiration when palpating under liver border	Cholecystitis
Grey Turner's sign	Flank ecchymosis	Intra-abdominal bleeding; hemorrhagic pancreatitis
Blumberg's sign	Rebound tenderness	Peritoneal irritation; inflamed or perforated appendix
Iliopsoas muscle	Right lower quadrant pain when right leg elevated against tension	Inflamed or perforated appendix from inflamed psoas muscle
Obturator muscle	Abdominal pain when right leg rotated at hip (internal or external rotation)	Inflamed or perforated appendix

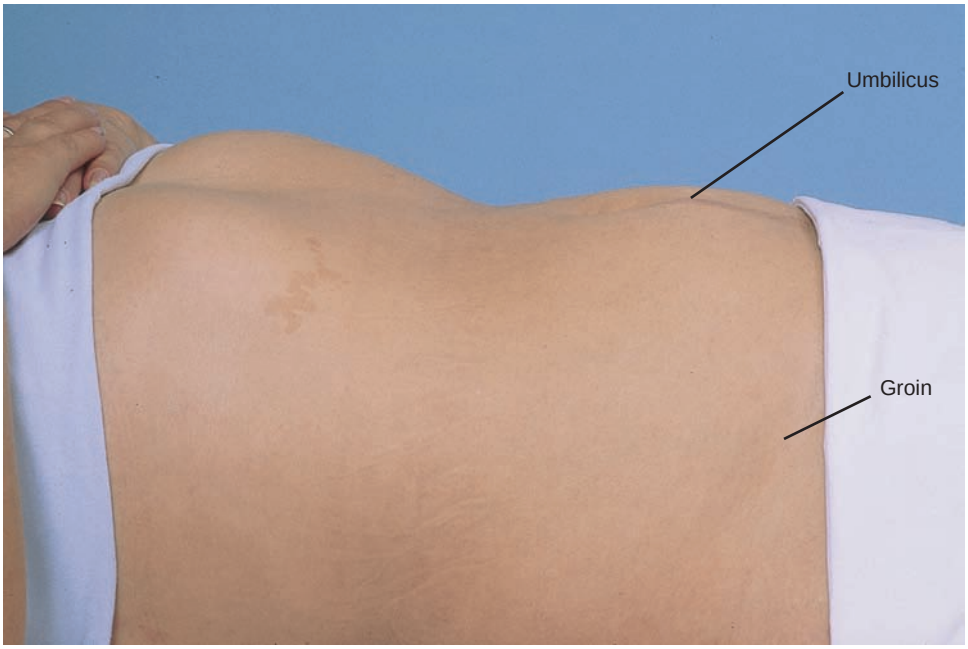

FIGURE 39-6 ▲ Inspection of the abdomen. (From Bickley L: Bates' Guide to Physical Examination and History Taking, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 435.)

or at a designated time for bedridden patients and those with indwelling catheters. The patient will normally be supine in the intensive care unit (ICU). Place the tape measure behind the patient and measure at the umbilicus. Record the distance in designated units (inches or centimeters). Take all future measurements from the same location. The abdomen may be marked with a pen to help identify the correct site.

Auscultation

Auscultation provides information on bowel motility and the vessels and organs that lie beneath the abdominal wall. The nurse applies light pressure on the diaphragm of the stethoscope when auscultating the four quadrants of the abdomen. The nurse starts below and to the right of the umbilicus and proceeds in a methodical direction through all four quadrants. To prevent contraction of the abdominal muscles that can obscure sounds, the nurse lifts the stethoscope completely off the abdominal wall when changing its location. Normally, air and fluid moving through the bowel by peristalsis create a soft, bubbling sound with no regular pattern, often with soft clicks and gurgles interspersed, approximately every 5 to 15 seconds. Colonic sounds are low pitched with a rumbling feature. A hungry patient may exhibit a "growling stomach" resulting from hyperperistalsis, called borborygmi. High-pitched, rapid, loud, and gurgling bowel sounds are hyperactive and may occur in a hungry patient. High-pitched tinkling and rushes of high-pitched sounds with abdominal cramping usually indicate obstruction. Bowel sounds that occur once every minute or less frequently are hypoactive and usually occur after bowel surgery or when feces fill the colon.[10] Absent bowel sounds may be associated with peritonitis or paralytic ileus.

Edema of the abdominal wall can be detected when an imprint of the diaphragm remains after light auscultation. The nurse uses the bell of the stethoscope to listen for vascular sounds over the abdominal aorta and the renal and femoral arteries. Figure 39-7 illustrates auscultation sites of the abdomen for vascular sounds. If the nurse hears a bruit (a continuous purring, blowing, or humming sound), percussion and palpation do not follow. If a bruit is a new finding, it is necessary to notify the physician. Table 39-3 describes abnormal abdominal sounds.

Percussion

The nurse percusses the abdomen lightly in all four quadrants of the abdomen, listening for the location and distribution of tympany and dullness (Fig. 39-8A). The percussion may proceed clockwise or up and down over the abdomen (see Fig. 39-8B,C). Abdominal percussion helps identify air, gas, and fluid in the abdomen and helps determine the size and location of abdominal organs. The percussion sound depends on the density of the underlying structure. The sound is dull over solid organs (eg, liver), a stool-filled colon, abdominal masses, or pleural effusions. The sound is tympanic over air, such as in the gastric bubble or air-filled intestine. To determine the size of the liver, the nurse percusses along the right midclavicular line (Fig. 39-9A). One method is to begin at the iliac crest and work upward. The point at which the sound becomes dull is marked. It is necessary to perform percussion down from the clavicle. The dull sound of the rib should not be mistaken for the superior edge of the liver. After marking the superior edge, the nurse measures the distance between the marks in centimeters. The normal liver measures 6 to 12 cm in height at the midclavicular line (see Fig. 39-9B).[4]

It may be necessary to postpone performing abdominal percussion on a critically ill patient, especially if there is abdominal guarding. The nurse percusses areas where the patient is not experiencing pain before examining painful areas. Abdominal percussion or palpation is contraindicated in a patient with suspected appendicitis, abdominal aortic aneurysm, or polycystic kidneys or in a patient who has received an abdominal organ transplantation to prevent rupture of the organs or aorta.[4]

Palpation

Abdominal palpation is necessary to establish the character of the abdominal wall, including the size, condition, and

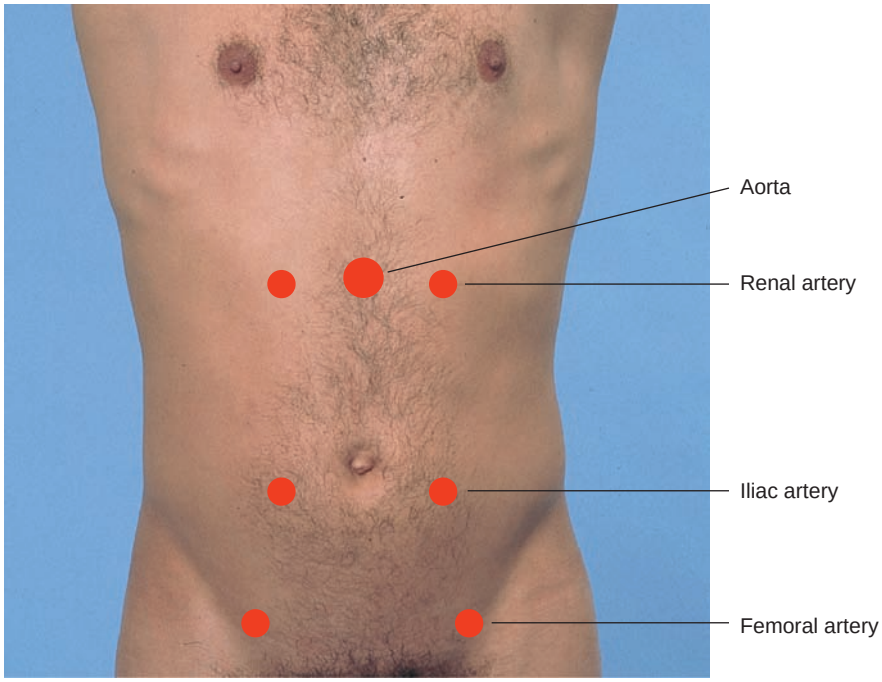

FIGURE 39-7 ▲ Auscultation sites for vascular sounds. (From Bickley L: Bates' Guide to Physical Examination and History Taking, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 436.)

consistency of abdominal organs; the presence of abdominal masses; and the presence, location, and degree of abdominal pain. Abdominal palpation includes light palpation, deep palpation, and ballottement.

Light palpation, which is performed first, identifies muscular resistance and areas of tenderness (Fig. 39-10). Fingertips are used to depress the abdominal wall 1 cm (0.5 inch). The nurse notes skin temperature, muscle resistance, tender areas, and masses. The femoral artery is subject to bilateral palpation. To ensure patient cooperation and relaxed muscles, the nurse always palpates a symptomatic area last.

When disease is present, palpation may result in somatic or organ pain. Somatic pain is localized and reflects inflammation of the skin, fascia, or abdominal surfaces. Guarding of the abdominal muscles accompanies somatic pain. Organ pain is visceral in nature and is usually dull, diffuse, and generalized.

Deep palpation is used to locate abdominal organs (enlarged spleen, edge of the liver, pole of the right kidney; the left

Table 39-3 Abnormal Abdominal Sounds

Sound and Description	Location	Sound	Possible Cause
Bowel sounds	All four quadrants	Hypoactive sounds unrelated to hunger	Diarrhea or early intestinal obstruction
		Hypoactive, then absent, sounds	Paralytic ileus or peritonitis
		High-pitched "tinkling" sounds	Intestinal air and fluid under tension in a dilated bowel; early intestinal obstruction
		High-pitched "rushing" sounds coinciding with an abdominal cramp	Intestinal obstruction
		Hyperactive sounds, long and prolonged (borborygmi)	Hunger, gastroenteritis
		Absence of sounds more than 5 min in all four quadrants	Temporary loss of intestinal motility; occurs with ileus
Systolic bruits (vascular "blowing" sounds resembling cardiac murmurs)	Abdominal aorta	Partial arterial obstruction or turbulent blood flow	Dissecting abdominal aneurysm
	Renal artery		Renal artery stenosis
	Iliac artery		Hepatomegaly
Venous hum (continuous, medium-pitched tone created by blood flow in a large, engorged vascular organ such as the liver)	Epigastric area and umbilicus	Increased collateral circulation between portal and systemic venous systems	Hepatic cirrhosis
Friction rub (harsh, grating sound resembling two pieces of sandpaper rubbing together)	Hepatic	Inflammation of the peritoneal surface of an organ	Liver mass

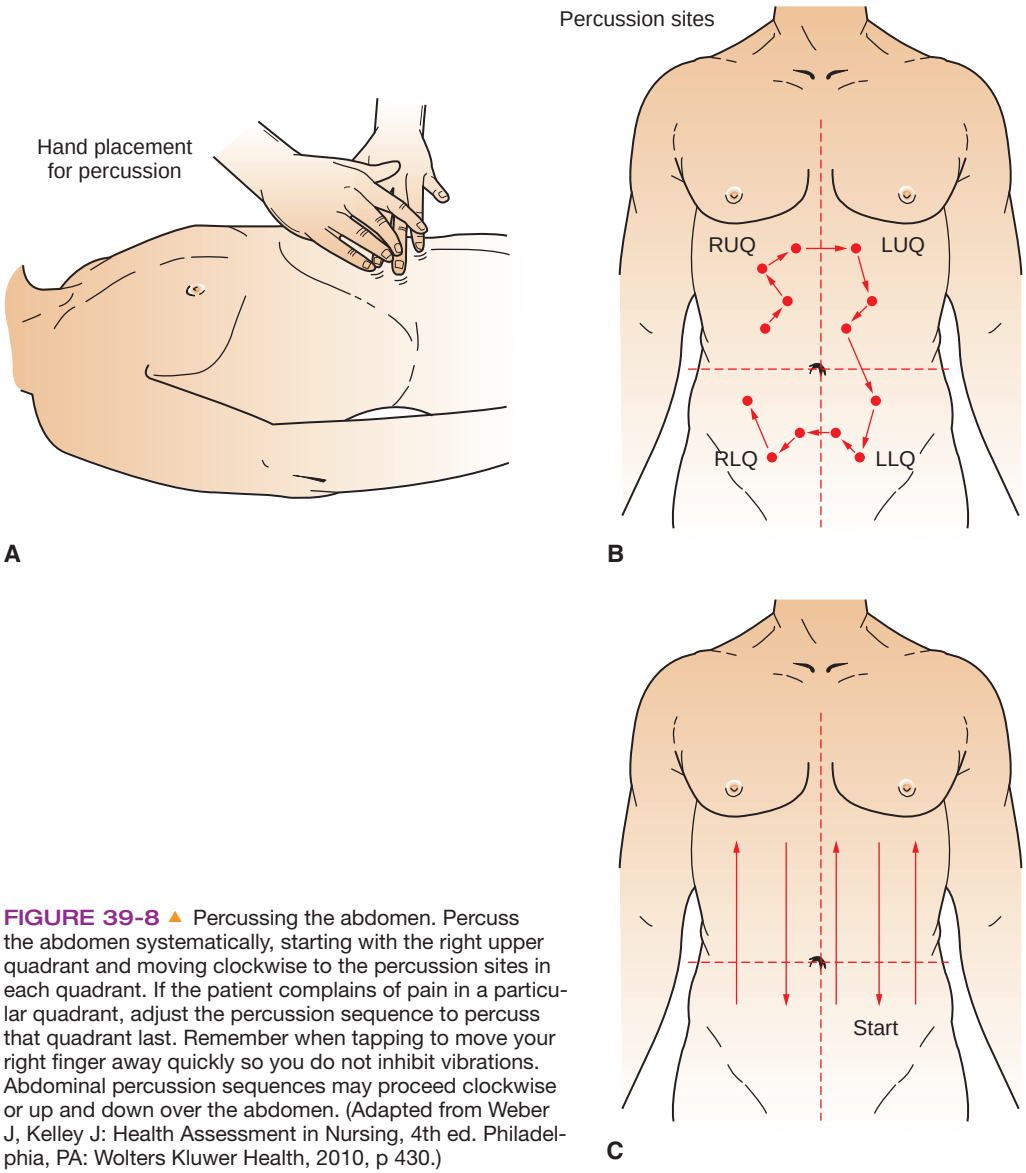

FIGURE 39-8 ▲ Percussing the abdomen. Percuss the abdomen systematically, starting with the right upper quadrant and moving clockwise to the percussion sites in each quadrant. If the patient complains of pain in a particular quadrant, adjust the percussion sequence to percuss that quadrant last. Remember when tapping to move your right finger away quickly so you do not inhibit vibrations. Abdominal percussion sequences may proceed clockwise or up and down over the abdomen. (Adapted from Weber J, Kelley J: Health Assessment in Nursing, 4th ed. Philadelphia, PA: Wolters Kluwer Health, 2010, p 430.)

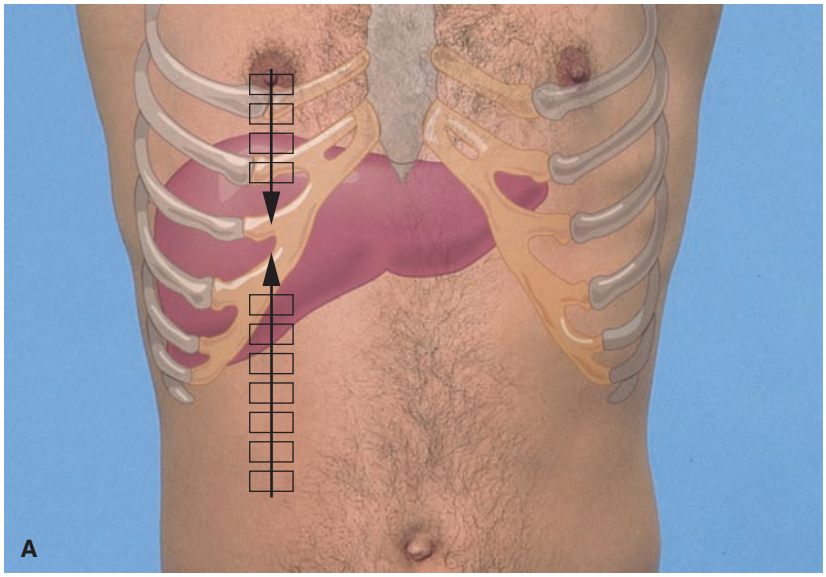
kidney is usually not palpable) and large masses (Fig. 39-11). The fingertips are used to depress the abdominal wall firmly to a depth of 7.5 cm (3 inch). Palpation in the epigastric area for the pulse of the aorta is warranted (Fig. 39-12). If the nurse finds an area of tenderness with light palpation, it is necessary to check rebound tenderness by quickly withdrawing the fingertips after depression. Rebound tenderness usually indicates inflammation of the peritoneum from an abdominal process, such as organ inflammation, infection, abscess formation, or perforated bowel (release of bowel contents into the abdomen). If the nurse palpates a mass, he or she notes its location, size, shape, consistency, type of border, degree of tenderness, presence of pulsations, and degree of mobility (fixed or mobile).[11]

The nurse palpates the spleen by standing at the patient's right side, reaching over the patient's abdomen. The left hand should be under the posterior ribs and pulling up gently on the patient, and the right hand should be below the left costal margin with the fingers pointing toward the patient's head. The nurse then asks the patient to inhale as the nurse presses inward and upward with the right hand while he or she provides support with the left hand (Fig. 39-13).

Palpation of the liver is easiest when one hand is under the patient at the level of the 11th rib while the other hand is on the abdomen at the level of the percussed liver edge dullness (Fig. 39-14). With the abdominal fingers pointing upward to lift the organ, the upper hand pushes down and upward to palpate the lower border of the liver. The liver edge should be firm and smooth. Finding an enlarged, nodular, or irregularly shaped liver warrants reporting.

Ballottement is the light, rapid tapping of the fingertips against the abdominal wall. This is used to elicit abdominal muscle resistance or guarding that may be missed with deep palpation or to detect the movement or bounce of a movable mass. In a patient with ascites, deep ballottement may be warranted. It is necessary to push the fingertips deeply inward in a rapid movement and then quickly release them, maintaining fingertip contact with the abdominal wall. Any movement of an organ lying beneath is felt, or a movable mass moves toward the fingertips.[3]



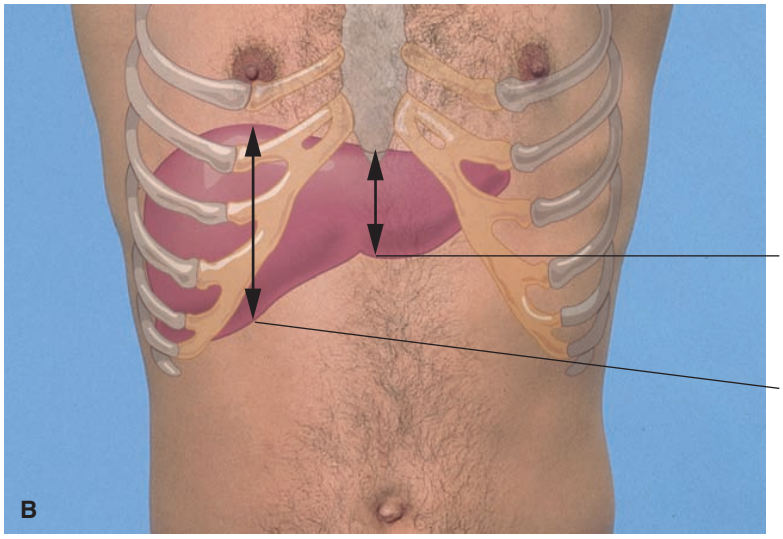


FIGURE 39-9 ▲ Percussing the liver. **A:** Determine the lower border of liver dullness in the midclavicular line. Next, identify the upper border of liver dullness in the midclavicular line. **B:** Measure in centimeters the distance between the lower border of liver dullness and the upper border of liver dullness. The distance is known as the vertical span of liver dullness. (From Bickley L: Bates' Guide to Physical Examination and History Taking, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 440.)

FIGURE 39-10 ▲ Performing light palpation. (From Bickley L: Bates' Guide to Physical Examination and History Taking, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 438.)

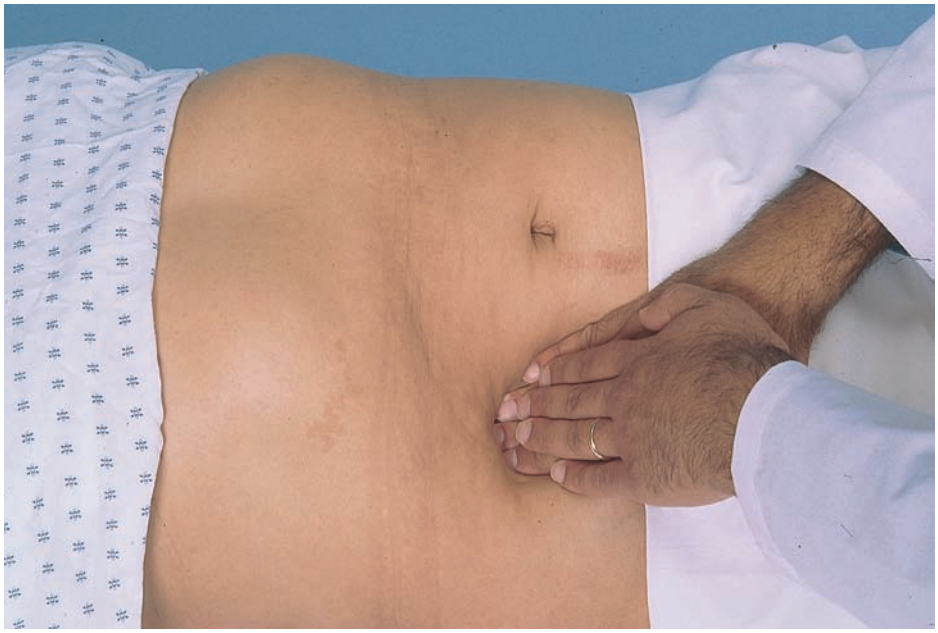

FIGURE 39-11 ▲ Two-handed deep palpation. (From Bickley L: Bates' Guide to Physical Examination and History Taking, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 439.)

Anus and Rectum

Assessment of the anus involves inspection and palpation. The skin around the anus is normally darker than the surrounding area. The nurse should inspect for inflammation, lesions, skin tags or warts, obvious fissures, and hemorrhoids. Palpation of the area with a well-lubricated gloved finger for outpouchings, nodules, tenderness, irregularities, and fecal impaction is necessary. Alteration in elimination due to immobility, limited or no GI intake, opioids, or decreased intestinal peristalsis may result from a patient's disease or its treatment. Constipation may compound matters and, if left untreated, can lead to fecal impaction.[11] Astute nursing assessment is critical in preventing and treating constipation or fecal impaction in any patient.

To assess anal sphincter tone, it is necessary to slip a well-lubricated tip of the index finger of a gloved hand into the anal canal. The nurse asks the patient who can cooperate to bear down to tighten the external sphincter around the inserted finger. He or she assesses the tone; it should tighten, exert even pressure all around, feel smooth, and cause no discomfort to the patient. A lax sphincter may indicate a neurological deficit. A very tight sphincter may result from scarring, spasticity caused by a fissure or other lesion, inflammation, or anxiety about the examination. Inserting the finger farther allows palpation of the walls of the rectum. It is necessary to assess the walls for any nodules, masses, irregularities, polyps, or tenderness. The wall should feel smooth, even, and uninterrupted.[3]

▲ Nutritional Assessment

Adequate nutrition of patients in the ICU improves outcomes, while malnutrition is strongly associated with increased morbidity and mortality rates among critically ill patients. GI complications are one of the main reasons why nutritional requirements of critically ill patients are not met. Nutritional support should be started in intensive care patients as early as possible. Enteral feeding should be prioritized but it is often necessary to supplement this with parenteral feeding as most intensive care patients are at risk of malnutrition.[12]

FIGURE 39-12 ▲ Palpating the aorta. (From Weber J, Kelley J: Health Assessment in Nursing, 4th ed. Philadelphia, PA: Wolters Kluwer Health, 2010, p 436.)

FIGURE 39-13 ▲ Palpating the spleen. (From Weber J, Kelley J: Health Assessment in Nursing, 4th ed. Philadelphia, PA: Wolters Kluwer Health, 2010, p 436.)

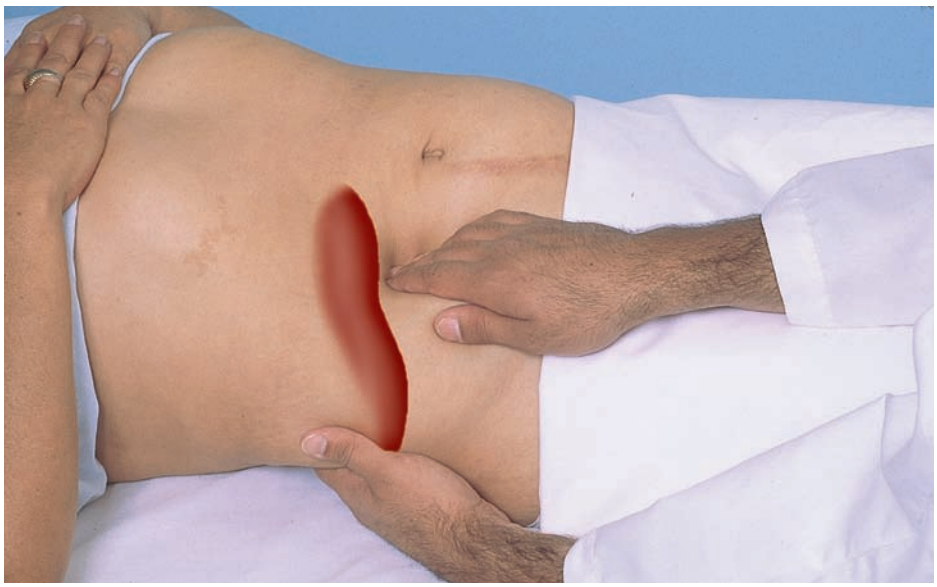

FIGURE 39-14 ▲ Bimanual technique for liver palpation. (From Bickley L: Bates' Guide to Physical Examination and History Taking, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 441.)

A critically ill patient's nutritional status may fall anywhere on a continuum ranging from optimal nutrition to malnutrition. The critical care patient may have an inadequate dietary intake because of illness or the disorder that caused the hospitalization, particularly if the disorder is GI. In addition, critically ill patients are at risk for GI problems from treatments that cause damage to the GI system and reduce the body's ability to absorb nutrients. Optimal nutrient intake provides adequate energy and can protect from complications of disease.[13]

The nurse plays an important role in evaluating the nutritional status of the patients under his or her care. Certain signs and symptoms that suggest possible nutritional deficiency are easy to note because they are specific. Conversely, fluid changes, such as edema or effusions, can mask protein and fat loss. The fact that nutritional disturbances can be subtle and are frequently nonspecific makes the need for assessment important.[14]

Nutritional assessment of the patient refers to a comprehensive evaluation of nutritional status, whereas nutritional screening is the process of identifying patients at risk for malnutrition or who are presently malnourished.[15] The detection of malnutrition in the ICU is critical to appropriately address its contribution to outcomes. Patients who are malnourished generally have longer hospitalizations and higher morbidity, mortality, and costs of care than those who are well nourished.[16]

Nurses caring for patients in the ICU are integral to the screening of patients for nutritional deficiencies or needs. Nurses assist with a formal nutritional assessment by providing information to nutrition support service and even completing screening tools for nutrition risk assessment. Serial weight measurement is perhaps the single most important indicator of nutritional status and is the evaluation that the nurse performs most often.

An initial nutritional assessment may begin with cursory data, as dictated by the patient's condition. A registered dietitian or nutritionist or a nutritional support team may perform a more comprehensive nutritional assessment. The parameters of the nutritional assessment include anthropometric measurement, laboratory studies, physical examination, and dietary evaluation. Anthropometric measurements include height, weight, body mass index, triceps skinfold thickness, and midarm and arm muscle circumference.[15] Table 39-4 lists laboratory studies performed to evaluate nutritional status. Table 39-5 presents information about the physical examination and its interpretation in nutritional disorders.

The dietary evaluation may consist of a 24-hour recall to elicit all the foods and beverages consumed in the preceding 24 hours. However, this method may overestimate or underestimate a patient's usual caloric intake because the patient's recollection may not reflect long-term dietary habits. The nurse assesses the quantity and quality of food ingested by asking the patient to recall his or her normal daily intake pattern. This approach provides more information about intake patterns and tends to reflect long-term dietary habits with greater accuracy. It is also necessary to consider a patient's past or current patterns of food intake, or both, such as vegetarian or kosher dietary practices, as well as cultural background and social situation.[14] Special consideration of the geriatric patient is warranted; age-related changes in the GI system may affect dietary intake and maintenance of adequate nutrition (Box 39-2).

Screening tools are used for nutrition risk assessment and to plan nutrition treatment in the ICU.[15] When patients are critically ill, it is often necessary to elicit this information from the patient's family members or significant other.

A number of quick and efficient screening instruments have been developed to determine the risk or presence of malnutrition in the critically ill patient. The Subjective Global Assessment (SGA) is an example of a simple and reliable screening tool for nutritional assessment that may predict the patient's outcomes in the critical care setting (Fig. 39-15, p. 883). The SGA has been used in many settings for nutrition assessment.[15,17,18]

An important factor that influences nutritional status is nitrogen balance, a sensitive indicator of the body's gain or loss of protein. An adult is in nitrogen balance when the

Table 39-4 Laboratory Studies to Evaluate Nutritional Status

Study	Normal Findings	Clinical and Nursing Significance
Hemoglobin	Males: 13–18 g/dL Females: 12–16 g/dL	Main component of red blood cells (RBCs) used to transport oxygen; identifies iron-carrying capacity of the blood Helps identify anemia, protein deficiency, excessive blood loss, hydration status Elevated with dehydration; decreased in overhydration
Hematocrit	Males: 40%–52% Females: 36%–48%	Identifies volume of RBCs Decreased value with overhydration, blood loss, poor dietary intake of iron, protein, certain vitamins
Albumin	3.5–5.5 g/dL	Assesses protein levels in the body; requires functioning liver cells Decreased with protein deficiency, blood loss secondary to burns, malnutrition, liver/renal disease, heart failure, major surgery, infections, cancer Elevated with dehydration
Total protein	6–8 g/dL	Decreased with overhydration, malnutrition, liver disease
Prealbumin	15–30 mg/dL	Transport protein for thyroxine (T_4) Short half-life makes it more sensitive than albumin to changes in protein stores Decreased in malnutrition in critically ill or those with chronic disease
Transferrin	200–400 mg/dL	Transport protein for iron; synthesized in the liver; shorter half-life than albumin; reflects current protein status; a more sensitive indicator of visceral protein stores Elevated in pregnancy or iron deficiency Decreased in acute or chronic infection, cirrhosis, renal disease, cancer
Retinol-binding protein	3–6 mg/L	Rapidly responds to nutritional depletion due to short half-life Decreased in overhydration and liver disease
Total lymphocyte count	More than 2,000 mm^3	Indicator of immunocompetence Mild: 1,200–2,000 Moderate: 800–1,199 Severe: <800 May indicate malnutrition when no other cause apparent; may point to infection, leukemia, or tissue necrosis

nitrogen intake equals the nitrogen output (in urine, feces, and perspiration). Nitrogen balance is a sign of health. A positive nitrogen balance exists when nitrogen intake exceeds nitrogen output and indicates tissue growth, such as occurs during recovery from surgery, and rebuilding of wasted tissue. A negative nitrogen balance indicates that the tissue is breaking down faster than it is being replaced. In the absence of an adequate intake of protein, the body converts protein to glucose for energy. This can occur with fever, starvation, surgery, burns, and debilitating diseases. Malnutrition occurs when a patient is in negative nitrogen balance. Malnutrition, in turn, interferes with wound healing, increases susceptibility to infection, and contributes to an increased incidence of complications, a protracted hospitalization, and an extended bed confinement.[15]

The nutritional assessment directs the nutritional prescription and assists in the development of the interventions. Enteral or parenteral nutrition may be initiated if oral intake is prohibited or threatened for longer than a week. If the GI tract of the patient is functioning, enteral feeding is the intervention of choice. For people without a functioning GI tract, total parenteral nutrition may be the nutritional treatment of choice. See Chapter 40 for a discussion of enteral and parenteral nutrition. The level of interventions is dictated by the patient's baseline nutritional state, disease status, risk for malnutrition from treatment, and anticipated response to therapy.[12]

▲ Laboratory Studies

Because the oral cavity is the only part of the GI tract that is visible, it is essential to combine the information gleaned from the history and physical examination with the results of laboratory and diagnostic studies to assess the rest of the GI tract. Many laboratory studies help in the diagnosis of GI and abdominal disorders in the critically ill patient. Parameters evaluated include serum electrolytes; levels of end products of metabolism, enzymes, and proteins; and hematological parameters.

Laboratory Studies Relating to Liver Function

The liver is responsible for many functions, the most significant being bile formation and secretion, protein and fat metabolism, detoxification of many substances, and the production of clotting factors and enzymes. Table 39-6 summarizes common laboratory studies relating to liver function.

A single laboratory test or single value from any laboratory test does not give an accurate assessment of an organ's function. A series of values from a laboratory study and combinations of studies provide a more precise picture. For example, if a patient's liver enzymes and bilirubin are elevated but the alkaline phosphatase (AP) level is normal, this usually

Table 39-5 Physical Assessment Interpretation in Nutritional Disorders

Body System or Region	Sign or Symptom	Implications
General	Weakness and fatigue Weight loss	Anemia or electrolyte imbalance, decreased calorie intake, increased calorie use, or inadequate nutrient intake or absorption
Skin, hair, and nails	Dry, flaky skin Dry skin with poor turgor Rough, scaly skin with bumps Petechiae or ecchymoses Sore that will not heal Thinning, dry hair Spoon-shaped, brittle, or rigid nails	Vitamin A, vitamin B complex, or linoleic acid deficiency Dehydration Vitamin A deficiency Vitamin C or K deficiency Protein, vitamin C, or zinc deficiency Protein deficiency Iron deficiency
Eyes	Night blindness; corneal swelling, softening, or dryness; Bitot's spots (gray triangular patches on the conjunctiva) Red conjunctiva	Vitamin A deficiency Riboflavin deficiency
Throat and mouth	Cracks at the corner of mouth Magenta tongue Beefy, red tongue Soft, spongy, bleeding gums Swollen neck (goiter)	Riboflavin or niacin deficiency Riboflavin deficiency Vitamin B_{12} deficiency Vitamin C deficiency Iodine deficiency
Cardiovascular	Edema Tachycardia, hypotension	Protein deficiency Fluid volume deficit
GI	Ascites	Protein deficiency
Musculoskeletal	Bone pain and bow leg Muscle wasting	Vitamin D or calcium deficiency Protein, carbohydrate, and fat deficiency
Neurological	Altered mental status Paresthesia	Dehydration and thiamine or vitamin B_{12} deficiency Vitamin B_{12}, pyridoxine, or thiamine deficiency

Adapted from Lee R, Neiman D: Nutritional Assessment, 5th ed. New York, NY: McGraw Hill, 2010.

indicates injury to the hepatocytes, such as in hepatitis and cirrhosis. If the liver enzymes are within normal range and the bilirubin and AP levels are elevated, this usually indicates an extrahepatic biliary obstruction, such as in a distal common bile duct obstruction from pancreatic cancer or a clip occluding the common bile duct from a laparoscopic cholecystectomy misadventure.

Laboratory Studies Relating to Pancreatic Function

Table 39-7 lists serum laboratory tests that relate to pancreatic function. Amylase and lipase are digestive enzymes secreted by the pancreas. Serum amylase is found in the pancreas, parotid glands, intestine, liver, and fallopian tubes. Lipase is

BOX 39-2 CONSIDERATIONS FOR THE OLDER PATIENT

Age-Related Changes of the GI System

Oral Cavity and Pharynx
- Injury/loss or decay of teeth
- Atrophy of taste buds
- Decreased saliva production
- Reduced ptyalin and amylase in saliva

Esophagus
- Decreased motility and emptying
- Weakened gag reflex
- Decreased resting pressure of lower esophageal sphincter

Stomach
- Degeneration and atrophy of gastric mucosal surfaces with decreased production of HCl
- Decreased secretion of gastric acids and most digestive enzymes
- Decreased motility and emptying

Small Intestine
- Atrophy of muscle and mucosal surfaces
- Thinning of villi and epithelial cells

Large Intestine
- Decrease in mucous secretion
- Decrease in elasticity of rectal wall
- Decreased tone of internal anal sphincter
- Slower and duller nerve impulses in rectal area

Table 39-6 Laboratory Studies Used to Evaluate Liver Function

Study	Normal Findings	Clinical and Nursing Significance
Bile Formation and Secretion		
Serum bilirubin		
Direct (conjugated)—soluble in water	0–5.1 micromol/L	Abnormal in biliary and liver disease; causes clinical jaundice
Indirect (unconjugated)—insoluble in water	0–14 micromol/L	Abnormal in hemolysis and in functional disorders of uptake or conjugation
Urine bilirubin	0	Urine is mahogany in color; shaking the specimen results in a light yellow foam; confirmed with Ictotest tablet or dipstick; false-positive results possible if patient is taking phenazopyridine (Pyridium).
Urobilinogen		Increased in cirrhosis, biliary obstruction with biliary tract infection, hemorrhage, and hepatotoxicity; decreased in biliary obstruction without biliary tract infection, hepatocellular damage, and renal insufficiency
Urine urobilinogen	Up to 0.09–4.23 micromol/24 h	Urine specimen is collected over a 2-h period after lunch and must be placed in a dark brown container and sent to the laboratory immediately to prevent decomposition.
Fecal urobilinogen	Up to 0.068–0.34 mmol/24 h	
Protein Studies		
Albumin	35–55 g/L	Decreased in cirrhosis, chronic hepatitis
Globulin	15–30 g/L	Increased in cirrhosis, chronic obstructive jaundice, viral hepatitis
Albumin/globulin ratio	1.5:1–2.5:1	Ratio reverses with chronic hepatitis or other chronic liver disease
Total serum protein	60–80 g/L	Individual protein measurements are of greater significance than total protein measurements.

(Continued on page 884)

Table 39-6 Laboratory Studies Used to Evaluate Liver Function (continued)

Study	Normal Findings	Clinical and Nursing Significance
Protein Studies		
Transferrin	220–400 mcg/dL	Decreased in cirrhosis, hepatitis, and malignancy; increased in severe iron deficiency anemia
Prothrombin time (PT) or International normalized ratio	11.0–14.0 s or 100% of control 0.8–1.2	Prolonged PT in liver disease will not return to normal with vitamin K administration, whereas prolonged PT resulting from malabsorption of fat and fat-soluble vitamins will return to normal with vitamin K administration.
Partial thromboplastin time	25.0–36.0 s	Increased with severe liver disease or therapy with heparin or other anticoagulants
Alpha-fetoprotein (AFP)	6–20 ng/mL	Elevated in primary hepatocellular carcinoma
Fat Metabolism		
Cholesterol	<200 mg/dL (adults)	Decreased in parenchymal liver disease; increased in biliary obstruction
High-density lipoprotein Men Women	 35–70 mg/dL 35–85 mg/dL	
Low-density lipoprotein	<130 mg/dL	
Very-low-density lipoprotein	25%–50%	
Liver Detoxification		
Serum alkaline phosphatase (AP)	20–90 units/L at 30°C	Level is elevated to more than three times the normal in obstructive jaundice, intrahepatic cholestasis, liver metastasis, or granulomas; also elevated in osteoblastic diseases, Paget's disease, and hyperparathyroidism
Ammonia	15–49 mcg/dL	An elevation indicates hepatocyte damage (liver converts ammonia to urea)
Enzyme Production		
Aspartate aminotransferase	8–20 units/L	Any elevation indicates hepatocyte damage.
Alanine aminotransferase	10–32 units/L	Any elevation indicates hepatocyte damage.
Lactate dehydrogenase	200–500 units/L	Any elevation indicates hepatocyte damage.
γ-Glutamyl transferase (GGT)	0–30 units/L at 30°C	An elevation in GGT along with an elevated AP usually indicates biliary disease; helpful in the diagnosis of chronic liver disease

Table 39-7 Laboratory Studies Used to Evaluate Pancreatic Function

Study	Normal Findings	Clinical and Nursing Significance
Serum amylase	25–125 units/L	In acute pancreatitis, the serum levels peak between 4 and 8 h after onset of condition, then fall to normal within 48–72 h; low levels usually indicate pancreatic insufficiency.
Urine amylase	2 h: 2–34 units 24 h: 24–408 units	Urine values 6–10 h behind serum values; low levels indicate pancreatic insufficiency.
Serum lipase	10–40 units/L (adults)	Elevated only in pancreatitis, markedly in acute pancreatitis and pancreatic duct obstruction; remains elevated after amylase returns to baseline
Serum glucose	65–110 mg/dL (fasting)	Patient must fast for 12 h before specimen is obtained.
Serum triglycerides	50–250 mg/dL	Patient must fast for 12 h before specimen is obtained; levels increased in alcoholic cirrhosis, diabetes mellitus (untreated), high-carbohydrate diet, hyperlipoproteinemia, and hypertension; levels decreased in malnutrition, vigorous exercise
Serum calcium Total Ionized	 8.2–10.2 mg/dL 4.65–5.28 mg/dL	 High total calcium levels seen in cancer of the liver, pancreas, and other organs Useful in tracking the course of disorders, such as cancer and acute pancreatitis
Fecal fat	2–5 g/24 h	Content of >6 g/24 h is suggestive of a decrease in the body's ability to absorb foods; indicative of pancreatic exocrine insufficiency as in chronic pancreatitis

Table 39-8 Other Selected Laboratory Studies Used in the Diagnosis of GI Disorders

Study	Normal Findings	Clinical and Nursing Significance
Stool specimen		
Occult blood	None	Positive test suggests possible malignancy.
Fat	2–5 g/24 h	Screening test for steatorrhea when malabsorption syndrome or pancreatic insufficiency is suspected
Ova and parasites	None	Positive test suggests infection.
Pus	None	Increased amount of pus may indicate ulcerative colitis, abscess, or anal or rectal fissure.
Pathogens	None	Common pathogens are *Salmonella typhi* (typhoid fever), *Shigella* (dysentery), *Vibrio cholerae* (cholera), *Yersinia* (enterocolitis), *Escherichia coli* and *Aeromonas* (gastroenteritis), *Staphylococcus aureus, Clostridium botulinum*, and *Clostridium perfringens* (food poisoning).
Urea breath test	Negative	Detects the presence of *Helicobacter pylori*
Hydrogen breath test	Negative	Determines the amount of hydrogen expelled in the breath after it is produced in the colon and absorbed into the blood; aids in the diagnosis of bacterial overgrowth in the intestine and short bowel syndrome

found primarily in the pancreas. In acute pancreatitis, serum amylase and lipase can be elevated four to six times the normal level, whereas in chronic pancreatitis, serum amylase and lipase levels may be normal or very low because the pancreas may no longer be producing the enzymes.

The pancreas produces insulin and glucagon, hormones that aid in the regulation of serum glucose levels. A disruption in normal pancreatic function or the presence of a tumor may alter the production of these hormones. Frequent blood glucose monitoring is warranted. Any elevation in the serum and urine glucose levels has a cascading effect on multiple body systems, which in turn affects the patient's overall condition.[19]

Other Laboratory Studies

Table 39-8 provides information about other selected laboratory studies that are used in the evaluation of GI disorders.

▲ Diagnostic Studies

The nurse caring for the critically ill patient coordinates the preparation for, and possibly the timing of, many diagnostic tests. The nurse prepares the patient, the family members, or both for the test by providing a thorough explanation of how the test is performed and what information the test is expected to yield. In addition, the nurse explains the need for informed consent to perform the test and answers any questions the patient or family members may have about the test. Table 39-9 summarizes the diagnostic studies for evaluating the GI tract, which can be divided into two categories, noninvasive and invasive.

Radiological and Imaging Studies

Body tissue has different densities that produce different shades of black and white on an x-ray. Bone tissue is high in density and appears white; air appears black; and soft tissue results in shades of gray. The stomach and intestines usually contain some air and appear darker. Solid organs, such as the pancreas, spleen, kidneys, or liver, appear grayer.[20]

Endoscopic Studies

The use of an endoscope is an important adjunct to radiographic studies because it allows direct observation of portions of the intestinal tract. A flexible fiberoptic endoscope is an instrument with a light and a lens at the end of a movable tip that can be manipulated through the intestinal tract by the operator. It also includes an instrument channel that allows for biopsy of lesions, such as tumors, ulcers, or areas of inflammation. Fluids can be aspirated from the lumen of the intestinal tract, and air can be insufflated to distend the intestinal tract for better observation. Cytology brushes and electrocautery snares can be passed through the scope. Special studies of the common bile duct and the pancreatic duct, by endoscopic retrograde cholangiopancreatography, use a side-viewing upper intestinal endoscope. Endoscopic ultrasonography with fine-needle aspiration is another procedure that uses an endoscope with an ultrasound probe and a biopsy needle at the end. The endoscope is inserted through an orifice and the ultrasound probe is used to bounce high-energy sound waves off internal organs and tissues that create a picture on a monitor. This allows the operator to place the needle to obtain cells from a mass or lymph nodes for biopsy.[21] Advances in

Table 39-9 Diagnostic Studies Used to Evaluate the GI Tract

Study	Description	Indications	Invasiveness	Preparation	Contrast
Abdominal film "flat plate of the abdomen"	Radiology test used to visualize a single flat plane; shows organ size, position, intactness, and normal gas patterns in the stomach, small intestine, and colon	Aids in diagnosis of intestinal obstruction, organ rupture, masses, foreign bodies, abnormal fluid or air ("stones, bones, gas, masses")	Noninvasive	None	No
Upper GI series (barium swallow)	Radiology test used to visualize the esophagus, stomach, and duodenum; barium enhances image; double-contrast study administers barium first followed by a radiolucent substance, such as air, to help coat bowel mucosa for better visualization of any type of lesion.	Aids in diagnosis of hiatal hernia, ulcers, tumors, foreign bodies, bowel obstruction	Noninvasive	NPO	Yes
Upper GI series with small bowel follow-through	Radiology test used to visualize the jejunum, ileum, and cecum	Aids in the diagnosis of tumors, Crohn's disease, Meckel's diverticulum	Noninvasive	NPO	Yes
Enteroclysis	Radiology test used to visualize entire small intestine; continuous infusion (through a duodenal tube) of air in a barium sulfate suspension along with methylcellulose fills the intestinal loops; transit of contrast filmed at intervals for progress through jejunum and ileum	Aids in diagnosis of partial bowel obstruction or diverticula	Invasive	NPO	Yes
Barium enema	Radiology test used to visualize the colon; barium enhances image; air may be introduced after the barium to provide a double-contrast study	Aids in diagnosis of polyps, tumors, fistulas, obstruction, diverticula, and stenosis	Noninvasive	Bowel cleansing	Yes
Gastric lavage	Aspiration of stomach contents and washing out of the stomach by a large gastric tube	Aids in diagnosis of upper GI bleeding; also used to arrest hemorrhage and prepare for further tests	Invasive	None	No
Paracentesis	Aspiration of peritoneal fluid	Laboratory studies (such as amylase and lipase to assess for pancreatitis), cytologic studies (to detect tumors), comfort measure (to alleviate accumulation of ascitic fluid)	Invasive	None	No
Peritoneal lavage	Irrigation of peritoneal cavity to examine irrigating fluid for blood	Blunt or penetrating trauma to the abdomen	Invasive	None	No

(continued on page 887)

Table 39-9 Diagnostic Studies Used to Evaluate the GI Tract (continued)

Study	Description	Indications	Invasiveness	Preparation	Contrast
Biopsy					
Percutaneous	A needle is placed through the skin to obtain tissue specimen for pathology evaluation	Aids in diagnosis of malignancy	Invasive	NPO	No
Fine-needle aspiration	A thin needle is used to obtain cells or minute tissue fragments from a suspect area for examination by light microscopy; usually guided by radiologists with fluoroscopy, ultrasound, computed tomography, or magnetic resonance imaging	Aids in diagnosis of malignancy	Invasive	NPO	No
Ultrasonography (sonogram)	Use of high-frequency sound waves over an abdominal organ to obtain an image of the structure	Aids in diagnosis of masses, dilated bile ducts, gallstones, and ascites	Noninvasive	NPO	No
Hepatobiliary scan	Intravenously injected radioisotope is primarily taken up by the liver and then secreted into the bile, allowing visualization of the biliary system, gallbladder, and duodenum (size, function, vascularity, and blood flow).	Aids in the diagnoses of common bile duct obstruction, acute and chronic cholecystitis, bile leaks, biliary dyskinesia, and biliary atresia; also used to evaluate liver transplant function	Noninvasive	NPO	Yes
Tagged red blood cell scan (technetium-labeled red blood cell scintigraphy)	Red blood cells are labeled with technetium and injected intravenously; images are obtained with a gamma camera that can identify areas of increased radioactivity as a site of slow or intermittent GI hemorrhage.	Aids in the diagnosis of GI bleeding	Noninvasive	None	Yes
Computed tomography (CT) scan	A radiological procedure that uses narrow x-ray beams to produce cross-sectional images of organs and tissues; can be performed with or without contrast medium; multidetector-row CT now provides more exact information even when combined with three-dimensional imaging, which can be rotated on a computer screen and allows different views for even more information.	Excellent for visualizing the abdomen, retroperitoneal structures, tumors, cysts, collection of fluid, air in a cavity, bleeding, or pulmonary embolism	Noninvasive	NPO	Yes/No

(continued on page 888)

Table 39-9 Diagnostic Studies Used to Evaluate the GI Tract (continued)

Study	Description	Indications	Invasiveness	Preparation	Contrast
Magnetic resonance imaging (MRI)	Diagnostic study that does not use radiation; obtains images by passing the patient through a tubular device that generates a powerful electromagnetic field; radiofrequency waves are transmitted into the patient in a controlled manner so that the patient's hydrogen ions (protons) emit radiofrequency signals that are processed by a computer to produce an image.	Useful in evaluating abdominal soft tissue and blood vessels, abscesses, fistulas, tumors, and sources of bleeding	Noninvasive	No metal devices attached to or implanted in the patient; patient must be able to lie quietly for a period of time.	No
Magnetic resonance cholangiopancreatography (MRCP)	Similar to MRI; because no contrast agent is required, MRCP is ideal for patients with allergies to iodine-based contrast medium.	Aids in the diagnosis of disorders affecting the pancreatic ducts and biliary tree	Noninvasive	No metal devices attached to or implanted in the patient	No
Percutaneous transhepatic cholangiography (PTC)	Radiological procedure done under fluoroscopy to examine the intrahepatic and extrahepatic biliary ducts after injection of contrast medium into the biliary tree through percutaneous needle injection	Helps to distinguish obstructive jaundice caused by liver disease from jaundice caused by biliary obstruction (eg, from a tumor, common bile duct injury, stones within the bile ducts, or sclerosing cholangitis)	Invasive	NPO	Yes
Percutaneous transhepatic biliary drainage (PTBD)	A biliary catheter is placed during a PTC; the biliary catheter may be placed to the obstruction or it may bypass the obstruction to allow the free flow of bile; catheter relieves jaundice and pruritus, improves nutritional status, allows easy access into the biliary tree for further procedures, and can be used as an anatomical landmark and stent at the time of surgery.	Biliary obstruction resulting in jaundice, cholangitis, sepsis, or pain	Invasive	NPO	Yes
Positron emission tomography (PET)	A computerized radiographic technique that uses radioactive substances to examine the metabolic activity of body structures PET scan can be combined with a CT scan so images can be acquired from both devices and can be taken sequentially at the same time for superimposed images.	Useful for precisely locating a tumor Provides metabolic activity revealed by the PET scan along with the anatomic information provided by the CT scan	Noninvasive	None	Yes
Angiography	A radiographic study of selected arteries and veins to see defects in the walls of the vessels; also used to evaluate blood flow through the vessels	Usually done when initial, noninvasive procedures are insufficient in revealing the cause of a suspected vascular defect	Invasive	NPO	Yes

Table 39-10 Endoscopic Studies Used to Evaluate the GI Tract

Study	Description	Indications	Invasiveness	Preparation	Contrast
Esophagogastroduodenoscopy	Endoscope passed through the mouth and advanced to visualize the esophagus, stomach, and duodenum; any abnormalities can be photographed and biopsied; bleeding areas may be cauterized and varices may be injected with sclerosing agents.	Helps to diagnose acute or chronic upper GI bleeding, esophageal or gastric varices, polyps, tumors, ulcers, esophagitis, gastritis, esophageal stenosis, and gastroesophageal reflux	Invasive	NPO	No
Colonoscopy	Flexible fiberoptic endoscope passed through the rectum and advanced to visualize the large intestine; any abnormalities can be photographed and biopsied; polyps can be removed and bleeding areas may be cauterized.	Helps to diagnose bleeding, diverticulosis, polyps, stricture, tumor, or inflammatory bowel disease (Crohn's disease or ulcerative colitis)	Invasive	Bowel cleansing	No
Proctoscopy (anoscopy)	Rigid scope passed through the rectum to visualize the mucosal surface of the anus and rectum	Helps to diagnose polyps, bleeding, tumors, and other defects	Invasive	None	No
Sigmoidoscopy	Flexible fiberoptic endoscope passed through the rectum and advanced to visualize the rectum, sigmoid colon, and proximal colon; any lesions can be biopsied.	Helps to diagnose tumors, polyps, diverticula, or bleeding	Invasive	Enema	No
Endoscopic retrograde cholangiopancreatography	Flexible fiberoptic endoscope inserted into the esophagus, passed through the stomach, and into the duodenum to visualize the common bile duct, hepatic bile ducts, and pancreatic ducts; the common bile duct and pancreatic duct are cannulated and contrast medium is injected into the ducts, permitting visualization and radiographic evaluation.	Can detect extrahepatic biliary obstruction (eg, from stones, tumors of the bile duct, strictures or injuries to the bile duct), intrahepatic biliary obstruction caused by stones or tumor; and pancreatic disease, such as chronic pancreatitis, pseudocysts, or tumors	Invasive	NPO	Yes
Endoscopic ultrasonography	Endoscopy and ultrasonography are used to visualize the GI tract; an ultrasonic transducer built into the distal end of the endoscope allows for high-quality resolution of the walls of the GI tract.	Useful in evaluating and staging tumors of the GI tract	Invasive	NPO	No

technology now allow specialized instruments direct intraductal visualization of all bile ducts and pancreatic ducts by steering the probe in four directions to access and inspect all four quadrants for diagnostic and therapeutic applications/interventions. This technique is called SpyGlass™.[22]

Table 39-10 describes endoscopic procedures used to evaluate the GI tract.

Other Diagnostic Studies

In addition to radiological and imaging studies and endoscopic procedures, other studies are specifically designed to aid in the diagnosis of GI disorders. Table 39-11 provides information about selected diagnostic studies used to diagnose specific GI disorders.

Table 39-11 Other Selected Diagnostic Studies Used in Diagnosing GI Disorders

Study	Description	Normal Findings
Gastric emptying studies	Liquid and solid components of a meal are tagged with a radionuclide marker. After ingesting the meal, the rate of passage of the radioactive substance out of the stomach is measured by a scintiscanner. Useful in diagnosing gastric motility disorders	Normal transit
Gastric analysis	Analysis of gastric juice yields information about the secretory activity of the gastric mucosa and the presence or degree of gastric retention, which is useful to help diagnose patients with pyloric or duodenal obstruction.	Normal contents
Gastric acid stimulation (usually performed in conjunction with gastric analysis)	Histamine or pentagastrin is given subcutaneously to stimulate gastric secretions. Gastric specimens are collected at intervals for analysis. Helps to determine the presence or absence of malignant cells	11–20 mEq/h after stimulation
Manometry	Measurement of pressures using a water-filled catheter connected to a transducer passed into the esophagus, stomach, colon, or rectum to evaluate contractility; useful in detecting motility disorders of the esophagus and lower esophageal sphincter; gastroduodenal, small intestine, and colonic manometry are used to evaluate delayed gastric emptying and gastric and intestinal motility disorders such as irritable bowel syndrome or atonic colon; anorectal manometry measures the resting tone of the internal anal sphincter and the contractility of the external anal sphincter, which is helpful in evaluation of chronic constipation or fecal incontinence.	Values differ at various levels of the intestine.
Gastric tonometry	Monitoring modality used to determine the perfusion status of the gastric mucosa using measurements of local PCO_2. The CO_2 diffuses from the mucosa of the stomach into the lumen of the stomach and then into the silicone balloon of the tonometer. The PCO_2 within the balloon serves as a proxy measure for gastric mucosal CO_2 ($PgCO_2$). In a normally perfused gastric mucosa, $PgCO_2$ is nearly equivalent to the $PaCO_2$. With hypoperfusion, the $PgCO_2$ increases and the gap between the $PgCO_2$ and the $PaCO_2$ increases. The gap is a very sensitive indicator of gastric hypoperfusion.	The $PgCO_2$ and the $PaCO_2$ are nearly equal.

▲ Clinical Applicability Challenges

CASE STUDY

Mr. H. is a 75-year-old male with a history of multiple primary cancers including prostate cancer treated with local radiation therapy, vocal cord cancer treated with partial laryngectomy, and colon cancer for which he had a subtotal colectomy with ileosigmoid anastomosis 1 year ago. The patient's other past medical and surgical history reveals mitral valve replacement for mitral valve regurgitation, atrial fibrillation, cerebrovascular accident with no residual deficits, type 1 diabetes mellitus, hypertension, and glaucoma.

Mr. H. received three rounds of adjuvant chemotherapy after his colon cancer surgery. A restaging CT scan of chest, abdomen, and pelvis showed no evidence of peritoneal or pulmonary lesions but a new lesion in the right lobe of the liver. PET/CT scan confirmed only site of metastases to be in the liver. Preoperative CEA level was 243, which was elevated from 81 three months ago.

The patient now presents to the ICU after partial hepatectomy for metastatic adenocarcinoma of the colon to the liver. Preoperative laboratory values reveal serum glucose ranges from 123 to 133 mg/dL, total protein 7.9, albumin 3.2, white blood count 6,710, hemoglobin 9.6, and hematocrit 35.9.

1. Discuss the risk factors for malnutrition for the patient in the case study.
2. What would be included in an educational plan for the patient and his family?
3. What abdominal assessment would the nurse perform when the patient in the case study is admitted to the ICU?

40 Patient Management: Gastrointestinal System

Valerie K. Sabol and Allison G. Steele

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Explain how the physiological stressors of illness and injury alter the body's needs for energy.
2. Describe the different forms of malnutrition.
3. Discuss enteral and parenteral nutrition with regard to indications, assessment, management, and complications.
4. Discuss common medications used for patients with gastrointestinal disorders.

Health and nutrition have a symbiotic relationship. Physiological stressors, such as illness and injury, alter the body's metabolic and energy demands. Although early identification and nutritional intervention can lessen morbidity and mortality risks in critically ill patients, the underlying disease process must be identified and corrected before the body can reverse abnormal nutrient metabolism. This chapter presents an overview of physiological stress and its effect on metabolism, types of malnutrition, and the indications, assessment, and management of enteral and parenteral nutrition support therapies and the complications associated with these therapies.

▲ Malnutrition

According to the laws of thermodynamics, energy can be neither created nor destroyed. Through the processes of metabolism, people obtain energy from the foods (or organic fuels) they consume. Metabolism has two parts: anabolism and catabolism. Anabolism is a building-up and repair process that requires energy. Catabolism consists of breaking down food and body tissues to liberate energy.

Glucose is the obligatory fuel of the body, and it is the primary fuel of the brain and nervous system in particular. The nervous system cannot store or synthesize glucose as a fuel source, so it relies on glucose extraction from the bloodstream. The liver regulates glucose entry into the circulatory system because it has the ability to both store and synthesize glucose. Excess glucose is converted and stored as either glycogen or fatty acids (triglycerides). Although glucose can be converted to fatty acids for storage, there is no pathway for the conversion of fatty acids back into glucose. Instead, fatty acids are used directly as a fuel source or are converted to ketones by the liver. After prolonged starvation, the body adapts to preserve vital proteins by using ketones, rather than glucose, as energy. Ketoacidosis occurs when ketone production exceeds utilization.

The pancreatic hormones glucagon and insulin have opposing functions in metabolic processes. Glucagon stimulates glycogenolysis (glycogen breakdown) and gluconeogenesis (glucose synthesis from other sources such as proteins) and increases lipolysis (fat breakdown and mobilization). Insulin, in contrast, helps transport glucose for storage into the cells and tissues, prevents fat breakdown, and increases protein synthesis.

Glycogenolysis is controlled by the hormone glucagon and the catecholamines epinephrine and norepinephrine, which are released from the adrenal medulla in times of stress. Once glucose and glycogen stores have been exhausted (usually within 8 to 12 hours), hepatic gluconeogenesis increases dramatically to meet metabolic demands. Hormones that stimulate gluconeogenesis include glucagon and the glucocorticoid hormone cortisol. If catabolic processes continue without the support of energy, amino acids, and essential nutrients, depletion of existing body stores compromises overall bodily health and function, and without intervention, malnutrition may develop.

The metabolic response to stress is characterized by increased release of cytokines (interleukin-1, interleukin-6, and tumor necrosis factor-α) and increased production of counter-regulatory hormones (catecholamines, cortisol, glucogen, and growth hormone).[1] These counter-regulatory hormones induce catabolism and oppose the anabolic effects of insulin. This results in hypermetabolism and hypercatabolism with loss of body energy stores through proteolysis, lipolysis, and glycogenolysis. Critical illness is typically associated with catabolic stress in which patients commonly demonstrate a systemic inflammatory response.

Approximately one third to one half of hospitalized patients have evidence of malnutrition.[2] Forty percent of patients experience considerable weight loss (more than 10 kg) during and after a stay in the intensive care unit (ICU).[3]

This unintentional weight loss may deplete vital nutrient reserves, which may predispose the patient to malnutrition. Malnutrition is associated with increased morbidity and mortality, delayed wound healing, increased length of hospitalization, increased complications, immunosuppression, and organ impairment.[2] Malnutrition from starvation alone can usually be corrected by replacing body stores of essential nutrients. However, malnutrition resulting from critical illness and disease processes that alter metabolism is not as easily rectified.

The degree of starvation and physiological stress determines the extent and type of malnutrition. The three major types of protein-energy malnutrition are marasmus, kwashiorkor, and protein–calorie malnutrition. Marasmus is a severe, cachectic process, whereby virtually all of the available fat stores have been exhausted from prolonged calorie deficiency. Severe muscle wasting is evident in marasmus; however, serum albumin levels may be within normal limits or only slightly reduced. Treatment requires nutrition and fluid volume replacement at slow rates to prevent the complications associated with sudden fluid shifts, electrolyte abnormalities, and cardiorespiratory failure.

In contrast to the adaptive response of relative protein sparing in marasmus, kwashiorkor and protein–calorie malnutrition are typically caused by an acute, life-threatening illness, such as surgery, trauma, or sepsis. Kwashiorkor is usually seen in children in developing countries who have had prolonged periods of protein malnutrition. Protein–calorie malnutrition is more commonly seen in developed countries and is due to depletion of fat, muscle wasting, and micronutrient deficiencies from acute and chronic illness. Typically, during periods of critical illness when the patient is relegated to NPO status (*nil per os*, nothing by mouth) for surgery, diagnostic testing, or a number of other medical complications, hypermetabolism and catabolism increase protein and energy demands. Although the critically ill patient may appear nourished, often this is due to the masking effects of generalized edema—the result of extracellular fluid shifts caused by low-protein oncotic pressures in the intravascular space. Other than edema, clinical signs of protein malnutrition include skin breakdown, poor wound healing, surgical dehiscence, or a combination of the three. Additionally, hair can easily be plucked, and hair remnants are often noted on the patient's pillowcase and sheets. Laboratory data reveal low serum albumin levels, and treatment requires aggressive repletion of protein stores. The fact that protein malnutrition is much easier to prevent than to treat reinforces the need for intense nursing vigilance over the patient's nutritional status.

Marasmus and kwashiorkor can coexist. Typically, this is seen when a patient with marasmus is exposed to an acute stressor such as surgery, trauma, or sepsis. Although each situation must be evaluated individually, aggressive protein and calorie replacement is often indicated. Regardless of the type (or types) of malnutrition, vigilant monitoring is crucial to the success of nutrition therapy.

▲ Nutritional Support

A nutritional assessment should be completed on all critically ill or injured patients early in their hospitalization to determine the need for nutritional support therapy. The timing of nutritional support therapy is based on evaluation of the preexisting nutritional status, the presence and extent of systemic response to inflammation, and the anticipated clinical course.[4,5] Nutritional support therapy delivered within 24 to 48 hours of admission, once patients are hemodynamically stable, is advocated.[5–7] Goals of care in nutritional support include the following: preventing and treating macronutrient and micronutrient deficiencies, maintaining fluid and electrolyte balance, maintaining immune function, preventing infection, and other complications associated with nutritional therapy, and improving patient morbidity and mortality. Meeting these goals involves a multidisciplinary approach that includes the nurse, physician, dietitian, and pharmacist. Sample nursing diagnoses are given in Box 40-1. After a dietitian determines nutritional needs, a method of delivering nutritional supplementation must be selected. In patients unable to meet their nutritional needs with oral intake, nutritional supplementation may be delivered by enteral or parenteral routes. Figure 40-1 outlines the decision-making process. Considerations for elderly patients are given in Box 40-2.

BOX 40-1 EXAMPLES OF NURSING DIAGNOSES

For the Patient With Gastrointestinal Problems

- Imbalanced Nutrition: Less Than Body Requirements
- Imbalanced Nutrition: More Than Body Requirements
- Risk for Aspiration related to reduced level of consciousness, depressed cough and gag reflexes, incompetent lower esophageal sphincter, delayed gastric emptying, displaced feeding tube
- Diarrhea related to altered dietary intake, malabsorption, concomitant drug therapy, type of formula, bacterial contamination, stress/anxiety
- Risk for Infection related to invasive procedure and delivery of high concentrations of glucose parenterally
- Disturbed Body Image
- Bowel Incontinence
- Risk for Imbalanced Fluid Volume
- Impaired Swallowing

Enteral Nutrition and Delivery

Enteral nutrition refers to any form of nutrition delivered to the gastrointestinal (GI) tract. For those patients with an intact GI tract, the enteral route is the preferred method of nutritional support. A clinical rule of thumb is, "If the gut works, use it."

The GI mucosa depends on nutrient delivery and adequate blood flow to prevent atrophy, thereby maintaining the absorptive, barrier, and immunological functions of the intestine. Enterocytes are tightly packed epithelial cells that line the intestinal lumen and function as a barrier to bacterial invasion. Gut-associated lymphoid tissue (GALT) lines the GI tract and is associated with maintenance of the immunological function of the mucosa. GALT produces immunoglobulin A (IgA), which is secreted across the GI mucosa in response to eating. IgA coats the luminal bacteria, preventing bacterial adherence to the enterocytes. Without food, the GI mucosa atrophies, and motility is impaired. In the event of atrophy, the tissue available to absorb nutrients decreases and GALT is impaired. Preservation of the intestinal mucosal integrity is

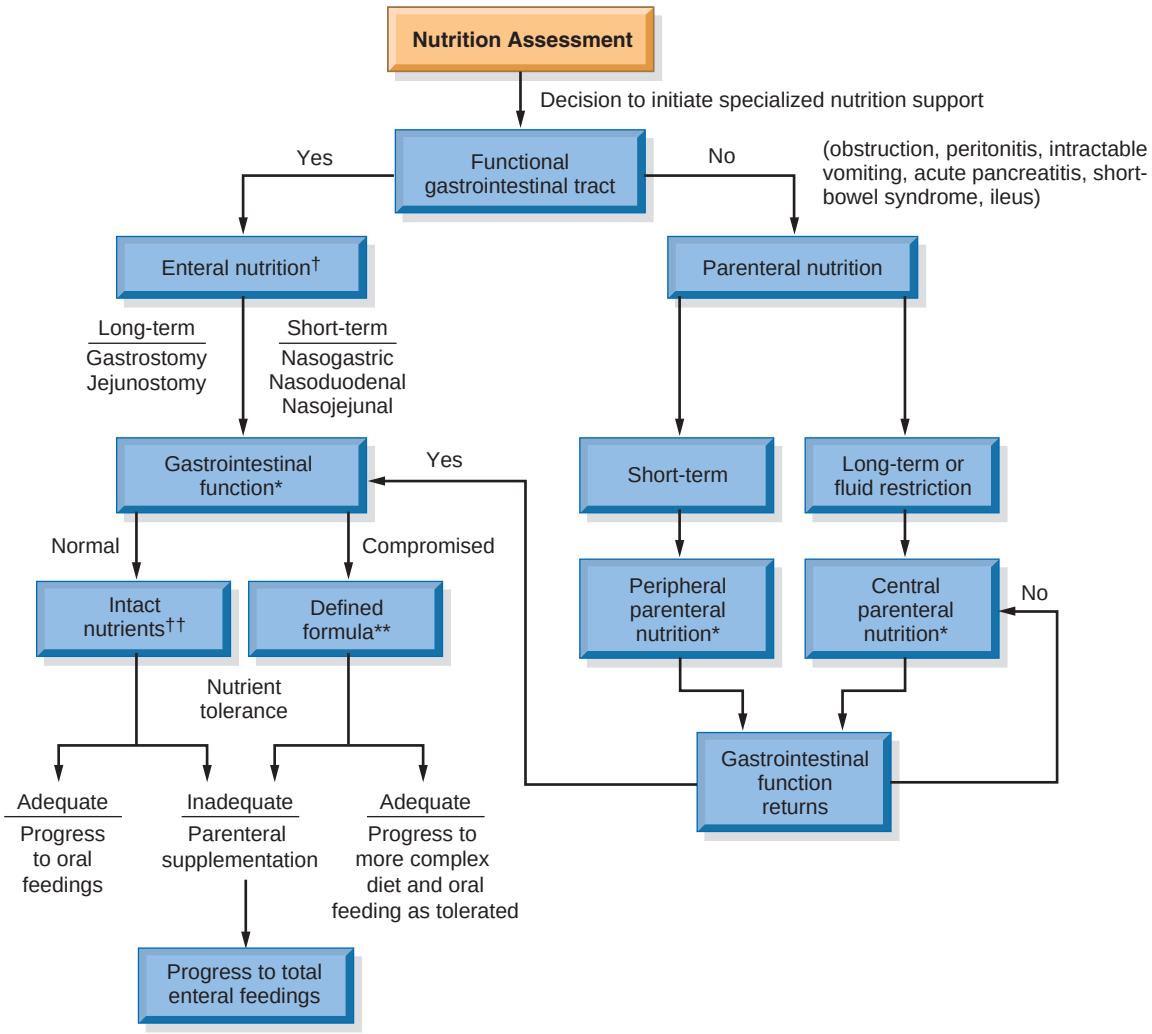

FIGURE 40-1 ▲ Route of administration of specialized nutrition support. *Formulation of enteral and parenteral solutions should be made considering organ function (eg, cardiac, renal, respiratory, hepatic). †Feeding may be more appropriate distal to the pylorus if the patient is at increased aspiration risk. ‡Elemental low-/high-fat content, lactose-free, fiber-rich, and modular formulas should be provided according to the patient's gastrointestinal tolerance. ††Polymeric, complete formulas, or pureed diets are appropriate. (Adapted from ASPEN Clinical Pathways and Algorithms for Delivery of Parenteral and Enteral Nutrition Support in Adults. Jacobs D (ed): Section II: Nutrition care process. J Parenter Enteral Nutr 26(1 Suppl):85A, 2002.)

also essential to preserve its function as a barrier. With atrophy, there is a loss of the tight junctions between enterocytes, resulting in increased mucosal permeability and decreased barrier function. This decreased barrier function can allow resident GI bacteria and endotoxins to enter the systemic circulation. This process, called bacterial translocation, can trigger immune and inflammatory responses that can lead to infection, sepsis, and multisystem organ failure. In addition to its trophic effects on the GI tract, enteral nutrition is associated with enhanced utilization of nutrients, decreased infectious complications, ease and safety of delivery, and lower cost.

Enteral nutrition is considered when the patient cannot or should not eat, intake is insufficient or unreliable, the patient has a functional GI tract, and access can be safely achieved. Mechanical obstruction is the only absolute contraindication to enteral feedings. In the setting of hemodynamic compromise (ie, the patient requires significant hemodynamic support including high-dose catecholamine agents, alone or in combination with large-volume fluid or blood product administration to maintain cellular perfusion), enteral nutrition should be withheld until the patient is fully resuscitated and/or stable.[5] Accordingly, each patient situation should be evaluated individually.

Enteral nutrition can be delivered through feeding tubes placed into the stomach or the small intestine. The expected duration of nutritional support, patient's overall condition, risk for aspiration, function of the GI tract, and placement technique should all be considered when deciding on which type of feeding tube to place. For most patient populations, nasoenteric tubes are widely used.

Nasoenteral Feeding and Feeding Tubes

A nasoenteric tube is indicated for short-term use in hospitalized patients, usually less than 4 to 6 weeks. Nasoenteral tubes are inserted through the nose and advanced through the

BOX 40–2 CONSIDERATIONS FOR THE OLDER PATIENT

Nutritional Requirements

- The risk for malnutrition increases as functional abilities decrease.
- The caloric needs of the elderly are generally less, secondary to decreased metabolism.
- Although protein requirements remain the same, it is important to monitor renal function.
- There is decreased ability to tolerate glucose loads.
- Atrophic gastritis occurs frequently in the elderly, which can result in decreased gastric acid secretion. The resultant achlorhydria or hypochlorhydria can lead to bacterial overgrowth and altered absorption of iron, vitamin B_{12}, folate, calcium, vitamin K, and zinc.
- Lactose intolerance increases with age; this intolerance to dairy products can contribute to osteopenia.
- Vitamin D deficiency in the elderly can be due to decreased dietary intake, decreased synthesis, or decreased exposure to sunlight.
- The elderly have less ability to regulate fluid balance, which places them at an increased risk for dehydration or overhydration.
- Encourage increased dietary fiber, fluids, and exercise to reduce the incidence of constipation.
- Decreased GI motility, exocrine function, and digestion or absorption may occur in the elderly.
- Physical changes in the jaw, including poor dentition or poorly fitting dentures, may interfere with mastication and adequate food intake.
- Swallowing may be more difficult because of decreased esophageal motility and decreased saliva production.
- Multiple medications or concomitant disease may contribute to anorexia or diminished sense of taste.

esophagus into the stomach (nasogastric tube), duodenum (nasoduodenal tube), or jejunum (nasojejunal tube). The tube is identified by the distal location of its tip. Most nasoenteric tubes are soft, flexible, small-bore polyurethane or silicone tubes that are 8 to 14 French in diameter and 20 to 60 inches in length, have markers to aid measurement, and are radiopaque to allow for radiographic confirmation of placement. The shorter lengths are used for nasogastric feedings, and the longer for nasoduodenal or nasojejunal feedings. As a general rule, the smallest-diameter tube of appropriate length is preferred because the smaller diameter has been associated with fewer complications and increased patient comfort. Small-diameter tubes may help prevent reflux and lessen the risk for aspiration because the small diameter reduces compromise of the lower esophageal sphincter. See Evidence-Based Practice Highlight 40-1 for information about the prevention of aspiration. In addition, small-diameter tubes cause less inhibition of swallowing, which is more comfortable for patients. Tubes made of polyvinyl chloride are less desirable because, over time, they can stiffen in the presence of acid, which can lead to patient discomfort and increased complications, such as tube perforation. Any nasally placed tube can cause sinusitis, erosion of the nasal septum or esophagus, otitis, vocal cord paralysis, epistaxis, or distal esophageal strictures, which may limit long-term use. Small, soft-bore tubes are less likely to cause these complications.

Most nasoenteric tubes have multiple ports staggered along their sides and tip, which minimize clogging and maximize flow. Many devices also have weighted tips and a stylet, which stiffens the tube to assist in placement. Another common feature of many nasoenteric tubes is a Y-port at the proximal tip, which allows for the administration of medications and irrigation without interrupting tube feeding.

NASOGASTRIC TUBES. Gastric feedings through a nasogastric tube are appropriate for patients who have intact gag and cough reflexes and adequate gastric emptying. Nasogastric tubes usually range from 8 to 12 French in diameter and 30 to 36 inches in length. Small-caliber nasogastric tubes are used solely for feeding, whereas large-caliber tubes can be used to decompress the stomach, monitor gastric pH, and deliver medications and feedings. Large-caliber nasogastric tubes are usually made of stiffer material and are often less comfortable for patients, possibly triggering self-extubation. These tubes are usually used to decompress and drain the stomach temporarily and are therefore typically for short-term use.

Advantages to gastric feeding include the ease of placement, the ease of checking residuals, and patient tolerability during enteral infusions. However, patients with nasogastric tubes are at the greatest risk for aspiration, especially when they are unconscious, mechanically ventilated, or otherwise unable to protect their airway. In a conscious patient, the mere physical appearance of the tube and associated discomfort may limit the clinical use of nasogastric tubes.

NASODUODENAL TUBES AND NASOJEJUNAL TUBES. Nasoduodenal tubes and nasojejunal tubes are thought to be better suited for long-term use than nasogastric tubes. Nasoduodenal tubes and nasojejunal tubes are advanced through the stomach, past the pylorus, and into the small intestine, usually in the third portion of the duodenum beyond the ligament of Treitz. In theory, the pyloric sphincter provides a barrier that reduces the risk for aspiration or regurgitation.

Transpyloric feeding can be given without regard to gastric emptying, providing an additional advantage over intragastric feeding. Candidates for transpyloric feedings include critically ill patients with a prior history of gastric aspiration, patients at risk for aspiration (such as ventilated patients), those with gastroparesis, those with gastric outlet obstruction, and patients with neurological conditions who are unable to protect their airway.

A common misconception is that enteral feedings should not be started if bowel sounds are absent. Bowel sounds are an indication of GI motility, not of absorption, and the presence or absent of bowel sounds or flatus is not required before the initiation of enteral feeding.[5,7] After injury and postoperatively, bowel sounds may not be detected for 3 to 5 days owing to gastric atony. The small bowel motility is less commonly impaired than the stomach or the colon and retains its absorptive and digestive capabilities, making it possible to accept enteral feedings immediately after surgery or trauma.

Nasoduodenal tubes and nasojejunal tubes range from 8 to 16 French in diameter and 152 to 240 cm in length. The length and diameter make it more difficult to check feeding residual because the lumen is smaller and tends to collapse

EVIDENCE-BASED PRACTICE HIGHLIGHT 40-1
Prevention of Aspiration

Expected Practice
- Maintain head-of-bed elevation at an angle of 30 to 45 degrees, unless contraindicated. (Level B)
- Use sedatives as sparingly as feasible. (Level C)
- For tube-fed patients, assess placement of the feeding tube at 4-hour intervals. (Level C)
- For patients receiving gastric tube feedings, assess for GI intolerance to the feedings at 4-hour intervals. (Level C)
- For tube-fed patients, avoid bolus feedings in those at high risk for aspiration. (Level E)
- Consult with physician about obtaining a swallowing assessment before oral feedings are started for recently extubated patients who have experienced prolonged intubation. (Level C)
- Maintain endotracheal cuff pressures at an appropriate level, and ensure that secretions are cleared from above the cuff before it is deflated. (Level B)

Supporting Evidence

Head-of-Bed Elevation
There is evidence that a sustained supine position (zero-degree head-of-bed elevation) increases gastroesophageal reflux and the probability for aspiration; for example, using a radioactive-labeled formula, endobronchial counts were higher when patients were lying flat in bed (0 degree) compared to when they were in a semirecumbent (45-degree) position.[2] Thus, elevating the head of the bed to an angle of 30 to 45 degrees, unless contraindicated, is recommended for patients at high risk for aspiration pneumonia (eg, a patient receiving mechanical ventilation and/or one who has a feeding tube in place).[3,4] Although effectiveness of the reverse Trendelenberg position in minimizing aspiration has not been studied, it is likely to produce similar results to an elevated backrest position.[4]

Sedation
Sedation causes reduced cough and gag reflexes and can interfere with the patient's ability to handle oropharyngeal secretions and refluxed gastric contents; in addition, sedation may slow gastric emptying.[5,6] To reduce the risk for aspiration, it is prudent to use the smallest effective level of sedation.

Assess Feeding-Tube Placement at Regular Intervals
Expert panels recommend that correct feeding-tube placement be verified at regular intervals to minimize the risk for aspiration.[3,4,7] If feedings are administered at the wrong site (such as the esophagus, or even the stomach of a patient who requires small-bowel feedings), the risk for aspiration is increased.[8] It is not uncommon for feeding tubes to become malpositioned during routine use. For example, in a study of 201 critically ill patients, it was found that the distal tips of 24 of 116 feeding tubes originally positioned in the small bowel were displaced upward into the GI tract (23 into the stomach and 1 into the esophagus).[9]

Assess for Gastrointestinal Intolerance to Tube Feedings
Tube-fed patients who experience frequent regurgitation and aspiration of gastric contents are at increased risk for poor respiratory outcomes.[1] Guidelines developed jointly by the Society of Critical Care Medicine and the American Society for Parenteral and Enteral Nutrition recommend that patients be monitored for tolerance to enteral feedings by noting abdominal distention, complaints of abdominal pain, observing for passage of flatus and stool, and monitoring GRVs.[10] Because gastric distention predisposes to regurgitation, it is recommended that GRVs be measured every 4 hours in critically ill patients.[4]

Practice varies widely in regard to GRVs; however, 200 and 250 mL are frequently cited values for initial concern.[11,12] In a study of 206 critically ill patients, two or more GRVs of at least 200 mL and one or more GRVs of at least 250 mL were found significantly more often in patients who experienced frequent aspiration.[11] Prokinetics are sometimes advocated to improve gastric emptying when GRVs exceed a stipulated value. Several sources recommend that feedings be stopped when GRVs exceed 500 mL.[4,7]

In a study of gastrointestinal (GI) symptoms in critically ill patients, investigators found that those with two or more simultaneous GI symptoms (such as high gastric aspirate volume, absent or abnormal bowel sounds, vomiting/regurgitation, diarrhea, bowel distension, and GI bleeding) were less likely to have successful enteral feedings than those with fewer than two GI symptoms (84% vs. 12.2%, respectively, $p < 0.001$).[13] Although bedside assessments for GI function such as GRVs and abdominal girth are difficult to evaluate,[14–16] they are frequently used in combination to provide an estimate of GI tolerance to enteral feedings. Small bowel feeding with the tube's ports situated at or below the Ligament of Treitz is strongly recommended for patients with persistent intolerance to gastric feedings and documented aspiration.[7]

Avoid Bolus Tube Feedings in Patients at High Risk for Aspiration
An expert panel has concluded that no recommendation can be made regarding the best type of formula delivery method (continuous or intermittent).[3] Also, no guidelines exist for bolus feedings. On the basis of logic, however, administering an entire 4-hour volume of formula over a period of a few minutes is more likely to predispose to regurgitation of gastric contents than is the steady administration of the same volume over a period of 4 hours.

Continuous feedings are used in most critical care units. Supportive of this action is a small study of neurologically impaired adult patients; aspiration was observed more frequently in those with intermittent feedings (3 of 17) than in those who received continuous feedings (1 of 17).[17] It is possible that the bolus method of feeding may decrease the lower esophageal pressure and thus predispose patients to reflux and aspiration.[18] Other researchers reported that adult burn patients who received continuous tube feedings had less stool frequency and less time required to reach nutritional goals than did intermittently fed patients.[19]

Swallowing Assessment Before Oral Feedings for Recently Extubated Patients
Tracheal intubation interferes with overall swallowing physiology.[20] Thus, it is reasonable to expect some degree of swallowing impairment when patients are initially extubated. A systematic literature review found that recently extubated patients were at increased risk for swallowing difficulties; more than 20% of the patients in many of the reviewed studies experienced dysphagia.[21]

Management of Endotracheal Tubes
A persistent low cuff pressure (<20 cm H_2O) predisposes patients to pneumonia, presumably by predisposing to aspiration of oropharyngeal secretions and/or refluxed gastric contents.[22] To minimize aspiration of secretions pooled above the endotracheal tube's cuff, hypopharyngeal suctioning should be performed before deflating the cuff.[3]

AACN Levels of Evidence

Level A Metaanalysis of quantitative studies or metasynthesis of qualitative studies with results that consistently support a specific action, intervention, or treatment

Level B Well-designed, controlled studies with results that consistently support a specific action, intervention, or treatment

on itself when aspirated. In addition, clogging of medications is more common than with nasogastric tubes. The primary disadvantage associated with nasoduodenal and nasojejunal tubes relates to the difficulty in initially placing the tubing tip past the pyloric sphincter.

Placing Nasoenteric Tubes

In most ICUs, skilled nurses or physicians routinely place nasoenteric tubes. Before placing a feeding tube, institutional policy and protocol should be reviewed because nasoenteric tube placement has many potential complications. Patients with a decreased level of consciousness, poor cough or gag reflex, or an inability or unwillingness to cooperate are at increased risk for pulmonary intubation. When a patient cannot cooperate or cough when the tube enters the bronchial tree, extra precautions must be taken to ensure proper placement. Feeding tubes placed in the bronchial tree can cause pulmonary hemorrhage or pneumothorax. A cuffed endotracheal tube (ETT) does not preclude accidental pulmonary intubation. Nasoenteric tubes can also be accidentally placed in the esophagus or, in patients with basilar skull fractures, in the intracranial space.

Nasogastric tube placement is usually easier than nasoduodenal or nasojejunal tube placement. When placing a nasoenteric feeding tube in the stomach, the nurse determines the length of tube insertion by measuring the distance from the tip of the nose, to the earlobe, to the tip of the xiphoid process. Before insertion, the nurse considers using a topical anesthetic or water-soluble lubricant to assist in placement. After placing the patient's bed in a high Fowler's position, the nurse slightly flexes the patient's head (if not clinically contraindicated) and passes the lubricated tip through the nares into the nasopharynx. While advancing the tube, the nurse asks the patient to swallow repeatedly. Having the patient sip water through a straw may also assist in tube placement (if not clinically contraindicated). Rotating the tube as it is advanced may also ease advancement.

When attempting to pass the nasoenteric tube tip past the pylorus, the nurse follows the same procedure described previously and then turns the patient to the right lateral decubitus position with the head of the bed at a 30- to 45-degree angle to take advantage of gravity and peristalsis. Nasoduodenal and nasojejunal tubes depend on gastric motility to carry the tip through the pylorus, but they have a tendency to coil in the stomach. Some nasoduodenal tubes and nasojejunal tubes have weights to aid in passage through the pylorus; however, the utility of the weighted tip is dubious. A promotility agent, such as metoclopramide or erythromycin, may be ordered before insertion because such a medication increases upper GI motility while relaxing the pylorus. Air insufflation, the process of inserting large amounts of air into the stomach, may also be helpful by distending the stomach and facilitating tube passage though the pylorus. If attempts to pass a nasoduodenal or nasojejunal tube are not successful within 24 hours, endoscopic or radiological assistance should be sought to advance the tip of the tube.

Before initiating tube feeding, proper tube placement must be confirmed by an abdominal radiograph. Feeding tubes placed surgically, by endoscopy, or under fluoroscopy do not require radiographic confirmation of placement. The external length of the tube is documented after placement is confirmed. The nurse marks the tube with tape or indelible ink at the point it enters the nares, rechecks tube placement before initiating intermittent feedings or medication administration and at least once each shift, and monitors tube placement during continuous tube feeding according to the institution's policy.

Auscultation, aspiration and inspection of aspirate, and pH testing have been used to monitor tube placement after initial placement is confirmed by an abdominal radiograph with varying degrees of accuracy. No one method is infallible, so using a combination of these methods is advised. Abdominal radiograph remains the gold standard. Injecting air into the tube and auscultation of the gastric bubble, although commonly used, is not an accurate method to verify initial tube placement. An air bubble sound can be transmitted to the epigastrium when the tube is in the esophagus. Although auscultation of insufflated air is not a reliable method to confirm initial feeding tube placement, it may still provide useful information. If no resistance is met, the tube is unlikely to be kinked, and if the patient immediately burps back air, the tip of the tube is probably in the esophagus.

Aspiration and inspection of the aspirate may help differentiate between gastric and intestinal placement, but not between intestinal and pulmonary placement. Fluid aspirated from the stomach is usually green, tan, brown, or bloody.[8] Small intestinal aspirate is usually golden yellow, clear, or bile colored and is often thicker than gastric aspirate.[8] Pulmonary fluid is usually tan, white, clear, or pale yellow and can closely mimic gastric or intestinal aspirates.[8] However, it is necessary to keep in mind that the diameter of small intestinal tubes may not allow withdrawal to check aspirate.

Measuring the pH of fluid aspirated from the feeding tube is another method of monitoring tube placement. The pH of esophageal secretions is usually 6.0 to 7.0, gastric aspirates 1.0 to 4.0, and intestinal contents 6.0 to 7.0.[8] However, the pH of gastric aspirate can be elevated with the infusion of enteral formulas, the use of acid-modifying medications, and the presence of bile reflux. The pH of both small intestinal aspirate and pulmonary fluid is usually greater than 6.0; therefore, if the pH of the aspirate is greater than 4.0, tube position cannot be determined based on pH alone.[8] For optimal results with pH testing, nothing that may alter the pH should be instilled in the tube for 60 minutes.

Capnometry and capnography detect carbon dioxide; these noninvasive monitoring techniques are used to monitor and evaluate respiratory function and ventilation. Observation of the presence or absence of a waveform is used to evaluate for accidental pulmonary placement of feeding tubes.

Suctioning and patient movement or coughing may potentially dislodge a feeding tube. If at any time tube location is in question, the nurse holds the tube feeding and requests an order for an abdominal radiograph to confirm placement. See Evidence-Based Highlight 40-2 for more information.

Securing Nasoenteric Tubes

Before securing any feeding tube, the nurse cleans the skin with alcohol to remove oils and dirt and considers applying a skin protectant to maintain skin integrity. Nasoenteric tubes should be secured in a way that avoids irritation or pressure on the nares, thereby preventing necrosis. The nurse allows the tube to hang straight from the nares and secures it to the bridge of the nose or the cheek with tape (or one of the many commercially available devices). For agitated or uncooperative patients, the nurse considers soft wrist restraints or mitts to avoid accidental self-extubation (refer to your institution's policy and procedure regarding the use of restraints). It is necessary to inspect the skin and nostrils every 4 to 8 hours for signs and symptoms of irritation, erythema, or skin breakdown. Patient comfort can be maximized by providing frequent mouth care and moistening of the nares.

Enterostomal Feeding and Feeding Tubes

If therapy is expected to last a month or more, a more permanent enterostomal device can be inserted through the abdomen into the stomach (gastrostomy) or jejunum (jejunostomy)[8] (Fig. 40-2). Enterostomal feeding tubes are also indicated when the nasal route is contraindicated and when the patient's swallowing is impaired or the oropharynx, larynx, or esophagus is obstructed. Enterostomal tubes are 18 to 28 French in diameter, made of silicone and polyurethane, and very durable.

GASTROSTOMY TUBES. Gastrostomy tubes have an internal retention bolster to prevent accidental dislodgment.

EVIDENCE-BASED PRACTICE HIGHLIGHT 40-2

Verification of Feeding Tube Placement (Blindly Inserted)

△ Expected Practice

- Use a variety of bedside methods to predict tube location *during* the insertion procedure:
  - Observe for signs of respiratory distress.
  - Use capnography if available.
  - Measure pH of aspirate from tube if pH strips are available.
  - Observe visual characteristics of aspirate from the tube.
  - Recognize that asucultatory (air bolus) and water bubbling methods are unreliable. (Level B)
- Obtain radiographic confirmation of correct placement of any blindly inserted tube prior to its initial use for feedings or medication administration.
  - The radiograph should visualize the entire course of the feeding tube in the GI tract and should be read by a radiologist to avoid errors in interpretation. Mark and document the tube's exit site from the nose or mouth immediately after radiographic confirmation of correct tube placement. (Level A)
- Check tube location at 4-hour intervals after feedings are started:
  - Observe four a change in length of external portion of the feeding tube (as determined by movement of the marked portion of the tube.
  - Review routine chest and abdominal x-ray reports to look for notations about tube location.
  - Observe changes in volume of aspirate from feeding tube.
  - If pH strips are available, measure pH of feeding tube aspirates if feedings are interrupted for more than a few hours.
  - Observe the appearance of feeding tube aspirates if feedings are interrupted for more than a few hours.
  - Obtain an x-ray to confirm tube position of there is doubt about the tube's location. (Level B)

△ Supporting Evidence

Bedside Methods to Determine Placement During Blind Tube Insertion

Signs of Respiratory Distress

- Symptoms such as coughing and dyspnea may occur when feeding tubes are inadvertently positioned in the airway, especially in patients with an impaired level of consciousness.[14–16] The occurrence of these signs should cause removal of the tube and a new insertion attempt.[17]

Capnography

- A carbon dioxide detector is helpful but is not sufficiently sensitive and specific to preclude the need for a confirmatory x-ray before initial use of a feeding tube.[22,23] In addition, a concurrently used CO_2 sensor failed to detect two of the four malpositioned tubes.[23] Also, a carbon dioxide sensor cannot determine where a feeding tube's tip ends in the GI tract (esophagus, stomach, or small bowel).[1]

pH and Appearance of an Aspirate

- Fasting gastric pH is usually 5 or less, even in patients receiving gastric-acid inhibitors.[17,24,25] Respiratory secretions typically have a pH greater than 6.[15,26] However, because gastric fluid occasionally has a high pH, the pH method is not sufficiently reliable to rule out the need for an x-ray to distinguish between gastric and respiratory tube placement.
- Small bowel secretions typically have higher pH values (≥6) than gastric juice; thus, observing for pH changes is useful in determining when a feeding tube has advanced from the stomach into the small bowel.[24,25,27] Using this method, it is often possible to limit the needed number of confirmatory x-rays to one.

(continued on page 899)

EVIDENCE-BASED PRACTICE HIGHLIGHT 40-2 (continued)

Verification of Feeding Tube Placement (Blindly Inserted)

- The pH method has no benefit in detecting placement of a feeding tube in the esophagus. Fluid withdrawn from the esophagus can be swallowed alkaline saliva or refluxed acid gastric juice.[28]
- In summary, while the pH method is helpful, it is not sufficiently accurate to eliminate the need for a confirmatory x-ray prior to first-time use of a feeding tube.
- Aspirate appearance is not sufficient to eliminate the need for a confirmatory radiograph prior to first-time use of a feeding tube; there is not confusion in differentiating between gastric and respiratory secretions.[6,15,16,30–36,37]

Listening Over Epigastrium for Air Insufflated Through Tube

- The auscultatory method is not reliable in distinguishing between respiratory and gastric placement or between gastric and small bowel placement.
- There are numerous anecdotal reports of blindly inserted tube entering the respiratory tract undetected by the auscultatory method, causing clinicians to assume that the tubes were correctly positioned in the stomach.[6,15,16,36,38–43] In a number of these cases, feedings or medications were administered and led to poor patient outcomes.[6,16,35,36,40,42–44]

Radiographic Confirmation

- A properly obtained and interpreted radiograph is recommended to confirm correct placement of any blindly inserted tube before its initial use for feedings or medication administration.[1,9,30,45,46,47] Because radiographs may be misinterpreted,[42,44,48] it is best to have a radiologist read the film to approve use of the tube for feedings.[1]
- Markings and documenting the tube's exit site at the time of radiographic confirmation of correct placement will be helpful in subsequent monitoring of the tube's location during its use for feedings.[49]

Checking Tube Location at Regular Intervals After Feedings Are Started

Feeding tube dislocation during feedings is a frequent problem.[49–51] Most often, it occurs when the tube is partially pulled out during movement or by an agitated patient.

Observing for Change in External Tube Length

- Observing for a change in length of the external portion of the feeding tube (as determined by movement of the marked portion of the tube) may be helpful in detecting tube dislocation.

Reviewing Routine Chest and Abdominal X-Ray Reports

- Reviewing routine chest and abdominal x-ray reports to determine if the radiologist has referred to feeding tube location can be quite helpful.

Observing for Changes in Volume of Feeding Tube Aspirates

- Observing the volume of fluid withdrawn from a tube at 4-hour intervals during continuous feedings or prior to each intermittent feeding may be helpful.[49] A sharp increase in residual volume may indicate displacement of a small-bowel tube into the stomach.
- Consistent inability to withdraw more than a few drops of fluid from the feeding tube may signal upward displacement into the esophagus.[28]
- It is often difficult to withdraw fluid from small-bore feeding tubes.[52] To avoid this problem, a proven method[53] calls for injecting 20 to 30 mL boluses of air into the tube with a large syringe (30 to 60 mL) and then slowly applying negative pressure to the plunger to withdraw fluid; it may be necessary to repeat the procedure several times.

Testing pH of Feeding and Observe the Appearance of Tube Aspirate if Feedings Are Off for Several Hours

- While feedings should never be interrupted solely for the purpose of pH testing, or observing the appearance of feeding tube aspirates, they are sometimes interrupted in preparation for tests or procedures. If the latter occurs, pH testing may be useful in distinguishing between gastric and small-bowel tube positions.[26,54] The pH method is of minimal benefit during continuous feedings because enteral formula buffers the pH of gastric and small bowel positions.[37] As indicated above, fasting gastric juice is usually grassy-green or clear and colorless, while small bowel juice is often bile-stained.

Listening Over Epigastrium for Air Insufflated Through the Tube

- The auscultatory method cannot distinguish between esophageal, gastric, or small bowl tube placement.

Obtain an X-Ray to Determine Tube Location if in Doubt

- When multiple bedside methods suggest that tube displacement has occurred, it is prudent to consider obtaining and x-ray to determine tube location.

Gastrostomy tubes may be used temporarily or for permanent feeding. If a gastrostomy tube is intended for permanent feedings, it may need to be replaced as the tube material deteriorates over time. Gastrostomy tubes may also be used for chronic gastric decompression. A low-profile gastrostomy device (LPGD), often referred to as a button, may be used to replace gastrostomy tubes in a mature gastrostomy tract, usually 3 to 6 months after initial placement or as an initial placement. LPGDs are anchored in the stomach and protrude through the abdomen, flush with the skin. These devices require a special extension adapter to connect with the tube-feeding bag, to check for residuals, and to use for decompression. This adapter may then be removed after use. Some LPGDs are equipped with a one-way antireflux valve to prevent leakage of gastric contents onto the skin. These devices are usually well accepted because they are durable, unlikely to irritate the skin, and difficult to dislodge. With agitated or confused adults who have a tendency to pull on their tubes, these advantages may be a benefit.

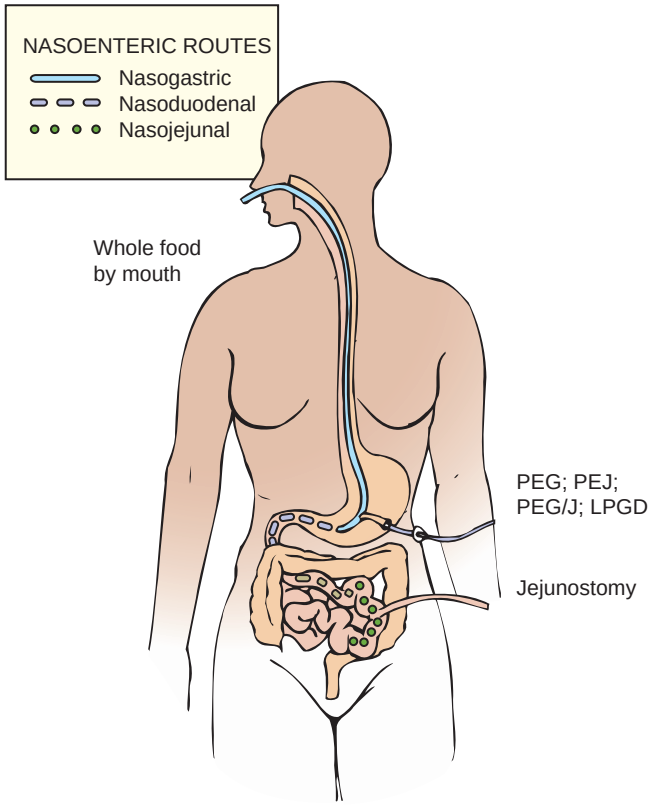

FIGURE 40-2 ▲ Possible routes for feeding. LPGD, low-profile gastrostomy device; PEG, percutaneous endoscopic gastrostomy; PEG/J, PEG modified with a jejunal extension tube; and PEJ, percutaneous endoscopic jejunostomy.

JEJUNOSTOMY TUBES. When gastric feedings are not possible or desired, jejunostomy tubes (J-tubes) are preferred for long-term feeding because they deliver enteral formula past the duodenum into the jejunum, decreasing pancreatic stimulation. J-tubes are indicated in patients who will benefit from jejunal feeding, particularly those with gastric disease, abnormal gastric emptying, upper GI obstruction or fistula, pancreatitis, or decreased gag reflex with significant risk for aspiration. J-tubes are contraindicated in patients with primary diseases of the small bowel (such as Crohn's disease) or radiation enteritis because of the increased risk for enterocutaneous fistula formation. A limitation of J-tubes is the potential for obstruction from the small diameter of the lumen.

Placing Enterostomal Tubes

Percutaneous endoscopic, open surgical, laparoscopic, and fluoroscopic techniques may be used to place a gastrostomy tube. J-tubes may be placed by percutaneous endoscopy or surgical methods. The patient's underlying disease and the physician's expertise need to be considered when selecting the appropriate placement technique.

PERCUTANEOUS ENDOSCOPIC GASTROSTOMY. Percutaneous endoscopic gastrostomy (PEG) has rapidly become the preferred method for placement of gastrostomy devices. A PEG may be performed at the bedside or in the endoscopy suite, using minimal sedation. Placement is through an abdominal incision using direct endoscopic visualization. Feeding may be administered as soon as 2 hours after placement.[8] Other advantages of PEG include increased comfort, decreased cost, and decreased recovery time. A candidate for a PEG must have an intact oropharynx and an esophagus free from obstruction. The only absolute contraindication to PEG is the inability to bring the gastric wall into apposition with the abdomen. Prior abdominal surgeries, ascites, hepatomegaly, and obesity may impede gastric transillumination and preclude placement of a PEG.

Complications of PEG are infrequent but include wound infection related to bacterial contamination by oral flora during insertion, necrotizing fasciitis, peritonitis, and aspiration. Pneumoperitoneum, a common finding after PEG placement, is not clinically significant unless accompanied by signs and symptoms of peritonitis. Prophylactic antibiotics are usually given 30 to 60 minutes before the procedure. Correct placement is then verified by endoscopy.

In patients with severe gastroesophageal reflux disease, gastroparesis, or increased risk for aspiration related to tube feeding, a PEG can be modified with a jejunal extension tube known as a PEG/J tube. The gastric lumen of a PEG/J tube is usually used for gastric decompression, and the jejunal lumen is used for the simultaneous delivery of enteral feeding. PEG/J tubes may decrease the risk for gastric aspiration; however, they do not necessarily provide the same protection against aspiration as jejunal tubes because the pylorus is compromised by the large catheter. The jejunal portion of a PEG/J tube may migrate back into the stomach and increase the risk for occlusion, gastric reflux, or aspiration. Both PEG and PEG/J tubes are held in place by internal and external retention devices. The internal device rests in the stomach, which prevents migration and leakage of gastric contents. The external retention device anchors the tube to the abdomen. These tubes have a high rate of mechanical dysfunction, which limits their long-term use.

SURGICAL GASTROSTOMY. Surgical gastrostomy tubes are inserted through an incision in the abdominal wall with the patient receiving general anesthesia. The stomach is usually sutured to the abdominal wall to create a permanent connection between the gastric and abdominal walls. Surgical placement of a gastrostomy is usually chosen if the surgeon wants to view the gastric anatomy clearly or as a secondary procedure during abdominal surgery. Disadvantages of surgical placement include the need for general anesthesia, increased recovery time, decreased comfort, and increased cost.

LAPAROSCOPIC GASTROSTOMY. A laparoscopically placed gastrostomy tube also requires general anesthesia or intravenous (IV) conscious sedation. Laparoscopic placement is usually reserved for patients with head, neck, or esophageal cancer. It is less invasive, is less painful, and usually involves fewer complications than a surgical gastrostomy.

FLUOROSCOPIC GASTROSTOMY. Direct percutaneous catheter insertion of a gastrostomy tube under fluoroscopy is indicated with high-grade pharyngeal or esophageal obstruction. Disadvantages to the use of fluoroscopy to place enterostomal devices include the inability to detect mucosal disease, the potential for prolonged exposure to radiation, the necessity of transport to the fluoroscopy suite, and increased cost.

Securing Enterostomal Tubes and Caring for the Enterostomy Site

Enterostomal tubes are secured to the abdominal wall to prevent dislodgment or migration of the tube, to avoid tension on the tubing, and to prevent the external retention device from digging into the skin. The length of the external tubing is documented to monitor for migration of the tubing.

To avoid tissue maceration, the insertion site is kept clean and dry by leaving it open to air (unless draining), and lifting or adjusting the tube is avoided for several days after the initial insertion. To avoid pulling the internal retention device taut against the gastric or intestinal mucosa, the amount of dressing between the device and the skin is limited. Any accumulated drainage may be cleaned with water. Serosanguineous drainage may be expected for 7 to 10 days after insertion. If no drainage is present, cleansing with soap and water is adequate. The skin around the insertion site and the retention device is assessed at least daily for skin breakdown, erythema, or drainage. The tissue usually heals within a month.

In-and-out play on the tubing is checked; it should be able to move one fourth inch to prevent erosion of gastric or abdominal tissue. If the anchor is too tight, the nurse should notify the physician immediately because this may indicate "buried bumper syndrome," a situation in which the retention device is imbedded in the tissue, thereby leading to mucosal or skin erosion. If a gastrostomy tube becomes accidentally dislodged, the nurse should notify the physician immediately so that the tube can be reinserted quickly before the tract closes.

Types and Delivery of Enteral Formulas

When selecting a tube feeding formula, nutrient requirements, the patient's clinical status, location of enteral access, GI function, cost, and duration must all be considered. Numerous tube feeding solutions are available for enteral nutrition, with many designed to assist in managing specific disease processes; however, no single formula is ideal for all patients. All contain proteins, carbohydrates, fats, vitamins, minerals, trace elements, and water. The difference lies in how these nutrients are structured and delivered. The dietary formula selected is based on the patient's ability to digest and absorb major nutrients, the total nutrient requirements, and fluid and electrolyte restrictions.

Polymeric solutions are the most commonly used formulas. These formulas are isotonic and can provide enough protein, carbohydrate, fat, vitamins, trace elements, and minerals to prevent nutritional deficiencies. They are considered nutritionally complete if given in enough volume to meet caloric needs. Standard formulas deliver 1 kcal/mL; some concentrated formulas may provide 2 kcal/mL.[9] The more concentrated formulas may be used for patients who require fluid restriction or in patients who have higher caloric requirements. All polymeric solutions contain intact proteins (most often meat, whey, milk, or soy proteins) that require normal pancreatic enzymes for digestion. Several disease-specific formulas are available.

Peptide (elemental or semielemental) formulas provide proteins as dipeptides, tripeptides, or free amino acids from hydrolysis of whey, milk, or soy proteins. Because peptides do not require pancreatic enzymes for digestion, elemental solutions are used when digestion is impaired, such as in pancreatic insufficiency, radiation enteritis, Crohn's disease, or short bowel syndrome secondary to surgical resection. Elemental solutions have no proven advantage in patients with normal gut function, are usually more expensive than polymeric formulas, and have an unpleasant taste.

Modular formulas contain individual nutrient components such as protein, carbohydrates, and fat that can be mixed or added to other formulas to individualize feedings to a patient's specific nutritional needs. The involvement of a dietitian is essential in the selection of these formulas.

Attention has recently focused on the role of enteral formulas that contain additional nutrients purported to enhance immune function. These formulas, referred to collectively as immunonutrition or immune-enhancing diets, have been reported to decrease infection rates, duration of mechanical ventilation, and length of hospitalization, but they have not been shown to affect mortality. Several nutrients that have attracted attention are glutamine, arginine, and omega-3 polyunsaturated fatty acids.

Glutamine is a nonessential amino acid that may become conditionally essential in critically ill adults.[9] Glutamine is an important fuel source for rapidly dividing cells, such as enterocytes, lymphocytes, and macrophages.[9] In addition, glutamine may improve immune function and reduce intestinal permeability.[9] Glutamine-enriched solutions should be considered in patients with burns and trauma.[5,7,9]

Another additive is arginine, which is also a nonessential amino acid that may become depleted in the critically ill. Arginine is a precursor of nitric oxide and is important in cell growth and proliferation, wound healing, and collagen synthesis.[9] Its role is controversial because increased nitric oxide production may increase tissue injury and trigger cardiovascular collapse in patients with sepsis or systemic inflammatory response syndrome.[5,10]

The omega-3 fatty acid is a precursor of prostaglandins, leukotrienes, and other inflammatory mediators. Use of an enteral formula with an antiinflammatory lipid profile fortified with omega-3 fatty acids or borage oil is recommended for patients with acute respiratory distress syndrome and severe acute lung injury.[5,7,10] These formulas have been shown to reduce the length of stay in the ICU, duration of mechanical ventilation, organ failure, and mortality when compared to standard formulas.[5]

When initiating enteral tube feedings, most clinicians recommend beginning with an isotonic formula at a slow rate, most often 20 to 30 mL/h, and increasing the rate incrementally every 8 to 12 hours until the goal rate is achieved. Dilution of formula may help tolerance but is not recommended because this may increase the time needed to meet the nutritional requirements.

Enteral feedings can be administered by bolus, gravity infusion, intermittent infusion, continuous infusion, or cyclic infusion. The tube tip location and tolerance generally dictate formula delivery. Gastric feedings are appropriate for patients who have intact gag and cough reflexes and adequate gastric emptying.

BOLUS FEEDINGS. Bolus feedings, considered the most natural method physiologically, are delivered by gravity by a large syringe in volumes as high as 400 mL over 5 to 15 minutes, three to five times a day.[8] The stomach is the

preferred site for bolus feedings. The stomach and pyloric sphincter regulate the outflow of feeding from the stomach. Bolus feedings allow for increased patient mobility because the patient is free from a mechanical device between feedings. Bolus feedings are usually initiated with 60 to 120 mL of full-strength formula every 8 to 12 hours until the goal is reached.[8] Unfortunately, as a result of high residuals, bolus feedings are usually not well tolerated and are often accompanied by nausea, bloating, cramping, diarrhea, or aspiration.

INTERMITTENT FEEDINGS. Intermittent feedings of 300 to 400 mL are administered by slow gravity drip four to six times a day over a period of 30 to 60 minutes. The stomach is the preferred site for intermittent infusion because of its capacity. Intermittent feedings are associated with a decreased risk for osmotic diarrhea. Advantages of intermittent feedings include freedom from dependence on a mechanical device and a power source, which can decrease cost and increase patient mobility.

CONTINUOUS FEEDINGS. If the tip of the nasoenteric tube is in the duodenum or jejunum, tube feedings must be delivered by infusion. Continuous infusions are administered over 24 hours with the aid of a feeding pump to ensure a constant flow rate. Continuous pump feedings are the preferred method for intestinal feeding because delivery that is too rapid may lead to "dumping syndrome," characterized by osmotic diarrhea, abdominal distention, cramps, hyperperistalsis, light-headedness, diaphoresis, and palpitations. When the tube is placed in the third portion of the duodenum, past the ligament of Treitz, continuous pump feedings are associated with decreased risk for aspiration. Initiate continuous feedings of full-strength formula at 10 to 40 mL/h advancing by 10 to 20 mL increments every 8 to 12 hours until goal is reached.[8] If the feeding is advanced slowly, the small bowel can usually tolerate feedings at a rate of 150 mL/h. The continuous method is best suited to the critically ill patient because it allows more time for nutrients to be absorbed in the intestine. Continuous infusion is often used in the ICU because there is decreased incidence of gastric distention and potential for aspiration. Continuous infusion tube feeding may also act prophylactically to prevent stress ulcers and metabolic complications. As with intermittent feedings, disadvantages include the dependence on a mechanical device and a power source.

CYCLIC FEEDINGS. Cyclic feedings are continuous feedings that deliver the total daily nutritional requirements in a shorter time frame, typically over 8 to 12 hours, to allow the patient freedom from 24-hour continuous feedings. Cyclic feedings of high density and high volume are typically given at night to allow hunger to develop during the day, but they may be given during the day if a patient has difficulty with regurgitation while lying supine. This schedule may assist the patient in progressing from enteral to oral consumption.

The ultimate goal is for patients to resume adequate oral intake. Enteral feeding may be discontinued when patients can drink enough liquid to maintain hydration and can eat two thirds of their nutritional requirements.

Complications of Enteral Nutrition

Although enteral nutrition is in general associated with fewer complications than parenteral nutrition, complications may still occur. These complications generally fall into GI, mechanical, metabolic, and infectious categories. Many of these complications can be prevented or treated by closely observing residuals and watching for signs and symptoms of gastric intolerance. See warnings in Evidence-Based Highlight 40-3.

GASTROINTESTINAL COMPLICATIONS. The patient's tolerance to enteral feeding depends on the rate of flow and the osmolality of the formula. Signs and symptoms of GI intolerance to enteral feeding include diarrhea, nausea, vomiting, abdominal

EVIDENCE-BASED PRACTICE HIGHLIGHT 40-3

Dye in Enteral Feeding

△ Expected Practice

- Dye should not be added to enteral feeding as a method for identifying aspiration of gastric contents.

△ Supporting Evidence

- Research has shown that dye in enteral feedings is often not visible in tracheal secretions following known aspiration events.[12,17] (Level B)
- A consensus statement from a multidisciplinary group of experts recommended that use of the dye method be discontinued since it lacks sensitivity for identifying aspiration of gastric contents.[3] (Level D)
- The addition of dye to enteral formula has been associated with several adverse events, including gastric bacterial colonization and diarrhea, systemic dye absorption, and death.[4,7,11,14] (Level A)
- The FDA issued a Public Health Advisory in 2003 based on reports of toxicity and death associated with dye in enteral feeding, although a direct causal relationship has not yet been definitively confirmed.[15] The majority of reported cases of toxicity and/or death occurred in patients with sepsis. (Level C)
- Use of glucose testing of tracheal aspirates is no longer recommended as a viable method to detect aspiration.3,18–20 (Level D, B)

AACN Levels of Evidence

Level A Meta-analysis of quantitative studies or metasynthesis of qualitative studies with results that consistently support a specific action, intervention, or treatment.
Level B Well-designed, controlled studies with results that consistently support a specific action, intervention, or treatment.
Level C Qualitative studies, descriptive or correlational studies, integrative review, systematic reviews, or randomized controlled trials with inconsistent results.
Level D Peer-reviewed professional organizational standards with clinical studies to support recommendations.
Level E Multiple case reports, theory-based evidence from expert opinions, or peer-reviewed professional organizational standards without clinical studies to support recommendations.
Level M Manufacturer's recommendations only.

Excerpted from American Association of Critical-Care Nurses Practice Alert. Available online at http://aacn.org. All references cited in this alert are available with the associated resources related to this chapter. Visit: http://thepoint.lww.com

discomfort, distention, and high residual returns. Food normally passes through the stomach at a rate of 2 to 10 mL/min; however, gastric emptying is delayed or absent in many critically ill patients. Unlike the stomach, the small intestine cannot act as a reservoir. If large residuals are withdrawn through a nasoduodenal tube or nasojejunal tube, the tube may have moved back into the stomach, and placement should be confirmed with an abdominal radiograph.

High Residuals. The monitoring of gastric residual volumes (GRVs) is a routine practice based on the assumption that GRVs are useful in predicting the risk for aspiration and pneumonia. However, studies have not shown a consistent relationship between GRV and aspiration; high GRVs do not indicate aspiration, and low GRVs do not preclude aspiration.[11] Additionally, there is no consensus among experts about what constitutes a high GRV, with reports varying from 100 to 500 mL. High GRVs have been thought to result from impaired gastric emptying caused by intolerance to enteral feedings; GRV is an imprecise measure of gastric emptying and may not take into account the volume of gastric and salivary secretions. In addition, it is difficult to determine whether gastric contents have been completely removed. Many clinicians stop tube feeding inappropriately, based on a single GRV of less than 400 to 500 mL. Although a GRV between 250 and 500 mL should raise suspicion of intolerance and cause the implementation of measures to reduce the risk of aspiration. One high value does not mean feeding failure, and automatic cessation of feeding can delay the patient's ability to meet his or her nutritional goals.[5,7] Tube feedings should not be stopped for GRVs less than 500 mL in the absence of other signs of intolerance.[5] The nurse must be sure to evaluate the clinical status of the patient before stopping tube feeding solely on the basis of one high GRV; the key is to monitor trends.[7,12] Residuals should be checked every 4 hours during the first 48 hours of gastric feeding, every 4 hours during continuous feedings and before initiating intermittent feedings.[1,8,11]

Tube feeding should be withheld if a patient demonstrates overt signs of regurgitation, vomiting, or aspiration. A common intervention involves holding the feeding for 1 to 2 hours and rechecking GRV every 1 to 2 hours until the GRV is less than 200 to 250 mL from a nasogastric tube or less than 100 mL from a gastrostomy tube, at which point feedings can be resumed. If GVR is greater than 250 mL after two measurements, providing a promotility agent should be considered.[1,8] This allows time for normal gastric emptying and reduces the risk for aspiration. It is necessary to remember that high infusion rates result in higher GRVs and to be aware of the institution's policy and protocol regarding high GRVs.

Nausea, Vomiting, and Bloating. Nausea, vomiting, and bloating are commonly associated with enteral feedings. Medications, rapid infusion rate, or improper tube placement may cause both nausea and vomiting. Nausea, vomiting, and bloating are most likely to occur when gastric emptying is delayed. The nurse carefully assesses medications that may contribute to these symptoms, and the medications should be eliminated, if possible. A change of formula, reduction in delivery rate, or addition of a prokinetic medication may also help.

Diarrhea. Diarrhea is the most common complication of enteral feedings; however, it is important to consider other etiologies before assuming that enteral feedings are the cause of diarrhea. Diarrhea in a patient receiving enteral feeding may result from the use of antibiotics or other diarrhea-inducing medications; altered bacterial flora; formula composition; intolerance to lactose, fat, or osmolality; a rate of infusion that is too high; hypoalbuminemia; or enteral formula contamination.

The liquid form of many medications may contain hypertonic sorbitol, which can have laxative effects. Antibiotics, antacids, magnesium, and prokinetic medications can also contribute to diarrhea. Antibiotics can contribute to diarrhea by causing overgrowth of *Clostridium difficile*. To assess for *C. difficile* infection, a stool sample is assessed for *C. difficile* toxin. Treatment options include antibiotic therapy with oral metronidazole, vancomycin, or cholestyramine (a bile acid sequestrant that binds the toxin). A patient who has received antibiotics should not receive antidiarrheals until *C. difficile* infection has been ruled out because diarrhea helps eliminate the toxin from the intestinal mucosa.

Bacterial overgrowth may cause diarrhea. Reduced gastric and small bowel motility may lead to small intestinal overgrowth, which can alter intestinal microflora. Acid suppression may also permit bacterial overgrowth because bacteria can colonize the GI tract when the gastric pH is greater than 6.0.

The infusion of enteral feedings too rapidly may cause diarrhea. Intolerance of lactose, fat, or osmolality may also lead to diarrhea. Reducing the infusion rate, changing to a peptide-based formula that is easier to digest, and giving an absorbing product, such as psyllium fiber (Metamucil), may help. The use of a fiber-containing formula may be helpful in bulking stools and correction of the diarrhea.

The composition of enteral formulas makes them an ideal medium for bacterial growth, which may result in diarrhea. Many organisms have been associated with enteral feedings, including coagulase-negative staphylococci, *C. difficile*, and Gram-negative bacilli, such as *Serratia*, *Klebsiella*, *Enterobacter*, *Proteus*, and *Pseudomonas* species. Bacterial contamination from the surface of the formula container, or even water added when the preparations are mixed or poured, may lead to diarrhea. Contamination of enteral feedings may also occur as a result of retrograde movement of bacteria from the patient's own GI tract. In addition, the aspiration of gastric residuals and the removal of guide wires from the feeding tube may contribute to contamination.

Contamination of the feeding administration set may also cause diarrhea. Breaks in the system should be minimized, and the use of a closed, prefilled, ready-to-hang solution should be considered to minimize contamination from pathogens. To prevent bacterial contamination, formulas that are reconstituted in advance should be immediately refrigerated and discarded within 24 hours if not used.[8] Formulas that are exposed to room temperature for longer than 4 hours should be discarded.[8] Sterile, premixed formulas should hang no longer than 8 hours.[8] The nurse checks the expiration date of the formula and discards the formula if it has expired. Closed system administration sets should be changed every 24 to 48 hours, and open system administration sets should be changed every 24 hours.[8] All practitioners should use good hand washing technique when handling equipment and wear gloves when handling feeding systems.

In patients receiving enteral feedings, a hyperosmotic formula may also contribute to diarrhea. If diarrhea decreases when the feedings are withheld, the formula may be the cause. After consultation with the dietitian, the nurse may consider changing the formula. Also, the nurse collects a stool sample to evaluate for an osmotic gap; this may help identify osmotic diarrhea.

Hypoalbuminemia may predispose patients to diarrhea by decreasing the osmotic pressure gradient. This decrease may lead to bowel edema and malabsorption. Any formula that is not absorbed may contribute to the diarrhea. Prealbumin level is monitored because it is a more reliable indicator of current nutritional status than serum albumin.

Constipation. Constipation associated with enteral feedings may be related to poor hydration, lack of fiber, bed rest, impaction, obstruction, and narcotics. Adequate hydration is ensured, and adding a stool softener should be considered along with minimizing narcotic administration, encouraging ambulation, and considering the addition of fiber to relieve constipation.

MECHANICAL COMPLICATIONS. Mechanical complications occur when the feeding tube becomes dislodged, occluded, or malpositioned.

Tube Dislodgment. Tube dislodgment by patients or staff accounts for most tube removals. Soft restraints or hand mitts should be considered for agitated patients to prevent accidental self-extubation (refer to your institution's policy regarding the use of restraints).

Tube Clogging. Precipitation of medications, clogging of pill fragments, or coagulation of formula may cause obstruction of any feeding tube, delaying the administration of nutrients and medications. To avoid clogging, the nurse flushes enteral feeding tubes every 4 hours during continuous feedings, before and after medication administration, after checking residuals, and when turning off feedings.[8] For flushing nasoenteric tubes, the nurse always uses a large 30- to 60-mL syringe to avoid rupturing the tube with excessive pressure and irrigates with 15 to 30 mL of sterile water.[8,13] The nurse frequently checks the enteral solution container for precipitation. Crushed tablets may leave a residue that blocks the tube. To prevent clogging, the nurse administers liquid medications when available. Flushing the tube before and after each medication, administration also helps avoid incompatibilities between medications and feedings and reduces the incidence of clogging. Medication should not be directly added to enteral formulas.[8,13]

An obstruction may exist if the formula does not flow by gravity, flushing an aspirate from the tube is not possible, or the occlusion alarm of the feeding pump sounds repeatedly. If an occlusion is suspected, the nurse uses a large piston syringe to flush the tube with warm water, using a gentle push–pull motion. Although many solutions have been proposed to assist in clearing an obstructed feeding tube, they offer no demonstrable benefit over tap water. A stylet should never be used to unclog a tube because of the risk for rupturing the feeding tube and perforating the esophagus, stomach, or small intestine. Recent studies show that pancreatic enzymes have been effective in unclogging a tube when water is unsuccessful, as long as the enzymes are activated before instillation.[8]

METABOLIC COMPLICATIONS. Multiple metabolic complications can accompany enteral nutrition. Fluid and electrolyte imbalance may occur because of fluid excess, fluid depletion by GI or renal losses, wound drainage, diuresis, fever, or inadequate free water intake. If dehydration is due to inadequate fluid intake, the nurse may need to give the patient extra fluid by bolus or by automatic flush using specialized feeding pumps. The average patient with good renal function needs 30 to 35 mL/kg of free water per day, if not medically contraindicated. Conversely, if cardiac or hepatic function is impaired, overhydration from enteral feedings may occur. The determination of the patient's baseline fluid requirements and accurate measurement of intake and output can help maintain fluid balance. The nurse should keep in mind that many of the patients seen in the ICU may be unable to convey feelings of thirst, secondary to intubation, or diminished levels of consciousness.

Hyperglycemia may occur if patients are being overfed, during hypermetabolic states, and as a result of steroid medications. Blood glucose is monitored during enteral therapy; a decrease in formula rate or concentration may help if hyperglycemia occurs. Bolus feeding may exacerbate hyperglycemia in patients with diabetes. If feedings are abruptly stopped, hypoglycemia is assessed, especially in patients receiving insulin.

INFECTIOUS COMPLICATIONS. Aspiration of enteral feeding resulting in hypoxia or pneumonia is a dreaded complication of enteral feeding. The incidence of aspiration of enteral formulas is as high as 50% to 75% in patients with ETTs. Loss of consciousness, mechanical ventilation, and many medications used in critically ill patients increase the risk for aspiration. To reduce this risk, the head of the bed should be maintained at a 30- to 45-degree angle.[5,8] If head of the bed elevation is medically contraindicated, a reverse Trendelenburg position is used unless medically contraindicated.[8] Intermittent or continuous feedings are used rather than rapid boluses because they allow the restoration of gastric pH, which can minimize gastric colonization. GRV is checked frequently, and signs of feeding intolerance are assessed. Feedings are discontinued at least 30 minutes before any procedure for which the patient must lie flat. If a procedure necessitates that the head of the bed be lowered, tube feedings may be withheld. The patient is returned to an elevated position, and the feedings are restarted promptly when the procedure is completed.[8] If a patient is intubated, secretions above the tube's cuff should be cleared before deflating the tube.

Pulmonary aspiration, although often subclinical, may be signaled by a low-grade fever, coughing, shortness of breath, rhonchi during or after enteral feeding infusions, and presence of a "sweet" formula odor emanating from tracheal or oral secretions during suctioning. The addition of Food, Drug, and Cosmetic (FD&C) blue dye No. 1 to enteral feeding formula to help visually identify aspirated feeding formula was a common practice for years. However, in 2003, the U.S. Food and Drug Administration (FDA) issued an FDA Public Health Advisory after several reports of toxicity, including bacterial colonization, diarrhea, systemic absorption, and death.[14] As a result, the American Association of Critical-Care Nurses Practice Alert advises that FD&C No. 1 dye should not be used in enteral feedings.[15] It is necessary that each nurse check his or her institution's policy and protocol regarding blue dye and its administration.

Checking tracheal suction fluid with a glucose strip and glucometer has been used to test for formula aspiration. Tracheobronchial secretions usually contain less than 5 mg/dL of glucose, so a reading greater than 20 to 25 mg/dL suggests aspiration, although there is some controversy concerning this procedure.

Parenteral (Intravenous) Nutrition

Parenteral nutrition is indicated when oral or enteral nutrition is not possible or when absorption or function of the GI tract is not sufficient (or is unreliable) to meet the nutritional needs of the patient. Before the inception of parenteral nutrition in the early 1960s, bowel rest was thought to be the cornerstone of treatment for many GI disorders. Today, except in cases of severe hemorrhagic pancreatitis, necrotizing enterocolitis, prolonged ileus, and distal bowel obstruction, some enteral nutrition is recommended to maintain gut integrity and function.[16] If a patient was healthy prior to critical illness with no evidence of protein–calorie malnutrition, use of parenteral nutrition should be reserved and initiated after the first 7 days of hospitalization.[5,7]

There are two types of parenteral (IV) nutrition: central and peripheral. Central parenteral nutrition, also known as total parenteral nutrition (TPN), is infused through a large central vein (Fig. 40-3). TPN has sometimes been referred to as "hyperalimentation" or "hyperal." These are not preferred terms because they imply that parenteral nutrition gives more nutrients than the patient may actually require. If TPN is expected to be needed for more than a few weeks, a more permanent device such a subcutaneously tunneled Hickman catheter or Port-a-Cath can be placed. Another central venous access device that can be used for long-term nutritional support is the peripherally inserted central catheter (PICC). A PICC is inserted peripherally into the basilic vein and advanced so that the tip of the catheter rests in the superior vena cava. Peripheral parenteral nutrition (PPN), unlike TPN, is infused into smaller, peripheral veins (eg, basilic vein) and is often used for short-term nutritional support (eg, 7 to 10 days) or as a supplement during transitional phases to enteral or oral nutrition (see Fig. 40-3). Because of the risks for phlebitis, concentrations of PPN formulas must not exceed 900 mOsm/L.[17] TPN differs from standard IV fluids in that all daily required nutrients are delivered to the patient in the form of macronutrients (carbohydrates, proteins, and fats) and micronutrients (electrolytes, vitamins, and trace minerals). Typically, the solution is infused at a constant rate over a 24-hour period to achieve maximal assimilation of the nutrients and to prevent hyperglycemia (or hypoglycemia). The aim of treatment is a continuous infusion that meets the caloric and nutritional requirements of the patient.

Critically ill patients often have issues with reliable IV access. TPN must be infused separately from other IV fluids, medications, and blood products because of the high risk for formula contamination and precipitation. Fortunately, the introduction of multiple-lumen catheters has greatly facilitated the care of patients who require multiple IV therapies by providing separate infusion ports and corresponding distal exit sites staggered along the catheter tubing. This separation prevents direct mixing of solutions before high-blood-volume dilution of the central veins. One port must be dedicated to exclusive use of TPN, whereas the remaining ports can be used for administering IV fluids and obtaining blood samples. When the central line is a single lumen, this lumen should be used exclusively for the infusion of TPN.

Composition of Parenteral Nutrition Formulas

TPN formulas typically contain three primary macronutrients: carbohydrates, lipids (fats), and amino acids (protein). This combination is called a mixed fuel source. When all three fuel sources are combined in one TPN bag, it is often referred to as a "3-in-1" admixture. To maintain strict sterility, the desired proportions of these nutrients are prepared under a laminar flow hood by a pharmacist. Because of differences in pharmacy equipment used to mix TPN, some facilities infuse lipids separately, usually in a glass bottle. Medications are not to be added to a TPN bag after it has been prepared by the pharmacist because of the risk for contamination

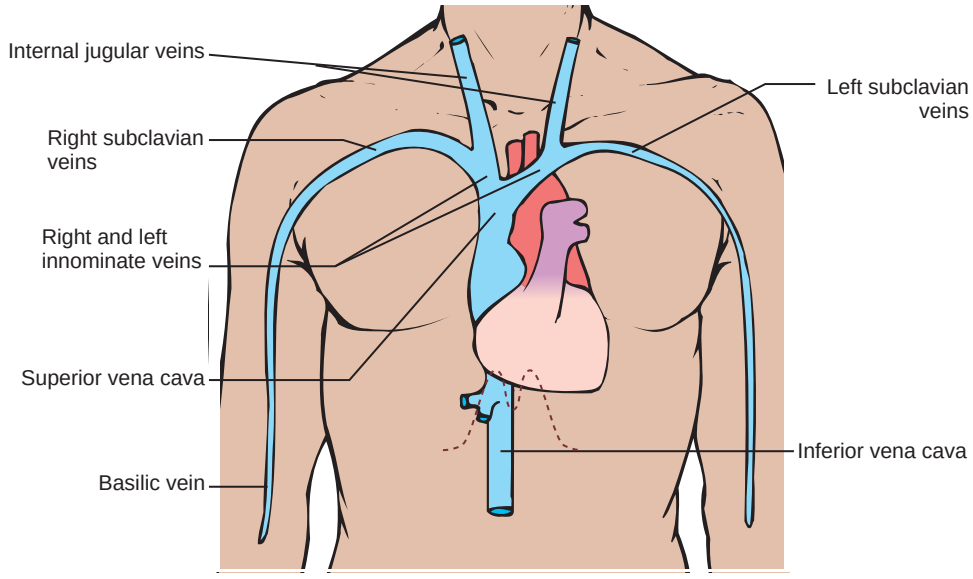

FIGURE 40-3 ▲ Venous anatomy for parenteral nutrition routes.

or precipitation of its contents. The current trend in TPN formulation is based on the specific needs of each patient; standard formulas are no longer widely prescribed.

CARBOHYDRATES. The primary source of energy in the body is carbohydrates (eg, dextrose). This macronutrient usually provides 40% to 60% of daily caloric requirements and is essential to central nervous system function. The most common and preferred source of carbohydrates is dextrose (D-glucose) because it is readily metabolized, stimulates the secretion of insulin, and is usually well tolerated in large quantities. Dextrose provides 3.4 kcal/g in IV form and contributes to most of the osmolality (or concentration) of the TPN solution. Initial TPN concentrations of dextrose may range from 50% to 70%, but final concentrations are diluted to approximately 25% to 30% after the addition of amino acids, lipid emulsions, and water.

Despite dilution, this concentration remains very high and requires delivery through a central venous catheter so that the higher blood volumes in the larger central veins are able to further dilute and disperse the solution. The superior vena cava is an excellent site for such delivery. Passage of a central venous catheter, by way of the subclavian vein into the superior vena cava, is the route of choice because it allows the patient the greatest freedom of movement without disturbing the insertion site. Jugular veins can also be used but may make it more difficult to keep dressings sterile, and these are not as comfortable for the patient because of limitations in neck movement. Regardless of the site, strict adherence to insertion and infection protocols must be followed, and radiologic verification of catheter tip placement is necessary before initial infusion. (Refer to your institution's central line care and infection control policies and procedures.)

The amount of dextrose prescribed in TPN is based on metabolic needs, which, once met, allows utilization of amino acids for protein synthesis rather than solely as an energy source. Adults require a minimum of 100 g/d of dextrose to perform vital metabolic activities; however, the maximal dose of dextrose varies based on an individual's needs, medical condition, and glucose tolerance. Recommendations suggest that dextrose must not exceed 7 g/kg/d.[18] One of the most common metabolic side effects of excessive dextrose concentrations is hyperglycemia, which often requires the use of insulin. Relatively tight blood glucose control is recommended to prevent complications associated with hyperglycemia. A protocol for moderately strict control of serum glucose between a range of 100 and 150 mg/dL may be appropriate.[5,7] In addition, excessive dextrose administration may put certain patients, such as those with pulmonary compromise, at risk for carbon dioxide retention and subsequent respiratory acidosis. Because one of the end products of dextrose metabolism is carbon dioxide, elevated levels may increase minute ventilation and hence the work of breathing. Overfeeding carbohydrates may make ventilator weaning difficult, if not impossible.

LIPIDS. Parenteral IV lipids, or fat emulsions, primarily contain long-chain linoleic and α-linolenic acids (essential fatty acids) from safflower and soybean vegetable oils. Lipid solutions also contain egg yolk phospholipids as emulsifiers, so it is important to check for a food allergy history before administration. Lipids provide a concentrated source of calories, 9 kcal/g, and they are important in maintaining connective tissue integrity and preventing fatty acid deficiency. Symptoms of fatty acid deficiency include rough, dry, scaly skin; nasolabial seborrhea; dull or dry hair, soft or brittle nails, poor wound healing, and diarrhea. Accordingly, patients should receive 2% to 4% of their daily energy requirements as linoleic acid and 0.25% to 0.5% of their daily energy requirements from α-linolenic acid.[18] The usual prescriptive dose of lipid emulsion infusion is approximately 1.0 to 1.3g/kg/d (not to exceed 2.5 g/kg/d) to supply up to 30% of the patient's caloric intake. Weekly administration of a 20% lipid emulsion (500 mL), however, is sufficient to prevent essential fatty acid deficiency in adults.[16,18]

Lipid emulsions are isotonic, and concentrations are available in 10%, 20%, and 30% solutions, providing 1.1, 2.0, and 2.9 kcal/mL, respectively.[17] The benefit of higher concentrations is that they provide a greater concentration of calories in less total fluid volume, an important consideration for many patients. In situations in which hyperglycemia has become problematic, dextrose solution concentrations and volumes may be reduced, and unless contraindicated, lipids concentrations and volumes can be increased. Lipids typically provide 15% to 30% of daily caloric intake; if delivery of lipids is higher than 30% of total caloric intake, vigilant monitoring for metabolic side effects is especially important. Baseline and weekly triglyceride trends monitor lipid tolerance. Elevated triglyceride levels exceeding 400 mg/dL suggest impaired lipid clearance and an increased risk for pancreatitis, so it is recommended that lipid emulsions be withheld until triglyceride levels return to normal.[19] Lipid concentrations may need to be adjusted for patients who may also be receiving additional lipids from sources other than TPN (eg, continuous infusion of propofol, a sedative delivered as a lipid emulsion). Lipid emulsions provide an excellent medium for bacterial growth, so increased manipulation and prolonged hang times are avoided. Adverse reactions to lipids include, but are not limited to, fever, chills, chest or back tightness, dyspnea, tachycardia, headache, nausea, and vomiting. If such reactions occur, the nurse stops the infusion immediately and reports the reaction to the physician and pharmacist. Long-term reactions to lipids include concerns over immune system suppression.[17] Before infusion, the nurse inspects lipid-containing TPN solutions for separation of the lipid solution, also known as cracking and coalescence. This loss of emulsion can be identified by yellow-brown marbling of the entire solution or as layering of oil at the surface of the TPN container. Such solutions are not safe for infusion and should be returned to the pharmacy for replacement.

AMINO ACIDS. All tissues require protein to maintain structure and facilitate wound healing. If protein intake is inadequate, the body becomes catabolic, seeking protein from skeletal muscle and vital organs. In TPN, protein is provided as a mixture of essential and nonessential crystalline amino acids, which are available in concentrations ranging from 5% to 15%. These concentrations supply approximately 15% to 20% of daily caloric needs. One gram of amino acids is equivalent to 1 g of protein, which provides 4 kcal/g. Adult amino acid requirements can range widely from 0.8 to 2.5 g/kg/d, and those patients with burns, wounds, draining fistulas, renal failure, or hepatic failure may need frequent adjustments in the amount of amino acids they receive.[16] For patients with renal disease, solutions with a higher concentration of essential amino acids are available. For patients with hepatic failure or hypercatabolic conditions, formulas with branched-

chain amino acids may be used. These formulas spare the breakdown of other muscle proteins to use as energy, possibly reducing the incidence of hepatic encephalopathy.

MICRONUTRIENTS. Vitamins, trace minerals, and electrolytes are considered micronutrients. Unfortunately, the U.S. Recommended Dietary Allowance requirements do not apply to parenteral nutrition for several reasons. First, the liver and GI tract absorptive processes are bypassed, resulting in elimination of these micronutrients through the urine without their being utilized. Second, many diseases alter the gut's ability to absorb fat-soluble vitamins and vitamin B_{12}. Finally, many nutrients adhere to the plastic tubing and IV solution bags or are destroyed by exposure to light and oxygen (especially vitamin A) before reaching the bloodstream.

With these factors in mind, standard aqueous multivitamin preparations have been created and provide higher levels of thiamine, pyridoxine, ascorbic acid, and folic acid.[20] Unfortunately, hypermetabolic conditions of critical illness can exacerbate deficiencies that require additional monitoring and potential supplementation; individual vitamin products are available for supplements as needed. Until recently, vitamin K was the only vitamin not included in the multivitamin preparation; it is provided by adding up to 10 mg/wk of the vitamin to the TPN solution (unless contraindicated by anticoagulation treatment). Because some parenteral formulas may now contain vitamin K, weekly supplementation is no longer necessary, but it is important to continue to monitor coagulation studies, especially if the patient is receiving anticoagulation treatment. Unlike patients who require additional nutrients, patients with liver or kidney disease may need to receive lower doses of certain vitamins.

Trace mineral elements are required to maintain biochemical homeostasis. They come in a variety of commercial mixtures but typically include chromium, copper, manganese, selenium, and zinc. Parenteral iron is not added to TPN solutions because of stability issues and the potential for adverse effects, and it may need to be supplemented in long-term therapy.

Most electrolyte standard mixtures contain sodium, potassium, calcium, magnesium, phosphorus, chloride, and acetate. Sodium bicarbonate is not added to TPN as precipitation with the other electrolytes may occur. Instead, acetate is used because it can be converted by the liver to bicarbonate. Depending on the patient's underlying disease process and physical assessment findings, specific electrolyte concentrations can be adjusted daily in the TPN solution. If an electrolyte deficiency is detected after the TPN solution has been prepared, or while infusing, additional IV supplements can be given separately by IV piggyback administration. Electrolyte supplements should never be added to the TPN bag after the pharmacist has formulated it because this would compromise the sterility of the solution and may cause the solution to precipitate.

MEDICATIONS. While preparing the TPN solution, the pharmacist can add medications, many of which are often necessitated by the TPN therapy itself. For instance, although insulin drips are now the current trend in managing hyperglycemia, insulin can be added to the TPN solution. Additionally, heparin can be added to reduce fibrin buildup along the catheter tip. The clinician ordering the medications consults with the pharmacist to ensure compatibility.

Complications of Parenteral Nutrition

Complications can be divided into three main categories: metabolic, infectious, and mechanical.

METABOLIC COMPLICATIONS. TPN has been recognized as a cause of severe morbidity and life-threatening complications.[21] This is often related to the infusion amount and flow rate. Specific complications include hepatic steatosis (fatty liver), intrahepatic and extrahepatic cholestasis (suppression of bile flow), and cholelithiasis (formation of gallstones). Although the exact mechanisms of these hepatic disorders are not completely understood, it has been observed that cholestasis is less likely to occur if some form of enteral feeding is maintained.[21] GI atrophy, and all of its associated complications, may occur from disuse. If not contraindicated, oral or enteral feedings should be initiated as soon as possible.

It is important to understand that many metabolic complications stem from the patient's underlying disease processes or from imprudent formula administration. Some metabolic disturbances can be prevented by checking each bag of parenteral nutrition solution for transcription accuracy, monitoring the IV pump for infusion accuracy, and monitoring the patient's response to therapy. Virtually any metabolic disturbance can occur during parenteral nutrition infusion: the most common metabolic complications include hyperglycemia, hypoglycemia, hypophosphatemia, hypokalemia, hypomagnesemia, and hypocalcemia. These metabolic disturbances, coupled with rapid fluid shifts and imbalances, may lead to a disorder called refeeding syndrome, which is discussed later.

Hyperglycemia. Hyperglycemia, or a blood glucose elevated over 220 mg/dL, can occur if the pancreas does not respond to the increased glucose load. Although hyperglycemia can be caused by either enteral or parenteral feedings, it is more commonly seen in patients receiving parenteral nutrition. Even slightly elevated blood glucose levels can impair the function of lymphocytes, leading to immunosuppression and increased risk for infection. Elevated glucose concentrations have been shown to reduce neutrophil chemotaxis and phagocytosis and may be an independent risk factor for short-term infections.[4] If the renal threshold for glucose reabsorption is exceeded, osmotic diuresis results in subsequent dehydration and electrolyte imbalances. Glycemic control can be achieved by increasing the amount of insulin in the TPN solution, by maintaining a continuous insulin drip during TPN administration, or by administering sliding-scale insulin subcutaneously at regular intervals. Once TPN is discontinued, insulin requirements become notably less or nonexistent. If new TPN solution is temporarily unavailable, administration of 10% dextrose in water ($D_{10}W$) is recommended to prevent rebound hypoglycemia. In addition, if a solution is "behind schedule," the infusion rate should not be increased to make up time because this may cause sudden metabolic fluctuations and fluid overload.

Refeeding Syndrome. Refeeding syndrome is one of the most critical complications that occur with the initiation of TPN. This condition is characterized by rapid shifts in electrolytes (phosphorus, potassium, magnesium, and calcium), glucose, and volume status within hours to days of nutrition implementation. Parenterally delivered glucose loads stimulate insulin release, which in turn stimulates intracellular uptake of phosphorus, glucose, and other electrolytes

for anabolic processes. Despite relatively normal serum phosphorus levels on standard laboratory reports, intracellular stores are markedly depleted in malnourished catabolic patients; severe hypophosphatemia (<1 mg/dL) can lead to neuromuscular, respiratory, and cardiac dysfunction. Low serum levels of potassium, magnesium, and calcium can precipitate cardiac dysrhythmias. The increased intravascular fluid volumes associated with parenteral nutrition can strain the viscerally depleted heart and possibly induce heart failure and myocardial damage. Risk factors for refeeding syndrome include marasmus, chronic alcoholism, anorexia nervosa, rapid refeeding, and excessive dextrose infusion.

Prevention of refeeding syndrome includes repletion of phosphorus, potassium, magnesium, and calcium before TPN initiation, limiting initial dextrose dosing, and titrating total volume and rate to evaluate for fluid overload and potential cardiac decompensation. Daily monitoring of phosphorous, potassium, and magnesium is recommended.[22] Weight-based phosphorus repletion algorithms (eg, 0.32 to 1.0 mmol/kg) have been shown to be highly efficacious in correcting hypophosphatemia during nutrition support therapy.[22] It is of paramount importance that the critical care nurse takes accurate intake and output measurements and daily weights because adequate parenteral nutrition often means giving 1.5 to 3 L of fluid/d in addition to other therapies. Progressive weight gain could be an early indicator of poor fluid tolerance.

INFECTIOUS COMPLICATIONS. Both the solution and the indwelling catheter are prime sites for infection because of the high glucose content. Any break in the system is a nidus for infection that can progress to a systemic infection if left unchecked. After initial preparation by a pharmacist, the access hubs on the bag of TPN are often covered with tape as a reminder that no additional solutions or medications are to be added.

At the bedside, the nurse changes the TPN solution bag and tubing according to institution policy, usually every 24 hours. He or she redresses the catheter insertion site per institution policy as well, usually every 24 to 72 hours, using either a sterile transparent or gauze dressing. Frequent dressing changes, however, have been shown to increase bacterial colonization. Fortunately, transparent dressings allow for easier observation of the catheter entrance site; visible inflammation indicates significant bacterial colonization and the need for prompt catheter removal.[23] It is important to check institutional policies and procedures regarding central and peripheral line dressing changes.

At the time of the dressing change, the nurse examines the site for signs of leakage, erythema, and/or inflammation, and then cleanses the site with an antibacterial solution to remove pathogenic organisms. Researchers have shown that chlorhexidine solution is a more effective local antiseptic than povidone-iodine solutions.[24,25] The use of impregnated chlorhexidine/silver sulfadiazine or minocycline/rifampin catheters could reduce the incidence of central venous catheter–related infections.[26] The presence of a tracheostomy or other open draining wounds near the IV insertion site requires special precautions to prevent site contamination.

Potential for infection can be minimized by meticulous catheter care. In critically ill patients, catheter-related infections range from local inflammation to systemic bloodstream infection and sepsis. Central venous catheters are a leading source of nosocomial bloodstream infection with an estimated 10% mortality.[23] If fever, rigors, or chills coincide with parenteral infusion, catheter-related sepsis should be suspected; slowing or stopping the infusion may cause fever to abate. Treatment of an infection may involve local topical antibiotics, systemic antibiotics, and, in many cases, catheter removal. If catheter sepsis is suspected, the catheter tip is usually cultured to identify the offending organism to ensure appropriate antibiotic coverage.

Mechanical Complications

Mechanical complications include those associated with central venous catheter insertion, such as trauma to the vessel, pneumothorax, catheter occlusion, thrombosis, and venous air embolism. After insertion of a central catheter, a chest radiograph is the standard method of confirming correct placement. If there is a clinical suspicion of catheter tip migration or other potential complications, further diagnostic testing is indicated.

Trauma to vessels and pneumothorax are complications that may warrant surgical intervention, insertion of a chest tube or tubes, or both. Catheter occlusion can simply be a result of the catheter tip lodging against the vessel wall or being physiologically "pinched" between the clavicle and first rib. Occlusion can also occur from fibrin buildup, blood or lipid deposition, drug precipitates, and catheter breakage. Another type of occlusion, "withdrawal occlusion," is an occlusion that allows infusion of a solution but prevents blood withdrawal. The addition of 6,000 units of heparin in the daily parenteral formula in hospitalized patients with temporary catheters reduces the risk of fibrin sheath formation and catheter infection.[4] Thrombosis formation in the lumen of the vessel often results from mechanical irritation (such as from traumatic catheter insertion), a small lumen, an extended duration of catheter use, the catheter material, or malpositioning. Nurses need to be aware that patients may have a thrombosis and may be asymptomatic, yet complain of vague head and eye swelling on the affected side. Vigilant assessments during parenteral nutrition administration are recommended. Treatment includes catheter removal, systemic anticoagulation, and thrombolytic therapy.

A venous air embolism is another serious complication; rapid introduction of air into the venous circulation can be fatal.[27] In a review of all patients in the literature with a cerebral air embolism associated with central venous catheters from 1975 to 1988, 54% occurred secondary to disconnection of the catheter, 31% occurred during removal of the catheter, and 15% occurred during insertion.[27] Any disruption of the closed catheter system (usually during line connection changes, when hanging a new bag of TPN, or in an accidental tubing disconnection) can increase the risk for an air embolism. If such an incident occurs, the patient will most likely experience acute, centrally located chest pain, dyspnea, and hypotension. Immediate nursing interventions include clamping the tubing of the catheter or occluding the catheter hub, attempting to aspirate air directly from the venous line (ie, for patients who have central venous access properly placed in the right atrium, attempts may be made to aspirate air bubbles from the distal port), administering 100% oxygen via a facemask, and positioning the patient head down on the left side (Durant's maneuver).[27] This position allows air to rise to the level of the right ventricle, away from

the pulmonary vasculature. Prevention of an air embolism can be facilitated by having the patient perform the Valsalva maneuver or simply hum audibly during line changes. In ventilator-dependent patients, positive intrathoracic pressure can be created by initiating mechanical lung inflations or "breaths." Finally, use of sterile occlusive dressings (eg, petrolatum gauze) over the catheter entrance site is an effective measure in preventing air from entering the track after the catheter has been removed.

Tapering Parenteral Nutrition

Tapering (gradually reducing) TPN is often initiated for those patients who are able to resume safely (and tolerate) approximately 50% to 75% of their nutritional needs by enteral or oral nutrition. In such instances, a calorie count is essential to be certain that the patient's nutritional needs are being met. If the parenteral nutrition needs to be interrupted or is to be discontinued, the infusion rate is decreased by half for 30 to 60 minutes. This allows for a plasma glucose response and prevention of rebound hypoglycemia.[19] Checking blood glucose levels for 30 to 60 minutes after discontinuation helps the nurse identify and manage immediate glucose abnormalities.

In situations in which poor prognosis does not warrant aggressive nutritional support, emotional and ethical dilemmas may surface for many nurses because feeding and hydration have long been basic tenets of nursing care. Although many institutions may have protocols in place regarding parenteral nutrition, treatment decisions and plans of care should be discussed on an individual basis. Frequent, ongoing discussions between the patient, family, and the health care team are imperative to providing the best possible care to each patient.

Role of the Nurse in Nutritional Support

Nurses are responsible for obtaining initial "dry weight" and weekly weight measurements, vital signs, intake and output measurements, and laboratory data and for providing enteral tube and IV catheter care throughout the duration of nutrition support therapies. Many complications, whether from enteral or parenteral nutrition, can be prevented by vigilant observation and care. If the patient is awake and alert, the patient's subjective assessment of tolerance can be very informative. The nurse obtains more objective signs of feeding tolerance through abdominal examinations, which assess bowel sounds and changes in abdominal girth. Also, the nurse monitors and records volume and frequency of both urine and stool.

The nurse must also monitor for clinical signs of dehydration (thirst, dry mucous membranes, tachycardia, and poor skin turgor) and fluid excess (peripheral edema and adventitious lung sounds). Early detection and subsequent interventions may prevent the occurrence of excessive fluid shifts and cardiac compromise. This is of special concern if the patient is severely malnourished, which may precipitate refeeding syndrome and other untoward complications. Meticulous feeding tube and IV catheter care are critical to preventing local and systemic forms of infection.

Care also includes providing information and emotional support to the patient and family. Examples include explaining the procedure, what to expect, risks, and expected outcomes (Box 40-3).

BOX 40-3 TEACHING GUIDE Living With Nutritional Support

General Care: Enteral Nutrition
- Administer enteral formulas as prescribed.
- Know potential complications and appropriate treatments.
- Avoid activities that may result in high impact or stress at the insertion site and report any activity that may have damaged the enteral access site.
- Return to previous activities (eg, work, leisure, sexual activity) after obtaining physician consent.

General Care: Parenteral Nutrition
- Administer parenteral formulas as prescribed.
- Monitor blood glucose levels closely to help determine tolerance for parenteral solutions.
- Know the potential complications and appropriate treatments.
- Avoid activities that may result in high impact or stress at the insertion site and report any activity that may have damaged the parenteral access site.
- Return to previous activities (eg, work, leisure, sexual activity) after obtaining physician consent.

Signs of Infections
- Understand the rationale for aseptic technique.
- Notify the nurse of symptoms of fever, localized warmth, redness, pain, or drainage at the feeding tube or IV insertion site.

Medications
- Follow instructions regarding medications.
- Know the names of medications and the dose, frequency of administration, side effects, and use of each medication.
- Know the proper technique of administering medications through the feeding tube and proper flushing technique.
- Never add medications to TPN solutions—they should be added by the supplier because of risk for contamination or precipitation of the formula.

Safety Measures
- Inform other health care providers about enteral or parenteral access devices and notify them about any medications that the patient may be taking.

Follow-Up Care
- Report any problems to the home care nurse.
- Adhere to schedule for follow-up visits with patient's physician or clinic.
- Ensure that patient/care giver learning includes determining procedures and risks, identifying patient and equipment problems early, troubleshooting, and following up with the health care provider.
- Refer to and communicate with home care services.
- Provide written instructions for patient.
- If possible, do not change the amount or rate of nutrition support on the day of discharge to home.

▲ Pharmacological Management of Gastrointestinal Disorders

Table 40-1 summarizes many of the common GI medications administered to critically ill patients who are concurrently receiving nutrition support therapy.

Table 40-1 Common Gastrointestinal Medications

Medication	Mechanism of Action	Indication	Common Adverse Effects	Comments
Antacids				
Aluminum carbonate	Neutralization of gastric acid; binding phosphates in the GI tract	Symptomatic relief of gastric irritation, prevention of urinary phosphate stone development, binding of phosphate in chronic renal failure	Fecal impaction, cramps, constipation, hypophosphatemia (when given in excessive doses)	Monitor phosphorus levels.
Aluminum hydroxide (Amphojel, AlternaGEL)	Neutralization of gastric acid; binding phosphates in the GI tract	Symptomatic relief of gastric irritation, hyperphosphatemia in chronic renal failure	Constipation, hypophosphatemia (when given in excessive doses)	Less phosphate binding than aluminum carbonate. Monitor phosphorus levels.
Calcium carbonate (Tums, Caltrate)	Neutralization of gastric acid	Symptomatic relief of gastric irritation, calcium supplementation	Headaches	Usually well tolerated. Monitor calcium and phosphorus levels.
Magnesium hydroxide (Milk of magnesia)	Neutralization of gastric acid	Symptomatic relief of gastric irritation, hypomagnesemia, constipation	Hypermagnesemia, abdominal cramping and diarrhea (with high doses)	Monitor magnesium levels.
Dihydroxyaluminum, sodium carbonate (Rolaids)	Neutralization of gastric acid; reduction of pepsin	Symptomatic relief of gastric irritation	Constipation	Use with caution in sodium-restricted patients.
Histamine Type 2 (H_2) Receptor Antagonists				
Cimetidine (Tagamet)	Inhibition of histamine at H_2 receptor sites on gastric parietal cells, which inhibits gastric acid secretion	GERD, PUD, acid hypersecretory states	Confusion, headaches, diarrhea	May cause rare blood dyscrasias. Monitor CBC.
Ranitidine (Zantac)	Inhibition of histamine at H_2 receptor sites on gastric parietal cells, which inhibits gastric acid secretion	GERD, PUD, acid hypersecretory states	Headaches, dizziness, constipation	May cause hepatotoxicity and rare blood dyscrasias.
Famotidine (Pepcid)	Inhibition of histamine at H_2 receptor sites on gastric parietal cells, which inhibits gastric acid secretion	GERD, PUD, acid hypersecretory states	Headaches, dizziness	May cause seizures, bronchospasm, constipation, or thrombocytopenia. Monitor CBC.
Nizatidine (Axid)	Inhibition of histamine at H_2 receptor sites on gastric parietal cells, which inhibits gastric acid secretion	GERD, PUD, acid hypersecretory states	Dizziness, headaches, diarrhea	
Proton Pump Inhibitors				
Omeprazole (Prilosec), lansoprazole (Prevacid), rapeprazole (Aciphex), pantoprazole (Protonix), esomeprazole (Nexium)	Suppression of gastric acid secretion by inhibition of H^+, K^+-ATPase pump (proton pump) of parietal cells, blocking final step in acid production	Reflux esophagitis, treatment of gastric and duodenal ulcers, pathological hypersecretory states (Zollinger-Ellison syndrome)	Headaches, diarrhea, abdominal pain	Less common side effects include nausea, vomiting, and dizziness.

(continued on page 911)

Table 40-1 **Common Gastrointestinal Medications** (continued)

Medication	Mechanism of Action	Indication	Common Adverse Effects	Comments
Pancreatic Enzymes				
Pancreatin (Creon, Donnazyme, Ultrase)	Assistance in the digestion of carbohydrates, fats, and proteins	Replacement in pancreatic enzyme deficiencies, cystic fibrosis	Nausea, diarrhea, cramping, anorexia, hypersensitivity reactions, perianal irritation	
Pancrealipase (Pancrease, Viokase)	Assistance in the digestion of carbohydrates, fats, and proteins	Replacement in pancreatic enzyme deficiencies, steatorrhea of malabsorption, cystic fibrosis, postgastrectomy, or postpancreatectomy	Nausea, diarrhea, cramping, anorexia, hypersensitivity reactions, perianal irritation	
Antidiarrheals				
Attapulgite (Kaopectate)	Absorption of toxins produced by bacterial and GI irritants; decrease in gastric motility and stool water content	Diarrhea	Increased potassium loss, interference with absorption of medications	
Bismuth subsalicylate (Pepto Bismol)	Slowing of motility; antimicrobial activity against GI microbes; antisecretory sensitivity	Diarrhea, prophylaxis of traveler's diarrhea	Tongue discoloration, dark stools	Assess electrolytes if diarrhea persists. Use cautiously in patients using other salicylates.
Cholestyramine (Questran)	Absorption of bile salts, which can cause diarrhea; absorption of *Clostridium difficile* toxin	Diarrhea caused by bile salts or *C. difficile*	Constipation	Because it may alter absorption of other medications, administer other medications at least 1 h before cholestyramine.
Loperamide (Imodium)	Slowing intestinal motility, including peristalsis	Acute and chronic diarrhea	Abdominal distention, constipation, drowsiness, dizziness, nausea, vomiting	
Tincture of opium (Paregoric, DTO)	Decrease in GI motility and peristalsis, decrease in digestive secretions	Acute diarrhea, relief of abdominal cramping	Drowsiness, lightheadedness, bradycardia	Side effects are related to opioid content. Other possible reactions include allergic reactions, vomiting, dizziness, sweating, constipation, and habituation.
Laxatives				
Bowel Evacuants				
Polyethylene glycol with electrolytes (Colyte, NuLytely, GoLYTELY)	Nonabsorbable solution that acts like an osmotic agent	Bowel cleansing before colonoscopy or bowel surgery	Transient bloating, nausea, cramping	
Bulk-Forming Agents				
Calcium polycarbophil (Fibercon), methylcellulose (Citracel), psyllium (Metamucil)	Nondigestable plant cell wall draws water into the feces and softens stool; absorption of excess water in the stool	Diarrhea, constipation	Flatulence, impaction (if feces are obstructed)	Generally well tolerated.

(continued on page 912)

Table 40-1 Common Gastrointestinal Medications (continued)

Medication	Mechanism of Action	Indication	Common Adverse Effects	Comments
Laxatives				
Lactulose (Cephulac, Enulose)	Hyperosmolality draws water into the intestinal lumen, increasing stool water content and softening stool; prevention of absorption of ammonia in the colon	Constipation, prevention and treatment of hepatic encephalopathy	Flatulence, cramping, impaction (if feces is obstructed)	For use in prevention and treatment of hepatic encephalopathy, titrate dose to two to three loose stools a day. Monitor serum ammonia levels.
Polyethylene glycol (MiraLax)	Nonabsorbable solution that acts like an osmotic agent	Constipation	Nausea, abdominal bloating, cramping, diarrhea	
Saline Laxatives				
Magnesium citrate (Citrate of Magnesium)	Magnesium and sodium salts are poorly absorbed, drawing water into the intestinal lumen	Constipation, cleansing of the colon before examination	Cramps, flatulence, nausea, vomiting	Do not use in renal disease. Observe for hypermagnesemia (watching for thirst, drowsiness, dizziness).
Sodium biphosphate (Fleet Phospha-soda, Fleet Enema)	Increase in water absorption in the small intestine through osmosis	Constipation, acute bowel evacuation before a bowel or colon examination	Nausea, cramps	May precipitate or exacerbate cardiac, renal, or seizure disorder.
Stimulants				
Bisacodyl (Dulcolax)	Increase in peristalsis by direct effect on nerve endings in colonic mucosa	Constipation, evacuation of bowel before examination		Can cause habituation with gradual lessening effect in long-term use. Administered orally onset is 6–10 h; Administered rectally, onset is 15–60 min.
Cascara	Increase in propulsive movements through chemical irritation of the colon	Constipation	Discoloration of urine (red or yellow-brown)	May cause habituation. Onset is 6–10 h.
Senna (Senokot, SenokotXTRA)	Stimulation of propulsion	Constipation	Discoloration of urine	Natural product from cassia
Phenolphthalein (Ex-Lax)	Stimulation of peristalsis (similar to bisacodyl)	Constipation		May cause an allergic reaction; discontinue use if rash develops.
Stool Softeners				
Docusate sodium (Surfak, Colace)	Increase in the penetration of the feces by water and fat; softening of the stool	Constipation	Cramping, diarrhea	Prolonged or excessive use may cause habituation or electrolyte abnormalities.
Stimulant/Stool Softeners				
Glycerin	Drawing water into the colon (by high osmotic pressure)	Constipation	Headaches, nausea, vomiting	
Antiemetics				
Trimethobenzamide (Tigan)	Inhibition of the chemoreceptor trigger zone, which then inhibits the vomiting center	Symptomatic relief of nausea and vomiting	Hypersensitivity, drowsiness, hypotension, diarrhea, depression, vertigo	

(continued on page 913)

Table 40-1 **Common Gastrointestinal Medications (continued)**

Medication	Mechanism of Action	Indication	Common Adverse Effects	Comments
Antiemetics				
Prochlorperazine (Compazine)	Blocking of dopamine receptors in the chemoreceptor trigger zone in the brainstem	Nausea, vomiting	Extrapyramidal side effects such as drowsiness, blurred vision, tachycardia, and respiratory depression	
Promethazine (Phenergan)	Competition with histamine in blood vessels and GI and respiratory systems to decrease allergic responses	Nausea, vomiting, motion sickness, sedation	Dizziness, drowsiness, constipation, urinary retention	Other reactions may include thrombocytopenia, agranulocytosis, and hemolytic anemia.
Dolasetron (Anzemet)	Blocking serotonin ($5\text{-}HT_3$) receptors in the chemoreceptor trigger zone and GI tract	Nausea and vomiting associated with chemotherapy, prevention and treatment of postoperative nausea and vomiting	ECG changes, hypertension, abdominal pain, diarrhea, urinary retention	
Granisetron (Kytril)	Blocking serotonin ($5\text{-}HT_3$) receptors in the chemoreceptor trigger zone and GI tract	Nausea and vomiting associated with chemotherapy and radiation	Headache, constipation, asthenia	Use with caution in patients with liver disease.
Ondansetron (Zofran)	Blocking serotonin ($5\text{-}HT_3$) receptors in the chemoreceptor trigger zone and GI tract	Nausea and vomiting associated with chemotherapy, prevention of postoperative nausea and vomiting	Diarrhea, bronchospasm, fatigue, constipation	
Other				
Sucralfate (Carafate)	Formation of a protective covering at ulcer site	Short-term treatment of peptic ulcers	Constipation	Because it may alter absorption of other medications, patient should take other medications at least 2 h before sucralfate.
Metoclopramide (Reglan)	Stimulation of upper GI motility; decrease in inhibitory tone	Diabetic gastroparesis, delayed gastric emptying, short-term treatment of GERD, prevention of postoperative nausea and vomiting, facilitation of small bowel feeding tube placement	Diarrhea, constipation, drowsiness, restlessness	May occasionally have extrapyramidal side effects.
Misoprostol (Cytotec)	Prostaglandin analog increases bicarbonate and mucus release and decreases acid secretions	Prevention of aspirin- and NSAID-induced ulcers	Diarrhea, nausea, vomiting, flatulence	Use with caution in pregnant women and in women of childbearing age; it increases uterine contractions, which may cause abortion.
Octreotide (Sandostatin)	Synthetic analog of somostatin, inhibition of the secretion of gastrin, vasoactive intestinal peptide, insulin, glucagon, motilin, secretin, and pancreatic polypeptides	Secretory diarrhea, acute variceal hemorrhage	Edema, flushing, dizziness, headache, abdominal pain, constipation, diarrhea, hyperglycemia, hypoglycemia	Monitor blood glucose and adjust insulin requirements.

CBC, complete blood count; ECG, electrocardiogram; GERD, gastroesophageal reflux disease; NSAIDs, nonsteroidal anti-inflammatory drugs; PUD, peptic ulcer disease.

▲ Clinical Applicability Challenges

CASE STUDY

K.M. is a 36-year-old man with a history of a gunshot wound to the abdomen status post multiple small bowel resections, which has resulted in short bowel syndrome. Because he cannot meet his caloric and protein requirements, protein–calorie malnutrition has resulted, and he now requires chronic TPN to meet his nutritional needs. A PICC is placed, and home TPN is initiated.

K.M. presents to the emergency department 4 months later with complaints of fever and chills. His vital signs include an oral temperature of 101.8°F; pulse 115 beats/min, blood pressure 102/58 mm Hg, and respirations 22 breaths/min. Point of care blood glucose level is 217 mg/dL.

1. What physical examination findings would you expect to find?
2. What diagnostic tests should be evaluated?
3. What is the most likely management of this patient?
4. What discharge teaching should this patient receive?

41 Common Gastrointestinal Disorders

Allison G. Steele and Valerie K. Sabol

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Examine the pathophysiological concepts that help define acute gastrointestinal bleeding (GIB), obstruction and ileus, acute pancreatitis (AP), hepatitis, and complications of liver disease.
2. Compare and contrast the pertinent history, physical examination, and diagnostic study findings for acute GIB, obstruction and ileus, AP, hepatitis, and cirrhosis.
3. Discuss laboratory studies that are useful in the diagnosis and management of acute GIB, obstruction and ileus, AP, hepatitis, and complications of liver disease.
4. Analyze the similarities and differences in caring for patients with acute GIB, obstruction and ileus, hepatitis, and complications of liver disease.
5. Explore the nursing role in assessing, managing, and evaluating a plan of care for patients with acute GIB, obstruction and ileus, AP, hepatitis, and complications of liver disease.

The critical care nurse will inevitably provide care for patients with common yet serious disorders of the gastrointestinal (GI) tract. Some of these disorders include gastrointestinal bleeding (GIB), intestinal obstructions, and complex inflammations, such as pancreatitis and hepatitis.

▲ Acute Gastrointestinal Bleeding

Acute GIB is a common, and potentially lethal, medical emergency seen in people admitted to the intensive care unit (ICU). There are 300,000 hospital admissions each year in the United States as a result of acute GIB.[1–4] The 10% mortality rate associated with acute GIB has remained constant over the past half century despite advances in diagnosis and treatment.[1–3] This constant mortality rate may result from the prevalence of comorbid disease in older adults and the widespread use of nonsteroidal anti-inflammatory drugs (NSAIDs). The cause of death is rarely from exsanguination but rather from the exacerbation of other medical illnesses. Prompt recognition and treatment of patients experiencing acute GIB requires a team approach.

Acute GIB is differentiated into upper and lower GIB. The ligament of Treitz at the junction of the duodenum and jejunum is the anatomic division between the upper and lower GI tracts. Upper GIB occurs from a source in the esophagus, stomach, or duodenum. Lower GIB occurs from a source in the jejunum, ileum, colon, or rectum. GIB from a lower GI source is less common than upper GIB.

Upper Gastrointestinal Bleeding

Etiology

The possible causes of acute upper GIB are listed in Box 41-1. A complete discussion of this list is beyond the scope of this chapter. The most commonly seen causes of acute GIB in the ICU are discussed in the following sections. See Spotlight on Genetics 41-1 for a discussion of Crohn's disease.

Peptic Ulcer Disease

Peptic ulcer disease, which includes both gastric and duodenal ulcers, accounts for approximately 40% to 60% of acute upper GIB.[1,2,5–7] The epithelial cells of the gastroduodenal mucosa are protected from the potentially damaging effects of gastric secretions, medications, alcohol, and bacteria by several protective mechanisms. These cells secrete mucins, phospholipids, and bicarbonate, which create a pH gradient between the acidic gastric lumen and the cell surface. Prostaglandins enhance this mucosal protection by increasing mucosal secretion, increasing bicarbonate production, maintaining mucosal blood flow, and enhancing the resistance of gastroduodenal cells to injury. In addition, the tight junctions of the epithelial cells resist diffusion. When these protective factors are overwhelmed by aggressive factors, the integrity of the gastric or duodenal mucosa is interrupted, which can result in peptic ulcer disease. Bleeding from peptic ulcer disease occurs when the ulcer erodes into the wall of a blood vessel.

BOX 41-1 Common Causes of Acute Gastrointestinal Bleeding (GIB)

Upper Gastrointestinal Bleeding

Esophageal Source
- Varices
- Esophagitis
- Ulcers
- Tumors
- Mallory-Weiss tears

Gastric Source
- Peptic ulcers
- Gastritis
- Tumors
- Angiodysplasia
- Dieulafoy's lesions

Duodenal Source
- Peptic ulcers
- Angiodysplasia
- Crohn's disease
- Meckel's diverticulum

Lower Gastrointestinal Bleeding
- Malignant tumors
- Polyps
- Ulcerative colitis
- Crohn's disease
- Ischemic colitis
- Infectious colitis
- Angiodysplasia
- Diverticulosis
- Hemorrhoids
- Massive upper gastrointestinal hemorrhage

SPOTLIGHT ON GENETICS 41-1

GI SYSTEM—CROHN'S DISEASE
- Crohn's disease is a complex, chronic disorder that primarily affects the digestive system. This condition typically involves abnormal inflammation of the intestinal walls, particularly in the lower part of the small intestine and portions of the large intestine and is most common in Western Europe and North America, where it affects 100 to 150 in 100,000 people.
- The *IL23R* gene is associated with Crohn's disease, and variety of genetic and environmental factors likely play a role in causing Crohn's disease. Although researchers are studying risk factors that may contribute to this complex disorder, many of these factors remain unknown.
- Crohn's disease may result from a combination of certain genetic variations, changes in the immune system, and the presence of bacteria in the digestive tract. Recent studies have identified variations in specific genes, including *ATG16L1*, *IL23R*, *IRGM*, and *NOD2*, that influence the risk of developing Crohn's disease. These genes provide instructions for making proteins that are involved in immune system function. Variations in any of these genes may disrupt the ability of cells in the intestine to respond normally to bacteria. An abnormal immune response to bacteria in the intestinal walls may lead to chronic inflammation and the digestive problems characteristic of Crohn's disease.
- Sequence analysis of the entire coding region or targeted mutation analysis is available in the diagnosis of Crohn's disease.

Genetic Home Reference-http://ghr.nlm.nih.gov, accessed July 14, 2011

Ruthruff B: Clinical review of Crohn's disease. J Am Acad Nurse Pract 19(8):392–397, 2007.

The primary risk factor for peptic ulcer disease is infection with the bacterium *Helicobacter pylori*. *H. pylori* infection has been associated with 90% of duodenal ulcers and 75% of gastric ulcers. *H. pylori* is a Gram-negative, spiral, flagellated rod that colonizes the mucous layer overlying the gastric epithelium. The flagellum of *H. pylori* facilitates the bacterium's ability to move and adhere to the mucous layer. *H. pylori* produces urease, which converts urea to ammonia and carbon dioxide. The ammonia buffers the acid surrounding the bacterium, creating a more hospitable environment that allows the bacterium to thrive in the acidic stomach. *H. pylori* infection predisposes the mucosa to damage by disrupting the mucous layer, liberating enzymes and toxins, and adhering to the epithelium. Inflammation is furthered by a host immune response. This chronic inflammation usually results in an asymptomatic chronic gastritis. However, in some instances, ulceration develops.

In the absence of *H. pylori* infection, the ingestion of aspirin or NSAIDs accounts for most cases of peptic ulcer disease. The ingestion of aspirin and NSAIDs may directly injure the mucosal layer. Ingestion enhances mucosal permeability and allows back-diffusion of acid. Systemic effects of chronic aspirin or NSAID use include inhibition of prostaglandin synthesis by the gastroduodenal mucosa, which decreases production of mucus and bicarbonate and also decreases mucosal blood flow. This alteration in mucosal cytoprotection may lead to the development of an ulcer. Upper GIB related to NSAIDs is more common in older patients. Cigarette smoking may also predispose individuals to peptic ulcer disease, and it is linked to prolonged healing rates and high ulcer reoccurrence.

Stress-Related Erosive Syndrome

Stress-related erosive syndrome, also called erosive gastritis, stress ulceration, and hemorrhagic gastritis, is a common cause of acute GIB in critically ill patients. Stress ulcers are different from the ulcers of peptic ulcer disease; they tend to be more numerous, shallower, and more diffuse. These ulcers may develop in the stomach, duodenum, and esophagus within hours of injury. They are usually shallow and cause oozing from superficial capillaries but may erode into the submucosa and cause massive hemorrhage.

The risk for developing a stress ulcer depends on the severity and type of illness (Box 41-2). The common feature of these risk factors is the relationship to physiological stress. Decreased perfusion of the stomach mucosa is probably the main mechanism of ulcer development. This contributes to impaired secretion of mucus, low mucosal pH, poor mucosal cell regeneration, and decreased tolerance to acidic gastric secretions.

Esophageal Varices

Portal hypertension usually develops as a result of cirrhosis, from increased resistance in the portal venous system caused by disruption of the normal liver lobular structure.

BOX 41-2 PATIENT SAFETY

Risk Factors for Stress-Related Erosive Syndrome

- Hypotension or shock
- Coagulopathy
- Respiratory failure requiring mechanical ventilation
- Sepsis
- Hepatic failure
- Renal failure
- Multiple or severe trauma
- Burns over 35% of the total body surface area
- Post–organ transplantation status
- Head or spinal cord injury
- History of peptic ulcer disease or upper GIB
- Prolonged stay in intensive care unit

This resistance impedes blood flow into, through, and out of the liver. In response to portal hypertension, collateral veins develop to bypass the increased portal resistance in an attempt to return blood to systemic circulation. As pressure rises in these veins, they become tortuous and distended, forming varicose veins or varices.

Esophageal varices account for 10% to 25% of acute upper GIB.[1,6] Varices are present in 50% of patients with cirrhosis at the time of diagnosis.[1,8–10] Varices may develop in the esophagus, stomach, duodenum, colon, rectum, or anus. The most clinically significant site of varices is the gastroesophageal junction because of the propensity of varices in this area to rupture, resulting in massive GI hemorrhage. The mortality rate associated with variceal bleeding is 15% to 50% with each episode.[6,8,10,11]

Mallory-Weiss Tears

Mallory-Weiss tears account for approximately 10% of acute upper GIB.[1] Mallory-Weiss tears are lacerations that occur in the distal esophagus, at the gastroesophageal junction, and in the cardia of the stomach. Bleeding from Mallory-Weiss tears occurs when the tear involves the underlying venous or arterial bed. Mallory-Weiss tears are strongly associated with heavy alcohol use or recent binge drinking and a prior history of forceful vomiting or retching, or violent coughing. Patients with portal hypertension have an increased risk for bleeding from Mallory-Weiss tears.

Dieulafoy's Lesions

Dieulafoy's lesions are vascular malformations of unusually large submucosal arteries, which lie in close contact with the mucosal surface. They can be found anywhere in the GI tract but are most likely to be found in the proximal stomach. Because of the large size of the artery, bleeding from a Dieulafoy's lesion may be massive and recurrent. When bleeding ceases, a Dieulafoy's lesion can be difficult to identify because there is no associated ulcer, and it is likely to be the origin of many upper GIBs of unknown cause.

Clinical Presentation

Regardless of the cause, patients with acute upper GIB have a clinical presentation consistent with the amount of blood loss. A patient's response to blood loss depends on the amount and rate of blood loss, age, degree of compensation, comorbidities, and rapidity of treatment. Patients with minimal loss may present with anemia and no further symptoms, whereas patients with rapid and severe loss may present with signs and symptoms of shock. If blood loss is moderate, the sympathetic nervous system responds with a release of the catecholamines epinephrine and norepinephrine, which initially cause an increase in heart rate and peripheral vascular vasoconstriction in an attempt to maintain an adequate blood pressure. Orthostatic changes (a decrease in blood pressure >10 mm Hg with a corresponding heart rate increase of 20 beats/min in the sitting or standing position) imply volume depletion of 15% or more.

With severe blood loss, signs and symptoms of shock appear. The release of catecholamines triggers the blood vessels in the skin, lungs, intestines, liver, and kidneys to constrict, thereby increasing the volume of blood flow to the brain and heart. Because of the decreased flow of blood in the skin, the patient's skin is cool to the touch. With decreased blood flow to the lungs, hyperventilation occurs to maintain adequate gas exchange.

The classic hallmarks of GIB are hematemesis, hematochezia, and melena. Patients with upper GIB usually present with hematemesis, the vomiting of fresh, unaltered blood or "coffee-ground" material; melena, the passage of foul-smelling, black, tarry, sticky stool; or both. A patient who presents with hematemesis is usually bleeding from a source above the ligament of Treitz. Reverse peristalsis is seldom sufficient to cause hematemesis if the bleeding point is below this area. The classic coffee-ground emesis associated with upper GIB results from the partial decomposition of the blood from contact with gastric secretions. Gastric acid converts bright red hemoglobin to brown hematin, accounting for the coffee-ground appearance of the drainage. Maroon or bright red blood results from profuse bleeding and little contact with gastric juices.

Melena is black from the breakdown of the blood in transit and suggests a long transit time through the GI tract. Melena is indicative of upper GIB in 90% of cases.[1] It may take several days after bleeding cessation for melenic stools to clear. After upper GIB, hemoccult stool test results may remain positive for 1 to 2 weeks. Melena should not be confused with greenish stool that results from iron ingestion or black stool caused by the ingestion of bismuth subsalicylate (Pepto-Bismol).

Hematochezia, the passage of maroon or bright red blood that may be mixed with stool, usually indicates bleeding from a lower GI source. Uncommonly, hematochezia can occur in the setting of massive, rapid hemorrhage from the upper GI tract, where the large amount of blood acts as a cathartic, resulting in rapid transit through the GI tract.

Occult GIB refers to small amounts of blood loss, which is not apparent to the patient. Obscure GIB refers to obvious bleeding with no easily identifiable source on routine examination.

Assessment

HISTORY. A prompt, careful, focused history may suggest the underlying cause of GIB. A history of epigastric pain or dyspepsia or a medical history of peptic ulcer disease is suggestive of peptic ulcer disease. A medical history of GIB should be elicited because most upper GI bleeds rebleed

from the same site. Heavy alcohol use increases the likelihood of cirrhosis and bleeding from esophageal varices. Patients with a history of tobacco use have a greater risk for duodenal ulcers. Underlying medical conditions may suggest an underlying cause; patients with renal failure frequently bleed from arteriovenous malformations. Vomiting, coughing, or retching before bleeding suggests a Mallory-Weiss tear. Prior use of NSAIDs or aspirin increases the risk for gastroduodenal ulcers and the likelihood of bleeding from these ulcers.

PHYSICAL EXAMINATION. The physical examination is directed initially to the assessment of hemodynamic stability with ongoing assessment of vital signs. Tachycardia and orthostatic hypotension indicate dehydration secondary to blood loss or vomiting. Orthostatic hypotension, syncope, lightheadedness, and tachycardia are suggestive of a greater than 15% blood volume loss and are predictive of a poor outcome.[1,3] If 40% of blood volume is lost, hypotension and hypovolemia occur, with decreased perfusion of the brain and heart.[1] Therefore, assessing for signs and symptoms of poor tissue perfusion, such as angina, cyanosis, and altered mental status, is important. A baseline electrocardiogram is critical in patients with known cardiac disease because blood loss may precipitate cardiac ischemia. A loss of circulating blood volume may also result in decreased cerebral perfusion. The nurse should be alert to signs of agitation or confusion, which may signal cerebral hypoperfusion. The abdomen is assessed for bowel sounds; abdominal tenderness; the presence of guarding, rigidity, or abdominal masses; and the stigmata of liver disease. Splenomegaly, ascites, and caput medusae suggest liver disease. A tender, board-like abdomen is suggestive of peritonitis, possibly as a result of perforation. A rectal examination is essential to assess for hematochezia and melena.

LABORATORY STUDIES. Laboratory studies can help determine the extent of bleeding and can often provide a clue to the etiology. Common laboratory abnormalities for the patient with acute GIB are listed in Box 41-3. The initial hematocrit and hemoglobin may not accurately reflect initial blood loss because plasma volume is lost in the same proportion as red blood cells (RBCs). Within 24 to 48 hours of the initial bleeding, redistribution of plasma from the extravascular to the intravascular space results in a decreased hematocrit. Fluids administered during resuscitation contribute to the hemodilution. Leukocytosis and hyperglycemia may reflect the body's response to stress. Hypokalemia and hypernatremia may result from loss through emesis. An elevated blood urea nitrogen (BUN) level reflects a large protein load from the breakdown of blood. A high BUN/creatinine ratio suggests an upper GI source of bleeding.[1] Coagulopathy with a prolonged prothrombin time (PT) can indicate liver disease or concurrent long-term anticoagulant therapy. Thrombocytopenia may be present in patients with cirrhosis and portal hypertension with splenomegaly. If large amounts of blood are lost, metabolic acidosis occurs as a result of anaerobic metabolism. Severe blood loss can result in hypoxemia because of decreased circulating hemoglobin with impairment of oxygen transport to cells.

BOX 41-3 Typical Laboratory Abnormalities in a Patient With Acute Gastrointestinal Bleeding

- Decreased hemoglobin and hematocrit
- Mild leukocytosis and hyperglycemia
- Elevated blood urea nitrogen (BUN) level
- Hypernatremia
- Hypokalemia
- Prolonged prothrombin time (PT)/partial thromboplastin time (PTT)
- Thrombocytopenia
- Hypoxemia

Management

RESUSCITATION. The initial management of any patient with acute upper GIB is directed at fluid resuscitation to reverse the effects of blood loss. Supplemental oxygen is provided to any patient with acute GIB to promote oxygen saturation and transport as well as to prevent ischemia and dysrhythmias. Intubation may be required for actively bleeding patients at high risk for aspiration, those with a diminished mental status, and those in respiratory distress. Patients with acute upper GIB should be given nothing by mouth (NPO) because urgent endoscopy or surgery may be required. A Foley catheter is inserted to monitor urine output as an indication of the adequacy of fluid resuscitation. All patients with hemodynamic instability, a drop in hematocrit, transfusion requirements greater than 2 units of packed red blood cells (PRBCs), or active bleeding may warrant an ICU admission.

Volume Resuscitation. Patients with acute GIB require immediate intravenous (IV) access with at least two large-bore (14- to 16-gauge) IV catheters or central access. A type and cross-match should be sent early in the course of the bleeding because blood losses of greater than 1,500 mL require blood replacement in addition to fluids. While awaiting cross-matched blood, lactated Ringer's or normal saline solution is infused to restore circulating volume and to prevent the progression to hypovolemic shock. PRBCs should be transfused for a hemoglobin of 7 g/dL or less to reestablish the oxygen-carrying capacity of the blood.[12] Other blood products, such as platelets and clotting factors, are ordered according to results of laboratory tests and the patient's underlying condition. Calcium replacement may be necessary if large numbers of banked RBCs are transfused because the citrate in banked blood products can bind calcium and lead to hypocalcemia. A pulmonary artery catheter or central venous catheter may be useful to help avoid overresuscitation in patients with underlying renal or cardiac disease. In patients with a coagulopathy, vitamin K can be given in the form of phytonadione (AquaMEPHYTON), 10 mg intramuscularly or very slowly IV, in an attempt to restore the PT to normal. For patients receiving anticoagulants, correction of coagulopathy is recommended but should not delay endoscopy.[12] Fresh frozen plasma is ordered to correct the abnormality if rapid correction of the abnormality is warranted.

Vasoactive drugs may be used until fluid balance is restored to maintain blood pressure and perfusion to vital body organs. Dopamine, epinephrine, or norepinephrine may be ordered to stabilize the patient until definitive treatment can be undertaken.

Nasogastric Intubation. A large-bore nasogastric tube is placed in all patients with GIB to aspirate and lavage gastric contents. A nasogastric tube documents the presence and activity of bleeding. The color of gastric aspirate is prognostically significant. Coffee-ground or black nasogastric drainage with melenic stools indicates a slow bleed, whereas bright red nasogastric drainage and bright red blood in the stools signify a rapidly bleeding upper GI source.

A nasogastric tube is also useful for decompression and lavage. Lavage helps clear blood from the stomach, which allows better visualization to identify the source of bleeding during endoscopy. Iced lavage should be avoided because it is uncomfortable, fails to control bleeding, can significantly decrease core body temperature, and can trigger cardiac dysrhythmias. Lavage should be performed with tap water or saline. A total of 250 to 500 mL is instilled through the nasogastric tube and then removed with a syringe or by intermittent wall suction until gastric secretions are clear. Nasogastric tubes are usually removed after lavage of stomach contents unless the patient is actively bleeding or is experiencing severe nausea and vomiting because a nasogastric tube may injure the gastric mucosa and contribute to bleeding.

Acid-Suppressive Therapy. Acid impairs platelet aggregation and clot formation and promotes fibrinolysis.[6,7,13] Patients with acute upper GIB should be treated with acid-suppressive therapy to decrease the risk for recurrent bleeding, particularly from peptic ulcers. High-dose proton pump inhibitors (PPIs) (omeprazole, lansoprazole, esomeprazole, pantoprazole, rabeprazole) should be used to maintain a gastric pH greater than 6.0.[6,7] PPI therapy should be maintained for at least 72 hours after hemostasis has been achieved to prevent lysis of clots.[6,7] PPI therapy can be given either IV or PO. In the United States, both pantoprazole and esomeprazole are available for IV infusion.

Acid-suppressive therapy with histamine (H_2)-antagonistic drugs (H2RAs) (cimetidine, ranitidine, famotidine, nizatidine) is not recommended for patients with acute nonvariceal bleeding.[12] H2RAs may be used as prophylactic therapy in patients at high risk for stress-related erosive syndrome, but their use is limited by the rapid development of tolerance.[14,15]

Antacids may also be ordered, but their use is limited because of frequent dosing requirements and potential side effects. Antacids act as a direct alkaline buffer and are administered to control gastric pH. Sucralfate, a basic aluminum salt of sucrose octasulfate, acts locally as a cytoprotective drug and can be ordered for stress-related erosive syndrome prophylaxis.

Pharmacotherapy for Decreasing Portal Hypertension. Even before a bleeding source is identified, decreasing portal pressure with vasopressin or octreotide should be considered for patients in whom variceal hemorrhage is suspected. Vasopressin (Pitressin) decreases portal hypertension by constriction of the splanchnic arteries, which reduces portal blood flow. Vasopressin should be administered through a central line. Complications of vasopressin therapy can limit its use. Vasopressin reduces coronary blood flow and increases blood pressure, which increases oxygen demand, and causes coronary artery constriction, which can potentially result in multiple cardiac dysrhythmias. Because vasopressin also reduces blood flow to the mesenteric circulation, bowel ischemia can develop. To minimize these potential side effects, vasopressin should be given concurrently with IV, sublingual, or topical nitroglycerin, which reduces its systemic effects.

Somatostatin is a natural polypeptide that lowers portal venous pressure by vasoconstriction of splanchnic circulation. Somatostatin causes selective vasoconstriction of the splanchnic circulation and is associated with fewer systemic side effects than vasopressin. IV infusion is necessary because of its short half-life.

Octreotide (Sandostatin), a synthetic analog of somatostatin with similar hemodynamic properties but a longer half-life, is available in the United States. Octreotide causes a decrease in splanchnic blood flow with a resultant decrease in intravariceal pressure, decreases secretion of gastric acid and pepsin, and stimulates mucous production. Octreotide is usually given as a 50 to 100 mcg IV bolus followed by 50 mcg/h for 3 to 5 days. The effects of octreotide are similar to vasopressin with concurrent nitroglycerin infusion without the impact on hemodynamics or cardiac output.

DEFINITIVE DIAGNOSIS. After patients with acute upper GIB are resuscitated, endoscopy is considered. Endoscopy can be performed urgently at the bedside and is the procedure of choice for the diagnosis and treatment of acute upper GIB. Endoscopy within 12 to 24 hours of the initial bleeding has the best results. Early endoscopy is essential in acute GIB because the treatment is directed by the cause. Endoscopy allows the identification of the bleeding site between 90% and 95% of the time because direct mucosal inspection is possible.[7] The patient's hemodynamic status and endoscopic appearance provide prognostic value. The presence of active bleeding, a nonbleeding visible vessel, adherent clot, ulcer size greater than 2 cm, and ulcer location on the posterior lesser gastric curvature or posterior duodenal wall indicate a high risk for of rebleeding with medical therapy alone.[7,12] Vital signs must be monitored closely during endoscopy. The left lateral decubitus position decreases the risk for aspiration from active bleeding.

When diagnostic endoscopy is unsuccessful because of massive hemorrhage, angiography can be used to define the site of bleeding or abnormal vasculature. Angiography can detect bleeding rates as low as 0.5 to 1.0 mL/min.[3] Angiography is insensitive in the detection of venous bleeding.

Barium studies, such as an upper GI series, are of no value in acute upper GIB. These studies lack therapeutic capability and preclude endoscopy and angiography because of retained barium. Barium studies are also often inconclusive if there are clots or superficial bleeding in the stomach.

THERAPEUTIC INTERVENTION. In addition to its use in diagnosis, endoscopy is the procedure of choice for treating a GIB. If this fails to meet the needs of the patient, then additional therapeutic options are available.

Endoscopy. In 90% of cases, endoscopic therapy results in hemostasis, although 20% to 25% of sites may rebleed within 72 hours.[5,6,16] Multiple therapeutic options are available, including injection sclerotherapy, thermal coagulation, the placement of hemostatic clips, and endoscopic variceal ligation (EVL). The optimal technique depends on multiple variables, including the type and appearance of the lesion and the experience of the endoscopist.

The primary methods of endoscopic control of upper GI hemorrhage from peptic ulcers include injection therapy and thermal methods. Injection therapy consists of the injection of an agent such as epinephrine around and into the bleeding vessel. Thermal methods include heater probe and bipolar electrocoagulation (where a probe is applied with pressure to heat and seal the bleeding vessel). Hemostatic clips, called endoclips, have also been used successfully to ligate bleeding blood vessels within a lesion.

EVL is the treatment of choice for variceal bleeding. In EVL, a rubber band is placed endoscopically around the base of each varix. This causes coagulative necrosis and sloughing of thrombosed varices. EVL can control acute variceal bleeding in 90% of cases, with a reduction in the rate of rebleeding to between 10% and 20%.[11,16] An alternative to EVL is sclerotherapy. Injection sclerotherapy involves injecting the varices with a sclerosing agent to stop the bleeding. These agents cause local tamponade and vasoconstriction, causing necrosis and eventual sclerosis of the bleeding vessel. Acute hemostasis rates are similar to those with EVL, but sclerotherapy is associated with a higher complication rate.

Angiography. Most cases of GIB resolve spontaneously or can be controlled during endoscopy. However, those patients with persistent bleeding may require angiography to control the source of bleeding. During angiography, arterial GIB can be controlled by the infusion of intra-arterial vasopressin or by the embolization of the artery by an interventional radiologist. If therapeutic endoscopy fails, this is a useful therapeutic option, particularly in those who are critically ill and poor surgical candidates.

Intra-arterial vasopressin causes a generalized vasoconstriction that produces a rapid reduction in local blood flow. Patients should be monitored closely for dysrhythmias and fluid retention with resultant hyponatremia. Repeat angiography is performed after the initial infusion, and the dose can then be titrated as needed. Once bleeding is controlled, this infusion may be continued in the ICU for 24 to 36 hours and then tapered over 24 hours. Patients should have cardiac monitoring during vasopressin therapy to watch for cardiac dysrhythmias. Nitroglycerin patches or drips may be used to counteract any ischemic changes.

Embolization of a bleeding vessel consists of occluding the vessel with material that can be either temporary or permanent. Biodegradable long-acting gelatin sponges are commonly used. These sponges cause hemostasis on contact when injected into the vessel. Steel coils, balloons, and silk thread can be used to block an artery mechanically, resulting in permanent occlusion. Uncommon complications include bowel ischemia, secondary duodenal stenosis, and gastric, hepatic, or splenic infarction.[12]

Balloon Tamponade. Variceal bleeding unresponsive to endoscopic therapy can be temporarily controlled with balloon tamponade in 60% to 90% of cases.[10,16] Most esophagogastric tubes have two balloons, one for the stomach and one for the esophagus, and a distal port for gastric drainage. The Sengstaken-Blakemore tube is the most widely used (Fig. 41-1).

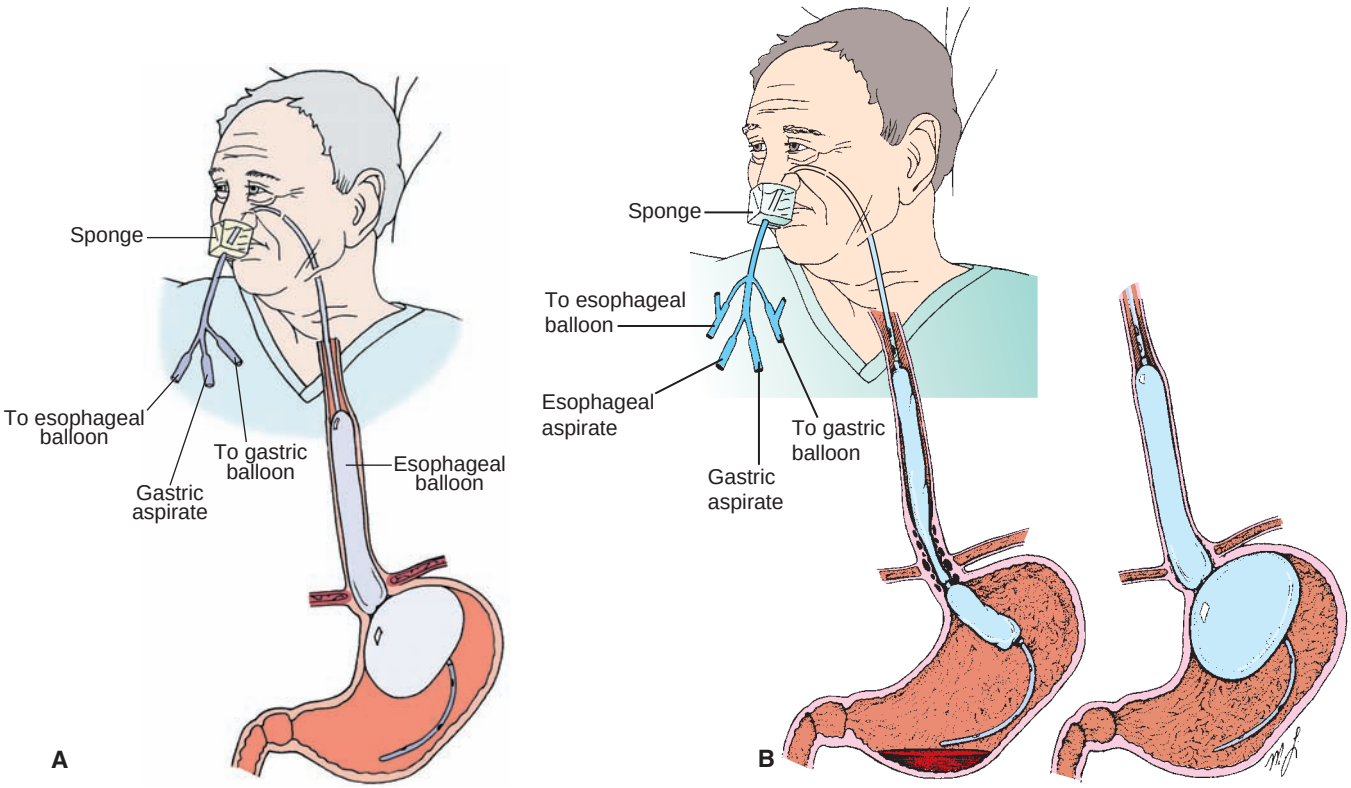

FIGURE 41-1 ▲ Comparison of two types of esophageal tamponade tubes. **A:** The Sengstaken-Blakemore tube is the best known. An additional tube must be placed in the proximal esophagus. **B:** The Minnesota esophagogastric tamponade tube includes an esophageal aspirate lumen.

With the use of balloon tamponade, pressure is exerted on the cardia of the stomach and against the bleeding varices. The tube is inserted to at least 50 cm to ensure gastric intubation. The gastric balloon is then slowly inflated with 250 to 300 mL of air, and gentle traction is applied until the gastric balloon fits snugly against the cardia of the stomach. Position is then confirmed by radiography. Traction is then placed on the tube where it enters the patient by means of a piece of sponge rubber, as shown in Figure 41-1, or by traction fixed to a head helmet device or the foot of the bed. If chest pain occurs, the gastric balloon must be deflated immediately because it may have shifted into the esophagus.

If bleeding continues, the esophageal balloon is inflated to a pressure of 25 to 39 mm Hg and maintained at this pressure for 24 to 48 hours. Although pressure for longer than 24 hours may be needed to control bleeding, it can cause edema, esophagitis, ulcerations, or perforation of the esophagus. After bleeding is controlled, the balloon is maintained and inflated for no longer than 12 to 24 hours to decrease the risk for gastric ischemia and necrosis. Unfortunately, rebleeding often occurs after balloon deflation unless additional therapeutic measures are taken.

A nasogastric tube should be placed in patients with a Sengstaken-Blakemore tube to aspirate oral and nasopharyngeal secretions that collect above the esophageal balloon, preventing aspiration of these secretions into the lungs. The Minnesota esophagogastric tamponade tube (see Fig. 41-1) has a suction port above the esophageal balloon in addition to the usual ports (two balloon, one gastric suction) of the Sengstaken-Blakemore tube. Nursing interventions for the patient with an esophageal tamponade tube are given in Box 41-4.

Transjugular Intrahepatic Portosystemic Shunt. A transjugular intrahepatic portosystemic shunt (TIPS) is a radiologic procedure that creates an intrahepatic shunt in an attempt to decrease portal pressure. The placement of a TIPS may be considered if other methods of managing esophageal varices fail.

Surgery. In the era of endoscopic therapy and PPIs, surgery is rarely used for the control of GIB. The indications for surgical intervention are severe hemorrhage unresponsive to initial resuscitation, massive bleeding that is immediately life threatening, unavailable or failed endoscopic therapy, perforation, obstruction, suspicion of malignancy, or continued bleeding despite aggressive medical therapies.

Surgical options for a bleeding peptic ulcer depend on the age and the condition of the patient, as well as on the location, size, and anatomy of the bleeding source. Emergency surgery of a bleeding duodenal ulcer may be a simple suturing (eg, oversew) of the ulcer. Bleeding duodenal ulcers can also be treated using one of the following procedures:

- Truncal vagotomy and pyloroplasty with suture ligation of the ulcer
- Truncal vagotomy and antrectomy with resection or suture ligation of the ulcer
- Proximal gastric vagotomy with duodenotomy and suture ligation of the ulcer

Bleeding gastric ulcers are commonly treated with one of the following procedures:

- Truncal vagotomy and pyloroplasty with wedge resection of the ulcer
- Antrectomy with wedge excision of the proximal ulcer
- Distal gastrectomy with or without truncal vagotomy
- Wedge resection of the ulcer

A vagotomy involves severing the vagus nerve, which innervates the gastric cells. This results in decreased gastric acid secretion. A truncal (gastric) vagotomy selectively cuts the vagus distribution to the stomach. A pyloroplasty is necessary in conjunction with the vagotomy because denervation of the vagus nerve affects gastric motility. A pyloroplasty allows for continued gastric emptying. An antrectomy removes acid-producing cells in the stomach. A Billroth I procedure includes a vagotomy and antrectomy with anastomosis of the stomach to the duodenum. A Billroth II procedure involves a vagotomy, resection of the antrum, and anastomosis of the stomach to the jejunum (Fig. 41-2). A gastric perforation can be surgically treated by simple closure or use of a patch to cover the mucosal hole.

Surgical decompression of portal hypertension can be used in patients with esophageal or gastric varices that are unresponsive to medical and endoscopic therapy. In this surgery, a portosystemic shunt is created, connecting the portal vein and the inferior vena cava to divert blood flow into the vena cava to decrease pressure.

BOX 41-4 NURSING INTERVENTIONS

For the Patient With an Esophagogastric Balloon Tamponade Tube

- Explain the purpose of the tube and the procedure to the patient.
- Lubricate and chill the tube as directed by the manufacturer.
- Identify and label the lumens of the tube.
- Check the patency of each lumen before insertion of the tube.
- Lavage the patient's stomach before insertion of the tube.
- Monitor the patient while the physician inserts the tube.
- Elevate the head of the bed to 30 degrees to prevent reflux.
- When a Sengstaken-Blakemore tube is in place, perform oropharyngeal suction frequently to prevent aspiration, *or* place a second nasogastric tube, if ordered, above the esophageal balloon to control secretions and prevent aspiration.
- Suction the esophageal port when a Minnesota tube is used.
- Maintain balloon pressure and traction.
- Maintain balloon position.
- Clean and lubricate the patient's nostrils frequently to prevent tube-caused pressure areas.
- Irrigate the nasogastric port every 2 hours to ensure patency and to keep the stomach empty.
- Teach the patient to avoid coughing or straining, which increases intra-abdominal pressure and predisposes to further bleeding.
- Have a second nasogastric tube, suction, and scissors available at the bedside.
- If the gastric balloon ruptures, the tube can rise into the nasopharynx, obstructing the airway. If this occurs, cut the tube immediately to deflate the balloon rapidly.
- Cut and remove the tube whenever there is a question of respiratory insufficiency or aspiration.
- Restrain the patient's arms if the patient is at risk for pulling out the tube. Agitation, confusion, and restlessness are risk factors.
- Assess for complications, including rupture or deflation of the balloon, pulmonary aspiration, and esophageal rupture.

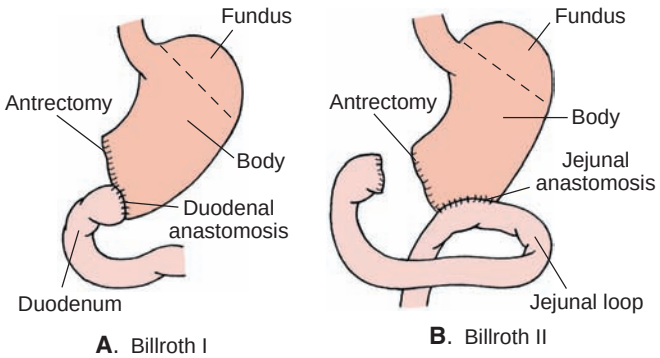

FIGURE 41-2 ▲ **A:** The Billroth I procedure includes a vagotomy and antrectomy with anastomosis of the stomach to the duodenum. **B:** The Billroth II procedure includes a vagotomy, antrectomy, and anastomosis of the stomach to the jejunum.

Medical Management. Once bleeding is controlled, management focuses on treating the underlying cause of the acute upper GIB and preventing rebleeding. For patients with peptic ulcer disease, eradication of *H. pylori* and elimination of NSAID use increase the healing rate and markedly reduce the recurrence of rebleeding. Patients treated for *H. pylori* should be retested to document eradication. PPI therapy should be continued at discharge based on etiology of bleeding. A combination of a PPI and a COX-2 inhibitor is recommended for use in patients who had previous bleeding from an ulcer and who require long-term aspirin or NSAID use.[12] Recurrent variceal hemorrhage occurs in approximately 70% of untreated patients within a year.[9,16] Esophageal varices can be obliterated in subsequent endoscopy sessions, and beta blockade with propranolol (Inderal) or nadolol (Corgard) to reduce portal pressure should be instituted to decrease the rebleeding rate. The dose should be titrated to achieve a 25% decrease in resting heart rate or a heart rate of about 55 beats/min as the desired end point.[6,9,11] The addition of isosorbide mononitrate may further decrease the risk for rebleeding. The use of prophylactic antibiotics in patients with acute bleeding varices has been shown to decrease the risk of rebleeding. Cessation of alcohol ingestion is imperative. See Box 41-5 for nursing interventions in the care of the patient with acute GIB.

BOX 41-5 NURSING INTERVENTIONS

For the Patient With Acute Gastrointestinal Bleeding

- Maintain a patent airway, elevate the head of the bed, and have suction available at the bedside to prevent aspiration of emesis or blood.
- Administer oxygen therapy to treat hypoxia that may result from decreased hemoglobin levels.
- Monitor pulse oximetry values.
- Assess and document signs and symptoms of shock, such as restlessness; diminished peripheral pulses; or cool, pale, or moist skin. Assess and document vital signs, urinary output, hemodynamic values, and oxygen saturation (SaO_2).
- Assess and document electrocardiographic monitoring and heart, lung, and bowel sounds.
- Assist with the placement of a central venous pressure (CVP) catheter or a pulmonary artery catheter.
- Monitor and document CVP, pulmonary artery pressure, pulmonary artery occlusion pressure, cardiac output, and systemic vascular resistance.
- Maintain IV access and administer IV fluids and blood products as ordered.
- Insert a nasogastric tube and lavage as ordered.
- Monitor gastric pH; consult with physician about specific pH range and antacid administration.
- Administer antisecretory medications as ordered to reduce gastric acid secretion.
- Administer vasopressin or octreotide as ordered.
- Maintain accurate intake and output every 1 to 2 hours and PRN.
- Record urine, nasogastric drainage, and emesis.
- Monitor electrolytes, which may be lost with fluids or altered due to fluid shifts, and report abnormal values.
- Monitor hemoglobin, hematocrit, red blood cell (RBC) count, PT, PTT, and BUN level and report abnormal values.
- Provide mouth care as needed.
- Explain all procedures to the patient.
- Prepare the patient for diagnostic procedures and therapeutic interventions.
- Monitor the patient for potential complications of endoscopy or colonoscopy, which include perforation, sepsis, pulmonary aspiration, and induced bleeding.
- Teach the patient the importance of seeking medical intervention if signs or symptoms of bleeding recur.
- Encourage smoking cessation and avoidance of alcohol.

Lower Gastrointestinal Bleeding

Etiology

Common causes of lower GIB are listed in Box 41-1 on page 917. Most cases of acute lower GIB that require ICU admission result from diverticulosis or angiodysplasia, although bleeding from neoplasm, colitis, inflammatory bowel disease, and hemorrhoids is also seen.

Diverticulosis

Diverticula are sac-like protrusions in the colon wall that usually develop at the point where arteries penetrate the colon wall. These vessels are separated from the bowel lumen only by the mucosa and are subsequently prone to injury. Diverticular bleeding accounts for 30% to 50% of all cases of acute lower GIB, with greater incidence in the elderly.[17–19] Most patients with diverticular bleeding will stop bleeding spontaneously, but up to 25% of bleeding may be massive, resulting in hemorrhage and the need for surgery.[18] Risk factors for diverticular bleeding include a diet low in fiber, aspirin and NSAID use, advanced age, and constipation.

Angiodysplasia

Angiodysplasia, also called arteriovenous malformation or angioma, is the term used to describe dilated, tortuous submucosal veins, small arteriovenous communications, or enlarged arteries. The walls of the vessels lack smooth muscle and are composed of endothelial cells. The incidence of angiodysplasia increases with age, owing to degeneration of the vessel walls; most cases occur in people older than 50 years, and two thirds occur in those older than 70 years. Acute lower GIB from angiodysplasia accounts for up to 20% of cases.[18] Angiodysplasia can occur anywhere in the colon, although

it most often occurs in the cecum or ascending colon. As opposed to bleeding from diverticula, bleeding from angiodysplasia may be venous or arteriovenous in nature and is therefore usually less severe than bleeding from diverticular disease, which is arterial. Angiodysplasia is a common cause of lower GIB in patients with renal disease.

Clinical Presentation

Acute lower GIB is defined by the presence of hemodynamic instability and the passage of hematochezia. Patients with diverticular bleeding usually describe the sudden onset of painless maroon or bright red hematochezia, although rarely, melena can occur. Diverticular bleeding is often painless, although patients may complain of cramping (which results from colonic spasm secondary to intraluminal exposure to blood). Blood loss from angiodysplasia usually presents as painless hematochezia.

If lower GIB is chronic, patients may present with iron deficiency anemia and symptoms related to the anemia, such as weakness, fatigue, or dyspnea on exertion. Massive bleeding from hemorrhoids is rare but can occur in patients with rectal varices from portal hypertension.

Assessment

HISTORY. Relevant findings in the medical history include abdominal surgery; a previous bleeding episode; peptic ulcer disease; inflammatory bowel disease; radiation to the abdomen or pelvis; or cardiopulmonary, renal, or liver disease. Knowledge of the patient's current medications and the existence of any allergies can also assist in diagnosis. A history of associated symptoms, including abdominal pain, fever, rectal urgency, tenesmus, weight loss, or a change in bowel habits or stool, should be elicited. The color and consistency of stool should be determined; in brisk bleeding, frequent red or maroon stools are more likely, and brown or infrequent stools are unlikely. The age of the patient may give a clue to diagnosis, because the risk for bleeding from diverticula and angiodysplasia increases with age.

PHYSICAL EXAMINATION. Often the physical examination findings are unremarkable. Vital signs are closely monitored to assess for hemodynamic instability. A palpable mass may reveal a neoplasm. A rectal examination is essential to assess for hematochezia and melena and exclude the possibility of bleeding hemorrhoids, which can occasionally present as a hemorrhage.

LABORATORY STUDIES. The initial laboratory studies include a complete blood count, serum electrolytes, BUN and creatinine levels, and PT and partial thromboplastin time (PTT). As in acute upper GIB, type and cross-match is mandatory before RBC transfusion.

Management

RESUSCITATION. The management of acute lower GIB requires aggressive fluid resuscitation, as described for acute upper GIB. Patients with hematochezia should have a nasogastric tube inserted to exclude an upper GI source of bleeding because 10% of suspected lower GIB occurs from upper GI sources.[6] The presence of bloody aspirate confirms an upper GI source of bleeding. However, the absence of blood does not exclude an upper GI source because bleeding from a site in the duodenum may not reflux into the stomach. Nasogastric aspirate that reveals bile without blood is unlikely in bleeding from an upper GI source. Once it is determined that bleeding is coming from a lower GI source, colonoscopy is the procedure of choice for both diagnosis and treatment.

DEFINITIVE DIAGNOSIS. Colonoscopy is the test of choice for the evaluation of lower GIB. It has a diagnostic accuracy of up to 95% in affected patients. Other advantages of colonoscopy are the ability to locate the source of the bleeding precisely, the ability to perform biopsies, and the potential for therapeutic intervention. Before colonoscopy in the acute care setting, the colon needs to be cleansed with 4 L of polyethylene glycol solution given orally or by nasogastric tube until the waste is clear. For those patients in whom bleeding has stopped, it is reasonable to perform colonoscopy on an elective rather than emergent basis. If a source of bleeding is identified during colonoscopy, therapeutic options include thermal coagulation or injection with epinephrine or other sclerosants, as discussed previously.

Endoscopy. Upper endoscopy should be performed if colonoscopy is unable to distinguish a lower GI source.

Radionucleotide Imaging. When colonoscopy fails to identify a bleeding source, radionucleotide scanning can detect bleeding that occurs at rates as low as 0.1 mL/min.[18] This is more sensitive than angiography but less specific than either colonoscopy or a positive angiogram. The two types of scanning available are the technetium (^{99m}Tc)–sulfur colloid and ^{99m}Tc pertechnetate–labeled autologous RBCs. Unfortunately, both of these techniques provide poor localization because of the peristaltic action of the bowel. However, these scans may be useful before angiography because a positive scan can aid in localizing the bleeding.

Angiography. Angiography is reserved for patients with massive, ongoing bleeding when endoscopy is not an acceptable option or with recurrent or persistent bleeding from a source not identified on colonoscopy. Angiography requires the active blood loss of 0.5 to 1.0 mL/min to localize a bleeding site because the contrast in the arterial system is present for only a short time.[18] A positive angiogram is associated with a high likelihood for surgical intervention. When an active source is identified, arteriographic intervention with intra-arterial vasopressin or embolization may be used. However, embolization with gelatin sponges, microcoils, or polyvinyl alcohol particles is replacing vasopressin because of the high incidence of complication and rebleeding after stopping the infusion. The nurse must be aware of the potential complications associated with arteriography, which include allergy to contrast medium, contrast-induced renal failure, bleeding from the arterial puncture site, and even embolism from thrombus.

SURGICAL INTERVENTION. Surgical management of lower GIB is indicated for massive or recurrent bleeding and in those patients with high transfusion requirements. An exploratory laparotomy to identify the source of the bleeding is often performed. A segmental bowel resection with a primary anastomosis is often necessary for definitive treatment of lower GIB. In patients who are unstable, a stoma and

mucous fistula may be created. In those patients with severe lower GIB without a localized source, a blind total colectomy may be the operative choice. Surgical management of diverticular bleeding is indicated if bleeding is not controlled with endoscopic or angiographic means or in patients with recurrent bleeding from the same segment.

▲ Intestinal Obstruction and Ileus

Intestinal obstruction occurs when the passage of intestinal contents through the lumen is impaired. This can result from either mechanical (anatomical) or nonmechanical causes. Intestinal obstruction is classified as either partial or complete, depending on the degree of obstruction. In a simple obstruction there is no ischemia, whereas in cases of strangulated obstruction, ischemia is present. A closed-loop obstruction describes a mechanical obstruction with a proximal and distal occlusion of the affected intestinal segment.

Bowel obstruction can occur in both the small and large bowel. The small bowel is most commonly affected, with the ileum as the most common site of obstruction. In large bowel obstruction, the sigmoid colon is the most common site of obstruction. The location of the obstruction, the degree of obstruction, and the presence of ischemia are important distinctions because treatment varies. Prompt recognition of bowel obstruction is important for the nurse because intestinal obstruction can progress to bowel strangulation, infarction, and perforation and result in potentially life-threatening peritoneal and systemic infection. The mortality rate associated with a strangulated obstruction is high.

The causes of mechanical obstruction are varied and classified as extrinsic, intrinsic, and intraluminal (Box 41-6). Extrinsic lesions occur outside of the bowel. Examples of extrinsic lesions are adhesions, hernias, volvulus (twisting of a segment of the bowel on itself), and masses. Intrinsic lesions extend into the bowel wall. Diverticulitis, neoplasms, and radiation enteritis are examples of intrinsic lesions. Intraluminal causes of obstruction can result from the ingestion of foreign bodies, intussusception, and neoplasms.

Small Bowel Obstruction

Etiology

Adhesions are the most common cause of small bowel obstruction (SBO) in adults and account for 50% to 75% of obstructions.[20–22] Adhesions most commonly occur after laparotomy for colectomy, appendectomy, or gynecological procedures. Adhesions can also develop after abdominal radiation, ischemia, or infection, or as the result of foreign bodies. Adhesions may develop only days after surgery and as late as 10 to 20 years later. Adhesive bands can form and contract and, in time, may entrap a loop of bowel.

Hernias are the cause of SBO in 10% to 15% of cases.[21,22] SBO secondary to hernia carries a high risk for complete obstruction and strangulation. The herniation of a portion of the bowel after laparotomy is called a Richter's hernia. The occurrence of SBO in the absence of previous laparotomy should suggest hernia as the cause.

BOX 41-6 Causes of Mechanical Obstruction

Extrinsic Lesions
- Adhesions and congenital bands
- Hernias
  - External hernias
  - Internal hernias
  - Diaphragmatic hernias
  - Pelvic hernias
- Volvulus
  - Gastric
  - Midgut
  - Cecal
  - Sigmoid
- Extrinsic masses
  - Benign or malignant tumors
  - Abscesses
  - Aneurysms
  - Hematomas
  - Endometriosis

Intrinsic Lesions
- Benign and malignant neoplasms
  - Adenocarcinomas
  - Lymphomas, lymphosarcomas
  - Carcinoid tumors
- Inflammatory conditions
  - Tuberculous enteritis, Crohn's disease
  - Strictures secondary to potassium chloride, nonsteroidal anti-inflammatory drugs, and ischemia
  - Radiation injury, caustic ingestants
  - Eosinophilic gastroenteritis, ameboma
  - Diverticulitis, pelvic inflammatory disease
- Intussusception
- Congenital defects
  - Hypertrophic pyloric stenosis, annular pancreas
  - Intestinal atresia/agenesis
  - Malrotation/volvulus
  - Intestinal duplication, mesenteric cysts
  - Meckel's diverticulum
  - Hirschsprung's disease
- Hematoma
  - Abdominal trauma
  - Thrombocytopenia
  - Henoch-Schönlein purpura

Intraluminal Causes
- Meconium ileus
- Barium impaction
- Fecal impaction
- Gallstone ileus
- Gastric bezoars
- Foreign bodies

From Yamada T, Alpers DH, Laine L, et al (eds): Textbook of Gastroenterology, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2003, p 834.

Tumors are uncommon in the small bowel, and primary neoplasms of the small bowel account for less than 5% to 10% of SBO.[21] Luminal compression of the small bowel or local invasion by gastric, pancreatic, colonic, and gynecological cancers can cause extrinsic compression, which accounts for most cases of SBO that result from malignancy. Intraluminal strictures that result from Crohn's disease, radiation therapy, ischemia, and certain drugs, such as enteric-coated potassium chloride or NSAIDs, are other possible causes of SBO.

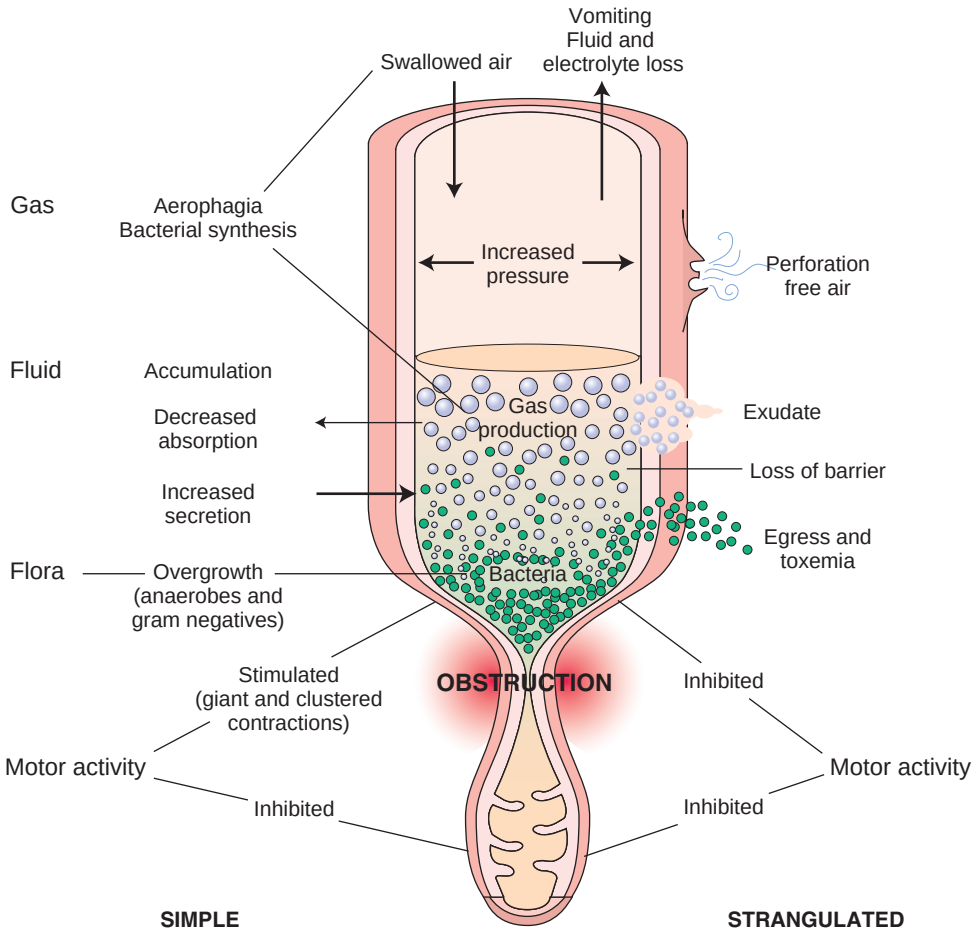

FIGURE 41-3 ▲ The pathophysiology of simple obstruction (**left**) and strangulated obstruction (**right**) in the small intestine. (From Yamada T, Alpers DH, Laine L, et al [eds]: Textbook of Gastroenterology, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2003, p 830.)

Pathophysiology

In SBO, large amounts of fluid and swallowed air accumulate in the intestinal lumen proximal to the obstruction, causing distention (Fig. 41-3). Fluid accumulates from oral intake; swallowed saliva; and gastric, biliary, and pancreatic juices. Swallowed air has a high nitrogen content and is poorly absorbed from the lumen.

As the obstruction continues, the bowel wall and lumen become edematous and distended. Increased intraluminal pressure leads to increased capillary permeability and movement of fluid and electrolytes into the abdominal cavity. This extravasation of fluid and electrolytes into the peritoneal cavity, combined with fluid lost through vomiting, can lead to hypovolemia, hypokalemia, and hyponatremia. Peristalsis decreases, and the normal functions of the intestine decrease or halt. In the absence of normal intestinal motility, bacterial overgrowth occurs. If oral intake continues, bacterial fermentation can contribute to gas accumulation. Within hours of acute obstruction, the contents of the lumen proximal to obstruction become malodorous and feculent because of this bacterial overgrowth.

Clinical Presentation

The severity of symptoms is related to the site and degree of obstruction, duration, and the presence and severity of ischemia (Table 41-1).Patients with SBO usually complain of the acute onset of intermittent, crampy, periumbilical pain. Bursts of peristalsis above the obstruction cause pain. The pain is often more severe the more proximal the obstruction. Patients with an incomplete obstruction often describe crampy abdominal pain after meals. The pain in incomplete obstruction may be exacerbated by the ingestion of high-fiber meals. Patients with a closed loop obstruction may describe pain out of proportion to physical findings.

In patients with proximal SBO, vomiting occurs frequently and early in the course of obstruction. The emesis is usually bilious, and vomiting often relieves the pain by deflating the distended bowel. Minimal abdominal distention usually accompanies proximal SBO.

In distal SBO, moderate abdominal distention and intermittent or constant pain are often present. Vomiting is intermittent. In ileal SBO, the emesis may be feculent secondary to bacterial overgrowth.

In strangulated SBO, the pain is more localized and may be steady and severe. When vomiting is protracted, dehydration and hypovolemia may occur.

Fever may be present secondary to an inflammatory process or in response to bowel ischemia or perforation. Constipation is also a common complaint, although patients may continue to pass gas and stool as the bowel distal to the obstruction empties. Obstipation is an important indicator of complete obstruction, but patients with a complete bowel obstruction evacuate the contents distal to the obstruction. Depending on the duration and severity of the obstruction, hemodynamic instability may develop as the result of massive fluid trapping in the lumen with leakage into the peritoneum.

Table 41-1 Clinical Features of Ileus and Obstruction Dependent on Anatomic Site

Feature	Ileus	Site of Obstruction			
		Gastric Outlet	Distal Duodenum	Jejunoileal	Colon
Pain	Mild	Mild	Mild	Moderate	Severe
Distention	Moderate to severe	Mild	Mild	Moderate	Severe
Emesis					
Amount/frequency	Small, infrequent	Copious, frequent	Copious, frequent	Smaller/less frequent	Uncommon
Nature	Sour, bilious	Clear, sour, HCl, KCl	Bile-stained, bitter, NaCl, $NaHCO_3$	Malodorous, feculent	Variable
Acid–base imbalance	Variable	Metabolic alkalosis	Metabolic acidosis	Dehydration, hypotension	Usually not severe

HCl, hydrogen chloride; KCl, potassium chloride; $NaHCO_3$, sodium bicarbonate; NaCl, sodium chloride.

From Yamada T, Alpers DH, Laine L, et al (eds): Textbook of Gastroenterology, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2003, p 833.

Assessment

HISTORY. A careful history provides clues to etiology. A medical history of previous abdominal surgery or trauma increases the risk for adhesions. Other pertinent medical history findings include inflammatory bowel disease, diverticulitis, abdominal or pelvic radiation, peptic ulcer disease, pancreatitis, and previous obstruction or cancer. Correlation to menses suggests endometriosis. A complete medication history is also essential. Patients with a psychiatric history should be questioned about ingestion of foreign objects.

PHYSICAL EXAMINATION. Patients with SBO often appear acutely ill. Inspection of the abdomen often reveals visible peristalsis and distention. Patients with a proximal SBO may have epigastric or periumbilical tenderness, whereas those with distal SBO often have more diffuse tenderness. Bowel sounds are usually hyperactive in the early course of the obstruction, then high-pitched and tinkling with loud rushes as peristaltic waves attempt to push intestinal contents past the obstruction. Bowel sounds decrease as the obstruction progresses and the bowel fatigues. Tachycardia, orthostatic hypotension, poor skin turgor, or dry mucous membranes may indicate dehydration. A palpable mass may represent a neoplasm or volvulus. It is necessary to perform a rectal examination to assess for blood, fecal impaction, or mass. Inspection may reveal scars and external hernias. Hepatomegaly, liver masses, and palpable periumbilical, inguinal, or supraclavicular lymphadenopathy suggest malignancy. Abdominal tenderness and palpable masses may suggest abscess. Fever, rigors, and declining clinical status suggest bowel strangulation. Borborygmi, rumbling, gurgling, and tinkling noises produced by hyperactive intestinal peristalsis are often audible and may correlate with abdominal cramping. If rebound tenderness is present, observe for signs and symptoms of shock because perforation is a possibility. Percussion of the abdomen may reveal resonance or tympany from fluid trapped in the intestine. Shifting dullness to percussion indicates ascites. Palpate for inguinal, femoral, and umbilical hernias. A tender mass at the site of a hernia suggests the etiology. Tachycardia, tachypnea, altered mental status, oliguria, and hypotension may all be present in hypovolemia.

LABORATORY STUDIES. There is no single laboratory value that is diagnostic for SBO. A mild leukocytosis is present with simple obstructions, whereas significant leukocytosis suggests strangulation. In proximal obstruction, potassium, sodium, hydrogen, and chloride may be lost in emesis, resulting in metabolic alkalosis. BUN, creatinine, sodium, and osmolality levels reflect the fluid and electrolyte shifts that occur as fluid leaks out of the intestine and electrolytes are either reabsorbed or lost. As dehydration increases, the hemoglobin and hematocrit levels are elevated, reflecting hemoconcentration. In ischemia or strangulation, amylase, lipase, alkaline phosphatase, creatine phosphokinase, aspartate aminotransferase (AST), alanine aminotransferase (ALT), and lactate dehydrogenase levels may rise. Often, heme-positive stools are present in ischemia or carcinoma. Metabolic acidosis suggests severe hypoxemia from hypoperfusion, and metabolic acidosis refractory to fluid resuscitation suggests strangulation.

IMAGING STUDIES. Various imaging studies are available to confirm diagnoses.

Radiography. When SBO is suspected, abdominal radiographs with the patient in upright, flat, and side-lying positions can confirm the diagnosis of obstruction, localize the site of obstruction, and assist in determining the degree of obstruction. Pneumoperitoneum seen in upright films suggests intestinal perforation. Normally, there is little air in the small bowel. In complete SBO, gas and fluid accumulate proximal to the obstruction. Multiple air–fluid levels may be visible, with a stepladder pattern that demonstrates multiple loops of bowel with different air levels. Distal to the obstruction, the bowel lumen empties and collapses within 12 to 24 hours. Successive films may also confirm the diagnosis, but distinguishing between a small and large bowel obstruction or ileus is difficult.

Barium studies may be helpful in the diagnosis of obstruction if plain films are nondiagnostic. Contrast-enhanced studies can differentiate between a complete or partial obstruction. Barium is the agent of choice if SBO is suspected because it provides a better contrast than water-soluble material. In SBO, the large amount of water present proximal to the obstruction dilutes water-soluble contrast. However, if there is any question about bowel perforation, barium should

be avoided because free barium in the peritoneum can cause significant inflammation. If colonic obstruction is suspected, a limited barium enema is used for diagnosis before barium is given by mouth.

Computed Tomography. Abdominal computed tomography (CT) can help identify obstructive lesions, neoplasms, hernias, and signs of ischemia. Abdominal CT with oral or IV contrast medium can help differentiate mechanical obstruction from pseudo-obstruction. Oral contrast seen in the colon on CT 12 hours after ingestion indicates incomplete SBO, whereas nonvisualization of oral contrast in the colon within 12 hours indicates complete SBO.[21] The CT diagnosis of a complete SBO requires a transition zone between dilated and collapsed loops of bowel, suggesting the point of obstruction. CT is less sensitive in the diagnosis of a partial SBO. CT can also assess the entire abdomen, which can suggest alternative diagnoses and identify any complications associated with obstruction. CT is also accurate in determining the presence of strangulation or a closed-loop obstruction.

Endoscopy. Direct visualization with endoscopy may confirm the obstruction in the colon or proximal small bowel and aid in determining the type of obstruction.

Management

MEDICAL MANAGEMENT. When possible, obstructions, especially incomplete obstructions, are treated medically rather than surgically. Oral food and fluid are withheld (ie, the patient is put on NPO status), and a nasogastric tube is placed to decompress the stomach or duodenum. Fluid and electrolytes are aggressively supplied IV with lactated Ringer's or saline solution. When possible, the underlying causes are treated. Total parenteral nutrition (TPN) may be required to provide nutritional support. A Foley catheter is inserted to allow continual assessment of the fluid replacement. In patients with renal or cardiac disease, a central venous pressure (CVP) or pulmonary artery catheter may guide fluid replacement.

About 90% of SBO resolve spontaneously, and if patients continue to pass gas and stool, supportive management is continued.[21] If patients show no improvement within 24 to 48 hours, or if fever or rebound tenderness occurs, a surgical evaluation is indicated. All patients with intestinal obstruction should be watched closely for signs and symptoms that reflect sepsis, perforation, ischemia, necrosis, or gangrene. Broad-spectrum antibiotics are started immediately when strangulation or sepsis is suspected. The mortality rate associated with bowel ischemia resulting from obstruction is high.

SURGICAL MANAGEMENT. Acute complete SBO is a surgical emergency. Acute complete SBO is suspected when the patient fails to pass gas, and stool and gas are not evident in the distal intestine on radiography. An acute complete SBO is accompanied by the risk for bowel strangulation. Patients with strangulated bowel, volvulus, and incarceration of bowel loop in a hernia or a closed-loop obstruction require immediate surgery. In addition, those patients who fail conservative therapy or experience a decline in clinical status warrant surgical intervention.

Surgical procedures include laparoscopic lysis of adhesions, reduction of volvulus, resection of the involved and surrounding area of bowel with impaired blood supply, bowel decompression, and possible ostomy. These patients may require a second surgery to assess bowel viability.

Colonic Obstruction

Etiology

Carcinoma, sigmoid diverticulitis, and volvulus are the three most common causes of colonic obstruction and together account for the majority of colonic obstructions. Malignancy is the most common cause of colonic obstruction in the United States, accounting for approximately 60% to 75% of cases.[21,23] Patients with colorectal cancer present with a colonic obstruction between 10% and 20% of the time.[21] Malignancy that causes colon obstruction occurs most commonly in the sigmoid colon. Extrinsic compression or colonic invasion from pelvic tumors may also cause a colon obstruction. Diverticulitis can cause strictures in the colon that can lead to mechanical obstruction, resulting in approximately 10% of cases of colonic obstruction.[21] Volvulus, which occurs most commonly in the sigmoid colon and the cecum, causes 10% to 15% of colonic obstructions in the United States.[21] A closed-loop obstruction is usually produced with volvulus and carries a high incidence of strangulation. Other causes of colon obstruction include anastomotic or inflammatory strictures.

Pathophysiology

When the ileocecal valve is competent, a closed-loop obstruction can occur because the cecum does not allow decompression of fluid and gas into the small bowel. As fluid and gas accumulate, the intraluminal pressure increases, and the colonic wall can become ischemic if this pressure exceeds the capillary pressure. In some cases, the cecum may become so severely distended that it inhibits intramural blood flow, which can result in necrosis and gangrene. In colonic obstruction, the normal colonic flora produces methane and ammonia, which contribute to the distention. Dehydration results when secretions are sequestered in the colon.

Patients with colonic obstruction have changes in intestinal flora and translocation of bacteria in mesenteric lymph nodes. This is the most likely cause of septic complications of colonic obstruction.

Clinical Presentation

The clinical presentation of patients with colonic obstruction depends on the degree of obstruction, the cause, the presence of comorbidity, the presence of closed-loop obstruction, and the competency of the ileocecal valve. Patients with colonic obstruction typically present with abdominal pain, distention, and progressive obstipation. The pain may be colicky or severe and unremitting if peritonitis is present. Severe, constant pain suggests gangrenous bowel. If vomiting occurs, it tends to be late in the course of obstruction, especially in patients with a competent ileocecal valve. Patients with volvulus may present with a sudden onset of marked abdominal distention. Patients with obstruction from colon cancer may describe a gradual development of symptoms like altered bowel habits or a change in stool caliber. Dehydration results when secretions become sequestered in the colon. Patients with a competent ileocecal valve may have greater

distention, which increases the risk for ischemia and perforation because an incompetent ileocecal valve allows decompression into the small intestine. Most patients with colonic obstruction complain of constipation; however, diarrhea may be present if stool is leaking past an obstruction. Patients may complain of dyspnea if diaphragmatic excursion is compromised by abdominal distention.

Assessment

HISTORY. A history of altered bowel movements, blood in the stool, or iron deficiency anemia is suggestive of carcinoma, as are weight loss and anorexia. Diverticulitis typically presents with left lower quadrant pain and associated fever. There may be a change in bowel habits as well. Bleeding is not usually associated with diverticulitis. A history of laxative use and constipation is common in patients with volvulus.

PHYSICAL EXAMINATION. Abdominal distention is common, and tympany is present with percussion. Signs of dehydration including tachycardia, hypotension, poor skin turgor, and dry mucous membranes may be seen. Bowel sounds are usually hyperactive initially but become progressively hypoactive. Abdominal masses and signs of peritoneal irritation may be elicited. The abdomen may be diffusely tender. Guarding or rebound tenderness suggests peritonitis. Ascites and hepatomegaly may be present in patients with colon cancer with liver metastasis. A rectal examination may be helpful in identifying rectal cancer. High fever and tachycardia, regardless of rehydration or the presence of peritoneal signs, suggest strangulation and warrant urgent surgical evaluation.

LABORATORY STUDIES. Iron deficiency anemia may be present if obstruction results from neoplasm. Marked leukocytosis suggests diverticulitis, ischemia, or perforation.

IMAGING STUDIES. Plain abdominal films in the supine and upright positions identify the site of obstruction and determine the degree of obstruction. Obstruction in patients with a competent ileocecal valve causes dilation confined to the colon. Small bowel distention may be visible on abdominal films in patients with acute colonic obstruction and in patients with intact ileocecal valves. Abdominal films may also suggest volvulus.

If a contrast enema is given, water-soluble contrast medium rather than barium may be considered. Barium should never be given orally unless a barium enema, CT scan, or colonoscopy has ruled out colonic obstruction. Oral barium accumulates proximal to the colonic obstruction, and water will continually be extracted, possibly causing a barium impaction. In patients with suspected volvulus, a water-soluble contrast enema may demonstrate a point of torsion.

CT may be valuable in distinguishing between an anatomic obstruction and a pseudo-obstruction. CT can also diagnose other causes of colonic obstruction, such as inflammation as a result of colitis or diverticulitis and perforation as a result of colorectal cancer.

Management

MEDICAL MANAGEMENT. The medical management of the patient with acute colonic obstruction is similar to that of the patient with SBO. Medical management focuses on fluid and electrolyte replacement. Oral intake is limited, or the patient is placed on NPO status. Nasogastric suction may assist in decompression of abdominal distention. A rectal tube may decompress the distal colon but has little effect on the proximal colon. Colonic decompression in the setting of a volvulus can be attempted by colonoscopy.

SURGICAL MANAGEMENT. Colonic obstruction usually requires surgery. The goals of surgery are to decompress the colon and to treat the obstructive lesion. Surgical management of the colonic obstruction is warranted if the patient fails to improve with medical management, the patient's clinical status deteriorates, or the patient has a complete colonic obstruction with a competent ileocecal valve. For obstruction of the left colon, operative decompression followed by primary anastomosis after intraoperative lavage is the treatment of choice. For obstruction in the transverse and right colon, primary resection and anastomosis can also be performed safely. Primary anastomosis should be avoided in a patient with an unprepared colon.

ENDOSCOPIC THERAPY. Stents that are placed endoscopically can be used as a temporary measure before surgical resection of obstruction from malignancy or as a palliative measure in nonoperative colorectal cancer. Endoscopic laser therapy, argon plasma coagulation, and snare polypectomy may be used to debulk obstructing tumors in patients unwilling or unable to have surgery.[23]

Ileus

Ileus, often called paralytic ileus or adynamic ileus, is the failure of intestinal contents to pass because of decreased peristalsis activity in the absence of mechanical obstruction. Ileus can have intra-abdominal or extra-abdominal causes (Box 41-7), many of which are likely to be seen in the ICU setting. Acute colonic pseudo-obstruction (ACPO), also called acute colonic ileus and Ogilvie's syndrome, is a variant of ileus characterized by massive colonic dilation in the absence of mechanical obstruction.

Etiology

Postoperative ileus (a transient inhibition of normal GI motility that usually lasts for 3 to 5 days after surgery) is the most common cause of a delayed discharge after surgery, abdominal or otherwise.[24,25] An underlying disease is present in the majority of ileus. Causes of ileus include metabolic abnormalities (electrolyte disturbances, diabetic ketoacidosis, uremia, heavy metal poisoning), drugs (narcotics, catecholamines, antihistamines, calcium channel blockers, adrenocorticotropic hormones, anticholinergics), and local or systemic inflammation (sepsis, peritonitis, ischemia, pancreatitis). Ileus may also be present after spinal cord injury. Blood-borne toxins, abnormalities in acid–base balance, electrolyte disturbances, and decreased oxygen supply are all possible causes of ileus.

Pathophysiology

Although the etiology of ileus can be defined, the pathophysiology of ileus is poorly understood. Postoperative ileus has been widely studied, and multiple mechanisms are thought

BOX 41-7 Causes of Adynamic Ileus and Acute Colonic Pseudo-Obstruction

Intra-Abdominal Causes

Reflex Inhibition
- Laparotomy
- Abdominal trauma
- Renal transplantation

Inflammatory Conditions
- Perforated viscus or penetrating wounds
- Bile peritonitis
- Chemical peritonitis
- Intraperitoneal hemorrhage
- Toxic megacolon
- Familial Mediterranean fever
- Acute pancreatitis
- Acute cholecystitis
- Celiac disease
- Inflammatory bowel disease

Acute Irradiation Injury
- Abdominal irradiation

Infectious Processes
- Bacterial peritonitis
- Appendicitis
- Diverticulitis
- Herpes zoster virus
- Anorectal herpes simplex virus

Ischemic Processes
- Arterial insufficiency
- Venous thrombosis
- Mesenteric arteritis
- Strangulation obstruction

Retroperitoneal Processes
- Ureteropelvic stones
- Pyelonephritis
- Retroperitoneal hemorrhage
- Pheochromocytoma
- Malignancy (Ogilvie's syndrome)

Extra-Abdominal Causes

Reflex Inhibition
- Craniotomy
- Spine or pelvic fractures
- Myocardial infarction
- Coronary bypass
- Open heart surgery
- Pneumonia, pulmonary embolus
- Burns
- Black widow spider bites

Drug-Induced
- Anticholinergic/ganglionic antagonists
- Opiates
- Chemotherapeutic agents
- Tricyclic antidepressants
- Phenothiazines

Metabolic Abnormalities
- Septicemia
- Electrolyte imbalance
- Heavy metal poisoning (lead, mercury)
- Porphyria
- Uremia
- Diabetic ketoacidosis
- Sickle cell disease
- Pulmonary failure

From Yamada T, Alpers DH, Laine L, et al (eds): Textbook of Gastroenterology, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2003, p 836.

to play a role, including sympathetic neural reflexes that inhibit normal bowel motility, local and systemic inflammatory mediators that result in bowel edema, and changes in neural and hormonal transmitters.[24,25] The effects of anesthesia, combined with inflammation or ischemia in the operative area, may also interfere with nerve conduction. Opioid narcotics may also contribute to postoperative ileus because they decrease propulsive motility of the intestine. In ileus, peristalsis ceases or is decreased, and distention of the intestine occurs as gas, fluid, and electrolytes accumulate in a process similar to that seen in mechanical obstruction.

Clinical Presentation

Patients with ileus may complain of diffuse abdominal discomfort and distention (see Table 41-1, p. 927). ACPO is more common in men and patients 60 years of age and older.[24] Nausea and vomiting are often predominant in patients with postoperative ileus. Vomiting is frequent, and the emesis usually contains gastric contents and bile. The vomiting of feculent material is rare. The pain is usually less intense than in small bowel or colonic obstruction. The patient with ileus also complains of constipation and usually denies the passage of flatus. Other common symptoms are nausea, anorexia, hiccups, and bloating.

Assessment

HISTORY. A history of thyroid or parathyroid disease, heavy metal exposure, diabetes mellitus, and scleroderma should be elicited to identify underlying causes.

PHYSICAL EXAMINATION. Abdominal distention is often prominent in ileus. Auscultation of the abdomen usually reveals infrequent or absent bowel sounds. The abdomen is usually resonant to percussion secondary to air in the dilated loops of intestine. Abdominal distention may cause labored breathing. Abdominal girth is assessed at frequent intervals. Peritoneal signs may indicate impending perforation. Tachycardia, orthostatic hypotension, poor skin turgor, or dry mucous membranes may indicate dehydration.

LABORATORY STUDIES. Electrolyte abnormalities commonly associated with ileus are similar to those seen in patients with mechanical obstruction.

IMAGING STUDIES. Abdominal radiography that shows massive colonic dilation confirms the diagnosis of ileus. In ileus, gas and fluid accumulate in loops of mildly dilated bowel proximal or adjacent to the site of an acute inflammatory process, such as appendicitis or pancreatitis. These loops are involved in localized ileus and are called sentinel loops. In ACPO, the entire colon becomes dilated, with the cecal diameter the greatest. Chest radiography may help identify pneumonia or other causes of ileus. Contrast-enhanced enema studies can be used to differentiate complete obstruction from partial obstruction and ileus. CT of the abdomen may identify causes that can contribute to ileus. Ultrasonography has no role in the diagnosis of ileus because the dilated loops of bowel prevent imaging.

Management

Treatment of ileus focuses on management of underlying causes. Because ileus may present in much the same way as mechanical obstruction, exclusion of mechanical causes is necessary. Treatment usually consists of supportive care. Patients with ileus have traditionally been placed on NPO status, although recent studies suggest that early feeding is safe. Fluid and electrolyte replacement is directed by clinical status and laboratory values as needed. Nasogastric suction limits the collection of swallowed air that can contribute to abdominal distention. Medications that can adversely affect colonic motility including narcotics and anticholinergics should be discontinued when possible. Laxative use should be avoided because these agents can provide a substrate for bacterial fermentation, which results in further gas accumulation. In addition, patients should be mobilized and encouraged to get out of bed if they are ambulatory.

If patients show no improvement in 3 to 5 days, a further search for underlying causes is initiated. Neostigmine has been effective in treating colonic ileus not responsive to conservative therapy. Neostigmine is a parasympathomimetic that can correct the autonomic imbalance thought to contribute to ileus. Neostigmine can cause bradycardia and dysrhythmias, so careful cardiac monitoring is required. Prokinetic medications, such as metoclopramide (Reglan) and erythromycin, have not been found to be effective in treating ileus.

Therapeutic interventions for decompressing the colon include colonoscopy, open or percutaneous cecostomy, and a decompression colostomy. Colonoscopy is the procedure of choice for decompression in patients who do not respond to conservative or medical therapy.

Surgery is indicated for patients who fail conservative management or in patients who develop a perforation or evidence of ischemia.

▲ Acute Pancreatitis

Acute pancreatitis (AP) is an acute inflammation of the pancreas that can also involve surrounding tissues, remote organs, or both. There are approximately 300,000 hospital admissions a year in the United States caused by AP.[26,27] AP refers to an acute attack in a previously healthy individual, with resolution of symptoms after the attack. Chronic pancreatitis refers to repeated attacks with continued symptoms. AP can be mild or severe. Mild AP is not associated with organ dysfunction or complications, and recovery is usually uneventful. Approximately 10% to 20% of patients with AP develop severe pancreatitis, also called necrotic or hemorrhagic pancreatitis.[26] In severe AP, there is extensive fat necrosis in and around the pancreas, pancreatic cellular necrosis, and hemorrhage in the pancreas. Severe AP is associated with local and systemic complications. The incidence of AP varies among populations based on the prevalence of precipitating factors, such as alcohol use and gallstone disease.

Etiology

There are multiple causes of AP (Box 41-8). Gallstones and excessive alcohol use together account for 70% to 80% of cases.[26–28]

Gallstones are responsible for 40% of cases.[26,27] Gallstones and biliary sludge may become lodged as they pass through biliary system, blocking pancreatic secretions from emptying into the duodenum. Reflux of bile into the pancreatic duct resulting from this obstruction is thought to be the inciting factor. Gallstone pancreatitis is more common in women.

Alcoholism is the second leading cause of pancreatitis and accounts for 35% of the cases of AP.[26,27] The exact mechanism by which alcohol induces AP is unknown. Alcohol may cause overstimulation of the pancreas and activation of pancreatic secretions within the pancreas. Alcohol may also have a direct toxic effect. Another theory is that alcohol causes sphincter of Oddi spasm, which causes pancreatic enzymes to back up into the pancreas.[26,27] Alcoholic pancreatitis is more common in men. AP is rarely the result of binge drinking unless the pancreas is already damaged by chronic alcohol use. Drinking five to eight alcoholic beverages a day for more than 5 years is a risk factor for the pancreatitis.[26,27]

BOX 41-8 Major Causes of Acute Pancreatitis

- Biliary disease: gallstones or microlithiasis, common bile duct obstruction, biliary sludge
- Pancreas divisum
- Alcohol abuse
- Drugs: thiazide diuretics, furosemide, procainamide, tetracycline, sulfonamides, azathioprine, 6-mercaptopurine, angiotensin-converting enzyme inhibitors, valproic acid
- Hypertriglyceridemia
- Hypercalcemia
- Idiopathic
- Miscellaneous (postoperative, ectopic pregnancy, ovarian cyst, total parenteral nutrition)
- Abdominal trauma
- Endoscopic retrograde cholangiopancreatography
- Infectious processes

Metabolic causes of AP include hypercalcemia and hypertriglyceridemia. Hypertriglyceridemia accounts for up to 4% of all cases of AP.[26–28] Many drugs, including diuretics, sulfonamides, metronidazole, aminosalicylates, and estrogen, can precipitate AP as a result of toxic metabolites or a drug reaction. Idiopathic pancreatitis is associated with pregnancy, the administration of TPN, or major surgery. Pancreatitis has also occurred after blunt or penetrating abdominal trauma or after endoscopic manipulation of the ampulla of Vater. Other possible precipitating factors include infectious processes, such as mumps, staphylococcal infection, scarlet fever, and viral infections, as well as the congenital variant of pancreas divisum. Pancreatitis may occur as an isolated event, or the patient may suffer repeated attacks.

Pathophysiology

The acinar cells of the pancreas synthesize and secrete digestive enzymes to assist in the breakdown of starch, fat, and proteins. Under normal circumstances, these enzymes remain inactive until they enter the duodenum. As pancreatic juice enters the duodenum, trypsinogen is activated by enterokinase into its active form, trypsin.

In AP, pancreatic enzymes become prematurely activated in the pancreas. This premature activation results in autodigestion of the pancreas and the peripancreatic tissue. The exact mechanism by which pancreatic enzymes become activated and initiate autodigestion is not fully understood. However, the activation of trypsinogen is thought to be the critical event that promotes the activation of other injurious enzymes, including elastase, kinases, and phospholipase A. Elastase can cause dissolution of elastic fibers in blood vessels, which can lead to hemorrhage. Activated kinins cause systemic vasodilation and increased vascular permeability, which promotes edema. Phospholipase A causes necrosis of the pancreas and the surrounding fatty tissue.

Pancreatic enzymes, vasoactive substances, hormones, and cytokines released from the injured pancreas cause a cascade of events that can lead to edema, vascular damage, hemorrhage, and necrosis. Systemic effects mediated by the immune system can lead to a systemic inflammatory response syndrome (SIRS), which can result in distant organ damage and multisystem organ failure. This immune response is independent of the event that causes AP but is responsible for the majority of the morbidity and mortality associated with it.

Clinical Presentation

Abdominal pain is the hallmark of AP and occurs in 95% of cases.[27] The severity of the pain correlates to the degree of pancreatic involvement. The pain is usually deep and boring, midepigastric or periumbilical, with radiation to the back, but it may radiate to the spine, flank, or left shoulder. The pain usually begins abruptly and increases in intensity over several hours. It is usually steady, but can be exacerbated by intake. Pain associated with gallstone pancreatitis may be more localized to the right upper quadrant, more colicky, and more variable in intensity. The pain is usually exacerbated when the patient lies supine and is usually relieved when the patient sits and leans forward or lies in a fetal position. Patients are often restless and agitated. Nausea and vomiting without pain relief is present 90% of the time.[27] Tachycardia, abdominal distention, and hypotension are other common symptoms. A low-grade fever may or may not be present. A persistent fever may indicate complications, such as peritonitis, cholecystitis, or intra-abdominal abscess.

The diagnosis of AP is often challenging because AP can mimic many other conditions. The differential diagnosis includes gastritis, perforated duodenal or gastric ulcers, acute SBO, ruptured ectopic pregnancy, sickle cell crisis, acute cholecystitis, mesenteric artery occlusion, and ruptured aortic aneurysm. Diagnosis is made on the basis of the patient's clinical presentation, history, physical examination findings, and the results of laboratory and radiographic studies (Box 41-9).

BOX 41-9 Clinical Manifestations of Acute Pancreatitis

Physical Examination Findings
- Abdominal pain
- Low-grade fever
- ± Jaundice
- Abdominal guarding or distention
- Paralytic ileus
- Grey Turner's sign
- Cullen's sign
- Nausea or vomiting without relief

Laboratory Findings
- Elevated serum and urine amylase
- Elevated serum lipase
- Elevated white blood cell (WBC) count
- Hypokalemia
- Hypocalcemia
- Elevated bilirubin, aspartate aminotransferase (AST), and PT (with liver disease)
- Elevated alkaline phosphatase level (with biliary disease)
- Hypertriglyceridemia
- Hyperglycemia
- Hypoxemia

Assessment

History

A careful history can provide important clues to diagnosis. A history of biliary tract disease, alcohol intake, diabetes, and medication use should be elicited to identify precipitating causes. A family history of AP may suggest hereditary causes. The patient may report anorexia, weight loss, nausea, vomiting, or abdominal distention. Assessment of the location, duration, quality, quantity, and precipitating factors of pain is important to help identify potential causes.

Physical Examination

Diffuse abdominal tenderness and guarding may be present during abdominal palpation. The upper abdomen may be distended and tympanic to percussion. Bowel sounds may be hypoactive or absent, owing to decreased intestinal mobility or paralytic ileus. Jaundice may be present in gallstone disease or from obstruction of the biliary tree from pancreatic edema. Ascites or palpable abdominal masses may be present. Patients with severe acute hemorrhagic pancreatitis may have signs of dehydration and hypovolemic shock. These signs may worsen when fluid is lost into the bowel lumen because of a paralytic ileus. The presence of a bluish discoloration of the lower abdominal flanks (Grey Turner's sign) or around the umbilical area (Cullen's sign) indicates hemorrhagic pancreatitis and an accumulation of blood in these areas. These findings are rare, but if they occur, the findings usually do not appear until 48 hours or more after onset of symptoms.

Laboratory Studies

No single laboratory study is diagnostic of AP; however, elevations of serum amylase and lipase enzymes are often seen in AP (see Table 39-7, p. 884). These enzymes are released as the pancreatic cells and ducts are destroyed. Serum amylase levels rise within 2 to 12 hours of the onset of symptoms and gradually return to baseline within 3 to 5 days in AP. In mild pancreatitis, amylase levels can be close to normal. If a few days have elapsed since symptoms began, amylase values can also be normal even with an active inflammatory process in the pancreas. The sensitivity of serum amylase is limited in patients with hypertriglyceridemia and in patients with an acute chronic alcoholic pancreatitis.[27] The specificity of serum amylase is decreased in biliary tract disease, tumors, salivary gland lesions, cerebral trauma, gynecological disorders, and renal failure. However, serum amylase levels that are more than three times the upper limits of normal are highly specific for pancreatitis.[26,27]

Compared with serum amylase levels, serum lipase levels rise later and remain elevated. Serum lipase levels usually

rise within 4 to 8 hours of the onset of symptoms, peak at 24 hours, and return to normal after 8 to 14 days. Because the serum lipase level stays elevated longer, it is a useful test in diagnosis if there is a delay in examination. Like amylase, serum lipase levels may be elevated in patients who have intra-abdominal inflammation or renal insufficiency.

Elevations of isoenzymes, urinary amylase, and the amylase values of pleural fluid and paracentesis drainage support the presence of AP. Leukocytosis, hypokalemia, hypocalcemia, and hypertriglyceridemia may be present but are not specific to AP. Leukocytosis frequently results from infection, stress, or dehydration. Persistent vomiting may result in hypokalemia. Hypocalcemia may indicate the presence of pancreatic fat necrosis because calcium binds with fatty acids during tissue necrosis. In addition, trypsin inactivates parathyroid hormone, which is needed for calcium absorption. Hyperglycemia may result from decreased insulin release from damaged beta cells, increased glucagon release, and the stress response. Hemoconcentration may occur as fluid is lost into the peritoneal space. Elevations in serum bilirubin, AST, and PT are common in the presence of concurrent liver disease. A greater than threefold elevation in ALT suggests biliary pancreatitis.[27] Alkaline phosphatase is elevated with biliary tract disease. Triglyceride levels associated with AP are usually greater than 1,000 mg/dL.[28]

Imaging Studies

Radiographs of the chest and abdomen are useful to exclude other causes of abdominal pain, including intestinal ileus, perforation, pericardial effusion, and pulmonary disease.

Abdominal ultrasonography is of limited use in visualization of the pancreas because of intestinal gas and adipose tissue. Abdominal ultrasonography is used to evaluate the biliary tree for gallstones, sludge, or ductal dilation as the etiology of pancreatitis. CT is the best imaging study to confirm the diagnosis and determine the severity of AP. CT can visualize the size of the pancreas and identify the presence of peripancreatic fluid, pancreatic pseudocysts, and abscesses. Dynamic CT done with contrast can help identify areas of necrosis in the pancreas. CT findings of extensive necrosis have correlated with a high risk for pancreatitis-related infection and death. Sequential CT allows for assessment of progressive disease or resolution. CT can also demonstrate fluid collection and areas of necrosis and can be used to guide percutaneous needle aspiration for culture.

Magnetic resonance cholangiopancreatography may have a sensitivity of more than 90% for bile duct stones. It can be used in patients who are pregnant and those who have allergies to the contrast used in CT or those with renal disease. Endoscopic retrograde cholangiopancreatography plays a role in locating and removing stones in the common bile duct if gallstone pancreatitis is present.

Tools for Predicting Severity

AP is self-limiting and mild in 80% to 90% of patients, resolving spontaneously within 5 to 7 days.[26] These patients usually require conservative care. However, in 10% to 20% of patients with AP, increased intrapancreatic and extrapancreatic inflammation results in a systemic inflammatory response. Although the mortality rate for severe AP is 10%, this value rises to 30% or more when there are complications.[26] Multiple assessment tools have been developed in attempts to identify patients who are likely to develop severe AP so that aggressive treatment and surveillance can decrease complications and mortality.

BOX 41-10 Ranson's Criteria for Acute Pancreatitis

Evaluate on admission or on diagnosis:
- Age more than 55 years
- Leukocyte count more than 16,000/mL
- Serum glucose more than 200 mg/dL
- Serum lactate dehydrogenase more than 350 IU/mL
- Serum AST more than 250 IU/dL

Evaluate during initial 48 hours:
- Fall in hematocrit more than 10%
- BUN level rise more than 5 mg/dL
- Serum calcium less than 8 mg/dL
- Base deficit more than 4 mEq/L
- Estimated fluid sequestration more than 6 L
- Arterial PaO_2 less than 60 mm Hg

Ranson's criteria have been widely used to assess the severity of AP (Box 41-10). Ranson's criteria consist of multiple clinical criteria used to identify those patients at risk for increased morbidity and mortality. The criteria assessed at admission indicate the severity of the acute inflammatory response, and the criteria assessed at 48 hours evaluate systemic effects. Three or more signs identified at the time of admission or during the initial 48 hours are predictive of severe AP, with an associated mortality rate of 10% to 20%.[26] Six or more have a corresponding mortality rate of 50%.[26] Ranson's criteria have a greater than 90% accuracy rate and are useful clinically in identifying high-risk patients. The primary disadvantage to Ranson's criteria is the 48-hour delay before the assessment is completed.

The Acute Physiology and Chronic Health Evaluation II (APACHE II) score has also been studied and found to be useful in predicting severity of AP (Table 41-2). The APACHE II uses the worst values of physiological measures, age, and previous health status at admission, at 24 hours, and at 48 hours to predict severity of AP. An APACHE II score on admission of eight or more predicted 68% of severe attacks.[26] An advantage of the APACHE II score is that it can be used daily. An APACHE II score that increases during the first 48 hours strongly suggests severe pancreatitis. Both Ranson's criteria results and APACHE II scores are comparable at 48 hours.

Extravasation and third spacing seen in severe AP can cause significant intravascular volume depletion. This depletion can lead to decreased perfusion of the pancreas and cause pancreatic necrosis. Some experts have proposed that hemoconcentration, as detected by an elevated serum hematocrit, is a reliable predictor of necrotizing pancreatitis; however, there is no consensus.

The presence of peripancreatic inflammation, peripancreatic fluid collection, and extent of pancreatic necrosis found on CT have been shown to predict severity of AP. The CT severity index uses CT findings to grade pancreatic severity.

Table 41-2 The Acute Physiology and Chronic Health Evaluation II (APACHE II) Classification System

	High Abnormal Range					Low Abnormal Range			
Physiologic Variable	**+4**	**+3**	**+2**	**+1**	**0**	**+1**	**+2**	**+3**	**+4**
Temperature rectal (°C)	41 or more	39–40.9		38.5–38.9	36.0–38.4	34–35.9	32–33.9	30–31.9	29.9 or less
Mean arterial pressure = (2 × diastolic + systolic)/3	160 or more	130–159	110–129		70–109		50–69		49 or less
Heart rate (ventricular response)	180 or more	140–179	110–139		70–109		55–69	40–54	39 or less
Respiratory rate (nonventilated or ventilated)	50 or more	35–49		25–34	12–24	10–11	6–9		<5
Oxygenation	500 or more	350–499	200–349		<200

APACHE II score **(sum of A + B + C): A** APS points + **B** age points + **C** chronic health points = total APACHE II.

From Triester SL, Kowdley KV: Prognostic factors in acute pancreatitis. J Clin Gastroenterol 34(2):167–176, 2002.

The use of serum markers to prognosticate severity has been tested. The most promising has been quantification of C-reactive protein (CRP). CRP rises in relation to severity, is inexpensive, and readily available. Unfortunately, CRP does not become significantly elevated until 48 hours after inflammation, which limits its use in diagnosis of AP.

Complications

The local and systemic complications of AP are summarized in Box 41-11.

Local Complications

The local effects of pancreatitis include inflammation of the peritoneum around the pancreas and fluid accumulation in the peritoneal cavity. These changes can lead to pancreatic pseudocyst, pancreatic abscess, and acute GI hemorrhage.

Pancreatic pseudocysts occur in up to 15% of all cases of AP. A pseudocyst is a collection of inflammatory debris and pancreatic secretions, enclosed by lined epithelial tissue and free of solid debris, that must be present for 4 weeks or more. The pseudocyst can rupture and hemorrhage or become infected, causing bacterial translocation and sepsis. A pseudocyst is suspected in any patient who has persistent abdominal pain with nausea and vomiting, a prolonged fever, and elevated serum amylase. Surgery may also be indicated for pseudocysts; however, it is usually delayed because most pseudocysts resolve spontaneously. Surgical treatment of the pseudocyst can be done through internal or external drainage or needle aspiration. Acute surgical intervention may be required if the pseudocyst becomes infected or perforates.

A pancreatic abscess is a walled-off collection of purulent material in or around the pancreas that usually occurs 6 weeks or more after the onset of AP. Signs and symptoms of an abdominal abscess or infected pancreatic necrosis include increased white blood cell count, fever, abdominal pain, and vomiting. Pancreatic infection from an abscess, pseudocyst, or necrotic tissue may be present whenever a patient has a temperature greater than 39°C (102.2°F), tachycardia, or leukocytosis or shows other signs of clinical deterioration. Often, infections after the onset of pancreatitis, if untreated, are fatal. Broad-spectrum antibiotics are given to those patients with suspected infection.

GI complications of AP include GIB and bacterial translocation. GIB, the most common GI complication of AP, includes bleeding from peptic ulcers, hemorrhagic gastroduodenitis, stress ulcers, and Mallory-Weiss syndrome. Decreased peristalsis can lead to bacterial translocation.

BOX 41-11 Major Complications of Acute Pancreatitis

Local
- Pancreatic necrosis
- Pancreatic pseudocyst
- Pancreatic abscess

Pulmonary
- Atelectasis
- Acute respiratory distress syndrome
- Pleural effusions

Cardiovascular
- Hypotensive shock
- Septic shock
- Hemorrhagic shock

Renal

- Gastrointestinal bleed

Pulmonary Complications

Enzymes and inflammatory cytokines that reach the pulmonary circulation are thought to cause the many pulmonary complications associated with AP. Leukocytes that reach the pulmonary microcirculation migrate into the interstitium, which results in endothelial permeability and tissue edema. This causes lung congestion and alveolar collapse, and it can lead to adult respiratory distress syndrome. Arterial hypoxemia can occur in patients with mild disease without clinical or radiographic findings to support the pulmonary dysfunction. Arterial blood gas results and pulse oximetry should be followed closely for the first few days to detect this complication. Treatment of hypoxemia includes vigorous pulmonary care (eg, deep breathing and coughing) and frequent position changes. Oxygen therapy can also be used to improve overall oxygenation status. Careful fluid administration is also necessary to prevent fluid overload and pulmonary congestion. Patients with acute respiratory compromise may require mechanical ventilatory support. Abdominal distention and diminished diaphragmatic excursion may also contribute to atelectasis seen in AP.

Cardiovascular Complications

Hemodynamically significant fluid sequestration is characteristic of fulminant pancreatitis. Another major systemic effect of enzyme release into the circulatory system is peripheral vasodilation, which in turn can causes hypotension and shock.

Decreased perfusion to the pancreas itself can result in the release of myocardial depressant factor (MDF). MDF decreases heart contractility and affects cardiac output. Perfusion of all body organs can then become compromised. Early and aggressive fluid resuscitation is thought to prevent the release of MDF. Trypsin activation causes abnormalities in blood coagulation and clot lysis. This promotes the development of disseminated intravascular coagulation (DIC) with its associated bleeding (see Chapter 49).

Renal Complications

Acute renal failure is thought to be a consequence of hypovolemia and decreased renal perfusion. Death during the first 2 weeks of AP usually results from pulmonary or renal complications.

Metabolic Complications

Metabolic complications of AP include hypocalcemia and hyperlipidemia, which are thought to be related to areas of fat necrosis around the inflamed pancreas. Hyperglycemia may occur as a result of damage to the cells of the islets of Langerhans; metabolic acidosis can result from hypoperfusion and activation of anaerobic metabolism.

Management

Medical Management

Conventional care of the patient with AP focuses on fluid and electrolyte replacement to maintain or replenish vascular volume and electrolyte balance, pain management, resting the pancreas in an effort to prevent the release of pancreatic secretions, and maintaining the patient's nutritional status (Box 41-12). Close observation and clinical judgment are the basis for therapy and management.

Fluid and Electrolyte Replacement

Most patients with AP require the infusion of IV fluids to replace fluid lost through third spacing into the retroperitoneal space or peritoneal cavity, and intravascular volume depletion as a result of inflammatory mediators and local inflammation caused by pancreatic enzyme exudates. Patients with severe AP may need up to 5 to 10 L of fluid replacement within 24 hours during their initial days of hospitalization. The goal is to administer enough fluid to obtain a circulating volume sufficient to maintain organ and tissue perfusion and prevent end-stage shock. Hypovolemia and shock are major causes of death early in the disease process when aggressive fluid resuscitation fails to reverse the shock process.

Colloid and crystalloid solutions, such as albumin and lactated Ringer's solution, are used for volume replacement. Patients with acute hemorrhagic pancreatitis may also need PRBCs to restore blood volume. Fluid replacement is evaluated by monitoring intake and output and daily weights. Patients with more severe disease may require hemodynamic monitoring with measurement of pulmonary artery occlusion pressure or CVP. Patients with severe disease whose hypotension fails to respond to fluid therapy may need medications to support blood pressure. The drug of choice is dopamine at low doses to maintain renal perfusion while supporting blood pressure.

Urinary output is a sensitive measure of the adequacy of fluid replacement, and it should be maintained at greater than 30 mL/h or 0.6 mL/kg/h. Blood pressure and heart rate are also sensitive measures of volume status.

Patients with severe hypocalcemia are placed on seizure precautions with respiratory support equipment on hand. The nurse is responsible for monitoring calcium levels, administering replacement solutions, and evaluating the patient's response to any calcium supplementation. Calcium replacements should be infused through a central line because peripheral infiltration can cause tissue necrosis. The patient also needs to be monitored for calcium toxicity; symptoms include lethargy, nausea, shortening of the QT interval, and decreased excitability of nerves and muscles. Hypomagnesemia may also be present, so magnesium may need to be replaced as well. Serum magnesium levels usually need to be corrected before calcium levels can return to normal. Potassium may need to be replaced early in the treatment regimen because it is lost through vomiting and sequestration of potassium-rich pancreatic juices.

Hyperglycemia is related to impaired secretion of insulin, an increased release of glucagon, or increased stress response. In some cases, hyperglycemia can be associated with dehydration or other electrolyte imbalances. Sliding-scale regular insulin may be ordered; it needs to be administered very cautiously because glucagon levels are only transiently elevated in AP. Successful fluid replacement is marked by return of alert mental status, urine output, cardiac output, stable hemodynamic values, and a normal serum lactate level.

Pain Management

Pain control is a nursing priority for patients with AP, not only because of the extreme discomfort but also because pain increases pancreatic enzyme secretion. Pain is related to the degree of pancreatic inflammation, can be severe and constant, and can last for many days.

Adequate pain control with the use of IV narcotics, preferably delivered by patient-controlled analgesia, is essential in the treatment of AP. Meperidine (Demerol) has traditionally been the analgesic of choice because of the potential for sphincter of Oddi spasm that can accompany opioid use. However, meperidine is not always effective, and other analgesics (including opioids) should not be withheld. Fentanyl citrate (Sublimaze) and hydromorphone (Dilaudid) have been used successfully to control the pain of AP.

Analgesia should be routinely administered at least every 3 to 4 hours to prevent uncontrollable abdominal pain. Use of a pain rating scale is recommended for evaluating the patient's response to medication. Be alert to the patient's respiratory status because narcotics can induce respiratory depression. A nasogastric tube attached to low intermittent suction can help ease pain considerably, although the use of a nasogastric tube is controversial in patients without vomiting. Patient positioning can also relieve some of the discomfort.

Resting the Pancreas

In some patients with AP, nasogastric suction is used to decompress the stomach and decrease stimulation of secretin. Secretin, which stimulates production of pancreatic secretions, is released in response to acid in the duodenum. Nausea, vomiting, and abdominal pain may decrease when a nasogastric tube is placed and connected to suction early in treatment. A nasogastric tube is also necessary in patients with severe gastric distention or a paralytic

BOX 41-12 COLLABORATIVE CARE GUIDE for the Patient With Pancreatitis

Outcomes	Interventions
Oxygenation/Ventilation	
Arterial blood gases (ABGs) are maintained within normal limits.	• Assist patient to turn, deep breathe, cough, and use incentive spirometer every 4 h and PRN. Provide chest physiotherapy. • Assess for hypoventilation, rapid and shallow breathing, and respiratory distress. • Monitor pulse oximetry, end-tidal CO_2, and ABGs. • Administer analgesics if splinting is reducing effective ventilation. • Provide supplemental oxygen as needed.
The patient's lungs are clear. The patient has no evidence of atelectasis, pneumonia, or acute respiratory distress syndrome.	• Auscultate breath sounds every 2–4 h and PRN. • Suction only when rhonchi are present or secretions are visible in endotracheal tube. • Hyperoxygenate and hyperventilate before and after each suction pass.
Circulation/Perfusion	
Blood pressure, heart rate, and hemodynamic parameters are within normal limits.	• Monitor vital signs every 1–2 h. • Monitor pulmonary artery pressures and right atrial pressure every 1 h and cardiac output, systemic vascular resistance, and peripheral vascular resistance every 6–12 h if pulmonary artery catheter is in place. • Maintain patent IV access. • Administer intravascular volume as indicated by real or relative hypovolemia, and evaluate response.
Serum lactate will be within normal limits.	• Monitor lactate daily until it is within normal limits. • Administer RBCs, positive inotropic agents, colloid infusion as ordered to increase oxygen delivery.
Patient will not experience bleeding related to acute gastrointestinal hemorrhage, coagulopathies, or DIC.	• Monitor PT, PTT, complete blood count daily or PRN. • Assess for signs of bleeding. Observe for Cullen's or Grey Turner's signs. • Administer blood products as indicated.
Fluids/Electrolytes	
Patient is euvolemic.	• Maintain patent IV access. • Monitor daily weights. • Monitor intake and output. • Measure abdominal girth every 8 h at the same location on the abdomen.
No evidence of electrolyte imbalance or renal dysfunction.	• Monitor electrolytes daily and PRN. • Assess for signs of lethargy, tremors, tetany, and dysrhythmias. • Replace electrolytes as ordered. • Monitor BUN, creatinine, serum osmolality, and urine electrolytes daily.
Mobility/Safety	
No evidence of complications related to bed rest and immobility.	• Initiate deep venous thrombosis prophylaxis. • Reposition frequently. • Ambulate to chair when acute phase has passed and hemodynamic stability and hemostasis is achieved.
Patient achieves or maintains ability to conduct activities of daily living and mobilize self.	• Consult physical therapist. • Conduct range-of-motion and strengthening exercises.
No evidence of infection, WBC within normal limits.	• Monitor for systemic inflammatory response syndrome (SIRS). Criteria: increased WBC count, increased temperature, tachypnea, tachycardia. • Use strict aseptic technique during procedures. • Maintain invasive catheter tube sterility. • Change invasive catheters, culture blood, line tips, fluids, etc., according to hospital protocol.
Skin Integrity	
Skin will remain intact.	• Assess skin every 8 h and each time patient is repositioned. • Turn patient every 2 h. • Consider pressure relief/reduction mattress.

(*continued on page 938*)

BOX 41–12 COLLABORATIVE CARE GUIDE for the Patient With Pancreatitis (continued)

Outcomes	Interventions
Nutrition	
Caloric and nutrient intake meets metabolic requirements per calculation (eg, basal energy expenditure).	• Provide parenteral feeding. • Maintain NPO status. • Consult dietitian or nutritional support service. • Adhere to fat or lipid restriction. • Provide small, frequent feedings.
Evidence of metabolic dysfunction is minimal.	• Monitor albumin, prealbumin, transferrin, cholesterol, triglycerides, and glucose levels.
Comfort/Pain Control	
Patient will have minimal pain, <5 on pain scale.	• Assess pain and discomfort using objective pain scale every 4 h PRN and after administration of pain medication. • Administer analgesics and monitor patient response. • Use nonpharmacological pain management techniques (eg, music, distraction, touch) as adjunct to analgesics.
Patient will have minimal nausea.	• Maintain nasogastric tube patency. • Monitor nausea and vomiting. • Administer antiemetic as ordered.
Psychosocial	
Patient demonstrates decreased anxiety.	• Listen to patient's worries and fears. • Assess patient's response to anxiety. • Support effective coping behaviors. • Teach alternative behaviors for those that are not helpful. • Help patient increase sense of control by providing information and explanation. • Allow choices when possible. • Provide as much predictability in routine as possible.
Teaching/Discharge Planning	
Patient/significant others understand procedures and tests needed for treatment. Significant others understand the severity of the illness, ask appropriate questions, anticipate potential complications.	• Prepare patient/significant others for procedures such as paracentesis, pulmonary artery catheter insertion, or laboratory studies. • Explain the widespread effects of pancreatitis and the potential for complications such as sepsis or acute respiratory distress syndrome. • Encourage significant others to ask questions related to pathophysiology, monitoring, treatments, etc. • Instruct patient and family in discharge regimen that may include wound care, medications, and dietary limitations.

ileus. Patients with AP should be placed on NPO status until the abdominal pain subsides and serum amylase levels have returned to normal. Starting oral intake sooner can cause the abdominal pain to return and can induce further inflammation of the pancreas by stimulating the autodigestive disease process.

Nutritional Support

For those patients with AP who are on prolonged NPO status with nasogastric suction because of paralytic ileus, persistent abdominal pain, or pancreatic complications, nutritional support is recommended. TPN has been traditionally used because it was believed that stimulation of the pancreas by solid or liquid nutrients caused pancreatic stimulation and adversely affected the course of AP. Increasing evidence suggests that the use of enteral nutrition delivered past the ligament of Treitz to the distal duodenum or jejunum is safe. In addition, enteral nutrition may reduce infectious complications by maintaining intestinal barrier function and avoiding some of the complications of parental nutrition. Lipid administration is avoided to prevent increasing triglyceride levels, which can exacerbate the inflammatory process. In the patient with mild AP, oral fluids can usually be restarted within 3 to 7 days, with solid food introduced slowly and as tolerated. Supplementation with TPN is appropriate if oral and enteral nutrition cannot provide enough calories to prevent catabolism.

Prolonged NPO status is often difficult for patients. Frequent mouth care and proper positioning of the nasogastric tube are important to maintain skin integrity and maximize patient comfort. Bed rest is prescribed to decrease the patient's basal metabolic rate; this, in turn, decreases the stimulation of pancreatic secretions.

Surgical Management

Surgery for AP is indicated if massive pancreatic necrosis is present in a patient with a worsening clinical status. A pancreatic resection for acute necrotizing pancreatitis can be performed to prevent systemic complications of the disease process. In this procedure, dead or infected pancreatic tissue is surgically removed. In some cases, the entire pancreas is removed. Broad-spectrum antibiotics are given to patients who require surgical débridement of necrotic tissue.

▲ Hepatitis

Etiology

Diffuse inflammation of the liver, otherwise known as hepatitis, is commonly a consequence of a viral infection, but can be secondary to bacterial, fungal, or parasitic infection; a result of toxic exposure; a side effect of a prescribed medication; or a consequence of an immunologic disorder (Box 41-13). Acute hepatitis lasts less than 6 months; it either resolves completely with return of normal liver function or progresses to chronic hepatitis, then cirrhosis, and possibly liver failure. Chronic hepatitis is an inflammatory process that lasts longer than 6 months and may also progress to cirrhosis and possibly liver failure.

Noninfectious Hepatitis

Noninfectious hepatitis can be caused by excessive alcohol consumption, autoimmune disorders, metabolic or vascular disorders (including right-sided heart failure), acute biliary obstruction, and many individual drugs and drug classes (depending on the amount ingested and length of exposure). Examples include but are not limited to acetaminophen (both intentional and unintentional overdosing), isoniazid, HMG-CoA reductase inhibitors, anticonvulsants, antimicrobials, alpha-methyldopa, amiodarone, and estrogens.[29] Although only a minority of chronic alcohol abusers develop the syndrome of alcoholic hepatitis, severe cases carry a significant mortality rate, particularly in the elderly.[30]

Other liver toxins include poisonous mushrooms (*Amanita phalloides*), ecstasy (methylenedioxymethamphetamine), and some herbal medicines (ginseng, comfrey tea, pennyroyal oil, and *Teucrium polium*).[29] Autoimmune hepatitis, a condition in which the patient's own immune system attacks the liver, causes inflammation and hepatocyte injury or death. Autoimmune hepatitis can be mistaken for an acute viral hepatitis if the patient presents with severe symptoms.

Infectious Hepatitis

Viral hepatitis is a highly contagious inflammatory condition. Just like noninfectious hepatitis, infectious hepatitis can be acute, or it can be chronic if infection lasts longer than 6 months. Viral infections of the liver parenchyma have been classified according to their specific infecting agent and corresponding serology markers. Hepatitis A, B, C, D, and E are summarized in Table 41-3. Other viral causes of hepatitis include herpes simplex virus, Epstein-Barr virus, cytomegalovirus, adenovirus, coxsackievirus B, and varicella-zoster virus. Typically, patients with viral hepatitis present with nonspecific, flu-like symptoms, such as malaise, nausea, vomiting, diarrhea, loss of appetite, midepigastric abdominal discomfort, and low-grade fever. In patients with hepatitis B virus (HBV), symptoms may be more severe.

BOX 41-13 Selected Causes of Hepatic Inflammation

Infectious Diseases
- Viral hepatitis (A, B, C, D, E)
- Epstein-Barr virus
- Cytomegalovirus
- Herpes simplex virus
- Coxsackievirus B
- Toxoplasmosis
- Adenovirus
- Varicella-zoster virus

Drugs and Toxins
- Alcohol
- Acetaminophen
- Isoniazid
- Salicylates
- Anticonvulsants
- Antimicrobials
- HMG-CoA reductase inhibitors
- α-Methyldopa
- Amiodarone
- Estrogens
- *Amanita phalloides* mushrooms
- Ecstasy (methylenedioxymethamphetamine)
- Herbal medicines (ginseng, comfrey tea, pennyroyal oil, *Teucrium polium*)

Autoimmune Diseases
- Autoimmune hepatitis
- Primary biliary cirrhosis
- Primary sclerosing cholangitis

Congenital Diseases
- Hemochromatosis (iron overload)
- Wilson's disease (copper deposition)
- α_1-Antitrypsin deficiency

Miscellaneous Causes
- Nonalcoholic fatty liver
- Fatty liver of pregnancy
- Severe right-sided congestive heart failure
- Budd-Chiari syndrome (vascular obstruction)

Hepatitis A

In the United States, the Centers for Disease Control and Prevention (CDC) have reported a significant decline in the incidence of acute hepatitis A virus (HAV); the incidence of acute liver failure from HAV is considered low at an estimated 2,000 to 3,000 total cases per year, with a higher mortality rate in patients either older than 50 or younger than 5 years of age.[31,32] However, sporadic outbreaks continue to be reported due to consumption of contaminated

Table 41-3 Summary of Types of Hepatitis

	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D	Hepatitis E
Incubation (days)	15–45	30–180	15–160	30–180	14–60
Onset	Acute	Insidious	Insidious	Acute or insidious	Acute
Transmission	Fecal/oral Contaminated food, water	Blood Sexual Perinatal Percutaneous	Blood May be sexual	Blood Sexual (comorbid infection with HBV)	Fecal/oral Contaminated food, water
Severity	Mild	Often severe	Moderate	May be very severe	Virulent, especially in pregnant women
Prognosis	Generally good	Worse with age, debility	Moderate	Fair, worse with chronic disease	Good, unless pregnant
Diagnosis					
Acute	Anti-HAV IgM	HBsAG Anti-HBc (IgM) HBeAg	HCV ELISA Anti-HCV RIBA HCV RNA	HDV Ag	Clinical
Chronic	—	Anti-HBc (IgG)	Anti-HCV	Anti-HDV	—
Prophylaxis (adults)	Immune globulin	Hepatitis B vaccine Immune globulin	?Immune globulin	None available	None available
Carrier	No	Yes	Yes	Yes	No

food or direct person-to-person contact.[32] HAV is caused by an RNA enterovirus transmitted through the oral–fecal route, predominantly by ingestion of contaminated water or raw or partially cooked shellfish. In most patients, symptoms of HAV infection are either relatively mild or nonexistent, although older patients are at greater risk for more severe symptoms. The incubation period ranges from 15 to 45 days after exposure. HAV infection causes only acute liver disease; recovery is usually complete and does not lead to chronic hepatitis or cirrhosis. Blood tests usually reveal elevations in the aminotransferases (ALT and AST), bilirubin concentrations, and alkaline phosphatase level. In severe cases, the PT may be prolonged. Diagnosis can be made with serology antibody testing. Anti-HAV immunoglobulin G (IgG) antibodies provide immunity and can be found in people who have had a previous HAV infection, but these are not helpful in diagnosing an acute infection. Instead, a positive anti-HAV IgM serology marker indicates HAV infection within the preceding 6 months. HAV infection does not induce a carrier state.

Early in the course of the disease, there is an incubation period during which the patient is asymptomatic but highly contagious, particularly with high HAV levels in the stool. After symptoms are apparent, the hepatitis infection can be misdiagnosed because many of the symptoms are similar to those of the flu. Some patients seek medical attention because they become jaundiced. The two most common physical examination findings are jaundice and hepatomegaly. Acute symptoms can progress or disappear once jaundice is present. By the time symptoms occur, the virus is no longer shed in the stool, and the patient is usually not infectious. Recovery is signaled by liver function test (LFT) results returning to normal.

After exposure to HAV, passive immunization can be achieved through the use of immune serum globulin. Most preparations of immune serum globulin contain adequate quantities of anti-HAV and should be given within 2 weeks of exposure. The immune serum globulin may not entirely abort an infection, but it significantly ameliorates the symptoms. It is usually given to intimate contacts of patients with HAV. There are also two U.S. Food and Drug Administration (FDA)–approved vaccines: Havrix and Vaqta. Vaccination is encouraged for all high-risk groups and all children aged 12 to 23 months and older.[33]

Hepatitis B

HBV is a DNA virus of the Hepadnaviridae family that replicates by reverse transcription. Infection causes both acute and chronic hepatitis, and the incubation period is 30 to 180 days, with the average at 12 weeks. HBV is spread by contact with blood or blood products. The antigen has been identified in body secretions, such as semen, mucus, and saliva; sexual exposure to a person with HBV is the most common mode of transmission.[32] It appears that a break in the skin or the mucous membrane is necessary for the transmission to occur. HBV is also transmitted parenterally through blood transfusions, occupational needlestick injuries, and the use of contaminated needles (eg, illicit drug use). Maternal perinatal transmission can also occur.

The diagnostic criteria of HBV include serologic markers, biochemical markers of liver disease (including elevated liver enzyme levels), and histologic changes in the liver. Incorrect interpretation of HBV serologic markers is common. Familiarity with the serology testing is important for the nurse who is assisting in the diagnostic evaluation of a suspected case of viral hepatitis to prevent inappropriate laboratory testing and patient discomfort. Hepatitis B surface antigen (HBsAg) is a protein that coats the outer surface of the HBV and is produced in

great excess during viral replication. HBsAg is the single most important test to detect infection with HBV. A positive result indicates that a patient is infected with HBV. If the presence of HBsAg is associated with an acute illness and a marked rise in the aminotransferases as well as the presence of hepatitis B core IgM antibody (IgM anti-HBc), the patient has acute HBV. If HBsAg disappears from the blood within 6 months, there is resolution of infection, and the patient does not advance to chronic disease. Patients with acute HBV infection who overcome their infection and eradicate the virus develop antibodies against hepatitis B surface antigen (anti-HBsAg). In some laboratories, these results may be reported as hepatitis B surface antibody (HBsAb) instead of anti-HBs. Regardless of the nomenclature, these people are protected against future HBV infection. A person who receives the HBV vaccine also develops HBsAb.

Clinical signs and symptoms of HBV infection during the acute phase are the same as those of HAV infection. Arthralgia, high fever, and rash are hallmark signs of an acute HBV infection. Acute HBV infection resolves in most adults; however, it can become chronic, particularly in those individuals with immune deficiencies. Those individuals who develop chronic HBV infection will continue to have high levels of HBsAg and can be infectious to others; individuals with a high viral load will also have an increased risk of chronic liver disease (eg, cirrhosis) and hepatocellular carcinoma.[32] Cirrhosis should be suspected if the patient develops hypersplenism, hypoalbuminemia (in the absence of nephropathy), thrombocytopenia, and prolongation of serum PT.[34] Although less than 1% of cases of those infected with HBV will progress to fulminant liver failure (typically occurs within 4 weeks of the onset of symptoms), it is associated with encephalopathy, multiorgan failure, and a mortality rate of 75% if not treated with liver transplantation.[35]

Antihepatitis B core (anti-HBc), also called hepatitis B core antibody (HBcAb), also appears early in the course of infection and may persist for many years, but it is helpful in evaluating an acute versus chronic infection because anti-HBc can be further divided into two subtypes. Anti-HBc (IgM) is the initial response to infection and lasts for 6 to 18 months after recovery from infection. Therefore, high titers of anti-HBc (IgM) indicate acute infection, and low titers indicate chronic liver infection. Anti-HBc (IgG) is the second subtype and is positive in patients who are either chronically infected or previously infected, persisting in the bloodstream for a lifetime. Once an infection by HBV is established with HBsAg and anti-HBc, further serological testing can be ordered. For instance, the presence of the hepatitis Be antigen (HBeAg) indicates active viral replication and helps in diagnosing disease severity, prognosis, and treatment options. Those patients who have a positive HBeAg are considered highly infectious.

HBV exposure is associated with high risk. After accidental exposure, such as an inadvertent needlestick, passive immunoprophylaxis can be achieved by using high anti-HBs titer hepatitis B immune globulin (HBIG). This is a pooled serum containing high titers of the anti-HBIG. It is recommended that HBIG be given within 48 hours of postexposure as inoculations to high-risk patients, to close contacts of patients with active HBV (within 2 weeks after sexual or personal contact with infected body fluids), and to those traveling to endemic areas who do not have time to go through the normal three-dose vaccination series.[35] Many new HBV nucleoside analog treatments are under review. The following medications are currently approved by the FDA for treating chronic HBV infection and include standard interferon alpha (INF-α 2b), pegylated interferon alpha (INF-α 2a), and four oral antiviral agents (ie, lamivudine, adefovir, entecavir, and telbivudine).[36]

Fortunately, vaccines exist for active immunization against HBV (ie, Recombivax-HB or Engerix-B). Vaccination, administered prophylactically over a 6-month period, provides active immunization against HBV. It is highly recommended for health care personnel at risk for infection with HBV. It is also recommended for people who have had intimate contacts with people already infected with HBV. Precautions to protect against exposure to blood-borne pathogens must be followed. In the United States, children are universally vaccinated against HBV. Other combination vaccine preparations include Twinrix (HBV and HAV), Comvax (HBV and *Haemophilus influenza* type b), and Pediarix (HBV, diphtheria, tetanus, pertussis, and polio viruses).[35]

Hepatitis C

Hepatitis C virus (HCV) has surpassed alcoholism to become the leading cause of liver cirrhosis and end-stage liver disease requiring liver transplantation in the United States; it accounts for 40% of cases of end-stage cirrhosis and 60% of hepatocellular carcinoma.[32,37] As diagnostic tests improved, HCV, formerly called non-A, non-B hepatitis, was identified in 1989. It is a single-stranded RNA virus related to the Flaviviridae family. There are 11 HCV genotypes (genotypes 1 to 11), many subtypes (a, b, c, and so forth), and about 100 different strains (1, 2, 3, and so forth).[37] These variations in genotype led to variations in clinical course, problems with vaccine development, treatment response, and, in many cases, duration of treatment. Genotypes 1 and 3 are widely distributed globally, with genotypes 1a and 1b accounting for 60% of all HCV infections.[37] Genotype 1a is predominately located in North America and Northern Europe and is generally associated with a poorer response to treatment compared to genotypes 2 and 3.[37]

HCV, a blood-borne virus, can cause both acute and chronic hepatitis. Of those people who develop acute HCV, chronicity can occur in as many 85%, and 5% to 20% reportedly develop cirrhosis over approximately 20 to 25 years.[32] People with HCV-related cirrhosis are at risk for developing end-stage liver disease (a risk of approximately 30% over 10 years) as well as hepatocellular carcinoma (a risk of approximately 1% to 2% per year).[32]

Before 1992, when testing for HCV was mandated, many people acquired HCV through blood transfusions. The main risk factors in the United States include shared contaminated needles from illicit drug use and occupational needlestick exposure. There are indications that the virus might also be transmitted through perinatal, sexual, and household contacts (eg, sharing of razors and toothbrushes), although these modes of transmission are not as common. It has also

been suggested that acupuncture, body piercing, tattooing, and even commercial barbering carry a risk for HCV transmission.[38] Incubation of HCV is 15 to 160 days, with an average of 7 weeks. Within 6 months of infection, patients may produce anti–hepatitis C antibodies, but these do not confer immunity.

Although most patients are asymptomatic, the most commonly reported symptoms of HCV infection include fatigue, anorexia, weight loss, and abdominal pain. Diagnostic evaluation for HCV infection includes an HCV enzyme-linked immunosorbent assay (ELISA; ordered when the aminotransferase levels are elevated and for screening patients on hemodialysis), an anti-HCV recombinant strip immunoblot assay (RIBA; ordered to confirm a positive HCV test or if a patient presents with symptoms of hepatitis), or an HCV RNA test (ordered when HCV RIBA findings are indeterminate, but there remains a high index of suspicion for HCV). HCV RNA, which tests for the presence of the virus RNA in the blood (rather than antibodies against the virus), is the gold standard for detecting HCV. HCV RNA levels are used to gauge response to treatment, but they are not serially checked because viral load has no correlation to the degree or rate of liver injury progression.[39]

The goal of treatment is virus eradication (ie, sustained virologic response, or SVR) and prevention or delay of cirrhosis, end-stage liver disease, and hepatocellular carcinoma. Current combination therapy consists of pegylated INF-α 2a or 2b plus ribavirin. Infection is considered eradicated when there is a sustained viral response (SVR), which is defined as the absence of HCV RNA (aviremia) at the end of treatment and then 6 months after treatment.[40] Genotypes 1 and 4 are considered the most difficult strains to treat; they require a longer duration of treatment (48 weeks) and have a lower posttreatment SVR rate (40%) compared with genotypes 2 and 3. Genotypes 2 and 3 require a shorter duration of treatment (24 weeks) and have a higher SVR rate of 79% to 82%.[40] Unfortunately, not all patients with an early virologic response to treatment become HCV RNA undetectable, and continuing treatment in these patients cannot lead to an SVR. These differences in treatment duration and outcomes highlight the importance of genotyping to determine who may benefit from combination therapy and optimal treatment duration. Currently, no vaccine is available to prevent HCV, and immune globulin does not afford protection to people who have been exposed.

Hepatitis D

Hepatitis D (delta virus or HDV) is an incomplete RNA virus that depends on HBV envelope proteins to reproduce; it cannot exist or be spread in the absence of HBV. HDV infection may occur as a superinfection in the patient who has chronic HBV, or it may occur simultaneously with an acute HBV infection. In the United States, HDV and HBV coinfection is almost exclusively observed in IV drug users.[40] HDV can progress to fulminant hepatitis and chronic disease. In the United States, HDV infection occurs primarily among people receiving multiple transfusions and those abusing illicit IV drugs. Early in the disease, the hepatitis D antigen (HDV Ag) is present in the blood. Later in the disease, antibodies to the HDV are present (anti-HDV).

Because this disease coexists with HBV, patients with HDV have symptoms similar to those of acute or chronic HBV, but symptoms may be more pronounced. Quantitative real-time polymerase chain reaction (PCR) assays for HDV RNA are monitored at 3 and 6 months. Current treatment includes standard INF, and recent research suggests that pegylated INF-α 2b may improve SVR. The addition of ribavirin has not been shown to provide any additional benefit.[41] Vaccination against HBV also protects against HDV infection.[40]

Hepatitis E

Hepatitis E virus (HEV) is a single-stranded RNA virus similar to HAV. Although rare and sporadic in industrialized countries, it is the most common epidemic, water-borne form of hepatitis in developing countries.[42] It is transmitted by the oral–fecal route from contaminated water and food. In some cases, the source of infection has been traced to contact with infected animals or animal products, notably swine.[43] The incubation period is 14 to 60 days, and it has an overall low mortality rate among the general population. Symptoms typically present with a prodrome of malaise and fever, followed by anorexia, nausea, vomiting, abdominal pain, hepatomegaly, and jaundice. Serum aminotransferase levels will be significantly elevated, but the infection is typically self-limited. For reasons that are still unclear, pregnant women have a more severe illness, with a mortality rate of 20% for women in their third trimester.[42,44] Because the incidence of HEV infection is rare in the United States, the nurse should pay careful attention if a patient presents with symptoms of hepatitis who has recently traveled or lived in endemic areas. A recently developed vaccine against HEV has been developed and is still under investigation.[45] Unfortunately, previous HEV infection is not necessarily protective.

Hepatitis F and Hepatitis G

It was formerly believed that a virus isolated from rare blood samples was a newly identified virus, labeled hepatitis F. However, further investigation has found this virus to be a variant of HCV, and additional research has failed to demonstrate the existence of a new virus. Little is known about the most recently identified virus, hepatitis G (HGV), which has been identified with PCR testing. It is a single-stranded enveloped RNA virus similar to HCV. As with HBV and HCV, HGV is transmitted by blood and body fluids; infection is diagnosed by seroconversion of HGV RNA in blood or liver tissue. No vaccine has been developed against HGV, and current treatment is supportive and focused on symptom management. Infection is considered benign and is rarely associated with elevated LFTs.

Pathophysiology

To improve patient outcomes, nurses must have a solid knowledge base regarding the underlying pathophysiology, assessment, and management of acute and chronic liver disease. Hepatocytes, the functional cells of the liver, perform many essential functions, including the metabolism of nutrients (eg, glucose, proteins, lipids, vitamins) and the detoxification of medications, alcohol, ammonia, toxins, and hormones. In addition, hepatocytes are responsible for synthesis of clotting factors, conjugation and secretion of bilirubin, and synthesis of bile salts. Abnormal liver function is usually not apparent

unless a significant acute insult occurs or chronic liver disease is fairly advanced. Liver failure occurs when there is a loss of 60% of the hepatocytes, and symptoms are usually detectable after 75% or more of the hepatocytes are injured or killed. Liver function testing and evaluation begin with a complete history and physical examination. Interpretation of liver serum enzymes, synthetic function, and cholestasis (or excretory function) tests are important for the nurse to understand and are discussed later in this chapter.

Acute liver disease, typically caused by viral or chemical insults, occurs suddenly and resolves, becomes chronic, or results in a patient's death. Chronic liver disease leading to cirrhosis, typically more insidious in nature, is the 12th leading cause of death in the United States.[46] Disease processes in the liver can affect the hepatocytes, the blood vessels, and the Kupffer cells, which are responsible for uptake and subsequent degradation of foreign and potentially harmful substances in the body. If the injury is mild and reversible, hepatocytes may regenerate, and liver function may return to normal. However, if the injury is more severe or sustained, regeneration may be incomplete, or the healing process may cause fibrosis. Fibrotic changes alter the liver architecture and can lead to cirrhosis and impediment of blood flow through the liver. An acute insult to the liver can progress to fulminant liver failure, which is defined as hepatic encephalopathy (HE) occurring within 8 weeks of jaundice. HE is a state of abnormal mental functioning as a result of the inability of the liver to remove ammonia and other toxins from the blood. If liver function does not return and liver transplantation is unavailable, fulminant liver failure can progress to cerebral edema, coma, and death from brain herniation.

Assessment

History

Questions regarding the patient's alcohol consumption and illicit drug use, use of prescription and over-the-counter medications, use of herbal supplements, surgical and transfusion history, occupational or travel exposure history, and sexual history may be helpful in determining the diagnosis, nursing plan of care, and teaching needs of the patient. In chronic hepatitis, most patients are asymptomatic except for mildly elevated liver enzymes. Constitutional symptoms vary widely but typically include malaise, fatigue, low-grade fever, nausea, vomiting, and sometimes diarrhea.

Physical Examination

When cirrhosis and portal hypertension resulting from chronic hepatitis are present, jaundice (yellow staining of the skin and mucous membranes as a result of bilirubin pigments) may be noted. Hepatomegaly (enlargement of the liver) may result in right upper quadrant tenderness and is a result of portal hypertension or congestion in the liver from altered blood flow resulting from cirrhosis. The liver edge is often firm and nodular. In advanced cirrhosis, although the left lobe may be enlarged, overall liver size is often decreased and difficult to palpate. Dullness of percussion over the liver span can provide serial observations of resolution of hepatitis or progression of cirrhosis. Splenomegaly as a result of portal hypertension and sequestration of fluid in the spleen may result in left upper quadrant tenderness. Muscle wasting and abdominal ascites may develop as a result of malnutrition, portal hypertension, and hypoalbuminemia from the liver's impaired ability to synthesize proteins. Peripheral edema may result from hypoalbuminemia, sodium retention, and ascites obstructing blood return from the lower extremities. Vitamin deficiencies may result in glossitis of the tongue and cheilosis of the lips. Bruising and bleeding tendencies may develop as a result of impaired production of clotting factors and sequestration of platelets in the spleen. Other manifestations include telangiectasis or spider nevi (usually of the upper half of the body). These lesions consist of a pulsating arteriole from which smaller vessels radiate. Palmar erythema, or redness of the palms, is a result of increased blood flow from hyperdynamic cardiac dysfunction associated with hepatitis (with ascites). In men, there may be a loss of body hair, testicular atrophy, and gynecomastia. These changes are thought to be related to altered hormone metabolism and estrogen excess in the liver.

Physical examination may also reveal abdominal wall vein dilation around the umbilicus, known as caput medusae. This is the result of portal hypertension and congestion and collateral vessel development (Fig. 41-4). This congestion may be auscultated as an arterial bruit (systolic phase) or a venous hum (both systolic and diastolic phases) over the liver and epigastrium. Encephalopathy, ascites, and peripheral edema, reflective of advanced disease, may be present. Other observable assessment findings include frothy, dark amber urine and clay-colored stools as a result of alterations in bilirubin excretion. Common signs and symptoms of noninfectious and

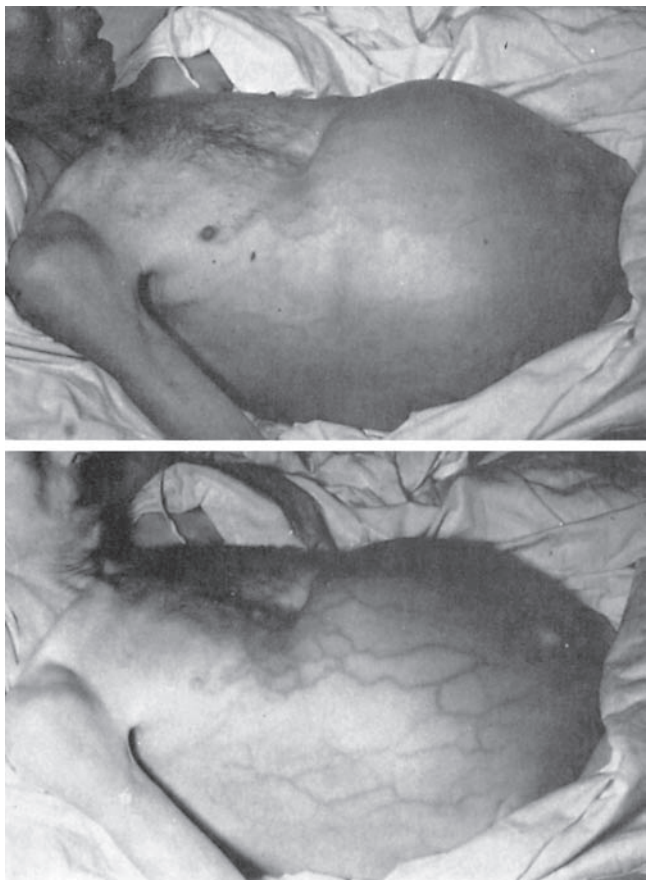

FIGURE 41-4 ▲ Collateral abdominal veins on the anterior abdominal wall in a patient with alcoholic liver disease as recorded by black and white photography (**top**) and infrared photography (**bottom**). (From Schiff L: Diseases of the Liver. Philadelphia, PA: JB Lippincott, 1982.)

infectious hepatitis are summarized in Table 41-4. Patients with signs and symptoms of hepatic decompensation (eg, portal hypertension, ascites, encephalopathy, and coagulopathy) should be hospitalized, evaluated, and treated more expeditiously than those patients who demonstrate adequate hepatic compensation and stability.

Table 41-4 Common Signs and Symptoms of Hepatitis

Signs and Symptoms	Cause
Constitutional	
Fever, chills	Immune response to viral infection
Generalized weakness, malnutrition	Inability to metabolize nutrients
Gastrointestinal	
Right upper quadrant pain	Hepatomegaly
Left upper quadrant pain	Splenomegaly
Loss of appetite	Ascites, fatigue
Abdominal distention	Ascites
Nausea, vomiting/hematemesis	Portal hypertension
Clay-colored feces	Inability to excrete conjugated bilirubin
Diarrhea	Impaired fat metabolism
Melena, hematochezia	Portal hypertension
Pulmonary	
Shortness of breath Increased work of breathing Decreased oxygen saturation Decreased partial pressure of oxygen	Ascites, decreased lung and diaphragmatic expansion
Cardiac	
Increased heart rate	Hypotension, sequestration of fluid in the liver and spleen, third spacing in the peripheral extremities from decreased protein metabolism/low albumin levels
Decreased blood pressure	
Dysrhythmias	Electrolyte disturbances
Peripheral edema	Impaired protein metabolism
Neurological	
Headache Depression/irritability Asterixis	Impaired metabolism of ammonia and other circulating toxins
Genitourinary	
Decreased urinary output	Decreased circulating volume and impaired glomerular filtration rate
Frothy, dark amber urine	Excretion of conjugated bilirubin (water-soluble bile)
Integumentary	
Jaundice	Impaired excretion of bile
Pruritus, dry skin	Impaired excretion of bile
Bruising, ecchymosis	Impaired ability to synthesize clotting factors
Spider nevi, caput medusae	Portal hypertension
Palmar erythema	Portal hypertension
Hair loss	Impaired metabolism of circulating hormones
Endocrine	
Hypoglycemia	Impaired glucose metabolism and storage
Increased weight	Ascites, third spacing of fluid
Gynecomastia, testicular atrophy (in men)	Inability to metabolize hormones (eg, estrogens)
Immune	
Infection, spontaneous bacterial peritonitis	Impaired Kupffer cell function, splenomegaly

Laboratory Studies

TESTS FOR EVALUATING HEPATOCELLULAR INJURY. The clinical significance of any liver chemistry must be evaluated in the context of the patient's history and clinical situation. Liver function test is a commonly used but inaccurate term. Some laboratory tests do measure liver synthetic function, and these include albumin, PT, and total bilirubin. However, other laboratory tests are markers of hepatocellular injury and include AST, previously known as serum glutamic oxaloacetic transaminase, and ALT, previously known as serum glutamic pyruvic transaminase. See Table 39-6 on page 883.

ALT and AST are enzymes present inside the hepatocytes. When hepatocytes are injured or die, they release AST and ALT into the serum. Therefore, the presence of these enzymes in the blood signals the presence of hepatocyte injury. However, AST and ALT lack sensitivity (for a particular diagnosis) in evaluating chronic liver injury for two reasons. First, AST and ALT are also found (to a lesser degree) in the skeletal muscle, and as such, elevations may be related to a skeletal muscle injury or overexertion. This is particularly true for AST because ALT is almost exclusively present in hepatocytes and is the most specific test for hepatocellular damage. Second, it is thought that dying hepatocytes synthesize less AST and ALT enzymes than healthy ones. Therefore, despite inflammation detected on a liver biopsy, patients with chronic hepatitis may have relatively normal levels of AST and ALT.

Despite these difficulties in laboratory interpretation, elevations of AST and ALT are often helpful in evaluating acute liver injury, response to treatment, and monitoring those at risk for liver disease because of medical interventions. Elevations of these enzymes suggest hepatocyte death, and the degree of elevation roughly approximates the amount of liver cell death. AST and ALT elevate at relatively equal levels, but an exception occurs in alcoholic hepatitis, in which AST levels tend to be higher than ALT levels. Although the AST/ALT ratio is not diagnostic, a ratio greater than 2:1 suggests alcohol-induced injury.[34] This is thought to be due to the depletion of vitamin B_6 (pyridoxine) in patients with chronic alcoholism; ALT synthesis is more strongly inhibited by pyridoxine deficiency than AST synthesis. In chronic hepatitis, AST and ALT levels are usually less than 10 times normal. However, in acute viral, toxin-induced, or ischemic hepatitis, these elevations may be greater than 1,000 units/L. In addition, alcoholic hepatitis causes smaller elevations (<300 units/L). Unfortunately, AST and ALT levels have low prognostic value.[34]

TESTS FOR EVALUATING LIVER SYNTHETIC FUNCTION. As mentioned earlier, albumin, total protein, and PT are measures of actual liver synthetic function. Because proteins are synthesized by the liver, albumin and other proteins are an index of liver function. Albumin is the predominant protein in the serum; patients with advanced liver disease and cirrhosis tend to have low serum concentrations (hypoalbuminemia). Because albumin is responsible for colloid osmotic pressure, low concentrations lead to leakage of intravascular fluids into interstitial spaces and peripheral edema. Because albumin levels are also influenced by poor nutrition and renal disease, care must be taken when interpreting laboratory test results.

The PT is a measure of the liver's capacity to synthesize clotting factors. The liver synthesizes blood clotting factors II, V, VII, IX, and X. An elevation in PT values is not seen until more than 80% of hepatocyte function is lost. However, because of the short half-life of factor VII, a PT is helpful in evaluating acute liver failure. Evaluation for vitamin K deficiency is performed because malabsorption or poor nutritional intake must be excluded in a patient who is hypoprothrombinemic. Failure of improvement in a PT level after vitamin K supplementation (5 to 10 mg orally for 3 days) may indicate intrinsic liver disease.

TESTS FOR EVALUATING CHOLESTASIS (EXCRETORY FUNCTION). Tests for cholestasis (lack of bile flow) help determine what is happening in the bile ducts. Obstruction of bile flow may be extrahepatic (eg, gallstones, postsurgical stricture, or malignancy) or intrahepatic (eg, poor hepatocyte function or damage to the small septal or intralobular bile ducts). Present in the biliary epithelium, elevated alkaline phosphatase and gamma-glutamyltransferase levels reflect damage to the bile ducts or obstruction of bile flow.

An elevated serum bilirubin level is roughly proportional to the amount of liver dysfunction or disease severity. Bilirubin is the major source of hemoglobin metabolism from the destruction of adult RBCs. The unconjugated (indirect) form of bilirubin is not water soluble and is bound to albumin as a means of transport to the liver for conjugation and subsequent excretion in the bile. In the hepatocytes, unconjugated bilirubin is combined with glucuronic acid to make it water soluble (or conjugated) for excretion into the bile and feces. Cholestasis causes reflux of conjugated bilirubin into the blood (a condition called conjugated hyperbilirubinemia), so the conjugated bilirubin is instead excreted through the kidneys. The urine becomes frothy and very dark amber in color from bilirubin pigments. The nurse may be asked to perform a dipstick test on the urine for bilirubin to confirm this clinical suspicion. Unconjugated hyperbilirubinemia results from a poor nutritional state (eg, decreased albumin available for transport of bilirubin to the liver) or hepatocyte dysfunction in the conjugation process. Jaundice is usually present when the serum bilirubin level is greater than 2.5 mg/dL.

Management

The primary treatment of acute hepatitis of any type is primarily supportive. Measures include providing rest and adequate nutrition and preventing further liver injury by avoiding hepatotoxic medications and substances. Hospitalization is rarely required but is needed in cases of disease complicated by hemodynamic instability, failure to maintain adequate nutrition and fluid intake, encephalopathy, blood coagulopathies, and renal failure.

In situations of hemodynamic instability, monitoring of blood pressure, heart rate, cardiac dysrhythmias, and urine output is essential. IV fluids will most likely be needed. It is important to avoid lactated Ringer's solutions because of the inability of the impaired liver to metabolize lactate, which could induce or exacerbate a metabolic acidosis. Frequent monitoring of hepatic enzymes and synthetic function is requested to evaluate disease progression and response to treatment interventions. Electrolyte, nutrient, and vitamin abnormalities from disease progression, malnutrition, and nausea and vomiting require repletion.

The nurse may have to assist in invasive treatments or procedures, such as placement of a Sengstaken-Blakemore tube for control of bleeding esophageal varices, paracentesis for ascites, and liver biopsy. In the event of fluid volume overload, diuretics, albumin, and protein supplements may be prescribed. Accurate intake and output, daily weight, and abdominal girth measurements may alert the nurse to significant volume shifts and potential hemodynamic or respiratory issues.

Maintaining adequate nutrition is a priority. Small, frequent meals and antiemetics are administered as needed. A high-calorie, low-protein diet is recommended to prevent complications associated with impaired protein and ammonia metabolism associated with acute HE. However, a low-protein diet is used only in the short term because seriously ill patients actually have increased protein requirements to build and maintain muscle mass and to assist in healing and repair. Parenteral nutrition is needed only if oral intake is impaired by intractable nausea and vomiting. Patients with severe fatigue require frequent rest and spacing of activities.

Because of the risk for coagulopathy, the nurse must monitor for bleeding gums, epistaxis, ecchymosis, petechiae, hematemesis, hematuria, and melena. Vitamin K may be prescribed to help reduce the effects of bleeding tendencies, and a PT may be ordered to monitor the efficacy of treatment.

Avoidance of alcohol, narcotics, barbiturates, and medications that are metabolized by the liver is recommended. Careful observation and documentation of patient responses (eg, mental status, level of consciousness) to medications and treatment regimens is recommended. Because of the liver's inability to metabolize or detoxify many foods, drugs, and toxins, the nurse may be asked to administer frequent medications, such as lactulose, neomycin sulfate, and metronidazole, to treat HE. Lactulose is a laxative that acidifies the colon to prevent the absorption of ammonia. The dose of lactulose is titrated so that the patient has two to three soft stools per day without diarrhea. Neomycin and metronidazole act as antibiotics to clear the colon of bacteria that produce ammonia.

If severe pruritus from jaundice is present, a bile salt sequestering agent (eg, cholestyramine), a topical emollient, or both can be used to help alleviate this symptom. Mittens may need to be used to prevent excessive scratching and subsequent skin breakdown in a confused patient.

Patient teaching for the patient with hepatitis includes measures to prevent infection and transmission, dietary limitations and alcohol avoidance, and the necessity for follow-up care. The patient is advised to monitor activity tolerance and fatigue. If signs and symptoms persist and liver enzymes remain elevated for greater than 6 months, the patient will progress to chronic disease. This is more common in HBV and HCV infection and is confirmed by liver biopsy.

▲ Complications of Liver Disease

Complications of advanced liver disease include cirrhosis, HE, hepatorenal syndrome (HRS), spontaneous bacterial peritonitis (SBP), and hepatocellular carcinoma.

Cirrhosis

Etiology

As noted earlier, chronic HCV infection and alcohol abuse are the most common causes of liver cirrhosis. However, cirrhosis of the liver can result from a number of other diseases, which include but are not limited to nonalcoholic steatohepatitis, hereditary hemochromatosis, Wilson's disease, and alpha$_1$-antitrypsin deficiency.

Pathophysiology

Cirrhosis, which develops over time, can cause severe alterations in the structural architecture of the liver and function of the hepatocytes. These changes are characterized by inflammation and liver cell necrosis, which can be focal or diffuse. Necrosis is followed by regeneration of liver tissue but not in a normal fashion. Fibrous tissue and regenerative nodules develop over time, which distorts the normal architecture of the liver lobule and alters blood flow. These fibrotic changes are irreversible, resulting in chronic liver dysfunction and eventual liver failure. Fatty deposits in the parenchymal cells may be seen initially. The cause of the fatty changes is unclear, but it may be a response to alterations in enzymatic function responsible for normal fat metabolism. Eventually, all of the liver's metabolic processes are altered.

Inflammation, fibrotic changes, and increased intrahepatic vascular resistance cause compression of the liver lobule, leading to increased resistance or obstruction of normal blood flow through the liver, which is normally a low-pressure system. This portal hypertension results in significant venous congestion and dilation (Fig. 41-5). Subsequently, nutrient-rich blood from the GI tract is shunted away from the liver, the first site of metabolism for many nutrients, drugs, and toxins. Pressure builds up in the systemic venous circulation, causing congestion where the portal and systemic venous systems connect: the esophagus, stomach, and rectum. These vascular changes result in varicose veins, or varices. Esophageal varices and gastric varices are of particular concern in the care of these patients because they are extremely friable. Rupture from these varices can result in massive internal bleeding that may be life-threatening. Portal hypertension also promotes increased collateral circulation and allows blood to flow from the intestines directly to the vena cava. This congestion is often seen as a collection of prominent vessels on the surface of the abdomen and is known as caput medusae. Splenomegaly results from the sequestration of trapped blood from portal hypertension. Of particular concern is the trapping of platelets, which can be seen clinically by bleeding tendencies and a thrombocytopenia on laboratory evaluation. Frank hematemesis or bleeding from esophageal and gastric varices can cause melena. Hemorrhoidal varices, or hemorrhoids, can also result from portal hypertension. Finally, portal hypertension may result in abdominal fluid accumulation, known as ascites. As liver disease progresses and cirrhosis develops, mild to moderate high-output cardiac dysfunction may occur. This hyperdynamic dysfunction is characterized by splanchnic and systemic vasodilation, an afterload effect

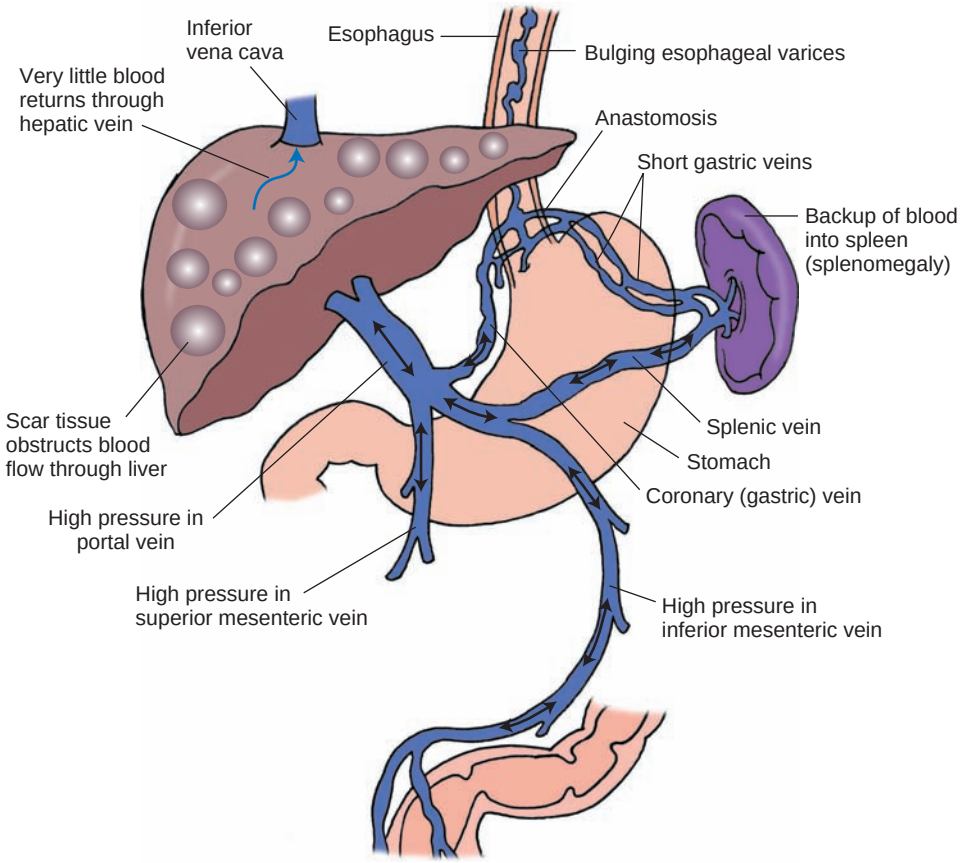

FIGURE 41-5 ▲ Esophageal varices develop from increased portal pressure. In an attempt to return blood to the systemic circulation, collateral veins develop to bypass increased portal resistance. These collateral vessels become tortuous and distended and are called varices.

that decreases cardiac work and elevates cardiac output. Clinically, it is seen as hypotension, tachycardia, and cardiac flow murmurs. As hepatic cirrhosis progresses, these clinical findings become more pronounced. Figure 41-6 illustrates clinical effects of cirrhosis.

Assessment

In some patients, cirrhosis may be subclinical. However, history and physical examination findings may reveal clues to altered liver function. For example, altered carbohydrate metabolism can result in unstable blood glucose levels. Altered fat metabolism can cause fatigue and decreased activity tolerance. Altered protein metabolism results in a decreased synthesis of albumin. Albumin is necessary for colloid osmotic pressure, which holds fluid in the intravascular space. A decrease leads to interstitial tissue edema and decreased plasma volume. Globulin, another protein, is essential for normal blood clotting. This, coupled with a decreased synthesis of many blood clotting factors and decreased metabolism of vitamins and iron, predisposes the patient to hematological complications that range from bruising to hemorrhage. A low-grade DIC also may develop. Portal hypertension, ascites, and lower extremity edema cause hypotension. Initially, the patient may have flushed skin and bounding pulses from the vasodilation in the portal venous system, which leads to a hyperdynamic state with peripheral circulation vasodilation and hypotension. Table 41-5 summarizes laboratory findings in patients with cirrhosis and impending liver failure.

Management

Management goals include preventing additional stress on liver function and early recognition and treatment of complications. Liver functions under stress include nutritional metabolism, clearing medication and metabolic waste products, and formation of clotting factors. Interventions include monitoring nutritional markers and providing nutrition; monitoring fluid balance, urinary output, electrolyte and chemistry studies, drug type, and dose requirements; monitoring bleeding times, platelet function, and hematocrit; and detecting signs of bleeding (Box 41-14). Bowel cleansing regimens may be ordered. The early recognition of complications includes detecting signs of impending liver failure: changes in neurological and mental status, increasing ascites, and HRS.

The critically ill patient in liver failure is often in some state of unconsciousness, with jaundiced skin and sclera. Coagulation times are prolonged, so bleeding is apt to occur from many sources. There is a risk for sores and skin breakdown because of the patient's debilitated state.

Maintaining fluid and electrolyte balance requires ongoing nursing assessment. Imbalance can result from replacement therapy, malnutrition, gastric suction, diuretics, vomiting, diaphoresis, ascites, diarrhea, inadequate fluid intake, and elevated aldosterone levels. The patient may complain of headache, weakness, numbness and tingling of extremities, muscle twitching, thirst, nausea, or muscle cramps and may become confused. The nurse is asked to monitor weight and CVP trends to help determine fluid

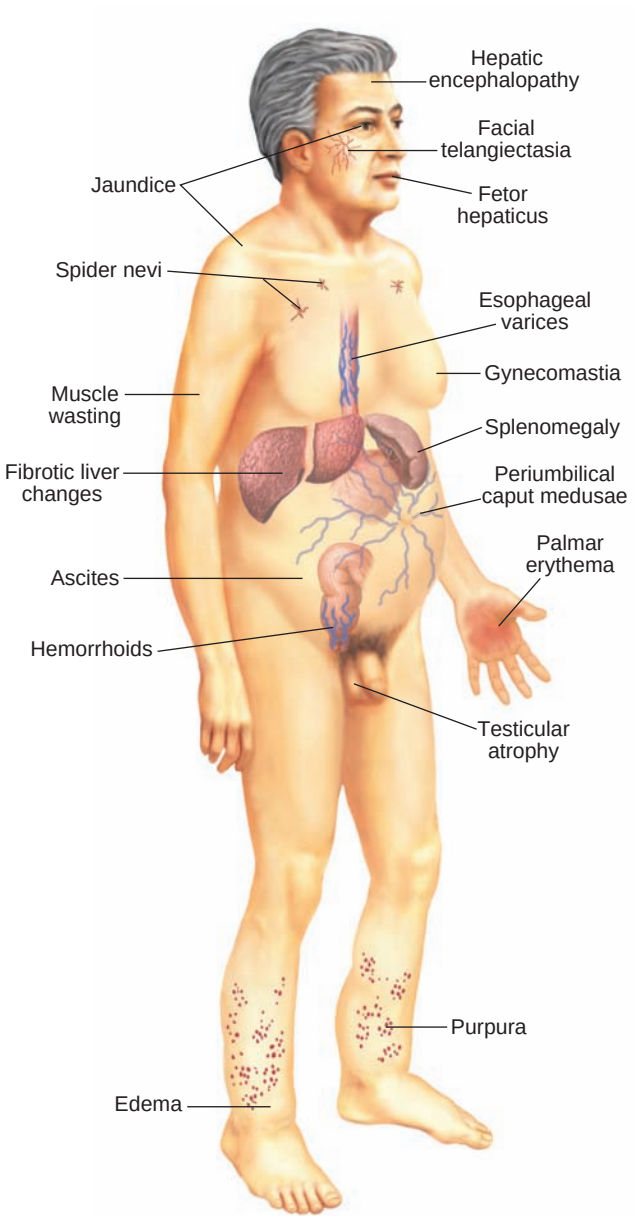

FIGURE 41-6 ▲ Clinical effects of cirrhosis of the liver. (From Porth CM: Pathophysiology: Concepts of Altered Health States, 8th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins, 2009, p 968.)

retention and vascular loading. Other assessment clues to monitor include any increase or decrease in urinary output, cardiac dysrhythmias, changes in mental status or level of consciousness, prolonged vomiting or frequent liquid stools, muscle tremors, spasms, edema, or poor skin turgor.

Impaired handling of salt and water by the kidney and other abnormalities in fluid homeostasis predispose the patient to ascites, an accumulation of fluid in the peritoneum. This complication can be problematic because it can restrict movement of the diaphragm, impairing the patient's breathing pattern. Therefore, monitoring respiratory status by the nurse is crucial. Ascites is managed through bed rest, a low-sodium diet of no more than 2,000 mg/d, fluid restriction, and diuretic therapy.[47] It has been demonstrated that ascites absorption has an upper limit of 700 to 900 mL/d during diuresis therapy. If diuresis exceeds this limit, it may be at the expense of the intravascular volume and may potentiate hemodynamic instability. Diuresis with spironolactone, an aldosterone antagonist, is first-line diuretic therapy for ascites, although combination therapy with furosemide is more effective.[47] Monitoring for electrolyte imbalance, particularly hypokalemia, is essential. In addition to strict intake and output balance and daily weights, abdominal girth should be measured daily.

Paracentesis is also used to treat ascites in patients unresponsive to salt restriction and maximal diuretic therapy.[47] In this procedure, ascitic fluid is withdrawn from the abdomen through percutaneous needle aspiration. As much as 4 to 6 L/d of ascitic fluid can be withdrawn, and close monitoring of vital signs is important during this procedure because a sudden loss of intravascular pressure may precipitate hypotension, decreased renal perfusion, and tachycardia. Volume expanders are recommended if 5 L or more of ascitic fluid are withdrawn during a single paracentesis procedure (eg, replacement of 5 g of albumin per liter of removed ascites fluid).[47] As with any invasive procedure, there is an increased risk for infection, particularly with repeated large-volume paracentesis procedures (eg, refractory ascites). Refractory ascites results from continued deterioration of liver function and increased portal pressure, increased circulating vasoconstrictors, and decrease in renal blood flow. Refractory ascites marks a sentinel deterioration in the patient's disease trajectory. Refractory ascites requires repeated paracentesis, with decreasing intervals of time between procedures. Unfortunately, paracentesis does not improve the overall poor prognosis, and all patients with refractory ascites should be referred for consideration for a liver transplantation.

A venous–peritoneal (VP) shunt is used to relieve ascites that is resistant to other therapies. The LeVeen shunt (Fig. 41-7) is inserted by placing the distal end of a tube in the abdominal cavity and tunneling the other end into a central vein (eg, the superior vena cava). This perforated intra-abdominal tube allows for ascitic fluid to flow into the central vein. Complications related to placement and use include sepsis, peritonitis, DIC, thrombi formation, and variceal hemorrhage. It is not recommended for patients with infected ascites, encephalopathy, or renal failure. Although the VP shunt controls ascites better than paracentesis, occlusion rates within the first year of placement are high. Because of the aforementioned complications, these shunts are rarely placed in current hepatology practice.

A nonsurgical approach to managing ascites and acute variceal hemorrhage is the TIPS, illustrated in Figure 41-8. The purpose of a TIPS is to decompress the portal venous system and therefore prevent rebleeding from varices or stop or reduce the formation of ascites.[47] TIPS has been associated with improved survival rates, improved renal function via improved flow, and it has even allowed some patients to stop hemodialysis.[47] Absolute contraindications to a TIPS procedure include congestive heart failure, severe tricuspid regurgitation, multiple hepatic cysts, uncontrolled systemic infection or sepsis, unrelieved biliary obstruction, and severe pulmonary hypertension (mean pressures more than 45 mm Hg; these patients are not candidates for liver transplantation). Using an angiographic catheter, a guide wire with a dilating balloon is inserted into the internal jugular vein and

Table 41-5 Laboratory Studies for Hepatic Injury and Function

Parameter	Normal	Increased	Decreased
Hepatocellular Injury			
ALT AST	5–35 IU/L 5–40 IU/L	Acute viral hepatitis (ALT more than AST) Biliary tract obstruction Alcoholic hepatitis (AST more than ALT) Ischemia or hypoxia (“shock liver”) Drug toxicity Right-sided heart failure Liver cancer	Vitamin B deficiency
Liver Synthetic Function			
Albumin	3.4–4.7 g/dL	Dehydration, shock	Chronic liver disease, malnutrition, malabsorption
Total protein	6.0–8.0 g/dL		
PT INR	11–15 s 0.8–1.2 s	Liver disease Vitamin K deficiency Anticoagulants	N/A
Cholestasis or Excretory Function			
Total bilirubin Conjugated (direct) Unconjugated (indirect) Alkaline phosphatase GGT	0.2–1.3 mg/dL 0.1–0.3 mg/dL 0.2–0.7 mg/dL 30–115 IU/L 9–85 units/L	Viral hepatitis Alcoholic hepatitis Obstructive jaundice Primary biliary cirrhosis	N/A

N/A, not applicable, PT, prothrombin time; ALT, alanine transaminase; AST, aspartate aminotransferase; GTT, gamma-glutamyl transpeptidase; INR, international normalized ratio.

is advanced through the liver parenchyma to connect the portal vein, where most of the blood flowing to the liver enters, to the hepatic vein, which empties blood into the inferior vena cava. A stent is then placed to create a conduit between the hepatic and portal vein, which decreases portal pressure. Complications include shunt occlusion, shunt stenosis, and HE. HE increases after a TIPS procedure because this portacaval shunt diverts portal blood flow away

BOX 41-14 COLLABORATIVE CARE GUIDE for the Patient With Cirrhosis and Impending Liver Failure

Outcomes	Interventions
Oxygenation/Ventilation	
The patient’s ABGs will be within normal limits.	• Monitor pulse oximetry and ABG values, respiratory rate and pattern, and ability to clear secretions. • Validate significant changes in pulse oximetry with co-oximetry arterial saturation measurement.
The patient has no evidence of pulmonary edema or atelectasis. Breath sounds are clear bilaterally.	• Assist patient to turn, cough, deep breathe, and use incentive spirometer every 2 h. • Provide chest percussion with postural drainage if indicated every 4 h. • Monitor effect of ascites on respiratory effort and lung compliance. • Position patient on side and with head of bed elevated to improve diaphragmatic movement.
Circulation/Perfusion	
Patient will achieve or maintain stable blood pressure and oxygen delivery. Serum lactate will be within normal limits.	• Monitor vital signs, including cardiac output, systemic vascular resistance, oxygen delivery, and oxygen consumption. • Monitor lactate daily until it is within normal limits. • Administer RBCs, positive inotropic agents, colloid infusion as ordered to increase oxygen delivery.
Patient will not experience bleeding related to coagulopathies, varices, hepatorenal syndrome.	• Monitor PT, PTT, complete blood count daily. • Assess for signs of bleeding (eg, blood in gastric contents, stools, or urine); observe for petechiae, bruising. • Administer blood products as indicated. • Assist with insertion and manage the esophageal tamponade balloon tube. • Perform gastric lavage as needed.

(*continued on page 950*)

BOX 41–14 *COLLABORATIVE CARE GUIDE for the Patient With Cirrhosis and Impending Liver Failure (continued)*

Outcomes	Interventions
Fluids/Electrolytes	
Patient is euvolemic. Patient will not gain weight due to fluid retention.	• Daily weights • Monitor intake and output. • Monitor electrolyte values. • Measure abdominal girth daily at the same location on the abdomen. • Monitor signs of volume overload: Cardiac gallop Pulmonary crackles Shortness of breath Jugular vein distention Peripheral edema • Administer diuretics as ordered.
Mobility/Safety	
Patient is alert and oriented. Ammonia level is within normal limits. Patient achieves or maintains ability to conduct activities of daily living and mobilize self. No evidence of infection, WBC within normal limits.	• Assess serum ammonia level. • Administer lactulose as ordered. • Monitor level of consciousness, orientation, thought processing. • Assess asterixis. • Take precautions to prevent falls. • Consult physical therapist. • Conduct range-of-motion and strengthening exercises. • Monitor SIRS criteria: increased WBC, increased temperature, tachypnea, tachycardia. • Use aseptic technique during procedures and monitor others. • Maintain invasive catheter tube sterility. • Change invasive catheters, culture blood, line tips, or fluids, provide site care, etc., according to hospital protocol.
Skin Integrity	
Skin will remain intact.	• Assess skin every 8 h and each time patient is repositioned. • Turn patient every 2 h. Assist or teach patient to shift weight or reposition. • Consider pressure relief/reduction mattress.
Nutrition	
Caloric and nutrient intake meet metabolic requirements per calculation (eg, basal energy expenditure). Evidence of metabolic dysfunction is minimal.	• Provide nutrition by oral, enteral, or parenteral feeding. • Adhere to sodium, protein, fat, or fluid restrictions as necessary. • Consult dietitian or nutritional support service to evaluate nutritional needs and restrictions. • Provide small, frequent feedings. • Monitor albumin, prealbumin, transferrin, BUN, cholesterol, triglycerides, bilirubin, aspartate transaminase, alanine transaminase. • Administer cleansing enemas and cathartics if ordered.
Comfort/Pain Control	
Patient will have minimal pain. Patient will have minimal pruritus.	• Assess pain and discomfort from ascites, bleeding, pruritus. • Administer analgesics cautiously and monitor patient response. • Bathe with cool water, blot dry. • Lubricate skin. • Administer antipruritic medication; apply to skin PRN as ordered.
Psychosocial	
Patient demonstrates decreased anxiety.	• Assess patient's response to illness. Provide time to listen. • Assess effect of critical care environment on the patient. • Minimize sensory overload. • Provide adequate time for uninterrupted sleep. • Encourage flexible visiting hours for family. • Plan for consistent care giver.

(*continued on page 951*)

BOX 41-14 COLLABORATIVE CARE GUIDE for the Patient With Cirrhosis and Impending Liver Failure (continued)

Outcomes	Interventions
Teaching/Discharge Planning	
Patient/significant others understand procedures and tests needed for treatment of hepatic dysfunction.	• Prepare patient/significant others for procedures such as paracentesis or laboratory studies. • Teach patient and family information regarding sodium, protein, and fluid restrictions. Give written instructions.
Patient/significant others are prepared for home care.	• Teach signs and symptoms of progressing hepatic failure (eg, change in mentation, skin coloration, ascites). • Teach signs and symptoms of occult bleeding and respiratory infection. • Teach home medication regimen. • Teach comfort measures.

from the liver parenchyma. Although TIPS is fairly successful in treating ascites, recent meta-analyses concluded that it can also be associated with the development of increased encephalopathy.[48]

Hepatic Encephalopathy

Patients with severe liver disease can progress to HE, a reversible decrease in neurologic function caused by liver disease. In general, clinical manifestations of HE can be subtle, with changes in memory, personality, concentration, and reaction times. HE can progress to more apparent neurologic cognitive changes, irritability or agitation, reversal of day and night schedules, somnolence, and eventually terminal coma if left untreated. These changes can be graded into stages (subclinical to stupor or coma) by evaluating both intellectual and neuromuscular function. In addition, they may fit into one of three clinical patterns. Type A is related to acute liver failure. Type B occurs in the setting of normal liver histology and the presence of a hepatic vascular bypass (eg, TIPS). Type C is due to cirrhosis and represents most cases in the ICU; it can be divided further into acute and chronic subcategories. Asterixis (a flapping tremor, usually of the hands) is a very early sign of HE. To test for this, the nurse should ask the patient to hold an arm and hand out, with fingers spread, as if stopping traffic and look for involuntary hand "flapping." Other signs are hyperreflexia and muscle rigidity.

The cause of the HE is thought to be related to the accumulation of toxic agents absorbed from the intestinal tract. These substances accumulate because the liver has lost the ability to metabolize and detoxify these substances. Elevated serum ammonia, a byproduct of protein and amino acid metabolism, is one of the suspected neurotoxins. Normally, ammonia is metabolized into urea before entering the systemic circulation, and the urea is then excreted. If the liver is unable to perform this detoxification or if a good portion of the portal blood is shunted around the liver from portal hypertension, the circulating level of ammonia rises. If ammonia and the other toxic agents can be reduced through effective therapy, the encephalopathy gradually clears. Although arterial ammonia levels are more reliable than venous samples, they are often more difficult to obtain and more painful for the patient. In addition, symptoms of HE may lag behind ammonia level elevations, and improvements in HE symptoms may occur before any improvement in ammonia levels.

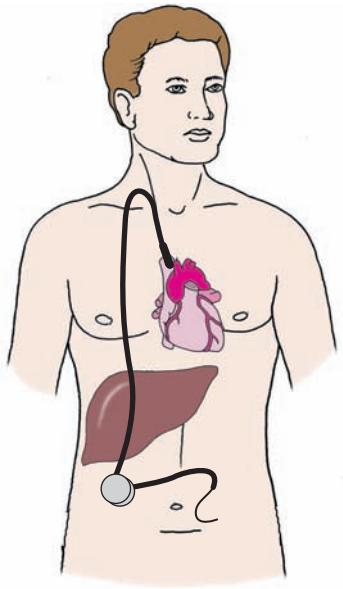

FIGURE 41-7 ▲ The distal end of the LeVeen shunt is tunneled into a central vein. The shunt allows ascites fluid to drain from the abdominal cavity.

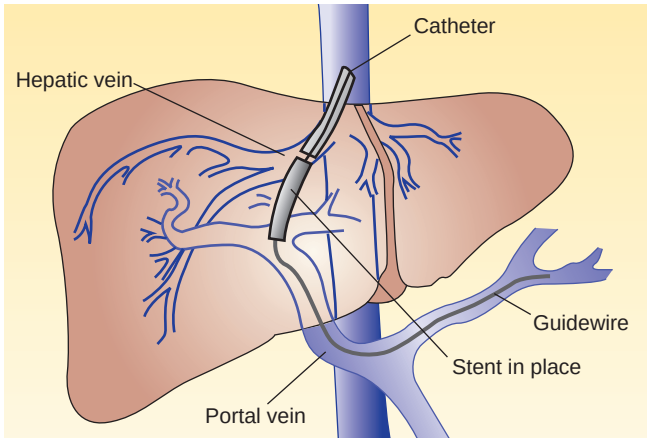

FIGURE 41-8 ▲ Transjugular intrahepatic portosystemic shunt. A stent is inserted through a catheter to the portal vein to divert blood flow and reduce portal hypertension. (From Smeltzer SC, Bare BG, Hinkle JL, et al: Brunner and Suddarth's Textbook of Medical–Surgical Nursing, 11th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2008, p 1297.)

Unfortunately, bypassing the liver with a shunt may result in decreased clearance and increased accumulation of toxins. HE can develop quite rapidly in patients with portosystemic shunts. People with portal hypertension can hemorrhage from esophageal varices or other sites in the GI tract. The hemorrhage produces a significant nitrogenous load to the intestinal tract in the form of blood, from which bacterial deamination produces the ammonia. Protein intake is limited to 20 to 40 g/d for the treatment of acute HE. Lactulose is used to facilitate bowel movements and clearance of nitrogenous products. Neomycin or metronidazole may be given to clear the gut of bacteria that promote nitrogenous production. Lactulose decreases the colonic pH to prevent the absorption of ammonia. Nursing measures to protect the patient with mental status changes from harm are a priority.

Hepatorenal Syndrome

HRS is the most frequently fatal complication of cirrhosis.[47,49] It is defined as the development of renal failure in patients with severe liver disease (acute or chronic) in the absence of any other identifiable cause of renal pathology.[47,49] Patterns of HRS have been defined as type 1 (acute), 2 (chronic), 3, and 4. The onset of type 1 is rapid, with a creatinine value of more than 2.5 mg/dL or a 50% reduction in initial 24-hour creatinine clearance and a decrease in glomerular filtration rate to less than 20 mL/min within 2 weeks. Type 1 is often observed in acute liver failure or alcoholic hepatitis, or following acute decompensation of a patient with a history of cirrhosis. Patients often appear jaundiced and have a significant coagulopathy; mortality from type 1 HRS is 80% (at 2 weeks) and usually results from a combination of liver and renal failure or variceal bleeding.[49] Type 2 HRS usually occurs in patients with diuretic-resistant ascites. Onset is more insidious, with deterioration in renal failure over months, but it is also associated with a poor prognosis. In both type 1 and 2 HRS, failure of the kidneys is the result of the extreme systemic vasodilation (from the portal hypertension of liver failure), which decreases the effective circulating blood volume. This leads to a compensatory increase in cardiac output and maximal renal vasoconstriction, which reduces renal perfusion and subsequent renal failure. Type 3 categorization defines patients with coexistent intrinsic renal dysfunction and advanced liver disease, whereas type 4 includes patients with acute liver failure.

Ascites, jaundice, hypotension, and oliguria are clinical findings in HRS; laboratory findings typically include azotemia, elevated serum creatinine, urine sodium less than 10 mEq/L, and hyponatremia. Management goals include therapies to support liver and kidney functions. Historically, liver transplantation had been the treatment of choice. However, because elevated pretransplantation serum creatinine levels have been demonstrated as a poor posttransplantation prognostic factor, it is now being suggested that both a liver and kidney transplantation would improve patient survival.[50,51]

Spontaneous Bacterial Peritonitis

Patients with liver disease may be more susceptible to infection because the hepatic Kupffer cells, which are responsible for uptake and subsequent degradation of foreign and potentially harmful substances in the body, do not function as efficiently. SBP occurs when there is a large accumulation of ascites without an identifiable intra-abdominal source of infection (eg, absence of recognizable intestinal perforation). Ascitic fluid contains low concentrations of albumin, which is thought to normally provide some protection against bacteria. Subsequent leakage of bacteria through the abdominal wall or from invasive procedures (eg, endoscopy, nasogastric tube, IV line, or indwelling bladder catheter placement) is thought to precipitate SBP.

Patients with SBP may complain of fever, chills, generalized abdominal pain, or tenderness with palpation (but rarely with rebound tenderness). However, symptoms may be minimal, with only subtle worsening of jaundice or encephalopathic trends.

SBP leads to renal impairment in approximately 10% to 30% of patients with cirrhosis,[49] and an estimated 28% of patients with SBP will develop HRS.[52] The two most common causative organisms are Gram-negative bacteria, *Escherichia coli*, or *Klebsiella*.[53] Subsequently, if SBP is suspected, the ascitic fluid should be evaluated for cell count, differential, and culture. While ascitic fluid bacterial cultures are pending, the diagnosis of SBP is highly likely if ascitic fluid leukocyte count is elevated at more than 500 cells/L (with a proportion of polymorphonuclear leukocytes of more than 50%). The patient should be treated with broad-spectrum antibiotic coverage until the results of these tests are returned. SBP must be differentiated from peritonitis secondary to an abscess or perforation because the latter needs immediate surgical treatment.

Common nursing diagnoses for the patient with a GI disorder are listed in Box 41-15.

BOX 41-15 EXAMPLES OF NURSING DIAGNOSES

For the Patient With a Gastrointestinal Disorder

- Imbalanced Nutrition: Less Than Body Requirements related to altered pancreatic or liver function, impaired digestion from inadequate bile or pancreatic enzyme production, poor eating habits, excessive alcohol intake, nausea, vomiting, or anorexia
- Excess Fluid Volume related to extravascular ascites, portal hypertension, and hypoalbuminemia
- Risk for Deficient Fluid Volume related to overly aggressive diuresis, GIB and coagulopathies, and peritoneal sequestration of intra-abdominal fluids
- Risk for Electrolyte Imbalance related to anorexia, nausea, and vomiting
- Risk for Aspiration related to delayed gastric emptying, intestinal obstruction, ileus, or GIB
- Impaired Gas Exchange related to decreased diaphragmatic excursion secondary to abdominal distention and potential for aspiration
- Decreased Cardiac Output related to hepatic portal hypertension or blood loss from GIB
- Acute Pain related to nasogastric tube irritation, pruritus related to accumulation of bilirubin pigment and salts, inflammation of the pancreas and surrounding tissues, and local peritonitis
- Readiness for Enhanced Self-Health Management, Ineffective Family Therapeutic Regimen Management related to insufficient knowledge of disease process, treatments, contraindications, dietary management, and follow up care

▲ Clinical Applicability Challenges

CASE STUDY

C.K is a 28-year-old female graduate student from China who presents to the emergency department with complaints of hematemesis. She reports dizziness and has had three episodes of vomiting with a large amount of bright red blood present in the emesis. She notes a 3-month history of abdominal distention and bulging flanks. Although the details of her medical history are unclear, she reports a history of "hepatitis." She admits to previous experimental intravenous drug use while attending college, currently drinks approximately three glasses of wine per day, and denies any tobacco history. She reports that she was told her liver function test values were elevated when she last saw her physician in China prior to her immigration 10 years ago. On physical examination her liver span is 6 to 8 cm, and her spleen is palpable. There is scleral icterus. Vital signs are blood pressure, 90/50 mm Hg and pulse rate, 122 beats/min.

Laboratory findings on admission:
Hematocrit (Hct), 22%
Prothrombin time, 20 s
Alanine aminotransferase, 122 units/L
Aspartate aminotransferase 96 units/L
Alkaline phosphatase 76 units/L
Total bilirubin 4.5 mg/dL

1. What is the likely etiology of C.K.'s hematemesis and distention?
2. What other laboratory tests would you expect will be ordered?
3. Discuss potential nursing interventions for C.K.

PART 10

ENDOCRINE SYSTEM

42

Anatomy and Physiology of the Endocrine System

Jane Kapustin

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Describe the production, action, and regulation of antidiuretic hormone, growth hormone, and the thyroid hormones.
2. Discuss how activated vitamin D, parathyroid hormone, and calcitonin each influence calcium concentrations in the blood.
3. Explain the production, action, and regulation of insulin.
4. Compare and contrast the pathophysiology of types 1 and 2 diabetes.
5. Describe the roles of counter-regulatory hormones, gut hormones, and glucagon on the regulation of blood glucose.
6. Explain how glucocorticoids are secreted.
7. Discuss the significant effects of glucocorticoid medications.
8. Summarize the renin–angiotensin mechanism for regulating mineralocorticoid secretion.

Communication between systems in the body is accomplished in three ways. One method of communication is the nervous system. A second method is the cellular secretion of chemicals that are released into the interstitial fluid. Examples of this method of communication include the chemicals that trigger a local inflammatory response, such as histamine, complement, and prostaglandins. The third method of communication is the cellular secretion of chemicals that are circulated through the bloodstream. This communication is known more commonly as the endocrine system (Fig. 42-1, Table 42-1). The secretions of endocrine cells are termed hormones. Hormones are molecules synthesized and secreted by specialized cells and released into blood vessels to exert biochemical effects on target cells distant from the site of origin. They control metabolism, transport of substances across the cell membrane, fluid and electrolyte balance, growth and development, adaptation, and reproduction.

Hormone action is specific and depends on linkage with a specialized hormone receptor on the target cell. This hormone–receptor complex is responsible for a series of biological responses. Hormones are either stimulatory or inhibitory. Either their actions are very organ specific, such as prolactin (which only affects the mammary glands), or their effects are generalized, such as insulin (which affects most cellular functions of the body).

Hormone production is maintained by a feedback loop mechanism involving the hypothalamic–pituitary axis system (Fig. 42-2, p. 958). Release of a specific hormone is made possible when the circulating level of that hormone is low (positive feedback). Conversely, when the circulating level of a hormone is high, the release of more hormone is inhibited (negative feedback) until a lower level is reached. This system is regulated by specialized sensors in the hypothalamus that continuously monitor hormone assays to maintain self-regulated homeostasis. Theoretically, when

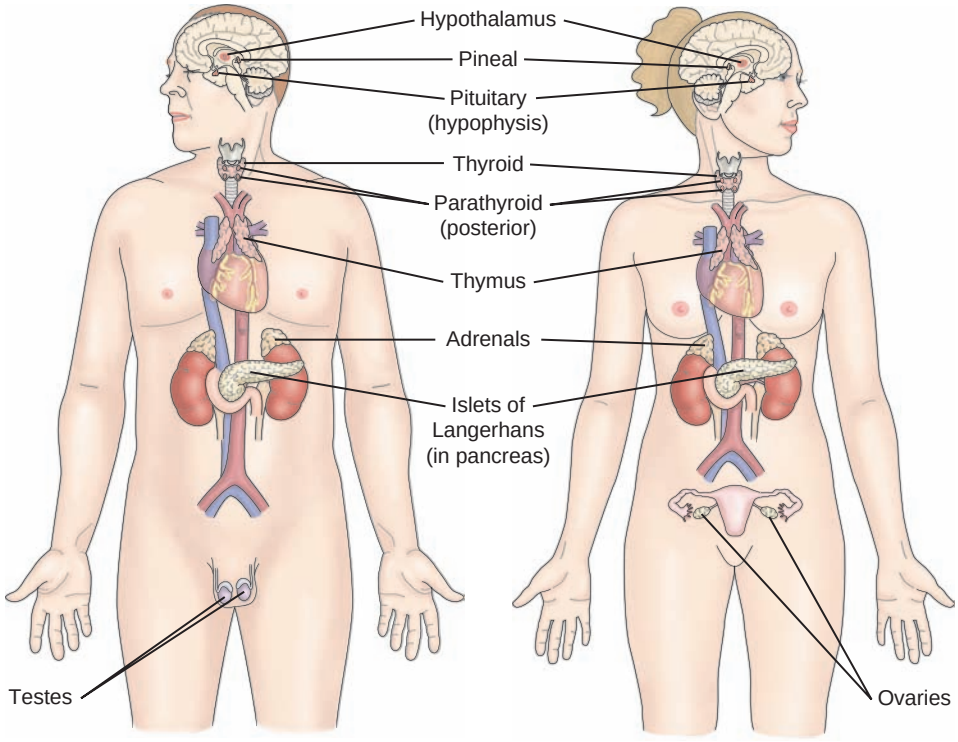

FIGURE 42-1 ▲ The endocrine system. (From Smeltzer SC, Bare BG, Hinkle JL, Cheever KH: Brunner & Suddarth's Textbook of Medical–Surgical Nursing, 12th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 1246.)

Table 42-1 Endocrine System in Summary

Endocrine Gland and Hormone	Principal Site of Action	Principal Processes Affected
Pituitary Gland		
Anterior Lobe		
Growth hormone (GH, somatotropin)	General	Growth of bones, muscles, and other organs
Thyroid-stimulating hormone	Thyroid	Growth and secretory activity of thyroid gland
Adrenocorticotropic hormone	Adrenal cortex	Growth and secretory activity of adrenal cortex
Follicle-stimulating hormone	Ovaries	Development of follicles and secretion of estrogen
	Testes	Development of seminiferous tubules, spermatogenesis
Luteinizing hormone or interstitial cell–stimulating hormone	Ovaries	Ovulation, formation of corpus luteum, secretion of progesterone
Prolactin (luteotropic hormone)	Testes	Secretion of testosterone
Melanocyte-stimulating hormone	Mammary glands and ovaries	Secretion of milk; maintenance of corpus luteum
β-Lipotropin	Skin	Pigmentation
Posterior Lobe		
Antidiuretic hormone (vasopressin)	Kidney	Reabsorption of water; water balance
	Arterioles	Blood pressure
Oxytocin	Uterus	Contraction
	Breast	Expression of milk
Pineal Gland		
Melatonin	Gonads	Sexual maturation
Thyroid Gland		
Thyroxine (T_4) and triiodothyronine (T_3)	General	Metabolic rate; growth and development; intermediate metabolism
Calcitonin	Bone	Inhibits bone resorption; lowers blood level of calcium

(continued on page 957)

Table 42-1 Endocrine System in Summary (continued)

Endocrine Gland and Hormone	Principal Site of Action	Principal Processes Affected
Parathyroid Glands		
Parathyroid hormone (PTH)	Bone, kidney, intestine	Promotes bone resorption; increases absorption of calcium; raises blood calcium level
Adrenal Glands		
Cortex		
Mineralocorticoids (eg, aldosterone)	Kidney	Reabsorption of sodium; elimination of potassium
Glucocorticoids (eg, cortisol)	General	Metabolism of carbohydrate, protein, and fat; response to stress; anti-inflammatory
Sex hormones	General	Preadolescent growth spurt
Medulla		
Epinephrine	Cardiac muscle, smooth muscle, glands	Emergency functions: same as stimulation of sympathetic nervous system
Norepinephrine	Organs innervated by sympathetic nervous system	Chemical transmitter substance; increases peripheral resistance
Islet Cells of Pancreas		
Insulin	General	Lowers blood glucose; utilization and storage of carbohydrate; decreases gluconeogenesis
Glucagon	Liver	Raises blood glucose; glycogenolysis
Somatostatin	General	Lowers blood glucose by interfering with release of GH and glucagon
Testes		
Testosterone	General	Development of secondary sex characteristics
	Reproductive organs	Development and maintenance; normal function
Ovaries		
Estrogens	General	Development of secondary sex characteristics
	Mammary glands	Development of duct system
	Reproductive organs	Maturation and normal cyclic function
Progesterone	Mammary glands	Development of secretory tissue
	Uterus	Preparation for implantation; maintenance of pregnancy
Gastrointestinal Tract		
Gastrin	Stomach	Production of gastric juice
Enterogastrone	Stomach	Inhibits secretion and motility
Secretin	Liver and pancreas	Production of bile; production of watery pancreatic juice (rich in $NaHCO_3$)
Pancreozymin	Pancreas	Production of pancreatic juice, rich in enzymes
Cholecystokinin	Gallbladder	Contraction and emptying

functioning properly, this system prevents the overproduction of hormones.

The effects of aging can influence the endocrine system as well (Box 42-1). As humans age, target organ sensitivity decreases. The target organs demonstrate the effects of aging by either increasing in pigmentation or shrinking in size. This, in effect, decreases hormone receptor binding. This phenomenon explains why older patients, women in particular, are at higher risk for development of hypothyroidism: aging can decrease production of triiodothyronine (T_3) and thyroxine (T_4) and can lead to thyroid gland atrophy.

Endocrine dysfunction can be identified as belonging to one of five major categories:

- Subnormal hormone production as a result of gland destruction or malformation
- Hormone excess
- Production of abnormal hormone resulting from gene mutation
- Hormone receptor disorders resulting from autoimmune processes
- Disorders of hormone transport or metabolism, resulting in increased levels of "free" hormones in the blood

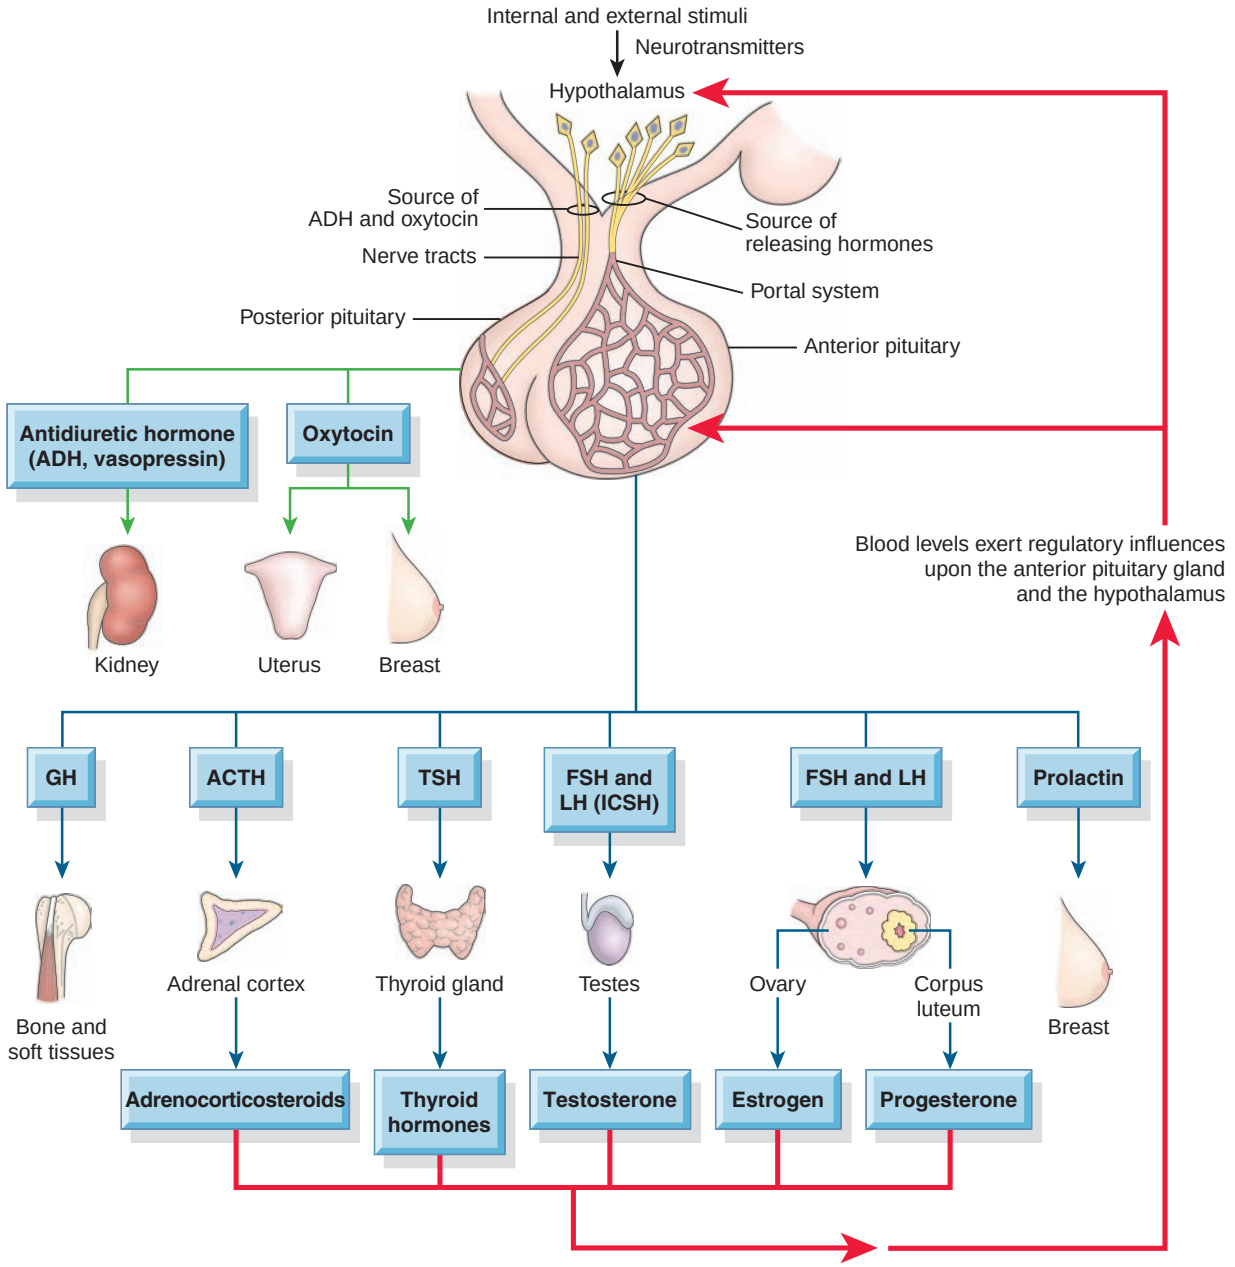

FIGURE 42-2 ▲ The feedback loop mechanism that controls hormone production. Sensors in the hypothalamus monitor hormone levels and initiate or suppress production accordingly. ACTH, adrenocorticotropic hormone; ADH, antidiuretic hormone; CNS, central nervous system; FSH, follicle-stimulating hormone; LH, luteinizing hormone; TSH, thyroid-stimulating hormone. (From Smeltzer SC, Bare BG, Hinkle JL, et al: Brunner & Suddarth's Textbook of Medical–Surgical Nursing, 12th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 1250.)

BOX 42-1 CONSIDERATIONS FOR THE OLDER PATIENT

Physiological Changes in the Endocrine System That Occur With Aging

- Production of thyroid hormone, cortisol, and aldosterone decreases with age.
- Levels of somatostatin, triiodothyronine (T_3), thyroxine (T_4), thyroid-stimulating hormone, aldosterone, renin, calcitonin, and vasopressin decrease with age, as does glucose tolerance.
- Levels of norepinephrine, parathyroid hormone, atrial natriuretic peptide, insulin, and glucagon increase with age.

▲ The Hypothalamus and Pituitary Gland

The key to understanding the physiology of the hormones of the pituitary gland lies in visualizing the anatomy of the gland and its blood supply. The hypothalamus and pituitary share two connecting pathways: a rich vascular network, which connects the hypothalamus with the anterior pituitary, and nerve fibers, which link the hypothalamus with the posterior pituitary. Together, these two glands form a unit that controls the thyroid gland, the adrenal glands, and the gonads, and exerts control over the growth and metabolism of the organism.

Because of the control the pituitary gland exerts over all body functions, it is often referred to as the master gland. It has two distinct regions: the anterior (front) lobe and the posterior (back) lobe. Located at the base of the skull in the sphenoid bone at a site referred to as the sella turcica, this well-protected gland is difficult to reach surgically because it is so deeply embedded in the skull. Despite being well protected, the pituitary is still susceptible to injury as a result of head or facial trauma, edema, or surgical complications. Because it is so vascular, the pituitary is extremely vulnerable to injury from ischemia and infarction.

The hypothalamus is a small area at the base of the brain connected to the posterior pituitary (also known as the neurohypophysis) by the pituitary stalk. This stalk is a direct outgrowth of the neuroectoderm of the base of the brain that drops during development of the gland into the bony sella turcica. This is in direct contrast to the anterior pituitary (adenohypophysis), which arises from the buccal endothelium and develops separately in the same bony structure. Besides being embryogenically separate, the blood supplies of the anterior and posterior pituitary differ. The hypothalamus has specialized nerve cells that are in constant communication with the third ventricle of the brain where continuous sampling of serum osmolality can occur. Information about the osmolality influences the release or inhibition of hormones. It is through this relationship that the hypothalamus influences the release of chemical and neural signals to maintain homeostasis. Because the hypothalamus controls the releasing or inhibiting hormones that influence the pituitary, it assumes the function of the coordinating center of the brain for endocrine, behavioral, and autonomic nervous system function. The hypothalamus is responsible for communicating emotion, pain, body temperature, and other neural input to the endocrine system.

The anterior pituitary hormones are controlled by releasing factors that are secreted from the hypothalamus and are called hypophysiotropic hormones. The hypophysiotropic hormones are secreted into the primary capillary plexus near the median eminence that supplies blood to the anterior pituitary (Fig. 42-3). This blood may also travel in a retrograde fashion and may be responsible for one level of feedback

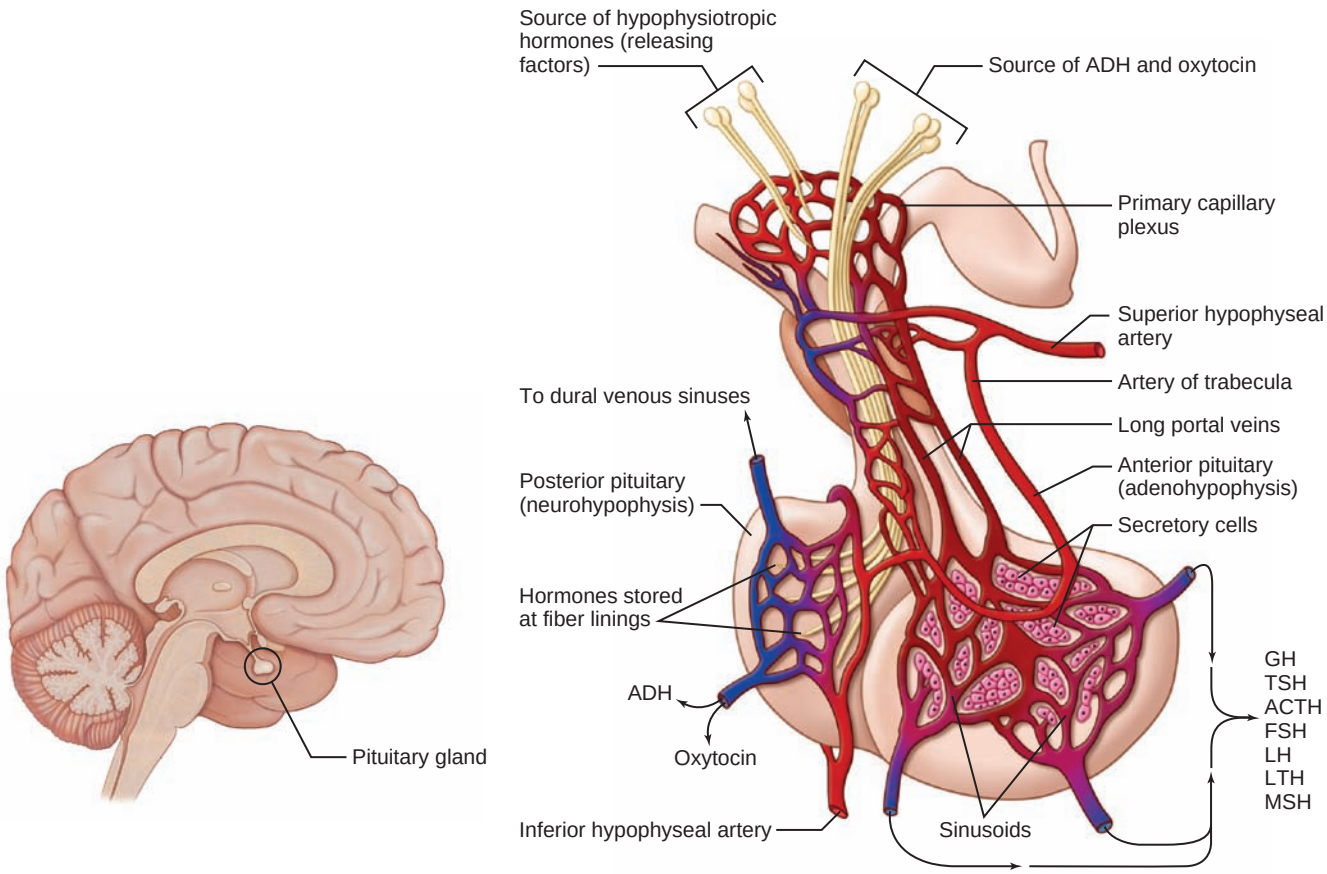

FIGURE 42-3 ▲ **A, B:** Highly diagrammatic and schematic representation of hypophyseal nerve fiber tracts and the portal system in the hypothalamus and pituitary gland. Releasing factors (hypophysiotropic hormones) produced by cell bodies in the hypothalamus trickle down axons to the proximal part of the stalk, where they enter the primary capillary plexus and are transported through portal vessels to sinusoids in the anterior lobe of the pituitary gland (ie, the adenohypophysis) for control of secretions. Antidiuretic hormone (ADH) and oxytocin, produced by other cell bodies in the hypothalamus, trickle down axons for storage in the posterior lobe of the pituitary gland (ie, the neurohypophysis) until they are needed. ACTH, adrenocorticotropic hormone; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinizing hormone; LTH, lactogenic hormone; MSH, melanocyte-stimulating hormone; TSH, thyroid-stimulating hormone.

control of the anterior pituitary and hypophysiotropic hormones. A given hypophysiotropic hormone regulates the secretion of one or two anterior pituitary hormones. Both growth hormone (GH, somatotropin) and prolactin are dually controlled by a stimulatory and an inhibitory hypophysiotropic hormone. The posterior pituitary is a direct neural extension of the hypothalamus, and the controlling factors reside in the neural chiasma of the hypothalamus; they are secreted by those cells into the posterior pituitary (see Fig. 42-3). In addition to controlling the pituitary gland through releasing factors, the hypothalamus controls other endocrine roles through releasing factors that control appetite, thirst, emotions, sleep–wake cycles, and cognition.

Such hypothalamic regulation of pituitary functioning can be disrupted by hypothalamic lesions. This can lead to oversecretion or undersecretion of one or more hormones released from the anterior or posterior pituitary. The hypothalamus also receives input from various higher and lower brain centers. These neural connections, together with the influence of the hypothalamus on the pituitary, provide the biological basis for the construction of conceptual models that describe how stress, emotions, environmental stimuli, and perceptions affect endocrine functions.

Posterior Pituitary (Neurohypophysis) Hormones

The posterior pituitary (neurohypophysis) makes up 20% of the gland. The two major hormones of the posterior pituitary gland are antidiuretic hormone (ADH, vasopressin) and oxytocin (see Table 42-1, p. 957). Because oxytocin does not have a role in critical care, it is not discussed here.

The two major actions of ADH are to concentrate the urine (by permitting only water reabsorption from the hypotonic tubular fluid in the distal nephron) and to constrict smooth muscles in the arterial wall. ADH binds to specific receptors in the distal renal tubules to increase their permeability to water. This results in increased water reabsorption but without electrolyte reabsorption. This reabsorbed water increases the volume and decreases the osmolality of the extracellular fluid (ECF). At the same time, it decreases the volume and increases the concentration of the urine excreted. Without ADH, the distal convoluted tubule would be impermeable to water. In the presence of ADH, the tubule and collecting duct are permeable to water, which diffuses from the hypotonic tubular fluid to the hypertonic tissue surrounding the tubules. This concentrates the tubular fluid and ultimately the urine.

The term *vasopressin* originated from the observation that large, supraphysiological dosages of ADH act on arteriole smooth muscle to elevate blood pressure. Although this pressor action of ADH does not appear to play a role in the normal homeostasis of blood pressure, it does counteract a fall in blood pressure that results from hemorrhagic or other drastic hypovolemic states and can be used pharmacologically for that purpose.

There are three major stimuli for the regulation of ADH secretion. The first is plasma osmolality, which is monitored by osmoreceptors in the anterior hypothalamus. An increase above the normal osmolality of plasma (290 mOsm/kg) results in neural stimuli from these receptors to the ADH-secreting cells, increasing ADH secretion. This increases water retention, thereby diluting the ECF and lowering the plasma osmolality back to normal. Similarly, a fall in plasma osmolality triggers a decrease or cessation in ADH secretion. This allows more water excretion, thereby raising the ECF osmolality. ADH secretion can be altered by changes in osmolality of less than 1%. This osmoreceptor-mediated reflex arc functions to maintain osmotic homeostasis of the ECF.

The second stimulus consists of changes in ECF volume. Stretch receptors in the low-pressure portion of the cardiovascular system (eg, the vena cava, the right atrium of the heart, and the pulmonary vessels) monitor blood volume. Stimuli from these receptors are conducted by afferent fibers to the hypothalamus (by way of the brainstem). A decrease in blood volume stimulates ADH secretion. The resultant increase in water retention elevates the blood volume. An increase in blood volume stops ADH secretion. This halts water retention, thereby restoring the normal volume of the ECF compartment. This mechanism alters ADH secretion in response to changes in body position. Movement from the recumbent to the upright position causes a temporary decrease in the stimulation of volume receptors because blood pools in the legs. This results in an increase in ADH secretion. Recumbency increases venous return from the legs. The increased volume triggers a decrease in ADH secretion, thereby increasing the volume of urine excreted.

The third stimulus, changes in arterial blood pressure, also can regulate ADH secretion. The hypothalamus receives information from pressure receptors located in the carotid sinuses and aorta. A fall in arterial pressure increases ADH secretion. The water retention thereby produced increases the plasma volume and pressure. A rise in arterial pressure produces the opposite effect. This mechanism is most important in compensating for large changes in arterial blood pressure (eg, impending or actual shock).

Various other stimuli have been shown to influence ADH secretion. Increased ADH secretion can be prompted by angiotensin II, pain, increased serum osmolality, hypovolemia, nausea and emesis, hypoglycemia, stress, acute infections, malignancies, nonmalignant pulmonary conditions, and trauma to the hypothalamic–hypophyseal system. Secretion of ADH is inhibited by decreased serum osmolality, hypervolemia, water intoxication, cold, trauma to the hypothalamic–hypophyseal system, carbon dioxide inhalation, and alcohol ingestion. Many drugs affect ADH secretion (Box 42-2).

Anterior Pituitary (Adenohypophysis) Hormones

This anterior lobe of the pituitary gland contains five morphologically different types of cells that secrete polypeptide hormones:

- Somatotrophs, which secrete GH (somatotropin)
- Mammotrophs, which secrete prolactin (luteotropic hormone, or LTH)
- Thyrotrophs, which secrete thyroid-stimulating hormone (TSH)
- Corticotrophs, which secrete adrenocorticotropic hormone (ACTH), β-lipotropin, β-endorphin, and melanocyte-stimulating hormone (MSH)
- Gonadotrophs, which secrete luteinizing hormone (LH) and follicle-stimulating hormone (FSH)

BOX 42-2 Drugs that Influence Antidiuretic Hormone (ADH) Secretion

Drugs That Stimulate ADH Secretion
- Diuretics
- Barbiturates
- Glucocorticoids
- Tricyclic antidepressants
- Carbamazepine
- Chlorpropamide
- Anesthetics
- Acetaminophen

Drugs That Inhibit ADH Secretion
- Alcohol
- Phenytoin
- Narcotics
- Lithium
- Demeclocycline
- Norepinephrine
- Chlorpromazine

Each type of cell is separately regulated by hypophysiotropic hormones (Fig. 42-4).

LTH, LH, and FSH are not significant in the critical care arena and are not discussed in this chapter. TSH, which stimulates cells of the thyroid gland to produce and secrete the two thyroid hormones, is discussed later in this chapter, and GH is described in the following paragraph.

The production and secretion of GH occurs in the anterior pituitary in response to GH-releasing hormone produced in the hypothalamus. Growth-inhibiting hormone inhibits the secretion of GH. GH acts both directly on target cells and indirectly by stimulating the liver and other as-yet-unidentified tissues to secrete various growth factors termed somatomedins. These growth factors are structurally similar to insulin. Direct actions of GH include increasing the breakdown of fats (lipolysis) in adipose cells and releasing the fatty acids produced by lipolysis into the bloodstream (this is termed its ketogenic effect); increasing hepatic glycolysis and thereby increasing plasma glucose levels; increasing the sensitivity of insulin-producing cells to certain stimuli; increasing the cellular uptake of amino acids; and stimulating erythropoiesis.

▲ The Thyroid and Parathyroid Glands

The thyroid gland is a bilobed, richly vascularized structure. The lobes lie lateral to the trachea just beneath the larynx and are connected by a bridge of thyroid tissue, the isthmus that runs across the anterior surface of the trachea (Fig. 42-5). Microscopically, the thyroid is composed primarily of spheroid follicles, each of which stores a colloid material in its center. The follicles produce, store, and secrete the two major thyroid hormones: T_3 and T_4. If the gland is actively secreting, the follicles are small and contain little colloid. Inactive thyroid tissue contains large follicles, each of which possesses a large quantity of stored colloid. Parafollicular cells (C cells), which produce the hormone calcitonin, are scattered between the follicles of the thyroid gland.

Each lobe of the thyroid gland typically contains two parathyroid glands: one in its superior pole and one in its inferior pole. Individual variation exists with respect to the number and distribution of parathyroid glands. Some people have more or fewer than four. Others have parathyroid tissue in the mediastinum. The parathyroid glands produce parathyroid hormone (PTH) that is active with maintaining calcium balance.

Thyroid Hormones

The follicular cells absorb tyrosine (an amino acid) and iodide from the plasma and secrete them into the central colloid portion of the follicle, where they are used in the synthesis of T_3 and T_4. (The subscript refers to the number of iodide molecules that each substance contains.) Two iodide molecules are attached, first one and then the other, to each tyrosine molecule. Two such doubly iodinated tyrosines are combined to form T_4. T_3, which is much more biologically active than T_4, is the predominant form of thyroid hormone

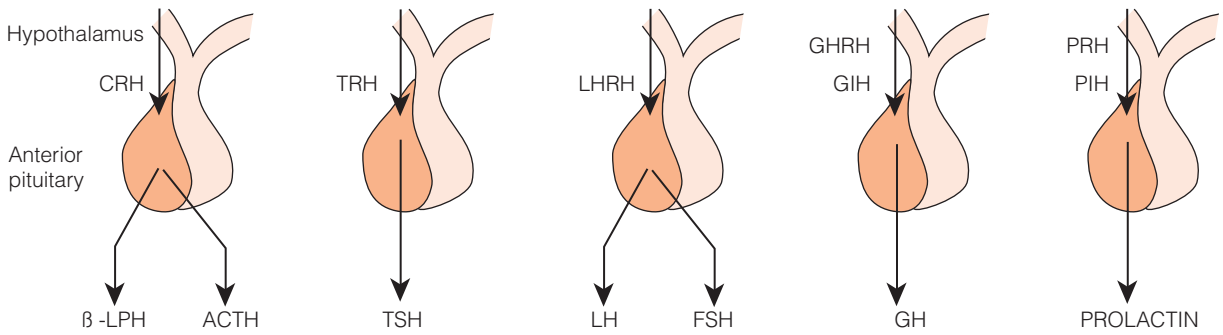

FIGURE 42-4 ▲ Effects of the hypophysiotropic hormones on the secretion of anterior pituitary hormones. The hypophysiotropic hormones are corticotropin-releasing hormone (CRH), thyrotropin-releasing hormone (TRH), luteinizing hormone–releasing hormone (LHRH), growth hormone–releasing hormone (GHRH), growth-inhibiting hormone (GIH), prolactin-inhibiting hormone (PIH); and prolactin-releasing hormone (PRH). CRH prompts the release of β-lipotropin (β-LPH) and adrenocorticotropic hormone (ACTH). TRH prompts the release of thyroid-stimulating hormone (TSH). LHRH prompts the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). GHRH and GIH promote and inhibit the secretion of GH, respectively. PRH and PIH promote and inhibit the secretion of prolactin, respectively.

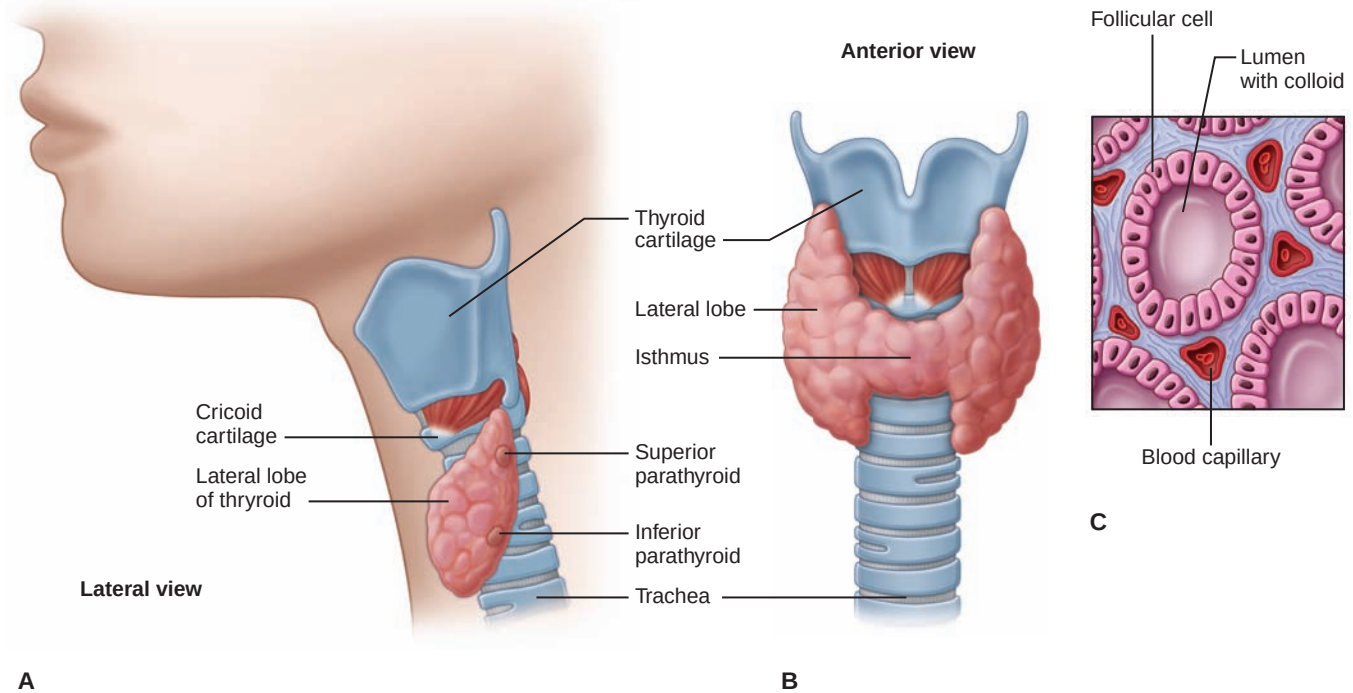

FIGURE 42-5 ▲ **A-C:** The thyroid gland. (Adapted from Porth CM, Matfin G: Pathophysiology: Concepts of Altered Health States, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 1031.)

produced and is formed by the combination of a doubly iodinated tyrosine with a singly iodinated one. Because of the role of iodine in the manufacture of thyroid hormones, storage and release of small amounts of radioactive iodine by the thyroid can be used to measure the activity of this gland. Because the thyroid gland is virtually the only tissue of the body that absorbs and stores iodine, larger amounts of radioactive iodine can be used to destroy portions of the thyroid gland as a treatment for hyperthyroidism.

T_3 and T_4 are stored in the colloid until they are needed. When they are to be secreted, the follicular cells transport them from the colloid to the plasma. Less than 1% of the secreted T_3 and T_4 remains free and physiologically active in the plasma. The remainder is bound to plasma proteins. The plasma proteins involved in transporting T_3 and T_4 are manufactured in the liver. Consequently, liver damage that decreases the plasma levels of these proteins can produce a condition resembling thyroid hormone excess (ie, hyperthyroidism). Plasma levels of these proteins can also be depressed by glucocorticoids, androgens, and L-asparaginase (an antineoplastic drug). They are elevated during pregnancy, and by estrogens, opiates, clofibrate, and major tranquilizers. Thyroid hormones are deiodinated and catabolized by the liver, kidneys, and various other tissues. A small amount of degraded hormone is added to the bile secreted by the liver and is excreted in the stool.

T_3 directly crosses target cell membranes, whereas T_4 is changed into T_3 by target cell membranes before crossing. The conversion of T_4 to T_3 occurs in the peripheral tissues of the liver and kidneys and accounts for 80% of the T_3 available for metabolic activity. T_4 is 100% produced in the thyroid.

The actions of thyroid hormones are widespread and apparently arise from their stimulation of the basal metabolic rate of most tissues (excluding tissues of the brain, anterior pituitary, spleen, lymph nodes, testes, and lung). Thyroid hormone increases the number of β_1- and β_2-adrenergic receptors in various tissues and the affinity of these receptors for catecholamines; thus, an increased heart rate and sweating often occur in hyperthyroidism. Thyroid hormones increase the catabolism of skeletal muscle proteins to such a degree that pronounced muscle weakness results from prolonged hyperthyroidism (thyrotoxic myopathy). Thyroid hormones increase the rate of carbohydrate absorption from the small intestine and decrease circulating levels of cholesterol.

Thyroid hormones are essential for the normal growth and development of many body systems, notably the skeletal and nervous systems. These hormones stimulate the secretion of GH and potentiate its effect on various tissues. Thyroid hormones are also necessary for normal levels of neuronal functioning. Thyroid insufficiency leads to slowed reflexes, slowed mentation, and decreased level of consciousness (through decreased levels of reticular activating system activity). Hyperthyroidism lowers synaptic thresholds in the central nervous system (CNS), causing hyperreflexia and a fine muscle tremor. The pervasive effects of thyroid hormones on the nervous system are best illustrated by cretinism, a condition resulting from congenital thyroid insufficiency.

The secretion of T_3 and T_4 by the thyroid gland is primarily regulated by the secretion of TSH from the anterior pituitary. In turn, TSH secretion is regulated by a hypothalamic neurosecretory material termed thyrotropin-releasing hormone (TRH). After receiving stimuli from TRH from the hypothalamus, the thyroid secretes TSH to stimulate the manufacture and secretion of T_3 and T_4. A negative feedback regulatory loop exists whereby increased levels of free (unbound) T_3 and T_4 suppress TSH secretion. Decreased

plasma TSH results in decreased thyroid function, which causes a fall in free plasma T_3 and T_4. Low T_3 and T_4 levels stimulate TSH secretion. If a TSH-induced increase in thyroid activity does not raise the plasma levels of free T_3 and T_4, the continued high levels of TSH eventually cause an increase in the size of the thyroid gland (nontoxic goiter). In this case, an enlarged thyroid is not associated with overproduction of hormone. This feedback loop maintains homeostasis of the daily secretion of TSH and thyroid hormones.

Calcitonin and Parathyroid Hormone

Calcitonin, which is secreted by the parafollicular cells of the thyroid gland, and PTH, which is produced and secreted by the parathyroid glands, exert a major influence on calcium metabolism in conjunction with 1,25-dihydroxycholecalciferol, which is produced by the action of the liver and the kidneys on vitamin D. Ultraviolet light changes 7-dehydrocholesterol provitamins in the skin to a group of compounds, collectively called vitamin D. One of these, D_3, can also be obtained from vitamin D–enriched and other foods. The liver converts D_3 to 25-hydroxycholecalciferol, which is then altered by kidney cells to a more active form, 1,25-dihydroxycholecalciferol. (The hypocalcemia seen in chronic renal disease results from an activated vitamin D deficiency.) Activated vitamin D acts on intracellular enzymes of the intestinal mucosal cells to increase calcium absorption. To a lesser extent, it also increases the active transport of calcium out of osteoblasts into the bloodstream. Both of these actions elevate plasma calcium levels. In vitamin deficiency states, the effect of decreased intestinal absorption outweighs any decrease in the mobilization of calcium from bone to produce an overall hypocalcia and poor mineralization of bone.

Vitamin D is synthesized in the skin, absorbed in the small intestine, and transported into the plasma bound to vitamin D–binding proteins. The metabolism of vitamin D is strictly regulated by phosphate concentration in the kidney and by PTH. Thus, the effect of a decrease in dietary phosphate or serum phosphate is to increase levels of 1,25-dihydroxycholecalciferol.

Parathyroid Hormone

PTH is a polypeptide produced and secreted by the chief cells of the parathyroid glands. This hormone is stored in secretory granules and released in response to a decrease in ionized calcium concentrations. It is cleaved into active form in the kidneys and liver. Plasma calcium and phosphate levels operate in a negative feedback loop to influence the activity of the renal enzyme system, which catalyzes the conversion of metabolically inactive vitamin D to the metabolically active form. High plasma calcium levels decrease this activation process, whereas low levels increase it. The formation of activated vitamin D is also facilitated by PTH and decreased by metabolic acidosis and hypoinsulinemia (diabetes mellitus).

PTH is transported free (unbound) in the plasma, has a half-life of less than 20 minutes, and is metabolically degraded by cells in the liver. A decrease in calcium concentration increases PTH secretion. PTH acts on two target tissues: bone cells and kidney tubules. In bone, it stimulates osteoclast activity and inhibits osteoblast activity. This results in bone reabsorption with consequent mobilization of calcium and phosphate from the bony matrix into the bloodstream. In the kidney, PTH increases the reabsorption of calcium by distal tubule cells and decreases the reabsorption of phosphate by proximal tubule cells. The effect of these multiple actions is elevation of plasma calcium levels and lowering of plasma phosphate levels.

Plasma calcium levels alter PTH secretion through a negative feedback loop. Secretion is inhibited by high plasma calcium levels and stimulated by low blood levels of calcium. The activated vitamin D deficiency–induced hypocalcemia, which occurs in chronic renal failure, typically produces a secondary hyperparathyroidism. Secretion of PTH by the parathyroid gland is also stimulated by hypomagnesemia, adrenergic agonists, and prostaglandins.

Calcitonin

This polypeptide hormone is produced by the parafollicular cells (C cells) of the thyroid gland. It can also be secreted by nonthyroidal tissue (eg, tissue of the lung, intestine, pituitary, and bladder). Calcitonin is transported unbound in the plasma. It has a half-life of 5 minutes and is predominantly metabolized in the kidney. Calcitonin lowers plasma calcium and phosphate levels by inhibiting osteoclastic bone reabsorption and increasing urinary phosphate and calcium excretion. Calcitonin levels are elevated during pregnancy and lactation, suggesting that calcitonin may help to protect the mother's skeleton from excess calcium loss during these periods of calcium drain.

Calcitonin does not function in the normal daily homeostasis of plasma calcium levels. It appears to serve more of an emergency function in that it is secreted only if the plasma calcium level exceeds 9.3 mg/dL. At high blood calcium levels, calcitonin secretion is stimulated by increased levels of plasma calcium. Calcitonin is also released by the action of gastrin, glucagon, and secretion of gastrointestinal hormones.

Table 42-2 summarizes the hormones secreted by the thyroid and parathyroid glands.

Table 42-2 Hormones of the Thyroid and Parathyroid Glands and Their Actions

Gland	Hormone	Action
Thyroid gland	Thyroxine (T_4)	Controls basic metabolic rate
	Triiodothyronine (T_3)	Induces growth and development
		Inhibits bone resorption
	Calcitonin	Inhibits calcium reabsorption in gastrointestinal tract
		Increases calcium excretion from kidney
Parathyroid gland	PTH	Promotes bone resorption
		Increases calcium reabsorption
		Increases calcium blood levels

▲ The Endocrine Pancreas

The pancreas lies transversely under the stomach between the duodenum and spleen. Because of its posterior position, it is essentially hidden and is not palpable. The pancreas has both endocrine and exocrine functions, which are under the control of different groups of cells. The organ is made up of two tissue types: the acini, the exocrine portion, and the islets of Langerhans, the endocrine portion. The acini secrete digestive enzymes into the duodenum, whereas the islets of Langerhans secrete hormones into the blood.

The islets of Langerhans secrete the peptide hormones involved in blood glucose regulation. The name "islets of Langerhans" refers to the more than 1 million ovoid islands (clusters) of cells that are scattered throughout the pancreas, predominantly in the tail. Because of this distribution of islet cells, acute attacks of pancreatitis, which usually spare the tail, tend to spare the islets. Episodes of chronic recurrent pancreatitis typically involve the entire pancreas. Consequently, chronic episodes can cause islet cell destruction and diabetes mellitus.

Each cell cluster is richly supplied with capillaries, into which its hormones are secreted. The islets are composed of four types of cells: α cells, which secrete glucagon; β cells, which secrete insulin; δ cells, which secrete somatostatin; and F cells, which secrete pancreatic polypeptide. The hormones secreted by the pancreas are summarized in Table 42-3.

Insulin

Insulin, an anabolic hormone, is regulated by a number of stimulatory and inhibitory factors. It is responsible for the control of blood glucose concentrations and storage of carbohydrate, proteins, and fats. Insulin facilitates the use of glucose as the main source of energy for most body tissues. Insulin is the only hormone with the ability to directly lower the blood glucose level. Also, insulin facilitates an increase in the cellular transport of glucose, amino acids, and fatty acids across cell membranes and modulates intracellular metabolic synthesis of nucleic acids. Cell membranes require a glucose transporter to carry glucose into the cell at a faster rate than diffusion. GLUT-4 is the glucose transporter for skeletal muscle and adipose tissue, and GLUT-2 carries glucose into β cells and liver tissue.

The precursor of insulin, proinsulin, is manufactured in the β cells of the islets of Langerhans. Proinsulin can be thought of as a "necklace" of amino acid beads and is stored as secretory granules in another cell structure. Proinsulin can be found in the plasma as a result of certain islet tumors (insulinoma) or overstimulation of the β cells. Connecting peptide (C-peptide) is a biologically inactive chain and is secreted into the bloodstream along with insulin. Because there is a 1:1 ratio between C-peptide and insulin, plasma C-peptide levels can be used to measure endogenous insulin secretion or degree of β-cell activity. Clinically, C-peptide levels can assist with distinguishing between types 1 and 2 diabetes (C-peptide is low in type 1 diabetes, reflecting autodestruction of β cells and no further production of insulin).[1]

The actions of insulin are summarized in Box 42-3. In addition to facilitating glucose uptake by muscle and adipose cells, insulin facilitates glucose uptake by connective tissue, leukocytes, mammary glands, the lens of the eye, the aorta, the pituitary gland, and α islet cells. In general, insulin enables glucose to be readily available for aerobic oxidation in muscle, adipose, and connective tissue cells. Facilitation of the preferential use of glucose as cellular fuel means that the cells do not need to oxidize fatty or amino acids. Instead, these can be conserved. Protein synthesis and fat storage are increased in liver, muscle, and adipose tissue. Breakdown of fats and proteins is decreased. Hepatic gluconeogenesis also is decreased or halted, and glycogen synthesis is increased.

Insulin acts only on a few types of tissues. However, the membranes of nearly all types of body cells possess insulin receptors. Binding of insulin to the insulin receptors initiates the physiological action of insulin on the cell. Plasma insulin has a half-life of approximately 5 minutes. About 80% of all circulating insulin is catabolized by liver and kidney cells.

Insulin secretion is influenced by a variety of factors as listed in Box 42-4. Monosaccharides are the primary regulatory mechanism for insulin secretion. Elevated plasma levels

Table 42-3 Hormones of the Pancreas and Their Actions

Hormone	Cell	Stimulant	Response
Insulin	β	Glucose	Decreased glucose level Increased fat storage Increased protein synthesis Increased glucogenesis
Glucagon	α	Decreased glucose level, exercise	Increased glucose level Increased gluconeogenesis Increased glycogenolysis
Somatostatin	δ	Hyperglycemia	Increased glucose Increased glycogen
Pancreatic polypeptide	F	Acute hypoglycemia	Increased gallbladder contraction Increased pancreatic enzymes

BOX 42-3 Major Actions of Insulin on Adipose and Muscle Cells

Muscle Cells	Adipose Cells
Increased glucose entry	Increased glucose entry
Increased K^+ uptake	Increased K+ uptake
Increased glycogen synthesis	Increased fatty acid entry and synthesis
Increased amino acid entry	Increased fat deposition
Increased protein synthesis	Increased conversion of glucose to fatty acids
Decreased protein catabolism	Inhibition of lipolysis
Increased ketone entry into cells	

BOX 42-4 Factors Affecting Insulin Secretion

Stimulators	Inhibitors
Glucose	Somatostatin
Mannose	2-Deoxyglucose
Amino acids (leucine, arginine, others)	Mannoheptulose
Intestinal hormones (gastric inhibitory peptide, gastrin, secretin, cholecystokinin, glucagon, others)	α-Adrenergic-stimulating agents (norepinephrine, epinephrine)
β-Keto acids	β-Adrenergic-blocking agents (propranolol)
Acetylcholine	Diazoxide
Glucagon	Thiazide diuretics
Cyclic adenosine monophosphate (AMP) and various cyclic AMP–generating substances	Phenytoin
β-Adrenergic-stimulating agents	Alloxan
Theophylline	Microtubule inhibitors
Sulfonylureas	Insulin

of glucose act in a negative feedback loop to increase the secretion of insulin. Lower levels of glucose decrease insulin output. Glucagon, β-adrenergic agonists, and theophylline increase insulin secretion. β Cells are also stimulated to secrete insulin by tolbutamide and other sulfonylurea derivatives; acetylcholine; impulses from vagal nerve branches to the islets; selected amino acids, such as arginine; and β-ketoacids. The mechanisms of action of these stimuli are as yet unclear. Insulin production is inhibited by α-adrenergic agonists, β-adrenergic blocking agents, diazoxide (Proglycem), thiazide diuretics, phenytoin (Dilantin), alloxan, agents that prevent glucose metabolism (eg, 2-deoxyglucose and mannoheptulose), somatostatin, and insulin itself.

Chronic stimulation of β cells, such as by a high-carbohydrate diet for several weeks, can cause a limited amount of hypertrophy and subsequent increase in the insulin-producing capacity. However, overstimulation produces β-cell exhaustion. Stimulation of these exhausted cells produces β-cell death and depletes the β-cell reserve. β-Cell activity is also decreased by the administration of exogenous insulin. Such decreased activity enables the cells to rest and results in temporary hyperproduction after the withdrawal of exogenous insulin.

Insulin Resistance

Insulin resistance, characteristic of type 2 diabetes, is the main defect seen with the development of hyperglycemia, hyperinsulinemia, and consequent β-cell exhaustion. Insulin resistance is a physiological condition in which a person needs more insulin to lower serum glucose effectively than would normally be required. To compensate for insulin resistance, the pancreas secretes more insulin in an attempt to maintain normal glucose levels. The degree of obesity directly affects the resistance to insulin in most patients with type 2 diabetes. One principal mechanism may be a defect in insulin receptor function because of a genetic mutation of the insulin receptor gene. The quantity and activity of insulin receptors also can be regulated by various factors. Increased amounts of insulin, obesity, acromegaly, excess glucocorticoids, and human immunodeficiency virus therapies can exacerbate insulin resistance by decreasing the receptors' number or activity, or both. Exercise and decreased circulating levels of insulin increase the activity of insulin receptors[2]; therefore, leading a sedentary lifestyle may contribute to insulin resistance.

Insulin resistance plays a role in other metabolic abnormalities including obesity, high levels of triglycerides, low levels of (HDL) lipoproteins, hypertension, and systemic inflammation, macrovascular disease, and abnormal fibrinolysis. These signs and symptoms are called metabolic syndrome, and obesity is the major factor that leads to the development of type 2 diabetes.

Additional conditions play a role in the pathogenesis of type 2 diabetes mellitus: β-cell dysfunction and excess hepatic glucose production that contributes to hyperglycemia. β-Cell dysfunction results when the pancreas is unable to meet the high demands for insulin because of insulin resistance. When type 2 diabetes mellitus is diagnosed, approximately 50% of β-cell function is already lost.

Several theories explain the development of β-cell dysfunction:

- Cell exhaustion results when the pancreas must keep up with the higher demands for insulin. Some functional and morphological changes occur to compensate for the increased demand, but eventually β-cell exhaustion occurs.
- Chronic hyperglycemia leads to the development of glucotoxicity—direct toxicity to the β cells.
- Chronic exposure of β cells to excess free fatty acids damages them, leading to lipotoxicity.
- Apoptosis, or programmed cell death, occurs secondary to chronic glucotoxicity and lipotoxicity. This leads to progressive β–islet cell loss.
- Abnormal deposition of amyloid matter leads to islet cell destruction.[3]

Insulin resistance interferes with normal cellular interactions between insulin, skeletal muscles, and adipose tissues. Insulin binds with cell surface receptors, causing a cascade of intracellular signals; this results in the translocation of glucose transporter cells to cell surfaces and allows entry of glucose into the cell. In addition, insulin may bind normally to receptors but has to work with disrupted signals, resulting in insufficient translocation of glucose transporter molecules. This ultimately leads to excess glucose accumulation.[2]

Insulin resistance triggers β cells to produce more insulin as a compensatory mechanism. Hyperinsulinemia initially meets the additional needs created by excess glucose. However, when β-cell function fails to satisfy these demands, hyperglycemia and type 2 diabetes mellitus ensue. This is termed the dual phenomenon or dual abnormality: insulin resistance and β-cell dysfunction.[3] Data from a landmark trial, the United Kingdom Prospective Diabetes Study, suggest that the process of declining β-cell function occurs for approximately 10 years before the diagnosis of type 2 diabetes is made.[4]

Glucagon

Glucagon, a polypeptide hormone, is manufactured and secreted by the α cells of the islets of Langerhans and is stimulated by pure protein meal ingestion that produces

an aminoacidemia. The half-life of plasma glucagon is 5 to 10 minutes. Glucagon influences enzyme systems in liver, fat, and muscle cells and is degraded mainly by the liver.

The major function of glucagon, which stimulates the synthesis of the gluconeogenic enzyme fructose-1,6-biphosphate, is to elevate blood glucose levels and then to enable this plasma glucose to enter and be used by the cells of the body (eg, the muscle cells) by stimulating the secretion of insulin. In this manner, glucagon prevents hypoglycemia between meals, during exercise, during the first few days of fasting, and after a high-protein meal. Dietary protein stimulates an increase in plasma insulin, which causes a rapid cellular uptake of absorbed dietary carbohydrates.

To elevate blood glucose levels, glucagon stimulates liver cells to perform glycogenolysis and gluconeogenesis. This increases the glucose concentration in liver cells, and because these cells can dephosphorylate intracellular glucose, this glucose can be released from the liver into the bloodstream. The fatty acids and amino acids needed for gluconeogenesis are supplied by the glucagon-stimulated breakdown of fats in adipose cells and the release of fatty acids into the bloodstream. If the supply of fatty acids is insufficient, glucagon also stimulates the breakdown of proteins into amino acids in muscle cells and the release of amino acids into the plasma. These fatty acids and amino acids are then taken up by hepatocytes and used as raw materials in gluconeogenesis. Glucagon also elevates plasma ketone levels by increasing hepatic ketone production, and promotes the secretion of somatostatin and GH.

Although glucagon opposes the effects of insulin on blood glucose levels, it also stimulates the secretion of insulin. This apparent contradiction is actually a logical second step in the biological function of this hormone. It enables the increased plasma glucose to enter and be used by various tissues. An elevated plasma glucose level stimulates insulin secretion, but this takes a while. The direct action of glucagon on β cells simply is faster.

As is the case with β cells, α cells are stimulated by β-adrenergic agonists, theophylline, elevated plasma levels of dietary amino acids (primarily those used in gluconeogenesis), and vagal (cholinergic) stimulation. Glucagon secretion is also prompted by glucocorticoids (eg, cortisol), catecholamines, GH, cholecystokinin (CCK), and gastrin. Exercise, physical stress, and infections also increase α-cell activity. Whereas the effects of exercise on glucagon secretion appear to be mediated by increased β-adrenergic activity, stress and infection probably operate by increasing plasma glucocorticoid levels. Dietary amino acids are believed to enhance glucagon secretion by their effects on CCK or gastrin, or both, because intravenous amino acids exert little or no effect on α cells.

Elevated plasma glucose levels enact a negative feedback loop to retard or halt the output of glucagon; however, plasma insulin must be present for this mechanism to operate. Like β-cell secretion, α-cell secretion is inhibited by adrenergic agonists, phenytoin, and somatostatin. Fatty acids and ketone bodies in the plasma can inhibit glucagon secretion, but this inhibition must be weak because plasma glucagon levels can be quite elevated during diabetic ketoacidosis.

In addition to glucagon, other hormones—cortisol, epinephrine, and GH—have great influence on the regulation of glucose and insulin. These counter-regulatory hormones have a synergistic effect on glucose production as a mechanism to protect the body during stress. They act to inhibit insulin while increasing glucagon, producing an insulin-resistant state, and increasing overall serum glucose levels to produce sufficient energy levels during "fight-or-flight" responses. These hormones elevate serum glucose levels to protect against hypoglycemia and to prepare the body for stress. However, they can also further aggravate a state of hyperglycemia and can lead to dangerous levels of glucose, as seen in diabetic emergencies.[5]

Another group of hormones, incretins, are released by the gut in response to nutrient ingestion. One hormone, glucagon-like peptide-1, is a potent insulin secretagogue released from the L cells in the distal small bowel that will assist with assimilating nutrients. It has a short half-life, inhibits glucagon secretion, delays gastric emptying, and reduces appetite and food intake. When used pharmacologically, incretins can lower blood glucose substantially.[6,7]

Somatostatin

This tetradecapeptide is produced not only by the δ cells of the pancreas but also by the hypothalamus, where it functions as an inhibitor of anterior pituitary GH secretion; neurons of the CNS, where it probably functions as a synaptic neurotransmitter agent; and δ cells in the gastric mucosa, where it inhibits the secretion of gastrin and other lesser known gastrointestinal hormones. Islet cell somatostatin is secreted into the bloodstream and therefore functions as a hormone. Little is known of the metabolism of somatostatin because it is so tightly bound with the actions of GH.

Somatostatin inhibits the release of insulin and glucagon from the pancreas. Pancreatic somatostatin inhibits the activity of all other islet cells. The biological significance of this action is not yet known. The only clinical data of relevance concern δ-cell tumors. These produce a clinical picture that resembles diabetes mellitus but that is reversible with tumor ablation. The secretion of somatostatin from islet cells is increased by glucose, certain amino acids, and CCK. Factors that inhibit islet somatostatin secretion are unknown.

Pancreatic Polypeptide

Not much is known about this islet hormone in humans. It is produced by the endocrine cells found in small clusters of cells located between the cells of the islets of Langerhans and the acinar cells of the pancreas. Its secretion in humans is enhanced by dietary protein, exercise, acute hypoglycemia, and fasting. Somatostatin and elevated plasma glucose levels decrease the secretion of this polypeptide. No definite actions of this hormone have been established for humans, but it appears to have a role in smooth muscle relaxation of the gallbladder.

▲ The Adrenal Glands

The adrenal glands lie at the superior pole of each kidney retroperitoneally. Each gland is composed of an inner core, the medulla, surrounded by an outer layer, the cortex (Fig. 42-6). Although they are structurally related, the medulla and cortex are derived from different embryological tissues and function as separate entities. The hormones produced by the adrenal glands are summarized in Table 42-4.

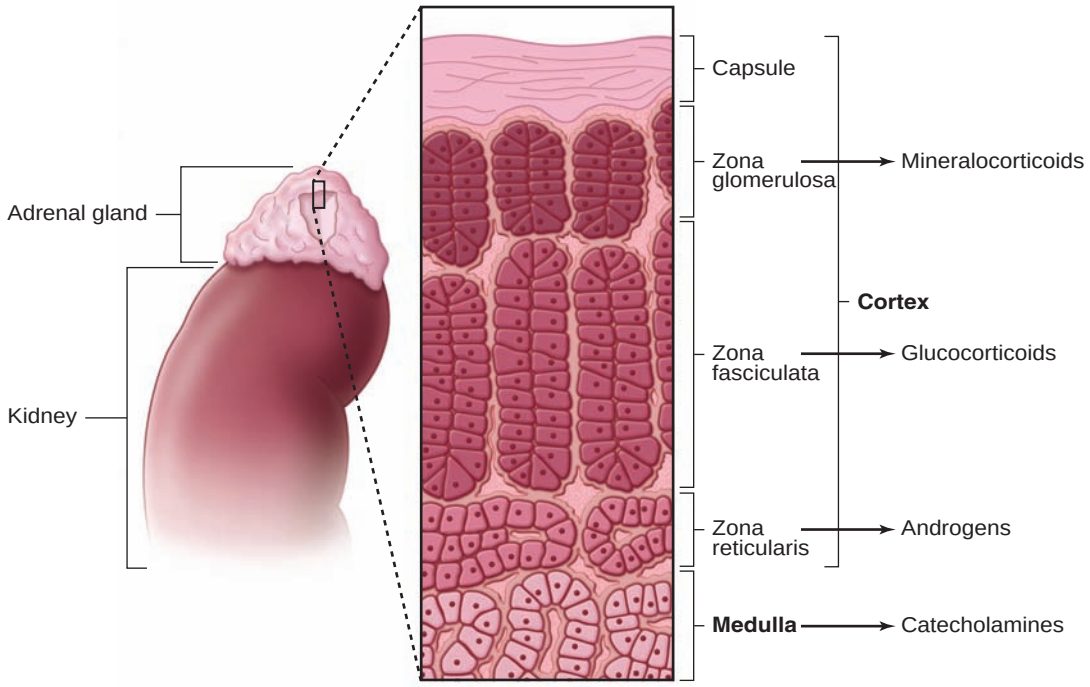

FIGURE 42-6 ▲ The adrenal gland has a cortex and a medulla. (Adapted from Seifter J, Ratner A, Sloane D: Concepts in Medical Physiology. Philadelphia, PA: Lippincott Williams & Wilkins, 2005, p 541.)

Medullary Hormones

The adrenal medulla is basically a modified sympathetic ganglion. The axons of preganglionic sympathetic neurons arrive from the thoracic cord by way of splanchnic nerves. They synapse in the adrenal medulla with modified postganglionic cells that have lost their axons and secrete chemicals directly into the bloodstream. Therefore, the adrenal medulla may appropriately be viewed as an endocrine extension of the autonomic nervous system.

Four chemicals are produced and secreted in the adrenal medulla by two morphologically different cell types:

- Dopamine, a precursor of norepinephrine
- Norepinephrine, the typical product of postganglionic sympathetic neurons
- Epinephrine, a methylated version of norepinephrine
- Opioid peptides (enkephalins).

Table 42-4 Hormones of the Adrenal Gland and Their Actions

Gland	Hormone	Action
Adrenal gland cortex	Mineralocorticoids	Reabsorption of sodium Elimination of potassium
	Glucocorticoids	Responds to stress Decreases inflammation Alters metabolism of protein and fat
Medulla	Epinephrine	Stimulates sympathetic system
	Norepinephrine	Increases peripheral resistance

Not much is known about the opioid peptides. The specific stimulus for their secretion has yet to be identified, and their physiological actions are unknown, as are their metabolism and fate. Dopamine, norepinephrine, and epinephrine are collectively termed catecholamines. They are stored in granules in the medullary cells. The secretion of these chemicals is triggered by stimulation of the preganglionic neurons that innervate the medulla. This causes the neurons to release acetylcholine, which in turn prompts the medullary cells to secrete. The half-life of plasma catecholamines is approximately 2 minutes. These compounds are rapidly degraded by plasma renal and hepatic catechol-*O*-methyltransferase enzymes into vanillylmandelic acid, metanephrine, and normetanephrine, which are excreted in the urine. Measuring urine levels of these compounds is significant if an adrenal tumor, pheochromocytoma, is suspected. In this case, the levels will be high, indicating that a catecholamine secreting tumor is likely.

Predictably, the epinephrine and norepinephrine secreted by the adrenal medulla mimic the effects of a mass discharge from sympathetic neurons. However, apart from this, they produce several metabolic actions. First, they elevate blood glucose levels by activating an enzyme, phosphorylase, which promotes hepatic glycogenolysis. Because liver cells possess the enzyme glucose-6-phosphatase, the glucose produced by this glycogen breakdown is able to diffuse out of hepatocytes and into the bloodstream. These hormones also induce muscle cells to participate in elevating blood glucose levels, although this process is less direct. These hormones can also elevate plasma glucose levels by stimulating the secretion of glucagon and can increase the uptake of glucose into body tissues by stimulating the secretion of insulin. Epinephrine and norepinephrine can also produce the opposite effects by stimulating α-adrenergic receptors on islet cells. Because of differential effects of both hormones on α- and β-adrenergic

receptors, the result is that epinephrine elevates plasma glucose levels much more than does norepinephrine.

A second metabolic effect of catecholamines is promotion of lipolysis in adipose tissue. This elevates plasma-free fatty acid levels and provides an alternative energy source for many body cells. Circulating catecholamines also increase alertness by stimulating the reticular activating system. Last, these hormones produce an increase in the metabolic rate of the body and a cutaneous vasoconstriction, both of which result in an elevation in body temperature. However, the accelerated metabolism requires the presence of the thyroid and adrenal cortex hormones.

Although the physiological action of adrenal medullary dopamine is unknown, exogenous dopamine is useful in combating certain shocks because it has a positive inotropic effect on the heart (by way of β receptors) and produces renal vasodilation and peripheral vasoconstriction. The overall effect of moderate dosages is elevation of systolic blood pressure (without an appreciable increase in diastolic blood pressure) together with retention or restoration of renal output.

Stimulation of the adrenal medulla glands is part of a general sympathetic–adrenal medulla (SAM) response to exercise and to perceived threats to biopsychological integrity and survival. (Cannon called the latter the "fight-or-flight" response.) Hypoglycemia also stimulates increased adrenal medullary secretion. The results of the SAM response enable the body to perform vigorous physical exertion optimally. The heart rate and blood pressure are increased (increasing perfusion), and blood flow is shunted away from the skin and gastrointestinal tract to more vital organs for exertion, such as skeletal muscles, brain, and heart. The reticular activating system is stimulated, fostering alertness. Blood glucose and fatty acid levels are raised, thereby increasing the available energy sources for cells. Pupils are dilated, increasing the field of peripheral vision and the amount of light entering the eyes. Sweat glands are stimulated, cooling the body in advance of and during the time that the body temperature is elevated as the result of the physical exertion. Most of this SAM response is mediated by sympathetic nerve fibers to various body structures; circulating catecholamines play only a minor role. Furthermore, many tissue responses (eg, those of muscle cells) to such sympathetic demands require glucocorticoids to enable the tissues to meet the demands of the SAM response, and the SAM response often accompanies the stress-induced secretion of adrenal steroids discovered by Selye. (This and the endocrine response to physical and psychological stress are discussed in the section on cortical hormones.)

Cortical Hormones

The adrenal cortex is composed of three histologically different layers (see Fig. 42-6).

Its exterior is covered by a capsule. The outermost layer, the zona glomerulosa, lies just beneath the capsule. It produces and secretes primarily mineralocorticoids, such as aldosterone. The inner two layers, the zona fasciculata and zona reticularis, manufacture and secrete glucocorticoids (cortisol and corticosterone) and adrenal androgens and estrogens. If these inner cortical layers are destroyed, they can be regenerated from zona glomerulosa cells.

Figure 42-7 depicts the metabolic pathways for synthesis of all adrenocortical hormones. Each of these metabolic steps is governed by a specific enzyme. Genetic deficiencies in one or more of these enzymes produce syndromes involving the underproduction or overproduction of various cortical hormones. Drugs that inhibit specific enzymes are used clinically

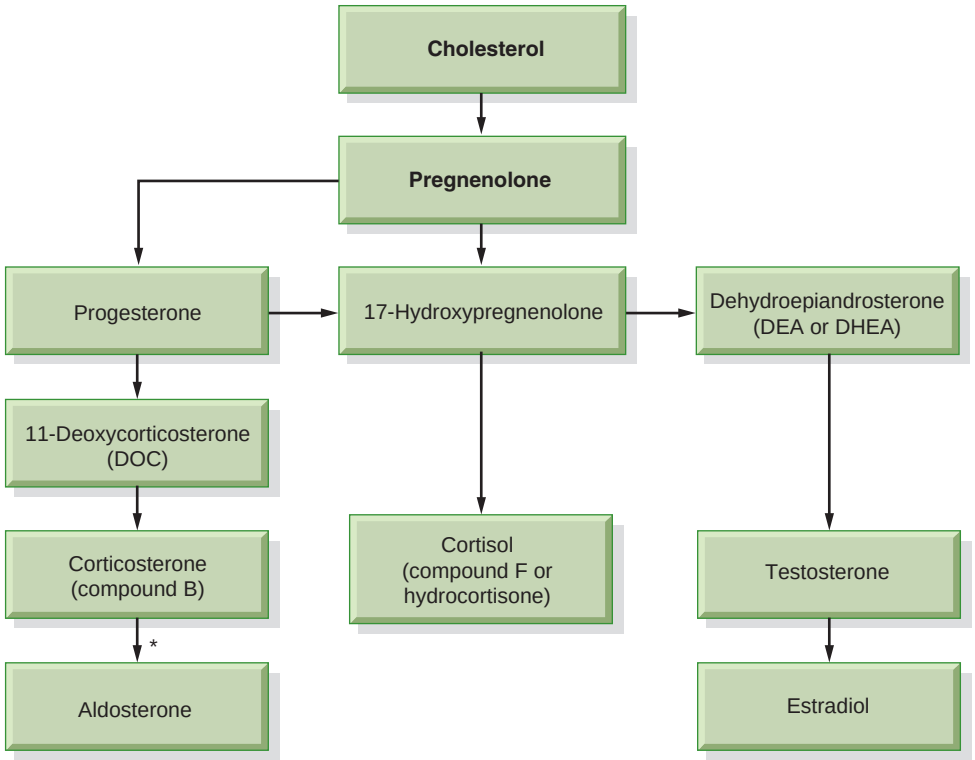

FIGURE 42-7 ▲ Biosynthetic pathways for adrenal cortical hormones. Only cells of the zona glomerulosa can convert corticosterone to aldosterone (*asterisk*). All the other pathways can be carried out by cells in all three layers of the adrenal cortex.

to assess cortical function. One such drug is metyrapone, which inhibits cortisol synthesis.

After secretion, plasma cortisol and, to a lesser extent, corticosterones are bound to a plasma globulin called corticosteroid-binding globulin (CBG), or transcortin. Only the unbound hormones are physiologically active. The bound glucocorticoids serve as a hormone reservoir that is used to replace degraded unbound hormones. The half-lives of plasma corticosterone and cortisol are approximately 50 and 80 minutes, respectively. CBG is manufactured by liver cells. Therefore, decreased hepatic function (eg, cirrhosis) can lead to subnormal quantities of plasma CBG, resulting in excess quantities of circulating unbound, active glucocorticoids, leading to hyperdynamic circulation. Only a small amount of aldosterone is bound to plasma proteins. Its half-life is approximately 20 minutes.

Adrenal steroids are degraded by the liver. Depressed hepatic function can retard the degradation of adrenal steroids, thereby producing a clinical picture of hormone excess. The soluble degraded steroid metabolites are excreted by the kidneys.

Glucocorticoids

As the name glucocorticoid suggests, cortisol and corticosterone influence glucose metabolism. They elevate plasma glucose levels by promoting hepatic gluconeogenesis and glycogenolysis. To facilitate gluconeogenesis, these hormones cause the breakdown of fat and proteins and the release of fatty and amino acids into the bloodstream, which carries them to the liver. Excessive gluconeogenesis can lead to severe hyperglycemia often seen in diabetic patients receiving glucocorticoids.

Glucocorticoids enable tissues to respond to glucagon and catecholamines; they also prevent rapid fatigue of skeletal muscle. Cortisol and corticosterone also act on the kidneys to permit the excretion of a normal water load in one of three ways: glucocorticoids make distal or collecting tubules more permeable to the reabsorption of water independently of sodium reabsorption, they increase the glomerular filtration rate (GFR), or they reduce the output of ADH.

The effects of glucocorticoids on plasma components are mixed. They decrease the number of plasma eosinophils and basophils but increase the number of circulating neutrophils, platelets, and erythrocytes. By suppressing production and increasing destruction, glucocorticoids decrease the number of lymphocytes. They also decrease the size of lymph nodes. A major function of lymphocytes is to provide either humoral immunity (with antibodies) or cell-mediated immunity. Stress-induced elevations in glucocorticoid secretion and the resulting decrease in lymphocytes may explain the decrease in immunocompetence that often occurs in people who are under psychological or physical stress.

Other effects of physiological levels of glucocorticoids include decreasing olfactory and gustatory sensitivity. People with adrenal insufficiency can detect various chemicals (eg, sugar, salt, urea, and potassium chloride) by either taste or smell with a sensitivity that is 40 to 120 times greater than normal.

The effects of pharmacological dosages of glucocorticoids are considered separately from those of normal physiological levels. In pharmacological dosages, glucocorticoids possess immunosuppressive, anti-inflammatory, and antihistaminic activity. Glucocorticoids suppress the immune system by inhibiting the production of interleukin-2 by T4 (helper) lymphocytes. Decreases in interleukin-2 reduce the proliferation of T8 (suppressor, cytotoxic) T cells and B lymphocytes. Glucocorticoids act in several ways to suppress the inflammatory response, including the influx of phagocytes and the activation of complement and kinins.

Conversely, glucocorticoids can be of great benefit in the treatment of certain noninfective inflammatory conditions (eg, rheumatoid arthritis and systemic lupus erythematosus). Glucocorticoids can also be beneficial in treating certain allergies (eg, asthma, hives, and minimal-change glomerular disease) because they prevent the release of histamines from mast cells. Their use as immunosuppressives enables patients to receive organ transplants. In any case, the potentially deleterious side effects of glucocorticoids usually require that they be used only after other treatments (eg, nonsteroidal anti-inflammatory drugs [NSAIDs] or antihistamines) have failed or if the benefits clearly outweigh the risks (eg, in renal disease or with organ transplants). In addition to immunosuppression, glucocorticoids trigger the development of all or part of Cushing's syndrome (eg, diabetes, hypertension, protein wasting, and osteoporosis) and inhibit growth in infants and children. The pharmacological and physiological actions of glucocorticoids are summarized in Table 42-5.

Regulation of glucocorticoid secretion is outlined in Figure 42-8. The secretion of glucocorticoids is triggered by the release of corticotropin-releasing hormone (CRH), a neurosecretory material released by the hypothalamus. CRH stimulates the cells of the anterior pituitary to secrete ACTH. Without the stimulus of ACTH, the cells of the zona fasciculata and zona reticularis do not secrete glucocorticoids. Elevated plasma glucocorticoid levels function in a negative feedback loop to decrease or halt the secretion of CRH and thereby indirectly inhibit the secretion of ACTH as well.

There is a diurnal rhythm to the secretion of CRH that causes a similar rhythm in the output of ACTH and glucocorticoids. The result is that maximal glucocorticoid secretion occurs between 6:00 AM and 8:00 AM in people sleeping from midnight to 8:00 AM in a 24-hour day. Tumors that secrete CRH, ACTH, or glucocorticoids do not demonstrate such a rhythm, a fact that is useful in their diagnosis. The biological clock that regulates this and other diurnal, or circadian, rhythms is located in the hypothalamus, just above the area where the optic nerves cross (optic chiasma).

The beneficial functions of normal levels of glucocorticoids in enabling tissues to respond to glucagon and catecholamines are more than adequate to meet the needs of the SAM mechanism for a short time. If these needs continue, additional stress-induced glucocorticoid secretion is required. Eventually, if the stress continues unameliorated, exhaustion of the adrenal cortex occurs, glucocorticoid levels drop, tissues are no longer able to meet the demands of the SAM mechanism, muscle fatigue occurs, readily available cell energy sources (eg, plasma glucose and fatty acid) are depleted, and vascular collapse and death result.

Mineralocorticoids

Aldosterone and glucocorticoids that have some mineralocorticoid function (eg, 11-deoxycorticosterone) increase

Table 42-5 Actions of Cortisol

Major Influence	Effect on Body
Glucose metabolism	Stimulates gluconeogenesis Decreases glucose use by the tissues
Protein metabolism	Increases breakdown of proteins Increases plasma protein levels
Fat metabolism	Increases mobilization of fatty acids Increases use of fatty acids
Anti-inflammatory action (pharmacological levels)	Stabilizes lysosomal membranes of the inflammatory cells, preventing the release of inflammatory mediators Decreases capillary permeability to prevent inflammatory edema Depresses phagocytosis by white blood cells to reduce the release of inflammatory mediators Suppresses the immune response Causes atrophy of lymphoid tissue Decreases eosinophils Decreases antibody formation Decreases the development of cell-mediated immunity Reduces fever Inhibits fibroblast activity
Psychic effect	May contribute to emotional instability
Permissive effect	Facilitates the response of the tissues to humoral and neural influences, such as that of the catecholamines, during trauma and extreme stress

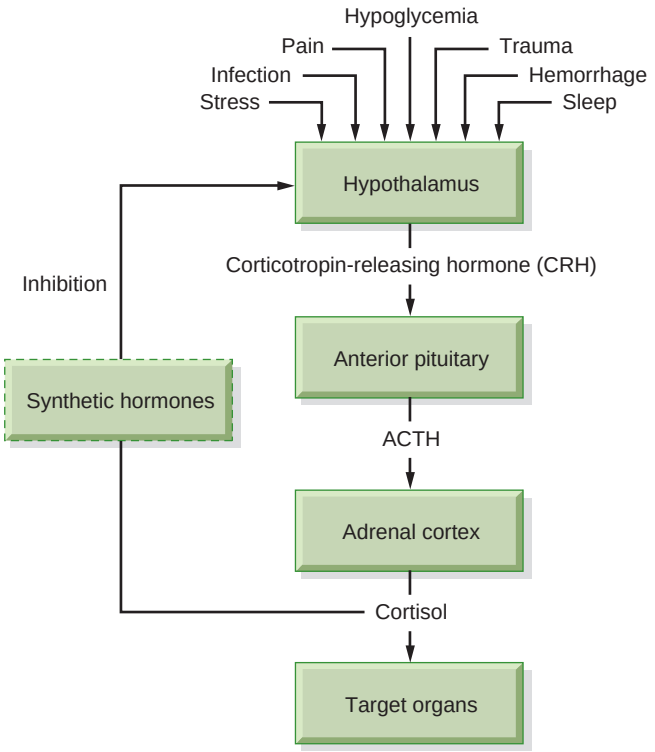

FIGURE 42-8 ▲ The hypothalamic–pituitary–adrenal (HPA) feedback system that regulates glucocorticoid (cortisol) levels. Cortisol release is regulated by adrenocorticotropic hormone (ACTH). Stress exerts its effects on cortisol release through the HPA system and corticotropin-releasing hormone (CRH), which controls the release of ACTH from the anterior pituitary gland. Increased cortisol levels incite negative feedback inhibition of ACTH release. Pharmacological doses of synthetic steroids inhibit ACTH release by way of the hypothalamic CRH.

sodium reabsorption by the cells of the collecting ducts and distal tubules of the nephrons. Because of the cation exchange system in the distal tubule cells, such sodium reabsorption can increase potassium secretion and thereby foster potential hypokalemia. The reabsorption of sodium osmotically causes water reabsorption. This expands the volume of ECF. The increase in blood volume causes an elevation in blood pressure. However, edema does not usually result. Above a certain level of aldosterone-induced sodium reabsorption, the expansion of the ECF compartment can trigger secretion of natriuretic hormone or decreased sodium reabsorption in the proximal tubule. Either of these effects opposes the action of aldosterone and sodium excretion.

The primary mechanism for regulating aldosterone secretion is the renin–angiotensin system (Fig. 42-9). Pituitary ACTH does not stimulate zona glomerulosa cells under normal conditions. Cells of the juxtaglomerular apparatus are wedged between the renal afferent arteriole as it enters the glomerulus and the distal tubule as it passes by this area. The juxtaglomerular apparatus contains baroreceptor cells that monitor the afferent arteriole blood pressure and other cells that monitor the sodium and chloride concentration in the urine in the distal tubule (the lower the concentration, the slower the formation of filtrate, if all other factors are equal). A decrease either in blood pressure or in the concentration of electrolytes stimulates the juxtaglomerular apparatus to secrete the glycoprotein hormone, renin. The major classes of stimuli that trigger renin secretion are decreased renal perfusion (eg, cardiac failure, dehydration, and hemorrhage) and low ECF salt concentrations (eg, from excessive use of diuretics).

Renin converts a circulating plasma globulin into angiotensin I. As the blood passes through the lungs (and to a lesser extent in other parts of the circulatory system), angiotensin I is converted to angiotensin II. This physiologically active chemical acts on the zona glomerulosa to promote aldosterone secretion, which leads to retention of salt and water, and contraction of vascular smooth muscle, thereby stimulating profound vasoconstriction. The result of both actions of angiotensin II is elevation of systemic blood pressure, which, among other things, improves renal perfusion.

The juxtaglomerular apparatus contains β_1 receptors and can be stimulated by sympathetic fibers. Prostaglandins also stimulate the juxtaglomerular apparatus. Sympathetic stimulation through β_1 receptors, renal artery hypotension, and decreased sodium delivery to distal tubules stimulate the secretion of renin. Therefore, the secretion of renin can be pharmacologically decreased by β-blockers (eg, propranolol or atenolol). Prostaglandin inhibitors (aspirin and NSAIDs)

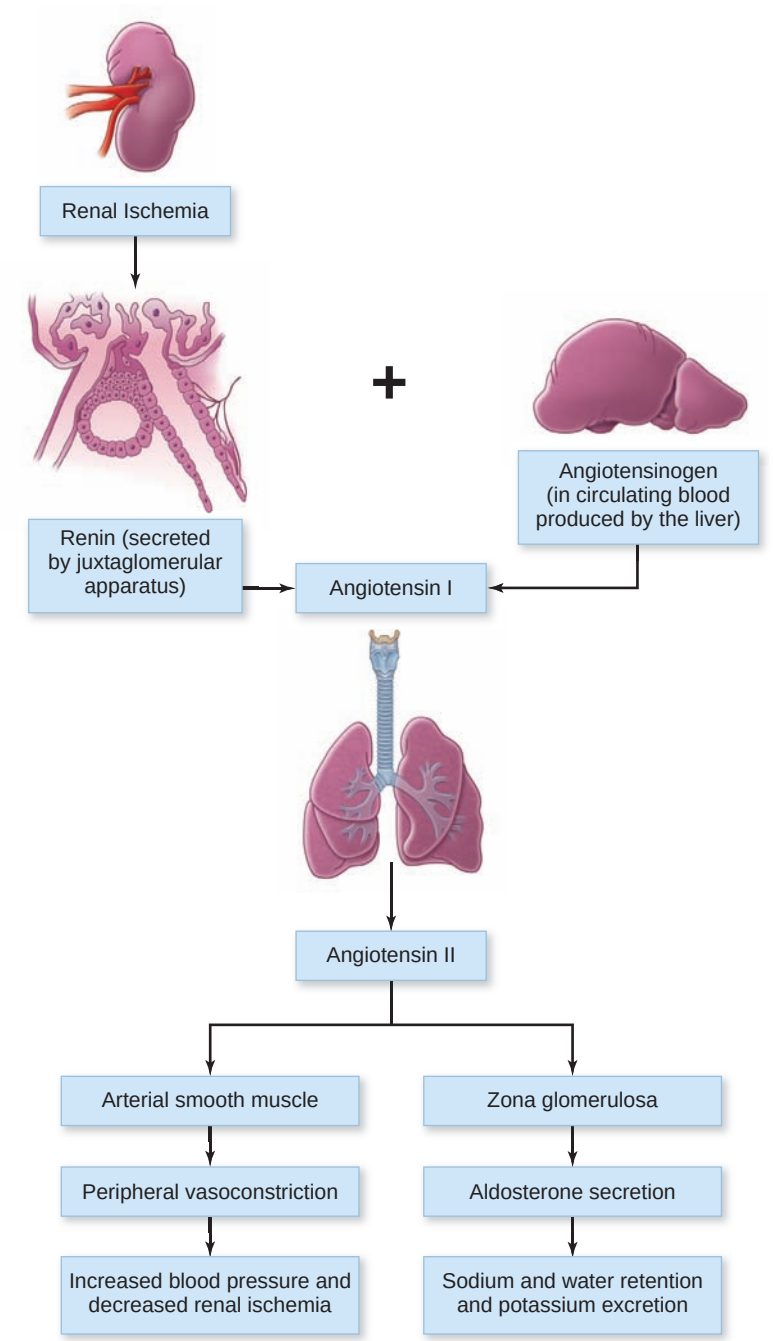

FIGURE 42-9 ▲ The renin–angiotensin system induces aldosterone secretion and vasoconstriction, which in turn elevates the systemic blood pressure.

can exert a similar action. Angiotensin-converting enzyme (ACE) inhibitors (eg, lisinopril) prevent the conversion of angiotensin I to angiotensin II. These effects have made ACE inhibitors and β-blockers useful as antihypertensive agents.

Aldosterone secretion is also stimulated by an increase in plasma potassium levels, but not by increased sodium levels. Another regulating factor for aldosterone secretion is posture. An upright body position increases aldosterone levels by increasing production and decreasing degradation. How this works is unclear, but because of this, aldosterone levels of bedridden patients are slightly subnormal. There also is a poorly understood diurnal rhythm of aldosterone secretion, with highest levels occurring in the early morning hours just before the person awakens.

▲ Atrial Natriuretic Peptide (Natriuretic Hormone)

Atrial natriuretic peptide (ANP) is manufactured by cells in the walls of the atria of the heart. The main stimulus for ANP secretion is atrial stretch. ANP increases renal excretion of salt and water. Some evidence suggests that ANP acts by increasing glomerular filtration. Other evidence indicates that ANP inhibits the membrane active transport mechanism responsible for the reabsorption of sodium by renal tubule cells. Decreased sodium reabsorption decreases the movement of water from the urine in the nephron back into the blood of the peritubular capillaries, thereby increasing

the elimination of water and salt from the body. ANP also inhibits the secretion of renin by the juxtaglomerular apparatus, thereby lowering plasma angiotensin levels. In addition, ANP inhibits the membrane active transport mechanism responsible for pumping sodium out of vascular smooth muscle cells. The consequent rise in intracellular sodium inhibits the entry of calcium ions, thereby lowering the intracellular concentration of calcium ions. The decrease in the intracellular free calcium promotes vasodilation and a lowering of the systemic blood pressure.

ANP is secreted in response to an increase in ECF volume caused by the ingestion of salt and water. The exact stimulus appears to be a stretch of the muscle fibers in the atrial walls, which results from the increased venous return that is caused by the rise in ECF volume. As the natriuresis causes the ECF volume to fall back to normal, the secretion of ANP stops. The capability of ANP to increase the GFR, together with its direct effects on the collecting tubules, results in a profound natriuresis and diuresis.

The metabolic fate of ANP is unknown, but circulating levels of this hormone are elevated in patients with congestive heart failure, cirrhosis, or renal insufficiency and are low in those with nephrotic syndrome or volume depletion. These results suggest liver and kidney regulation.

▲ Clinical Applicability Challenges

SHORT ANSWER QUESTIONS

1. Discuss the effects of hypothalamic and pituitary dysfunction on antidiuretic, thyroid, and adrenal hormone secretion.
2. Describe the negative feedback mechanisms that affect the synthesis and production of thyroxine (T_4) by the thyroid gland.
3. Review the mechanisms by which insulin, glucagon, counter-regulatory hormones, and gut derived hormones regulate blood glucose levels.

43 Patient Assessment: Endocrine System

Jane Kapustin

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Analyze the relationship between dysfunction of the hypothalamus and the pituitary gland and the signs and symptoms of the resultant disorder.
2. Compare and contrast the signs and symptoms of hypothyroidism and hyperthyroidism.
3. Formulate a plan for collecting history and physical examination data focusing on endocrine function.
4. Differentiate between normal and abnormal findings for an adrenal gland disturbance.
5. Explain laboratory tests used to diagnose acute endocrine disorders.

Endocrine disorders can affect all body systems and are usually caused by the overproduction or underproduction of hormones. This chapter presents an overview of the history, physical examination, and diagnostic studies that help diagnose the following specific endocrine disorders: thyroid crisis; myxedema coma; adrenal crisis; syndrome of inappropriate antidiuretic hormone (SIADH); diabetes insipidus; diabetic ketoacidosis (DKA); hyperglycemic hyperosmolar state (HHS); and hypoglycemia. It builds on the content presented in Chapter 42, which explored the far-reaching effects of the endocrine system on body functions. This chapter also provides a foundation for understanding specific applications described in Chapter 44.

Because the endocrine system affects so many general areas of the body, assessment must include a variety of signs and symptoms. General manifestations of disorders are evident through vital signs, energy level, fluid and electrolyte imbalances, and ability to carry out activities of daily living. Other parameters to be observed include heat or cold intolerance, changes in weight, fat redistribution, changes in sexual functioning, and altered sleep patterns. Box 43-1 summarizes the approach used to assess a patient suspected of having an acute endocrine disorder.

Because the endocrine system exerts control over the entire body, many laboratory tests that have been discussed in other chapters are applicable to the assessment of an acute endocrine disorder. For example, fluid and electrolyte problems accompany many acute endocrine disorders. Therefore, serum sodium, potassium, magnesium, and osmolality are assessed. Blood urea nitrogen and creatinine levels may also help assess renal involvement (see Chapter 29). Arterial blood gases, bicarbonate levels, and anion gap calculation may be necessary to diagnose acidosis. Laboratory studies specific to endocrine gland dysfunction are described in the following sections and summarized in Table 43-1.

Similarly, in the evaluation of endocrine disorders, it is often necessary to evaluate body systems other than the endocrine system using diagnostic studies. For example, electrocardiography and cardiac monitoring may be needed to diagnose cardiac problems, whereas a chest radiograph may be necessary to detect pulmonary problems, such as the pleural effusion that can occur in myxedema coma. Computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound may be used to localize tumors.

▲ The Hypothalamus and Pituitary Gland

Some of the hormones of the hypothalamus and the pituitary have a profound impact on the critically ill patient and are described in detail in this section. They include antidiuretic hormone (ADH), adrenocorticotropic hormone (ACTH), and thyroid-stimulating hormone (TSH). Those hormones that are mainly responsible for normal physiological functioning of the reproductive system are not significant in the care of the critically ill adult and therefore are not covered in this section (oxytocin, follicle-stimulating hormone [FSH], luteinizing hormone [LH], growth hormone [GH], melanophore-stimulating hormone [MSH]).

The pituitary gland hormones are under the control of the hypothalamus. The posterior lobe of the pituitary stores and secretes ADH (vasopressin) in response to serum osmolality. Because the primary function of ADH is to control water excretion by the kidney, attention must be focused on the patient's hydration status (manifests as fluid volume

BOX 43-1 HEALTH HISTORY for Endocrine Assessment

Chief Complaint
Patient's description of the problem

History of the Present Illness
Hypothalamus and pituitary disorders: excessive or inadequate urinary output, excessive thirst, poor skin turgor, cognitive changes, dehydration, or water intoxication
Thyroid disorders: Cold or heat intolerance; edema; cognitive changes, such as slowed mentation, agitation, memory impairment, and stupor; tremulousness; insomnia; fatigue; tachycardia, atrial fibrillation; bradycardia; hypoventilation; constipation; diarrhea; menstrual cycle irregularities; skin problems; husky voice; diplopia, exophthalmos; eye pain, change in vision; depression; hematuria
Parathyroid disorders: apathy, fatigue, weakness, tetany, joint pain
Diabetes mellitus: weight gain or loss, excessive urination, excessive thirst, excessive appetite, blurred vision, dental caries, poor wound healing, chronic vaginitis, neuropathy, nocturia, dehydration, cognitive changes
Adrenal disorders: nausea, vomiting; striae; central obesity with peripheral wasting; moon facies; hirsutism; petechiae, easy bruising; dehydration; fatigue, lethargy

Past Health History
Relevant childhood illnesses and immunizations: history of adenoid or neck/chest radiation, mental retardation, iodine deficiency
Past acute and chronic medical problems: diabetic emergencies, hypertension, high cholesterol, tachydysrhythmias, congestive heart failure, myocardial infarction, Graves' disease, Hashimoto's thyroiditis, head injury, cerebral vascular accident, pancreatitis, unexplained infections
Risk factors: age, heredity, gender, race, tobacco use, alcohol use, elevated cholesterol, obesity, sedentary lifestyle, growth spurt cycles, pregnancy, gestational diabetes, delivery of an infant weighing more than 9 pounds, anemia
Past surgeries: neurosurgical procedures, thyroidectomy, parathyroidectomy, adrenalectomy
Medications: amiodarone, phenytoin, carbamazepine, chlorpropamide, corticosteroids, opioids, lithium, aspirin, iodides, heparin, levothyroxine (Synthroid), neoplastic drugs, estrogen, methadone, androgens, β-blockers, nonsteroidal anti-inflammatory drugs, potassium, diuretics
Allergies and reactions to medication, foods, contrast dye, latex, or other materials
Transfusion history
Family history: thyroid disease, diabetes, lipid disorders, cerebral aneurysms, cancers, autoimmune disorders
Personal and social history: tobacco, alcohol, substance abuse; occupation; living environment; diet, exercise; sleep patterns; cultural beliefs; spiritual/religious beliefs; leisure activities

Review of Other Systems
HEENT: headaches, dizziness, weakness, visual changes
Lymphatics: edema, lymphadenopathy
Genitourinary: sexual dysfunction, infertility, abnormal vaginal bleeding

excess or deficit) and serum and urine osmolality to acquire information about the general functioning of this part of the pituitary.

History and Physical Examination

The nurse obtains important information about the nature of endocrine disorders by conducting a thorough history. Because disorders of the pituitary that could result in critical care admission affect fluid and electrolyte balance, the nurse inquires about general hydration status. Specific parameters are included in the endocrine health history (see Box 43-1).

Physical examination of the patient includes assessment of hydration status. Skin turgor, buccal membrane moisture, vital signs, and weight are assessed. A patient with hypovolemia (as seen in diabetes insipidus) would experience weight loss from excretion of large volumes of dilute urine. Eventually, the patient would experience tachycardia, hypotension, poor skin turgor, dry buccal membranes, and cognitive changes associated with dehydration and hypernatremia. Conversely, a patient with hypervolemia (as seen in SIADH) would display signs of water intoxication, such as edema, scant urinary output, weight gain (1 liter of fluid equals 2.2 pounds of weight), hypertension, moist buccal membranes, good skin turgor, and cognitive changes associated with hyponatremia.

For patients experiencing fluid balance alterations, the nurse needs to maintain strict measuring of intake and output. Urine specific gravity is measured routinely, noting the nature of the urine (color, concentration, and volume). In addition, critically ill patients with fluid imbalance often have advanced monitoring techniques in place, such as central venous pressure or hemodynamic monitoring with a pulmonary artery catheter. Vigilant monitoring of the patient's fluid status needs to be maintained.

Laboratory Studies

Serum Antidiuretic Hormone

The normal serum ADH level is 1 to 13.3 pg/mL. This radioimmunoassay level distinguishes between central diabetes insipidus and SIADH. Elevated serum ADH compared with low serum osmolality and elevated urine osmolality confirms the diagnosis of SIADH. Conversely, reduced levels of ADH with a correspondingly high serum osmolality, hypernatremia, and reduced urine concentration indicate central diabetes insipidus. Table 43-2 compares and contrasts laboratory values for diabetes insipidus and SIADH.

Urine Specific Gravity

Specific gravity reflects the kidneys' ability to dilute and concentrate urine. The range depends on hydration, urine volume, and the amount of solids in the urine. The specific gravity can be measured by using a multiple-test dipstick that has a reagent for specific gravity or by using a refractometer. Low specific gravity (1.001 to 1.010) is seen in diabetes insipidus and is accompanied by copious, dilute urine. Increased specific gravity (1.025 to 1.030) is seen in diabetes mellitus with dehydration; the urine in general is more concentrated with smaller volumes.

Table 43-1 Sampling of Laboratory Studies Used to Assess Acute Endocrine Disorders

Test	Normal Adult Values	Abnormal Values
Total T_4	4–12 mcg/dL	High in hyperthyroidism Low in hypothyroidism
Free T_4	0.8–2.7 ng/mL	High in hyperthyroidism Low in hypothyroidism
Free T_4 index	4.6–12 ng/mL	High in hyperthyroidism Low in hypothyroidism
Free T_3	260–480 pg/dL	Low in hypothyroidism
Thyroid-stimulating hormone	260–480 pg/dL	High in hypothyroidism (primary) Low in hypofunction of anterior pituitary (secondary hypothyroidism)
Cortisol	8 AM 5–23 mcg/dL 4 PM 3–16 mcg/dL	High in Cushing's disease (increased ACTH secretion by pituitary) High in stress, trauma, and surgery Low in hyposecretion of ACTH by pituitary and adrenal insufficiency
Cortisol stimulation	Should increase to 18 mcg/dL	Low or absent in adrenal insufficiency and hypopituitarism
Urine vanillylmandelic acid (VMA) and catecholamines	VMA up to 2–7 mg/24 h Catecholamines: 270 mcg/24 h	High in pheochromocytoma High in hypothyroidism and diabetic acidosis
Urine specific gravity	1.010–1.025 with normal hydration and volume	Low in diabetes insipidus High in diabetes mellitus with dehydration High in SIADH
Urine ketones	Negative	Positive in diabetic ketoacidosis

SIADH, syndrome of inappropriate antidiuretic hormone; T_3, triiodothyronine; T_4, thyroxine.

Serum Osmolality

Serum osmolality ranges from 270 to 300 mOsm/kg and measures the concentration of diluted particles in the bloodstream. Elevated serum osmolality (hemoconcentration) stimulates the release of ADH, which enhances the reabsorption of fluid and sodium at the nephron level. Through this process, extracellular fluid (ECF) volume is restored, and the plasma becomes less concentrated.

Conversely, hemodilution or decreased serum osmolality inhibits ADH, causing excess fluid to be eliminated by the kidneys to maintain homeostasis. Concentration of the plasma is restored.

Urine Osmolality

This test is a more exact measure of urine concentration. It is also a more useful test when performed in conjunction with serum osmolality. It can be used to diagnose kidney function, diabetes insipidus, and psychogenic water drinking. The urine osmolality is increased in Addison's disease, SIADH, dehydration, and renal disease. It is decreased in diabetes insipidus and psychogenic water drinking. The normal range is 300 to 900 mOsm/kg/24 h and 50 to 1,200 mOsm/kg in a random sample.

Water Deprivation Test

Water restriction is a useful test because healthy people respond with a rapid decrease in urine volume when water intake is withheld. However, people with diabetes insipidus have no decrease in urine volume in response to severe water restriction. This signifies that the normal mechanism of ADH release in the face of water restriction and dehydration is dysfunctional. This test is rarely performed in a critical care unit because the patient is too ill and fragile to withstand the rigors of severe dehydration. The preferred test is measurement of serum ADH to diagnose diabetes insipidus.

Antidiuretic Hormone Administration

One final laboratory test used to diagnose diabetes insipidus is ADH administration. Exogenous ADH (vasopressin or Pitressin) given subcutaneously to the person suspected of having diabetes insipidus causes a temporary increase in urine osmolality. For a brief time, the person displays the appropriate response to ADH by conserving water at the kidney level, and urine output slows down in an attempt to restore ECF. This test also helps distinguish between the two types of diabetes insipidus: nephrogenic and central. In nephrogenic diabetes insipidus, the person does not demonstrate a reaction

Table 43-2 Comparison of Laboratory Values in Diabetes Insipidus and Syndrome of Inappropriate Antidiuretic Hormone (SIADH)

Laboratory Test	Diabetes Insipidus	SIADH
Antidiuretic hormone	Decreased	Increased
Serum osmolality	Increased	Decreased
Sodium	Increased	Decreased
Urinary output	Increased	Decreased
Urine specific gravity	Decreased	Increased
Urine osmolality	Decreased	Increased

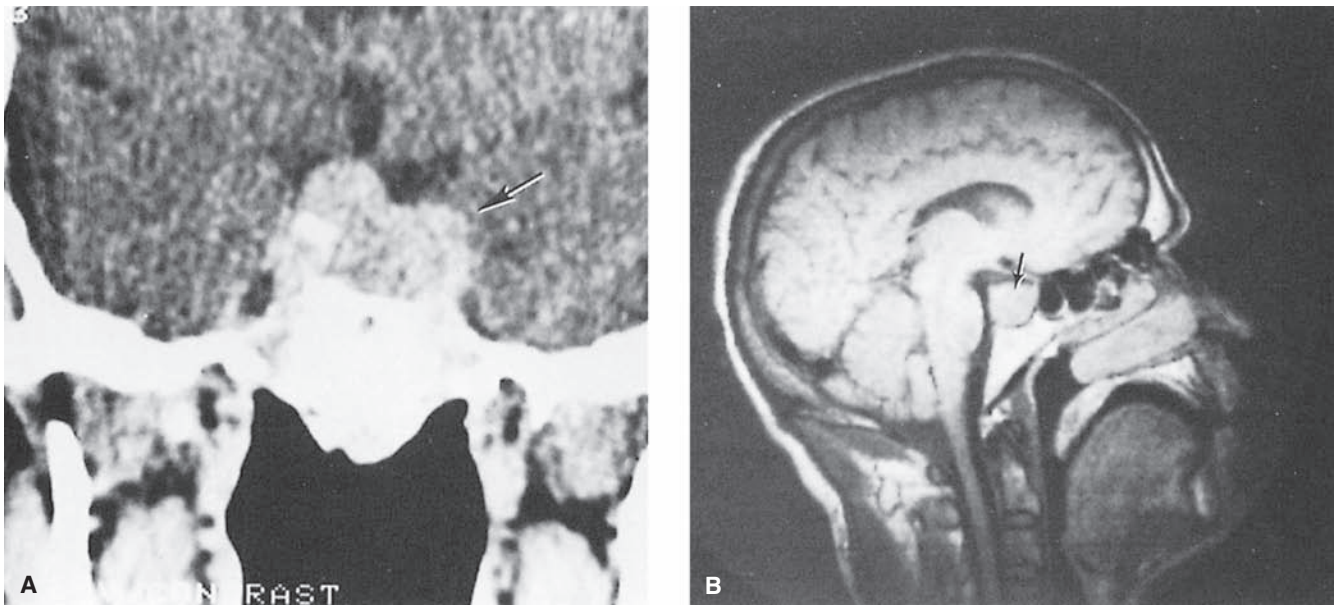

FIGURE 43-1 ▲ **A:** Computed tomography scan showing a suprasellar pituitary tumor (*arrow*) in a thyroid-toxic patient with a thyroid-stimulating hormone (TSH)–secreting pituitary tumor. **B:** T1-weighted magnetic resonance image in the same patient showing a 2- × 2-cm pituitary tumor (*arrow*). T1-weighted images are favorable for demonstrating anatomical detail. (Adapted from Smallridge RC: Thyrotropin-secreting pituitary tumors. Endocrinol Metab Clin North Am 16:3, 1987.)

to exogenous ADH because the kidney receptors in the collecting duct are unresponsive to ADH. People with central diabetes insipidus respond readily to the exogenous ADH.

Diagnostic Studies

Diagnostic imaging studies are frequently used for patients suspected of having pituitary or hypothalamic disorders. CT and MRI are essential in diagnosing primary diseases affecting this area of the brain. Examples of disorders that affect the pituitary–hypothalamic axis are brain tumors, aneurysms, edema from surgical exploration or traumatic injuries, and necrotic lesions. Imaging techniques are used to view the sella turcica and the surrounding structures, including the pituitary within the bony encasement of the middle cranial fossa. Angiography assists with precise viewing of the vascular supply in the area. Figure 43-1 provides examples of MRI and CT scans of a pituitary tumor.

The critically ill patient requires monitoring at all times during these procedures. Quite often, the patient requires sedation to eliminate all patient motion in an effort to ensure clear images. CT is often used with contrast media to highlight specific areas of the brain, and the patient needs to be monitored for adverse allergic reactions if sensitive to iodine, which may be contained in the contrast agent. Institutional policies and procedures need to be followed during diagnostic testing.

▲ The Thyroid Gland

The thyroid hormones are regulated by the hypothalamus and the pituitary gland in a negative feedback system as previously described. Low levels of triiodothyronine (T_3) and thyroxine (T_4) cause the hypothalamus to secrete thyrotropin-releasing hormone (TRH), which then stimulates the anterior pituitary gland to release TSH. TSH stimulates the production and release of the thyroid hormones (Fig. 43-2).

Increased thyroid hormone production results in hyperthyroidism, which can lead to an extreme form of thyrotoxicosis. This is a rare, life-threatening illness necessitating critical

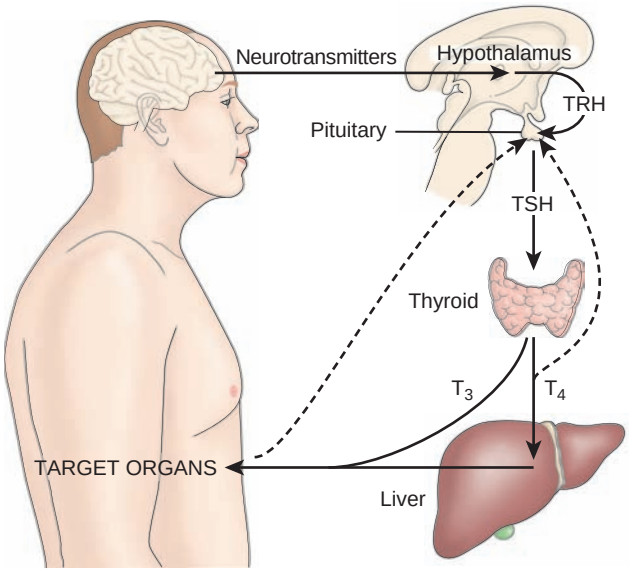

FIGURE 43-2 ▲ The hypothalamic–pituitary–thyroid axis. Thyrotropin-releasing hormone from the hypothalamus stimulates the pituitary gland to secrete TSH. TSH stimulates the thyroid to produce thyroid hormone (T_3 and T_4). High circulating levels of T_3 and T_4 inhibit further TSH secretion and thyroid hormone production through a negative feedback mechanism (*dashed lines*). (From Smeltzer SC, Bare BG, Hinkle JL, et al: Brunner & Suddarth's Textbook of Medical–Surgical Nursing, 12th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 1254.)

Table 43-3 Manifestations of Hypothyroid and Hyperthyroid States

Symptoms of Thyroid Dysfunction		Signs of Thyroid Dysfunction	
Hyperthyroidism	**Hypothyroidism**	**Hyperthyroidism**	**Hypothyroidism**
Nervousness	Fatigue, lethargy	Tachycardia or atrial fibrillation	Bradycardia and, in late stages, hypothermia
Weight loss despite an increased appetite	Modest weight gain with anorexia	Increased systolic and decreased diastolic blood pressures	Decreased systolic and increased diastolic blood pressures
Excessive sweating and heat intolerance	Cold intolerance	Hyperdynamic cardiac pulsations with an accentuated S_1 sound	Dry, coarse skin, and intensity of heart sounds sometimes decreased
Palpitations	Swelling of face, hands, and legs	Warm, smooth, moist skin	Dry, coarse, cool skin, sometimes yellowish from carotene, with nonpitting edema and loss of hair
Frequent bowel movements	Constipation	Tremor and proximal muscle weakness	Impaired memory, mixed hearing loss, somnolence, peripheral neuropathy, carpal tunnel syndrome
Muscular weakness of the proximal type and tremor	Weakness, muscle cramps, arthralgias, paresthesias, impaired memory and hearing	With Graves' disease, eye signs such as stare, lid lag, and exophthalmos	Periorbital puffiness

care admission for management of the patient. Conversely, hypothyroidism can occur, resulting in a severe hypometabolic state. If hypothyroidism is untreated, myxedema coma can develop in the patient, which is most likely to be managed and treated in a critical care unit.

History and Physical Examination

Thyroid hormones affect nearly every cell and tissue in the body. Therefore, manifestations of these disorders are widespread. The typical course of disease progression is insidious, and the nurse needs to take a detailed history to uncover signs and symptoms of either hypothyroidism or hyperthyroidism. History taking focuses on the variety of expected signs and symptoms associated with hypothyroidism and hyperthyroidism. Table 43-3 compares and contrasts the two disorders. Box 43-2 explores the incidence of thyroid disorders in the older patient.

Because of their deep, protected locations in the body, the endocrine glands are in general inaccessible to palpation, percussion, and auscultation. The exception is the thyroid gland, which can be examined physically when it is enlarged. Assessment begins with inspection of the anterior neck area for enlargement, nodules, and symmetry of the gland. The patient is then asked to swallow while the nurse observes the thyroid rising. Next, the thyroid is palpated for size, shape, symmetry, and presence of tenderness (Fig. 43-3). See Box 43-3 for a more detailed description of the steps for palpating the thyroid gland. Thyromegaly (goiter) or thyroid nodules can be detected by palpation. Both lobes of the gland and the isthmus are palpated. Occasionally, a thyroid bruit

BOX 43-2 CONSIDERATIONS FOR THE OLDER PATIENT

Endocrine Disorders

- Expect a higher prevalence of hypothyroidism in the elderly population. Often, the older patient presents with atypical initial symptoms such as depression, apathy, and immobilization.
- Hyperthyroidism in the elderly is much less common; however, the older patient may present with a subclinical picture. Common complaints such as weight loss, fatigue, palpitations and tachycardia, mental confusion, and anxiety are typically attributed to "old age," thus making the disorder harder to detect. Worsening heart failure or unstable angina may result, and often the elderly patient presents with new-onset atrial fibrillation. For these reasons, the highly sensitive thyroid-stimulating hormone (TSH) test should be considered for the older patient with cardiovascular and neurological manifestations.
- The older adult experiences increased insulin resistance and hyperinsulinemia and is, therefore, at higher risk for developing type 2 diabetes.
- Hyperglycemic hyperosmolar state affects the frail elderly population, with the acutely ill older patient at higher risk. Be suspicious of the older patient with diabetes and the new onset of acute illness, such as myocardial infarction, pancreatitis, pneumonia, or other serious infections or illnesses.
- Another expected result of aging is the decrease in secretion of aldosterone and cortisol. This can result in a diminished response to acute illness or trauma. The older patient may have a decreased ability to maintain appropriate fluid and electrolyte balance. In general, older adults display diminished responses to stressors, such as critical illness or trauma.

FIGURE 43-3 ▲ The thyroid is examined from behind, with the patient in a sitting position, avoiding hyperextension of the neck. (From Bickley LS, Szilagyi PG: Bates' Guide to Physical Examination and History Taking, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 242.)

can be detected by listening over the gland with the bell of the stethoscope. A bruit is caused by excessive or turbulent blood flow associated with hyperthyroidism and the resultant hypermetabolic state.

Other assessment parameters include noting vital sign changes, skin changes (including edema), neurological changes, and weight changes associated with either disorder. Hypothyroidism is frequently associated with hypotension, bradycardia, hypoventilation, and subnormal temperature. The patient often has dry, flaky skin; edema over the pretibial area; and a deep or husky voice. The patient displays slowed cognitive functioning with slower-than-normal verbal responses, slowed rapid alternating movements, and decreased deep tendon reflexes.

Patients with hyperthyroidism have more neurological manifestations, such as tremor, nervousness, insomnia and restless movements, and hyperactive reflexes. Vital signs are characteristic: hypertension, tachycardia, tachypnea, and hyperthermia. The patient may have a goiter with detectible bruit. Also, the patient may have exophthalmos or proptosis of the eyes. The eyes may unilaterally or bilaterally protrude from the eye sockets, rendering the patient unable to close one or both eyes (Fig. 43-4).

BOX 43-3 Steps for Palpating the Thyroid Gland

- Ask the patient to flex the neck slightly forward to relax the sternomastoid muscles.
- Place the fingers of both hands on the patient's neck so that your index fingers are just below the cricoid cartilage.
- Ask the patient to sip and swallow water as before. Feel for the thyroid isthmus rising up under your finger pads. It is often but not always palpable.
- Displace the trachea to the right with the fingers of the left hand; with the right-hand fingers, palpate laterally for the right lobe of the thyroid in the space between the displaced trachea and the relaxed sternomastoid. Find the lateral margin. In similar fashion, examine the left lobe.
- The lobes are somewhat harder to feel than the isthmus, so practice is needed.
- The anterior surface of a lateral lobe is approximately the size of the distal phalanx of the thumb and feels somewhat rubbery.
- Note the *size*, *shape*, and *consistency* of the gland and identify any *nodules* or *tenderness*.

If the thyroid gland is enlarged, listen over the lateral lobes with a stethoscope to detect a *bruit,* a sound similar to a cardiac murmur but of noncardiac origin.

Laboratory Studies

Thyroid-Stimulating Hormone Test (Thyrotropin Assay)

The TSH test is a highly sensitive test used to diagnose hypothyroidism and hyperthyroidism. The third-generation immunometric assay tests of TSH are 100 times more sensitive than the earlier methods for measuring TSH, and this test is the preferred method for diagnosing and monitoring progression of thyroid disease. Box 43-4 provides a review of common thyroid tests. Table 43-4 lists medications that may interfere with thyroid tests.

The TSH test measures circulating TSH from the anterior pituitary. TSH stimulates the release and distribution of the T_3 and T_4 stored in large amounts in the thyroid gland. Measuring TSH helps determine whether the hypothyroidism is primary (ie, caused by dysfunction of the thyroid gland)

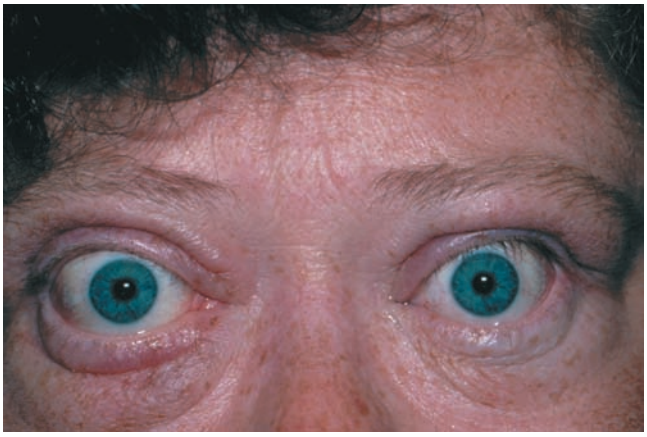

FIGURE 43-4 ▲ A woman with Graves' disease (hyperthyroidism). Note the exophthalmos. (From Goodheart HP: Goodheart's Photoguide of Common Skin Disorders: Diagnosis and Management, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2003, p 391.)

BOX 43-4 Laboratory Evaluation of the Thyroid

Tests That Assess Thyroid Function
- Radioactive iodine uptake

Tests That Assess the Hypothalamic–Pituitary Axis
- Sensitive TSH
- TSH-releasing hormone stimulation test

Tests That Assess Thyroid Hormone Binding Peripherally
- Total thyroxine (T_4) and total triiodothyronine (T_3)
- Free T_4 and free T_3
- In vitro uptake tests (T_3 resin uptake)
- Thyroid hormone–binding ratios (free T_4 index)
- T_4-binding globulin

Diagnostic Studies
- Iodine-131, technetium-99m scans
- Ultrasonography
- Computed tomography
- Magnetic resonance imaging
- Computerized rectilinear thyroid

Miscellaneous Tests
- Thyroid antibodies (thyroid peroxidase, thyroid-stimulating immunoglobulin)
- Thyroglobulin
- Calcitonin
- Basal metabolic rate

or secondary (ie, caused by hypofunction of the anterior pituitary gland). A high TSH level helps diagnose primary hypothyroidism. Measuring the TSH level also helps guide medication titrations for patients requiring exogenous thyroid hormone.

However, the levels of TSH and free T_4 are highly influenced by stress in critically ill patients because of problems with protein levels that are often seen in critical care. Malnutrition, hepatic dysfunction, pregnancy, and drugs affect the TSH and free T_4 levels, and actual thyroid disease is not present. This is termed euthyroid sick syndrome.[1] Therefore, the results of the TSH test need to be analyzed carefully in the critically ill patient. The normal adult value for TSH is 0.4 to 5.4 mIU/L.

Total Thyroxine

Total T_4 measures both the free T_4 and the portion carried by thyroxine-binding globulin (TBG). T_4 is increased in hyperthyroidism and decreased in hypothyroidism. Any factor that affects protein binding affects the results of the total T_4. These factors include pregnancy; estrogen or androgen therapy; and taking oral contraceptives, salicylates, or phenytoin. Normal values depend on the laboratory method used. The normal value is 9.8 to 22.6 mcg/dL in infants; childhood norms are up to 5.6 to 16.6 mcg/dL. Normal adult values range from 4.6 to 12 mcg/dL and are higher during pregnancy. Older adults have lower values because plasma proteins decrease as people age.

Free Thyroxine and Free Thyroxine Index

Free T_4 and free T_4 index measure the free part of T_4, the part that is not bound to protein. Free T_4 is the metabolically active form of the hormone that can be used by tissues. It makes up a small part of the total T_4. The free T_4 test is more useful than the total T_4 test in diagnosing hypofunction and hyperfunction of the thyroid gland because it helps diagnose thyroid function when TBG levels are abnormal. This test can also evaluate thyroid replacement therapy. Radioisotopes can interfere with test results, and heparin can give false high readings. This test can be performed by direct assay or by indirect measurement. The direct assay normal value is 0.8 to 2.7 ng/mL, whereas the free T_4 index is 4.6 to 12 ng/mL.

Free Triiodothyronine

Free T_3 measures the circulating T_3 that exists in the free state in the blood, unbound to protein. This is one measure to evaluate thyroid function. T_3 is about five times more potent than T_4 and is more metabolically active. Decreased values indicate hypothyroidism. Radioisotopes also affect results. Normal adult values are 260 to 480 pg/dL.

Triiodothyronine Resin Uptake Test

The T_3 resin uptake test is an indirect measure of TBG available to bind T_3 and T_4. It is increased with thyrotoxicosis.

Calcitonin

Calcitonin, or thyrocalcitonin, is a hormone secreted by the thyroid. It is secreted in response to high levels of calcium and reduces the calcium level by increasing its deposition in bone.

Thyroid Antibodies

Several autoimmune thyroid diseases produce detectable antibodies. Specifically, Graves' disease, Hashimoto's thyroiditis, and chronic autoimmune thyroid disease cause elevations in antithyroid antibodies, detectable by immunoassay techniques. These conditions can lead to severe hypothyroidism or hyperthyroidism if not treated.

Thyroglobulin

Thyroglobulin can be measured by radioimmunoassay and is elevated in most thyroid disorders. This test has limited diagnostic value because it is nonspecific. It is used clinically to follow the progression of disease in a patient being treated for thyroid cancer.

Diagnostic Studies

Thyroid Scan and Radioactive Iodine Uptake

The radioactive iodine uptake test measures the rate of iodine uptake by the thyroid gland after the administration of iodine-123 tracer (by capsule, solution, or intravenous injection). A scintillation counter then measures gamma rays released from the breakdown of the tracer in the thyroid, producing a visual representation of the radioactivity in the thyroid gland, neck, and mediastinum. Scan time is about 20 minutes. Normally, the radioactive iodine is evenly distributed in the thyroid gland, and the scan shows a normal size, position, and shape.

Table 43-4 Medications That May Interfere With Thyroid Tests

Substance Determined	Drugs Causing Increased Values or False-Positive Values	Drugs Causing Decreased Values or False-Negative Values
Calcitonin (plasma)	Estrogen/progestin, calcium, cholecystokinin, epinephrine, glucagon	Octreotide, phenytoin
Thyroxine (T_4) free (serum)	Amiodarine, aspirin, carbamazepine, danazol, furosemide, levothyroxine, phenytoin, probenecid, propranolol, oral contraceptives, radiographic agents, tamoxifen, thyroxine, valproic acid	Amiodarone, anabolic steroids, anticonvulsants (eg, carbamazepine), asparaginase, clofibrate, corticosteroids, furosemide, isotretinoin, levothyroxine, methadone, methimazole, octreotide, phenobarbital, phenytoin, ranitidine
Free triiodothyronine (T_3) (serum)	Amiodarone, aspirin, carbamazepine, fenoprofen, levothyroxine, phenytoin, ranitidine, thyroxine	Amiodarone, carbamazepine, corticosteroids, methimazole, phenytoin, propranolol, radiographic agents, somatostatin
Free thyroxine index (serum)	Amiodarone, amphetamine, furosemide, levothyroxine, oral contraceptives, Phenobarbital, propranolol	Aspirin, carbamazepine, clomiphene, corticosteroids, co-trimoxazole, ferrous sulfate, iodides, isotretinoin, lovastatin, methimazole, phenobarbital, phenytoin, primidone, radioactive iodine
Thyroglobulin (serum)	Amiodarone	Carbamazepine, neomycin, thyroxine
Thyroid stimulating hormone (serum)	Aminoglutethimide, amphetamine, atenolol, calcitonin, carbamazepine, chlorpromazine, clomiphene, estrogen, ethionamide, ferrous sulfates, furosemide, iodides, lithium, lovastatin, mercaptopurine, metoprolol, morphine, nitroprusside, phenytoin, potassium iodide, prazosin, prednisone, propranolol, radiographic agents, rifampin, sulfonamides, thyrotropin-releasing hormone (TRH)	Amiodarone, anabolic steroids, antithyroid drugs, aspirin, carbamazepine, clofibrate, corticosteroids, danazol, dobutamide, dopamine, fenoldopam, growth releasing hormone, hydrocortisone, interferon, levodopa, levothyroxine, nifedipine, octreotide, phenytoin, pimozide, pyridoxine, somatostatin, thyroxine, troleandomycin
Thyroxine-binding globulin (serum)	Carbamazepine, clofibrate, diethylstilbestrol, estrogens, mestranol, oral contraceptives, perphenazine, phenothiazines, progesterone, tamoxifen, thyroid agents, warfarin	Anabolic steroids, asparaginase, aspirin, chlorpropamide, colestipol, corticosteroids, cortisone, cytostatic therapy, phenytoin, propranolol, sulfonamides
Triiodothyronine (T_3) total (serum)	Amiodarone, amphetamine, clofibrate, estrogens, fenoprofen, fluorouracil, insulin, levothyroxine, mestranol, methadone, opiates, phenothiazines, phenytoin, propylthiouracil, prostaglandins, ranitidine, rifampin, somatotropin, tamoxifen, terbutaline, TRH, valproic acid	Amiodarone, anabolic steroids, androgens, anticonvulsants (eg, phenytoin), asparaginase, aspirin, arenolol, cholestyramine, cimetidine, clomiphene, clomipramine, colestipol, corticosteroids, co-trimoxazole, furosemide, interferon, iodides, isotretinoin, lithium, methimazole, metoprolol, neomycin, netilmicin, oral contraceptives, penicillamine, phenobarbital, phenytoin, potassium iodide, propranolol, propylthiouracil, radiographic agents, reserpine, salicylates (eg, aspirin), somatostatin, sulfonylureas
Triiodothyronine uptake (blood)	Anabolic steroids, androgens, aspirin, colestipol, corticosteroids, cytostatic therapy, dicoumarol, heparin, phenytoin, propranolol, salicylates, sulfonamides, thyroid agents, warfarin	Antiovulatory drugs, antithyroid drugs, carbamazepine, clofibrate, diethylstilbestrol, estrogens, heparin, heroin, mestranol, methadone, oral contraceptives, perphenazine, phenothiazines, progesterones, tamoxifen, thiazide diuretics (eg, hydrochlorothiazide), thyroid agents, warfarin

From Fischbach FT, Dunning MB: A Manual of Laboratory and Diagnostic Tests, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 1239; pp 1253–1254

The thyroid scan may be performed in conjunction with a radioactive iodine uptake study. After the patient takes the radioactive iodine, a count is made over the thyroid gland with a scintillation counter at specific times. These nuclear tests can indicate areas of increased and decreased function and provide data to diagnose hyperthyroidism, hypothyroidism, nodules, ectopic thyroid tissue, and cancer of the thyroid.

Fine-Needle Biopsy

Fine-needle biopsy is the diagnostic tool of choice for detecting malignancy for a thyroid nodule. It is often the initial test for evaluation of any thyroid mass. The test is safe, quick, and accurate, and results are usually available within hours to several days.

Ultrasound

Ultrasound of the thyroid gland uses high-frequency sound waves to produce an image of the gland. Ultrasound is an easy, noninvasive procedure that has no radiation risks and can be performed at the bedside. The test produces good images of structures and can detect masses, nodules, cysts, and enlargements of the gland.

▲ The Parathyroid Gland

The parathyroid gland produces parathyroid hormone (PTH), which maintains blood calcium and phosphorus levels, neuromuscular activity, blood clotting function, and cell membrane permeability. The four parathyroid glands are located just posterior to the thyroid gland and are sometimes damaged during thyroid surgery.

The output of PTH is regulated by the serum level of calcium under a negative feedback system. Overproduction of PTH results in hyperparathyroidism and is characterized by bone decalcification and the development of renal stones containing calcium.

Hypocalcemia, as a result of hypoparathyroidism, manifests neurologically as tetany (general muscular hypertonia, tremor, and spasmodic movements) when calcium levels dip below 5 to 6 mg/dL. The patient may complain of numbness, tingling, and cramps in the extremities. As the hypocalcemia worsens, the patient experiences bronchospasm, laryngeal spasm, carpopedal spasm (flexion of the elbows and wrists with extension of the carpophalangeal joints), dysphagia, photophobia, cardiac dysrhythmias, and seizures.

History and Physical Examination

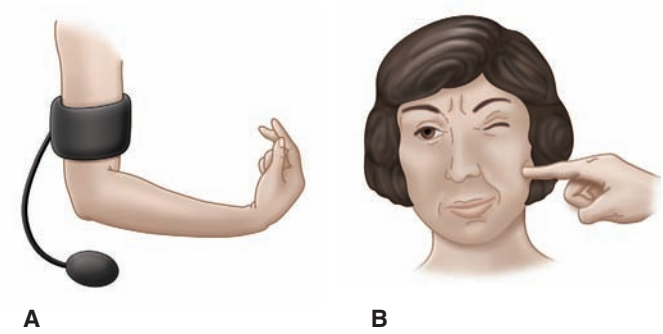
The nurse establishes a history of electrolyte imbalance, specifically related to calcium and phosphorus. Additional information includes a history of a variety of other symptoms listed in the endocrine health assessment (see Box 43-1). The patient may present with kidney stone symptoms, such as severe flank pain, groin pain, frequent urination, hematuria, and nausea and vomiting. The patient may experience joint and bone pains and may sustain pathological fractures, especially of the spine. The nurse remains vigilant for signs of tetany and related complications.

Tetany can be assessed by evaluating the patient for Trousseau's sign or Chvostek's sign (Fig. 43-5). Trousseau's sign is positive when carpopedal spasm is induced by occluding the blood flow to the arm for 3 minutes with the use of a blood pressure cuff. If tapping over the facial nerve just in front of the parotid gland causes twitching of the mouth or eye, the patient has a positive Chvostek's sign.

Laboratory Studies

Normal calcium levels range from 8.6 to 10.3 mg/dL. Most (99%) of body calcium is in the bone, and the remaining 1% is in the ECF. Nearly 50% of serum calcium is ionized or free, whereas the remainder is bound to albumin.

Marked serum calcium elevations (levels >10.3 mg/dL) are the most obvious manifestation of hyperparathyroidism, and common causes include primary hyperparathyroidism, malignancy, sarcoidosis, vitamin D toxicity, hyperthyroidism, and some medications, such as thiazide diuretics and lithium.



A B

FIGURE 43-5 ▲ Tetany is caused by tonic spasm of the intrinsic hand muscles. Evaluate the patient for Trousseau's sign (**A**) or Chvostek's sign (**B**).

Low serum calcium levels are the marker for hypoparathyroidism. Tetany develops at calcium levels of 5 to 6 mg/dL or lower. Common causes of hypocalcemia include hypoalbuminemia, renal failure, hypoparathyroidism, acute pancreatitis, tumor lysis syndrome, severe hypomagnesemia, and multiple citrated blood transfusions.

▲ The Endocrine Pancreas

Disorders of the endocrine pancreas are characterized by chronic hyperglycemia and result in major shifts of fluids and electrolytes as well as in blood glucose levels. The risk for developing diabetes increases with age. The two main types of diabetes are type 1 and type 2, and both forms of diabetes can lead to serious illnesses requiring critical care.

History and Physical Examination

A complete history is multisystem focused because glucose dysfunction affects every system of the body. A good family history is obtained to document the role of familial patterns often seen in type 2 diabetes. The characteristics of patients at risk for developing type 2 diabetes are reviewed in Box 43-5.

BOX 43-5 PATIENT SAFETY

Risk Factors Associated With Developing Type 2 Diabetes

- Family history of diabetes (parents, grandparents, siblings)
- Obesity (body mass index > 27 kg/m^2)
- Race and ethnicity (African American, Native American, Hispanic American, Asian American, Pacific Islander)
- Age greater than 45 years
- History of impaired fasting glucose or impaired glucose tolerance
- Hypertension
- High-density lipoprotein cholesterol less than 35 mg/dL
- Triglyceride level greater than 250 mg/dL
- History of gestational diabetes, the delivery of a baby greater than 9 pounds, or both

For the patient with known diabetes who enters the critical care arena, the nurse focuses on gathering information about the extent of the disease and its duration, the onset of complications, the medications taken for the disease, and other past medical and surgical history. Chronic complications, such as neuropathy, retinopathy, and nephropathy, are explored as well as the coexistence of related medical conditions such as hypertension, hyperlipidemia, obesity, and peripheral vascular disease. Refer to Box 43-1 on page 974 for a health history review of the endocrine system.

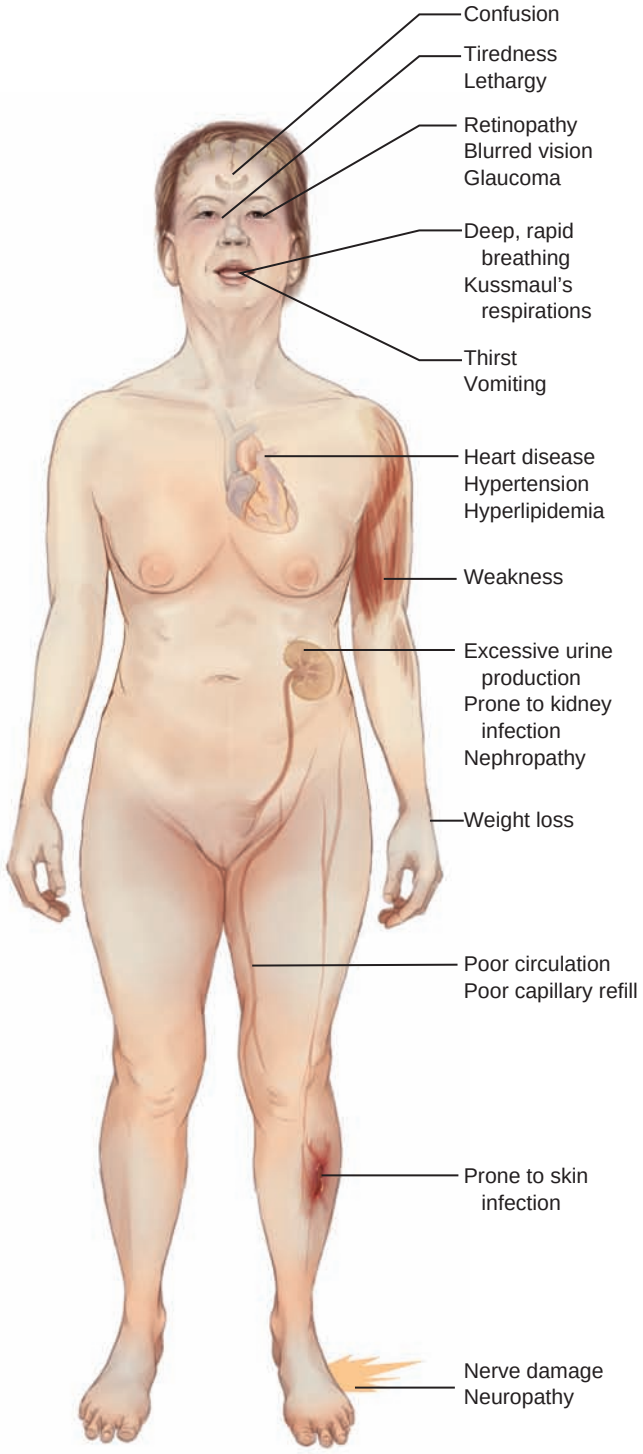


FIGURE 43-6 ▲ Clinical features of diabetes mellitus.

Physical examination focuses on the severe fluid and electrolyte and neurological dysfunction seen with acute diabetes complications such as DKA, HHS, and hypoglycemia. Observation of fluid status and hydration is essential. Skin turgor, buccal membranes, weight, urine specific gravity, and vital signs are assessed. The nurse monitors the patient's neurological status frequently as well as central venous pressures and other advanced monitoring if available. The presence of a fruity odor on the breath (associated with ketonemia) should be noted. In addition, the patient may display Kussmaul's respirations as an attempt to rapidly exhale excess carbon dioxide. This respiratory pattern is characterized by deep, rapid breathing. Figure 43-6 summarizes the physical features seen in the patient with diabetes mellitus.

Laboratory Studies

Fasting Blood Glucose Level and Fingerstick Glucose Analysis

The fasting blood glucose level provides a foundation for managing diabetes mellitus. Very high blood glucose levels can occur in DKA and HHS. In addition, elevated glucose levels can occur in Cushing's syndrome, high-stress states, pancreatitis, and chronic renal and liver disease. Hypoglycemia can occur in Addison's disease, pancreatic tumors, starvation, and hypopituitary problems. The normal value for fasting glucose in adults is 65 to 110 mg/dL. Two-hour postprandial blood glucose testing helps further evaluate carbohydrate metabolism, and the normal value is 65 to 126 mg/dL. The American Diabetes Association (ADA) criteria for the diagnosis of diabetes are given in Box 43-6.

In addition, the ADA recognizes an intermediate group of people who have glucose levels less than 126 mg/dL but nonetheless have glucose levels too high to be considered normal. If their fasting glucose is greater than 100 mg/dL but less than 126 mg/dL, they have the abnormality known as impaired fasting glucose (IFG). If the oral glucose tolerance test (GTT) is performed to diagnose glucose abnormalities, the 2-hour postload level of less than 140 mg/dL is considered normal, a level of 140 to 199 mg/dL is considered impaired glucose tolerance (IGT), and a level greater than 200 mg/dL is provisionally diagnostic of diabetes.[2] Patients with IFG or IGT are now diagnosed with "prediabetes"; they are at high risk for developing diabetes as well as cardiovascular disease. IFG and IGT are associated with metabolic syndrome, which is manifested by increased abdominal obesity, high triglyceride levels, low high-density lipoprotein cholesterol levels, and hypertension.[3]

Numerous drugs can interfere with glucose regulation, including corticosteroids, diuretics, lithium, phenytoin, β-blockers, and estrogen. Hypoglycemic reactions can result from sulfonylureas, insulin, alcohol, β-blockers, angiotensin-converting enzyme inhibitors, and aspirin.

Fingerstick glucose testing can be used at the bedside for immediate feedback regarding the patient's glucose status. In addition, patients can be taught to use fingerstick devices at home to monitor their glucose levels and responses to medication. Standardization of the equipment must be ensured when these devices are used for patient monitoring.

BOX 43-6 Criteria for the Diagnosis of Diabetes Mellitus

1. A1C = 6.5% or greater. The test should be performed in a laboratory using a method that is NGSP (National Glycohemoglobin Standardization Program) certified and standardized to the DCCT assay.*

OR

2. Fasting plasma glucose (FPG) = 126 mg/dL (7.0 mmol/L) or more. Fasting is defined as no caloric intake for at least 8 hours.*

OR

3. Two-hour plasma glucose level 200 mg/dL (11.1 mmol/L) or more during an oral glucose tolerance test. The test should be performed as described by the World Health Organization, using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.*

OR

4. In a patient with classic symptoms of hyperglycemia or hyperglycemic crisis, a random plasma glucose level of 200 mg/dL (11.1 mmol/L) or more.

*In the absence of unequivocal hyperglycemia, criteria 1 to 3 should be confirmed by repeat testing. DCCT, Diabetes Control and Complications Trial

From American Diabetes Association. Position statement: Diagnosis and Classification of Diabetes Mellitus. Diabetes Care 35(1):S12, 2012.

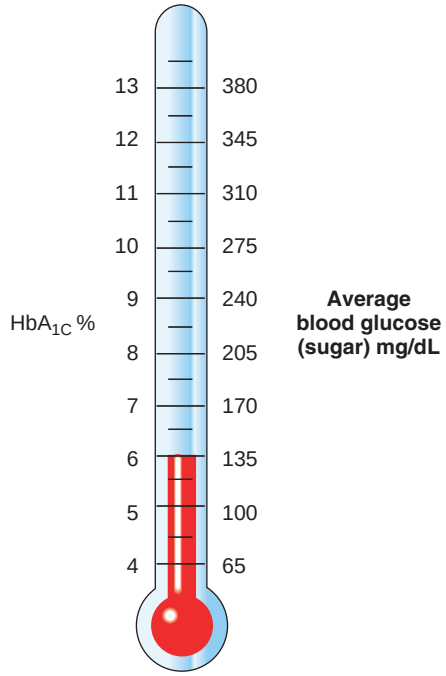

FIGURE 43-7 ▲ Comparison of glycosylated hemoglobin (HbA_{1c}) to average blood glucose level. The normal range is shown in *red*.

In general, point-of-service testing such as this may not be appropriate for the critically ill patient because fingerstick testing requires adequate tissue perfusion for accuracy, and many critically ill patients do not have this required level of perfusion. Testing glucose from more direct sources of blood (ie, veins, venous lines, central lines, arterial lines) may enhance accuracy.

Glycosylated Hemoglobin

Glycosylated hemoglobin (HbA_{1c}) testing offers information about the average amount of serum glucose that is bound to hemoglobin for the 100- to 120-day life span of erythrocytes. This information is now used to diagnose diabetes[4] and to assess data trends for a person who has been previously diagnosed with diabetes. The percentage result (normal: 4% to 7%) reflects an average of 3 months and enhances accuracy because it controls for many variables such as stress, exercise, fasting state, interfering medications, and recent changes in patient compliance. In comparison with the highly variable, "snapshot view" that is provided by a fasting glucose level, HbA_{1c} testing provides insight into the patient's overall status over the previous months.[5] Figure 43-7 compares the HbA_{1C} value to the average blood glucose value.

Fructosamine

Serum fructosamine level measures glycosylation of serum protein albumin. Albumin has a half-life of approximately 2 weeks, as opposed to the half-life of hemoglobin. It is a useful index that reflects chronic glycemic control in patients with diabetes for whom HbA_{1C} may be inaccurate, such as those with anemia or hemoglobin abnormalities (eg, sickle cell disease).[6]

Insulin

This test helps measure abnormal carbohydrate metabolism by measuring the amount of circulating serum insulin in the fasting state. Insulin is released in response to serum glucose levels. When glucose is elevated, insulin levels should increase as well. Abnormally high levels of insulin may help diagnose insulinoma, a tumor of the islets of Langerhans. The normal adult value is 6 to 24 mcU/mL.

A low insulin level helps diagnose diabetes mellitus, especially in the presence of an abnormal GTT. A fasting blood sample is tested. If the insulin test is performed in conjunction with a GTT, blood samples are drawn at that time. Oral contraceptives and recent administration of radioisotopes interfere with results.

C-Peptide Level

C-peptide is a single chain of amino acids connecting A and B chains of insulin in the proinsulin molecule. It has no known physiological function, but because it persists in higher concentrations than insulin, it may be a more accurate reflection of insulin levels. It provides a useful monitor of average β-cell insulin secretion and can be used to distinguish between types 1 and 2 diabetes mellitus. Normal values are 0.5 to 2.0 ng/mL and indicate that the body is still producing some insulin. Low values (or no insulin C-peptide) indicate that the person's pancreas is producing little or no insulin, as in type 1 diabetes.[7]

Glucagon

This hormone, produced in the alpha cells in the islets of Langerhans, controls the production, storage, and release of glucose. Normally, insulin opposes the action of glucagon. This test measures the production and metabolism of glucagon. A deficiency occurs when pancreatic tissue is lost because of chronic pancreatitis or pancreatic tumors. Increased levels occur in diabetes, acute pancreatitis, and catecholamine secretion (such as occurs with infection,

high stress levels, or pheochromocytoma). Chronic renal failure and cirrhosis of the liver can also increase glucagon levels. Normal fasting values are 50 to 200 pg/mL.

Serum Ketones

Measuring serum ketones reveals information about the use of fat metabolism in lieu of carbohydrates as seen in the critically ill person with diabetes. The normal serum ketone level is 2 to 4 mg/dL. Ketonemia (acetone, β-hydroxybutyrate, and acetoacetate) is manifested by Kussmaul's respirations and a fruity, sweet-smelling odor on the exhaled breath. These signs are the result of the patient's attempt to maintain a normal pH during extreme metabolic acidosis. In DKA, metabolic acidosis is primarily the result of the accumulation of acetoacetic acid and β-hydroxybutyric acid, the preferred method for estimating the severity of DKA.[8]

Urine Ketones

Ketones are not normally found in the urine. Ketones in the urine are associated with diabetes and other diseases of altered carbohydrate metabolism. People with diabetes should test for ketones whenever their urine or blood glucose is high. Because ketones appear in the urine before they can be detected in the blood, this test is often used in the emergency department when screening for acidosis. The test is performed by dipping a ketone reagent strip in a fresh urine sample. The presence of ketones in the urine results from lipolysis or fat breakdown in the absence of adequate insulin.

▲ The Adrenal Gland

The adrenal gland is anatomically and functionally divided into two distinct parts—the outer cortex and the inner medulla (see Chapter 42, Fig. 42-6). The two regions secrete different hormones. The cortex produces mineralocorticoids (eg, aldosterone), glucocorticoids (eg, cortisol), and androgens. The medulla secretes catecholamines such as epinephrine, norepinephrine, and dopamine. Disorders of the adrenal gland have widespread effects on the human body because these hormones regulate major body functions, such as fluid and electrolyte balance, sympathetic nervous system responses, inflammation, and metabolism.

The secretion of hormones by the adrenal gland is regulated in a negative feedback system through the hypothalamic–pituitary axis. The hypothalamus releases corticotropin-releasing hormone, which in turn stimulates the release of ACTH from the anterior pituitary. ACTH then stimulates the adrenal cortex to secrete cortisol.

History and Physical Examination

Refer to Box 43-1 for a review of relevant health history questions related to adrenal disorders. Clinical manifestations of adrenal gland dysfunction depend on the nature of the lesion and which hormone is adversely affected. Adrenal medulla lesions may affect the release of catecholamines and cause sudden, severe headache, diaphoresis, palpitations, and other symptoms associated with paroxysmal hypertension. One such lesion is pheochromocytoma, a benign adrenal medulla tumor that mediates this severe outpouring of catecholamines.

Another common pathology affecting the adrenal gland is a pituitary tumor that leads to hypersecretion of ACTH. The resulting disease, Cushing's syndrome, manifests as central obesity, unusual fat deposits, thin extremities, fragile skin, skin discoloration (striae), sleep disturbances, and catabolism (Fig. 43-8). The same clinical picture can result from chronic exogenous steroid use.[9]

Adrenal insufficiency from autoimmune Addison's disease can lead to an adrenal crisis. The patient lacks adequate stimulation of the adrenal gland, or the adrenal gland is rendered ineffective and stops secreting adequate levels of hormone. Consequently, the patient becomes lethargic, dehydrated, and unable to mount any stress response to handle acute illness or trauma.

The critically ill patient often suffers from mild forms of adrenal insufficiency because the patient's normal stores of hormones are used quickly in response to the illness. Many require exogenous steroids to assist with recovery. A summary of the clinical manifestations of adrenal cortical insufficiency and glucocorticoid excess is given in Table 43-5.

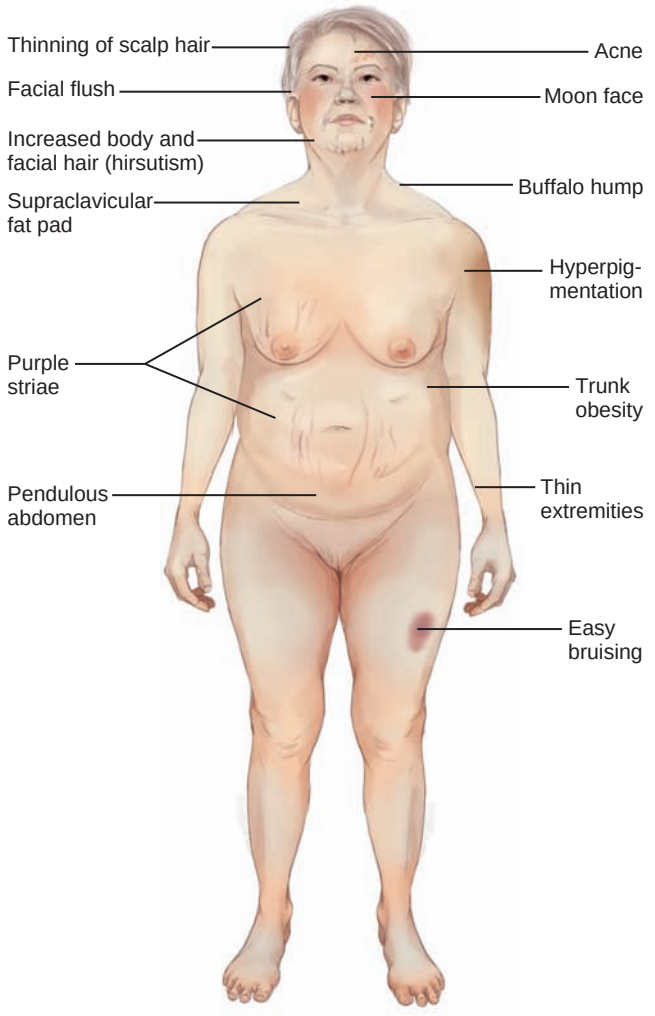

FIGURE 43-8 ▲ Clinical manifestations of Cushing's syndrome.

Table 43-5 Manifestations of Adrenal Cortical Insufficiency and Excess

Parameter	Adrenal Cortical Insufficiency	Glucorticoid Excess
Electrolytes	Hyponatremia* Hyperkalemia*	Hypokalemia
Fluids	Dehydration* (eg, elevated BUN)	Edema
Blood pressure	Hypotension Shock* Orthostatic hypotension	Hypertension
Musculoskeletal	Muscle weakness* Fatigue*	Muscle wasting Fatigue
Hair and skin	Skin pigmentation	Easy bruisability Hirsutism, acne, and striae (abdomen and thighs)
Inflammatory response	Low resistance to trauma, infection and stress	Decrease in eosinophils, lymphocytopenia
Gastrointestinal	Nausea, vomiting* Abdominal pain*	Possible gastrointestinal bleeding
Glucose metabolism	Hypoglycemia*	Impaired glucose tolerance Glycosuria Elevated blood glucose
Emotional	Depression and irritability	Emotional lability to psychosis
Other	Menstrual irregularity Decreased axillary and pubic hair in women	Oligomenorrhea Impotence in the male Centripetal obesity (moon face and buffalo hump)

*Occurs with acute adrenal insufficiency.

BUN, blood urea nitrogen.

Laboratory Studies

Cortisol (Hydrocortisone)

This test evaluates the ability of the adrenal cortex to produce the glucocorticoid hormone cortisol. Cortisol is elevated in adrenal hyperfunction and decreased in adrenal hypofunction. Adrenal hyperfunction may be caused by excess secretion of ACTH by the pituitary gland (Cushing's syndrome), high stress, trauma, and surgery. Adrenal hypofunction may be the result of anterior pituitary hyposecretion, hepatitis, and cirrhosis.

Cortisol secretion is diurnal; it is normally higher in the early morning (6:00 AM to 8:00 AM) and lower in the evening (4:00 PM to 6:00 PM). This variation is lost in patients with adrenal hyperfunction and in people under stress. Serum samples are drawn between 6:00 AM and 8:00 AM and between 4:00 PM and 6:00 PM. Normal 8:00 AM values are 5 to 23 fg/dL or 138 to 635 mmol/L. Normal 4:00 PM. values are 3 to 16 fg/dL or 83 to 441 mmol/L.

Cortisol (Dexamethasone) Suppression

When healthy people receive a low dose of dexamethasone (chemically similar to cortisol), ACTH production is suppressed. However, people with adrenal hyperfunction and some with endogenous depression continue to produce ACTH and do not have a diurnal variation of cortisol.

For this test, dexamethasone is given at bedtime. Blood samples are taken the next day at 8:00 AM and 4:00 PM. Medications are discontinued for 24 to 48 hours before this test is started, especially estrogens, phenytoin, and cortisol-related preparations. Radioisotopes should not be given within 1 week of this test. This test is the test of choice to diagnose Cushing's syndrome.[10]

Cortisol Stimulation

This test measures the response of the adrenal glands to an injection of cosyntropin (Cortrosyn, a synthetic ACTH preparation). Blood is drawn for a fasting 8:00 AM cortisol level before cosyntropin is administered, and then blood samples are taken 30 and 60 minutes after it is administered. The adrenal glands normally respond to the cosyntropin by synthesizing and secreting adrenocorticoids. The plasma cortisol level should increase to at least 18 fg/dL. The response to cosyntropin is decreased or absent in people with adrenal insufficiency or hypopituitarism. Long-term steroid therapy affects results. This test may be contraindicated in the presence of infections, inflammatory diseases, and cardiac disease. Cortisol stimulation is the preferred test to diagnose Addison's disease.

Urine and Plasma Catecholamine Levels

Urine vanillylmandelic acid, a metabolite of catecholamines, is rarely used diagnostically today. It is preferred to measure free and fractionated plasma metanephrines, fractionated and total urine metanephrines, and plasma normetanephrines since they yield higher sensitivity levels for pheochromacytoma. Since they have high concentration in the urine and are easy to detect, a 24-hour urine test is performed when a person is suspected of having hypertension due to pheochromocytoma. Elevated levels of catecholamines can be found

in patients with hypothyroidism, DKA, neuroblastomas, and ganglioneuromas.

Urine should not be collected when the patient is fasting. Test results are also affected by many drugs and foods, such as tea, coffee, vanilla, and fruit juice. Therefore, some laboratories restrict certain foods for 2 days before testing and on the day of testing. Certain drugs may also be discontinued for 4 to 7 days before testing. Normal adult values for urine vanillylmandelic acid are 2 to 7 mg/24 h, and for catecholamines, 270 fg/24 h.

Urine 17-Ketosteroids and 17-Hydroxycorticosteroids

These 24-hour urine collection tests reflect adrenal function by measuring the urinary excretion of steroids. They are used infrequently because they have been replaced by serum immunoassays.

Diagnostic Studies

Adrenal Scan

This scan is used to identify the site of certain tumors or sites that produce excessive amounts of catecholamines. The radionuclide iobenguane (^{131}I) is injected intravenously, and scans are performed on days 2, 3, and 4. Sometimes, only 1 day is needed, and other times imaging is needed on days 6 and 7. Normally, tumors and sites of hypersecretion are absent. If ACTH levels are elevated, MRI of the pituitary should be done to seek the source.

▲ Clinical Applicability Challenges

CASE STUDY

Mrs. R., a 61-year-old African American female, arrives in the emergency department after experiencing severe chest pressure, nausea, and diaphoresis at 5:30 AM. She takes a fluid pill for high blood pressure and reports nocturia at least three times. She smokes about a half pack of cigarettes a day (positive history of smoking 1 pack/d for over 40 years) and drinks one to two glasses of wine per week. She is allergic to penicillin (rash). Currently, she works as a secretary part-time and does not exercise much. She has been overweight all of her adult life and has gained about 12 pounds this past year.

The nurse notes that Mrs. R. is fully oriented, obese, with slightly diaphoretic skin and dry buccal membranes. Her vital signs are blood pressure, 165/110 mm Hg; heart rate, 102 beats/min; and respiratory rate, 24 breaths/min. She is afebrile.

Mrs. R.'s laboratory results show a glucose level of 220 mg/dL, serum ketones are mildly positive, and white blood cells are normal. Mrs. R.'s electrocardiogram shows sinus rhythm (rate, 86 to 94 beats/min) with ST elevation in inferior leads. She denies acute chest pain upon arrival as the staff prepares to start an intravenous line.

1. Mrs R. has not been diagnosed with diabetes. Explain how she will be diagnosed using the American Diabetes Association's criteria.
2. Since Mrs. R. was not diagnosed with diabetes previously, discuss several reasons why she may be displaying signs and symptoms of diabetes currently.
3. What specific risk factors for type 2 diabetes mellitus are illustrated in this case study?

44 Common Endocrine Disorders

Jane Kapustin

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Examine the pathophysiological principles that help explain thyrotoxic crises, myxedema coma, adrenal crises, syndrome of inappropriate antidiuretic hormone secretion, diabetes insipidus, diabetic ketoacidosis, hyperglycemic hyperosmolar state, and hypoglycemia.
2. Distinguish key precipitating factors, history, and clinical manifestations of endocrine disorders.
3. Discuss five laboratory studies that are useful in diagnosing acute endocrine disorders.
4. Analyze the similarities and differences in caring for patients with endocrine disorders.
5. Explore the nursing role in assessing, managing, and evaluating a plan of care for patients with endocrine disorders.

Endocrine disorders have multisystem effects. At the same time, acute illness may lead to hypofunction and, less commonly, hyperfunction of the neuroendocrine system. Patients with acute illness who are at risk for endocrine dysfunction may have a preexisting endocrine disorder. Although that disorder may have already been diagnosed, many endocrine dysfunctions are not recognized before acute illness. For this reason, endocrine dysfunction should be considered in the assessment and management of all critically ill patients.

▲ Hypothalamic–Pituitary–Adrenal Function During Critical Illness

Severe illness and stress activate hypothalamic–pituitary–adrenal (HPA) axis, resulting in the release of cortisol from the adrenal cortex. This mechanism is key to providing for positive adaptation to severe stressors and for general cellular and organ homeostasis. The nervous and endocrine systems are both influenced by the responses to stress, and the actions of these systems are intertwined and interdependent. For example, the neurosensory pathways and chemical mediators in the vascular system will detect a potential stressor, and the endocrine and immune systems will be stimulated to provide both an interaction and reaction to deal effectively with it. Table 44-1 defines the hormones that are intricately involved in the response to stress. The stress response is first activated at the level of the central nervous system (CNS). Communication occurs along the many neuronal pathways in the cerebral cortex, limbic system, thalamus, hypothalamus, pituitary gland, and reticular activating system (Fig. 44-1). One area of the brainstem, the locus ceruleus, is responsible for the autonomic nervous system release of norepinephrine, one of the most basic survival responses to stress. This release causes a chain of events that prepares humans for mounting an appropriate reaction to the stressor. In turn, the corticotropin-releasing factor induces the secretion of the adrenocorticotropic hormone (ACTH), which triggers the synthesis and release of cortisol from the adrenal gland.[1]

Acute and chronic stressful events can initiate a significant physiological response in an effort to maintain homeostasis. The "fight-or-flight" response is the initial reaction to a severe stressor, and release of norepinephrine and epinephrine follows. Activation of the HPA axis occurs in response to stress and critical illness, and secretion of cortisol, the primary glucocorticoid hormone, results. Cellular actions of cortisol include stimulation of gluconeogenesis, anti-inflammatory effects of the immune system, maintenance of vascular tone and endothelial integrity, increased sensitivity to pressors, reduction of nitric oxide–mediated vasodilation, and modulation of angiotensinogen synthesis. This hormone plays an important role in survival from major stressful events. Cortisol stimulates the HPA axis during acute and chronic events, such as surgery, sepsis, trauma, burns, and other severe critical illnesses. Initially, elevated cortisol levels are typically detected in the critically ill. If the stressor is prolonged, cortisol levels become depleted. Refer to Table 44-1 and to Chapter 42 for a review of the hormones activated in the neuroendocrine response to stress.

This chapter now presents an overview of the pathophysiology, assessment, management, and complications of patients with acute endocrine disorders. These disorders are

Table 44-1 Hormones Involved in the Neuroendocrine Response to Stress

Hormones Associated With the Stress Response	Source of the Hormone	Physiological Effects
Catecholamines (norepinephrine, epinephrine)	Locus ceruleus, adrenal medulla	Produces a decrease in insulin release and an increase in glucagon release resulting in increased glycogenolysis, gluconeogenesis, lipolysis, proteolysis, and decreased glucose uptake by the peripheral tissues; an increase in heart rate, cardiac contractility, and vascular smooth muscle contraction; and relaxation of bronchial smooth muscle
Corticotropin-releasing factor	Hypothalamus	Stimulates ACTH release from anterior pituitary and increased activity of neurons in locus ceruleus
Adrenocorticotropic hormone (ACTH)	Anterior pituitary	Stimulates the synthesis and release of cortisol
Glucocorticoid hormones (eg, cortisol)	Adrenal cortex	Potentiates the actions of epinephrine and glucagon; inhibits the release and/or actions of the reproductive hormones and thyroid-stimulating hormone; and produces a decrease in immune cells and inflammatory mediators
Mineralocorticoid hormones (eg, aldosterone)	Adrenal cortex	Increases sodium absorption by the kidney
Antidiuretic hormone (ADH, vasopressin)	Hypothalamus, posterior pituitary	Increases water absorption by the kidney; produces vasoconstriction of blood vessels; and stimulates the release of ACTH

SPOTLIGHT ON GENETICS 44-1

FRAGILE X SYNDROME

- Fragile X syndrome occurs in approximately 1 in 4,000 males and 1 in 8,000 females, and is a genetic condition that causes a range of developmental problems including learning disabilities and cognitive impairment.
- Mutations in the *FMR1* gene cause fragile X syndrome. The *FMR1* gene provides instructions for making a protein called fragile X mental retardation 1 protein, whose function is not fully understood.
- Nearly all cases of fragile X syndrome are caused by a mutation in which a DNA segment, known as the CGG triplet repeat, is expanded within the *FMR1* gene. Normally, this DNA segment is repeated from 5 to about 40 times. In people with fragile X syndrome, however, the CGG segment is repeated more than 200 times. The abnormally expanded CGG segment turns off (silences) the *FMR1* gene, which prevents the gene from producing fragile X mental retardation 1 protein.
- Genetic testing is available to diagnose fragile X syndrome.

thyroid dysfunctions, adrenal gland dysfunctions, antidiuretic hormone (ADH) dysfunctions, and emergencies in patients with diabetes. Spotlight on Genetics 44-1 discusses the genetic disorder, Fragile X Syndrome.

▲ Thyroid Dysfunction

Thyroid dysfunction is a common clinical problem in the United States. Women are 5 to 10 times more likely than men to present with thyroid disease. The most common thyroid conditions are hyperthyroidism, hypothyroidism, and thyroid nodule. Clinical presentations may be quite subtle; therefore, patients with endocrine manifestations must be regarded with a high index of suspicion. Extremes of these two conditions are discussed in greater detail in this chapter. Figure 44-2 compares the signs and symptoms of hyperthyroidism and hypothyroidism.

Thyrotoxic Crisis

Thyrotoxic crisis is a severe form of hyperthyroidism often associated with physiological or psychological stress. When the thyroid state worsens critically, it is called thyrotoxic

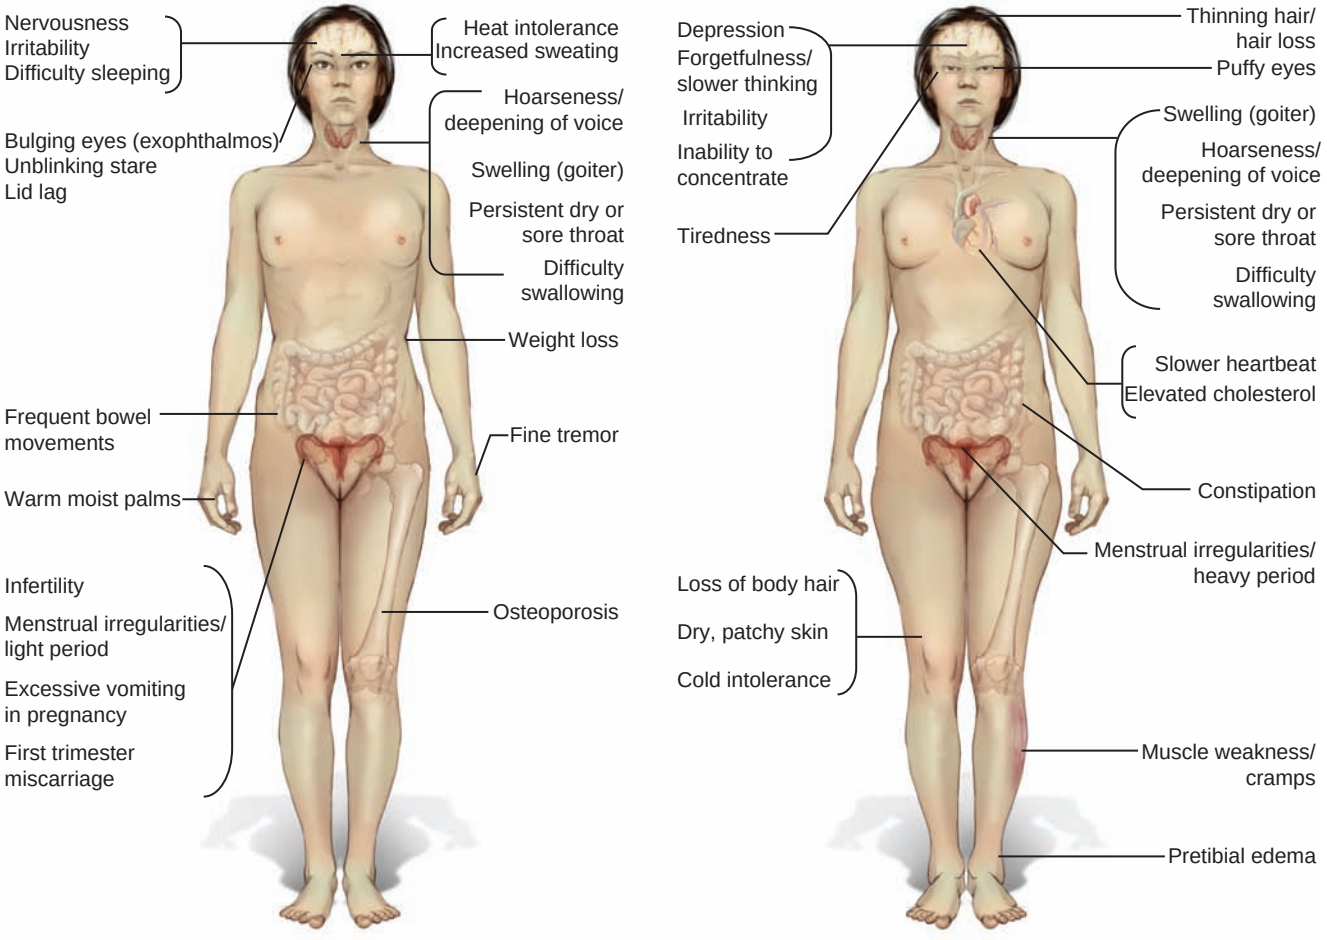

FIGURE 44-2 ▲ Clinical manifestations of hyperthyroidism **(A)** and hypothyroidism **(B)**.

BOX 44-1 Conditions Associated With Hyperthyroidism or Thyrotoxicosis

Endocrine Disorders
- Graves' disease
- Nodular goiter
- Toxic multinodular adenoma
- Radiation-induced thyroiditis
- Subacute thyroiditis

Drugs
- Iatrogenic thyroid replacement
- Accidental or purposeful ingestion of thyroid medication
- Contrast media dye
- Amiodarone
- β-Blockers

Tumors
- Metastatic thyroid cancer
- Hypophyseal tumors
- Hypothalamus tumor
- Hydatidiform mole

crisis. Rapid deterioration and death can occur if the condition is untreated. These patients must be admitted to the intensive care unit for supportive measures, antithyroid medications, steroids, and continuous nursing care. Consultation with an endocrinologist and cardiologist is essential. Even without preexisting coronary artery disease, untreated thyrotoxic crisis can cause angina pectoris and myocardial infarction, heart failure, cardiovascular collapse, coma, and death. The condition may develop spontaneously, but it occurs most frequently in people who have undiagnosed or partially treated severe hyperthyroidism.

By definition, hyperthyroidism is a condition in which the actions of the thyroid hormones result in greater-than-normal responses. Specific diseases that can cause hyperthyroidism include Graves' disease, exogenous administration of levothyroxine, thyroiditis, toxic nodular goiter, toxic multinodular goiter, and thyroid cancer. Certain drugs, such as contrast material for radiographic procedures or amiodarone (an antiarrhythmic drug), may precipitate the thyrotoxic state because of their high iodine content. The conditions associated with hyperthyroidism are summarized in Box 44-1.

Pathophysiology

The cause of thyrotoxic crisis, often referred to as thyroid storm, is poorly understood. Physiological mechanisms that are thought to induce thyrotoxic crises include the sudden release of large quantities of thyroid hormone, low tissue tolerance to triiodothyronine (T_3) and thyroxine (T_4), adrenergic hyperactivity, and excessive lipolysis and fatty acid production. The abrupt release of large quantities of thyroid hormone is thought to produce the hypermetabolic manifestations seen during thyrotoxic crises. The many different endocrine, reproductive, gastrointestinal, integumentary, and ocular manifestations are caused by increased circulating levels of thyroid hormone and by stimulation of the sympathetic nervous system.

Adrenergic hyperactivity is considered a possible link to thyrotoxic crisis. Although thyroid hormone and catecholamines potentiate each other, catecholamine levels during thyrotoxic crisis are usually within the normal range. It is uncertain whether the effects of hypersecretion of thyroid hormone or increased catecholamine levels cause heightened sensitivity and thyroid overfunction. Thyroid–catecholamine interactions result in an increased rate of chemical reactions, increased nutrient and oxygen consumption, increased heat production, alterations in fluid and electrolyte balance, and a catabolic state.

Another mechanism that may contribute to thyrotoxic crisis is excessive lipolysis and fatty acid production. With excessive lipolysis, increased fatty acids are oxidized and produce an overabundance of thermal energy that is difficult to dissipate through vasodilation.

Assessment

HISTORY AND PHYSICAL EXAMINATION. Accurate identification of the precipitating factor for thyrotoxic crisis allows for proper treatment to be initiated. Precipitating factors for people with recognized and unrecognized existing thyroid disease are listed in Box 44-2. Hyperthyroidism's most common form, Graves' disease, is an autoimmune condition caused by thyroid-stimulating immunoglobulins. It is not always apparent that the patient is suffering from

BOX 44-2 PATIENT SAFETY

Risk Factors for Development of Thyroid Crisis

In the Presence of a Known Preexisting Condition

Precipitating factors
- Infection
- Trauma
- Stress
- Coexistent medical illness (eg, myocardial infarction, pulmonary disease)
- Pregnancy
- Exposure to cold

Medications
- Chronic steroid therapy
- β-blockers
- Narcotics, anesthetics
- Alcohol, tricyclic antidepressants
- Glucocorticoid therapy
- Insulin therapy
- Thiazide diuretics
- Phenytoin
- Chemotherapy agents
- Nonsteroidal anti-inflammatory agents (NSAIDs)

In the Presence of an Unknown Preexisting Condition

Precipitating factors
- Pituitary tumors
- Radiation therapy of the head and neck
- Autoimmune disease
- Neurosurgical procedures
- Metastatic malignancies (eg, lung, breast)
- Surgery
- Long-term illness
- Shock
- Postpartum status
- Trauma

BOX 44-3 PATIENT SAFETY

Possible Indications of Thyroid Emergencies

Thyroid Storm	Myxedema Coma
Tachycardia	Bradycardia
Hyperthermia	Hypothermia
Tachypnea	Hypoventilation
Diaphoresis	
Hypercalcemia	Hyponatremia
Hyperglycemia	Hypoglycemia
Metabolic acidosis	Respiratory and metabolic acidosis
Diarrhea	
Cardiovascular collapse	Cardiovascular collapse
Cardiogenic shock	Decreased vascular tone
Hypovolemia	
Cardiac dysrhythmias	
Irritability	
Depressed level of consciousness (LOC)	Depressed LOC
Emotional lability	Seizures, coma
Psychosis	
Tremors, restlessness	Hyporeflexia
Weight loss	Weight gain

this particular disease. Therefore, subtle clues need to be explored, such as the patient's exposure to iodine, prior or current use of thyroid hormone, anterior neck pain, thyroid enlargement, exophthalmos (ie, protrusion of one or both eyes) or other eye symptoms, pregnancy, a history of goiter, and a family history of thyroid disease.

Signs and symptoms of hyperthyroidism affect all body systems and include sweating, heat intolerance, nervousness, tremors, palpitations, tachycardia, hyperkinesis, and increased bowel sounds. Extremes of these manifestations, specifically a temperature greater than 104°F (40°C) in the absence of an infection, tachycardia, and CNS dysfunction, may be present in hyperthyroidism. CNS abnormalities include agitation, restlessness, delirium, seizures, or coma. Signs of thyroid emergencies are listed in Box 44-3.

As discussed in Box 44-4, older patients may not have the classic signs and symptoms of thyrotoxic crisis, causing this condition to be overlooked. However, they frequently have suggestive signs and symptoms. In these circumstances, the nurse asks older patients if they have heart disease and what medications they take. This can be important in determining whether there is underlying thyroid disease because β-blocker medication may mask cardiovascular clues.

BOX 44-4 CONSIDERATIONS FOR THE OLDER PATIENT

Hyperthyroidism

Elderly patients with hyperthyroidism often present with atypical signs and symptoms of the disorder. Apathetic hyperthyroidism, as seen in the older patient, manifests with a single symptom such as depression, atrial fibrillation, heart failure, or muscle weakness. Thus, the elderly patient may present with palpitations, shortness of breath, tremor, and nervousness, but many other symptoms, as seen in younger patients, are masked. Much time can transpire until the patient deteriorates into full-blown thyroid storm.

LABORATORY STUDIES. Laboratory studies may show elevated total T_4, free T_3, and free T_4 levels. The thyroid-stimulating hormone (TSH) level is extremely low (usually <0.1 mcg/mL) in hyperthyroidism. TSH is suppressed because the levels of circulating hormones, T_3 and T_4, are also elevated. Recall that TSH is secreted when thyroid hormone levels are low.

Serum electrolytes, liver function tests, and complete blood counts, although not diagnostic, may help uncover abnormalities that require treatment. They may also help identify the precipitating cause. Electrolyte imbalances from dehydration, excessive bone resorption, and increased insulin degradation often occur. The serum calcium level is often elevated, whereas potassium and magnesium levels are decreased, and liver function test values are increased. Hyperglycemia resulting from insulin resistance and breakdown of stored glucose often occurs.

DIAGNOSTIC STUDIES. Diagnostic tests include the radioactive iodine uptake test, whose result is usually increased. Electrocardiography (ECG) and cardiac monitoring may show atrial fibrillation, supraventricular tachycardia, sinus bradycardia, heart block, conduction disturbances, and ventricular dysrhythmias, all reflective of the hypermetabolic state and the synergized catecholamines.

Management

Management goals for thyrotoxic crises are fourfold: (1) treating the precipitating factor or factors, (2) controlling excessive thyroid hormone release, (3) inhibiting the thyroid hormone biosynthesis, and (4) treating the peripheral effects of thyroid hormone.[1]

Antithyroid drugs (Table 44-2) are used to control thyroid release or biosynthesis. Propylthiouracil (PTU) is the preferred agent during pregnancy, although it can only be given orally. PTU is preferred because it blocks the conversion of T_4 to T_3 in peripheral tissues and binds iodine to prevent synthesis of the hormone. If the oral route is not possible, methimazole can be given rectally. PTU has been associated with severe hepatic side effects and close monitoring is warranted to avoid irreversible damage.

Iodine solutions, such as sodium iodide IV or potassium iodide (SSKI) or Lugol's solution orally, are given to block the release of thyroid hormone. These agents should not be given until 1 hour after the administration of antithyroid medications. Lithium is the choice for patients who are iodine sensitive. Glucocorticoids may be ordered because they also inhibit thyroid hormone release.

Emergency removal of excess circulating hormone replacement therapy can be accomplished by instituting plasmapheresis, dialysis, or hemoperfusion adsorption. Cholestyramine may be used to assist with oral absorption of excess hormone.

Blocking the catecholamine effects that may result in cardiovascular decompensation secondary to decreased stroke volume and reduced cardiac output may be instituted. β-Blockers, specifically propranolol, are used to treat the symptoms of the hyperthyroidism rather than the primary thyroid disease. This therapy may be ordered to restore cardiac function by decreasing the catecholamine-mediated symptoms. The response to β-blockers is carefully monitored because intrinsic cardiac disease may worsen as a result of the negative inotropic effects.[2] Digoxin, diltiazem (Cardizem),

Table 44-2 Drugs Used to Treat Hyperthyroidism

Drug	Dose	Action	Nursing Considerations
Propylthiouracil (PTU)	Loading: 800–1,200 mg Maintenance: 100–400 mg every 4–6 h orally (PO)	Blocks synthesis of hormones (conversion of T_3 to T_4)	Monitor cardiac parameters. Observe for conversion to hypothyroidism. Must be given by mouth. Watch for rash, nausea, vomiting, agranulocytosis, lupus syndrome, hepatitis.
Methimazole	10–20 mg every 6–8 h PO	Blocks synthesis of thyroid hormone	More toxic than PTU. Watch for rash and other symptoms as for PTU.
Sodium iodide	1 g every 12 h (intravenous [IV])	Suppresses release of thyroid hormone	Given 1 h after PTU or methimazole. Watch for edema, hemorrhage, gastrointestinal upset.
Potassium iodide	2–5 gtts every 8 h PO	Suppresses release of thyroid hormone	Discontinue for rash. Watch for signs of toxic iodinism.
SSKI	5–10 gtts every 8 h PO	Suppresses release of thyroid hormone	Mix with juice or milk. Give by straw to prevent staining of teeth.
Dexamethasone	2 mg every 6 h IV	Suppresses thyroid hormone release	Monitor intake and output. Monitor glucose. May cause hypertension, nausea, vomiting, anorexia, infection.
β-Blocker (eg, propranolol)	1–3 mg every 1–4 h IV	β-Adrenergic blocking agent	Monitor cardiac status. Hold for bradycardia or decreased cardiac output. Use with caution in patients with heart failure.

diuretics, or a combination of these agents may also be used to treat congestive heart failure or supraventricular tachydysrhythmias. Oxygen is delivered to address the additional metabolic requirements. The goal of therapy is to decrease myocardial oxygen consumption, decrease the heart rate (ideally to below 100 beats/min), and increase cardiac output.

Corticosteroids may be used to help treat coexisting adrenal insufficiency and thyroid storm. Intravenous (IV) dexamethasone or hydrocortisone can be given to assist with blunting excess thyroid hormone release in this emergency state.

Management also focuses on monitoring multisystem effects from the hypermetabolism of thyrotoxic crisis and the response to treatment. Cardiovascular function, fluid and electrolyte balance, and neurological status require close attention. It is necessary to assess blood pressure, heart rate and rhythm, respiratory rate, and extra heart sounds every hour.

The nurse evaluates fluid status and laboratory values. Hourly monitoring of body temperature is warranted because the patient is at risk for hyperthermia. Antipyretic agents, particularly acetaminophen, are recommended for fever control; aspirin is not appropriate because it increases free T_3 and T_4 levels. Tepid baths or a cooling blanket may be necessary. It is important to avoid cooling to the point of shivering and piloerection because this may have a rebound effect of raising body temperature. IV fluids are necessary to replace the fluids lost from excessive hyperthermia, tachypnea, diaphoresis, and diarrhea that often accompany thyrotoxic crisis.

The nurse assesses neurological status at least hourly. Seizure precautions and safety measures prevent injury. If the patient's level of consciousness (LOC) decreases, it is important to assess airway patency and safety issues. Maintaining a calm environment is necessary to help manage the extreme agitation and restlessness seen in the patient with thyrotoxic crisis.

Energy and nutritional needs are heightened because of the hypermetabolism. Interventions include administering glucose-containing solutions, nutritional support, vitamin supplementation, and sedation if needed. The nurse monitors the patient's glycemic status because the administration of corticosteroids and excess glucose-rich nutrients may lead to hyperglycemia in some patients. Box 44-5 lists examples of nursing diagnoses for the patient in thyrotoxic crisis.

Effective therapy can be expected to result in clinical improvement within 24 to 48 hours. The nurse monitors the patient's mental status carefully and also checks for stabilization of vital signs and normalization of body temperature. Patient follow-up to prevent another episode is

BOX 44-5 EXAMPLES OF NURSING DIAGNOSES

For the Patient in Thyroid Crisis

- Deficient Fluid Volume related to hypermetabolic state
- Hyperthermia related to hypermetabolic state
- Decreased Cardiac Output related to hypermetabolic state and heart failure
- Risk for Ineffective Cerebral Tissue Perfusion
- Risk for Injury related to altered mental status

necessary and may involve lifelong medication or suppressive therapy with thyroid ablation.

Myxedema Coma

Hypothyroidism is a common disorder with a broad clinical spectrum—patients may be asymptomatic, or they may be severely ill with myxedema coma. Hypothyroidism is more common among women, and the incidence increases with age. Approximately 10% to 15% of elderly patients have elevated TSH associated with hypothyroidism, and routine screening of high-risk populations is often done in primary care settings.[3]

Myxedema coma is a rare, life-threatening emergency brought on by extreme hypothyroidism. It usually is seen in older patients during winter months after certain precipitating factors, such as stress, exposure to extreme cold temperatures, or trauma. In addition to coma, complications of myxedema coma include pericardial and pleural effusions, megacolon with paralytic ileus, and seizures. Death can result if severe hypoxia and hypercapnia are not reversed.

Pathophysiology

Deficient production of thyroid hormone results in the clinical state termed hypothyroidism. Hypothyroidism, a chronic disease, is 10 times more common in women than in men. It occurs in all age groups but most commonly in those older than 50 years. It is more common than hyperthyroidism.

Hypothyroidism can be primary or secondary. Primary causes include congenital defects, loss of thyroid tissue after treatment for hyperthyroidism, defective hormone synthesis from an autoimmune process, and antithyroid drug administration or iodine deficiency. Secondary causes include peripheral resistance to thyroid hormone, pituitary infarction, and hypothalamic disorders. Transient hypothyroidism can occur after withdrawal of prolonged T_4 or T_3 treatment. The common causes of hypothyroidism are summarized in Box 44-6.

Hypothyroidism usually affects all body systems. A low basal metabolic rate and decreased energy metabolism and heat production are characteristic. The patient with chronic hypothyroidism may have myxedema, an alteration in the composition of the dermis and other tissues. The connective fibers are separated by an increased amount of protein and mucopolysaccharides. This binds water, producing nonpitting, boggy edema, especially around the eyes, hands, and feet; it is also responsible for thickening of the tongue and the laryngeal and pharyngeal mucous membranes, resulting in slurred speech and hoarseness.

BOX 44-6 Causes of Hypothyroidism

- Destruction of the thyroid gland (eg, surgery, radioactive iodine, external radiation to the neck)
- Infiltrative disease (eg, sarcoidosis, amyloidosis, lymphoma)
- Autoimmune disease (eg, Hashimoto's disease, post-Graves' disease)
- Thyroiditis (eg, viral, silent, postpartum)
- Drug induced (eg, iodides, lithium, amiodarone)
- Hereditary hypothyroidism
- Thyrotropin-releasing hormone deficiency
- Thyroid-stimulating hormone deficiency

Assessment

HISTORY AND PHYSICAL EXAMINATION. Signs and symptoms of hypothyroidism include fatigue, weakness, decreased bowel sounds, decreased appetite, weight gain, and ECG changes. Myxedema coma is a rare manifestation of hypothyroidism, characterized by severe depression of the sensorium, hypothermia, hypoventilation, hypoxemia, hyponatremia, hypoglycemia, hyporeflexia, hypotension, and bradycardia. Patients with myxedema coma do not shiver, although body temperatures below 80°F (26.6°C) have been reported. The diagnosis of myxedema coma depends on recognizing the clinical symptoms and identifying the underlying precipitating factor. The most common precipitating factor is pulmonary infection; other factors include trauma, stress, infections, drugs (eg, narcotics or barbiturates), surgery, and metabolic disturbances (see Box 44-3).

LABORATORY STUDIES. A decrease in T_4 and free T_4 levels is most common, whereas sodium is usually decreased, and potassium is increased. TSH is markedly elevated in severe hypothyroidism. Arterial blood gas (ABG) findings usually show a severe hypercapnia with decreased arterial oxygen tension (PaO_2) and increased arterial carbon dioxide tension ($PaCO_2$).

DIAGNOSTIC STUDIES. A chest radiograph detects pleural effusion. ECG changes include bradycardia, a prolonged PR interval, and decreased amplitude of the P wave and QRS complex. Heart block may develop.

Management

The most serious complication of hypothyroidism is progression to myxedema coma and death, if the condition is untreated. A multisystem approach must be used in treating this emergency. Mechanical ventilation is used to control hypoventilation, hypercapnia, and respiratory arrest. IV hypertonic normal saline and glucose solutions correct the dilutional hyponatremia and hypoglycemia. Fluid administration plus vasopressor therapy may be necessary to correct hypotension.

Pharmacological therapy includes the administration of thyroid hormone and corticosteroids. There are several approaches to this aspect of medical management. Initial drug therapy includes 300 to 500 mcg T_4 IV to saturate all protein-binding sites and establish a relatively normal T_4 level. Subsequent doses may include 75 to 100 mcg daily. IV or oral T_3 is an alternative order. Guidelines for T_3 replacement are 25 mcg IV every 8 hours for the first 24 to 48 hours. Oral T_3 doses every 8 hours are also ordered. Hormone replacement should occur slowly, with continuous monitoring of the patient during treatment to avoid sudden increased metabolic demand and resultant myocardial infarction. Methodical fluid replacement and rewarming of the patient also help to avoid complications.

Additional interventions include treating abdominal distention and fecal impaction and managing hypothermia by gradually rewarming the patient using blankets and socks. Mechanical devices are not used. The nurse monitors

the patient for neurological status and changes in LOC and implements seizure precautions. Care of the comatose patient includes preventing complications related to aspiration, immobility, skin breakdown, and infection. Monitoring of cardiovascular and respiratory function is necessary. Fluid administration must also be monitored because of a risk for fluid overload. An important aspect of care is to detect early signs of complications. As the patient recovers, interventions focus on patient self-care and education.

Patient follow-up includes a thorough investigation of how the severe hypothyroidism occurred and how it can best be avoided in the future. Patient teaching, family follow-up, medical alert activation, and involvement of community supports may be necessary for this complex patient.

▲ Adrenal Gland Dysfunction

Adrenal Crisis

Pathophysiology

Adrenal insufficiency, also known as hypoadrenalism or hypocorticism, is a rare but life-threatening dysfunction of the adrenal cortex. Adrenal hormone insufficiency may be either primary (ie, directly involving the adrenal gland) or secondary (ie, due to hypothalamic–pituitary disease).

Primary adrenal insufficiency is termed Addison's disease. The most common cause of primary hypoadrenalism in the industrialized West is autoimmune adrenalitis. Autoimmune antibody formation leads to the gradual destruction of the adrenal gland, resulting in adrenal insufficiency. The second leading cause of primary adrenal insufficiency is destruction of the gland secondary to *Mycobacterium tuberculosis* infection. Worldwide, tuberculosis remains the most common cause of primary adrenal insufficiency. Other causes include bilateral hemorrhage of the glands secondary to bacterial infection with sepsis and shock, metastatic malignancies, acquired immunodeficiency syndrome (AIDS), fungal infections, surgical adrenalectomy, and sarcoidosis.

The most common cause of secondary adrenal insufficiency is iatrogenic, resulting from abrupt withdrawal of exogenous ACTH or as a complication of cortisol therapy. Suppressed ACTH secretion as a result of exogenous cortisol therapy disrupts the body's natural feedback loop that controls cortisol secretion, rendering the patient in an acute state of adrenal insufficiency. Other causes of secondary adrenal insufficiency include metastatic carcinomas of the lung or breast, pituitary infarction, surgery or irradiation, and CNS disturbances, such as basilar skull fractures or infections.

Acute adrenal insufficiency or adrenal crisis occurs when there is a change in the chronic condition or massive adrenal hemorrhage. In addition to the chronic disease, severe infection, septic shock, trauma, surgical procedure, or some extra stress occurs, precipitating acute adrenal crisis in the patient. The patient is therefore unable to meet the requirements for normal metabolic function or increased metabolic needs as necessary for stress or illness. Any stressed, critically ill patient can develop adrenal insufficiency as a result of suddenly imposed extraneous stressors. As the patient struggles to survive, he or she quickly depletes cortisol stores and may require exogenous replacement.[4]

Assessment

HISTORY AND PHYSICAL EXAMINATION. Symptoms of adrenal insufficiency are the same for primary and secondary disease. Because adrenal insufficiency affects both glucocorticoids and mineralocorticoids, many body functions are affected, including glucose metabolism, fluid and electrolyte balance, cognitive state, and cardiopulmonary status. Weakness, fatigue, anorexia, nausea, vomiting, diarrhea, and abdominal pain may be initial clues to adrenal crisis. These findings are nonspecific until linked with the history of a chronic condition requiring past or present corticosteroid use.[5] Specifically, use of more than 20 mg of hydrocortisone or its equivalent, taken for longer than 7 to 10 days, has the potential for suppressing the HPA axis.

Hyperpigmentation on areas of the elbows, knees, hands, or buccal mucosa is seen in primary adrenal insufficiency. The presence of hyperpigmentation, secondary to the deposition of melanin in the skin, strengthens the clinical picture of adrenal crisis. The most common physical changes include signs of severe dehydration, such as weight loss and orthostatic hypotension. Dehydration occurs secondary to the nephrons' insufficient ability to reabsorb sodium and water. Signs and symptoms of an impending adrenal crisis are summarized in Box 44-7.

LABORATORY STUDIES. Laboratory values in acute conditions of glucocorticoid and mineralocorticoid deficiency show hyponatremia, hyperkalemia, decreased serum bicarbonate levels, and elevated blood urea nitrogen (BUN). Metabolic acidosis may occur because of dehydration. Hypoglycemia is usually present. Other abnormal laboratory findings include anemia and lymphocytosis with eosinophilia. In primary adrenal insufficiency, the patient presents with chronically elevated ACTH levels. ACTH levels are normal or decreased in the patient with secondary adrenal insufficiency.

BOX 44-7 PATIENT SAFETY

Indications of Impending Adrenal Crisis

Aldosterone Deficiency
- Hyperkalemia
- Hyponatremia
- Hypovolemia
- Elevated (blood urea nitrogen [BUN])

Cortisol Deficiency
- Hypoglycemia
- Decreased gastric motility
- Decreased vascular tone
- Hypercalcemia

Generalized Signs and Symptoms
- Anorexia
- Nausea and vomiting
- Abdominal cramping
- Diarrhea
- Tachycardia
- Orthostatic hypotension
- Headache, lethargy
- Fatigue, weakness
- Hyperkalemic electrocardiographic changes
- Hyperpigmentation

Serum cortisol levels and cortisol stimulation (ACTH stimulation) tests are also used to confirm the diagnosis. Cortisol levels below 15 mcg/dL are indicative of adrenal dysfunction. In primary adrenal insufficiency, repeated injections of ACTH (or Cortrosyn) do not cause a rise in cortisol levels because the adrenal gland is dysfunctional. In secondary adrenal insufficiency, ACTH injections cause a normal but delayed response.

DIAGNOSTIC STUDIES. A computed tomography (CT) scan of the adrenal glands and the head may be done to detect tumors or other pathology of the adrenal and pituitary gland.

Management

The immediate goal of therapy is to administer the needed hormones and restore fluid and electrolyte balance. Hydrocortisone, 100 mg IV, is administered immediately, followed by 100 mg every 6 to 8 hours. Fluid resuscitation is also started immediately with normal saline and 5% dextrose solutions. The rate of fluid and electrolyte replacement is dictated by the degree of volume depletion, serum electrolyte levels, and clinical response to therapy. Associated medical or surgical problems may indicate the need for invasive blood pressure and hemodynamic monitoring.

Another management goal is to prevent complications. This includes monitoring signs and symptoms of electrolyte imbalance (hyponatremia and hypercalcemia) and respiratory and cardiovascular function. The nurse looks for changes in blood pressure, heart rate and rhythm, skin color and temperature, capillary refill time, and central venous pressure (CVP). There is a risk for orthostatic hypotension, bradycardia, and dysrhythmias. The nurse also monitors neuromuscular signs, such as weakness, twitching, hyperreflexia, and paresthesia.

Emotional support, a simple explanation, and a quiet environment are effective in assisting the patient emotionally through the physiological crisis. Once the acute crisis is over, patient education is a goal of care. Patient education is necessary because the ultimate prognosis depends on the patient's ability to understand and follow through with self-care. Self-care includes knowing the medication regimen, stress factors and their effect on the disease, and the signs of impending crisis; wearing a medical identification tag or bracelet, or carrying a wallet card; and taking medication as prescribed.

Pheochromocytoma

Pheochromocytoma is a rare catecholamine-secreting tumor that arises from chromaffin cells in the adrenal gland. Because of the excessive catecholamine secretion, pheochromocytoma may precipitate life-threatening hypertension or cardiac dysrhythmias when norepinephrine or epinephrine is released in larger quantities. The trigger for the release of catecholamines is unknown, but the high levels can lead to severe hypertension, atrial fibrillation, ventricular fibrillation, myocardial infarction, or cerebral infarction.

Pheochromocytomas can occur in people of all ages and ethnicities, and the peak incidence is between the third and fifth decades of life. The classic symptomatic triad includes headaches, palpitation, and sweating. When associated with severe, paroxysmal hypertension, the triad is found to be over 90% sensitive and specific for pheochromocytoma. Typically the symptoms worsen with time and become more severe as the tumor grows.

Diagnosis is based on the suspicion of pheochromocytoma for the patient who presents with paroxysmal hypertension and other associated symptoms. Choice laboratory studies include measurement of fractionated plasma and urine metanephrines and normetanephrines. Vanillylmandelic acid is rarely measured because of its limited ability to detect a true positive result (low sensitivity). Diagnosis is confirmed with imaging studies such as abdominal magnetic resonance imaging or CT. Medical care includes surgical resection of the tumor and careful control of the hypertension. Medications that are required preoperatively to control blood pressure and to prevent hypertensive crisis include α-blockers and β-blockers. Usually, the hypertension is no longer a problem postoperatively.

▲ Antidiuretic Hormone Dysfunction

Two disorders involve ADH dysfunction. One, syndrome of inappropriate antidiuretic hormone secretion (SIADH), is an excess of ADH. The second, diabetes insipidus, involves a deficiency of ADH. Both of these disorders can produce severe fluid and electrolyte imbalances and adverse neurological changes. Recall that ADH is synthesized in the hypothalamus and stored in the posterior pituitary. It is released when stimulated by specific conditions and causes the renal tubules to reabsorb more water and sodium.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

Pathophysiology

In SIADH, there may be either increased secretion or increased production of ADH. The increase in ADH occurs despite normal initial osmolality. As a result, increased ADH production causes an increase in total body water. SIADH is considered whenever the patient experiences hypotonic hyponatremia with elevated urine osmolality, the hallmark of the disorder. In SIADH, no edema or hypovolemia is associated with the hyponatremia.

The secretion of ADH is considered "inappropriate" in that it continues despite the decreased osmolality of the plasma. The normal feedback system regulating the release and inhibition of ADH fails, and ADH secretion continues. The circulating ADH acts on the renal tubules, causing reabsorption of water that is inconsistent with the body's needs. Other reasons for the continued secretion of ADH are also lacking. There is no hypokalemia and edema; cardiac, renal, and adrenal function are normal; and there is normal or expanded plasma and extracellular fluid (ECF) volumes.

Occasionally, the cause of SIADH is a pituitary tumor, but more commonly it occurs as the result of a bronchogenic (oat cell) or pancreatic carcinoma. These tumors actually secrete ADH but are independent of normal physiological controls. Other possible causes of SIADH include head injuries; other endocrine disorders; pulmonary diseases, such as pneumonia and lung abscesses; CNS infections or tumors; and drugs. Box 44-8 outlines the most common causes of SIADH.

BOX 44-8 Common Causes of Syndrome of Inappropriate Antidiuretic Hormone Secretion

Malignancies
- Bronchogenic carcinoma
- Pancreatic adenocarcinoma
- Prostate or thymus cancer
- Leukemia

Central Nervous System Causes
- Head injury
- Hemorrhage (subdural hematoma, subarachnoid hemorrhage)
- Brain abscess
- Infection, abscess, meningitis
- Hydrocephalus

Pulmonary Causes
- Mechanical ventilation
- Chronic obstructive pulmonary disease
- Respiratory failure
- Lung abscess, infection, pneumonia

Medications
- Nicotine
- Opiates, morphine
- Chlorpropamide, hypoglycemics, insulin
- Antineoplastics
- Tricyclic antidepressants, SSRIs
- Anesthetics
- Clofibrate
- Diuretics

Other Causes
- Human immunodeficiency virus, acquired immunodeficiency syndrome
- Senile atrophy
- Pain
- Fear
- Myocardial infraction
- Idiopathic

Assessment

HISTORY AND PHYSICAL EXAMINATION. SIADH is characterized by water retention and eventually water intoxication secondary to sustained ADH effect. The hyponatremia in SIADH has two components, an early dilutional component caused by increased intravascular water, and a later, clinically undetectable component, caused by the increased urinary sodium excretion.

The signs and symptoms produced by SIADH are predominantly neurological and gastrointestinal. The most common signs and symptoms are personality changes, headache, decreased mentation, lethargy, abdominal cramps, nausea, vomiting, diarrhea, anorexia, decreased tendon reflexes, disorientation, confusion, and finally, seizures and coma. Many patients remain asymptomatic until the sodium level drops well below 125 mEq/L. Subtle neurological findings such as altered mental state, slight confusion, anorexia, inability to concentrate, and complaints of weakness may be the earliest indication of impending problems.

Hyponatremia is the clinical focus and probable cause of hospital admission. When the serum sodium falls to less than 120 to 125 mEq/L, more pronounced symptoms associated with cerebral edema, such as headache, nausea and vomiting, restlessness, muscular irritability, and seizures often result. When the condition develops acutely (ie, within 24 hours), a mortality rate of 50% has been reported. Children and the elderly are more susceptible to hyponatremia because of their lower body water content.

Physical evidence of hyponatremia includes dyspnea, jugular venous distention, restlessness, hypothermia, weight gain, mild to no edema, reduced and concentrated urine, anorexia, abdominal cramps, and disorientation. Often, the nurse is the first to identify these early, subtle signs.

LABORATORY STUDIES. The main laboratory abnormalities in SIADH are a plasma hyponatremia and hypoosmolality. The urine simultaneously is hyperosmolar, and there is a high excretion of urinary sodium. The urine specific gravity is high (concentrated), usually greater than 1.025, and the overall urinary output is lower (<30 mL/h). Other laboratory findings include low BUN, creatinine, and uric acid levels; hypocalcemia and hypokalemia; and decreased hemoglobin and hematocrit values. The diagnosis can be confirmed by radioimmunoassay of plasma ADH, which is inappropriately elevated relative to plasma osmolality. Table 44-3 presents a comparison of laboratory values in SIADH and diabetes insipidus.

Management

There are three goals in SIADH management: (1) treating the underlying disease, (2) alleviating excessive water retention, and (3) providing the comprehensive care needed when the patient has a depressed LOC.

Table 44-3 Laboratory Values: Syndrome of Inappropriate Antidiuretic Hormone Secretion (SIADH) and Diabetes Insipidus

Value	Normal	SIADH	Diabetes Insipidus
Serum ADH	1–5 pg/mL	Increased	Decreased
Serum osmolality	285–300 mOsm/kg	<285 mOsm/kg	>300 mOsm/kg
Serum sodium	133–145 mEq/L	<33 mEq/L	>145 mEq/L
Urine osmolality	300–1,400 mOsm/kg	>300 mOsm/kg	<300 mOsm/kg
Urine specific gravity	1.005–1.030	>1.030	<1.005
Urine output	1.0–1.5 L/24 h	Below normal	30–40 L/24 h
Fluid intake	1.0–1.5 L/24 h	Goal: <600–800 mL/24 h (restricted fluid intake)	>50 L/24 h

Treatment of the underlying cause of SIADH may or may not be possible, depending on the pathological process. Surgical resection, radiation, or chemotherapy may alleviate some of the water retention caused by some cancers. No drug completely inhibits the release of ADH from the pituitary gland or a tumor. When the cause of the SIADH is unknown, the treatment consists of fluid restriction.

The first step in managing SIADH is to restrict fluid intake. In mild cases, fluid restriction is sufficient. It slows renal blood flow and glomerular filtration, enhancing proximal tubular reabsorption of salt and water; increases aldosterone secretion; and enhances distal tubule sodium reabsorption. As a general guideline, water intake should not exceed urinary output until the serum sodium concentration normalizes and symptoms abate. Fluid restriction is usually successful for the patient with sodium levels between 125 and 135 mEq/L.

In severely symptomatic patients with acute hyponatremia, administration of 3% hypertonic saline solution and furosemide is used to correct hyponatremia in an emergency situation. Infusion of hypertonic saline solution at 0.1 mg/kg/min prevents rapid volume overload and pulmonary edema. Usually, 300 to 500 mL given IV over 4 to 6 hours is appropriate.

One major complication to avoid is central pontine myelinolysis. This may occur when correction of hyponatremia by hypertonic saline infusion is too rapid. Rapid correction of hyponatremia may lead to brain dehydration, cerebral bleeding, demyelination, neurological injury, or death. Initial signs and symptoms include seizures, movement disorders, akinetic mutism, quadriparesis, and unresponsiveness. The best plan is to replace sodium at a rate no faster than 1 to 2 mEq/L/h to avoid the syndrome.

Other medications effectively interfere with the ADH–renal tubule interaction. Conivaptan (Vaprisol) is an inhibitor of ADH that can be administered IV for hospitalized patients with euvolemic hyponatremia. It blocks vasopressin receptors in the renal collecting ducts to decrease water reabsorption. Patients receive an initial IV infusion of 20 mg over 30 minutes followed by an infusion of 20 to 40 mg/d for 4 days. Demeclocycline, an antibiotic, has been effective because it interferes with the normal ADH effect in kidney tubules. The usual dosage is 600 to 1,200 mg/d for 3 to 4 days. Other medications that block the effects of ADH at the tubules include phenytoin (Dilantin), lithium, and fludrocortisone (Florinef).

The nurse monitors fluid and electrolyte balance, especially the serum sodium level, In addition, it is necessary to evaluate intake and output, including hourly urine amounts, and observe for signs of fluid overload. Output should exceed intake. Adequate intake of dietary protein and salt need to be encouraged.

The nurse evaluates the patient's neurological status. Rapid changes in sodium levels can result in neurological deterioration. When the serum sodium is less than 125 mEq/L, there is a significant risk for neurological symptoms, including disorientation and decreasing consciousness. Seizure precautions may be necessary. Complications of SIADH include neurological deterioration leading to seizures, coma, and death.

Patients may find it difficult to limit their fluid intake. Mealtimes may also be difficult because menus are aimed at meeting nutritional needs without increasing fluid intake. Providing good oral care and offering substitutions for fluids (eg, Toothettes, lemon-glycerin swabs) may be helpful for the persistently thirsty patient. Providing information and emotional support and acknowledging the deprivation may help patients through this period.

Diabetes Insipidus

Pathophysiology

Diabetes insipidus is a disease characterized by water imbalance resulting from inadequate ADH or resistance to ADH, leading to water diuresis and dehydration. Polyuria is the hallmark of the disorder, and the kidneys can excrete great quantities of dilute urine, at times up to 20 L/d. Normally, the posterior pituitary releases ADH, which then acts on the distal renal tubules to promote reabsorption of water. When there is an absence of or deficit in ADH, the kidneys lose their ability to reabsorb water and control fluid output (see Chapter 42).

Diabetes insipidus may manifest in two forms: central or nephrogenic. Central diabetes insipidus is the more common condition that results in ADH deficiency and responds favorably to exogenous vasopressin administration. This type of diabetes insipidus is the disease most often encountered in the critical care environment. Nephrogenic diabetes insipidus is a rare genetic disorder that results from the failure of the kidney to respond to ADH. Only central diabetes insipidus is discussed in this chapter.

Diabetes insipidus can be transient, temporary, partial, or permanent, depending on the initial cause and circumstances surrounding the patient illness or injury. The osmolality sensors of the hypothalamus control ADH release from the posterior pituitary. As the osmolality increases, the osmoreceptors are stimulated, releasing more ADH. In the kidneys, ADH causes more water and sodium to be absorbed, restoring adequate fluid balance. In the absence of ADH, the renal tubules and collecting ducts are impermeable to water. Consequently, large volumes of dilute urine are excreted. Serum osmolality and sodium rise, and the patient continues to become progressively more dehydrated. The thirst sensation may or may not be affected, depending on the patient's LOC. For patients with an impaired thirst mechanism, dehydration and hypovolemic shock will result more quickly if the condition is not corrected.

Diabetes insipidus can develop after any event that causes edema or direct damage to the neurohypophysis. After surgery, diabetes insipidus may occur when regions of the brain around the hypothalamus and pituitary are affected. It can occur after head injuries, gunshot wounds, and lesions that disrupt blood supply to the area. Damage to the sphenoid bone, maxillofacial injuries, hypothalamic tumors, and nasopharyngeal tumors that invade the base of the skull may also lead to the development of diabetes insipidus. Direct trauma or ischemic events involving the hypothalamus, such as hemorrhage, infection, or neoplasm, may result in diabetes insipidus. Also, diseases or drugs that affect the renal collecting tubules may lead to diabetes insipidus. There is also a psychogenic polydipsia, in which excessive water is consumed, resulting in excess output.

After trauma or surgery, diabetes insipidus can be transient until initial edema subsides. The neurohypophysis is very sensitive to extraneous pressure; consequently, these

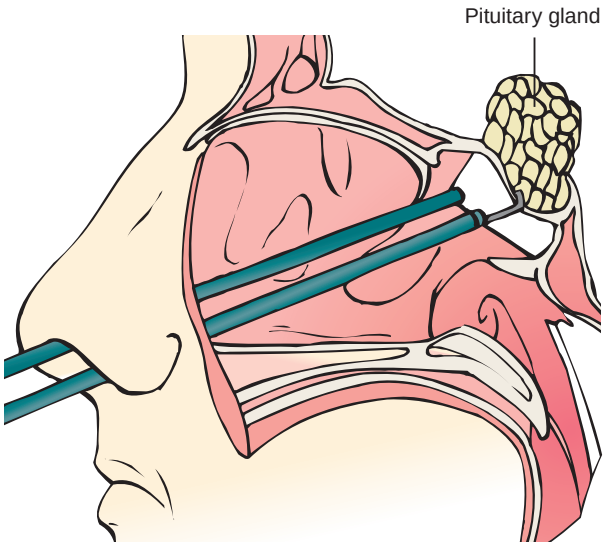

FIGURE 44-3 ▲ The transsphenoidal approach to a pituitary tumor can lead to transient diabetes insipidus. The neurohypophysis is very sensitive to extraneous pressure; consequently, these structures may be unable to produce, secrete, or release antidiuretic hormone as needed. The resultant diabetes insipidus resolves as the edema (from the surgery) resolves.

structures may be unable to produce, secrete, or release ADH as needed. The patient displays temporary signs of diabetes insipidus. As the edema abates, ADH secretion resumes its normal course, and the diabetes insipidus eventually is corrected. In some cases of severe trauma or hemorrhage, the structures may be completely damaged, and the patient may permanently develop diabetes insipidus.

The classic example of the transient type of disorder is illustrated by the patient undergoing a transsphenoidal approach for a hypophysectomy to remove a pituitary tumor. In most cases, the patient experiences temporary problems related to an inability to synthesize, store, or release ADH due to edema of the hypothalamus and pituitary. This patient requires close monitoring for the development of diabetes insipidus and may need treatment. Figure 44-3 illustrates a transsphenoidal approach to a pituitary tumor.

Assessment

Polyuria, polydipsia, and dehydration are the hallmarks of diabetes insipidus. Patients can excrete from 3 to 20 L of urine/d. When patients are alert, they experience excessive thirst and excessive urinary output. They try to increase their fluid intake, but this can cause exhaustion and eventually result in dehydration. On the other hand, when people are not alert enough to detect thirst and increase their fluid intake, they can quickly become hypovolemic because of the fluid loss. If left untreated, this can lead to death.

Signs of dehydration include dry skin, dry mucous membranes, confusion, sunken eyeballs, constipation, poor skin turgor, lethargy, muscle weakness, muscle pain, and pallor. Vital signs are adversely affected, with severe tachycardia, hypotension, low CVP, and a possible rise in body temperature. Weight loss may be apparent.

Recognizing diabetes insipidus may be more difficult when patients are recovering from surgery because steroids and cerebral dehydrating agents used before and during surgery promote diuresis for the first postoperative day or so. If awake, the patient complains of progressive thirst if diabetes insipidus is present. Urine output increases and persists regardless of the amount of fluid intake. Urine specific gravity falls or remains at about 1.001 to 1.005. Urine is copious, clear, and almost colorless. Plasma osmolality increases, often to levels greater than 300 mOsm/kg. Urine osmolality decreases to 50 to 100 mOsm/kg. The urine sodium concentration is below normal, whereas the serum sodium concentration is elevated (see Chapter 43, Table 43-2, p. 975). The water deprivation test is also helpful to diagnose diabetes insipidus. These tests, combined with the constellation of signs and symptoms, lead to the diagnosis. Table 44-3 on page 997 presents laboratory values for patients with diabetes insipidus.

Management

The objective of therapy is to prevent dehydration and electrolyte imbalance, while treating the underlying cause and preventing complications. Hypotonic IV solutions, such as 0.45% sodium chloride solution, are administered to match the urine output. The volume of replacement fluids depends on the degree of dehydration and the amount needed to reverse hypovolemic shock.

A variety of replacement ADH (vasopressin) therapies are available. Desmopressin acetate is synthetic ADH that can be administered IV, orally, or as a nasal spray. Aqueous vasopressin (Pitressin) may be given as an IV bolus, continuous infusion, or subcutaneously. The medications can be used for temporary or permanent ADH replacement. Permanent hormone replacement requires more patient and family education. In addition, the patient should obtain medical identification to carry at all times. Table 44-4 reviews the commonly administered medications for diabetes insipidus.

Management also focuses on monitoring fluid and electrolyte balance. The nurse detects fluid excesses or deficits by evaluating hourly intake and output, serum and urine electrolytes and osmolality results, and urine specific gravity. In addition, changes in blood pressure, pulse, and respirations, as well as the onset of pulmonary crackles, neck vein distention, peripheral edema, and increasing CVP and pulmonary artery occlusion pressure (PAOP, also known as pulmonary artery wedge pressure) are noted. The nurse observes skin turgor and mucous membranes and changes in alertness and cognition. Drowsiness, confusion, and headache may indicate water intoxication. Body weight is another indicator of fluid status.

Complications

Major complications of diabetes insipidus are cardiovascular collapse and tissue hypoxia. Seizures and encephalopathy can also result from fluid and electrolyte imbalance. Prognosis is excellent as long as the patient receives prompt and aggressive treatment.

Table 44-4 Commonly Administered Drugs for Diabetes Insipidus

Drug	Dosage	Route of Administration	Duration of Drug	Adverse Effects
Desmopressin	5–20 mcg each day	IV, by mouth, nasal spray (cannot be given if nasal passages are blocked)	8–24 h	Headache, chest pain, nausea, diarrhea, edema
Aqueous pitressin	2–4 units every 4–6 h	Intramuscularly, subcutaneously, intranasally	1–8 h	Headache, chest pain, nausea, diarrhea, edema
Pitressin tannate in oil	2.5–5 units	Intramuscularly	36–48 h	Headache, chest pain, nausea, diarrhea, edema
Lysine vasopressin nasal spray	5–20 units three to seven times daily; titrate to output	Intranasally	2–6 h	—
Chlorpropamide (Diabinese)	100–250 mg/d	By mouth	60–72 h	Hypoglycemia, headache, tinnitus, alcohol intolerance, gastrointestinal disturbances, diarrhea
Clofibrate	250–500 mg	By mouth	6–8 h	Gastrointestinal disturbances

▲ Emergencies for Patients With Diabetes Mellitus

Diabetes mellitus is a complex and chronic metabolic disorder characterized by hyperglycemia and defects in insulin secretion. Figure 44-4 illustrates how chronic hyperglycemia is associated with long-term organ dysfunction, particularly of the eyes, kidneys, nerves, heart, and blood vessels. These long-term microvascular and macrovascular complications of retinopathy, neuropathy, nephropathy, and cardiovascular disease are the primary causes of morbidity and mortality in people affected with diabetes.

The incidence of diabetes in the United States has risen dramatically, and diabetes morbidity and mortality are also increasing. Diabetes is one of the most common diseases in the United States, with an estimated 25.8 million adults afflicted, representing 8.3% of the population.[6] Prevalence rates approach 50% in certain population subgroups (Native American, Hispanic American, African American). This rate is strongly related to the epidemic of obesity and the socioeconomic inequalities that plague the United States.

The pathogenic processes associated with diabetes mellitus range from autoimmune destruction of the islet beta cells of the pancreas (type 1 diabetes mellitus) to insulin resistance (type 2 diabetes mellitus). The derangements of carbohydrate, protein, and fat metabolism all result from deficient action of insulin on target tissues. The main effect is hyperglycemia. Hyperglycemia is manifested as polyuria, polydipsia, polyphagia, weight loss, and blurred vision. Acute, critical illnesses associated with diabetes are hyperglycemia with ketoacidosis and nonketotic hyperosmolar state.

Often almost half of patients with type 2 diabetes mellitus are not diagnosed until complications have already developed, and many suffer acute syndromes requiring emergency department evaluation, intensive care management, or both.

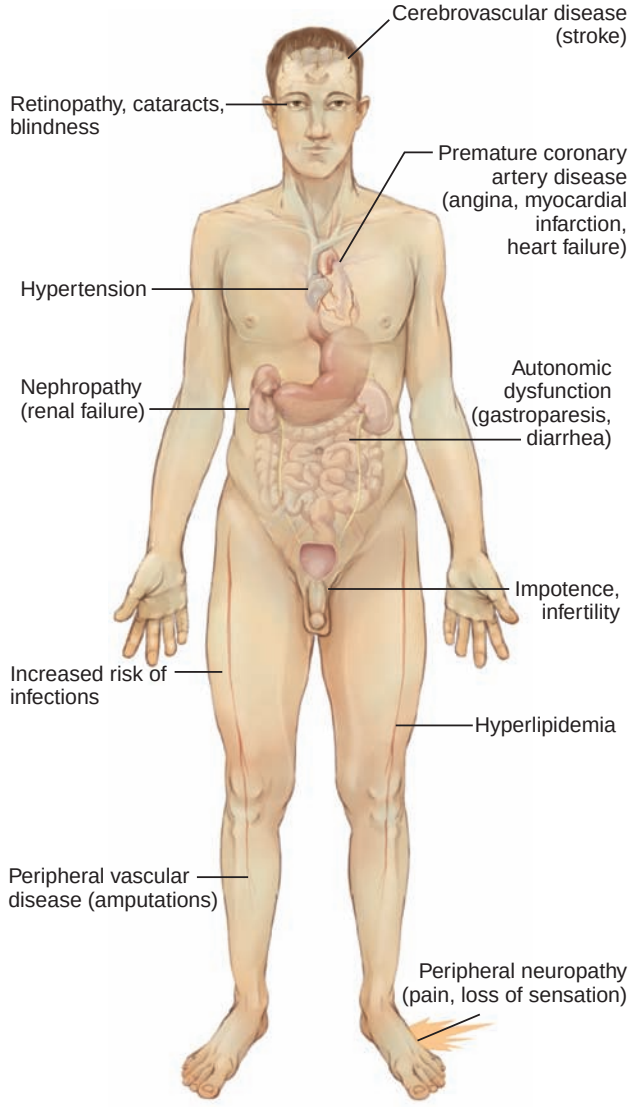

FIGURE 44-4 ▲ The complications of diabetes can be widespread.

Table 44-5 Comparison of Type I and Type 2 Diabetes Mellitus

	Type 1 Diabetes	Type 2 Diabetes
Etiology	Autoimmune destruction of islet cells	Insulin resistance
Incidence	5%–10%	90%–95%
Age of onset	Usually before 35 y	Usually after 35 y
Speed of onset	Usually rapid	Usually gradual
Nutritional state	Usually thin	Usually overweight, obese
Endogenous insulin	Absent	Low or high, rarely absent
Symptoms	Polyuria, polydipsia, polyphagia, weight loss	Same, plus blurred vision, fatigue
Ketosis	Frequently present with poor control	Infrequent
Treatment goal	Exogenous insulin management	Weight loss, exercise, improved insulin resistance
Treatment	Exogenous insulin, diet control, exercise, weight maintenance	Oral agents, diet control, exercise, weight loss

The critical care nurse must be vigilant in identifying high-risk patients. Box 43-6 on page 983 contains the American Diabetes Association's Position Statement on the diagnostic parameters for diabetes.

Most patients with diabetes can be classified into two main groups, those with type 1 diabetes mellitus and those with type 2 diabetes mellitus (Table 44-5). The cause of type 1 diabetes is an absolute deficiency of insulin secretion. This insulin secretion impairment results from autoimmune destruction of the beta cells of the pancreas. Markers of immune destruction include islet cell autoantibodies (ICAs), glutamic acid decarboxylase (GAD-65) antibodies, islet cell antibodies (ICA512-1A-2), and insulin antibodies (IAAs). The best predictor for future development of type 1 diabetes is the expression of multiple autoantibodies.[6] The rate of islet cell destruction is variable, and it occurs more rapidly in younger patients and more slowly in older patients. Some children and adolescents present with ketoacidosis as the first manifestation of the disease. As the islet cell destruction occurs, the patient is rendered insulin dependent for survival.

Type 1 diabetes is primarily a disease of the young, with a peak incidence at ages 10 to 12 years for females and 12 to 14 years for males. Although onset occurs mainly during childhood or at puberty and most patients receive a diagnosis before age 20 years, the disease can occur at any age. Type 1 diabetes accounts for approximately 5% to 10% of all cases of diabetes. A genetic predisposition for type 1 diabetes may exist because it appears that genetically predisposed patients contract the disorder after an environmental factor (viruses, congenital rubella, enteroviruses) triggers the autoimmune destruction of the islet cells, leading to insulin deficiency.[7,8] These patients are rarely obese. Type 1 diabetes is associated with other autoimmune diseases, such as Graves' disease, Addison's disease, and autoimmune polyendocrine syndromes.

Type 2 diabetes mellitus manifests as insulin resistance with relative, rather than absolute, insulin deficiency. Most of the patients with this form of diabetes do not require insulin, at least initially. The specific cause of insulin resistance is multifactorial; however, these patients do not suffer from autoimmune destruction of the islet cells of the pancreas. Most patients are overweight or obese, and excess adiposity itself can lead to insulin resistance. Ketoacidosis seldom occurs in this form of diabetes because the patient still secretes just enough insulin to avoid critical illness. When the patient does sustain severe complications associated with hyperglycemia, usually he or she has concomitant illness such as myocardial infarction, infection, or trauma. Because of the high incidence of insulin resistance and relative insulin deficiency, hyperglycemic hyperosmolar state (HHS) usually develops in patients with type 2 diabetes when they become critically ill.

Type 2 diabetes can go undiagnosed for many years because this disease progresses slowly. However, the patient is at high risk for developing macrovascular and microvascular complications. Quite often, these patients have normal to higher-than-normal insulin levels because of the ensuing insulin resistance that they develop. Insulin resistance develops, and their circulating insulin is insufficient to prevent hyperglycemia. Insulin resistance is best treated with weight loss, exercise, and pharmacological management. The medications to treat type 2 diabetes range from insulin secretagogues and medications that affect insulin sensitivity to insulin. Refer to Table 44-6 and Figure 44-5 for a review of the commonly used oral medications for type 2 diabetes and their mechanisms of action.

Eventually, many people with diabetes require insulin as their disease progresses. The risk for developing type 2 diabetes increases with age, obesity, sedentary lifestyle, and family history of type 2 diabetes. Its incidence varies with ethnicity but is increasingly more common in African Americans, Hispanics, Native Americans, South Pacific Islanders, and Asian Americans. Epidemiological and genetic studies suggest a strong genetic basis for developing type 2 diabetes; however, candidate genes that account for the majority of cases have not been identified. Type 2 diabetes is a multifactorial disorder with genetic and environmental implications.[6]

Results from two landmark trials involving people with types 1 and 2 diabetes mellitus, the Diabetes Control and Complications Trial (DCCT)[9] and the United Kingdom Prospective Diabetes Study (UKPDS),[10] have profoundly affected the current management of diabetes. These two trials have demonstrated that very tight glycemic control is necessary to avoid the costly and life-threatening complications resulting from poorly controlled diabetes. This approach extends to the management of diabetic emergencies in the critical care arena as well, and another landmark trial conducted in 2001 demonstrated significant improvement in patient outcomes when glycemic control was maintained at 80 to 110 mg/dL. The evidence that was produced by these trials significantly changed the management of diabetes among the critically ill and created a need for continuous

Table 44-6 Oral Drugs Used to Treat Diabetes Mellitus

Drug	Example	Action	Duration of Action	Nursing Considerations
First-generation sulfonylureas	Tolinase, Diabinese	Stimulates pancreatic insulin secretion	12–60 h	Side effects include hypoglycemia, gastrointestinal disturbances, and rash Contraindicated in pregnancy Seldom used
Second-generation sulfonylureas	Glyburide, Glucotrol, Micronase, Amaryl	Stimulates pancreatic insulin secretion	10–24 h	Side effects include hypoglycemia, gastrointestinal disturbances, and rash Safer in elderly patients
Biguanides	Metformin (Glucophage)	Reduces hepatic glucose production, increases insulin sensitivity	8 h	Lactic acidosis is a serious side effect (stop when using contrast medium for x-rays); other side effects include gastrointestinal disturbances (eg, flatulence, diarrhea, nausea) Use with caution in patients with renal disease Improves insulin resistance Promotes weight loss
Thiazolidinediones	Actos	Enhances insulin's effects at receptor sites	12–24 h	Will not increase level of circulating insulin Side effects include edema, weight gain, and anemia Monitor liver function tests Improves lipid profile Extreme caution with heart failure
α-Glucosidase inhibitors	Precose, Miglitol	Inhibits metabolism of carbohydrates in intestines	8 h	Take with meals Side effects include gastrointestinal symptoms (eg, flatulence, abdominal pain, diarrhea, nausea) Use with caution in patients with renal disease
Meglitinides	Prandin	Stimulates β-cell insulin release		Side effects include hypoglycemia, upper respiratory infection, headache, and diarrhea Use with caution in patients with hepatic or renal disease
Amino acid derivatives (insulin secretagogue)	Starlix	Stimulates β-cell insulin release		Side effects include hypoglycemia, gastrointestinal disturbances (eg, nausea), upper respiratory tract symptoms, and dizziness Use with caution in patients with hepatic disease
Incretion mimetics				
Glucagon-like peptide-1 (GLP-1) analogues		Decreases postprandial glucose rise and slows gastric emptying, promotes satiety	8–12 h	Given subcutaneously May produce weight loss
Exenatide	Byetta Bydureon (weekly injected exanatide)			
Liraglutide	Victoza			
Amylin analogue	Symlin	As above		
Dipeptidyl peptidase-4 inhibitor		Increases availability of GLP-1 above actions	12–24 h	May produce weight loss
Linagliptin	Tradjenta			
Sitagliptin	Januvia			
Saxagliptin	Onglyza			
Combination therapy Glyburide and metformin	Glucovance	As above with each drug	As above with each drug	As above with each drug

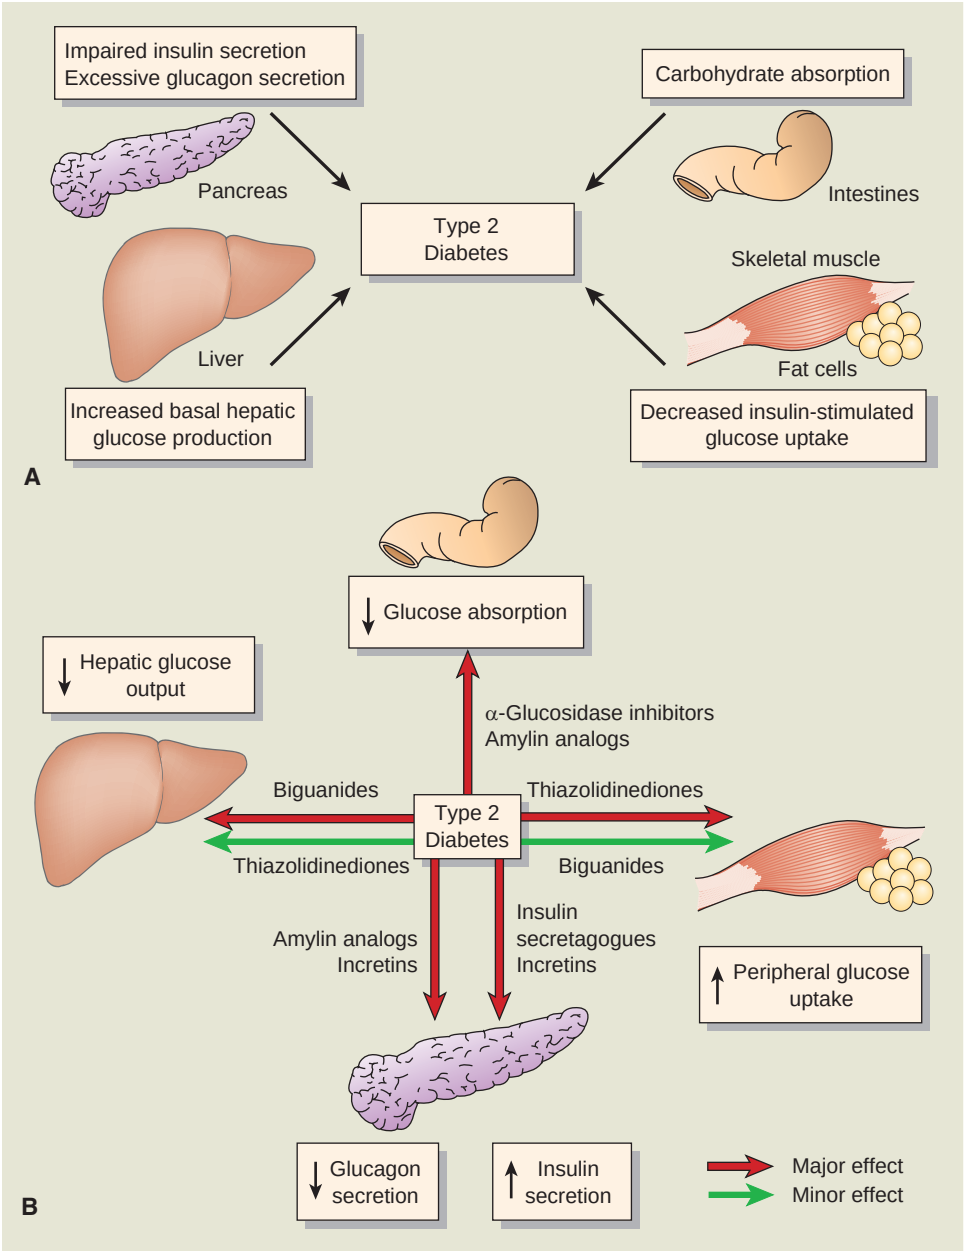

FIGURE 44-5 ▲ A: Factors leading to elevated blood glucose levels in type 2 diabetes mellitus. **B:** Mechanisms of action of the oral hypoglycemic agents used in the treatment of type 2 diabetes mellitus. (From Porth CM: Pathophysiology: Concepts of Altered Health States, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 1063.)

IV insulin infusions to control the patient's glucose at all times. The critical care nurse needs to monitor the patient very closely to avoid serious complications associated with insulin infusions.

New evidence now exists that questions the need for very strict glycemic control in the hospital setting. In 2008, the Action to Control Cardiovascular Risk in Diabetes[11] trial, aiming to lower Hb A_1C levels below 6% to study effects on cardiovascular risk, was discontinued prematurely after participants in the intensive-therapy group experienced higher mortality rates. The Normoglycemia in Intensive Care Evaluation–Survival Using Glucose Algorithm Regulation (NICE-SUGAR)[12] trial, a large randomized prospective study that assessed the effects of intense glucose lowering on critically ill adults (80 to 108 mg/dL), demonstrated that study participants experienced unacceptably severe hypoglycemic episodes of less than 40 mg/dL and an associated higher risk of mortality than among the control group. The two trials' results have questioned the need for very strict glycemic control in critically ill patients.

Diabetic Ketoacidosis

Pathophysiology

Diabetic ketoacidosis (DKA) is a critical illness that manifests with severe hyperglycemia, metabolic acidosis, and fluid and electrolyte imbalances. DKA results from severe insulin deficiency that leads to the disordered metabolism of proteins, carbohydrates, and fats. The concomitant elevation of counter-regulatory hormones such as growth hormone (GH), cortisol, epinephrine, and glucagon exacerbates the condition, leading to further hyperglycemia and hyperosmolality, ketoacidosis, and volume depletion. Figure 44-6 outlines these mechanisms and their interrelationships.

DKA continues to be an important cause of morbidity and mortality among people with diabetes. DKA is responsible for more than 100,000 hospital admissions per year in the United States. Most patients with DKA have type 1 diabetes mellitus; however, it is possible for patients with type 2 diabetes to manifest DKA during catabolic stress associated with severe critical illness. DKA is associated with less than 2% mortality rate overall, but it is a common cause of death among children and adolescents with type 1 diabetes mellitus.[13] Treatment can cost more than one of every four health care dollars spent on direct medical care for adults with type 1 diabetes mellitus, resulting in up to 2.4 billion U.S. dollars annually.[13] The cause of death is rarely a direct result of the metabolic acidosis or from hyperglycemia; instead, death is more often related to the underlying illness that precipitated the metabolic decompensation. Therefore, successful treatment requires prompt attention to the precipitating causes of the hyperglycemic event.

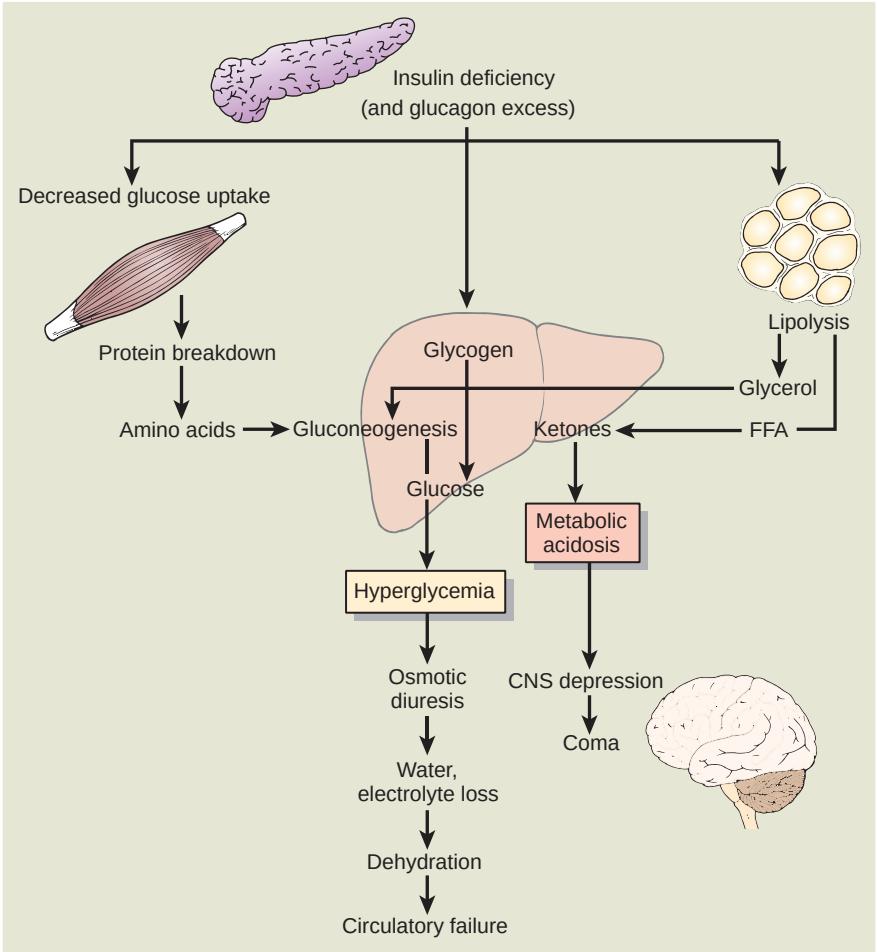

FIGURE 44-6 ▲ Mechanisms of diabetic ketoacidosis (DKA). DKA is associated with very low insulin levels and extremely high levels of glucagon, catecholamines, and other counter-regulatory hormones. Increased levels of glucagon and catecholamines lead to mobilization of substrates for gluconeogenesis and ketogenesis by the liver. Gluconeogenesis in excess of that needed to supply glucose to the brain and other glucose-dependent tissues produces a rise in blood glucose levels. Mobilization of free fatty acids from triglyceride stores in adipose tissue leads to accelerated ketone production and ketosis. (From Porth CM: Pathophysiology: Concepts of Altered Health States, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 1068)

Three major physiological disturbances exist in DKA: (1) hyperosmolality from hyperglycemia, (2) metabolic acidosis from accumulation of ketoacids, and (3) volume depletion from osmotic diuresis. Each of these three disturbances may be more or less severe in any patient. Furthermore, interactions among these disturbances may occur, aggravating (or possibly partially compensating for) one another.

HYPERGLYCEMIA AND HYPEROSMOLALITY. The first major consequence of DKA is hyperosmolality resulting from hyperglycemia. The hyperglycemia seen in DKA is the result of insulin deficiency and excessive hepatic (gluconeogenesis) and renal (glycogenolysis) glucose production and reduced glucose utilization in peripheral tissues. With insulin deficiency, the plasma glucose level rises. As illustrated in Figure 44-7, the concomitant effects of the counter-regulatory hormones, particularly cortisol and catecholamines, further aggravate hyperglycemia by enhancing gluconeogenesis, insulin resistance, and lipolysis. This leads to hepatic fatty acid oxidation to ketone bodies (β-hydroxybutyrate and acetoacetate), ketonemia, and metabolic acidosis.

The central mechanism that protects against hyperosmolality is excretion of glucose by the kidneys. Glucose is filtered at the kidney glomerulus. With normal circulating blood volume and a normal glucose load, all this glucose is reabsorbed into the bloodstream. However, when the blood glucose level exceeds the normal threshold of about 180 mg/dL, glucose begins to escape into the urine because the reabsorption capacity of the tubules is exceeded. As the glucose load to be filtered increases, glucose is lost rapidly in the urine. Eventually, nearly all of the additional glucose put into the circulation is lost into the urine. The renal "escape valve" serves as a protective device to prevent extreme accumulation of glucose in blood. Indeed, in people with diabetes whose circulating blood volume is well maintained, it is extremely unusual to find blood glucose levels in excess of 500 mg/dL because of the intense glucose diuresis. Conversely, any patient whose blood glucose level is higher than this level has a severely reduced circulating blood volume, renal damage, or both.

Glycosuria is largely responsible for volume depletion. Additionally, high ketone levels cause osmotic diuresis that leads to hypovolemia and decreased glomerular filtration rate. A vicious cycle occurs in a patient whose diabetes is badly out of control and who cannot take in enough sodium and water to compensate for urinary losses. Hyperglycemia leads to volume depletion, which in turn reduces urinary glucose losses and permits the blood glucose level to rise even higher.

This hyperosmolality of body fluids and dehydration probably accounts for the lethargy, stupor, and ultimately, coma that occurs as DKA worsens. Diabetic patients who have ketoacidosis without hyperosmolality are less likely to have changes in consciousness.

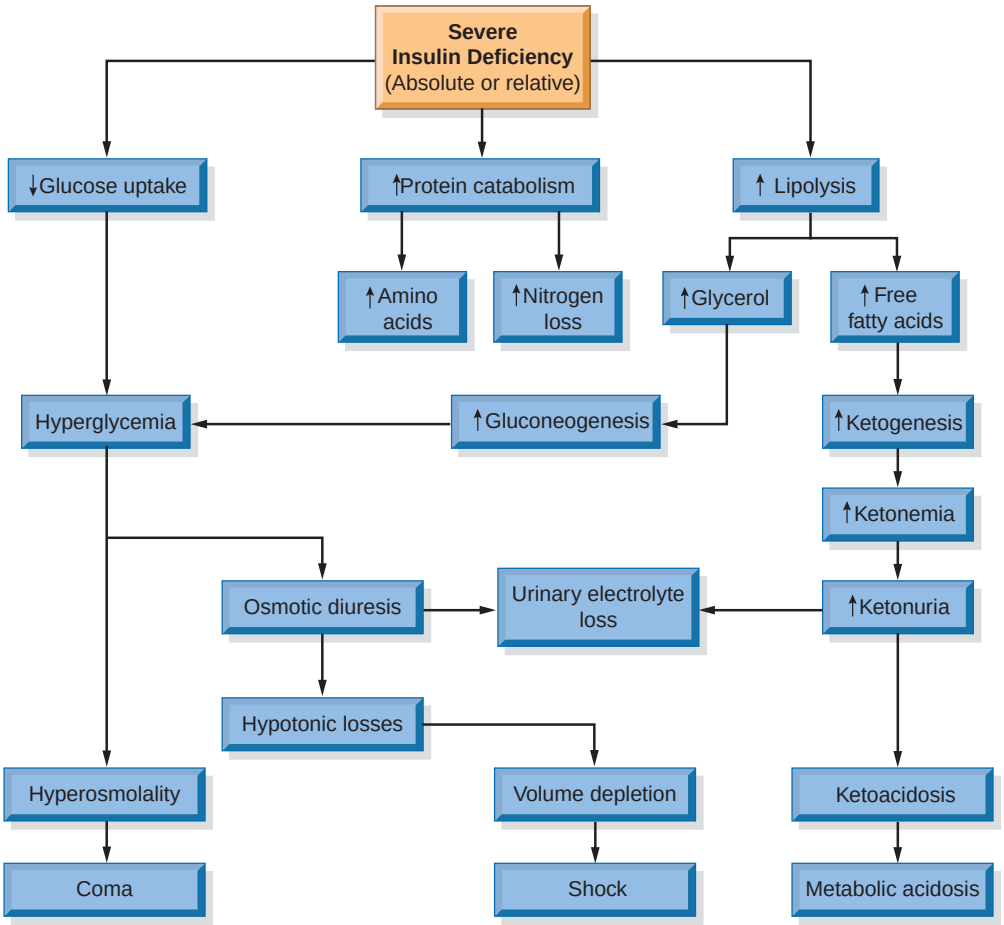

FIGURE 44-7 ▲ The metabolic consequences of severe insulin deficiency and the interrelations of these consequences lead to DKA.

KETOSIS AND ACIDOSIS. The second major consequence of severe insulin deficiency is uncontrolled ketogenesis (see Fig. 44-7). The combination of insulin deficiency and enhanced effects of the counter-regulatory hormones causes the activation of lipase in adipose tissue. Lipase causes the breakdown of triglycerides into glycerol and free fatty acids (FFAs); massive amounts of FFAs are released as precursors of ketoacids. In the liver, they are oxidized to ketone bodies.

As ketoacids enter the ECF, the hydrogen ion is stripped from the molecule and neutralized by combining with the bicarbonate ion buffer, thereby protecting the pH of the ECF and leaving behind ketoacid anion residues. The resulting carbonic acid breaks down into water and carbon dioxide gas, which is exhaled. As ketoacid anions accumulate, they progressively displace bicarbonate from the ECF. The usual laboratory determination of electrolytes does not measure ketoacid concentration directly. However, an excess of total measured cations (sodium plus potassium) over total measured anions (chloride plus bicarbonate) provides a clue to the presence of these so-called unmeasured anions. This excess, referred to as the anion gap, can serve as an indirect measure of the quantity of ketoacids present.

The following formula is used to calculate the anion gap:

$$(\text{Sodium}) - (\text{chloride} + HCO_3)$$

The normal value is less than 15 mEq/L. An abnormal result indicates metabolic acidosis. For example, if sodium = 144 mEq/L, chloride = 92 mEq/L, and bicarbonate = 26 mEq/L, then the anion gap is 26 mEq/L, a value that indicates severe metabolic acidosis. As the ketoacids continue to accumulate, the serum bicarbonate falls and the anion gap increases. If this continues, the pH falls, and the acidosis becomes life-threatening.

Another cause of metabolic acidosis in DKA is the formation of lactic acidosis resulting from poor tissue perfusion and hypovolemia. This further exacerbates the anion gap, decreasing the serum bicarbonate level. Neutrality of body fluids is protected primarily by the bicarbonate buffering system, which determines the pH at all times by the ratio of bicarbonate anion to carbon dioxide in plasma. If bicarbonate anion is lost because of its displacement by ketoacid anions, excess carbon dioxide gas must be driven off at the level of the lung by hyperventilation. This process keeps the ratio at or close to its usual value of 20:1 and maintains the pH close to its physiological value of 7.4. Hyperventilation, which is gradual at first and then rapidly becomes more vigorous and more obvious as the arterial pH drops below 7.2, is a characteristic physical finding in DKA.

This dramatic increase in ventilation, which occurs more by an increase in the depth than in the frequency of breathing, is known as Kussmaul's respirations. It is associated with the classic "fruity" odor of the breath in DKA. The presence of clearcut Kussmaul's respirations is a signal that the ECF pH is at or below 7.2, a relatively severe degree of acidosis.

VOLUME DEPLETION. Ketoacids are excreted in the urine largely as sodium, potassium, and ammonium salts. This contributes to the third pathophysiological problem of DKA: volume depletion and fluid and electrolyte loss as a result of osmotic diuresis. The fluid loss associated with DKA is approximately 6 L.

Although loss of glucose through the kidneys helps protect against the ravages of extreme hyperosmolality, the diabetic patient who develops ketoacidosis pays a price for this glycosuria. Glucose remaining in the glomerular filtrate, after the renal tubules have reabsorbed all they can, forces water to remain in the tubules. This glucose-rich filtrate then flows out of the body, carrying with it water, sodium, potassium, ammonium, phosphate, and other salts. This rapid urine flow and obligate loss of water and electrolytes is known as an osmotic diuresis. Salts of ketone bodies and the urea resulting from rapid protein breakdown and accelerated gluconeogenesis also contribute to the solute load in the renal tubule, further aggravating the diuresis. The average amounts of salts and water lost to the body through osmotic diuresis during the development of DKA have been measured. Overall water loss in a 70-kg adult patient with DKA can be 5 to 8 L, or 15% of total-body water.

The fluid lost to the body is slightly hypotonic; it contains a slight excess of water compared with the volume of salts. This is expected from an osmotic diuresis due to glucose and urea. The fluid losses result from the combination of many different factors, including the intensity and duration of the hyperglycemia and osmotic diuresis; the amount of water and electrolyte replaced orally during this time; the presence of other fluid and electrolyte losses, such as vomiting, diarrhea, or sweating; and the integrity of renal function.

Sodium and water make up the central structure of the ECF, including the vascular volume. When large quantities of sodium and water are lost in the urine, the body perceives it as a serious threat to the maintenance of the circulation. A variety of compensatory mechanisms are called into play to prevent vascular collapse and shock. For example, an increase in pulse rate usually occurs, which helps maintain cardiac output in the face of shrinking intravascular volume.

At least as important, however, is a protective shift in body fluid brought about by the hyperglycemia. Because free glucose is limited almost entirely to the extracellular water, an osmotic pressure gradient is set up across the cell membrane, between the extracellular compartment and the interior of the cells. Therefore, the higher the blood glucose, the more water is drawn out of cells and into the extracellular space. Therefore, as sodium and water are lost into the urine, shrinking the ECF, they are "replaced" (at least as to their osmotic effect) by glucose entering from the liver and by water entering from all cells. This re-expands the ECF.

Although hyperosmolality produces damaging CNS effects and osmotic diuresis, it provides a temporary mechanism for preventing vascular collapse. Despite these compensatory mechanisms, circulatory volume falls as DKA progresses. This leads to decreased glomerular filtration, decreased tissue perfusion, metabolic acidosis, and shock.

As the vascular volume falls, glomerular filtration also falls. This decreasing renal function leads to increasing blood levels of glucose, potassium, urea nitrogen, and creatinine. The excretion of potassium by the kidney occurs through the exchange of potassium for sodium. Therefore, adequate sodium must be present at the exchange site in the kidney for the rate of potassium excretion to keep pace with the need for excretion. If renal perfusion falls, enough sodium may not be available for this exchange. As a result, despite a total-body depletion of potassium, the serum potassium level may rise above normal, even to dangerously high levels.

A second major consequence of diminished vascular volume is a generalized decrease in tissue perfusion. Well before the drop in volume has reached the point at which blood pressure actually falls and full-blown shock occurs, blood is shunted away from many tissues, and the perfusion of nearly all tissues suffers. The resulting decrease in oxygen causes those tissues to shift to some degree of anaerobic glucose metabolism. This results in the increased production of lactic acid. The release of lactic acid into the circulation lowers the bicarbonate further, aggravating the already existing metabolic acidosis. Therefore, in patients with DKA, combined lactic acidosis and ketoacidosis is a common finding.

The loss of phosphate in the urine worsens tissue hypoxia. As body phosphate stores are depleted, circulating plasma phosphate levels fall quite low, depriving the red blood cells of organic phosphate compounds. Under these circumstances, the red blood cells become depleted of certain key phosphate derivatives, increasing the tightness of oxygen binding to the hemoglobin in these cells. Therefore, less oxygen is given up, and tissue hypoxia worsens.

Finally, if vascular volume falls low enough, compensation mechanisms fail, blood pressure drops, and true shock supervenes, changing the situation. A rapidly worsening cycle of acidosis, tissue damage, and deepening shock may then occur, leading ultimately to irreversible vascular collapse and death. The full-blown syndrome of DKA is characterized by major contributions from all three major pathophysiological disruptions, each of which is primarily responsible for one of the major clinical features: coma, shock, and metabolic acidosis. There is evidence to suggest that hyperglycemia crisis is associated with severe inflammatory state due to the elevation of proinflammatory cytokines, C-reactive protein, reactive oxygen species, and lipid peroxidation as well as plasminogen activator inhibitor-1. This partially explains the hypercoagulable state associated with hyperglycemic crisis.[14]

Causes

The most common cause of DKA is infection, occurring in 30% to 50% of cases. Urinary tract infection and pneumonia account for the majority of infections.[13] Other precipitating factors include inadequate insulin therapy, severe illness (cerebrovascular accident [CVA], myocardial infarction, pancreatitis), alcohol abuse, trauma, and drugs. In addition, many people with type 1 diabetes present with DKA on initial diagnosis. Also, many patients with type 1 diabetes suddenly discontinue their insulin and deteriorate; reasons for insulin omission in younger patients include fear of weight gain, fear of hypoglycemia, rebellion against authority, and the stress of chronic disease. In one study of 341 females with type 1 diabetes, psychological problems complicated by disorders were a contributing factor in 20% of cases.[14] Other reasons given for sudden discontinuation of insulin or oral medications include lack of knowledge and poor compliance related to lack of financial resources. Noncompliance with therapy has been implicated as a major precipitating cause of DKA in urban African American and medically indigent patients.[12]

Assessment

Initial laboratory analysis should include an immediate glucose level using a venous sample and glucose meter measurement at the bedside to confirm the diagnosis. While these preliminary data are collected, the nurse inserts an IV line and starts volume replacement. A more considered assessment follows, which begins with details of the history and physical examination, a search for precipitating causes, and more complete laboratory tests. Physical examination and laboratory findings in DKA are summarized in Box 44-9.

BOX 44-9 Signs of Diabetic Ketoacidosis (DKA)

- Hyperventilation
- Kussmaul's respirations and "fruity" breath
- Lethargy, stupor, coma
- Hyperglycemia
- Glycosuria
- Volume depletion
- Hyperosmolality
- Increased anion gap (>7 mEq/L)
- Decreased bicarbonate (<10 mEq/L)
- Decreased pH (<7.4)

HISTORY AND PHYSICAL EXAMINATION. If ketoacidosis is strongly suspected, an effort is made to establish the diagnosis quickly so that life-preserving therapy can be started. Initial data collection includes an abbreviated history from the family or friends of an unconscious patient, a search for a diabetic identification card, and rapid assessment for clinical clues of volume depletion. After asking about the diabetic regimen, medications, and recent changes in health, the clinician should perform a review of systems. Questions concern appetite, weight change, food and fluid intake, thirst, abdominal bloating and discomfort, bowel function, and urinary frequency and amount. During the interview, he or she should observe the patient's cognition and responsiveness.

DKA develops rapidly, and patients may display polydipsia, polyuria, and weight loss several days before ketoacidosis is established. Frequently, abdominal pain and vomiting are presenting symptoms. Approximately 40% to 75% of patients experience abdominal pain that mimics an acute abdomen; the severity of abdominal pain often correlates with more severe metabolic acidosis. Other possible findings include thirst, frequent urination, poor appetite, nausea and vomiting, fatigue, weakness, and drowsiness. The patient may also have symptoms related to urinary tract infection, upper respiratory infection, and chest symptoms because infection is often a precipitating factor.

The physical examination includes blood pressure, heart and respiratory rate, breathing pattern, heart sounds and rhythm, breath sounds, capillary refill, skin color and warmth of extremities, temperature, signs of hydration (eg, skin turgor, mucus pool under tongue), deep tendon reflexes, LOC, and an abdominal examination. Possible findings include hyperventilation, Kussmaul's respirations and fruity breath, dehydration, abdominal distention, dry mucous membranes, flushed skin, poor skin turgor and perfusion, hypotension, tachycardia, and varying degrees of responsiveness from lethargy to coma. Even though infection is often concurrent, the patient may be normothermic due to vasodilation. Severe hyperthermia is a poor prognostic sign.

LABORATORY STUDIES. Laboratory studies include blood glucose, chemistries, osmolality, anion gap, pH, ABGs,

urine acetone, and glucose. Possible findings include hyperosmolality, increased anion gap (>7 mEq/L), decreased bicarbonate (<10 mEq/L), and decreased pH (<7.4). The serum glucose may range from 300 to 800 mg/dL or higher. Sodium, potassium, creatinine, and BUN levels are all elevated. Magnesium and phosphate may also be high. Patients with DKA often present with leukocytosis and the presence of greater than 10% neutrophil bands. The key diagnostic feature of DKA is the presence of serum ketones per the nitroprusside test or by direct measurement of β-hydroxybutyrate.[12]

DIAGNOSTIC STUDIES. Tissue cultures of the throat, urine, or blood may also be performed to determine the presence of infection. A chest radiograph should be obtained to rule out acute infection, and an ECG should be obtained.

Management

The severity of DKA can be categorized as mild, moderate, or severe depending on the level of metabolic acidosis and altered mental state. Treatment goals for the patient with DKA include the following:

- Improve circulatory volume and tissue perfusion
- Correct electrolyte imbalances
- Decrease serum glucose concentration
- Correct ketoacidosis
- Determine precipitating events

Treatment protocols for the adult with DKA are given in Figure 44-8, and a Collaborative Care Guide is given in Box 44-10.

FLUID REPLACEMENT. The immediate threat to life in a critically ill ketoacidotic patient is volume depletion. After establishing an IV line, the nurse rapidly infuses 0.9% (normal) saline solution. The goal is to reverse the severity of the extracellular volume depletion and restore renal perfusion as soon as possible. The first liter may be infused in 1 hour in patients with normal cardiac function; on average, the rate will be equal to 15 to 20 mL/kg body weight per hour. This replaces only a fraction of the extracellular loss in the average patient, which can range from 6 to 10 L.[14]

Fluid replacement continues at roughly 1 L/h until the heart rate, blood pressure, and urine flow indicate that hemodynamic stability is attained. Hypotonic solutions, such as 0.45% (half normal) saline solution, can be administered at a rate of 150 to 250 mL/h after the intravascular volume has been restored, or if the serum sodium level is greater than 155 mg/dL. Other plasma expanders, such as albumin and plasma concentrates, may be necessary if low blood pressure and other clinical signs of vascular collapse do not respond to saline solution alone.

Rapid infusion of saline solution in DKA has possible complications. It can dilute plasma proteins and lower the osmotic pressure of the plasma. This allows fluid to leak out of the vascular space through the capillary walls and contributes to the development of pulmonary edema or cerebral edema, particularly in children and older adults. Therefore, patients must be observed carefully during the first 24 to 36 hours for signs of pulmonary or cerebral edema.

Volume losses continue throughout the first hours of treatment until the glycosuria and osmotic diuresis are controlled. The next step of fluid replacement can be based on an estimate of the patient's total-body fluid loss. About 80% of the fall in blood glucose level during treatment of DKA is due to glucose loss into the urine, rather than the result of insulin-induced changes in glucose production and consumption. Therefore, in the earliest phases of treatment, insulin therapy complements fluid and electrolyte replacement. Lowering of glucose levels will occur more rapidly (as long as 6 hours) than correction of ketoacidosis (as long as 12 hours).

INSULIN THERAPY. Insulin therapy is the cornerstone for managing ketoacidosis for several reasons. It decreases the production of ketones by shutting off the supply of FFAs emerging from adipose tissue. It inhibits hepatic gluconeogenesis, thereby preventing further glucose from being added to the ECF. Simultaneously, hepatic ketogenesis is further reduced. Insulin also restores cellular protein synthesis. This effect occurs more slowly and permits the restoration of normal potassium, magnesium, and phosphate stores in tissues. Insulin also increases peripheral glucose utilization.

Careful glycemic control is the goal for managing patients with diabetes in the acute care setting. However, the blood glucose level should not fall too fast or too far. Sudden and rapid lowering of the blood glucose with insulin allows water to move very rapidly back into the cells. This can potentially lead to vascular collapse. Instead, early volume replacement should include sodium and water either before or along with insulin therapy.

It is necessary to give low-dose regular insulin by continuous IV infusion rather than by IV bolus or subcutaneous doses for more severe DKA or HHS cases. Subcutaneous insulin injections given every 1 to 2 hours are an alternative to IV insulin for mild or moderate DKA, and usually rapid-acting analog insulin (lispro, aspart, or glulisine) is used.[12] Box 44-11 on page 1012 summarizes guidelines for insulin administration.

Initially, insulin administration involves giving an IV bolus of regular insulin at 0.15 units/kg body weight followed by a continuous infusion of regular insulin at a dose of 0.1 units/kg/h (5 to 10 units/h). This produces a steady decline in glucose concentrations at a rate of 65 to 125 mg/h. A recent prospective study demonstrates that an hourly insulin infusion of 0.14 units/kg/h without initial bolus is sufficient to lower glucose and suppress hepatic ketone body production.[14]

When the plasma glucose reaches 250 mg/dL, it is necessary to decrease the insulin infusion to 0.5 units/kg/h and add dextrose (5% or 10%) to the IV fluids. To prevent cerebral edema that may occur when the blood–brain barrier is affected by extreme fluid shifts, avoidance of hypoglycemia is warranted at this point. It is vital to start subcutaneous insulin 1 to 2 hours *before* IV insulin is stopped.[13] See Table 44-7 on page 1013 for commonly used insulins.

POTASSIUM AND PHOSPHATE REPLACEMENT. The initial plasma potassium in patients with DKA can range from very low to very high. Therefore, potassium is not given until the laboratory report is available. Beginning IV potassium therapy in the presence of unrecognized hyperkalemia and inadequate renal mechanisms for handling potassium loads can be fatal. Although the ECG can provide clues to the presence of high or low potassium levels, potassium therapy should not be based on the ECG alone.

If the initial serum potassium level is low, IV potassium is usually started right away. This is particularly important because

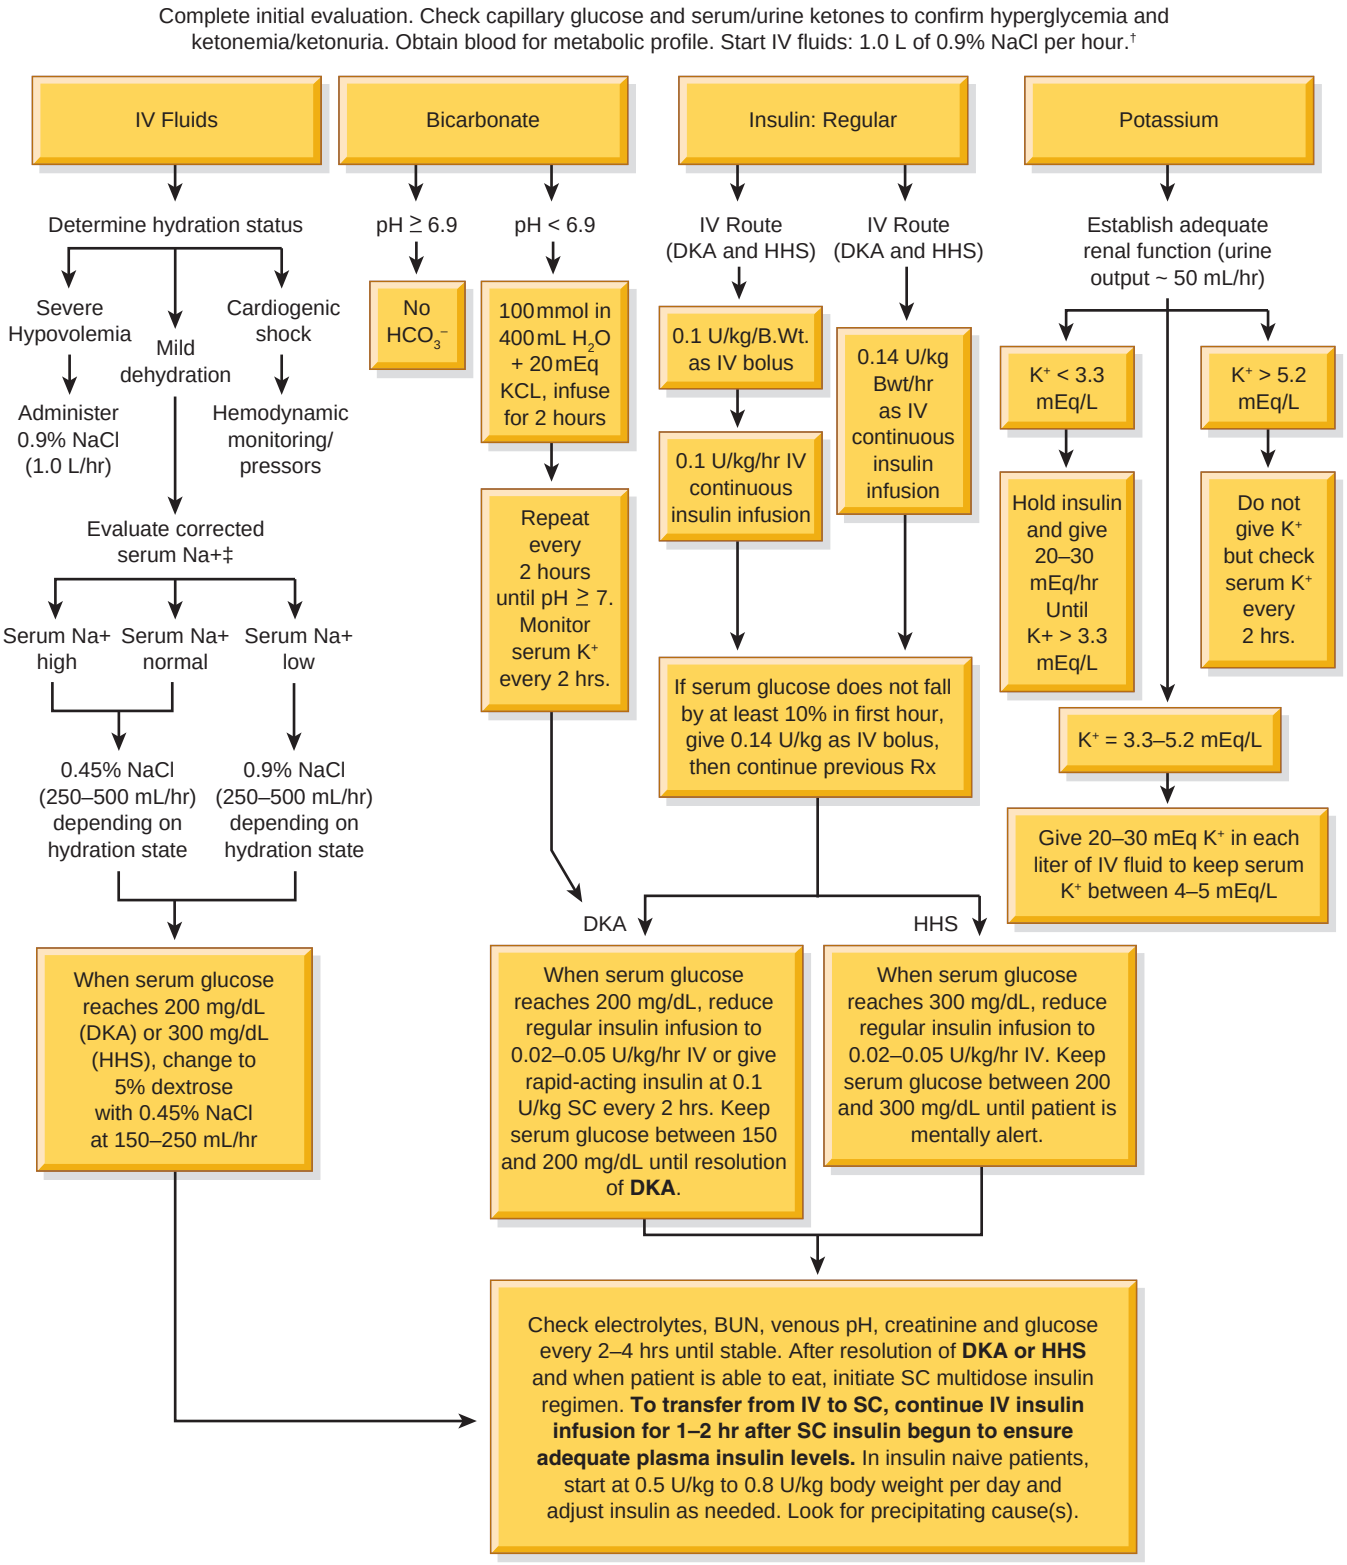

FIGURE 44-8 ▲ Protocol for management of adult patients with DKA or hyperglycemic hyperosmolar state (HHS). DKA diagnostic criteria: blood glucose 250 mg/dL, arterial pH 7.3, bicarbonate 15 mEq/L, and moderate ketonuria or ketonemia. HHS criteria: serum glucose greater than 600 mg/dL, arterial pH greater than 7.3, serum bicarbonate greater than 15 mEq/L, and minimal ketonuria and ketonemia.

†15 to 20 mL/kg/h; ‡serum Na should be corrected for hyperglycemia (for each 100 mg/dL glucose, add 1.6 mEq to sodium value for corrected serum value). Bwt, body weight; IV, intravenous; SC, subcutaneous. (From Kitabchi AE, Umpierrez GE, Miles JM, et al: Hyperglycemic crises in adult patients with diabetes. Diabetes Care 32(7):1335–1343, 2009)

BOX 44–10 COLLABORATIVE CARE GUIDE for the Patient With DKA

Outcomes	Interventions
Oxygenation/Ventilation	
Arterial blood gases are maintained within normal limits.	• Provide chest physiotherapy, turn, deep breath, cough, incentive spirometer every 4 h and PRN.
No evidence of acute respiratory failure.	• Continuously monitor patient's respiratory rate, depth, and pattern. Observe for Kussmaul's respiration, rapid and shallow breathing, and other signs of respiratory distress. • Monitor arterial blood gases, pulse oximetry, and, if intubated, end tidal CO_2. • Provide supplemental oxygen. • Prepare for intubation and mechanical ventilation (see Box 25-16).
The patient's lungs are clear. There is no evidence of atelectasis or pneumonia.	• Auscultate breath sounds every 2 h and PRN. • Take daily chest x-ray. • Provide chest physiotherapy every 4 h. • Mobilize out of bed as soon as patient is stabilized.
Circulation/Perfusion	
Blood pressure and heart rate are within normal limits. If pulmonary artery catheter is in place, hemodynamic parameters are within normal limits.	• Monitor vital signs hourly and PRN. • Assess for dehydration/hypovolemia: tachycardia, decreased central venous pressure (CVP) and pulmonary artery occlusion pressure (PAOP). • Assess for hypervolemia: neck vein distention, pulmonary crackles and edema, increased CVP and PAOP. • Administer vasopressor agents if hypotension is related to vasodilation.
Patient is free of dysrhythmias.	• Monitor electrocardiography (ECG) continuously. • Evaluate and treat the cause of dysrhythmias (eg, acidosis, hypoxia, hypokalemia/ hyperkalemia).
Fluids/Electrolytes	
Evidence of rehydration without complications: • balanced intake and output • normal skin turgor • hemodynamic stability • intact sensorium	• Infuse normal saline or lactated Ringer's solution, then 0.45% normal saline solution. • Monitor serum osmolality, urine output, neurological status, and vital signs closely during rehydration. Observe for complications of DKA (eg, shock, renal failure, decreased LOC, and seizures). • Assess BUN, creatinine, and urine for glucose and ketones.
Normal serum electrolytes and acid–base balance.	• Assess and replace electrolytes, Mg, and PO_4, as indicated. • Closely monitor potassium fluctuations as serum glucose is decreased and acidosis reversed. • Assess arterial pH and bicarbonate level every 2–4 h during rehydration and insulin administration.
Serum glucose returns to normal range.	• Monitor serum glucose every 30–60 min, then every 1–4 h after level is <300 mg/dL. • Administer intravenous (IV) insulin bolus then continuous low-dose infusion. • Infuse D5 half normal saline solution or D5W, after glucose level is <300 mg/dL.
Mobility/Safety	
The patient will be free of injury related to altered sensorium or seizures.	• Place on seizure and falls precautions. • Assess neurological status hourly, then every 2–4 h after initial rehydration phase.
Maintain muscle tone and joint range of motion.	• Provide range-of-motion exercises every 4 h. • Reposition in bed every 2 h. • Mobilize to chair when condition stable. • Consult physical therapist.

(continued on page 1011)

BOX 44–10 *COLLABORATIVE CARE GUIDE for the Patient With DKA (continued)*

Outcomes	Interventions
Skin Integrity	
Skin will remain intact.	• Assess risk for skin breakdown using the Braden Scale (see Fig. 51-7, p. 1164). • Initially assess skin and circulation every 1–2 h for 12 h. • If risk for skin breakdown is low, assess skin every 8 h and each time patient is repositioned. • Turn patient every 2 h. • Consider pressure relief/reduction mattress if at risk for skin breakdown.
Nutrition	
Calorie and nutrient intake meet metabolic requirements per calculation (eg, basal energy expenditure).	• Provide parenteral feeding if patient is fasting (NPO). • Provide clear, then full liquid diet, and assess patient response. • Progress to diabetic diet (ADA). • Consult dietitian or nutritional support service regarding special nutritional needs.
No evidence of metabolic dysfunction.	• Monitor albumin, prealbumin, transferrin, cholesterol, triglycerides, glucose, and protein levels.
Comfort/Pain Control	
Patient will have minimal pain, <5 on pain scale.	• Assess pain and discomfort. If pain present, use objective pain scale every 4 h PRN and following administration of pain medication. • If analgesics are needed, administer cautiously due to risk of respiratory and neurological complications. • Consider nonpharmacological pain management techniques (eg, distraction, touch).
The patient's nausea, vomiting, and abdominal pain or tenderness will resolve.	• Maintain nasogastric tube patency. • Assess bowel sounds every 1–2 h. • Administer antiemetic as ordered. • Provide ice chips and frequent oral hygiene.
Psychosocial	
Patient demonstrates decreased anxiety.	• Provide nonjudgmental atmosphere in which patient can discuss concerns and fears. • Provide patients who are intubated with a method to communicate. • Provide patients with decreased LOC with sensory input. • Provide for adequate rest and sleep.
Teaching/Discharge Planning	
Patient/significant others understand the tests needed for treatment.	• Prepare patient/significant others for procedures such as electroencephalography, ECG, and multiple laboratory studies.
Significant others understand the severity of the illness, ask appropriate questions, and anticipate potential complications.	• Explain the widespread effects of diabetes and the potential for complications of DKA such as seizures, renal failure, or vascular collapse. • Encourage significant others to ask questions related to complications, pathophysiology, monitoring, treatments, etc.
Patient/significant others are prepared for home care.	• Teach patient and family information needed to manage diabetes: diabetic diet, skin care, glucose monitoring, insulin administration, signs and symptoms of hypoglycemia and hyperglycemia, and appropriate actions. • Discuss sick-day management and factors that can precipitate DKA. • Initiate contacts with diabetic support groups, social services, and home health agency.

BOX 44-11 NURSING INTERVENTIONS

For Insulin Administration

- Administer insulin IV to the patient with DKA to minimize the trauma of repeated injections.
- Use only human regular insulin in IV insulin infusions because it is less antigenic than animal (beef, pork) insulins.
- Administer the insulin infusion through an IV infusion pump. Flush tubing well with insulin mixture before infusing to patient to prevent tubing from absorbing too much insulin.
- When the serum glucose level reaches 250 mg/dL, the IV fluids should be changed to a glucose-based solution.
- Changes in blood glucose level and clinical state should indicate a clear cut beneficial response to insulin and fluid replacement. If blood glucose level does not drop and blood pressure and urine output do not stabilize, insulin or fluid replacement may not be adequate.

both insulin and saline solutions drive the potassium even lower, possibly to dangerously low levels at which skeletal muscle paralysis and cardiac arrest may occur. If the initial potassium is normal or high, IV potassium is usually withheld until the level has begun to drop and urine flow is established. Potassium is usually replaced at concentrations of 20 to 40 mEq/L of IV fluid, depending on the serum potassium level. Failure of the potassium level to fall can occur for the following reasons:

- Persistent, uncorrected acidosis (which drives potassium out of cells and into ECF)
- Hyperosmolality
- Intrinsically impaired renal function
- Insufficient circulating volume

Phosphate levels usually also drop during therapy, aggravating any preexisting tendency of red blood cells to bind oxygen more tightly. Therefore, many patients receive phosphate in the middle and later phases of therapy. It is usually combined with potassium replacement in the form of potassium phosphate salts added to the IV infusion. Patients who are receiving IV phosphate therapy should be watched carefully for signs of tetany: tingling around the mouth or in the hands, neuromuscular irritability, carpopedal spasm, or even seizures. Tetany can occur because phosphate lowers the level of circulating calcium.

BICARBONATE REPLACEMENT. Patients with mild or moderate ketoacidosis who are treated with salt, water, and insulin eventually excrete and metabolize the ketone bodies remaining in ECF. As this process continues, more bicarbonate anions are reabsorbed from the renal tubules, and the bicarbonate deficit is slowly repaired. Sometimes the large amounts of chloride administered along with the sodium in IV saline solution can produce a transient hyperchloremia; this delays the full return of the bicarbonate level to normal for several days.

Bicarbonate replacement in patients with DKA remains controversial because evidence-based research has failed to demonstrate benefit in patients with an arterial pH between 6.9 and 7.1.[13] However, most experts recommend bicarbonate replacement with severe acidosis as indicated by an arterial pH of 7.0 or less. It is also necessary to give bicarbonate when there is cardiac decompensation. The bicarbonate deficit can be calculated and replaced IV over several hours to raise the level at least to the 10- to 12-mEq/L range. Sodium bicarbonate should be administered by slow IV infusion over several hours. It is administered as a bolus injection only in the case of cardiac arrest. Sodium bicarbonate administration can cause a rapid reduction in plasma potassium concentration and sodium overload.

REESTABLISHING METABOLIC FUNCTION. Gastric motility is greatly impaired in DKA. Gastric distention with dark, hemopositive fluid and vomiting is common. Abdominal pain, tenderness, and a paralytic ileus may also be due to DKA. The patient may need a nasogastric tube to decompress the stomach. This increases comfort and decreases the risk for aspiration. Patients should not eat or drink in this phase of illness. Ice chips may decrease thirst. Later, when distention lessens and motility returns, oral intake begins in order to provide the complex nutritional requirements for recovery.

Metabolic abnormalities should not be corrected too rapidly, especially in patients in whom DKA has been developing for a long time. The key risks during this phase are worsening stupor or coma, hypotension, and hyperkalemia. Osmotic or pH disequilibrium may occur when blood glucose or bicarbonate has been corrected too rapidly. The patient's mental state may worsen even though the blood chemistries are improving. Rapid reduction of blood glucose without sufficient sodium and water replacement may be responsible for hypotension. However, sepsis, myocardial infarction, and other causes of shock may also cause hypotension. Hyperkalemia usually results from premature potassium infusion, persistent acidosis, and insufficient volume replacement. However, there may be an early occlusion of the arterial supply to a limb. This can cause large amounts of potassium to leak into the circulation. Therefore, limbs are monitored for asymmetrical pallor, coolness, and rubor.

Although patients begin to improve during the initial phase of treatment, recovery usually takes place over approximately 12 days. Reversal of most metabolic abnormalities and replenishment of body stores of many nutrients (eg, magnesium, protein, and phosphate) occur during this time. Once recovery is well underway, it is time to help the patient and family understand how to prevent a recurrence.

Patient Education

Many cases of DKA are preventable with good education. Patients and families who are well informed about diabetes may be more likely to recognize early signs of complications, minimize their development, and seek help if they begin to occur. Although people usually understand the need for insulin injections when they are hungry and eating normally, they may not understand why they need their insulin when they are ill, have no appetite, are not eating, or are vomiting. Box 44-12 outlines appropriate teaching points after an episode of DKA. Box 44-13 presents a "sick day" plan for managing diabetes.

Table 44-7 Types of Insulin

Preparation	Brand	Onset (h)	Peak (h)	Duration (h)	Nursing Points
Very Rapid Acting					
Insulin analog	Humalog (Lispro) NovoLog (Aspart) Glulisine (Apidra)	<0.5	0.5–1.5	3–5	Must take with food (shorter acting than regular)
Short Acting					
Regular (R)	Humulin R Novolin R Velosulin BR	0.5–1	2–3	5–8	Only form available for IV continuous infusion
Intermediate Acting					
NPH	Humulin N Novolin N	1–4	4–12	10–16	
Insulin Regular (R)	Humulin R U-500	0.5–1.0	1.7–4	6–8	5 times the concentration of insulin; for patients on high doses of insulin
Long Acting					
Insulin glargine Insulin detemir	Lantus Levemir	1–2 0.8–2	None 3–9	24 Up to 24	
Combination					
					Mixture of long- and short-acting insulins
NPH and R (70/30)	70/30 (70% NPH, 30% regular) 50/50 (50% NPH, 50% regular)	0.5–3	Dual	12–14	
Humalog Mix (75/25)	75% insulin lispro protamine 25% insulin lispro (Humalog mix 75/25)	0.1–0.25	Dual	10–16 h	
Humalog Mix (50/50)	50% insulin lispro protamine 50% insulin lispro	0.1–0.25	Dual	10–16 h	
NovoLog Mix (70/30)	70% insulin aspart protamine 30% insulin aspart	0.1–0.25	Dual	10–16	

Hyperosmolar Hyperglycemic State

Sometimes a marked hyperglycemia and hyperosmolality without ketoacidosis develop in patients with diabetes; this is characteristic of HHS. Usually, patients with HHS are middle-aged or older (55 to 70 years), have undiagnosed type 2 diabetes, and are frequently residents of nursing homes. HHS is the initial manifestation in 7% to 17% of patients.[14]

HHS has a higher mortality rate than any other complication of diabetes, reflecting the higher morbidity associated with patients affected by this type of diabetic emergency. Often, these elderly, obese patients suffer from other severe medical conditions, such as congestive heart failure or kidney disease. Extremely high levels of glucose, coupled with severe dehydration in a vulnerable, elderly patient with other medical illnesses, explain the higher mortality rate associated with this diabetic complication. HHS is compared with DKA in Table 44-8.

Pathophysiology

It is not known specifically why some people with diabetes develop HHS rather than DKA, although it is speculated that these patients may have just enough insulin to prevent

BOX 44-12 TEACHING GUIDE Self-Management After Ketoacidosis

- A person with diabetes, as any other person, must have insulin, even if no food is being taken in.
- The amount of insulin required when the person with diabetes is not eating is about half the total needed when eating.
- The amount of insulin required when a person with diabetes is fasting must be spread out as an insulin "trickle" rather than as an insulin "burst."
- Illness generally increases the need for insulin so that even if the person with diabetes is not eating, he or she may actually require more than 50% of the usual daily dose.
- Always keep enough insulin on hand for daily injections.
- Know how to reach a health care provider for timely phone advice.
- When you are ill, adjustments for managing your diabetes may need to be made (see Box 44-13).

BOX 44-13 TEACHING GUIDE "Sick Day" Plan for Managing Diabetes

- Take your usual daily dose of insulin or oral hypoglycemic agent.
- Place an early call to your health care provider to inform him or her of your symptoms and actions.
- Monitor your blood glucose every 4 hours or a minimum of four times a day.
- Test your urine for ketones every 4 hours if your blood glucose level is 240 mg/dL or greater.
- Inject small, supplemental doses of short-acting insulin several times daily, if necessary, according to blood glucose test results until glucose levels come under control.
- Consume liberal amounts of fluids, such as water, tea, broth, apple and grape juice, and popsicles.
- Eat easily digested carbohydrates, such as custard, pudding, cream soup, saltine crackers, and toast, if you are unable to eat your normal diet.

ketosis. Pathophysiologically, the mechanisms of disease are the same as for DKA. A reduction in circulating insulin coupled with the effects of counter-regulatory hormones such as cortisol and epinephrine leads to the development of hyperglycemia and the extreme hyperosmolar state. Usually, the patient has coexisting impaired renal excretion of glucose and antecedent renal insufficiency or prerenal azotemia. Because basal insulin levels are unaffected, excessive ketone production does not occur. The acidosis that these patients develop is attributed to lactic acidosis from poor tissue perfusion instead of ketoacidosis.

HHS develops slowly over days to weeks, and patients often experience polydipsia, polyuria, and progressive decline in LOC. Marked dehydration occurs if the patient is unable to maintain an adequate fluid intake. The typical fluid loss associated with HHS is 9 L. As dehydration worsens, the patient develops increasing serum glucose concentrations and serum osmolality. The life-threatening cycle of hyperglycemia, hyperosmolality, osmotic diuresis, and profound dehydration triggers the sympathetic nervous system fight-or-flight response. The counter-regulatory hormones epinephrine and cortisol stimulate gluconeogenesis and increase hepatic

Table 44-8 Comparing Signs and Symptoms of Diabetic Ketoacidosis (DKA) and Hyperglycemic Hyperosmolar State (HHS)

Characteristics	DKA	HHS
Onset	Gradual or sudden, usually <2 d	Gradual, usually >5 d
Previous history of diabetes mellitus	85% (15% have new onset)	60%
Type of diabetes mellitus	Type 1	Type 2
Age of patient	Usually younger than 40 y	Usually older than 60 y
Mortality risk	1%–15%	20%–40%
Drug history	Insulin	Steroids, thiazides, oral agents
Physical signs	Polydipsia, polyuria, dehydration, Kussmaul's respirations, mental status changes, "fruity breath," febrile at times, ketoacidosis, nausea and vomiting	Dehydration; obtundation; hypothermia; toxic appearance; Kussmaul's respirations absent; nonketotic
Glucose level	Mean, 600 mg/dL Range, 250–1,200 mg/dL	Mean, 1,100 mg/dL Range, 400–4,000 mg/dL
Ketones	Present	Absent
Osmolarity	Mean, 320 mOsm/L	Mean, 400 mOsm/L
Arterial pH	Mean, 7.07	Mean, 7.26
Bicarbonate	Markedly low (<10 mEq/L)	Normal or >15 mEq/L
Anion gap	>12 mEq/L	<12 mEq/L, variable

Adapted from Kitabchi AE, Umpierrez GE, Miles JM, et al: Hyperglycemic crises in adult patients with diabetes. Diabetes Care 32(7):1335–1343, 2009.

glucose production. Dehydration worsens and leads to CNS dysfunction. Confusion and lethargy ensue quickly. Hemoconcentration of the blood increases the risk for clot formation, thromboemboli, and infarctions in major organs.

Causes

Infection is a major cause of HHS, occurring in 30% to 60% of patients. Urinary tract infections and pneumonia are the most common associated infections. In some cases, acute illness such as CVA, myocardial infarction, or pancreatitis provokes the release of counter-regulatory hormones resulting in hyperglycemia. HHS may also occur secondary to extreme stress associated with severe medical illness, such as stroke, myocardial infarction, pancreatitis, trauma, sepsis, burns, or pneumonia. Often, HHS results from excessive exposure or carbohydrate intake, such as dietary supplements, total enteral support with tube feedings, or peritoneal dialysis. Elderly people are at particularly high risk, especially those who have impaired cognition and who are in long-term chronic care facilities. Drugs, such as corticosteroids, thiazide diuretics, sedatives, and sympathomimetics, affect carbohydrate metabolism adversely and may lead to glucose impairment.

Assessment

HISTORY AND PHYSICAL EXAMINATION. The nurse assesses the patient for precipitating or associated events. This syndrome can be iatrogenic (eg, induced by certain medications such as steroids, hemodialysis against hyperosmolar glucose solutions, or prolonged IV hypertonic glucose infusions such as those given for total parenteral nutrition). It can also be precipitated by serious medical illnesses such as pneumonia or pancreatitis.

Often family members or long-term care personnel report that the patient has become a bit drowsy, taken in less food and fluid over several days, and slept more until he or she became difficult to awaken. The patient often arrives at the hospital with serious volume depletion and in a stupor or coma. The signs and symptoms of HHS are given in Table 44-8.

The clinical manifestations may take days to weeks to develop, and the patient often displays weakness, polyuria, polydipsia, and impaired mental state ranging from confusion to coma. Dehydration is manifested by tachycardia, hypotension, low cardiac output, poor skin turgor, rapid respirations without Kussmaul's breathing, and warm, flushed skin. The presence of hypothermia is a poor prognostic sign in HHS.

LABORATORY STUDIES. Laboratory values for HHS are similar for those with DKA with four main exceptions:

1. The hyperglycemia in HHS is, by definition, a blood glucose level greater than 600 mg/dL, and this is a significantly higher level than in DKA. Glucose can be in excess of 2,000 mg/dL.
2. Plasma osmolality is higher than in DKA and is reflective of more severe dehydration. In addition to extracellular sodium and water losses, a large additional "free water" deficit exists, probably because patients do not become thirsty, causing them to take in decreasing amounts of fluid. As a result, patients have very high serum levels of sodium and glucose. Serum osmolality is extremely high (>310 to 320 mOsm/kg).
3. Patients may have some degree of ketosis as well but usually are nonketotic. In DKA, the degree of ketosis is much more severe.
4. In HHS, acidosis is not present or is very mild. In HHS, the anion gap attributable to ketoacids usually is less than 7 mEq/L. The patient may present with azotemia, hyperkalemia, and lactic acidosis.

Management

Therapy for HHS is directed at correcting the volume depletion, controlling hyperglycemia, identifying the underlying cause of HHS and treating it. The volume depletion is usually greater in HHS than in DKA. Rapid rehydration is more cautiously carried out because of the fragile state of the patient, who often has comorbidities. Isotonic saline or hypotonic saline solution is administered initially to correct the fluid imbalance, and some patients may require as many as 9 to 12 L of fluid overall. The nurse should be vigilant for the signs of fluid overload during rehydration.

Critically ill patients require hemodynamic monitoring during fluid resuscitation, especially elderly patients with cardiac or renal disease. Careful monitoring of fluid intake, urine output, blood pressure, hemodynamic pressures, pulse, breath sounds, and neurological status is one of the nurse's primary responsibilities. In addition, the patient requires frequent monitoring of laboratory test findings.

Patients receive low doses of insulin along with the fluid replacement. It is necessary to give low-dose insulin by continuous infusion (0.1 mg/kg/h) because these patients are vulnerable to the sudden loss of circulating blood volume that occurs with higher doses of insulin and a rapid blood glucose reduction. As the glucose level returns close to normal (250 to 300 mg/dL), it is appropriate to stop the insulin infusion and add dextrose to the IV fluids to prevent a sudden drop in the blood glucose level. At this point, subcutaneous administration of insulin can proceed.

Investigation of the underlying cause of HHS is warranted, and treatment, if possible, is necessary. For example, management of underlying infection from pneumonia involves aggressive use of antibiotics, chest physiotherapy, turning, and coughing and deep breathing or suctioning as needed to clear the infiltrate. Removal of exogenous sources of glucose (tube feedings, peritoneal dialysis, medications) is appropriate while treating the hyperglycemic state.

Older patients who develop HHS have frequent complications and high mortality rates. They often have difficulty handling the fluid volume shifts that occur during the development and treatment of this disorder. The nurse gives fluid slowly to avoid complications associated with cerebral edema, such as seizures and an altered neurological state. These patients are also at risk for intravascular thrombosis and focal seizures because of the hemoconcentration of the blood and the hyperosmolar state. Use of seizure precautions is necessary at all times. Treatment of acute cerebral edema usually involves infusion of osmotic diuretic such as 20% mannitol. Because these patients usually have a preexisting cardiac or renal history that predisposes them to complications, fluid resuscitation should proceed slowly and carefully.

Critical care management continues until the patient's hyperglycemic state has stabilized, his or her neurological condition and vital signs return to normal, and the precipitating

cause has resolved. Discharge criteria also include having an adequate plan in place for the patient to maintain glycemic control and avoid future hyperglycemic emergencies.

Patient Education

As with patients with DKA, the patient and family experiencing HHS need education. The prevention of many cases of HHS and DKA entails better access to medical care, proper education, and effective communication with a health care provider during an intercurrent illness. Many uninsured or underinsured patients stop insulin therapy for economic reasons. The nurse must assess for this possibility.

For the person with newly diagnosed diabetes, the nurse needs to provide information about the pathophysiology of the disease, the signs and symptoms of complications, and methods of treatment, including medications, diet, and exercise. Information about how to manage "sick days" and other tips to avoid acute complications such as HHS must be part of the educational plan.

The patient may need instruction on home management and glucose testing. Often the critical care staff consults with the diabetes educator as the patient's educational plan is being formulated. The main theme should focus on effective techniques to avoid emergency intervention in the future. It is necessary to make appropriate referrals to a diabetic educator, social worker, dietitian, or a combination of these because diabetes outcomes are optimized when a team approach is used.

Hypoglycemia

Hypoglycemia is a well-recognized complication among patients with type 1 diabetes, and it is the most common diabetes-related emergency.[16] The issue of hypoglycemia is well documented in the landmark DCCT,[9] in which people with diabetes who maintained strict, intensive therapy for their diabetes experienced a threefold greater incidence of severe hypoglycemia than those patients with less strict treatment protocols. The UKPDS[10] demonstrated some increased incidence of hypoglycemia among people with type 2 diabetes, although few severe, life-threatening cases were documented in the study.

Insulin-induced hypoglycemia reactions often occur in the midst of the patient's daily life; this can be, at the very least, embarrassing, and at worst, dangerous. Mild hypoglycemia causes unpleasant symptoms and discomfort; however, severe hypoglycemia can lead to life-threatening complications such as seizures, coma, and even death if not reversed. Even though measurable recovery from hypoglycemia is rapid and complete within minutes after proper treatment, many patients remain emotionally (and possibly physiologically) shaken for hours or even days after insulin reactions. In extreme situations, prolonged or recurrent hypoglycemia, although uncommon, has the potential to cause permanent brain damage and can even be fatal.

Pathophysiology

Minute-to-minute dependence of the brain on glucose supplied by the circulation results from the inability of the brain to burn long-chain FFAs, the lack of glucose stored as glycogen in the adult brain, and the unavailability of ketones. The brain recognizes its energy deficiency when the serum glucose level falls abruptly to about 45 mg/dL. The term neuroglycopenia refers to the degree of hypoglycemia sufficient to cause brain dysfunction resulting in personality changes and intellectual deterioration. The exact level at which symptoms occur varies widely from person to person, however, and it is not uncommon for levels as low as 30 to 35 mg/dL to occur (eg, during glucose tolerance tests) with no symptoms whatsoever among the long-term diabetic population. See Box 44-14 for common signs and symptoms of hypoglycemia.

BOX 44-14 Signs and Symptoms of Hypoglycemia

Signs
- Hypothermia
- Tachypnea
- Tachycardia
- Dysrhythmias
- Hypertension
- Diaphoresis
- Tremulousness
- Hunger
- Nausea
- Belching

Symptoms
- Headache
- Personality changes
- Palpitations
- Blurred vision
- Combativeness, confusion, coma, convulsions

Symptoms result from either the sympathetic nervous system response to hypoglycemia or the neuroglycopenic response. The hypothalamus reacts to the lower glucose levels to mount the adrenergic response, including tachycardia, palpitations, tremors, and anxiety. The goal is to activate the counter-regulatory hormones (glucagon, catecholamines, cortisol, GH) to raise the glucose level and protect vital organs from hypoglycemia. This involves glycogenolysis and gluconeogenesis.

Assessment

Occasional reactions occur in even the most stable insulin-dependent diabetic patient. As long as the reactions are mild, they can usually be tolerated without difficulty and are not cause for alarm or for changes in regimen. Frequently, the precipitating event is clear (eg, a skipped meal or an unusually strenuous bout of exercise). Box 44-15 reviews the common causes of hypoglycemia.

When hypoglycemic reactions are frequent, recurrent, or severe, it is important to identify the cause and prevent further reactions. Otherwise patients may limit their functional activities and may become unwilling or unable to drive. They may overeat in an effort to prevent reactions. Usually the underlying mechanism can be discovered. If not, the patient should be admitted for work up and further evaluation.

HISTORY AND PHYSICAL EXAMINATION. The nurse asks about food intake and exercise because these often contribute to hypoglycemia. Problems with insulin dosage or

BOX 44-15 Common Causes of Hypoglycemia

- Insulin shock
- Insulinoma
- Inborn errors of metabolism
- Stress
- Weight loss
- Postgastrectomy
- Alcohol excess
- Glucocorticoid deficiency
- Fasting hypoglycemia
- Profound malnutrition
- Prolonged exercise
- Severe liver disease
- Severe sepsis
- Drug effects
  - Ethanol
  - Salicylates
  - Quinine
  - Haloperidol
  - Insulin
  - Sulfonylureas
  - Sulfonamides
  - Allopurinol
  - Clofibrate
  - β-Adrenergic agents

administration may be noted. It is necessary to investigate every detail of insulin therapy thoroughly, including insulin purchase and its appearance, species, and units; syringes, injection sites, and injection technique; and especially any recent change in any part of the regimen. The nurse explores for flaws and inconsistencies in reporting. Prescription errors, mismatched syringe and insulin units, use of new injection sites, and other errors may emerge.

The administration or withdrawal of other drugs may be the precipitating event for recurrent insulin reactions. For example, salicylates in large doses can reduce blood glucose and, in combination with insulin, can produce hypoglycemia. Also, the nurse asks about the use of glucocorticoid medications. Because these medications cause insulin resistance, insulin doses are often raised to meet the increased insulin demand. If the steroids are then tapered without reducing the insulin dose, hypoglycemic reactions can occur. Alcohol often causes hypoglycemia. Not only do patients often eat less when they have a few drinks, but also alcohol shuts off gluconeogenesis by interfering with intermediate biochemical steps in the liver. When combined with injected insulin, this frequently leads to hypoglycemia. Oral hypoglycemic agents can also produce severe and long-lasting hypoglycemia. Patients who experience such episodes tend to be older and undernourished with impaired renal or hepatic function. Nevertheless, any patient on oral agents can become hypoglycemic, especially when substances such as salicylates and alcohol potentiate the effects of the oral agents.

Another common mechanism that can cause hypoglycemia is an atypical (eg, early or late) response to insulin therapy. Once the response pattern is defined, it is possible to adjust the insulin regimen and eliminate the insulin reactions. Occasionally, when a stable, reaction-free patient begins to experience hypoglycemic episodes, the clinician should explore the likelihood of insulin sensitivity due to weight loss or the onset of azotemia.

As the blood glucose level falls below normal, the CNS responds in two distinct ways: first, with impairment of higher cerebral functions, and second, soon thereafter, with an "alarm" response in vegetative functions. Patients most commonly describe the symptoms of mild or early insulin reactions as fuzziness in the head, trouble thinking or concentrating, shakiness, light-headedness, or giddiness. These changes occur when the cerebral cortex is deprived of its main energy supply, usually when the blood glucose level has fallen to 50 mg/dL or less or is rapidly declining. The cerebral cortex is apparently the most sensitive to the loss of glucose.

Changes in personality and behavior vary with the person and may not be apparent to them during an insulin reaction. Changes range from silly, manic, inappropriate behavior to withdrawn, sullen, grumpy, irritable, suspicious behavior. There may be difficulties in motor function, such as trouble walking and slurred speech, and patients who are well into insulin reactions may closely resemble people who have been drinking alcohol in excess.

Some patients experience aphasia, vertigo, localized weakness, and even focal seizures with their insulin reactions. Such focal changes usually occur when there is prior damage to a specific area of the cortex, such as a head injury or CVA.

Closely following the cortical changes is a series of autonomic neurological responses. The primary response is discharge from the centers that control adrenergic autonomic impulses. This results in the release of norepinephrine throughout the body and epinephrine from the adrenals. Tachycardia, pallor, sweating, anxiety, and tremor are characteristic signs of hypoglycemia and are important early warning signs for patients who recognize a reaction. Headache can occur, and the stress response can occasionally trigger secondary sequences of symptoms, including angina or pulmonary edema in patients with fragile cardiovascular disease.

As hypoglycemia persists and worsens, consciousness is progressively impaired, leading to stupor, seizure, or coma. This is characteristic of severe hypoglycemia. The autonomic centers controlling fundamental systems, such as respiration and blood pressure, are the most resistant to hypoglycemia and continue to function even when most other cerebral functions are lost.

The more profound the hypoglycemia and the longer it lasts, the greater the chance of transient or even permanent cerebral damage after the blood glucose level is restored. There does not seem to be a clear duration threshold for such damage, but severe hypoglycemia lasting more than 15 to 30 minutes can result in some symptoms that persist for a time after glucose is given. Blood glucose measurement, before the administration of glucose if possible, verifies the diagnosis; but waiting for a glucose test result should be avoided in an emergency situation.

Management

Treatment for insulin reactions is always glucose. If the patient can swallow, the most convenient form is a glucose- or sucrose-containing drink because it probably gets through the stomach and into the absorbing intestine in this form in the shortest possible time. If the patient is too groggy, stuporous, or uncooperative to drink, the glucose is in the form of an IV bolus of 25 g of 50% dextrose given over several minutes. If this route or dosage is unavailable, 1 mg of glucagon given subcutaneously or intramuscularly reverses the symptoms by inducing a rapid breakdown and release of glucose into the bloodstream from hepatic glycogen stores.

The amount of glucose needed to reverse an insulin reaction acutely is not large. In an average-sized adult, less than 15 g (three teaspoons) of glucose can raise the blood glucose from 20 to 120 mg/dL. Glucose in almost any oral form will serve. Typical treatments for hypoglycemia include three glucose tablets, 6 oz of regular cola, 6 oz of orange juice, 4 oz of skim milk, or 6 to 8 Lifesaver candies. Starch, found in crackers and cookies, is broken down to free glucose after passing through the stomach and is absorbed so rapidly that blood glucose rises virtually as fast as with free glucose or sucrose.

Patients frequently express concern about what to do if they do not respond to the initial therapy, and they fear that they might "never wake up" from a nocturnal insulin reaction. The nurse must reassure them that if the first bolus of glucose consumed does not seem to work, the sensible thing to do is to take in more. Insulin reactions are always reversible with enough glucose. The response to oral glucose, of course, takes time, perhaps 5 to 15 minutes, whereas the response to IV glucose should occur within 1 or 2 minutes at most. Failure to respond fully in the appropriate time indicates that not enough glucose has been given, that the diagnosis is incorrect, or that the hypoglycemia has been long and severe enough to produce persistent, although not necessarily permanent, cerebral dysfunction.

Patient Education

The nurse should teach all people with diabetes to report hypoglycemic reactions to their health care provider for adjustments in their medical regimen. If they are taking insulin, they should know when to expect peak effects of the drug so that they can predict high-risk times for hypoglycemia. They should always carry a high-glucose snack with them for emergency use. The nurse should encourage them to carry medical identification at all times.

▲ Clinical Applicability Challenges

CASE STUDY

J., a 17-year-old female, was admitted to the hospital with symptoms of fever, nausea, vomiting and right flank pain for 2 days. She had been diagnosed with diabetes mellitus at 7 years of age and has been taking a maintenance insulin regimen of 18 units of longer-acting insulin glargine (Lantus) at bedtime and a sliding scale dose of aspart (NovoLog) before meals. For the past 2 days, she omitted her insulin because she was not eating anything.

Her vital signs are temperature 102°F; pulse, 120 beats/min; respirations, 32 breaths/min and deep; and blood pressure, 80/52 mm Hg. She is lethargic but fully oriented, complaining of chills and flank pain. Admission laboratory work reveals hematocrit, 48.6%; white blood cells, 36,400/mm^3; glucose, 610 mg/dL; sodium, 138 mEq/L; potassium, 5.7 mEq/L; chloride, 90 mEq/L; bicarbonate, 4 mEq/L; blood urea nitrogen, 43 mg/100 mL; creatinine, 2.2 mg/dL; serum ketones, 4+; and urine glucose and ketones 4+, blood 4+, leukocyte esterase+ and nitrites +. Arterial blood gas values are arterial blood pH, 7.06; PaO_2, 90 mm Hg; $PaCO_2$, 13 mm Hg; and bicarbonate, 2.5 mEq/L. Her contrast-enhanced helical/spiral computed tomography scan confirms right-sided pyelonephritis.

Emergency department physicians diagnose J. with moderate to severe diabetic ketoacidosis with right pyelonephritis. The initial therapy consists of several liters of normal saline solution infused intravenously and 20 units regular insulin by intravenous push, followed by an infusion of insulin at 5 units/h during the first 6 hours. She is immediately started on broad-spectrum antibiotics, antipyretics, and morphine for pain. Her mental status improves as her pain is controlled and she is rehydrated.[17] The flow sheet below summarizes the biochemical changes over the first 15 hours.

Biochemical Flow Sheet Indicating Diabetic Ketoacidosis for J.

Time	Sugar	pH	Na	K	Cl	HCO_3	BUN/ Creatinine
1:00 PM	610	7.06	138	5.7	90	4	40/2.1
3:00 PM	492		137	4.8	101	6	41/1.7
5:15 PM	375	7.25	137	4.1	106	8	45/1.4
10:00 PM	303		139	4.7	114	15	27/1.2
4:00 AM	204		143	4.3	113	22	22/1.1

By the time of discharge 5 days later, J. is eating well, her fever is gone, and she has well-controlled blood glucose levels on her usual doses of insulin glargine and insulin aspart.

1. J. receives the diagnoses of ketosis and acidosis. What are the indicators of ketosis and acidosis?

2. J. experiences volume depletion and electrolyte imbalances. Why does this occur and what are the clues?

3. What are the main teaching points regarding future management of J.'s diabetes in this case?

HEMATOLOGICAL AND IMMUNE SYSTEMS

45

Anatomy and Physiology of the Hematological and Immune Systems

Thomasine D. Guberski

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Describe the blood and its components and the function of each component.
2. Delineate the clotting factors and the role each plays in coagulation.
3. Describe the anatomy and physiology of the immune system.
4. Differentiate between innate and adaptive immunity including humoral and cell-mediated immunity.

Because cells for both the hematological and the immune systems originate in bone marrow, the systems are interrelated. As a result, a change in one system can manifest itself in the other system. For example, a decrease in the number of white blood cells results in an immune system that is less able to resist infection. The anatomy and physiology of these two systems are discussed separately in this chapter, but the reader should keep in mind their close relationship.

▲ Hematological System

Veins, venules, capillaries, arterioles, and arteries constitute an intricate network of conduits for the transportation of blood, which carries respiratory gases, nutrients, and waste products to and from body tissue. Patency of the conduits and containment of blood within the vasculature depend on the integrity of the transporting conduits. A delicate balance must be maintained in the vasculature to ensure both its patency and the liquid state of blood so that neither thrombosis nor hemorrhage occurs. This delicate balance is provided by the hemostatic and fibrinolytic systems working in concert.

Blood and Its Functions

Blood is an aqueous solution of colloid and electrolytes that serves as a medium of exchange between body cells (interior environment) and the exterior, or external, environment. It has distinct characteristics, including variable color (arterial blood is bright red; venous blood is dark red), viscosity (blood is three to four times thicker than water), a pH of 7.35 to 7.4, and a volume of approximately 70 to 75 mL/kg of body weight (5 to 6 L). Plasma constitutes approximately 55% of blood volume, whereas cellular elements suspended in the plasma constitute the remaining 45%. The vital functions of blood are as follows:

- Transport of oxygen and absorbed nutrients to cells
- Transport of carbon dioxide and other waste products to the lungs, kidneys, gastrointestinal system, and skin
- Transport of hormones from endocrine glands to target organs and tissues
- Protection of the body from life-threatening microorganisms
- Regulation of acid–base balance
- Protection from blood loss through hemostasis
- Regulation of body temperature by heat transfer

See Chapter 16 for a more detailed discussion of circulation.

Components of Blood

Plasma

Plasma, the liquid portion of the blood contains a wide variety of organic and inorganic components (Table 45-1). The concentration of these components reflects diet, metabolic demand, hormones, and vitamins. Plasma is approximately 90% water and 10% dissolved solutes. The most prevalent solutes by weight are the plasma proteins and clotting factors. Serum is plasma that has had clotting proteins removed.

Plasma proteins play a role in transport, volume regulation, immune function, and coagulation. Most plasma proteins, including albumin and fibrinogen, are synthesized by the liver; however, the immunoglobulins are synthesized by B lymphocytes. Albumin is essential for regulation of the colloidal osmotic pressure, which is critical for movement of water and solutes through the microcirculation. Plasma also is a carrier molecule for normal blood components and exogenous agents, such as drugs. Immunoglobulins (antibodies) are essential for defense against infectious microorganisms (see the Immune System section in this chapter for a further description). Fibrinogen is the clotting factor that forms the fibrin clot, essential to the clotting cascade.

Lipoproteins, which include the plasma lipids, triglycerides, phospholipids, cholesterol, and fatty acids, are carried through the blood as complexes with the plasma proteins. Also contained within the plasma, electrolytes (sodium, potassium, calcium, magnesium, chloride, bicarbonate, phosphate, and sulfate) maintain the pH and osmolality of the blood. Plasma nutrients, such as glucose, and gases, such as oxygen and carbon dioxide, are circulated to and from the tissues. Waste products, a final component of plasma, are carried to the appropriate organ for excretion.

Table 45-1 Organic and Inorganic Components of Arterial Plasma

Constituent	Amount/Concentration	Major Functions
Water	93% of plasma weight	Medium for carrying all other constituents
Electrolytes	Total <1% of plasma weight	Maintain H_2O in extracellular compartment; act as buffers; function in membrane excitability
Na^+	142 mEq/L (142 mM)	
K^+	4 mEq/L (4 mM)	
Ca^{2+}	5 mEq/L (2.5 mM)	
Mg^{2+}	3 mEq/L (1.5 mM)	
Cl^-	103 mEq/L (103 mM)	
HCO_3^-	27 mEq/L (27 mM)	
Phosphate (mostly HPO_4^{2-})	2 mEq/L (1 mM)	
SO_4^{2-}	1 mEq/L (0.5 mM)	
Proteins	7.3 g/dL (2.5 mM)	Provide colloid osmotic pressure of plasma; act as buffers; bind other plasma constituents (eg, lipids, hormones, vitamins, minerals, etc.); clotting factors; enzymes; enzyme precursors; antibodies (immune globulins); hormones; transporters
Albumins	4.5 g/dL	
Globulins	2.5 g/dL	
Fibrinogen	0.3 g/dL	
Transferrin	250 mg/dL	
Ferritin	15–300 mcg/L	
Gases		
CO_2 content	22–32 mmol/L plasma	Byproduct of oxygenation, most CO_2 content from HCO_3 and acts as a buffer
O_2	PaO_2 80 torr or greater (arterial); PvO_2 30–40 torr (venous)	Oxygenation
N_2	0.9 mL/dL	Byproduct of protein catabolism
Nutrients		Provide nutrition and substances for tissue repair
Glucose and other carbohydrates	100 mg/dL (5.6 mM)	
Total amino acids	40 mg/dL (2 mM)	
Total lipids	500 mg/dL (7.5 mM)	
Cholesterol	150–250 mg/dL (4–7 mM)	
Individual vitamins	0.0001–2.5 mg/dL	
Individual trace elements	0.001–0.3 mg/dL	
Iron	50–150 mcg/dL	
Waste products		
Urea (blood urea nitrogen)	7–18 mg/dL (5.7 mM)	End product of protein catabolism
Creatinine (from creatine)	1 mg/dL (0.09 mM)	End product from energy metabolism
Uric acid (from nucleic acids)	5 mg/dL (0.3 mM)	End product of protein metabolism
Bilirubin (from heme)	0.2–1.2 mg/dL (0.003–0.018 mM)	End product of red blood cell destruction
Individual hormones	0.000001–0.05 mg/dL	Functions specific to target tissue

Cellular Elements

Summarized in Table 45-2 along with their functions, the cellular elements of the blood are erythrocytes (red blood cells), leukocytes (white blood cells), and platelets. All blood cell types are believed to be derived from a single stem cell known as the pluripotent stem cell, as shown in Figure 45-1. The production of blood cells (hematopoiesis) occurs in the bone marrow and is a two-stage process that involves mitotic division (proliferation) and maturation (differentiation). Each blood cell line results from pluripotential cells that become committed to a specific cell line when they receive specific biochemical signals. These signals occur when one or more populations of circulating cells have decreased to a certain level. Mitosis occurs, and proliferation continues until the needed number of mature daughter cells enters the circulation.

Erythrocytes

There are approximately 5 million erythrocytes per cubic millimeter of blood. They are produced in the red bone marrow found in the sternum, ribs, skull, vertebrae, and bones of the hands, feet, and pelvis. Normal cell formation requires nutrients such as iron, vitamin B_{12}, folic acid, and pyridoxine. Reticulocytes (immature nucleated red blood cells) are released from the bone marrow and circulate for 1 to 2 days while maturing into adult cells. The average life span of an erythrocyte is 115 to 130 days. Dead red blood cells are eliminated mainly by phagocytosis in the liver and spleen.

The erythrocyte is a small, biconcave disk that is reversibly deformable. The flattened, biconcave shape has a surface area: volume ratio that is optimal for the diffusion of gases into and out of the cell. Reversible deformability allows the cell to alter its shape to squeeze through the microcirculation and then return to its normal shape.

Hemoglobin is the iron-containing substance of the erythrocyte. The normal amount of hemoglobin in the body is 12 to 18 g/dL of blood, with the lower level more common in women and the higher level more common in men. Hemoglobin is composed of a red compound called heme (which contains iron and porphyrin) and a simple protein called globin. One iron atom is present for each heme molecule. Total body iron ranges from 2 to 6 g. Two thirds of this is in hemoglobin, whereas the rest is stored in the bone marrow, spleen, and liver. When red blood cells break down, hemoglobin splits

Table 45-2 Cellular Components of the Blood

Cell	Structural Characteristics	Normal Amounts in Circulating Blood	Function	Life Span
Erythrocyte (red blood cell)	Nonnucleated cytoplasmic disk containing hemoglobin	4.2–6.2 million/mm^3	Gas transport to and from tissue cells and lungs	80–120 d
Leukocyte (white blood cell)	Nucleated cell	5,000–10,000/mm^3	Bodily defense mechanisms	See below
Lymphocyte	Mononuclear immunocyte	25%–33% of leukocyte count (leukocyte differential)	Humoral and cell-mediated immunity	Days or years, depending on type
Monocyte and macrophage	Large kidney-shaped mononuclear phagocyte	3%–7% of leukocyte differential	Phagocytosis; mononuclear phagocyte system	Months or years
Eosinophil	Segmented polymorphonuclear granulocyte with granules stainable by eosin dyes	1%–4% of leukocyte differential	Phagocytosis; response to parasites, control of allergic reactions;	8–12 d
Neutrophil	Segmented polymorphonuclear granulocyte with granules stainable by neutral staining	57%–67% of leukocyte differential	Phagocytosis, particularly during early phase of inflammation, bacterial killing	4 d
Basophil	Lobate nuclear granulocyte with granules stainable by basic dyes	0%–0.75% of leukocyte differential	Similar to mast cell, secretes inflammatory mediators (eg, histamine, chemotactic factors for eosinophils and neutrophils), involved with allergic reactions	Few hours to days
Platelet	Irregularly shaped cytoplasmic fragment (not a cell)	140,000–340,000/mm^3	Hemostasis following vascular injury; normal coagulation and clot formation/retraction	8–11 d

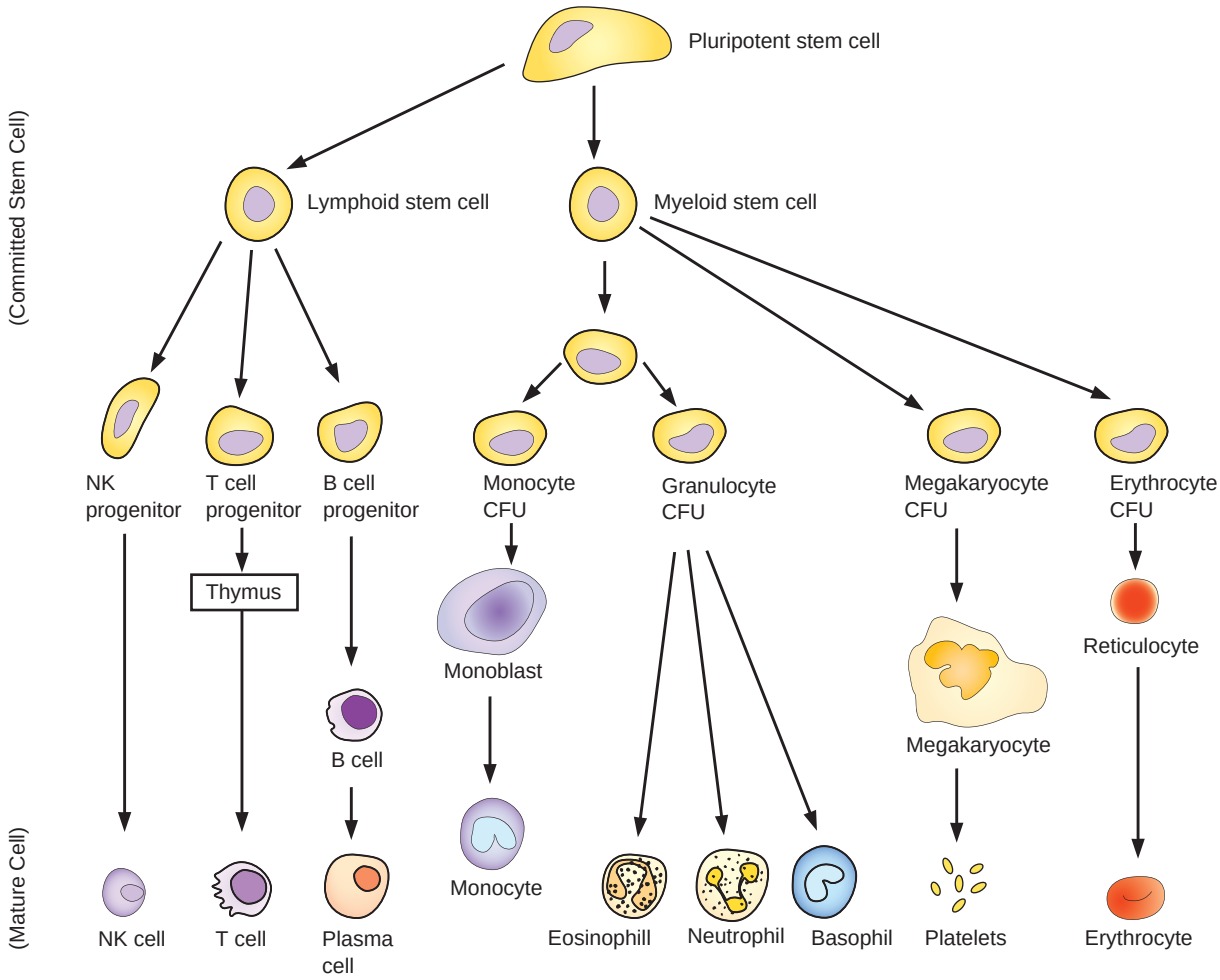

FIGURE 45-1 ▲ Major maturational stages of blood cells. CFU, colony-forming unit; NK, natural killer cell. (From Porth CM: Pathophysiology: Concepts of Altered Health States, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 259.)

into heme and globin factors. The liver stores the iron portion of heme for production of new hemoglobin, and the remainder is converted into bilirubin, which is excreted in feces and urine after conjugation by the liver. This conjugation process is important to the excretion of bilirubin, which causes jaundice when it accumulates in the tissues (see Chapter 38). Each red blood cell contains 200 to 300 million molecules of hemoglobin, which combines with oxygen to form oxyhemoglobin. Hemoglobin also combines with carbon dioxide. Thus, the blood can carry oxygen to the tissues and carbon dioxide from the tissues to the alveoli of the lungs, where it is expelled into the atmosphere. Hemoglobin can also combine preferentially with carbon monoxide, which displaces oxygen.

Respiration is a major function of erythrocytes. Hemoglobin combines with oxygen in the lungs. The saturation of hemoglobin with oxygen is influenced by the partial pressure of oxygen available in the lungs, the temperature of the blood, the pH of the blood, and the amount of intracellular 2,3-biphosophyglycerate. For example, people who live at sea level and vacation in high altitudes, where the partial pressure of oxygen in the lungs is lower, may experience shortness of breath with activity because less oxygen is available to combine with hemoglobin.

Leukocytes

Leukocytes, or white blood cells, are transported in the circulation but act primarily in the body tissues, defending the body against microorganisms and foreign antigens and removing debris, such as dead or injured host cells. There are approximately 5,000 to 10,000 white blood cells per cubic millimeter of blood. The two major categories of leukocytes are granulocytes and agranulocytes.

Granulocytes make up approximately 70% of all white blood cells and include neutrophils, eosinophils, and basophils. They are produced by the bone marrow from myeloid stem cells, and their function depends on the type of enclosed granule. Polymorphonuclear leukocytes, or neutrophils, fight bacterial and fungal infections and digest foreign particulate matter or break down products from cells through phagocytosis. Neutrophils are present during the early acute phase of an inflammatory reaction. After bacterial invasion or tissue injury, they migrate from the capillaries into the inflamed area, reaching their peak activity in 6 to 12 hours. In the inflamed area, they destroy and ingest microorganisms and other debris. They die in 1 or 2 days, releasing digestive enzymes that dissolve cellular debris and prepare the inflamed site for healing.

Eosinophils are particularly important in detoxifying foreign protein. They ingest antigen–antibody complexes, attack parasites, and are elevated during allergic reactions. Eosinophils have surface receptors for immunoglobulins and histamine.

Basophils contain cytoplasmic granules with vasoactive amines (histamine, bradykinin, and serotonin), which are thought to play a role in the symptoms of acute systemic allergic reactions. Basophils also contain the anticoagulant heparin, histamine, and other vasoactive substances.

Agranulocytes (monocytes, macrophages, and lymphocytes) are leukocytes that do not contain lysosomal granules in their cytoplasm. Agranulocytes also come from the myeloid stem cell. Monocytes (immature macrophages) and macrophages comprise the mononuclear phagocyte system. They are responsible for the phagocytosis of dead leukocytes and erythrocytes in the blood and for processing antigenic material as neutrophils start to decrease in number. Some of the circulating macrophages migrate out of the blood vessels in response to inflammation or infection, whereas others migrate to fixed sites in lymphoid tissues of the liver, spleen, lymph nodes, peritoneum, or gastrointestinal tract, where they may remain active for months or years. Lymphocytes are immunocompetent cells that are involved in producing antibodies and maintaining the immune response. The most important classifications are B and T lymphocytes, which are discussed later in the chapter.

Platelets

Platelets are disk-shaped cytoplasmic fragments formed from bone marrow stem cells, specifically, a giant cell called the megakaryocyte. Platelets maintain capillary integrity, accelerate coagulation, and retract clots. There are approximately 250,000 to 500,000 platelets per cubic millimeter of blood; one third resides in a reserve pool in the spleen. Platelets live about 10 days; when they die, they are removed from the circulation by macrophages, mostly in the spleen.

Blood Coagulation

Hemostatic homeostasis is maintained through three interdependent components: blood vessels, platelets, and blood coagulation factors. In the course of normal wear and tear, the endothelial lining of blood vessels is subject to damage that requires local repair to prevent blood leakage. The body repairs the vessels through a process called coagulation. In this process, damage to, or sloughing of, the endothelium exposes the underlying collagen. This exposed collagen attracts and activates platelets to adhere to it, which begins the formation of platelet plugging. With the attraction of platelets to the exposed collagen, an initial barrier of platelets is formed. These platelets release small amounts of adenosine diphosphate, which attracts additional platelets that stick to each other. Following this process, there is a release of platelet factor 3 from the platelet membrane, which interacts with various blood coagulation proteins and accelerates clotting.

Platelets play two major roles in the clotting process. First, the platelet plug temporarily plugs the leak in the blood vessel. This plug provides the architectural foundation for the building of the fibrin clot. Second, platelets initiate clotting by way of the intrinsic pathway through the release of platelet factor 3.

Coagulation Factors

Coagulation factors are designated by Roman numerals and numbered according to the order in which they were first identified. When the factors are in active form, they are designated by a lowercase "a" (eg, factor XIIa). Box 45-1 lists the factors by Roman numeral and common name.

Coagulation Pathways

Blood coagulation proteins, or coagulation factors, are found in the extrinsic and intrinsic pathways to coagulation. Tissue factor TFVIIa activates the coagulation pathway.[1] There is interplay between the extrinsic and intrinsic pathways and activation of factor VII, found in the extrinsic pathway, can activate intrinsic pathway factor XI. Likewise, several factors in the intrinsic pathway activate factor VII.

Extrinsic Pathway

The extrinsic pathway is a series of chemical reactions that originate outside the injured structure. Critical steps are shown in Figure 45-2. Injury to tissues and blood vessels triggers coagulation and results in the release of factor III (thromboplastin) into the circulation. Factor III, catalyzed by factor VII (proconvertin), activates factor X (Stuart-Prower factor). In the presence of calcium ions, factor V (proaccelerin), and platelet factor 3, factor Xa catalyzes the conversion of factor II (prothrombin) to IIa (thrombin) and factor I (fibrinogen) to the fibrin clot.

The result of the interaction among the blood vessels, platelets, and blood coagulation factors is the formation of factor Xa, which, as noted, converts prothrombin to thrombin and results in fibrin formation. The intrinsic and extrinsic pathways merge at factor Xa into a final common pathway to clot formation. Figure 45-2 diagrams the sequence of clot

BOX 45-1 Coagulation Factors

I	Fibrinogen
II	Prothrombin (thrombin in active form–IIa)
III	Thromboplastin
IV	Calcium
V	Proaccelerin
VI	Unassigned
VII	Proconvertin; prothrombinogen; convertin
VIII	Antihemophiliac factor A (factor VIIIR–von Willebrand)
IX	Antihemophiliac factor B; Christmas factor; platelet cofactor II
X	Stuart-Prower factor; prothrombinase
XI	Plasma thromboplastin antecedent
XII	Hageman factor; glass factor
XIII	Fibrin-stabilizing factor; Laki-Lorand factor

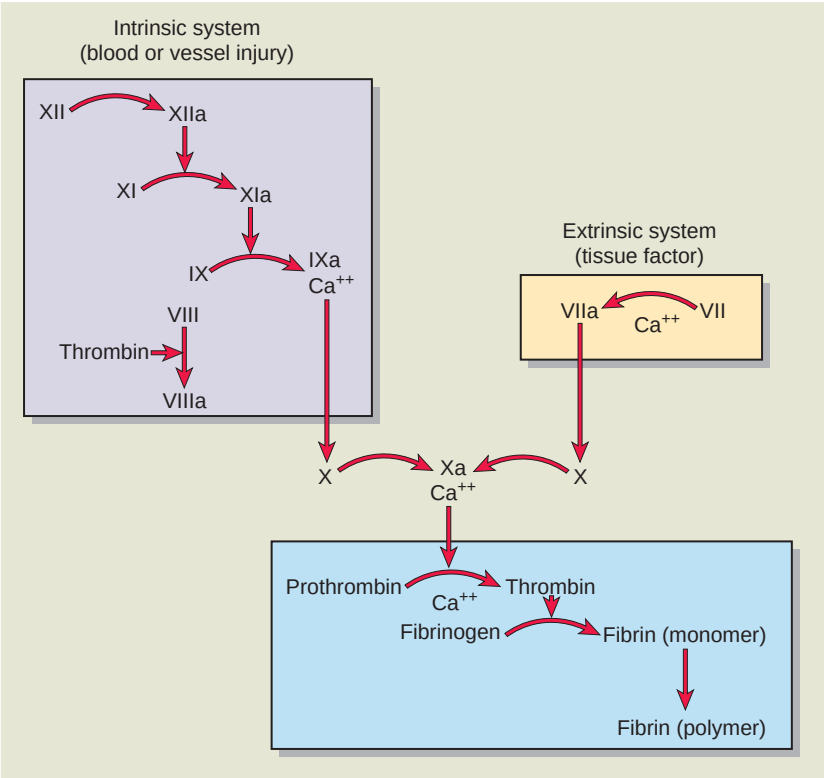

FIGURE 45-2 ▲ The coagulation cascade. (From Porth CM: Pathophysiology: Concepts of Altered Health States, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 265.)

formation. Note that the activation of factor VIII (antihemophiliac factor A) by thrombin causes the activation of factor X, resulting in a self-perpetuating effect.

Calcium plays an important role along the clotting cascade. Many coagulation factors carry two negative charges. Calcium, with its two positive charges, creates a strong affinity for the factors to bind at the site of clotting.

Intrinsic Pathway

Normally, blood coagulation factors circulate in an inactive state. After an initiating stimulus, changes in the coagulation factors occur immediately. The stimulus, damaged subendothelium, causes molecular alteration in any inactive coagulation factor, known as a proenzyme, converting it to an active form. The product of this enzymatic reaction activates the next coagulation factor in a chainlike reaction, leading to final clot formation. This chain of chemical reactions is termed the intrinsic pathway, which indicates its origin from within the tissue.

The release of platelet factor 3 initiates the activation of the intrinsic pathway by activating factor XII (Hageman factor). It is also a necessary component for complex reactions at the levels of factors V and VIII. The exposed collagen, phospholipids from injured erythrocytes and granulocytes, antigen–antibody complexes, and endotoxins are thought to be other activators of factor XII. These activators convert factor XII to the active enzymatic form XIIa, which acts on the next clotting proenzyme, factor XI (plasma thromboplastin antecedent), converting it to XIa. Factor XIa is responsible for the activation of factor IX (antihemophiliac factor B), which requires calcium ions. The activation of the next factor, factor X, requires factor VIII and platelet factor 3. The conversion of factor II to factor IIa (thrombin) requires factor V, platelet factor 3, and calcium ions.[2] Thrombin acts on fibrinogen, converting it to fibrin. This initial soluble fibrin clot is stabilized by factor XIII in the presence of calcium.

Again, the activation of factor VIII by thrombin creates the activation of factor X, resulting in a self-perpetuating effect. Thrombin enhances the activity of factor VIII so that it interacts more rapidly with factor IXa and thus catalyzes the activation of factor X. At this point, the intrinsic and extrinsic coagulation cascades merge. Thrombin also interacts with platelets, resulting in the release of platelet factor 3, which activates factor XII.

Coagulation Inhibitors

Unchecked activation of the blood clotting factors would cause clots to form on top of the platelet plug, releasing thrombin in the process of clotting, further attracting platelets to the clot site, and causing additional clots to form at the local site of the vessel leak (Fig. 45-3). There would be total vessel occlusion if there were no mechanisms operating to maintain the blood in a fluid state and prevent uncontrolled clotting.

However, there is a well-controlled balance between clot formation and clot inhibition. Through the action of physiological coagulation inhibitors, the blood is maintained in its fluid state, and blood vessels remain patent. These inhibitors—adequate blood flow, mast cells, antithrombin III, the mononuclear phagocyte system, and the fibrinolytic system—work by limiting reactions that promote clotting and by lysing any clots that do form, thereby preventing total occlusion of the vessels. Maintaining adequate blood flow facilitates the quick delivery of dilute-activated clotting factors to the

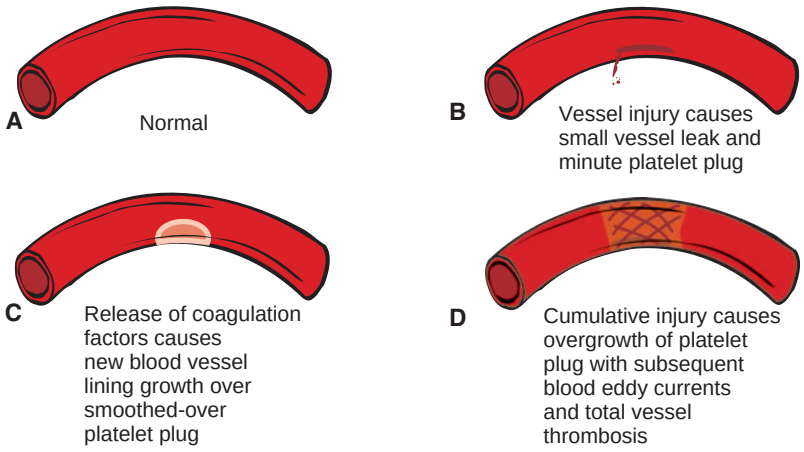

FIGURE 45-3 ▲ A–D: Sequence of thrombus formation in blood vessels.

liver, where they are cleared from circulation. Also, mast cells, which are located in most body tissues, produce heparin (which has a low anticoagulant activity compared with that of commercially produced heparin). Next, the liberation of antithrombin III in response to thrombin inactivates the circulating thrombin and neutralizes activated factors XII, XI, and X. This retards the conversion of fibrinogen to fibrin, thereby stopping sequential activation of clotting factors. Also, the mononuclear phagocyte system, composed of tissue macrophages located throughout the body, inhibits coagulation by clearing activated factors from the blood. Finally, the fibrinolytic system interferes with thrombin at its site of action on fibrinogen. It also involves a chain reaction whereby activation of a series of proenzymes produces lytic enzymes capable of dissolving clots.

The proenzyme plasminogen circulates in the blood. It is believed that the endothelial cells that constitute the endothelial lining of blood vessels release plasminogen activator, converting plasminogen to plasmin. In addition, activated factor XII, thrombin, kallikrein, and substances in the tissues are thought to be involved in the conversion of plasminogen to plasmin. Plasminogen activator levels are transiently elevated in response to exercise, stress, anoxia, and pyrogen. Plasmin, then, is the dissolving, or lytic, enzyme that lyses fibrin and attacks factors V, VIII, IX, and fibrinogen.

Finally, the lysis of fibrinogen and fibrin results in the liberation of fibrin degradation products (FDPs). FDPs inhibit platelet aggregation, exhibit an antithrombotic effect, and interfere with formation of the fibrin clot.

Fibrinolytic System Inhibitors

Similar to coagulation inhibitors, there are inhibitors of the fibrinolytic system. These inhibitors prevent inappropriate lysis of needed clot formation. The mononuclear phagocyte system clears FDPs from the circulation. Also, antiplasmin, a protein circulating in the blood, binds with plasmin and renders it inactive. The level of circulating antiplasmin far outweighs plasmin concentrations, and plasmin is neutralized rapidly.

It is evident that the systems of hemostasis and fibrinolysis, in conjunction with their system inhibitors, function within a narrow margin to ensure the liquidity of the blood and patency of the vasculature. An upset in these systems can result in clinical evidence of thrombosis, hemorrhage, or the catastrophic event of disseminated intravascular coagulation.

▲ Immune System

The immune system is composed of the following organs and cells: spleen, lymph nodes, thymus, bone marrow, appendix, tonsils and adenoids, B and T lymphocytes, eosinophils, basophils, and phagocytes. The organs of the system are connected with one another and with other organs through a network of lymphatic vessels. Immune cells and foreign particles are conveyed through the vessels in lymph fluid.

As noted, the hematological and immune systems are closely related. In addition to both originating in the bone marrow, blood carries components of the immune system throughout the body. The coagulation system helps keep microorganisms at the inflammatory site. The following are functions of a healthy immune system:

- Protection of the body from destruction by foreign agents and microbial pathogens
- Degradation and removal of damaged and dead cells
- Surveillance and destruction of malignant cells

Immune Response

The immune system is the body's internal response to substances recognized as foreign. People have two types of immunity: innate (general) immunity and adaptive (acquired) immunity. Innate immunity is the body's capacity to resist invasion by foreign agents. The innate immune system has an array of toll-like receptors, that exist on cells at the host–environment interface and have direct and early contact with potential pathogenic microorganism.[3] The receptors interact with membrane patterns shed by infectious agents and trigger the innate immune response.[3] In addition, innate immunity makes use of phagocytes and natural killer cells (NKCs) in its inflammatory response to microorganisms. Innate immunity is nonspecific and has no memory.

Adaptive immunity is the specific capacity of a person's immune system to identify a substance as foreign and mount an antibody response. It occurs when a person develops his or her own antibodies in response to exposure to an antigen.

Antibodies function as memory cells, so that subsequent exposures to specific antigens cause a quicker response. Adaptive immunity also occurs when another source supplies a person with antibodies. The maternal-to-fetal transfer of antibodies is an example of one person supplying antibodies to another. Because it may take several days for acquired immunity to generate sufficient activity to protect a person, a major role of the innate immune system is to limit microbial replication until the specific immune response is mobilized.

Basically, the immune system protects the body, or "self," from invasion by "nonself." The concept of immune tolerance infers a nonactive immune system with self while producing immunity to foreign substances.[4] Any foreign substance capable of eliciting a specific immune response is referred to as an antigen. Antigens are most often composed of proteins, but polysaccharides, complex lipids, and nucleic acids also can act as antigenic materials; bacteria, viruses, fungi, parasites, and foreign tissue are all antigens. For instance, transplant rejection occurs when the body recognizes transplanted tissues or organs as foreign. Discrete, immunologically active sites on antigens enable immunoglobulins, lymphocytes, or antibodies to identify target cells, against which destructive forces are directed. Immune responses are not equally potent. The intensity of the system's response is affected by the route of invasion, the dosage of the antigen, and the antigen's degree of foreignness.

Immunological competence refers to the immune system's capacity to identify and reject foreign materials. The system's failure to recognize antigens and mobilize effective defenses results in infection or malignancy. Failure to recognize markers of self can result in autoimmune diseases, such as multiple sclerosis, rheumatoid arthritis, or systemic lupus erythematosus. The system's "battle against imaginary enemies," such as pollen or dust, may result in allergies.

The major histocompatibility complex, essential for recognizing self from nonself, is a group of genes contained in a section of chromosome 6 that encode molecules that mark a cell as self. These genes vary widely in structure from one person to another. Their presence is a major factor in transplant rejection because they determine to which antigens one responds and how strongly. They also allow immune cells to recognize and communicate with one another.

Innate Immunity

Innate immunity is present in all healthy people and forms the first line of defense against illness. Previous exposure to an organism or toxin is not required for activation. Also, mechanisms of innate immunity do not distinguish among microorganisms of different species and do not alter in intensity on re-exposure. Innate immune defenses include physical, chemical, and mechanical barriers; biological defenses; phagocytosis; inflammatory processes; and cytokines, dendritic cells, macrophages and neutrophils.

Physical, Chemical, and Mechanical Barriers

Physical barriers prevent harmful organisms and other substances from gaining entrance into the body or body cavities. These barriers include skin, mucous membranes, the epiglottis, respiratory tract cilia, and sphincters. Chemical barriers such as antibacterial agents, antibodies, and acid solutions create an environment hostile to many pathogens. Lysozymes in tears, lactic acid in vaginal secretions, and hydrochloric acid in gastric secretions all act as chemical barriers. Mechanical barriers help rid the body of potentially harmful substances through some action (eg, lacrimation, intestinal peristalsis, urinary flow).

Biological Defenses

Under normal conditions, large areas of the human body are colonized with microorganisms of low pathogenicity. The skin and mucous membranes of the oropharynx, nasopharynx, intestinal tract, and parts of the genital tract each have their own microflora, referred to as normal flora. These microorganisms influence patterns of colonization by competing with more harmful organisms for essential nutrients and by producing substances that inhibit the growth of other microorganisms. Vitamin D deficiency may increase the risk of infection in epithelial tissues that directly interact with the environment,[5,6] thereby reducing the effectiveness of biological defenses.

Phagocytes and Phagocytosis

Phagocytosis is a process by which injured cells and foreign invaders are ingested by leukocytes, specifically, neutrophils and mononuclear phagocytes (monocytes and macrophages). Both cell types originate from stem cells in the bone marrow and, although structurally different, approach phagocytosis in a similar manner.

Surface receptors on their cell membranes allow them to attach to foreign substances and then engulf, internalize, and destroy these substances using enzymes present in their cellular interior. Both neutrophils and macrophages are attracted to the site of microorganism invasion by chemokines. Neutrophils provide the "first-wave" cellular attack on invading organisms during the acute inflammatory process. The number of neutrophils at the site peaks in 6 to 12 hours after inflammation begins. The second wave of cells is primarily monocytes. Monocytes spend only a short time in the bloodstream before escaping through the capillary membranes into the tissue. Once in the tissue, they swell to much larger sizes to become macrophages, which either attach to certain tissues and destroy bacteria, or wander through the tissue phagocytizing foreign matter. These cells are strategically placed throughout the body tissues, where they can exist for months and even years. Macrophages in different tissues differ in appearance because of environmental variations and are known by different names (ie, Kupffer's cells in the liver, alveolar macrophages in the lungs, histiocytes in the skin and subcutaneous tissue, and microglia in the brain).

Inflammatory Responses

Inflammation is an acute physiological nonspecific response of the body to tissue injury caused by factors such as chemicals, heat, trauma, or microbial invasion. It is the primary process through which the body repairs tissue damage and defends itself against infection. The initial inflammatory response is localized but may lead to systemic consequences such as fever, malaise, and neutrophilia. The inflammatory response contains three stages:

1. The vascular stage involves an immediate but short-term vasoconstriction, followed by vasodilation of arterioles and venules and hyperemia and swelling resulting from

the secretion of histamine, prostaglandins, serotonin, and kinins.
2. The cellular exudate stage is characterized by neutrophilia, secretion of colony-stimulating factors into the interstitial fluid, and formation of exudate, a clear serous fluid with a high protein count. The functions of exudate are to transport leukocytes and antibodies to the inflammatory site, dilute toxins and irritating substances, and transport materials necessary for tissue repair. As the inflammatory process continues, the serous exudate changes to a creamy white fluid containing cellular debris.
3. The tissue repair and replacement stage, in which inflammatory material is removed and connective tissue cells proliferate. Collagen synthesis occurs, resulting in tissue replacement.

The most important result of these processes is accumulation at the site of injury of large numbers of neutrophils and macrophages, which inactivate or destroy invaders, remove debris, and begin the initial tissue repair.

Cytokines

Cytokines are chemical messengers produced by T lymphocytes that function as immune system hormones and play a role in adaptive immunity and in mediating the inflammatory response. They enhance cell growth, promote cell activation, direct cellular traffic, stimulate macrophage function, and destroy antigens. They are also called interleukins (ILs) because they serve as messengers between leukocytes. Interferons and tumor necrosis factor are also cytokines.

IL-1 augments the synthesis of IL-2, IL-3, IL-4, interferon-γ, and IL-2 receptors. It can also activate lymphokine-activated killer cells. IL-2 binds to specific receptors on activated T cells and markedly enhances the cytolytic activity of NKCs, which are a specialized group of lymphoid cells that act directly, without prior sensitization, to lyse a variety of malignant and virus-infected cells. IL-3 and B-cell differentiation factor provide critical signals for the growth and maturation of antigen-primed B cells.

Cytokines can be classified as either lymphokines (secreted by lymphocytes) or monokines (secreted by monocytes or macrophages). Interferons (a type of lymphokine) provide some protection to the body against invasion by viruses until more slowly reacting specific immune responses take over. Interferons are produced when a virus infects a host cell; they affect the transcription and translation of viral genes. In addition, interferons appear to be involved in protecting the body against some forms of cancer. Specifically, these substances have been demonstrated to interfere with cellular division and proliferation of abnormal cells. They also enhance the activity of NKCs.

Adaptive Immunity

If a foreign agent persists despite innate immune responses, the activation of adaptive immune responses occurs. To be most effective, these responses require previous exposure to a foreign agent or organism. The cellular components of these types of responses are capable of distinguishing among microorganisms and can alter their intensity and response time significantly on re-exposure.

Two types of adaptive immune responses have been identified: cell-mediated immunity and humoral immunity. Most foreign substances stimulate both cellular and humoral immune responses; this results in an overlapping of their reactions and maximal protection against damage from the invading substances.

B and T Lymphocytes

B and T lymphocytes originate from stem cells produced in the bone marrow. During fetal development and shortly after birth, primary lymphoid organs are the sites where these cells differentiate and mature into the competent cells responsible for cell-mediated and humoral immune responses. For B lymphocytes, this preprocessing is believed to occur in the bone marrow and, possibly, the fetal liver; for T lymphocytes, it occurs in the thymus gland.

As they develop, both B and T lymphocytes acquire receptors for specific antigens that commit them to a single antigenic specificity for their lifetime. Subsequently, each of these "preprogrammed" B or T lymphocytes (on activation by its specific antigen) is capable of producing tremendous numbers of clones or duplicate lymphocytes. The different types of T cells produced are categorized according to their function, as shown in Table 45-3.

Table 45-3 Types of T Cells and Their Functions

Cell Type	Function
Cytotoxic T cells (T8)	Direct-attack cells capable of killing many microorganisms; predominant effector cell Virus-infected cells, cancer cells, and transplanted cells especially susceptible
Helper-inducer T cells (T4)	Most numerous Play pivotal role in overall regulation of immune response Often called "master conductor" Secrete lymphokines
Suppressor T cells (T8)	Act as negative feedback controllers of T4 cells May also limit ability of immune system to attack body tissues
Memory T cells	Sensitized to antigens during specific immune responses Remain stored in body Capable of initiating far more rapid response by T cells on re-exposure to same antigen

Lymphoid System

After preprocessing in the primary lymphoid organs, B and T lymphocytes migrate to secondary lymphoid tissues, where the interaction with antigens and immune responses actually occurs. Secondary lymphatic tissue is located extensively in the lymph nodes. It is also found in special lymphoid tissue, such as that of the spleen, tonsils, adenoids, appendix, bone marrow, and gastrointestinal tract. This lymphoid tissue is placed advantageously throughout the body to intercept invading organisms or toxins before they can enter the bloodstream and disseminate widely.

Cell-Mediated Immune Response

Cell-mediated immunity provides a response to fungi, parasites, and intracellular bacteria. It also plays a major role in the rejection or acceptance of certain tissue grafts, the stimulation and regulation of antibody production, and defense against various malignant changes. As noted, T lymphocytes contain an antigen receptor that allows for the binding of a specific type of antigen.

Each T cell, when activated by its specific antigen, is capable of producing large numbers of clones. After preprocessing, T cells migrate to lymphoid tissue, where they act as effector cells (directly attacking antigens and malignant cells) and regulators of both the cellular and humoral immune response.

Antigenic stimulation of T lymphocytes initiates the cell-mediated response. This step of the response may be mediated by macrophages that bind to the antigen, facilitating its recognition. The macrophages then produce cytokines, which stimulate T lymphocytes, increase B-lymphocyte proliferation, and activate phagocytes. People with impaired cell-mediated immunity are at high risk for infections with pathogens that replicate within cells such as viruses or parasites.[3]

Humoral Immune Response

The humoral immune response is extracellular; that is, it occurs in blood and tissue fluid. It begins in response to most bacteria, bacterial toxins, and the extracellular phase of viral invasion. Humoral immunity involves two types of serum proteins: immunoglobulins (Igs) and complement. Vitamin D can decrease immunoglobulin production and slows differentiation of B-cell precursors into plasma cells.[5]

Igs are antibody molecules made by B lymphocytes that differentiate to plasma cells and memory cells. The plasma cells then secrete antibodies that bind to antigens; the resulting antigen–antibody complexes are ingested by phagocytes. After the complexes are eliminated, the memory cells remain in circulation and in lymphoid tissue to mature into plasma cells when the antigen is encountered again. Immunoglobulins are specific to antigens and are of several types:

- IgA (two types) concentrates in body fluids, such as tears, saliva, and secretions of respiratory and gastrointestinal tracts; it guards entrances to the body.
- IgM tends to remain in the bloodstream, where it is effective in killing bacteria.
- IgG (four types) is able to enter tissue spaces and works efficiently to coat microorganisms before phagocytosis occurs.
- IgD is found mostly in the membrane of B cells, where it is believed to regulate the cells' activation.
- IgE is normally present in only trace amounts; it is responsible for symptoms of allergy by activating mast cells.

Complement is a nonspecific series of 15 proteins that circulate in an inactive form in the bloodstream. These proteins activate one another in a cascading sequence when the first complement molecule C1 encounters an antigen–antibody complex. The end product of the cascade is a cylinder that lyses the cell membrane of the target cell, allowing fluids and molecules to flow in and out, which kills the target cell.

Complement can be activated in three ways. Classic activation is initiated by the antibody–antigen complex. The alternate pathway and lectin pathways are not initiated by antibodies but start in response to bacteria, fungi, and mannose found on the surfaces of some bacteria (Fig. 45-4).[2] In addition, complement facilitates the interaction of antigens and antibodies and enhances all aspects of the inflammatory process, especially increasing vascular permeability and phagocytosis.

Combined Immune Responses

The specific immune response is complex and involves the interaction of macrophages, complement proteins, and the cellular components of both the cellular and humoral systems (Fig. 45-5). Macrophages initially function to recognize, process, and present the antigen to antigen-specific T lymphocytes in the lymphoid tissues. Helper–inducer T4 cells are subsequently activated with the help of a chemical factor (IL-1) released by the presenting macrophage. The T4 cells proliferate and produce their own chemical substances, known as lymphokines, which in turn stimulate the activation and proliferation of antibody-producing B lymphocytes, cytotoxic T cells, suppressor T cells, and phagocytic macrophages. The production of antibodies leads to the activation of complement proteins. All these components work together to destroy the antigen, either through complex processes involving direct attack or through modulation by chemical processes. Suppressor T cells provide feedback to the T4 helper cells to halt these defense reactions when they are no longer needed, and memory cells reactivate them on re-exposure to the antigen.

Impaired Host Resistance

The various components of the immune system provide a complex network of mechanisms that, when intact, defend the body against foreign microorganisms and malignant cells. However, in some situations, components of the system can fail, resulting in impaired host resistance. Often the state of immunosuppression is chemically induced by drugs or medications, such as corticosteroids and cytotoxic chemotherapeutic agents. People who acquire an infection because of a deficiency in any of their host defenses are referred to as immunocompromised, or immunosuppressed.

The exact effects of, and symptoms related to, defects in host defense vary according to the part of the immune system affected (Table 45-4). General features associated with compromised host resistance include recurrent infections, infections caused by usually harmless agents (opportunistic organisms), chronic infections, skin rashes, diarrhea, growth impairment, and increased susceptibility to certain cancers.

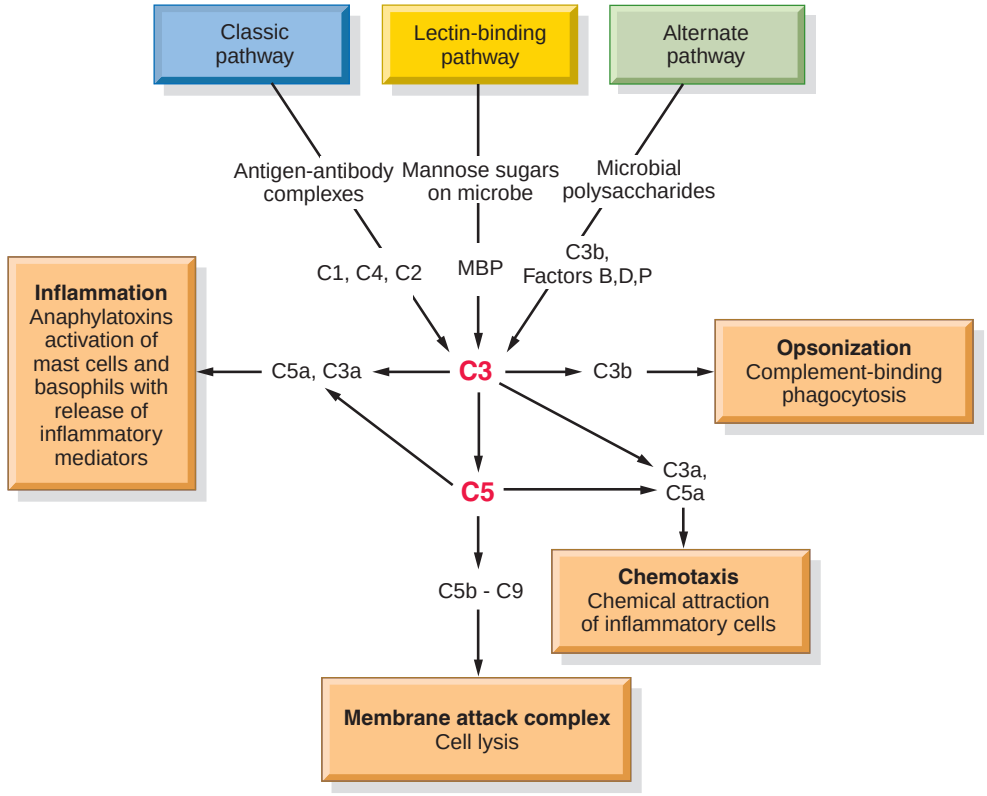

FIGURE 45-4 ▲ Classic, lectin, and alternative complement pathways. (From Porth CM: Pathophysiology: Concepts of Altered Health States, 7th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2005, p 381.)

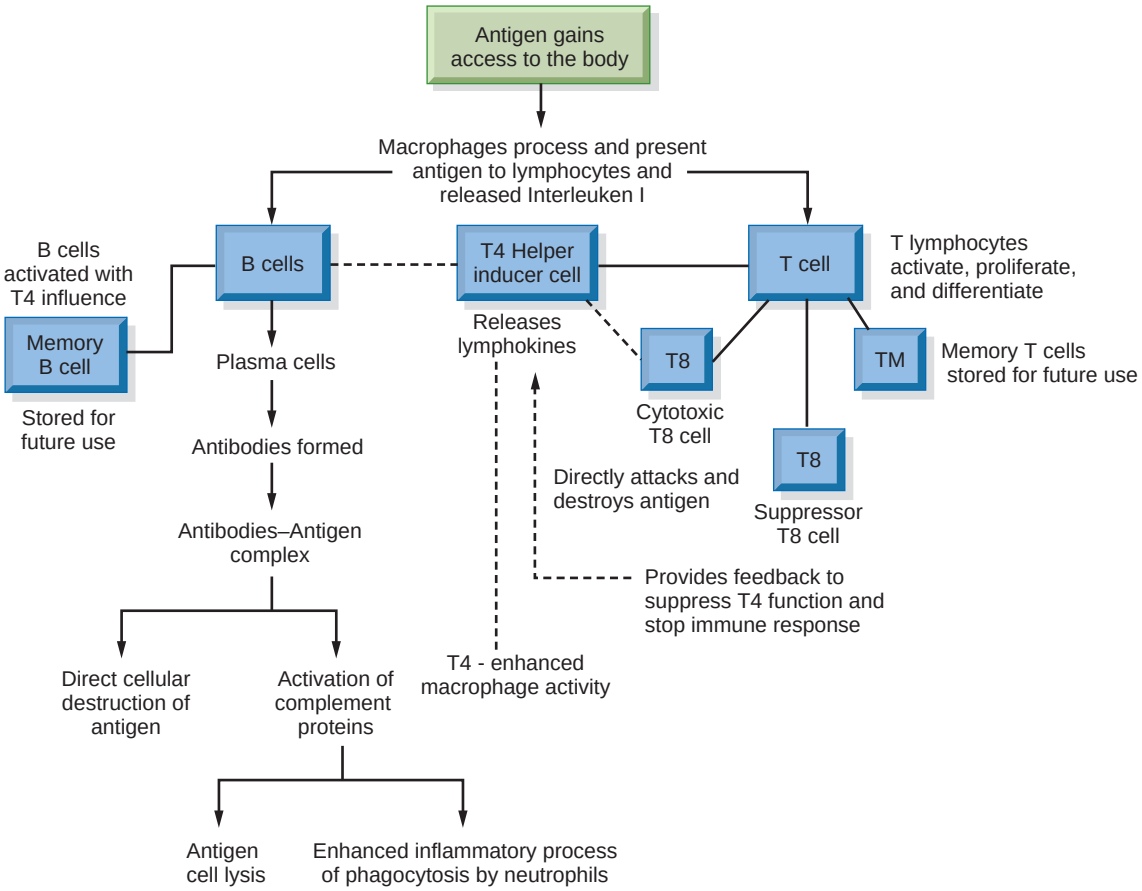

FIGURE 45-5 ▲ A schematic representation of the combined immune responses.

Table 45-4 Risk Factors for Compromised Host Defenses

Host Defect	Diseases, Therapies, and Other Conditions Associated With Host Defects
Impaired phagocyte functioning	Radiation therapy Nutritional deficiencies Diabetes mellitus Acute leukemias Corticosteroids Cytotoxic chemotherapeutic drugs Aplastic anemia Congenital hematological disorders Alcoholism
Complement system deficiencies	Liver disease Systemic lupus erythematosus Sickle cell anemia Splenectomy Congenital deficiencies
Impaired cell-mediated (T lymphocyte) immune response	Radiation therapy Nutritional deficiencies Aging Thymic aplasia AIDS Hodgkin's disease/lymphomas Corticosteroids Antilymphocyte globulin Congenital thymic dysfunctions
Impaired humoral (antibody) immunity	Chronic lymphocytic leukemia Multiple myeloma Congenital hypogammaglobulinemia Protein-losing enteropathies (inflammatory bowel disease)
Interruption of physical/mechanical/ chemical barriers	Traumatic injury Decubitus ulcers/skin defect Invasive medical procedures Vascular disease Skin diseases Nutritional impairments Burns Respiratory intubation Mechanical obstruction of body drainage systems, such as lacrimal and urinary systems Decreased level of consciousness
Impaired mononuclear phagocyte system	Liver disease Splenectomy

▲ Clinical Applicability Challenges

SHORT ANSWER QUESTIONS

1. Individuals have been encouraged to use sunblock to reduce the risk of skin cancer. Discuss the effects on the immune system.
2. A patient is receiving anticoagulant medication. What is the effect on the coagulation inhibitors?
3. Explain the mechanism that causes a blunted white blood cell response in individuals with a viral infection.

46 Patient Assessment: Hematological and Immune Systems

Kenneth Rempher and Patricia Gonce Morton

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Describe areas of a patient's history and physical assessment pertinent to assessing hematological and immune disorders.
2. Differentiate diagnostic tests used to assess hematological and immune disorders.
3. Synthesize the results of a patient's history, physical examination, and diagnostic tests to identify hematological and immune disorders.
4. Describe key aspects of the assessment of the immunocompromised patient.

Hematological and immune disorders encompass numerous ailments, many of which are life threatening. In general, hematological disorders can be classified as overproduction or underproduction of hematological components or dysfunction of these components. Immune disorders usually are caused by underactivity or overactivity of immune system elements. Immune disorders can be inherited, or they can be acquired through disease or treatments, such as chemotherapy and transplant immunosuppression. The hematological and immune systems are complex and closely interrelated; therefore, disorders or dysfunctions of one system often alter the effectiveness of the other.

▲ Assessment

History

The patient history is essential when evaluating potential hematological or immune disorders. While discussing the chief complaint, a patient may state symptoms that seem vague and unrelated, so a detailed history is critical. It is important to keep in mind the complex physiology of these systems when assessing a patient's health history (see Chapter 45). After obtaining information about the chief complaint and history of the present illness, the nurse inquires about the patient's past health history, family history, and personal and social history (Box 46-1). The patient's immunization history and occupation may provide helpful clues. A review of relevant systems concludes the history. Table 46-1 summarizes conditions and treatments that may predispose patients to hematological and immune disorders (see Chapters 48 and 49). Box 46-2 summarizes special considerations for older patients.

Physical Examination

A thorough physical examination is necessary to identify physical signs that may indicate a hematological or immune system disorder. Table 46-2 on page 1037 summarizes physical findings that may suggest various disorders of these systems. (Many of these disorders are further described in Chapter 49.) The physical examination of the hematologically or immunocompromised patient focuses on four major areas: skin, liver, spleen, and lymph nodes. The entire examination must be thorough to help identify the exact source of the problem. The nurse examines the patient's skin for pallor or jaundice as well as for signs of abnormal bleeding. He or she also evaluates the patient's joints for pain, swelling, and limited range of motion, which may suggest hemarthrosis from coagulopathy or sickle cell anemia. Superficial mucocutaneous bleeding and a dependent distribution of petechiae can indicate thrombocytopenia, whereas clusters of palpable, pruritic petechiae can suggest vasculitis. Extensive superficial purpura, deep hematomas, or hemarthroses may indicate a coagulation disorder. The nurse also notes skin rashes, pruritus, and excoriations. It is necessary to assess the extremities for areas of redness, tenderness, warmth, or swelling, which can indicate thrombophlebitis. Leg and ankle ulcers may be present in patients with sickle cell anemia. The nurse assesses the lips and nail beds for cyanosis; digital clubbing may be present in patients with chronic hypoxemia. For more information on assessment of nails, see Chapter 51.

The nurse also examines the patient's eyes and mouth. Visual changes can indicate hyperviscosity from polycythemia or retinal infarcts from sickle cell anemia. It is important to assess the nares, gums, and mucous membranes of the mouth for signs of bleeding. The oral examination is a good time to ask about bleeding gums while brushing. Pallor of the oral mucosa can be a significant indicator of anemia. Tongue changes can occur in

BOX 46-1 HEALTH HISTORY for Hematological and Immune Assessment

Chief Complaint
- Patient's description of the problem

History of the Present Illness
- Complete analysis of the following signs and symptoms (using the NOPQRST format; see Box 17-1, p. 207)
- Unusual bruising or bleeding, frequent infections, fatigue/malaise, headache, dizziness/gait disturbance, pain, enlarged lymph nodes, fevers, night sweats, weakness, limb pain/limp, seizure, weight loss, abdominal pain, vomiting, heat intolerance, poor wound healing, nevi

Past Health History
- Relevant childhood illnesses and immunizations—mononucleosis, malabsorption, hepatitis, pernicious anemia
- Past acute and chronic medical problems, including treatments and hospitalizations—anemia, cancer, infections, autoimmune hemolytic anemia/Evans syndrome, hemochromatosis, hereditary spherocytosis, iron deficiency anemia, polycythemia, hemophilia, sickle cell disease, thalassemia, idiopathic thrombocytopenia, glucose-6-phosphate dehydrogenase (G6PD) deficiency, aplastic anemia, myelodysplastic syndrome, cirrhosis, HIV, major trauma, sepsis
- Risk factors—recent exposure to benzenes, pesticides, mustard gas, antineoplastic agents
- Past surgeries—splenectomy, cardiothoracic surgery, total gastrectomy
- Past diagnostic tests and interventions—bone marrow aspiration, radiation therapy, chemotherapy, multiple blood transfusions, administration of blood products (cryoprecipitate)
- Medications—chemotherapeutic agents, antibiotics, antihypertensives, diuretics, glucocorticoids, nonsteroidal anti-inflammatory drugs, aspirin, heparin, warfarin, antiplatelet agents
- Allergies and reactions
- Transfusions

Family History
- Health status or cause of death of parents and siblings—cancer, anemia, hereditary spherocytosis, G6PD deficiency, sickle cell anemia, methemoglobinemia, thalassemia, Glanzmann's thrombasthenia, von Willebrand's disease, polycythemia

Personal and Social History
- Tobacco, alcohol, and substance use
- Family composition
- Occupation and work environment—exposure to chemicals: benzenes, mustard gas, cigarette smoke, butadiene, dioxins (pesticides), hexachlorobenzene, ozone, polybrominated biphenyls, polychlorinated biphenyls, phenols, toluene-di-isocyanate vinyl chloride, lead, naphthalene
- Living environment; see above
- Diet (insufficient intake of foods rich in iron and folic acid, including liver, eggs, whole grains, breads, cereals, potatoes, leafy green vegetables, fruits, and legumes). Assess for poor intake of foods rich in vitamin B_{12}, including liver, fish, and fortified cereals.
- Sleep patterns—disruptive sleep patterns modulate changes in immune system activity[1]
- Exercise—regular exercise is associated with optimizing immunity[2]
- Cultural beliefs
- Spiritual or religious beliefs—refusal of blood products, including transfusions is a core belief for some patients, including some Jehovah's Witnesses[3]
- Coping patterns and social support systems
- Leisure activities
- Sexual activity
- Recent travel

Review of Systems
- HEENT: oral infections, gum bleeding, epistaxis, mouth sores, sore throat, smooth tongue texture, jaundiced sclera, conjunctival pallor, retinal hemorrhages
- Cardiac: tachycardia, S_4 sounds
- Respiratory: recent upper or lower respiratory infections, hemoptysis
- Gastrointestinal: blood in emesis, blood in stools, dark tarry stools, unintentional weight loss, splenomegaly, hepatomegaly, splenic bruits, and rubs
- Musculoskeletal: weakness, bone pain, back pain, arthralgia
- Neurological: mental status changes, pain to touch, position and vibratory sensation, tendon reflexes
- Genitourinary: blood in urine, urinary tract infections
- Reproductive: heavy menstruation, vaginal bleeding

patients with an iron deficiency and megaloblastic anemias. Inspection of the throat and palpation of lymph nodes to assess for infection or malignancy is warranted. Figure 46-1 shows palpation of the lymph nodes in the neck.

Tachycardia and tachypnea may be present in patients with anemia or infection. An S_4 heart sound may be heard in persons with severe anemia. Dyspnea on exertion and orthostatic changes in blood pressure can be other symptoms of anemia and not just volume insufficiency. Many patients present with new-onset chest pain made worse by anemia. As the body loses oxygen carrying capacity resulting from loss of hemoglobin, the myocardium becomes stressed and can trigger angina. It is necessary to perform thorough lung auscultation and inspection of sputum, if present, to rule out respiratory infection and hemoptysis. Symptoms of intermittent claudication (see Chapter 19) and angina pectoris (see Chapter 21) indicate problems with oxygen delivery in patients with polycythemia. Polycythemia is an unusual myeloproliferative disease in which there is excessive production of erythrocytes. The increased number of erythrocytes results in increased blood volume, increased viscosity of blood, and clogging of microcirculatory blood vessels, which leads to decreased tissue perfusion. Subsequently, patients with polycythemia commonly experience hypertension as part of the sympathetic response to decreased tissue perfusion.

Pertinent physical assessment findings of the abdominal and pelvic region include lymphadenopathy, splenomegaly, and hepatomegaly, which can indicate a number of hematological or immune conditions. Figure 46-2 shows the technique for palpating the spleen in the supine and side-lying positions. Figure 46-3 on page 1039 shows the degrees of splenomegaly. The nurse also thoroughly assesses for urinary tract infections, vaginal infections (including those with

Table 46-1 Hematological and Immune Disorders Based on Patient History

Patient History	Potential Disorder
Chronic disease (inflammation, infection)	Anemia
Nutritional deficiencies (iron, folate, vitamin B_{12})	Anemia
Nutritional deficiencies (vitamin K, malabsorption)	Coagulopathy
Endocrine (thyroid, pituitary) dysfunction	Anemia
Hypersplenism	Anemia, thrombocytopenia
Acquired immunodeficiency syndrome	Anemia, neutropenia
Malignancy	Pancytopenia
Chemical exposure	Neutropenia, hemolytic anemia
Prosthetic heart valve or vascular graft	Hemolytic anemia
Collagen vascular disorder	TTP
Hypersensitivity reaction	TTP
Viral, bacterial, or fungal infection	TTP
Uremia	Coagulopathy
Chronic alcoholism	Coagulopathy
Liver disease	Coagulopathy, thrombosis
Vasculitis	Thrombosis
Atherosclerosis	Thrombosis
Chronic obstructive pulmonary disease	Polycythemia
Smoking	Polycythemia
Congenital cardiac disease	Polycythemia
Previous Therapies/Medications	
Heparin	Thrombocytopenia
Antibiotics	Agranulocytosis
Carbamazepine	Agranulocytosis
Alkylating agents	Leukemia, lymphoma, pancytopenia
Blood transfusion	Anemia
Aspirin, nonsteroidal anti-inflammatory drugs	Coagulopathy
Warfarin	Coagulopathy
Steroids	Leukocytosis
Various drugs, chemicals, and toxins (see Box 49-1, p. 1135)	Hemolytic anemia
Family History	
Sickle cell anemia	Anemia
Thalassemia	Anemia
Congenital hemolytic anemia	Anemia
Polycythemic disorders	Polycythemia vera
von Willebrand's disease	Bleeding disorder
Hemophilia	Bleeding disorder

TTP, thrombotic thrombocytopenic purpura.

yeast), and perirectal inflammation. In addition, the nurse checks all body secretions and fluids (stool, urine, emesis, or gastric secretions) for the presence of blood.

Neurological abnormalities may be present in patients with hematological conditions. Altered mental status, paresis, aphasia, dysphasia, coma, seizures, paresthesia, and visual problems may be caused by thrombotic thrombocytopenic purpura (TTP; see Chapter 49). An altered level of consciousness, papilledema, vomiting, and bradycardia with widening pulse pressure are signs of increased intracranial pressure, which may be caused by intracranial bleeding in patients with coagulopathy.

BOX 46-2 CONSIDERATIONS FOR THE OLDER PATIENT

Risk Factors for Hematological Disorders

- Decreased iron intake, resulting from poor dentition (difficulty chewing meat) or a fixed income (making sources of iron such as meat or supplements unaffordable), can place the older adult at risk for iron deficiency anemia. Older adults may also experience low-grade gastrointestinal bleeding as a result of nonsteroidal antiinflammatory drug use for the treatment of arthritis, from hemorrhoids and polyps, or from undiagnosed colon cancer. This blood loss may also place them at risk for iron deficiency anemia.
- Poor absorption of vitamin B_{12} (as a result of atrophic gastritis) places the older adult at risk for megaloblastic anemia.
- Declining immune function places the older adult at risk for leukemia, lymphoma, and multiple myeloma.
- Anticoagulation therapy (eg, to treat atrial fibrillation) can result in platelet dysfunction and places the older adult at risk for hemorrhage. This is a particularly significant risk in older adults who are disoriented or have decreased mobility.

▲ Diagnostic Studies and Results Interpretation

Laboratory test results are usually the most sensitive and specific determinants of hematological and immune problems. Specialized testing may be required to ascertain whether the components are functioning properly. Because patients with severe presentations of hematological and immune conditions may be seen in the intensive care unit (ICU), tests to differentiate the conditions and their causes are presented here.

Tests to Evaluate Red Blood Cells

Red blood cells (RBCs) are essential for oxygenating tissues. An overproduction of RBCs results in polycythemia, which is indicated by a high hematocrit level and an increased RBC mass (see Chapter 49). Anemia is a condition marked by a decrease in the RBC mass caused by decreased production of RBCs, increased RBC destruction, a combination of these two conditions, or acute blood loss. All patients being evaluated for anemia should have a complete blood count (CBC) with RBC indices, a reticulocyte count, iron studies, and a peripheral smear analysis. Abnormalities in these test results indicate the need for subsequent testing.

Table 46-2 Findings Indicating Possible Hematological or Immune Disorders

Physical Findings*	Related Information From Patient History	Possible Disorder
Pallor, dyspnea, dizziness, tachycardia, glossitis	Fatigue Headache Pica (compulsive craving for clay, laundry starch, earth, or ice)	Iron deficiency anemia
As above, also smooth tongue, stomatitis, icterus, paresthesias, gait ataxia, mental status changes	Fatigue Headache Premature graying of hair	Megaloblastic anemia
Bleeding (ecchymosis, petechiae, epistaxis, hemorrhage), pallor, dizziness, tachycardia	Fatigue Headache History of frequent infections (eg, upper respiratory, cellulitis, perirectal) Previous viral infection (hepatitis, infectious mononucleosis, HIV, cytomegalovirus) Family history of aplastic anemia	Aplastic anemia
Pallor of conjunctiva, mucous membranes, palms and soles of feet; dyspnea; dizziness; tachy- cardia; bone pain; pain in chest or abdomen; splenomegaly; fever; leg and ankle ulcers; painless hematuria	African American descent Family history of sickle cell anemia Frequent infections Impaired vision Damage to joints Chronic renal failure History of stroke	Sickle cell anemia
Pallor, dyspnea, dizziness, jaundice, splenomegaly, cholelithiasis	Mediterranean descent, also Middle Eastern, South and Southeast Asian, and African	Thalassemia
Splenomegaly, hepatomegaly, facial and conjunctival plethora, hypertension, pruritus, dizziness, headache, thrombosis, thrombophlebitis	Visual disturbances Epigastric distress Cardiovascular insufficiency Bleeding tendency Numbness and burning of toes (from peripheral vascular insufficiency)	Polycythemia
Mouth sores, sore throat, lymphadenopathy, splenomegaly, hepatomegaly, infection (signs of infection may be minimal)	History of recurrent, severe infections Fatigue Recent radiation or chemotherapy treatment	Leukopenia
Infection, bleeding, bone pain, splenomegaly, skin and gum lesions, leukostasis if WBC count is extremely high (headache, confusion, Central nervous system infarctions, acute respiratory insufficiency, pulmonary infarctions)	History of recurrent infections Fatigue Anorexia Weight loss	Acute or chronic leukemia
Bone pain, pallor, weakness, fatigue	History of recurrent infections Renal insufficiency Hypercalcemia (thirst, lethargy, confusion, polyuria, constipation)	Multiple myeloma
Weight loss, fever, night sweats, painless lymphadenopathy, splenomegaly, abdominal pain	Fatigue Anorexia History of infections	Hodgkin's disease or non-Hodgkin's lymphoma
Superficial mucocutaneous bleeding, petechiae on dependent areas of the body, epistaxis, hemoptysis, hematemesis, hematuria, rectal bleeding, vaginal bleeding, intra-abdominal hemorrhage (diffuse abdominal pain, restlessness, anxiety, pallor, rigidity, dusky coloration of abdominal skin, tachycardia, tachypnea, and hypotension), intracranial bleeding (headache, vomiting, decreasing level of consciousness, papilledema, bradycardia)	History of viral or bacterial infection Hypersplenism Malignancies affecting the bone marrow History of immune disorders Alcoholism Pregnancy	Thrombocytopenia

(continued on page 1038)

Table 46-2 Findings Indicating Possible Hematological or Immune Disorders (continued)

Physical Findings*	Related Information From Patient History	Possible Disorder
Confusion, headache, altered mental status, paresis, aphasia, dysphagia, coma, seizures	Paresthesias Visual disturbances	TTP
Superficial purpura, mucocutaneous bleeding, hemorrhage, joint pain and swelling (from bleeding into joints), deep hematomas	History of excessive or recurrent bleeding in patient or family members Alcoholism Hepatitis Liver disease Malnutrition Malabsorption syndromes (affects absorption of vitamin K from gastrointestinal tract)	Coagulation disorder

TTP, thrombotic thrombocytopenic purpura; WBC, white blood cell.

*Findings listed may not always be present.

Complete Blood Count

The CBC provides an overall indication of bone marrow production of RBCs, white blood cells (WBCs), and platelets. It also indicates the patient's hemoglobin level, hematocrit value, RBC indices, and WBC differential. (See Chapter 17, Table 17-2 for normal hemoglobin and hematocrit values.) Patients usually extract about 25% of the oxygen from saturated hemoglobin. An increase in oxygen extraction can occur in patients with extreme anemia. As the patient's extraction increases, so does his or her oxygen debt and shock state. Anemia from any cause is a major determinant in tissue hypoxia.

Red Blood Cell Indices

RBC indices are laboratory values that describe RBC structure or function. Table 46-3 presents RBC indices and some of the conditions that can cause abnormal laboratory results.

Peripheral Smear

The peripheral smear can indicate disorders of the structure of RBCs. Table 46-4 lists various abnormalities detected by examining the peripheral smear, along with further testing that may be appropriate.

Mature RBCs do not contain a nucleus. Nucleated RBCs mature in the bone marrow and are not normally present in peripheral blood. They appear in the peripheral smear after profound stimulation, such as that from acute hemorrhage, hypoxemia, hemolytic anemia, or megaloblastic anemia. If these causes are ruled out, the appearance of nucleated RBCs may be caused by infiltrative processes in the bone marrow from malignancy, myelofibrosis, or granuloma. Nucleated RBCs may also be seen in asplenic patients because the spleen normally recognizes and removes these abnormal cells.

Spherocytes and elliptocytes are abnormally shaped RBCs. They usually appear in patients with a hereditary disorder that causes RBC membrane defects. These irregular cells are trapped and destroyed in the spleen, causing hemolytic anemia. Testing for RBC osmotic fragility demonstrates that these cells are more likely to lyse than normal RBCs. Serum lactate dehydrogenase and serum bilirubin levels should be ordered if hemolysis is suspected.

The presence of Rouleaux formations (the RBCs on the peripheral smear resemble a stack of coins) can indicate multiple myeloma.[1] If clinical findings support this suspicion, serum protein electrophoresis and urine analysis for Bence Jones protein are the next steps in determining a diagnosis.

Target cells, sickled cells, and RBC cytoplasmic inclusions on the peripheral smear suggest the need for hemoglobin electrophoresis and analysis of hemoglobin F and A_2 levels. The most common anemias diagnosed in this manner are β-thalassemia and sickle cell anemia.

The presence of schistocytes in a patient with a prosthetic heart valve may indicate mechanical hemolysis. Schistocytes in a patient with fever, thrombocytopenia, renal dysfunction, and neurological abnormalities require immediate interventions for suspected TTP (see Chapter 49).

Tests to Evaluate White Blood Cells

Because WBCs detect and destroy pathogens, an elevated WBC count usually indicates infection and tends to correlate with the severity of the infection.

Table 46-3 Red Blood Cell Indices: Laboratory Abnormalities

Test	Normal Value	Significance	Possible Causes for Abnormal Results
Mean corpuscular volume	82–98 m^3	Indicates the average volume of a red blood cell (RBC) in the blood sample. Low value indicates RBCs are smaller than normal (microcytic). High value indicates RBCs are larger than normal (macrocytic).	Decreased: Anemia (iron deficiency, sickle cell, hemolytic), α- or β-thalassemia, chronic disease, radiation therapy, endocarditis, diverticulitis, warm autoantibodies Increased: Alcoholism, cirrhosis, folate deficiency, vitamin B_{12} deficiency, pancreatitis, chronic lymphocytic leukemia, aplastic anemia
Mean corpuscular hemoglobin	26–34 pg	Indicates the average weight of hemoglobin in each RBC.	Decreased: Anemia (iron deficiency, microcytic, normocytic) Increased: Anemia (macrocytic, pernicious), cold agglutinin conditions, presence of monoclonal blood proteins, heparin sodium, heparin calcium
Mean corpuscular hemoglobin concentration	31%–38%	Indicates the amount of hemoglobin in the RBC compared with its size. Results expressed as hypochromic or normochromic, referring to the concentration of hemoglobin and color of RBCs.	Decreased: Anemia (iron deficiency, chronic, megaloblastic, microcytic, sideroblastic) Increased: Cold agglutinins, hereditary spherocytosis, intravascular hemolysis, heparin calcium, heparin sodium
Red cell distribution width	13.4%–14.6%	Measures the amount of homogeneity in the RBC width in the blood sample. Much variation in RBC width indicates the red cell distribution width is elevated. RBCs of similar size indicates red cell distribution width is low.	Decreased: Defects in iron reutilization Increased: Iron deficiency states
Reticulocyte count	1%–2%	Indicates the amount of immature RBCs that have been recently released from the bone marrow, expressed as a percentage of the total RBCs. Low reticulocyte count in presence of decreased RBCs indicates possible bone marrow dysfunction.	Decreased: Alcoholism, anemia (aplastic, iron deficiency, megaloblastic, pernicious), chronic infection, myxedema, radiation therapy Increased: Hemolytic anemia, hemorrhage, leukemia, malaria, polycythemia, pregnancy, sickle cell anemia, thalassemia, TTP
Serum iron	Adult men 50–160 mcg/dL Adult women 40–150 mcg/dL	Indicates the amount of iron in the serum. Low serum iron needs to be correlated with other testing (ie, ferritin, transferrin, and total iron binding capacity) to determine if iron deficiency anemia is present.	Decreased: Acute blood loss, iron deficiency anemia, gastrectomy, malabsorption, malignancy, rheumatoid arthritis, uremia Increased: Acute hepatitis, aplastic anemia, blood transfusion, hemochromatosis, lead poisoning, pernicious anemia, thalassemia, vitamin B_6 deficiency
Serum ferritin	Adult men 15–200 ng/mL Adult women 40 y or more, 11–122 ng/mL Adult women <40 y 12–263 ng/mL	Correlates well to the size of iron stores in the body. Ferritin is stored in the liver and reticuloendothelial system and released into the serum to meet the body's demand for iron.	Decreased: Hemodialysis, inflammatory bowel disease, iron deficiency anemia, gastrointestinal surgery, pregnancy Increased: Anemia (chronic, hemolytic, megaloblastic, pernicious, sideroblastic), chronic infection, chronic inflammation, chronic renal disease, excess ingestion of iron, hepatic disease, liver disease, malignancy, multiple blood transfusions, rheumatoid arthritis, thalassemia
Total iron-binding capacity	250–400 mg/dL	Indicates the maximum amount of iron that can be bound to transferrin. Useful for differentiating anemia from chronic inflammatory disorders.	Normal: Chronic inflammatory disorders Increased: Iron deficiency anemia
Serum transferrin	200–400 mg/dL	Plasma protein that transports iron by binding iron to serum transferrin receptors. Emerging as more sensitive indicator of iron deficiency and may replace more conventional indices (serum iron and ferritin).	Decreased: Cirrhosis, hemochromatosis, inflammatory states, renal disease, hemorrhage, hepatitis, hypothyroidism, microcytic anemia, pernicious anemia, thalassemia Increased: Iron deficiency states

From Chernecky CC, Berger BJ: Laboratory Tests and Diagnostic Procedures, 5th ed. Philadelphia, PA: WB Saunders, 2008.

Table 46-4 Peripheral Smear Red Blood Cell Abnormalities

Abnormality	Potential Diagnoses	Further Testing
Nucleated RBCs 	Acute hemorrhage, hypoxia, megaloblastic anemia	Vitamin B_{12} and folate levels; assess for bleeding; O_2 saturation, arterial blood gases for hypoxia
Spherocytes, elliptocytes 	Hemolytic anemia from hereditary spherocytosis, hereditary elliptocytosis	Reticulocyte count, serum bilirubin, serum lactate dehydrogenase, direct Coombs', osmotic fragility
Rouleaux formations 	Multiple myeloma	Serum protein electrophoresis, urine for Bence Jones proteins
Target cells, sickle cells, red cell cytoplasmic inclusions 	Sickle cell anemia, thalassemia	Hemoglobin studies (hemoglobin electrophoresis, hemoglobin F and A_2)
Schistocytes 	TTP, mechanical homolysis	Reticulocyte count, serum lactate dehydrogenase, serum bilirubin, coagulation studies, cardiac auscultation

White Blood Cell Count

The WBC count measures circulating leukocytes and should always be assessed in conjunction with the WBC differential and the patient's clinical condition. The WBC differential is relative and describes the percentages of the WBC subtypes (neutrophils, eosinophils, basophils, monocytes, and lymphocytes). WBC subtypes can also be measured using absolute numbers. It is important to consider both the absolute and relative values of the WBC subtypes when assessing the differential. For example, 60% segmented neutrophils may seem within normal limits, but if the total WBCs are 18,000 cells/mm^3, the absolute value (18,000 × 0.60) is 10,800 cells/mm^3, which is well above normal. Table 46-5 indicates normal absolute and differential values for the WBC count.

Conditions other than infection that may elevate the WBC count include use of steroids, trauma, stress, leukemia, hemorrhage, tissue necrosis, and dehydration. Table 46-5 summarizes abnormalities of WBC overproduction and potential physiological causes. In some cases, patients with leukemia have WBC counts greater than 100,000 cells/mm^3 because of excessive bone marrow production of blast cells (immature granulocytes). These patients are at risk for leukostasis, in which blasts aggregate in the capillaries of the brain and lungs. Clinical findings of leukostasis include headache, confusion, central nervous system infarcts, acute respiratory insufficiency, and pulmonary infiltrates.

A low WBC count usually indicates decreased production caused by immunosuppressive therapy or a disorder of bone marrow production due to infiltrative processes or bone marrow failure. Decreases in circulating neutrophils may be caused by decreased production from bone marrow injury, bone marrow infiltration, nutritional deficiencies, or congenital defects of the stem cells in the bone marrow. Other causes of neutropenia are splenic sequestration and destruction, immune-mediated granulocyte destruction, or overwhelming infection. Lymphocytopenia is most commonly caused by malignancy, followed by collagen vascular disease. Acquired immunodeficiency syndrome (AIDS) and AIDS-related complex are other notable causes of lymphocytopenia (see Chapter 48).

There are numerous potential abnormalities in the WBC differential. A left shift refers to an increase in the number of bands (neutrophil precursors), which usually indicates an

Table 46-5 White Blood Cell (WBC) Count and Differential: Laboratory Abnormalities

Test	Normal Value: Relative	Normal Value: Absolute (cells/mm^3)	Significance	Possible Causes of Abnormal Results
WBC count		4,500–10,000	Measures number of WBCs	Infection, inflammation, leukemia, trauma, stress
Differential	All percentages for various types of WBCs must add up to 100%		Describes the percentage of each WBC found in blood	See examples of specific cell type below
Granulocytes	50%–70%		Type of WBC categorized by presence of granules in cytoplasm	See specific granulocyte subtypes below
Segmented neutrophils	3%–5%	2,500–7,000	Mature neutrophil with nuclei segmented into lobes	Increased: bacterial infection, inflammatory disorder, tissue destruction, malignancy, drug-induced hemolysis, diabetic ketoacidosis, myeloproliferative disorders, idiopathic, smoking, obesity Decreased: compromised immune system, depressed bone marrow, heart-lung bypass, hemodialysis, overwhelming infection, tuberculosis, typhoid
Band neutrophils	1%–3%	135–500	Immature neutrophil with nuclei that have smooth edges, unsegmented	Increased: acute stress, active bacterial infection Decreased: compromised immune system
Eosinophils	0.4%–1%	100–300	Also known as acidophils (acid loving); combat infections caused by parasites; play a role in allergic reactions; cause bronchoconstriction in asthma	Increased: parasitic infection, asthma, allergies, dermatoses (hives and eczema), adrenal insufficiency Decreased (note: a low eosinophil count is not a cause for concern); Cushing's disease; administration of glucocorticosteroids; various pharmaceuticals
Basophils	4%–6%	40–100	Similar mechanism to mast cells in allergic response; triggered by immunoglobulin E binding to antigens; releases proinflammatory mediators	Increased: hyperlipidemia, viral infections (smallpox, chickenpox), inflammatory conditions (ulcerative colitis, chronic sinusitis, asthma), Hodgkin's lymphoma, increased estrogen, hypothyroidism, myeloproliferative disorders Decreased: stress, hyperthyroidism, pregnancy
Monocytes	25%–35%	200–600	Monocytes become macrophages after migration into tissue; macrophages perform phagocytosis	Increased: viral infection, parasitic infection, myeloproliferative disorders, inflammatory bowel disease, sarcoidosis, cirrhosis, drug reactions Decreased: administration of glucocorticoids, aplastic anemia, lymphocytic anemia
Lymphocytes		1,700–3,500	Primary source of viral defense and antibody production	Increased: viral infections, pertussis, tuberculosis, acute lymphoblastic leukemia, cytomegalovirus infection, mononucleosis, post transfusion, splenomegaly, hyperthyroidism, connective tissue disorder Decreased: AIDS, bone marrow suppression, aplastic anemia, steroid use, neurological disorders (multiple sclerosis, myasthenia gravis, Guillain-Barré syndrome)

infectious process. The presence of blasts in the peripheral blood is always an aberrant finding and suggests the presence of leukemia or a myeloproliferative disorder.

T- and B-Lymphocyte Tests

As discussed in Chapter 45, lymphocytes are classified as T cells and B cells. T cells are important in the body's ability to distinguish between self and nonself. Monoclonal antibodies against specific lymphocyte surface proteins are used to identify types of circulating lymphocytes and their subset populations, which can be useful in characterizing hematological malignancies and identifying immunological and autoimmune diseases. A specific example of this is assessment of the $CD4^+$ subpopulation of T cells in patients with AIDS; a $CD4^+$ count of less than 400/mm^3 is associated with a poorer prognosis. Table 46-6 lists possible causes of lymphocytosis and lymphopenia.

When an antigen stimulates B cells, they differentiate into plasma cells and produce antibodies. Although plasma cells reside in lymphoid tissue, their antibody production can be evaluated through serum and urine protein electrophoresis. Autoimmune diseases occur when the body produces antibodies directed against its own tissues. These diseases can be organ specific (eg, Graves' disease in the thyroid) or widely disseminated and involve multiple organs, such as systemic lupus erythematosus, which can attack almost every body system. Laboratory testing is aimed at the detection of serum antibodies against various tissues. C-reactive protein, antinuclear antibody, rheumatoid factor, and erythrocyte sedimentation rate are additional tests used in diagnosing autoimmune disorders.[2]

Tests to Evaluate Disorders of Primary Hemostasis

Laboratory testing that evaluates hematological dysfunction should be guided by the information gathered in the history and physical examination. Family history, underlying clinical conditions, and the duration and type of abnormal bleeding can indicate appropriate testing and diagnostic workup. Because hematological and immune disorders are so pervasive in the human body, the nurse must be careful not to disregard innocuous symptoms. The patient's history must be thorough.

Primary bleeding disorders are caused by problems with platelets and small blood vessels that can result in subtle bleeding. For instance, mucocutaneous bleeding, petechiae, and superficial purpura may be early signs of impending critical illness. Decreased platelets or increased capillary fragility can cause the sudden appearance of petechiae, especially in dependent areas, such as the lower extremities.

Platelet Count

The primary phase of hemostasis involves aggregation of platelets at the site of vessel injury. These platelets initiate the coagulation cascade, which results in the deposit of fibrin at the site of injury to stabilize the clot (secondary hemostasis). See Chapter 45, Figure 45-2 for an illustration of the processes that occur during hemostasis.

When evaluating primary hemostasis, one first obtains a platelet count from the CBC. A platelet count of less than 150,000/mm^3 is abnormal, but bleeding from thrombocytopenia alone usually does not happen unless the platelet count falls below 20,000/mm^3.[3] However, prolonged bleeding from surgery or trauma may occur with platelet counts of 40,000 to 50,000/mm^3. Severe, spontaneous hemorrhage may result when platelet counts reach 5,000 to 10,000/mm^3. Causes of thrombocytopenia include decreased bone marrow production, splenic sequestration due to splenomegaly, or peripheral destruction of platelets by the body's own immune system. Disseminated intravascular coagulation (DIC) and TTP (see Chapter 49) are other serious disorders that involve low platelet counts. Drugs are the first suspect in thrombocytopenia (Box 46-3); once the nurse has ruled them out, she or he moves to consider other causes (Box 46-4). Finally, one must consider that

Table 46-6 Possible Causes of Lymphocytosis and Lymphopenia

Finding	Possible Causes
Lymphocytosis	Lymphatic leukemia, Epstein-Barr virus, viral infections of the upper respiratory track, cytomegalovirus, measles, mumps, chickenpox, acute HIV infection, infectious hepatitis, tuberculosis, Crohn's disease
Lymphopenia	Aplastic anemia, Hodgkin's disease, acquired immune deficiency syndrome, congestive heart failure Drugs include chemotherapeutic agents, immunosuppressive medications, radiation therapy

BOX 46-3 PATIENT SAFETY

Drugs That Decrease Platelet Production or Function

The drugs listed below may cause complications, interactions, or other undesired effects.

- Aspirin
- Barbiturates
- Cimetidine
- Chemotherapeutic agents
- Chloramphenicol
- Chlorothiazides
- Digitalis
- Digitoxin
- Furosemide
- Glyburide
- Ibuprofen
- Penicillin
- Phenobarbital
- Quinidine
- Streptomycin
- Sulfonylureas
- Tetracycline

From Fischbach FT, Dunning MB: A Manual of Laboratory and Diagnostic Tests, 8th ed. Philadelphia, PA: Wolters Kluwer: Lippincott Williams & Wilkins, 2009.

BOX 46-4 Causes of Platelet Disorders in the Intensive Care Unit

Thrombocytopenia
Heparin (1% to 3%)
Sepsis (>50%)
AIDS (40% to 60%)
Disseminated intravascular coagulation (DIC)
Thrombotic thrombocytopenic purpura (TTP)

Abnormal Platelet Function
Renal insufficiency
Cardiopulmonary bypass
Aspirin
Dextran

The incidence of platelet disorders is indicated in parentheses.

From Marino PL: The ICU Book, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 1998, p 710.

some people may produce adequate numbers of platelets but ones that function abnormally.

An elevated platelet count greater than 400,000/mm^3 indicates increased platelet production or decreased platelet destruction. These platelets may function abnormally, causing aberrant bleeding and clotting. A cause of primary thrombocytosis is bone marrow disease. Causes of reactive thrombocytosis include chronic inflammation, infection, malnutrition, acute stress, malignancy, splenectomy, or the postoperative state.

Peripheral Smear

A peripheral blood smear may reveal megathrombocytes (large platelets), which may be present during premature platelet destruction. Also, note that some patients' platelets clump when exposed to ethylenediamine tetraacetic acid (the anticoagulant used in the "purple top" or CBC tube). Examination of the peripheral smear shows this clumping, and a repeat CBC in a heparinized "green top" blood collection tube reveals an accurate platelet count.

Platelet Function Assay

The platelet function assay is a screening method that tests platelet function in adhesion and aggregation quality. This test is helpful in the evaluation of platelet function in patients with menorrhagia, drug-induced platelet dysfunction, and high-risk pregnancy.

Bleeding Time

The bleeding time test assesses the length of time required for a clot to form at the site of vessel injury. A prolonged bleeding time in a patient with a normal platelet count may indicate a disorder of platelet function that requires further testing. Remember that patients can bleed to hemorrhage with a normal platelet count if the platelets are not functioning. A deficiency in factor VIIIR (von Willebrand's disease) results in decreased ability of the platelets to adhere to the injured vessel wall. Uremia from renal failure, drugs (especially aspirin), foods, and spices can also cause abnormal platelet function. Box 46-3 lists some drugs known to decrease platelet production or function. Platelet aggregation studies are performed to detect inherited or acquired disorders in platelet function.

Prothrombin Time and Activated Partial Thromboplastin Time

Screening for coagulation abnormalities includes evaluating the prothrombin time (PT) and the activated partial thromboplastin time (aPTT). Prolongation of either of these tests indicates coagulation factor deficiencies or inhibition. The PT test screens for dysfunction in both the extrinsic portion that includes tissue thromboplastin and factor VII and in the common pathway that includes factors X, V, and II and fibrinogen. Prolongation of PT can result from disorders, such as liver disease, vitamin K deficiency, clotting factor deficiencies, or DIC. Numerous medications, including allopurinol, aspirin, β-lactam antibiotics, chlorpropamide, digoxin, diphenhydramine, and phenytoin sodium, can also cause a prolonged PT. PT is also used to monitor patient response to anticoagulation therapy with warfarin.

In 1983, the World Health Organization introduced the international normalized ratio (INR) to provide a common standard for interpretation of PT. The INR value depends on the sensitivity ratio of the thromboplastin reagent used in the laboratory to the International Reference Preparation. It is now widely accepted practice to assess the level of anticoagulation and warfarin dosing based on the INR ratio.

The aPTT measures how well the coagulation sequences of the intrinsic pathway (factors XII, XI, IX, VIII) and the common pathway (factors X, V, II, and fibrinogen) are functioning. An elevated aPTT could indicate disorders of any coagulation factors except VII and XIII. Clinical conditions associated with an elevated aPTT include DIC, von Willebrand's disease, and liver disease. Drugs that may affect aPTT include chlorpromazine, codeine, phenothiazines, salicylates, and warfarin. The aPTT test is also used to monitor patient response to heparin therapy.

- **Thrombin time:** Thrombin time is a test that measures the clotting time of a sample of plasma to which thrombin has been added. Thrombin is important in converting fibrinogen to fibrin in the final phase of the coagulation cascade. Thrombin time is increased in conditions such as DIC, liver disease, clotting factor deficiencies, shock, and hematological malignancies. Decreased thrombin time occurs with thrombocytosis.
- **Fibrinogen level:** Fibrinogen is converted by thrombin to fibrin, which then combines with platelets to form a stable clot. Patients with DIC, severe liver disease, sepsis, TTP, or trauma have a low fibrinogen level. Elevated fibrinogen levels occur in conditions involving tissue damage and inflammation.
- **Fibrin degradation product level:** Fibrin degradation products (FDPs) accumulate when a large amount of clotting has occurred and has then been broken down. Increased FDPs, along with an elevated PT/aPTT, decreasing platelets, and a low fibrinogen level, indicate possible DIC (see Chapter 49).
- **D-Dimer:** D-Dimer is a more specific test than FDP measurement for detecting an event in which fibrin is being broken down. Its indications include ruling out and monitoring DIC, deep venous thrombosis, venous and arterial thrombotic conditions, and the monitoring of thrombolytic therapy. Recent studies continue to support the often disputed claim that D-dimer is beneficial in the evaluation of acute pulmonary embolism.[4]

Tests to Evaluate Disorders of Secondary Hemostasis

Disorders of secondary hemostasis involve clotting factor deficiencies and are characterized by recurrent oozing of blood and hematoma formation. The onset of these symptoms may be delayed because of the initial plugging of the vessel injury; however, defective clotting mechanisms fail to provide a stable fibrin clot.

When assessing disorders of secondary hemostasis, one must determine whether the disorder is congenital or acquired. A history of excessive or recurrent bleeding in the individual or family members suggests a congenital disorder as the more likely cause. Table 46-7 describes potential complications experienced by people with congenital bleeding disorders. The most common congenital bleeding disorders are von Willebrand's disease, hemophilia A, and hemophilia B. PT and aPTT are ordered for patients with suspected congenital disorders, along with factor VIIIR, VIII, and IX assays. A deficiency in von Willebrand's factor (VIIIR) results in the decreased ability of platelets to adhere to the injured vessel wall and a deficiency of factor VIII. A deficiency of factor VIII causes hemophilia A; a deficiency of factor IX causes hemophilia B. Table 46-8 summarizes laboratory abnormalities that indicate these congenital disorders.

An acute bleeding problem without a prior history of chronic bleeding suggests an acquired disorder. Acquired disorders of hemostasis occur with vitamin K deficiency, severe trauma, hemorrhage, massive transfusion, overwhelming infection, severe liver disease, and DIC. A deficiency of vitamin K decreases synthesis of prothrombin, factor VII, factor IX, and factor X. Liver disease impairs the absorption of vitamin K by decreased production of bile salts necessary for vitamin K absorption from the gut or through obstruction of the biliary system. Dysfunctional hepatocytes in the liver are unable to produce the vitamin K–dependent factors, as well as fibrinogen; factors V, XI, XII, and XIII; and other clotting factors. Some patients with liver disease may demonstrate thrombotic tendencies caused by decreased liver synthesis of anticoagulants, such as protein C, protein S, plasminogen, and antithrombin III.

Laboratory testing for an acquired disorder of hemostasis varies based on the suspected etiology of the disorder. In general, testing includes PT, aPTT, thrombin time, bleeding time, liver enzyme and liver function tests, fibrinogen levels, and FDPs. Table 46-9 summarizes laboratory abnormalities that indicate some of the acquired coagulation disorders.

Table 46-7 Potential Complications in Congenital Bleeding Disorders

Site	Potential Complication
Abdomen	Hypotension, hypovolemic shock (eg, retroperitoneal)
Muscle	Compartment syndrome
Joint	Hemarthrosis with destruction of bone and cartilage in joint capsule
Intracranial	Increased intracranial pressure
Retropharyngeal	Airway obstruction
Gastrointestinal	Anemia, melena
Urinary tract	Hematuria; clots in ureters may occur after factor administration

From Stabler SP: Hemophilia. In Wood ME (ed): Hematology/Oncology Secrets, 3rd ed. Philadelphia, PA: Hanley & Belfus, 2003.

A hypercoagulable state causes an increased tendency for thrombosis. Box 46-5 summarizes some of the risk factors for hypercoagulability. Hereditary thrombotic disease is a group of genetic abnormalities causing defects of coagulation, fibrinolysis, or their regulatory systems. Laboratory abnormalities in hereditary hypercoagulability include deficiencies of antithrombin III, protein C, protein S, plasminogen, tissue plasminogen activator, and dysfibrinogen; however, 65% to 70% of the causes remain unknown. Lupus anticoagulant (LA) is an autoimmune disorder in which patients have an elevated aPTT, yet thrombosis develops in 30% of the patients. LA is confirmed by the presence of anticardiolipin antibodies, positive platelet neutralization procedure, or positive dilute Russell viper's venom test.

Tests to Evaluate Hematological and Immune Disorders

Table 46-10 lists common laboratory tests to assess immune system functioning. Diagnostic tests for human immunodeficiency virus (HIV) are listed in Chapter 48, Table 48-4.

Bone marrow aspiration and biopsy are the most important diagnostic tests for determining bone marrow function. The biopsy provides information about the precursors of the blood's components to determine whether hematological

Table 46-8 Laboratory Abnormalities in Congenital Bleeding Disorders*

	PT	aPTT	vWF	vWF Antigen	VIII	IX	BT†
von Willebrand's	N	↑	↓	↓	↓	N	↑
Hemophilia A	N	↑	N	N	↓	N	↑
Hemophilia B	N	↑	N	N	N	↓	↑

*Other congenital bleeding abnormalities are rare and not mentioned in this text.

†BT depends on the severity of the condition; it may be normal in mild cases.

PT, prothrombin time; aPTT, activated partial thromboplastin time; vWF, von Willebrand's factor; VIII, factor VIII; IX, factor IX; BT, bleeding time; N, normal.

Table 46-9 Laboratory Abnormalities in Acquired Bleeding Disorders

	PT	aPTT	TT	FDP	Plt
Vitamin K deficiency	X	X			
Liver disease: Acute hepatitis, early liver disease	X				
Chronic liver disease	X	X	X	X	X
DIC	X	X	X	X	X
Massive transfusion	X	X	X		X

PT, prothrombin time; aPTT, activated partial thromboplastin time; TT, thrombin time; FDP, fibrin degradation products; Plt, platelets; DIC, disseminated intravascular coagulation; X, elevated laboratory result.

abnormalities are a production defect. Bone marrow examination is useful in detecting infiltrative processes, such as malignancy, which can affect blood cell production. This procedure is also performed to determine response to therapy in patients with hematological malignancies or solid tumor infiltration of the bone marrow.

Tissue biopsy may be performed on skin lesions in which malignancy (eg, cutaneous T-cell lymphoma) or an autoimmune process (eg, pemphigus) is suspected. Lymph node biopsy is required for lymphadenopathy that does not appear to be caused by an infectious process.

Internal lymph nodes of the chest, abdomen, and pelvis can be evaluated by computed tomography (CT) scanning. A CT scan may be used to determine the presence of masses in suspected malignancy, especially lymphoma. Positron emission tomography is used in lymphoma and non-Hodgkin's lymphoma to diagnose and stage cancer, evaluate response to therapy, and assess for recurrence. Liver disease, an important factor in coagulopathy, and splenomegaly may also be evaluated through a CT scan. A skeletal survey (skull, vertebrae, ribs, pelvis, arms, forearms, thighs, and lower legs) is done in patients with suspected multiple myeloma to assess for the typical "punched-out" lytic lesions that occur in this condition.

Intradermal skin testing is used to evaluate cell-mediated immunity. Various antigens are injected just below the skin's surface to check for delayed-type hypersensitivity. Commonly used antigens include mumps, *Candida* species, trichophytin, and tuberculin. If the patient fails to respond to the injected antigens, they are said to have cutaneous anergy. This implies a defect in the patient's cellular immunity. Some causes of cutaneous anergy include AIDS; acute leukemia; chronic lymphocytic leukemia; carcinoma; Hodgkin's disease; non-Hodgkin's lymphoma; congenital immune conditions; bacterial, fungal, or viral infections; immunosuppressive medications; cirrhosis; and malnutrition.

BOX 46-5 *PATIENT SAFETY*

Risk Factors for Hypercoagulability

Physiological
- Pregnancy
- Postpartum
- Venous stasis
- Age more than 40 years
- Immobilization
- Varicose veins
- Previous venous thromboembolism

Pathological
- Malignancy
- Liver disease
- Disseminated intravascular coagulation
- Polycythemia
- Lupus anticoagulant
- Vascular injury
- Sepsis
- Heart failure
- Myocardial infarction
- Inherited abnormalities

Environmental
- Smoking
- Stress
- Heat

Iatrogenic
- Surgery
- Postsurgical
- Oral contraceptives
- Estrogens

▲ Assessment of the Immunocompromised Patient

Immunocompetence refers to the body's ability to protect itself against disease (see Chapter 45). Figure 46-4 illustrates areas to be assessed for immunocompetence.

It is essential that critically ill patients' immunocompetence be assessed at frequent intervals. Physical and psychological stress from overwhelming illness or trauma in the critically ill patient can depress functioning of the immune system. Invasive procedures, indwelling catheters, intravenous lines, mechanical ventilation, nutritional compromise, and the intensive care environment itself can predispose patients to infections and sepsis. As always, handwashing is the best tool available for these patients. Also, patient teaching and aseptic technique are essential to minimize exposure to infectious organisms. The nurse closely monitors potential sites of infection, changes or fluctuations in body temperature, nutritional status, and laboratory findings for indications of compromised immune function or the onset of infection. Septic shock is a life-threatening complication that can develop rapidly in immunocompromised patients. Patient outcomes are greatly improved when septic shock is detected in its early stages and interventions are instituted promptly. Box 46-6 presents signs of early septic shock (also see Chapter 54).

History

Reducing susceptibility to infection is key to the care of patients in the ICU, and the history can identify susceptibility and guide critical care nursing practice. The type of infection often provides the clues regarding the nature of

Table 46-10 Common Laboratory Tests of the Immune System

Laboratory Test	Reference Range	Use
C-reactive protein	Not available; levels <10 mg/L indicate patient no longer has clinically active inflammation; high or increasing levels are consistent with infection and/or inflammation	Evaluation of various inflammatory conditions, including rheumatoid arthritis and systemic lupus erythematosus
Antinuclear antibody	Low titers are negative; elevated titers demonstrate an elevated concentration of antinuclear antibodies	Screening and diagnosis of autoimmune disorders
Human leukocyte antigen (HLA) typing	Reported as phenotype for each of the six HLA loci tested. HLA (protein marker found on most of the body's cells) typing involves either serologic or DNA methods. Antibody screen test is reported as the percentage of panel reactive antibodies (PRAs); percent PRA is number of wells reactive with patient's serum expressed in percent. Cross-match is reported as compatible or incompatible.	Determination of tissue compatibility for organ transplantation; also used to determine paternity and to diagnose HLA-related disorders
Erythrocyte sedimentation rate (ESR)	1–13 mm/h for males; 1–20 mm/h for females	Evaluation of inflammatory state; females tend to have a higher ESR; ESR increases with age
Immunoglobulins (Igs)	IgA: 160–260 mg/dL IgG: 950–1,550 mg/dL IgM: 50–300 mg/dL IgD: 0–9 mg/dL IgE: 0.002–0.2 mg/dL	Assessment of immunodeficiency state and certain cancers, including multiple myeloma and macroglobulinemia; also used to assess response to immunizations
Complement system	C3: 75–150 mg/dL C4: 13–40 mg/dL	Diagnosis of systemic lupus erythematosus and other immunological disorders

the immune defect. For example, patients with defects in humoral immunity may have recurrent or chronic bacterial infections, such as meningitis or bacteremia. Repeated viral or fungal infections can indicate a defect in cell-mediated immunity. (See Chapter 45 for a review of humoral and cell-mediated immunity.)

Risk Factors for Immunocompromise

Certain factors, such as chronological age, place critically ill patients at a higher risk of immunocompromise. A patient who has a chronic disease or is already immunosuppressed may also be predisposed to further immune difficulties. Finally, certain medications and treatments can alter a patient's immunocompetence, as can his or her nutritional status and skin integrity. Nurses should be especially aware of these risk factors during their assessment of immunocompetence.

Age

The patient's chronological age influences immunocompetence. Immune response may be depressed in the very young because of the underdevelopment of the thymus gland. Older patients experience a decline in immune system function, making them more susceptible to infections. Thus, they should be closely assessed for alterations in their immunocompetence. Box 46-7 describes factors that contribute to the overall decline of immunocompetence in older people.

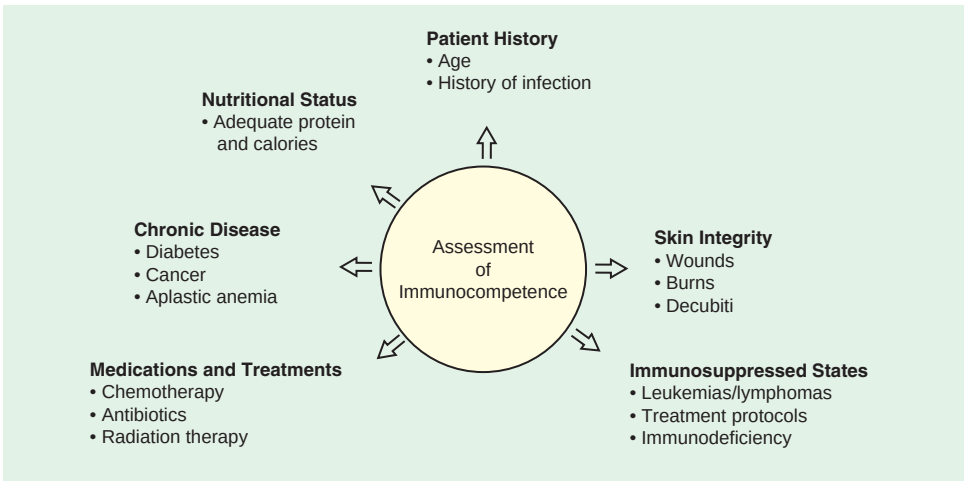

FIGURE 46-4 ▲ In addition to obtaining his or her history, assessment of the immunocompromised patient should cover six major areas.

BOX 46-6 PATIENT SAFETY

Signs of Early Septic Shock

- Fever
- Chills
- Confusion
- Irritability
- Tachycardia
- Tachypnea
- Decreased peripheral pulses
- Hypotension
- Warm, dry skin

Chronic Disease

Many chronic diseases are associated with compromised immune functioning. Diabetes, hepatic disorders, cancer, and aplastic anemia are just a few examples of diseases in which immune deficiencies occur. Because many critically ill patients have an underlying chronic disease, the existence and severity of such diseases should be considered contributing factors to immunocompromise when these patients are assessed.

Immunosuppressed States

Patients with leukemia, lymphoma, multiple myeloma, and other hematological conditions can experience impaired immunity and recurrent infections. Immunodeficiency states can be congenital or acquired. People with congenital immunodeficiencies frequently do not survive childhood. Immunodeficiency syndromes in adults may occur through a spontaneous defect in the immune system or through HIV infection (see Chapter 48).

Patients who are severely immunosuppressed have impaired responses to infectious agents and may not display the typical signs of infection. Fever and redness or pus at infection sites may be diminished because of the decreased numbers of WBCs required to promote these physical signs. Nurses should thus be extremely vigilant about monitoring for potential infection.

Medications and Treatments

Many medications affect immunocompetence. Antibiotics, such as tetracycline and chloramphenicol, impair bone marrow function. Steroids display many immunological effects, including decreased lymphocyte and antibody concentration. Patients who have received organ or bone marrow transplants (see Chapter 47) often must remain on medications (eg, cyclosporine) that severely suppress the immune system. Patients placed on treatment regimens with any immunosuppressive medications are monitored for early symptoms of infection that would indicate compromise in immune functioning.

Various treatments also impair immunocompetence. Treatment protocols for patients with cancer can lead to life-threatening complications, such as infection and sepsis. Biological therapy with interferon-α and interleukin-2 can cause leukopenia. Patients who receive multiple transfusions with RBCs can demonstrate suppressed immunity. Most chemotherapeutic agents and radiation to the pelvis, spine, ribs, sternum, skull, and metaphyses of the long bones can adversely affect the bone marrow's ability to produce WBCs. The lowest point in WBC levels, or the nadir, may not be seen until several days or weeks after the initiation of treatment. The absolute neutrophil count (ANC) is calculated in neutropenic patients to determine the degree of immunosuppression. The ANC is calculated as follows:

1. Add segmented neutrophils and band neutrophils (from the WBC differential).
2. Multiply the total WBC count by the total obtained in step 1.

Example:

Segs = 42%

Bands = 10%

Total WBC count = 4,100 cells/mm^3

42 + 10 = 52%

4,100 × 0.52 = 2,132 cells/mm^3 (ANC)

Usually, protective measures, such as those summarized in Box 46-8, are instituted for patients with an ANC of less than 1,000 cells/mm^3.[5] However, all patients in the ICU are considered at risk for immunocompromise and should have the benefit of scrupulous handwashing, rigorous monitoring, and protective interventions.

BOX 46-7 CONSIDERATIONS FOR THE OLDER PATIENT

Factors Contributing to Diminished Immunocompetence

- Decline in immune system functioning
- Decreased nutritional intake (decreased taste, poor teeth, declining appetite)
- Chronic illnesses (diabetes, chronic obstructive pulmonary disease, renal disease)
- Increased risk for malignancy
- Possible urinary incontinence
- Prostatic hypertrophy and urinary retention
- Skin breakdown and impaired wound healing
- Decreased ability to care for self
- Impaired communication
- Decreased mobility

BOX 46-8 NURSING INTERVENTIONS

For the Immunocompromised Patient*

- Provide a private room or uninfected roommate.
- Use a laminar flow or positive pressure room.
- Maintain strict handwashing with antiseptic soap.
- Use no rectal thermometers, enemas, or suppositories.
- Restrict staff and visitors with infections (or require masks).
- Provide patient with a mask when he or she goes to other departments or crowded areas.
- Permit cooked foods only.
- Allow no fresh flowers or live plants.
- Avoid sources of stagnant water (vases, water pitchers, humidifiers, denture cups).

*Precautions taken may vary according to institutional policy and the severity of immunosuppression.

Nutritional Status

The patient's nutritional status has a major impact on immune function. Inadequate intake of protein and calories can alter immune responses and resistance to infection by decreasing lymphocyte and antibody production as well as impairing wound healing. A multidisciplinary approach including a nutritionist can assist the nurse in assessing dietary intake and nutritional requirements for the critically ill immunocompromised person. Supplemental intravenous or enteral feedings may be necessary to prevent further deterioration of the body's nutritional status and ability to fight infection.

Skin Integrity

The integumentary system, including the skin and mucous membranes, provides a physical barrier to infection. Surgical or traumatic wounds, burn injuries, or pressure sores breach these physical defenses and predispose the critically ill patient to infection. Also, in a critical care setting in which intravenous and intraarterial catheters, urethral catheters, or endotracheal tubes are used, multiple portals of entry for pathogens can provide simultaneous sites for potential infection. Therefore, all wounds and portals of entry should be carefully monitored for signs and symptoms of infection.

▲ Clinical Applicability Challenges

CASE STUDY

T.R. is a 53-year-old African American male with a history of hypertension, diabetes mellitus, end-stage renal disease, and hyperlipidemia who presented to the emergency department status postdialysis with chief complaint of weakness in bilateral lower extremities. T.R. reports being "too weak to stand up" and also complains of "cloudy thinking." He also states that he has had "chills" and the "shakes" for the last 48 hours.

T.R. appears to be unbathed and in poor general health. A moist, bloody dressing is found over the catheter site. The area around the catheter insertion site is red and warm to the touch.

T.R. is febrile with a temperature of 39.8°C. Blood pressure (BP) is 85/45 mm Hg, heart rate is 168 beats/min, respiratory rate is 20 breaths/min, SpO_2 at 94% on room air. He is in no apparent distress but is lethargic. There is no jugular venous distention, lungs are clear to auscultation bilaterally, and there is no wheezing, crackles, or ronchi. A 12-lead ECG demonstrates normal sinus rhythm with a right bundle branch block and nonspecific T-wave inversion.

Results from a chemistry panel include sodium 129 mEq/L; potassium 5.0 mEq/L; chloride 96 mEq/L; bicarbonate 26 mEq/L; BUN 22 mg/dL; creatinine 2.12 mg/dL; and glucose 90 mg/dL.

On admission to the emergency department, a blood specimen is drawn for a complete blood count with differential, and the following results were reported: WBC 12.9×10^3 µL; neutrophils 91.5%, lymphocytes 1.6%; monocytes 7.4%; eosinophils 0%; and basophils 0%. The following day, after being admitted to the intermediate care unit, T.R.'s WBCs were 15.89×10^3 µL with the following differential: neutrophils 90.4%, lymphocytes 3.2%; monocytes 5.7%; eosinophils 0%; and basophils 0%. His hemoglobin and hematocrit were stable at 9.8 g/100 mL and 29%, respectively. He remained febrile with a temperature of 38.0°C and hypotensive with a BP of 90/62 mm Hg.

1. What is T.R.'s primary health problem?
2. Based on assessment of the WBC differential, what type of infection is T.R. most likely to have?
3. Identify at least three subjective findings that are consistent with T.R.'s primary health problem.
4. Identify at least four objective findings that are consistent with T.R.'s primary health problem and discuss how these findings are implicated in the primary health problem.
5. What is the significance of the abnormal hemoglobin and hematocrit values?

47 Organ and Hematopoietic Stem Cell Transplantation

Sandra A. Mitchell, Jo Ann Hoffman Sikora, and Elizabeth Holderness

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Analyze the criteria used to evaluate and prepare patients for transplantation.
2. Evaluate the principles of organ and hematopoietic stem cell compatibility and immunosuppression.
3. Discuss nursing assessment and management for patients undergoing solid organ transplantation (kidney, liver, heart, pancreas, lung) or hematopoietic stem cell transplantation (HSCT).
4. Describe the early and late-phase complications of organ and HSCT.

Transplant research began in the early 1900s, but kidney transplantation did not become a realistic treatment for chronic renal failure in humans until the early 1950s. Heart and liver transplantations followed in the 1960s and since the 1980s, have steadily increased in frequency as a treatment for end-stage organ failure. Pancreas transplantation also began in the mid-1960s with good graft survival rates being achieved in the 1980s. The number of lung transplantations is small, primarily because of a lack of medically suitable donors. Table 47-1 gives survival rates for solid organ transplantations.

During the past 40 years, hematopoietic stem cell transplantation (HSCT) has evolved from an experimental treatment for patients with advanced acute leukemia into a therapeutically effective modality that is now standard therapy for selected diseases. HSCT, which is known to be curative in several malignant and nonmalignant disorders, is a transplantation using hematopoietic stem cells at various stages of differentiation and maturation. Decreased treatment-associated mortality and improved supportive care have helped make this possible.

Astute nursing care is essential to prevent treatment-related complications and death. Other factors that may affect the outcomes of HSCT include the type and stage of disease at the time of transplantation, the type of transplant (allogeneic versus autologous), the degree of human leukocyte antigen (HLA) matching in allogeneic transplants, the stem cell source, the intensity of the conditioning regimen, the ages of both the donor and the recipient, and the experience of the transplantation center. In general, the transplant-related mortality risk in allogeneic HSCT is about 20% to 30% higher than in autologous HSCT. The transplant-related mortality rate in autologous HSCT is less than 5% at most centers.

Even when a patient is cured of the original disease, he or she may experience delayed and long-term complications that can shorten or negatively affect the quality of his or her remaining life. These complications include infections, chronic graft-versus-host disease (GVHD; seen in allogeneic HSCT), thyroid dysfunction, pulmonary complications, cataracts, and the development of second malignancies. In general, autologous transplantation has fewer long-term complications, largely because no GVHD is associated with autologous transplantation. Disease-free survival 5 years after HSCT varies substantially, depending on the age of the recipient, the underlying disease, prognostic risk factors, disease status at the time of transplantation, the type of HSCT procedure, and the extent of prior treatment. Depending on these factors, disease-free survival rates vary from 10% to 75%[1–7] (Table 47-2). Advances in histocompatibility matching, immunosuppression, stem cell collection, and cryopreservation techniques, as well as the development of safer and less toxic conditioning regimens along with more effective drugs to manage posttransplantation infections and stimulate hematopoiesis, have helped increase the success of HSCT.[8]

This chapter describes the major aspects of care for patients receiving kidney, liver, heart, pancreas, and lung transplantations and HSCT. It covers principles that apply to all types of transplantation and discusses content unique to specific types of transplants.

Table 47-1 Graft and Patient 1-Year Survival Rates for Adult Solid Organ Transplants Performed in 2005–2006

Organ	Graft Survival Rate (%)	Patient Survival Rate (%)
Kidney—living donor	95	98
Kidney—deceased donor	90	95
Heart	87	87
Lung	82	84
Liver—living donor	85	90
Liver—deceased donor	82	87
Pancreas	81	98
Kidney–pancreas	92 (kidney); 86 (pancreas)	95
Intestine	72	78

▲ Indications for Transplantation

Many factors influence the indications and patient eligibility for transplantation. Currently, end-stage disease is the primary reason for most organ transplantations. HSCT is now used when bone marrow is defective or destroyed by a disease process or as a result of treating an underlying disease.[9] New information concerning patient outcomes, complications, surgical techniques, immunosuppressive drugs, and availability of organs and hematopoietic stem cells is also considered. Table 47-3 presents indications for transplantation.

Table 47-2 Disease-Free Survival 5 Years After Hematopoietic Stem Cell Transplantation

Disease and Stage	Allogeneic (% Survival)	Autologous (% Survival)
Acute myeloid leukemia		
First remission	45–70	40
First relapse, second or later remission	23–45	20–30
Refractory, multiply relapsed	10–15	<10
Acute lymphocytic leukemia		
First or second remission	30–60	40
Relapse	10	—
Chronic myelogenous leukemia		
Chronic phase	50–70	—
Accelerated or blastic phase	10–30	—
Aplastic anemia		
Untranfused	80–90	—
Transfused	50–70	—
Myelodysplastic syndrome	10–25	—
Hodgkin's lymphoma	—	50–80
Non-Hodgkin's lymphoma	40–50	30–60
Multiple myeloma	20–40	<10*

*15%–25% with tandem autologous transplantation.

▲ Patient Evaluation and Contraindications to Transplantation

Selecting the ideal candidate for transplantation is an intricate process. To evaluate a patient's suitability for transplantation, a comprehensive multisystem analysis is performed. This includes both physiological and psychosocial factors that affect the patient's chance for a successful transplantation. During this evaluation phase, treatment of newly diagnosed conditions occurs, and clinicians make plans to ensure adequate nutrition, mobility, and muscle strength. The goal is to have the patient in the best possible physical condition for transplantation. When transplantations are performed earlier, rather than later in the disease process, there are fewer disabilities and a greater chance for survival.

Financial guidance is provided so that patients and families know what their insurance will cover and the nature and amount of their expected out-of-pocket expenses. Costs for transplantations range from $200,000 to $800,000 for the first year, including organ procurement, transplantation, and hospitalization. Medications after transplantation can cost $27,000 to $32,000 a year.[10–12] Transplantation centers may require proof of the patient's ability to cover medication expenses before accepting a patient for transplantation.

The following general criteria guide the selection of candidates for transplantation:

- Biological rather than chronological age is evaluated individually. Individuals eligible for transplantation may range from newborns to 70-year-olds. People older than age 55 may be at increased risk for complications.
- Acute or chronic infection is absent or has been treated. Localized liver infection may be an exception. Inflammatory diseases, such as systemic lupus erythematosus, do not rule out transplantation but should be quiescent at the time of the procedure.
- For the patient undergoing HSCT for a malignancy, care is taken to distinguish patients who can be saved by transplantation from those who may relapse or succumb to the rigors and toxicities of treatment.

Table 47-4 lists organ-specific criteria for transplantation. In general, evaluations common to all transplantation procedures include the following:

- ABO typing
- Tissue typing, HLA matching, mixed lymphocyte culture (MLC) matching
- Transfusion history
- Infectious disease screening (tuberculin skin test, human immunodeficiency virus [HIV], hepatitis B surface antigen, hepatitis C virus, Epstein-Barr virus, cytomegalovirus [CMV], toxoplasmosis titers, herpes simplex, varicella virus, venereal disease)
- Liver function studies

Table 47-3 Indications for Transplantation

Organ	Indications for Transplantation	Common Causes
Kidney	End-stage renal disease	Hypertension, diabetes mellitus, glomerular nephritis, urological disorders, cancer, nephrotoxins, trauma, hemolytic disorders, congenital anomalies
Liver	Adults: irreversible liver disease, malignancy, and hepatic failure resulting in synthetic liver dysfunction Children: biliary atresia, alpha-1-antitrypsin deficiency	Acute or chronic hepatitis, primary sclerosing cholangitis, primary biliary cirrhosis, hepatocellular carcinoma, Budd-Chiari syndrome, alcoholic cirrhosis
Heart	End-stage heart failure	Ischemic cardiomyopathy, idiopathic cardiomyopathy, valvular heart disease, congenital anomalies
Pancreas	Type 1 diabetes mellitus with end-stage renal disease either alone or in combination with a kidney transplant	Diabetes mellitus
Lung	Chronic obstructive pulmonary disease	Emphysema and bronchiectasis, idiopathic pulmonary fibrosis, emphysema due to alpha-1-antitrypsin deficiency, primary pulmonary hypertension
Heart–lung	Eisenmenger's syndrome	Pulmonary hypertension with irreversible right-sided heart failure not amenable to heart transplantation alone
Hematopoietic stem cell	Malignant disorders	Leukemias, myelodysplastic syndrome, Hodgkin's lymphoma, non-Hodgkin's lymphoma, multiple myeloma, and selected solid tumors (eg, renal cell tumors, germ cell tumors, neuroblastoma, pinealoblastoma)[1]
	Nonmalignant disorders	Aplastic, sickle cell, and Fanconi's anemias; selected metabolic disorders; thalassemia; and immunodeficiency syndromes[1]

- Renal function studies
- Complete blood count (CBC)
- Coagulation studies
- Gastrointestinal evaluation (depending on age and history)
- Gynecological examination
- Electrocardiogram (ECG)
- Chest radiograph
- Dental examination to rule out infection
- Social history, review of patient motivation, ability to follow postoperative regimen, and psychiatric evaluation.

Contraindications are based on conditions and behaviors that decrease the chance of survival. For solid organ transplantation, these include serious active infection or sepsis, recent cancer (unless that is the reason for transplantation), current substance abuse, HIV infection, severe cachexia, active peptic ulcer disease, psychiatric disorders that impair the ability to give informed consent or adhere to the treatment regimen, and repeated noncompliance. Table 47-4 lists these contraindications.

▲ Donor Selection

After a person is determined to be a candidate for transplantation, a donor source must be selected.

Determining Compatibility

Determination of compatibility in transplantation involves the evaluation of two major antigen systems. The primary determinant for solid organ transplantation is ABO grouping. A mismatch in compatibility may cause an immediate reaction leading to organ loss.

Organ Transplantation

The rules of compatibility that apply to the administration of blood products also apply to solid organ transplantation: type A blood has the A antigen, type B blood has the B antigen, type AB blood has both A and B antigens, and type O blood has neither antigen.

Histocompatibility testing (tissue typing) is the identification of donor and recipient antigens and the evaluation of donor antigens against recipient antibodies. This evaluation determines the compatibility between donor and recipient, which predicts the chances of graft acceptance. In the HLA antigen system, genes of the major histocompatibility complex code for the antigens that compose a person's tissue type. These genes contain information for antigens present on the surface of the nucleated cells and serve to signal the immune system in differentiating self from nonself. The major histocompatibility complex involved in the immune response includes class I antigens (A, B) and class II (DR) antigens. Class I antigens (HLAs) are present on the surface of all nucleated cells and platelets, whereas class II antigens are found on the surface of lymphocytes. Each person has six A-, B-, and DR-locus antigens that are inherited as a haplotype (ie, a single unit), receiving one HLA haplotype from each parent. Individuals have two HLA haplotypes, one for each chromosome. Offspring then share one haplotype with each parent, and on average, there is a one in four chance that they will share both haplotypes with at least one

Table 47-4 Criteria, Contraindications, and Evaluations in Transplantation

Organ	Specific Criteria	Contraindications	Specific Evaluation
Kidney	• End-stage or near end-stage renal failure (defined as a glomerular filtration rate of <10 mL/min) • Pre–end stage preferable for some patients (ie, children, patients with diabetes mellitus, and those for whom there is a living donor)	• Severe or uncorrectable coronary artery disease, peripheral vascular disease, or pulmonary disease • Severe cardiomyopathy	• Voiding cystourethrogram to evaluate for obstruction or reflux (medical history dependent) • Cardiac evaluation (age and medical history dependent)
Liver	• Malnutrition • Severe blood clotting abnormalities • Variceal bleeding • Hepatic encephalopathy • Severe, intractable ascites • Severe, intractable pruritus	• Multiple uncorrected congenital anomalies • Advanced cardiopulmonary disease • Severe pulmonary hypertension	• Abdominal computed tomography (CT) scan (to detect hepatoma) • Doppler ultrasound (to identify patency of portal vein) • Liver disease studies and autoimmune markers, such as ceruloplasmin, carcinoembryonic antigen, alpha-fetoprotein, antimitochondrial and antinuclear antibody • Endoscopic retrograde cholangiopancreatography/cholangiogram (if indicated, usually for patients with cholestasis) • Liver biopsy (if indicated) • Upper and lower endoscopy (if indicated)
Pancreas	• End-stage renal failure (combine kidney and pancreas transplant) • Absence of (or corrected) coronary artery disease	• Severe or uncorrectable coronary artery disease, peripheral vascular disease, or pulmonary disease • Previous major amputation • Blindness (not absolute contraindication) • Severe cardiomyopathy	• Thallium stress test or coronary angiogram • Cardiology consult • Gastric emptying study • Ophthalmology evaluation • Endocrine studies: glycosylated hemoglobin, serum amylase and lipase, islet cell antibody, urine, and serum peptide measurements
Heart	• Cardiac disease, New York Heart Association Class IV (or advanced III) • Condition not amenable to other forms of medical or surgical therapy • End-stage cardiac disease with less than a 25% likelihood of survival at 1 y without a transplant • Patients with potentially fatal dysrhythmia not amenable to other therapies	• Fixed pulmonary hypertension with pulmonary vascular resistance: more than 6–8 Wood units (more than 480–640 dynes/s/cm^{-5} or pulmonary arteriolar gradient >15 mm) • Recent unresolved pulmonary infarct (increased posttransplant risk for pulmonary infection) • Advanced or poorly controlled diabetes mellitus	• Right heart catheterization; full cardiac catheterization if indicated • Cardiopulmonary exercise testing (MVO_2) • Pulmonary function tests, including diffusion capacity (DLCO) • Cardiac rehabilitation consultation • Multigated acquisition (MUGA) analysis or echocardiogram
Lung	• Untreatable end-stage pulmonary disease (parenchymal or vascular) • Medical therapy ineffective • Estimated survival (without lung transplant) less than probability of survival with lung transplant	• Significant coronary artery disease • Poor nutritional status (ie, <10%–15% of ideal body weight) • Previous cardiothoracic surgery • Corticosteroid use >15 mg/d • Ventilation dependency	• Quantitative ventilation/perfusion scan • Cardiac evaluation • Full pulmonary function testing, including DLCO, arterial blood gases (ABGs), lung volume • 6-min walk test (rehabilitation assessment) • Nutritional assessment

(continued on page 1055)

Table 47-4 Criteria, Contraindications, and Evaluations in Transplantation (continued)

Organ	Specific Criteria	Contraindications	Specific Evaluation
Hematopoietic stem cells	• *Malignant disorders*: replacement of hematopoietic and immune system destroyed by high-dose chemotherapy or radiation with new immune system that can recognize malignant cells as foreign and mount immunological response against tumor • *Nonmalignant disorders:* replacement of an immune or hematopoietic system that is either defective or has failed	• Poor or no response to conventional-dose chemotherapy for malignant disorders (exception is acute leukemia that fails to respond to induction therapy [primary induction failure]; high-dose chemotherapy and allogeneic transplant is an accepted indication) • Poor performance status (using Karnofsky Performance Status scale to assess physical functioning) • Advanced cardiopulmonary or renal disease (left ventricular ejection fraction <50%; DLCO <70; creatinine clearance, 60 mL/min [exception may be multiple myeloma patients]) • Brain metastasis • Age >70 y	• Disease restaging, including CT scans, nuclear medicine scans, bone marrow aspirate and biopsy, lumbar puncture, immunoglobulin levels, cytogenetics, molecular diagnostics, and measures of minimal residual disease • DNA procurement for future engraftment studies • ABO and Rh typing • Human leukocyte antigen (HLA) typing and HLA-matched platelet transfusion support (allogeneic transplant patients only) • Chest x-ray, ECG and MUGA scan, pulmonary function tests, including DLCO, 24-h urine for creatinine clearance • Baseline CT scans of chest and sinuses, particularly if there are symptoms or a history of repeated infections • Dental evaluation, including full mouth x-rays and cleaning • Sperm/fertilized embryo banking • Autologous stem cell backup if patient is undergoing unrelated or mismatched transplantation • Consultations with radiation therapy and infectious disease

of their siblings. There is also a one in four chance that they will share neither haplotype with their siblings. Many possible alleles occur at each locus, resulting in a large number of HLA combinations. Therefore, it is rare that unrelated people have identical antigens.

The higher the number of antigens that match, the higher the likelihood of compatibility, and the lower the risk for rejection. A six-antigen match is associated with the greatest potential for successful transplantation. HLA matching is performed for both solid organ and hematopoietic stem cell transplants. It is most important in kidney and stem cell transplantation. Transplantation requires the suppression of the normal immune response with the postoperative administration of antirejection medications to prevent graft rejection. The greater the similarity of the donor and recipient tissue type, the less likely the occurrence of rejection.

In the case of living related donors, a direct white blood cell (WBC) cross-match may be performed. The sera of the donor and the recipient are tested and evaluated for cell death. For those patients not receiving living related donation, screening is routinely performed against a pool of lymphocyte samples from multiple random donors against the sera of the recipient. The percentage of samples to which the recipient reacts is referred to as the panel reactive antibody (PRA) percentage. A high PRA is predictive of a high risk for rejection, and a prospective cross-match, such as is used in living donors, would be advised. PRA should be repeated monthly because the titer may change from time to time.

Blood transfusions are avoided if possible in patients awaiting organ transplantation because of the risk for antibody production and a resultant high PRA or positive cross-match between donor and recipient. If blood transfusions are necessary, leukocyte-filtered blood should be administered.

Hematopoietic Stem Cell Transplantation

Selection of a donor for HSCT is based on the type and stage of the underlying disease, age, comorbidities, and availability of an appropriate HLA- and MLC-matched donor. MLC matching is performed to observe for interaction between the potential donor's cells and recipient cells. Low reactivity indicates greater compatibility.

There are many sources of hematopoietic stem cells. The types of HSCT may be differentiated in terms of the hematopoietic stem cell donor, the method used to collect the cells, and the intensity of the conditioning regimen (Box 47-1).

For patients who receive hematopoietic stem cells from another person (ie, allogeneic transplant), donor selection is based on the availability of HLA- and MLC-matched donors, who may or may not be related. A related donor is usually a sibling (siblings have the greatest chance of matching on both HLA and on other minor and as yet unrecognized antigens). If more than one donor is HLA-identical to the patient, donor selection is based on sex compatibility with the patient, ABO

BOX 47-1 Types of Hematopoietic Stem Cell Transplantation

Differentiated based on *donor* source for stem cells
Autologous—self
Syngeneic—identical twin
Allogeneic—nonself
- Related
- Unrelated (National Marrow Donor Program)

Cord blood
- Related
- Unrelated (cord blood bank)

Differentiated based on *method* of collecting stem cell
- Bone marrow harvest
- Peripheral blood stem cell collection by apheresis

Differentiated based on *intensity* of conditioning regimen
- Myeloablative: high doses of chemotherapy and sometimes radiation therapy given to destroy hematopoietic and immune systems of recipient. Transplantation of new stem cells allows hematopoietic and immune reconstitution. High morbidity and mortality rates restrict this treatment to younger patients and those in good medical condition.
- Reduced intensity: lower chemotherapy doses (those that do not fully destroy patient's own hematopoietic and immune systems) are given along with immunosuppression to facilitate engraftment of donor hematopoietic cells. Significant long-term risks for infection and chronic graft-versus-host disease (GVHD) persist.

compatibility with the patient, negative viral titers, overall health, younger donor age, minimal donor exposure to blood products, and donor nulliparity because all these factors are associated with an improved outcome of HSCT.

If the patient does not have a suitable family donor, a search for an unrelated donor may be undertaken. The National Marrow Donor Program (NMDP) is a federally funded registry that coordinates the donor search and matching process. The NMDP maintains the world's largest and most diverse registry of more than 6 million volunteer blood stem cell donors and more than 60,000 cord blood units donated by parents after their infant's birth. Umbilical cord blood is another potential stem cell source, particularly in pediatric allogeneic transplantation. The NMDP also works with the American Red Cross and with international registries to access 4 million additional donors and cord blood units around the world.

A difference in ABO blood groups between patient and donor does not interfere with donor selection; however, it does present unique clinical problems. The hematopoietic stem cell product may have to be depleted of red blood cells (RBCs) to prevent, during infusion, a hemolytic reaction caused by ABO antibodies still circulating in the patient's bloodstream. After engraftment and approximately 100 days after transplantation, the patient will seroconvert to the ABO type of the donor.

Living Donors

Living donors are increasingly being used in kidney, liver, pancreas, and lung transplantation. Living donors are used exclusively in HSCT. There is an increase in the use of living organ donors, but there is a dire shortage of organs for transplantation. The number of transplantation candidates is growing, and the number of cadaveric organ donors has remained relatively constant.

Once identified, a potential donor has a thorough medical evaluation to determine that the organ functions normally, there is no underlying disease, and donation would not jeopardize the donor's well-being in any obvious way. After successful completion of this evaluation, a living donor transplantation may occur.

People continue to raise ethical questions about the use of living donors. Long-term studies of living donors have shown that the risks and adverse effects of donation are rare, and, in fact, some donors report beneficial psychological effects from donating. However, some question the risk of coercion in living donors, especially when the donor is the parent of a child who will die without a transplantation. To ensure freely given and informed consent, there may be an assessment by a psychiatrist and involvement of a non–transplant-related physician, together with education and counseling of the donor.

Kidney Donor

Historically, living donors have been blood relatives because tissue matching was considered more likely. However, more recently, living kidney donors have been spouses and friends, and the results have been comparable with those obtained with living blood-related donors. Although either kidney may be used for transplantation, the left is preferred because the left renal vein is longer than the right.[13]

Liver Donor

Living donor liver transplantation involves the removal of a portion of the liver from a living adult for transplantation into a recipient. The 1-year graft survival rate in the United States is 85%.[10]

Pancreas Donor

Transplanting part of the pancreas from a living person is rarely performed. The donor must not be at risk for diabetes mellitus.

Lung Donor

Recently, the use of living related donors in lung transplantation has been successful. Either the lobe of one lung from one parent is transplanted into the child, or one lobe from each parent is used for a bilateral lobar transplantation. The major advantage of lobar transplantation is that it enables children to have the transplantation either at a time when they are in the best condition or when they become critically ill and a cadaveric donor is unavailable.

Cadaveric Donors

If a cadaveric donor is needed, the recipient is placed on the national waiting list. The National Organ Transport Act was designed to improve the organ matching and placement process. The act outlawed the sale of human organs and authorized grants to establish and operate organ procurement

organizations (OPOs). The United States is divided into approximately 60 areas; an OPO is responsible for recovering and transporting organs to transplantation hospitals in each area. The United Network for Organ Sharing (UNOS) is the private, nonprofit organization that administers organ waiting lists and allocates organs throughout the United States on behalf of the recipients.[11]

Patients are placed on the UNOS national list based on blood type and listing date. The size of hearts, lungs, and livers is important for donation. The waiting time varies by organ. Patients awaiting heart transplantation are risk stratified based on condition and classified according to status. Those awaiting heart transplantation who require inotropic medications or ventricular assist devices may have a higher priority (status 1) than those waiting at home on stable oral heart failure medications (status 2). Patients awaiting lung transplantation are ranked using a new UNOS-developed lung allocation system that uses medical information specific to each patient to estimate the severity of illness and chance of success following transplantation. The UNOS score is used to prioritize recipients who are awaiting a lung transplant. A candidate with a higher lung allocation score receives higher priority for a lung offer when a compatible lung becomes available.[11] Patients awaiting liver transplantation are also risk stratified based on the model for end-stage liver disease (MELD) score. Status rankings 1, 2A, 2B, and 3 are used based on the severity of the disease process. A patient who is projected to live less than 7 days without transplantation is status 1, whereas a patient who is living at home with chronic liver disease is status 3.[11]

Despite the continued need for transplantations, the supply of donor organs remains inadequate. Currently, according to UNOS, about 107,000 patients are awaiting organ transplantation in the United States.[11] The Scientific Registry of Transplant Recipients reported that in 2007, there were 14,339 organ donors; this number includes living and deceased donors.[10] In 2008, the reported conversion rate, which is the ratio of actual donors to identified eligible donors multiplied by 100, was 66%.[14] Lack of consent to a request for donation is the primary cause of the gap between the number of potential donors and the number of actual donors.

A major factor in the discrepancy between potential and actual donors is lack of education for potential donor families.[15] When a patient is determined to be brain dead, or support is withdrawn from a patient who is not brain dead, many hospitals alert the local OPO as a matter of policy. In some larger institutions, a nurse with advanced training in the area of organ donation and family support is trained as a donor advocate. The role of this nurse is to support the family in the grieving process while initiating the discussion of organ donation. It is important that all potential organ donors be identified. Often, potential donors are victims of trauma, cerebral aneurysm, or a variety of other circumstances. Potential donors may be precluded from donating solid organs for reasons, such as advanced age, infection, or coma, though such donors may be considered for donation of the cornea, skin, or cardiovascular tissue (such as heart valves or portions of the aorta).

Determination of Death

With current technology, death can be determined in two ways. The absence of cardiopulmonary function is the better-known method; however, the absence of brain function (brain death) also is a common method of determining death (see Chapter 36 for neurological criteria for determining death). Most patients who are organ donors are pronounced dead based on the absence of brain function. The critical care nurse should be familiar with the laws in his or her state related to "brain death" and with the institutional policies for the determination of death.

Role of the Nurse

Critical care nurses are an integral part of the organ donation team. Almost all organ donors die in critical care units; therefore, the critical care nurse is a key person in identifying potential donors. Moreover, the nurse plays an important role as advocate by making certain that all efforts are made to determine and act on the patient's wishes regarding donation. Nurses also play a vital role in supporting the family psychologically, particularly when they are trying to accept the donor's death. The role of the donor coordinator has developed to allow a nurse with specialized skills to interact with the potential donor's family during the process and to provide support for the nursing staff caring for the donor. When a decision is made for organ donation, the nurse also plays an important role in supporting the donor physiologically.

The care of the potential donor, once identified, becomes the responsibility of the OPO. A nurse who is specially trained to maintain hemodynamic stability of the donor works with the bedside nurse to care for the patient. It is essential to maintain hemodynamic stability so that the vital organs are perfused adequately. Given the massive hemodynamic shifts seen following brain death, hemodynamic management occurs in two phases. In the first phase, hemodynamic surges consequent to endogenous catecholamine mobilization produce hypotension. Short-acting agents, such as nitroprusside or esmolol, which are easily titrated and have a short duration of action, are used to control blood pressure and heart rate. Phase 2 begins after depletion of catecholamine stores, at which time the donor experiences a dramatic fall in blood pressure. Initial intervention in phase 2 involves rapid replacement of circulating blood volume with crystalloid or colloid intravenous (IV) fluids. Aggressive fluid resuscitation in this phase must account for the relative fluid volume deficit produced by a vasodilatory state from endogenous catecholamine depletion as well as the systemic inflammatory response.[16] The goal of blood pressure management in phase 2 should be to sustain a mean arterial pressure of 70 mm Hg. Recommended pharmacological therapy for vasopressor support includes dopamine or dobutamine, with target doses of less than 10 mcg/kg/min if the focus is cardiac donation. In other instances, norepinephrine may be used, with a target dose of 0.5 to 5.0 mcg/min. The administration of vasopressors and inotropes, in addition to providing cardiovascular support for the organ donor, promotes a lower incidence of kidney rejection and better long-term graft survival.[17] As the need for vasopressors and inotropes increases, the possibility for multiorgan recovery decreases.

Optimal pulmonary management, including suctioning for airway clearance and aspiration precautions, is necessary. Ventilator management should include close titration of fluids to minimize the risk for pulmonary edema. Positive end-expiratory pressure should be less than 5 cm H_2O, and

peak airway pressures should be maintained at less than 30 mm Hg if possible. Ventilation with tidal volumes of 10.0 to 12.0 mL/kg may maintain minute ventilation and attenuate risk for barotrauma.[18]

It is also essential to assess urine output hourly to detect diabetes insipidus. This is common in organ donors and is caused by failure of the posterior pituitary to produce or release antidiuretic hormones. This can lead to electrolyte imbalances. It may be necessary to order aqueous vasopressin or desmopressin acetate to reduce urine output and help maintain fluid balance.

Laboratory results, such as electrolytes, CBC, liver and renal function tests, and arterial blood gases (ABGs) values, are necessary to assess organ function and determine appropriate intervention. An ECG and echocardiogram are required for heart donation. Serial chest radiographs, bronchoscopy, sputum for Gram stain and visual inspection at the time of organ procurement are required for lung donation.

Role of the Donor Coordinator

The role of the donor coordinator developed as a result of the disparity between potential donors and the numbers of patients awaiting organ donation. The donor coordinator introduces the concept of organ donation by a nurse not associated with transplantation. This approach results in the highest rates of consent.[16] Kidneys are the most commonly transplanted organ, and heart, lung, liver, pancreas, intestine, cornea, skin, bone, and other organs or tissue may also be donated. The donor coordinator is involved in coordinating and procuring all transplantable organs. In addition, the donor coordinator usually ensures that the family has the information necessary to give informed consent and provides them with access to bereavement support. The donor coordinator also serves as a resource for the health care team and as a liaison between the transplantation program and the critical care area. Cooperation between the critical care staff and the transplantation program helps ensure that the option of donation is offered to families of all potential donors.

Preservation Time

There is a broad range of acceptable preservation times for organs. However, the goal is to transplant organs as soon as possible. Kidneys can be stored for up to 48 hours using pulsatile perfusion preservation and for 24 to 36 hours using cold storage. Livers can be stored for up to 20 hours, pancreas up to 12 hours, and hearts and lungs for 4 to 6 hours. To decrease cellular injury, organs are stored in a solution and kept in ice. The preservative solutions used are different for each organ and are based on the metabolic needs of the organ, with center-specific variability. The focus of preservation is to protect the organ from ischemic injury.[19]

▲ Assessment and Management in Organ Transplantation

The role of the transplant coordinator extends across the continuum of care from preevaluation of potential recipients through transplantation and follow-up. This person is responsible for coordinating the evaluation and teaching the recipient and family about the evaluation testing process, the listing process, and organ allocation. A major contribution is reviewing preoperative through postoperative procedures, the immunosuppressive regimen, and follow-up care. In many institutions, a nurse practitioner, who also provides medical care and follow-up for the patients, fulfills this role.

Preoperative Phase

The immediate preoperative phase, which is usually only a matter of hours, includes comprehensive laboratory studies, chest radiograph, ECG, and, for kidney transplant recipients, dialysis within 24 hours of transplantation. Laboratory studies usually include CBC, prothrombin time (PT), partial thromboplastin time (PTT), electrolytes, blood glucose, blood urea nitrogen (BUN), creatinine, liver function tests, type and cross-match, and urinalysis.

Surgical Procedure

Kidney

Typically, the kidney is placed retroperitoneally in the iliac fossa. The hypogastric or internal artery and the external iliac vein are usually used for vascular anastomosis. When it is mechanically difficult to access these vessels, as with children, it may be necessary to anastomose the renal vessels to the inferior vena cava and aorta.

Two common types of ureteral anastomoses can be performed. In the first procedure, the donor ureter is implanted into the recipient's bladder by a vertical cystotomy and a submucosal antireflux tunnel because the ureter lacks innervation and normal peristalsis. In the second type, used less frequently, the donor kidney is anastomosed at the ureteropelvic junction to the recipient ureter. An indwelling catheter is used for both types of anastomoses, and occasionally, a ureteral stent may be used. In either case, hematuria is present for several days. In the first, more common procedure, clots may be seen in the urine because of the vascular nature of the bladder. In the second, less common, procedure, the urine changes to pink within the first postoperative day because there are no sutures in the bladder.

Liver

The liver is transplanted orthotopically, that is, in its normal position after the native liver is removed. Four vascular anastomoses must be performed: the suprahepatic vena cava, the infrahepatic vena cava, the portal vein, and the hepatic artery (Fig. 47-1). Then the liver is reperfused, and the bile duct is anastomosed, usually to the recipient bile duct.[20] A T-tube is usually inserted. During liver transplantation, a rapid infusion system is used for administering blood and blood products, a cell saver is often used to limit the amount of banked blood required, and a pump for venovenous bypass is often used in adults to return blood to the heart. This is performed by inserting a catheter into the saphenous or femoral vein and another into the axillary vein (usually on the left side), which allows blood to circulate from the lower extremities back to the heart. Surgery usually takes between 8 and 16 hours.

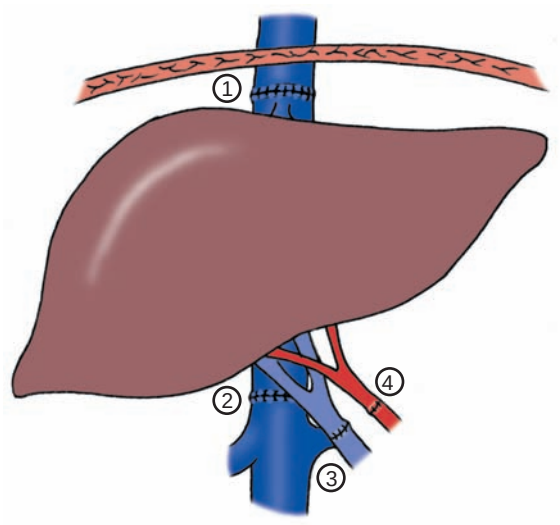

FIGURE 47-1 ▲ Diagram of vascular anastomoses in liver transplantation: (*1*) suprahepatic vena cava, (*2*) infrahepatic vena cava, (*3*) portal vein, and (*4*) hepatic artery.

Heart

Procedures for heart transplantation include orthotopic and heterotopic approaches. Orthotopic transplantation involves replacing the damaged heart with the donor heart. With heterotopic transplantation, the patient's own heart is not removed. The donor heart is positioned so that the chambers and blood vessels of both hearts can be connected, thus allowing the donor heart to assist the damaged heart.

ORTHOTOPIC TRANSPLANTATION. Orthotopic heart transplantation (OHT) is the most common heart transplantation performed. The surgeon excises the recipient's heart and implants the donor heart in its place. A median sternotomy incision is made, cardiopulmonary bypass is initiated, and the recipient's heart is removed by incising the left and right atria, pulmonary artery, and aorta. The Lower and Shumway technique has been the gold standard for OHT. The atrial septum and posterior and lateral walls of the recipient's atria are left intact, including the areas of the sinoatrial node, inferior and superior venae cavae to the right atrium, and pulmonary veins to the left atrium. The remnant atria serve as anchors for the donor heart.

The donor atria are trimmed to preserve the anterior arterial walls, sinoatrial node, and internodal conduction pathways. Then anastomoses are made between the recipient and donor left and right atria, the pulmonary arteries, and the aortas. Atrial and ventricular pacing wires are placed at the time of surgery so that temporary pacing can easily be initiated. Cardiopulmonary bypass is weaned off, and the donor heart assumes the role of providing the cardiac output (Fig. 47-2A).

An alternative to the atrial-to-atrial cuff technique is the bicaval technique (see Fig. 47-2B), which preserves atrial anatomy disrupted by the Lower and Shumway technique. The donor atria are intact, and the anastomoses are between the donor and recipient inferior and superior venae cavae rather than the atria. This avoids the loss of atrial anatomy, which has been responsible for the development of posttransplantation complications, such as mitral and tricuspid regurgitation, atrial thrombus formation, and tachydysrhythmia.[21]

HETEROTOPIC TRANSPLANTATION. Heterotopic transplantation, or piggyback procedure, is an infrequently used technique. The recipient's heart is left in place, and the donor heart is placed next to it in the right chest. The two hearts are connected in parallel by anastomoses made between the donor and recipient left and right atria, aortas, and pulmonary arteries using a synthetic tube graft. By allowing blood to flow through either or both hearts, two functional hearts work together to provide the cardiac output (Fig. 47-3).

Heterotopic transplantation may be used in patients with pulmonary hypertension in whom the donor heart alone would not have a strong enough right ventricle to pump against the increased pulmonary vascular resistance. It can also be used as a lifesaving procedure in urgent cases if the only available donor heart is too small for the size of the recipient. Limitations of heterotopic transplantation include thromboembolism from the native heart with need for anticoagulation, limited space in the chest cavity, and, in ischemic heart disease, ongoing angina and the possibility of ischemia-induced dysrhythmias in the native heart. The survival rates are less favorable for heterotopic transplantation than for orthotopic transplantation.

Pancreas

Transplantation of the entire pancreas is performed most commonly. Pancreas transplantation may be performed in combination with kidney transplantation for recipients with end-stage renal disease secondary to diabetes mellitus. The pancreas and kidney may be transplanted at the same time or months apart. Clinical trials are ongoing to determine the feasibility and outcomes of islet cell transplantation for patients with type 1 diabetes not controlled with insulin. With this experimental procedure, only the insulin-producing islet cells are transplanted. The recipient still requires immunosuppressive medications to prevent rejection.

The pancreas is placed into a heterotopic position, usually the right iliac area. Techniques vary for vascular and exocrine anastomoses. The most controversial aspect of the surgical technique is the approach for draining exocrine secretions. The exocrine duct may be occluded, or exocrine secretions may drain either into the small bowel or bladder. There is no consensus about the best approach, and all have advantages and disadvantages.

Lung

Both single- and double-lung transplantations are performed. In single-lung transplantations, the left lung mainstem bronchus is longer, which makes the procedure easier technically. The preferred lung is based on perfusion abnormalities (as determined by ventilation–perfusion scan) and functional abnormalities. Anastomoses are made at the mainstem bronchus, pulmonary artery, and cuff of atrium containing pulmonary veins. Cardiopulmonary bypass is not always necessary and depends on the patient's pulmonary artery pressure, blood pressure, and gas exchange. Incision is made at the fifth intracostal space using a posterior lateral thoracotomy for single-lung transplantations, whereas a median sternotomy incision or a clamshell incision is made for double-lung transplantations. Surgeons telescope the recipient's bronchus into the donor lung or vice versa, or perform an end-to-end

anastomosis with omentopexy in which an omental flap is wrapped around the tracheal anastomosis to increase blood supply to the area.

Postoperative Phase

Immediately after surgery, transplant recipients require care in a closely monitored area until their condition stabilizes. Kidney transplant recipients often go to a postanesthesia care unit and then directly to a transplant unit. Other organ recipients go to an intensive care unit (ICU) from the operating room. When a patient arrives in the postanesthesia or intensive care area, the nurse makes the following assessments:

- Blood pressure, heart rate, respirations, oxygenation and ventilator settings, temperature, central venous pressure, and cardiopulmonary hemodynamics. In renal transplant recipients, it is necessary to take blood pressure on an extremity that does not have a functioning vascular access site because even momentary interference with arterial blood flow may lead to access malfunction.
- Patient's level of consciousness and degree of pain
- Number of IV and arterial lines, noting the site, type of solution, and flow rate

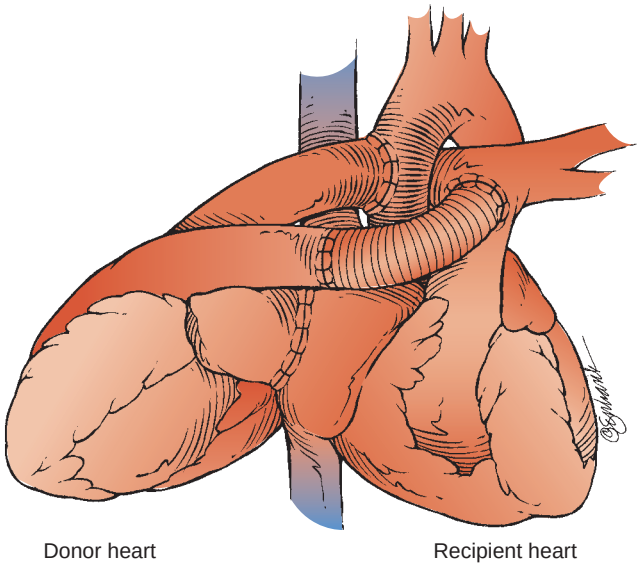

FIGURE 47-3 ▲ Heterotopic method of heart transplantation. The donor heart is anastomosed with a Dacron graft to the recipient's heart, resulting in this ECG tracing. Note the "extra" QRS at an independent rate. (From Smeltzer SC, Bare BG: Brunner and Suddarth's Textbook of Medical-Surgical Nursing, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2004, p 775.)

- Abdominal or chest dressing for drainage, noting the presence of drains and amount and type of drainage
- Presence of bladder and possible ureteral catheters and patency and urinary drainage
- Attachment of nasogastric tube to appropriate drainage system and amount and character of drainage
- Most recent hemodynamic and intraoperative laboratory results

Kidney

Care of the kidney transplant recipient emphasizes assessing renal function and administering immunosuppressive therapy. Therefore, answers to the following questions help guide care:

- Are the patient's own kidneys present in addition to the graft, and if so, how much urine do they produce daily? This information helps determine how much urine is from the transplanted kidney.
- What are the preoperative results of laboratory tests (BUN, creatinine, hematocrit)?
- How much and what kind of IV fluid has the patient received?
- What immunosuppressive drugs were given before or during surgery? What immunosuppressive therapy should be given after surgery?

Nursing responsibilities also involve the following:

- Observing the function of the transplanted kidney
- Monitoring fluid and electrolyte balance
- Helping avoid sources of infection
- Detecting early signs of complications
- Supporting the patient and family through the recovery phase

In addition, at regular intervals, the nurse evaluates the patency and the vascular access used for dialysis. This is done by placing either fingers or a stethoscope directly over the access site and feeling or listening for a characteristically loud, pulsating noise called a *bruit*. If the patient has been maintained on peritoneal dialysis and the catheter is in place, it is essential that the catheter system is sterile and capped.

RENAL GRAFT FUNCTION. The amount of urine produced by the transplanted kidney varies from a large amount (200 to 1,000 mL/h) to small amounts (<20 mL/h). The degree of renal function is related to ischemic injury in the donor kidney, usually from either hypotensive periods in a cadaveric donor or from the time the kidney is stored outside the body (preservation time). Renal function is better when kidney preservation time is less than 24 hours. Most posttransplantation dysfunction is reversible but may take up to 4 weeks to return to normal.

Assessments of renal function include periodic BUN and creatinine levels and, in some centers, a β_2-microglobulin level. The glomerular basement membrane readily filters this low–molecular-weight globulin, which the proximal renal tubules reabsorb and metabolize almost completely.

A renal scan is a radionuclide test used to determine renal perfusion, filtration, and excretion. It is usually performed in the first 24 hours to obtain baseline data and then periodically thereafter when laboratory values or clinical changes suggest an alteration in renal function.

URINARY DRAINAGE PROBLEMS. When a change in urinary output occurs, such as a large volume in 1 hour and a diminished amount in the next, mechanical factors that interfere with urinary drainage should be suspected. Clotted, kinked, or compressed tubing in the urinary drainage system may be the cause of the decreased output. When the catheter is occluded by a clot, the patient may complain of pain, feel an urgency to void, or have bloody leakage around the catheter. Milking is the preferred way to dislodge clots because irrigation, even under aseptic conditions, increases the risk for infection. However, gentle irrigation with strict aseptic technique may be necessary. Small amounts of irrigant (30 mL or less) are recommended because patients commonly have small bladders. Vigorous irrigation also could cause extravasation at the ureteral anastomosis site.

URINARY LEAKAGE. Urinary leakage on the abdominal dressing and severe abdominal discomfort or distention may indicate retroperitoneal leakage from the ureteral anastomosis site. It is important to report decreased urinary output or severe abdominal pain in the presence of good renal function and adequate pain medication because technical and surgical complications can result in loss of graft function.

HYPERKALEMIA. The most frequent electrolyte disturbance in the acute postoperative phase is hyperkalemia. If the graft functions and excretes a high volume of urine, it is usually also able to excrete the excessive serum potassium created by surgical tissue damage. If the patient is oliguric or anuric after surgery, the serum potassium may increase to

unacceptable levels. Interventions include administration of glucose and insulin to transport potassium into the cell and administration of oral polystyrene sulfonate.

Liver

Immediate postoperative care focuses on hemodynamic stability, adequate oxygenation, fluid and electrolyte balance, adequate hemostasis, and graft function. An arterial line and pulmonary artery catheter are in place. The pulmonary artery catheter readings help monitor cardiac function and fluid status because high cardiac output and low systemic vascular resistance related to the effects of end-stage liver disease continue immediately after surgery.

Vasopressors and additional fluid boluses may be required in the first 24 to 36 hours. Central venous pressure should be maintained at greater than 10 cm H_2O to balance the importance of good cardiac function against the risk for passive congestion of the liver. Hypotension is most often caused by intra-abdominal bleeding. An increase in abdominal girth or excess bloody drainage from Jackson-Pratt drains is indicative of a severe problem.

OXYGENATION. Adequate ventilation is crucial for graft perfusion and helps reduce the risk for pulmonary complications. The critical care team determines ventilator settings, and the nurse monitors the arterial (SaO_2) and mixed venous (SvO_2) oxygen saturations. Pulse oximetry may be used, but severe jaundice may interfere with saturation measurements. Postoperative pleural effusion is common owing to the presence of ascites and risk of injury to the diaphragm during surgery. A chest tube may be required for drainage.

Ventilator support is usually withdrawn when the patient is fully awake. However, if the patient is going to receive a monoclonal antibody, such as muromonab-CD3, the first dose should be given before extubation because there is a risk for pulmonary edema as a reaction to the medication.

COAGULATION. Abnormal clotting factors, bleeding at the site of anastomosis, and impaired graft function may all contribute to problems with hemostasis. Therefore, the nurse monitors PT, PTT, fibrinogen, and factor V level along with the amount, color, and consistency of bleeding from the incision and drainage tubes.

The patient may need infusions of platelets, RBCs, or cryoprecipitate. Blood products should be leukocyte reduced to avoid introduction of CMV, especially if the patient is negative for CMV. It is necessary to take care to avoid overcorrecting coagulation deficiencies, which could lead to vascular thrombosis of the extremities or the graft. As a result of the venovenous bypass system, there is also a risk for phlebitis or thrombosis in the femoral and axillary access site. This may be indicated by ipsilateral swelling in these extremities. Anticoagulation or an inferior vena cava filter may be necessary if deep venous thrombosis develops.

ELECTROLYTE BALANCE. Hyperglycemia; hyperkalemia; metabolic alkalosis; and calcium, phosphorus, and magnesium disorders may occur. Hyperglycemia is an indication that the liver is able to store glycogen and convert it to glucose. Hyperkalemia can indicate nonfunctional hepatocytes and, in turn, a nonfunctional graft. Metabolic alkalosis is related to the citrate in stored blood (metabolized to bicarbonate), hypokalemia, diuretic therapy, and the administration of large volumes of fresh frozen plasma. This usually resolves spontaneously, but hypoventilation in response to the alkalosis may slow weaning from mechanical ventilation. Calcium, phosphorus, and magnesium disturbances primarily result from the administration of fluid and blood products.

Some degree of postoperative renal dysfunction is also common due either to hepatorenal syndrome or hypotension during surgery. In addition, some immunosuppressive medications are nephrotoxic. This can affect fluid and electrolyte balance. On occasion, when dialysis is needed, continuous arteriovenous or venovenous hemofiltration is used because it interferes least with hemodynamic stability.

LIVER FUNCTION. Function of the transplanted liver can range from excellent to primary nonfunction. Although the cause of primary nonfunction is not known, it is believed to be related to preservation injury, and retransplantation is necessary. Liver function is initially assessed by bile production, coagulation factors, and later by liver function tests. Measuring bile production from the biliary drainage tube helps assess the excretory function of the liver and is a good early indicator of graft function. PT and the international normalized ratio (INR) provide a measure of the synthetic function of the liver. Aminotransferases (alanine aminotransferase and aspartate aminotransferase) provide information about the degree of hepatic injury related to preservation. In addition, improvement in the clearance of lactate, encephalopathy, and glucose metabolism are also assessments of liver function. All liver function test results are elevated initially and gradually decrease.

Heart

Postoperative care of the heart transplant recipient is similar to that for any person undergoing cardiac surgery. However, there are several major differences, including changes in cardiac rhythm and function caused by denervation of the donor heart and the potential for right ventricular failure. Only the more common orthotopic transplantation is discussed here.

REMNANT P WAVES. In the standard atrial cuff technique, the recipient sinoatrial node and portions of the recipient atria are left intact at the time of surgery. Therefore, two P waves are usually seen on the ECG. The recipient sinoatrial node initiates an impulse that depolarizes the remnant recipient atria; however, this depolarization wave usually does not cross the atrial suture line. The donor sinoatrial node initiates the impulse that causes depolarization of the entire donor heart and elicits the QRS complex. Because the two sets of atria beat independently of each other, two different P waves may appear on the ECG. Remnant P waves may be identified by their dissociation or lack of relationship to the QRS complexes. They usually occur at a slower rate than the donor P waves, and their rate may speed up or slow down because the remnant P waves are still under autonomic nervous system influence, whereas the donor P waves are denervated. The two sets of atria may also be in different rhythms. For example, the recipient atrial remnants may be in atrial fibrillation while the donor heart is in normal sinus rhythm.

EFFECTS OF DENERVATION. During removal of the donor heart, the nerve supply is severed, resulting in a lack of autonomic nervous system innervation of the transplanted

heart. Because of the loss of vagal influence, the resting sinus rate is higher than normal—usually between 90 and 110 beats/min—and heart rate variations caused by respiration do not occur.

Decreased donor sinoatrial node automaticity can also occur after transplantation as a result of injury to the node during procurement, transport, surgical procedure, or postoperative edema of the atrial suture line. Usually, these problems resolve within 1 to 2 weeks after transplantation, but temporary pacing may be needed to maintain an adequate heart rate. Atropine, which blocks vagal stimulation, is ineffective in treating bradydysrhythmias in the transplanted heart because there is no parasympathetic innervation. If the sinus rate is reduced, junctional rhythms can occur earlier than normal because of the loss of vagal tone.

Normal cardiovascular reflexes are also removed by denervation. In the normal heart, the body's increased metabolic demands cause direct compensatory stimulation of the heart by the sympathetic nervous system, which immediately increases heart rate, contractility, and cardiac output. Because direct sympathetic nervous system stimulation of the transplanted heart is absent, this response is mediated through release of circulating catecholamines from the adrenal medulla. Therefore, increases in heart rate, contractility, and cardiac output occur much more slowly than normal. With exercise, heart rate and cardiac output increase gradually over 3 to 5 minutes and remain elevated longer after exercise. Prolonged warm-up before and cooldown after exercise help compensate for these changes.

Orthostatic hypotension can occur because the normal, immediate reflex tachycardia, which compensates for venous pooling with position change, does not occur. When patients begin ambulating, they should be cautioned to change position gradually to prevent orthostatic hypotension.

Because of denervation, the cardiac effects of medications normally mediated by the autonomic nervous system are abnormal. Atropine, which increases heart rate by blocking parasympathetic influence, is ineffective. Isoproterenol, a positive chronotropic agent, has been widely used because it stimulates myocardial receptors directly for pharmacological management of symptomatic bradydysrhythmias. However, isoproterenol is not widely available. Instead, dobutamine and epinephrine, along with temporary epicardial pacing, are frequently used.

Digitalis preparations are ineffective in decreasing the heart rate or increasing the atrioventricular nodal refractory period because these effects are mediated primarily by the parasympathetic nervous system. Digitalis does increase myocardial contractility by its direct action on myocardial cells. Beta-blocking drugs or calcium channel blockers (eg, verapamil) can be used to control supraventricular tachydysrhythmias in the transplanted heart; carotid sinus pressure, the Valsalva maneuver, and digitalis are ineffective.

Finally, denervation prevents transmission of pain impulses from ischemic myocardium to the brain, so the patient does not experience angina. Severe myocardial ischemia or infarction may go unnoticed. For this reason, ECG stress testing and annual coronary angiography or coronary vascular ultrasonography are usually performed.

POTENTIAL FOR VENTRICULAR FAILURE. Posttransplantation ventricular failure, causing decreased cardiac output, occurs for the same reasons as in other cardiac surgical procedures. In addition, a prolonged ischemia time, inotropic support of the donor, or rejection can cause myocardial depression in a transplant recipient.

Right ventricular failure is the most common cause of primary graft failure after transplantation. Reasons for right-sided heart dysfunction are not entirely clear but are related to acute changes in pulmonary vascular resistance. The newly transplanted heart is required to work against elevated pulmonary pressures secondary to long-standing heart failure in the recipient.[22] Postoperative changes in pH or ABGs can cause pulmonary vascular spasm. Both pulmonary hypertension and spasm increase the pulmonary vascular resistance or resistance to ejection of blood by the right ventricle. The normal right ventricle of the donor heart may be unable to increase its output acutely to overcome a high preexisting pulmonary vascular resistance. Signs of acute right ventricular failure include elevated central venous pressure and jugular venous distention. Left ventricular cardiac output decreases because the right ventricle is unable to pump enough blood through the lungs.

Treatment of posttransplantation right-sided heart failure involves the use of drugs to decrease right heart afterload (dobutamine, milrinone, inhaled nitric oxide). Inhaled nitric oxide, a direct pulmonary vasodilator, may be administered through the ventilator circuit, thereby avoiding the systemic affects of the drugs that are administered IV. Conditions that increase right heart afterload (eg, hypoxia, acidosis, excessive blood transfusions) should be avoided.

Pancreas

The critical care of a pancreas transplant recipient is comparable to the critical care of any patient who has had major abdominal surgery. The differences relate to pancreatic function, the type of surgical procedure, and secondary effects of diabetes mellitus.

Blood glucose response usually returns within the first few postoperative hours; however, an insulin drip may be required until the blood glucose level is normal. Pancreatic function is monitored by glucose levels before and after meals, by the results of glycosylated hemoglobin, and sometimes by glucose tolerance testing. Even minor abnormalities may indicate rejection or vascular thrombosis of the graft.

When a section of duodenum is used for exocrine drainage, the prevention of infection is particularly challenging. Antibiotics are usually administered until the intraoperative culture of the duodenum is reported. When the bladder is used for exocrine drainage, bicarbonate wasting in the urine may occur. The standard method for pancreatic transplantation involves drainage of exocrine secretions into the urinary bladder with venous outflow into the systemic circulation. Despite the high success rate associated with this approach, it often leads to complications, which can include urinary tract infections, reflux pancreatitis, metabolic acidosis, and hyperinsulinemia. Depending on the patient's ability to void, the catheter may be needed for several days or possibly weeks if there is long-standing neurogenic bladder dysfunction secondary to diabetes mellitus. The surgical approach remains center and surgeon specific.

It is necessary to keep a nasogastric tube in place until bowel activity returns. This may take 3 to 5 days if there is diabetic gastroparesis. If the nasogastric tube remains in place, enteral or parenteral feedings may be necessary.

Lung

On arrival to the ICU, the lung transplant recipient is anesthetized, intubated, and mechanically ventilated. Usually, extubation occurs 24 to 36 hours after surgery when the patient's oxygenation is optimized and secretions are minimal. Extubation usually proceeds more quickly in patients with emphysema and a single-lung transplant than in patients with pulmonary hypertension, who may need a longer intubation period.

The lung transplant recipient does not have a cough reflex because of denervation. Therefore, when suctioning, the nurse avoids inserting the catheter where it can cause damage. The surgical team performs frequent bronchoscopy to ensure intact anastomoses and pulmonary toileting. A common problem in the immediate posttransplantation period is pulmonary edema due to a phenomenon known as "reperfusion" injury. As a result, it is best to maintain the patient in a relatively hypovolemic state for the first few days. Diuresis begins when the patient is hemodynamically stable.

The lungs are constantly exposed to the outside world, and therefore prevention of infection is especially important after lung transplantation. Antibiotics are given prophylactically and are determined by donor cultures, preoperative serology results, and sputum samples. Patient care measures to prevent infection include giving oral care, encouraging physical activity early in the postoperative course, and performing daily respiratory and chest physiotherapy. Continuous pulse oximetry is used to monitor oxygen saturation, and daily chest radiographs help monitor progress. Infection control measures by staff include washing hands and using aseptic suctioning technique. Staff and visitors with active infections should avoid caring for or visiting the patients.

▲ Assessment and Management in Hematopoietic Stem Cell Transplantation

HSCT involves replacing diseased, destroyed, or nonfunctioning hematopoietic cells with healthy progenitor cells, also called stem cells. Stem cells are primitive hematopoietic cells capable of self-renewal, and they are pluripotent, meaning that they are capable of maturation into an RBC, WBC, or platelet. These stem cells may be collected directly from the bone marrow spaces by a bone marrow harvest procedure, or from the peripheral blood, by apheresis. HSCT is an important advance in restoring hematopoietic function in patients whose bone marrow has been destroyed by high-dose chemotherapy and radiation therapy (see Table 47-1, p. 1052).

In both autologous and allogeneic HSCT, peripheral blood stem cells have become the preferred source of hematopoietic stem cells for grafting, although for selected allogeneic HSCT recipients, bone marrow grafting may offer specific advantages over peripheral blood stem cells. Collection of cells through apheresis is easier and less costly and may also result in a more rapid recovery of neutrophil and platelet counts. In unrelated allogeneic transplantation, the source of stem cells may be either a bone marrow harvest procedure or a peripheral blood stem cell collection. Table 47-5 presents a detailed comparison of autologous and allogeneic stem cell transplantation. Box 47-2 outlines the benefits and limitations of the various sources of stem cells for transplantation.

Table 47-5 Comparison of Autologous and Allogeneic Stem Cell Transplantation

	Autologous	Allogeneic
Indications	Hematological malignancies and solid tumors Possible role in treatment of autoimmune disorders Future role in combination with gene therapy to treat genetic disorders and HIV infection	Hematological malignancies, aplastic anemia, congenital bone marrow disorders, immune deficiency states, some inborn errors of metabolism
Source of stem cells	Stem cells collected from bone marrow or peripheral blood of the patient and then reinfused after high-dose conditioning regimen Stem cells given to rescue the patient from hematological toxicity of conditioning regimen	Marrow, peripheral blood, cord blood, family donors, unrelated donors, HLA-matched or partially matched
Preparative regimen	High-dose chemotherapy to eradicate malignant disease	High-dose chemotherapy and sometimes total-body radiation as intensive therapy for malignant disease and to provide immunosuppression to allow engraftment (makes "space" for incoming stem cells)
Posttransplantation treatment	Supportive care, transfusions, growth factors, immune manipulation	Supportive care, transfusions, growth factors, immune manipulation, prophylaxis and treatment of graft-versus-host disease (GVHD)
Risk for infectious complications	Lower risk; infections occur mainly in early posttransplantation period	Higher risk; sustained risk for infection for months or years
Major complications	Preparative regimen toxicity, disease recurrence or progression	Preparative regimen toxicity, disease recurrence or progression, GVHD, immunodeficiency
Treatment-related mortality rate	Usually <5%	5%–30% depending on many patient-, donor-, and disease-related factors

Adapted from Barrett J: In Treleaven J, Barrett AJ (eds): Hematopoietic Stem Cell Transplantation in Clinical Practice. Edinburgh, UK: Elsevier Limited, 2009.

BOX 47-2 Sources of Stem Cells: Benefits and Limitations

Peripheral Blood Stem Cell Collection/Apheresis
- Easier collection for autologous patients and potentially easier for allogeneic donors
- Shorter duration of myelosuppression
- In theory, there is thought to be less tumor contamination from peripherally derived stem cells.
- Incidence of GVHD may be same or higher

Bone Marrow Harvest
- Harvest-related pain
- General anesthesia required
- May be more cost-effective or more convenient for donors

Cord Blood
- Plentiful and relatively easy to harvest if obstetricians are trained
- Inexpensive
- Excellent source to increase pool of unrelated donors
- May be associated with less GVHD
- Currently limited to individuals who weigh less than 50 to 70 kg; with ex vivo expansion, techniques may become more widespread

Stem Cell Harvesting, Mobilization, and Collection

Stem cells are most numerous in the bone marrow spaces, and some circulate in the peripheral blood. The process of harvesting and collecting hematopoietic stem cells differs depending on whether progenitor cells will be obtained through a bone marrow harvest or collected from the peripheral bloodstream.

When stem cells are obtained from the bone marrow, the harvesting procedure is performed in the operating room with the patient anesthetized. Multiple aspirations are obtained from each posterior iliac crest using large-bore needles until a total of 2 to 3 × 10^8 nucleated cells per kilogram of recipient body weight is obtained. The total volume of aspirate is 1 to 2 L. The marrow is placed in a heparinized tissue culture medium and filtered for the removal of fat and bone particles, and the cells are taken directly to the recipient's room for infusion. The bone marrow harvest procedure usually takes 1 to 2 hours. Pressure dressings are applied to the aspirate sites, and the donor is usually admitted to the hospital for overnight observation. The harvest sites may be mildly uncomfortable for 2 to 7 days after the procedure.

Hematopoietic stem cells may also be collected from the peripheral blood. However, because stem cells are not abundant in the peripheral blood, chemotherapy or colony-stimulating factors (CSFs) (granulocyte colony-stimulating factor [G-CSF] or granulocyte–macrophage colony-stimulating factor [GM-CSF]) must be given before collection to drive progenitor cells into the peripheral circulation. This process is termed *mobilization* or *priming*. The chemotherapy that patients receive for stem cell mobilization is also useful for tumor reduction. For related and unrelated donors, colony-stimulating factors alone are used to increase the number of stem cells in the peripheral blood. Protocols vary, but G-CSF or GM-CSF is given by a subcutaneous injection daily. Stem cell collections begin after 4 or 5 days of cytokine injections.

Hematopoietic progenitor cells are collected from the peripheral blood by a method called *leukapheresis*. A commercial cell separator machine collects the progenitor cells and returns the remainder of the plasma and cellular components to the bloodstream. This is performed either through wide-bore double-lumen central catheters or large-bore antecubital IV catheters. The procedure takes approximately 3 to 4 hours, and the number of leukapheresis procedures required is determined by the number of stem cells harvested at each session. The goal is to collect 5 × 10^6 CD34-positive cells per kilogram of recipient body weight. The CD34-positive antigen is an antigen expressed on the surface of early progenitor cells. With autologous hematopoietic progenitor cells, the cells are immediately cryopreserved and stored in liquid nitrogen until the recipient is ready for reinfusion. The donor may experience a transient hypocalcemia reaction with chills, fatigue, tingling in the lips and extremities, and vertigo resulting from the citrate infusion, which is used to prevent clotting of the blood during the procedure. The symptoms can be prevented or treated by taking a calcium supplement.

Conditioning Regimen

After the progenitor cells have been obtained, the recipient begins the conditioning regimen designed to prepare him or her to receive transplanted stem cells. The goal of the conditioning regimen depends in part on whether the transplant is autologous or allogeneic and on the nature of the recipient's underlying disease. In allogeneic transplantation, the purpose of conditioning is to eradicate any malignant disease, eliminate the bone marrow to create a space for the new donor stem cells, and provide sufficient immunosuppression to allow engraftment of the transplanted stem cells. In autologous transplantation, immunosuppression is not required because the recipient of the hematopoietic stem cells is also the donor, and therefore, there is no tissue incompatibility. However, the high-dose therapy is still needed to eradicate malignant disease.

High-dose chemotherapy is based on the hypothesis that increasing the total dose or dose rate will kill more tumor cells, resulting in improved response and survival rates. Drugs with different (ie, nonoverlapping) nonhematological dose-limiting toxicities are combined in maximal doses.[23] Alkylating agents (cyclophosphamide, carboplatin, busulfan, thiotepa, cisplatin, melphalan, carmustine), etoposide, cytarabine, and sometimes total-body irradiation are used to destroy the bone marrow and eradicate disease. The regimen is administered over 2 to 8 days. The individual drugs that may be used in combination as part of the transplant conditioning regimen may have several adverse effects (Table 47-6).

The stem cell recipient is then allowed 1 to 2 rest days to clear the chemotherapeutic agents from the system before the infusion of stem cells. Bone marrow aplasia occurs within days after the conditioning regimen is completed. The acute toxicity from the regimen can last for a few weeks or until engraftment occurs.

Table 47-6 Nonhematological Adverse Effects of High-Dose Therapy Regimens

Drug or Therapy	Adverse Effects
Busulfan	Interstitial pulmonary fibrosis, hepatic dysfunction (including veno-occlusive disease of the liver), acute cholecystitis, generalized seizures, mucositis, skin adverse effects (hyperpigmentation, desquamation, acral erythema), nausea and vomiting
Carmustine (BCNU)	Hepatic, pulmonary, and central nervous system adverse effects, cardiac adverse effects (dysrhythmias and hypotension), nausea and vomiting
Cytosine arabinoside (Ara-C)	Cerebellar toxicity, encephalopathy, seizures, conjunctivitis, skin adverse effects (rash, acral erythema), nausea and vomiting, diarrhea, renal insufficiency, liver function abnormalities, pancreatitis, noncardiogenic pulmonary edema, fever, arthralgias
Cyclophosphamide	Cardiac adverse effects (cardiomyopathy, congestive heart failure, hemorrhagic cardiac necrosis, pericardial effusion, ECG abnormalities), interstitial pulmonary fibrosis, hemorrhagic cystitis, elevation in liver enzymes, nausea and vomiting, metabolic adverse effects (syndrome of inappropriate antidiuretic hormone secretion)
Carboplatinum	Nausea and vomiting, nephrotoxicity, liver function abnormalities (including veno-occlusive disease of the liver), ototoxicity
Cisplatinum	Nausea and vomiting, neurotoxicity (peripheral neuropathy, ataxia, visual disturbances), ototoxicity, renal adverse effects
Etoposide	Hypersensitivity reactions, hypotension, liver function abnormalities and chemical hepatitis, renal dysfunction, nausea and vomiting, metabolic adverse effects (metabolic acidosis), mucositis, stomatitis, painful skin rash (on the palms, soles, and periorbital area)
Ifosfamide	Hemorrhagic cystitis, nausea, vomiting
Melphalan	Acute hypersensitivity reaction, renal adverse effects, mucositis, nausea and vomiting, hepatic toxicity (including veno-occlusive disease of the liver)
Thiotepa	Hyperpigmentation, acute erythroderma, dry desquamation, liver function abnormalities (including veno-occlusive disease of the liver), mucositis, esophagitis, dysuria, hypersensitivity reactions
Total-body irradiation	Nausea and vomiting, diarrhea, fever, parotitis, xerostomia, stomatitis, erythema, pneumonitis, veno-occlusive disease of the liver

Research is under way to study whether a reduced-intensity conditioning regimen (sometimes called nonmyeloablative) followed by allogeneic HSCT provides improved transplantation outcomes for selected candidates. Reduced-intensity transplantation may provide a treatment option for patients who, because of advanced age or preexisting lung, kidney, or liver damage, cannot tolerate the toxicities of a traditional allogeneic transplant.[24] The theory behind a reduced-intensity transplantation is that the immune-mediated graft-versus-tumor effect provided by the new immune system, rather than the conditioning regimen itself, cures the disease. Specific regimens under investigation include fludarabine, single-dose total-body irradiation, and a combination of potent immunosuppressive medications. These regimens are not without risk, and patients undergoing reduced-intensity transplantation still experience many of the expected complications of myeloablative allogeneic transplantation. The problems encountered in the early posttransplantation period, such as infection, bleeding, and regimen-related toxicities, may be reduced compared with myeloablative transplantation, but the risk for GVHD and the long-term risks for infection continue to be important.

Transplantation/Hematopoietic Stem Cell Infusion

In allogeneic HSCT, the stem cells are usually infused immediately after they are collected. Autologous stem cells are cryopreserved with dimethylsulfoxide (DMSO) and must be thawed in a warm normal saline bath at the bedside immediately before reinfusion.

The actual infusion of stem cells is a relatively simple procedure, much like a blood transfusion. The cells are infused into a central venous catheter over 30 to 60 minutes, depending on the total volume of the product. Patients usually are premedicated with acetaminophen, hydrocortisone, and diphenhydramine, and they are prehydrated to maintain renal perfusion. Diuretics, mannitol, and antihypertensives may be required to prevent volume overload and manage hemodynamic changes during infusion. Vital signs are monitored, and oxygen and cardiac monitoring are readily available.

Complications of allogeneic HSCT may include pulmonary edema, hemolysis, infection, and anaphylaxis; however, these are rare. A garlicky odor or taste may occur; excretion of DMSO causes this. DMSO-associated RBC hemolysis may also occur, and patients require vigorous hydration to prevent renal toxicity. An infusion reaction that may include bradycardia (rarely heart block), hypertension, and an acute hypersensitivity reaction is another potential adverse effect of DMSO during the administration of cryopreserved autologous HSCT. During HSCT, monitoring for volume overload and for complaints suggestive of embolism, such as chest pain, dyspnea, and cough is necessary. Patients may also experience an acute hemolytic transfusion reaction if they are receiving hematopoietic stem cells from an ABO-mismatched donor.

Engraftment

After IV infusion, the hematopoietic stem cells migrate to the bone marrow spaces, where they are attracted by chemotactic factors. Engraftment occurs when the transplanted progenitor cells begin to grow and manufacture new hematopoietic cells in the bone marrow. Engraftment is generally defined as an absolute neutrophil count greater than 0.5×10^9/L for 3 consecutive days and a platelet count greater than 20×10^9/L achieved without transfusion support. The rate of engraftment depends on the source of the progenitor cells, the total progenitor cell dose, the use of colony-stimulating factors, the complications the patient experiences in the pre-engraftment period, and the choice of prophylaxis against GVHD. Time to engraftment in HSCT varies according to the origin of the hematopoietic stem cells: for bone marrow–derived stem cells, 2 to 3 weeks; for peripheral blood stem cells, 11 to 16 days; and for cord blood–derived stem cells, 26 days (average; as long as 42 days).

Patients usually receive their conditioning treatment and immediate posttransplantation care in an inpatient unit. However, improved symptom management and technological advances, including the use of hematopoietic growth factors, have allowed earlier discharge from the hospital. Box 47-3 presents the criteria for hospital discharge after HSCT. Many institutions now have outpatient care facilities available for transplant recipients that permit outpatient treatment and evaluation 7 days per week.[25]

After the transplantation but before complete hematopoietic cell engraftment, patients experience severe pancytopenia and immunosuppression, and the resulting complications may include infection and bleeding. Patients take hematopoietic growth factors (eg, G-CSF, GM-CSF) to accelerate neutrophil recovery, thereby reducing the period of pancytopenia and the highest risk for infection. While patients have pancytopenia, until their blood counts begin to recover, they typically receive broad-spectrum antimicrobial drugs directed at bacteria, viruses, and fungi, as well as blood components, such as platelets and packed RBCs.

All blood products given to HSCT recipients require filtration to remove WBCs that may transmit CMV and irradiation to prevent transfusion-associated GVHD. Studies have determined that leukodepletion by either bedside filtration during transfusion or by prestorage leukocyte depletion of blood products is an effective method of preventing transfusion-associated CMV infection in HSCT because leukocytes transmit CMV.[26] In addition, filtered blood products may also prevent febrile transfusion reactions and delay alloimmunization.[27,28] However, use of a leukocyte depletion filter does not affect the risk for transmission of viral hepatitis.

Transfusion-associated GVHD is a rare but almost uniformly fatal complication of transfusion, resulting from the infusion of immunocompetent lymphocytes capable of proliferation into an immunocompromised recipient who is unable to destroy them.[26] The infused lymphocytes recognize host tissues as foreign and mount a reaction.

To prevent transfusion-associated GVHD, all cellular blood products except for stem cell grafts and donor lymphocytes given for graft-versus-tumor effect, should be irradiated with 2500 cGy prior to transfusion.[26] The blood component should be labeled as irradiated. It is not radioactive, and no additional precautions for handling the blood product are required. Other patients can use irradiated blood products; the irradiating process does not alter the efficacy or cellular content of the product and does not harm the recipient in any way. Patients who have undergone allogeneic or autologous HSCT should receive irradiated cellular components, both before and after stem cell transplantation.[25] Most centers recommend that allogeneic stem cell recipients receive irradiated blood products for the rest of their lives. Box 47-4 presents a collaborative care guide for the patient with allogeneic HSCT.

BOX 47-3 Criteria for Hospital Discharge After Hematopoietic Stem Cell Transplantation

Discharge from hospital is usually permitted when:
- The patient has been afebrile for at least 24 hours.
- A 24-hour outpatient medical facility is available.
- Family care giver support is available.
- The patient is independent in basic activities of daily living.
- Acute posttransplantation complications have been resolved or controlled.
- The patient is achieving oral intake of at least 1,500 mL/d, or a plan to meet the patient's fluid needs through self-administration of IV fluids or daily IV fluid administration in clinic is in place.
- Nausea and vomiting are controlled.
- The patient is able to tolerate oral medications.
- Availability of appropriate transfusion support in a clinic environment and access to irradiated blood products have been determined.
- The patient's platelet count is supportable with no more frequent than daily platelet product.
- The patient's white blood cell count is greater than 1×10^9/L.
- A hematocrit of 25% is supportable with no more than daily transfusion of one unit of packed red blood cells (RBCs).

▲ Immunosuppressive Therapy

In solid organ transplantation, the transplanted organ is foreign to the recipient, whose immune system eventually will recognize this and mobilize to reject the transplanted organ. Therefore, immunosuppressive therapy is necessary to suppress the immune response so the transplanted organ will be accepted. In allogeneic HSCT, because the immune system is generated from donor cells, immunosuppressive therapy is used to prevent GVHD, a response in which donor T lymphocytes attack the recipient's cells. The challenge of immunosuppressive therapy is to provide the recipient with adequate immunosuppression without undue toxicity, unfavorable reactions, and excess susceptibility to opportunistic infections. Therapeutic regimens may be individualized based on the needs of a particular patient.

To suppress the immune response in both solid organ and hematopoietic stem cell transplant recipients, several drugs may be necessary (Table 47-7, p. 1072). A single medication usually cannot do this effectively. Therefore, immunosuppressive regimens include medications that complement each

BOX 47–4 COLLABORATIVE CARE GUIDE for the Allogeneic Hematopoietic Stem Cell Transplantation

OUTCOMES	INTERVENTIONS
Oxygenation/Ventilation	
The patient will demonstrate pulmonary hygiene techniques, including coughing, deep breathing, incentive spirometry, and daily exercise as tolerated. The patient will demonstrate improvement in respiratory pattern and lung sounds, with subjective reduction in complaints of dyspnea, cough, pleuritic chest pain, and weakness. The patient's risk for aspiration will be eliminated or minimized.	• Auscultate lung sounds and vital signs and pulse oximetry every 4 h and PRN. • Note skin color capillary refill and presence of central or peripheral cyanosis. • Assess the quality of respirations including use of accessory muscles, nasal flaring, and grunting. • Note cough and complaints of shortness of breath, orthopnea, or pleuritic pain. • Determine effects of medications that may affect respiratory status, including narcotics and sedatives. • Suction oropharynx or nasotrachea to remove secretions. • Encourage deep-breathing and coughing exercises, and teach patient proper use of incentive spirometry. • Encourage patient to maintain optimal level of activity, including walking, exercise bicycle, and working daily with physical therapist. • Instruct patient on methods of preventing respiratory complications related to mucositis or aspiration, such as avoiding drinking liquids after using topical local anesthetics, keeping head of bed elevated and having oral suction in a convenient location. • Implement measures to manage anemia and control bleeding, if present. • Administer supplemental oxygen as indicated. • Administer diuretics as ordered.
Circulation/Perfusion	
The patient will exhibit the absence or control of signs and symptoms of potential physiological problems: **Bleeding/hemorrhage** **Hypotension** secondary to sepsis, hemorrhage, medication side effects, or dehydration **Hypertension** secondary to medication side effects **Dehydration** secondary to decreased oral fluid intake as a result of nausea, vomiting, or mucositis, or increased fluid losses through fever, diarrhea, or insensible fluid losses through the skin	• Develop a nursing plan to manage individual cardiovascular problems. Cardiovascular problems may include hypertension, orthostatic hypotension, sepsis-induced hypotension, dysrhythmias, pericarditis, superior vena cava syndrome, thrombus formation, and myocardial infarction. • Replace fluid losses with packed RBCs or hydration. • Use appropriate measures to decrease fluid losses secondary to fever, diarrhea, vomiting, or hemorrhage. • Administer antihypertensives, diuretics, antiarrhythmics, or vasoactive drugs as ordered and monitor their effectiveness. • Provide information to patient and family regarding cardiac status, and rationale for specific nursing interventions. • Monitor platelet count and coagulation profile carefully, especially in patients experiencing hypertension. • Instruct patient about appropriate safety measures during period of altered cardiac status. Patients who are orthostatic may become dizzy when standing. Provide assistance as needed. • Although hypotension and hypertension may occur without symptoms, alert patient to these signs and symptoms, and encourage prompt reporting to the health care team. Common signs of hypertension include headache and visual disturbance. Hypotension may be associated with dizziness, visual disturbances, tachycardia, and cool or diaphoretic skin. • Emphasize the importance of taking oral antihypertensive medications when scheduled.
Fluids/Electrolytes	
The patient will exhibit the absence of or control of signs and symptoms of potential physiological problems: **Veno-occlusive disease of the liver,** as manifested by sudden weight gain, increase in bilirubin, aspartate aminotransferase, and alkaline phosphatase levels, hepatomegaly, ascites, and encephalopathy **Renal insufficiency/failure,** as manifested by a decreased urine output or rising serum creatinine	• Strictly monitor intake, output, and fluid balance every 4–8 h. • Check weight twice daily. • Measure abdominal girth daily in patients with veno-occlusive disease. • Perform pulmonary assessment, including pulse oximetry, respiratory rate, quality, and presence of adventitious breath sounds. • Perform cardiac assessment, noting presence of orthostatic hypotension, extra heart sounds, or neck vein distention. • Assess for peripheral and sacral edema. • Monitor serum electrolytes, liver function tests, and urine specific gravity once or twice daily as ordered.

(continued on page 1069)

BOX 47-4 *COLLABORATIVE CARE GUIDE for the Allogeneic Hematopoietic Stem Cell Transplantation (continued)*

OUTCOMES	INTERVENTIONS
Fluids/Electrolytes	
Dehydration secondary to decreased oral fluid intake as a result of nausea, vomiting, or mucositis, or increased fluid losses through fever, diarrhea, or insensible fluid losses through the skin. **Electrolyte disorders** secondary to steroid-induced hyperglycemia, syndrome of inappropriate antidiuretic hormone secretion, tumor lysis syndrome, or medication-induced electrolyte shifts	• Monitor for and treat steroid-induced hyperglycemia. • Adjust dose or eliminate nephrotoxic drugs in patients with renal insufficiency or renal failure. • Administer intravenous fluids as ordered to replace gastrointestinal losses and to supplement inability to consume sufficient oral fluids. • Administer electrolyte replacements as ordered. • Administer antiemetics and antidiarrheal agents as ordered. • Monitor stools for volume, consistency, color, and odor. • Monitor for fluid losses through sloughing of the skin.
Mobility/Safety	
The patient will: Maintain baseline strength and endurance and minimize focal muscle weakness, fatigue, and dyspnea Participate in measures to prevent a decrease in strength and endurance Experience minimal complications from decreased mobility Use safety measures to prevent injury	• Encourage patient to continue daily activities throughout the transplantation course. Provide rationale and explain the complications of inactivity to both patient and family. • Develop an individualized plan to address factors contributing to limited mobility, including pain, nonadherence, depression, medication side effects, nausea, generalized weakness and malaise, and altered level of consciousness. • Refer to physical and occupational therapy for assessment and treatment. • Encourage focused exercises that provide proximal muscle strengthening in patients on corticosteroids. • Encourage patient to maintain maximal independence in activities of daily living (ADLs) and self-care. • Develop a schedule that allows adequate rest by coordinating all activity and treatments (ADLs, medications, health team rounds). • Identify signs of impaired activity tolerance and set specific goals for improving tolerance/endurance in activities.
Skin Integrity	
The patient will: Maintain skin integrity Demonstrate techniques of skin care Demonstrate basic understanding of skin GVHD Exhibit control of symptoms associated with skin GVHD	• Assess skin daily for maculopapular rash, erythema, sloughing, or open lesions. • Monitor skin for the development of signs of infection such as warmth, erythema, swelling, or tenderness. • Apply skin emollients and other topical agents, including topical antimicrobial agents, as ordered. • Consider use of antipruritic or steroid topical agents to manage symptoms of itching and inflammation. • If skin breakdown occurs, consult enterostomal therapist or wound management specialist concerning nonadherent, absorptive dressings and the role of special beds/mattresses. • Monitor patient for dehydration if there are increased insensible losses of fluid through the skin. • Teach patient and family the importance of avoiding direct sun exposure and the importance of using sun block and protective clothing when outdoors because sun exposure can initiate a flare of GVHD of skin.
Nutrition	
The patient will: Have nutritional balance maintained through diet and parenteral nutrition Demonstrate understanding of dietary restrictions related to a specific gastrointestinal problem Demonstrate methods for maintaining nutritional requirements as an outpatient	• Evaluate oral mucosal integrity and note presence of oral problems. • Note subjective data, including complaints of nausea, loss of appetite, taste changes, early satiety, pain or abdominal cramping, and any precipitating factors. • Monitor calorie counts, intake and output totals, and weights to determine adequacy of nutritional intake. • Develop a multidisciplinary plan for nutritional management. Discuss approaches to use when experiencing taste changes; thick, viscous saliva and mucus; xerostomia; early satiety; nausea/vomiting; mucositis or esophagitis; and other troubling symptoms. • If patient is receiving high-dose steroids, ensure increased protein intake and calcium and vitamin D supplementation. Consider restricted concentrated carbohydrate intake if hyperglycemia is present. Consider restricted sodium intake if fluid retention is especially problematic. • Increase protein intake in patients with extensive skin or gastrointestinal GVHD.

(Continued on page 1070)

BOX 47–4 *COLLABORATIVE CARE GUIDE for the Allogeneic Hematopoietic Stem Cell Transplantation (continued)*

OUTCOMES	INTERVENTIONS
Nutrition	
	• Consider multiple vitamin without iron (to prevent iron overload), and folic acid supplementation 1 mg orally daily. • Maintain nutritional requirements through use of hyperalimentation as required. • Encourage patient to try different foods as tolerated. • Advance diet as tolerated and note response to advancement. • Encourage small, frequent meals and a bedtime snack. • Medicate for nausea or pain as needed. • Encourage family members to be supportive and patient. Pressure from family or staff can produce anxiety that will have a negative effect on eating habits.
Comfort/Pain Control	
Patient will be able to: Identify activities that increase or decrease pain Relate location and characteristics of pain as well as degree of pain relief to the health care team Participate in daily care without interference from pain or side effects of pain control measures Achieve acceptable level of pain control	• Monitor for the potential sources of pain/discomfort in the hematopoietic stem cell transplant recipient, including: Pain associated with diagnostic or therapeutic procedures Neuropathic pain secondary to immunosuppressive medications Mucositis/esophagitis Rectal pain/hemorrhoids Painful urination from hemorrhagic cystitis Abdominal pain secondary to infections, severe diarrhea/enteritis, or liver distention Cutaneous discomfort secondary to GVHD of skin • Teach patient importance of reporting pain and the effectiveness of pain relief measures to health care team. • Assess location, onset, frequency, intensity, and quality of pain. Use a 0–10 pain scale to assess patient's perception of pain and to assist in evaluating effectiveness of treatment. For patients unable to communicate, monitor changes in vital signs and observe for increased restlessness, which could indicate inadequate pain control. • Premedicate patient before potentially painful procedures. • Teach proper and safe use of patient-controlled analgesia if ordered. • For patients receiving continuous infusion, consider the need for a bolus of analgesic before disconnecting patient from continuous infusion, while disconnected, and after resuming continuous infusion. • Suggest consultation with pain management team if indicated. • Monitor narcotic dosages and patient response carefully in patients with hepatic dysfunction secondary to veno-occlusive disease or GVHD. • In the nonventilated patient, adjust analgesic dosages in the presence of markedly deceased respiratory rate or markedly altered level of consciousness.
Psychosocial—Individual and Family	
Patient and family will be able to: Identify effective and ineffective coping patterns Identify personal strengths Verbalize their needs Actively participate in problem solving Use resources and support systems to strengthen their coping skills	• Provide opportunities for patient and family to communicate with each other, as well as with psychosocial support professionals and other health care team members. • Reinforce successful coping skills (ie, clearly verbalizing needs, using activities that reduce stress, and effective patient/family/team communication). • Provide reassurance and review support systems, options, and resources available to support effective coping. • Establish trust and congruence in goals and objectives. • Provide information in a timely and specific manner. • Allow patient as much choice and control as appropriate and feasible. • Avoid the use of approaches that foster dependency (coercion, persuasion, manipulation). • Demonstrate caring, respect, and concern for patient and family. • Use positive reinforcement.

(continued on page 1071)

BOX 47–4 COLLABORATIVE CARE GUIDE for the Allogeneic Hematopoietic Stem Cell Transplantation (continued)

OUTCOMES	INTERVENTIONS
Teaching/Discharge Planning	
The patient and family will demonstrate knowledge of: The overall process of HSCT and the expected complications and self-care requirements, including preparative regimen and side effects, infusion of peripheral stem cells and side effects, engraftment, complications, discharge criteria, follow-up care, symptoms to report, protective precautions (neutropenic and thrombocytopenic precautions), dietary restrictions, and specific psychomotor skills, including central venous catheter care, medication administration, and vital sign monitoring The structure of the inpatient unit, unit routines, and the programs and resources available to make their inpatient stay more comfortable and facilitate their self-care The importance of the active involvement of patient and family in the daily care and decision making throughout the HSCT process On discharge, patient and family will demonstrate knowledge of: Signs and symptoms that should be reported immediately to the health care team, including fever, chills, skin rash, bleeding, nausea, vomiting, diarrhea or abdominal pain, shortness of breath, cough, dyspnea, and an inability to take oral medication or consume sufficient fluids Names of medication, rationale for each medication, the required schedule for administration, and potential side effects Contact telephone numbers for day and after-hours care Psychomotor skills necessary for administration of oral and IV medications, self-care of central venous catheter, and any other self-care skills such as administration of total parenteral nutrition and home IV hydration	• Orient patient to unit, room environment, ancillary services, and general routines. The patient and family may be initially overwhelmed by the amount of new information and may require reinforcement of information. • Allow patient and family to share concerns and request additional information about the transplantation process. • Encourage questions throughout the transplantation process, and provide clarification on all aspects of treatment. • Explain the need for active patient and family involvement in daily care and decision making throughout the HSCT process. • Teach the importance of daily hygiene, diligent oral care, daily exercise, nutrition, and other routines. • Encourage patient to maintain open communication with health care team. • Integrate discharge teaching while fostering patient family participation in daily care. • Provide patient with written instructions on outpatient self-care guidelines, medication schedule, and other self-care activities. • Refer to home health agency for continued education and support of patient at home, as indicated. • Provide teaching/instruction using methods adapted to patient's learning style. Discuss with patient how he or she learns best: by doing, by listening, or by watching. • Document teaching provided, areas requiring continued reinforcement and follow-up, and learning outcomes achieved in the patient's record.

other and increase the effectiveness of the immunosuppression. The foundation of most immunosuppressant regimens for solid organ transplantation is triple, or three-drug, therapy. The combination of drugs used for organ transplantation and HSCT may differ.

Triple therapy is a combination of low-dose prednisone, azathioprine or mycophenolate mofetil (MMF), and cyclosporine A or tacrolimus. By combining these three agents, the dose of each drug is lower so that patients experience fewer adverse effects than they would from one drug alone. For example, the risk for aseptic necrosis, diabetes mellitus, cataracts, and gastrointestinal complications attributed to chronic steroid therapy is greatly reduced with the combination therapy. Because the dosage of azathioprine is low, the potential for hepatotoxicity and leukopenia is decreased. Problems associated with higher doses of cyclosporine A, including lymphoma, hirsutism, hepatotoxicity, gingival hyperplasia, seizures, and gastrointestinal disturbances, occur at a lower frequency.

Quadruple, or sequential, therapy is a combination of the same three drugs that are used in triple therapy (prednisone, azathioprine or MMF, and either cyclosporine A or tacrolimus) plus antithymocyte antibody preparations or monoclonal antibody, monomurab-CD3. The calcineurin inhibitors, cyclosporine A or tacrolimus, are withheld until renal function is present. All four drugs are given for several days, after which the polyclonal or monoclonal antibody preparation is discontinued. A triple-drug regimen is then continued for maintenance therapy.

Because of the nephrotoxicity of calcineurin inhibitors and the risks for drug accumulation and resultant toxicity in the absence of renal function, not using the calcineurin inhibitors in the early posttransplantation period has advantages. Quadruple therapy permits both broad and specific immunosuppression while limiting toxicity until renal function has improved. However, it does have a disadvantage: the potential inability to use the polyclonal or monoclonal antibody preparation for treatment of rejection episodes or as "rescue" therapy.

Text continued on page 1078

Table 47-7 Selected Immunosuppressive Drugs Used in Solid Organ and Hematopoietic Stem Cell Transplantation

Drug	Mechanism of Action	Dosing/Administration	Adverse Reactions	Comments
Cyclosporine A (Sandimmune, Neoral)	Prevents IL-2 gene expression and thus impairs IL-2 synthesis and activation of T lymphocytes	Solid organ transplant dosing: Initial dosing of 4 mg/kg/d (IV); maintenance dosing of 5–15 mg/kg/d (PO). HSCT dosing: usually 1.5 mg/kg IV every 12 h, 0.75 mg/kg every 6 h or 3 mg/kg/d as a continuous infusion Dosage is adjusted to achieve therapeutic levels. IV to PO conversion: approximately 1:3 Dosage dependent on achieving and sustaining therapeutic blood levels based on laboratory evaluation Therapeutic monitoring not required once drug dosage is being tapered	Metabolic: hyperkalemia and hyperglycemia, hypomagnesemia, hyperlipidemia, hyperuricemia, diabetes mellitus Neurotoxicity: headache, tremor, insomnia, paresthesia, dizziness, seizures GI: diarrhea, nausea, constipation, anorexia, vomiting, abdominal pain, ascites, elevated liver function tests Renal: elevated creatinine, nephrotoxicity Cardiovascular: hypertension, chest pain Hematological: anemia Cutaneous: acneiform rash, striae Other: peripheral edema, infection, impaired wound healing, osteoporosis, gingival hyperplasia, flushing, sweating, hirsutism	• Bioavailability differs between oral solution and capsule formulation. Once regimen is established, patients should be instructed not to change formulation or brand. • Take with food. • Instruct patient on importance of strict adherence to administration schedule and to notify health care team immediately if unable to take due to GI side effects. • Monitor serum creatinine, blood urea nitrogen (BUN), potassium, magnesium, glucose, and triglyceride levels. • Avoid potassium-sparing diuretics. • Replete electrolytes as indicated. • Coadministration with grapefruit juice may increase cyclosporine levels and should be avoided. • Drug–drug interactions can lead to subtherapeutic or toxic cyclosporine levels. Drugs that inhibit or induce cytochrome P-450 are most responsible (see Table 47-14, p. 1088). • Cyclosporine trough levels to be drawn before administration of morning dose. Therefore, doses are usually timed for 10:00 AM and 10:00 PM to allow trough blood draw at morning clinic visit. Instruct patient to bring dose to clinic and to administer once trough level drawn. • Should not be used simultaneously with tacrolimus. • Tacrolimus should be discontinued 24 h before starting cyclosporine. In the presence of increased tacrolimus levels, initiation of cyclosporine should usually be further delayed. • Doses should be adjusted for renal dysfunction. • Monitor levels carefully in patients with renal or hepatic dysfunction.
Tacrolimus (Prograf)	Impaired synthesis of IL-2 and prevents T-lymphocyte proliferation; interferes with the gene transcription for a variety of cytokines including IFN-γ, TNF-α	Solid organ transplant dosing: 0.10 mg/kg/d (IV); 0.05–0.2 mg/kg/d (PO) HSCT dosing: usually 1–2 mg PO every 12 h; 0.05–0.1 mg/kg/d as a continuous IV infusion, with dosage adjusted to achieve therapeutic levels	Metabolic: hyperkalemia and hypokalemia, hyperglycemia, hypomagnesemia, hyperlipidemia, hypophosphatemia, diabetes mellitus Neurotoxicity: headache, tremor, insomnia, paresthesia, dizziness, seizures GI: diarrhea, nausea, constipation, anorexia, vomiting, abdominal pain, ascites, elevated liver function tests	• Take on empty stomach. • Instruct patient on importance of strict adherence to administration schedule and to notify the health care team immediately if unable to take due to GI side effects. • Monitor serum creatinine, BUN, potassium, magnesium, phosphorus, glucose, and triglyceride levels. • Avoid potassium-sparing diuretics. • Replete electrolytes as indicated • Coadministration with grapefruit juice may increase tacrolimus levels and should be avoided.

		IV to PO conversion: approximately 1:4 Dosage dependent on achieving and sustaining therapeutic blood levels based on laboratory evaluation Therapeutic monitoring not required once drug is being tapered	Renal: elevated creatinine, nephrotoxicity Cardiovascular: hypertension, chest pain Hematological: anemia, leukocytosis, thrombocytopenia Cutaneous: pruritus, acneiform rash Pulmonary: pleural effusion, atelectasis, dyspnea Other: peripheral edema, infection, impaired wound healing, osteoporosis	• Drug–drug interactions can lead to subtherapeutic or toxic tacrolimus levels. Drugs that inhibit or induce cytochrome P-450 are most responsible (see Table 47-14, p. 1088). • Tacrolimus trough levels to be drawn before administration of morning dose. Therefore doses are usually timed for 10:00 AM and 10:00 PM to allow trough blood draw at morning clinic visit. Instruct patient to bring dose to clinic and to administer once trough level drawn. • Should not be used simultaneously with cyclosporine. • Cyclosporine should be discontinued 24 h before starting tacrolimus. In the presence of elevated cyclosporine levels, initiation of tacrolimus is delayed. • Doses should be adjusted for renal dysfunction. • Monitor levels carefully in patients with renal or hepatic dysfunction.
Methylprednisolone (IV) Prednisone (PO)	Decreases cytotoxic T-cell proliferation, inhibits production of IL-1 and IFN-g, prevents production of IL-2, inhibits neutrophils function by stabilizing leukocyte lysosomal membrane and inhibiting chemotaxis	Dosage varies according to institutional protocols Dosage: 0.5–2 mg/kg/d every 12 h, with tapering schedule determined based on starting dose and patient response During solid organ transplant rejection: Methylprednisolone may be given in IV bolus up to 1 g/dose	Metabolic: fluid and electrolyte imbalance, diabetes mellitus, hyperlipidemia Neurotoxicity: tremors, seizures, headache, difficulty concentrating, insomnia GI: GI irritation Cardiovascular: hypertension, dysrhythmias Cutaneous: bruising, fragile skin Neurotoxicity: tremors, seizures, headache Other: hunger, peripheral edema, infection, impaired wound healing, hirsutism, osteoporosis, weight gain, steroid myopathy, cataracts/ glaucoma, cushingoid changes, psychiatric disturbances (steroid psychosis, mood changes, confusion)	• Usually used in combination with cyclosporine or tacrolimus. • Consult physical therapy for proximal muscle strengthening exercise program. • Instruct patient in strategies to prevent or treat hyperglycemia, and in diabetic self- management. • Administer oral corticosteroids with food/milk to minimize GI upset. • Administer H_2 blockers or proton pump inhibitor, as ordered. • May increase tacrolimus or cyclosporine levels. • Report complaints of visual changes and consult ophthalmology. • For patients on long-term steroids or otherwise at risk for or experiencing osteopenia (eg, patients with acute lymphocytic leukemia, postmenopausal), ensure regular dual-energy x-ray absorptiometry scans, calcium and vitamin D supplementation, and specific treatment for osteopenia with antiresorptive agents such as pamidronate, alendronate. • Tapering calendar specifying the dosage to be taken each day can help facilitate adherence in patients who are on tapering doses of steroids, or an alternate-day steroid regimen.
Mycophenolate mofetil (MMF) (CellCept)	Antimetabolite that selectively inhibits the proliferation of T and B lymphocytes by interfering with purine nucleotide synthesis	Dosage: 1–1.5 g IV or PO every 12 h depending on institutional guidelines	Metabolic: hyperkalemia and hypokalemia, hyperlipidemia, hypophosphatemia, hyperglycemia Neurotoxicity: headache, insomnia, tremors, seizures GI: diarrhea, nausea, constipation, anorexia, vomiting, abdominal pain, hepatotoxicity Renal: elevated creatinine, nephrotoxicity Cardiovascular: hypertension, hypotension, dysrhythmias Hematological: anemia, leukocytosis, thrombocytopenia Cutaneous: acneiform rash Pulmonary: cough, dyspnea Other: fever, edema, pain, infection, muscle weakness, anxiety, depression	• MMF should be taken on an empty stomach. • Monitor complete blood count (CBC) at regular intervals and adjust dosage for pancytopenia, as ordered. • Monitor liver function tests (bilirubin and serum aminotransferases) at regular intervals, adjust dosage for liver function abnormalities, as ordered. • Monitor serum levels of the MMF metabolic to guide treatment in patients with renal dysfunction. • In the setting of renal impairment, or when coadministered with probenecid, acyclovir, or ganciclovir, the drug concentrations of MMF and of these drugs may increase. • There may be decreased MMF absorption when coadministered with magnesium oxide, aluminum- or magnesium-containing antacids, or cholestyramine.

(Continued on page 1074)

Table 47-7 **Selected Immunosuppressive Drugs Used in Solid Organ and Hematopoietic Stem Cell Transplantation** (continued)

Drug	Mechanism of Action	Dosing/Administration	Adverse Reactions	Comments
Methotrexate	Antimetabolite that inhibits dihydrofolate reductase, thereby hindering DNA synthesis and cell reproduction, and thus inhibiting lymphocyte proliferation	Institutional protocols vary Usual dose: 5–15 mg/m^2 given IV on days 1, 3, 6, and 11 after transplantation	Myelosuppression, mucositis, photosensitivity, interstitial pneumonitis, hepatotoxicity, nephrotoxicity	• Dose and schedule for methotrexate prophylaxis for GVHD vary by institution. Common regimen is 5–15 mg/m^2 on days 1, 3, 6 and 11 posttransplantation. • Doses may be adjusted or held for severe mucositis and renal or hepatic insufficiency. Doses may need to be adjusted for hypoalbuminemia. • Wait until at least 24 h after stem cell infusion to give day +1 dose.
Rituximab (Rituxan)	Rituximab binds specifically to the B-lymphocyte cell surface antigen CD20, inducing B-cell death. CD20 is a protein located on normal pre-B and mature B lymphocytes	375 mg/m^2 by IV infusion given weekly for 4 wk Administer slowly. The first infusion of rituximab should be initiated at a rate of 50 mg/h. If hypersensitivity or infusion-related events do not occur, the infusion rate should be increased by 50 mg/h increments every 30 min to a maximum of 400 mg/h. Subsequent infusions can be initiated at 100 mg/h, with increases of 100 mg/h every 30 min to a maximum of 400 mg/h. Protect from sunlight. Do not filter	Mild to moderate infusional toxicities consisting of fever and chills/rigors in the majority of patients during the first rituximab infusion. Other frequent infusion reaction symptoms include nausea, pruritus, angioedema, asthenia, hypotension, headache, bronchospasm, throat irritation, rhinitis, urticaria, rash, vomiting, myalgia, dizziness, and hypertension. These reactions generally occur within 30–120 min of beginning the first infusion and resolve with slowing or interruption of the rituximab infusion and with supportive care (diphenhydramine, acetaminophen, IV saline solution, and vasopressors). The incidence of infusion reactions is highest during the first infusion (77%) and decreases with each subsequent infusion. Other adverse effects include lymphopenia and decreased serum immunoglobulins, which can contribute to risk for serious infections, including hepatitis B reactivation with fulminant hepatitis, progressive multifocal leukoencephalopathy, and other opportunistic infections. Adverse effects also include cardiac dysrhythmias, renal toxicity, bowel obstruction and perforation; neutropenia and anemia; and cough, rhinitis, bronchospasm, dyspnea, interstitial pneumonitis, and bronchiolitis obliterans.	• Premedication consisting of acetaminophen and diphenhydramine should be considered before each infusion. • Medications and equipment necessary for the management of hypersensitivity/anaphylaxis should be readily available (eg, epinephrine, antihistamines, corticosteroids, oxygen). • Assess baseline vital signs. Check CBC with differential and renal function. • Because of the potential for transient hypotension during infusion antihypertensive medication should not be taken 12 h prior to infusion. • The infusion should be interrupted if infusion-related reactions occur. Mild side effects usually resolve with temporary discontinuation of the infusion or administration of meperidine, diphenhydramine, or other supportive therapy such as bronchodilators or IV saline. • Patients experiencing chills should be offered blankets and comfort measures until the reaction subsides. Administration of acetaminophen as often as every 3 h as needed is recommended. • Most patients who experience non–life-threatening reactions are able to complete the full course of therapy. Once the infusion-related side effect has completely resolved and the patient is comfortable (usually about 30 min), rituximab may be restarted at half the previous infusion rate. After restarting the infusion, recurrence of the side effect usually does not occur. • Patients and family members should be advised concerning infusion-related side effects and informed that driving or operating equipment cannot be resumed until the effects of sedation are gone. • Women of childbearing age should receive instructions to ensure that they are using effective contraceptive methods during therapy and for 12 mo after therapy is completed. Infant nursing should be discontinued until circulating levels are no longer detectable, which is usually 12 mo after therapy is completed. • The safety of immunization with live viral vaccines following rituximab therapy has not been studied, and vaccination with live virus vaccines is not recommended.

Daclizumab (Zenapax)	Monoclonal antibody against the IL-2 receptor expressed on activated T cells. Binds to the IL-2 receptor in a nonactivating fashion, competing with IL-2 and thereby inhibiting IL-2 driven proliferation of the activated T lymphocyte IL-2–induced proliferation of activated (antigen-stimulated) T lymphocytes is a critical step in proliferation and ultimately tissue destruction	Institutional protocols vary Usual dose: 1 mg/kg by IV administration	Constipation, nausea, vomiting, diarrhea, abdominal pain, abdominal distention, edema, tremor, headache, dizziness, nephrotoxicity, chest pain, tachycardia, fever, pain, fatigue, hypertension, hypotension, dyspnea, pulmonary edema, coughing, musculoskeletal pain, back pain	• Anaphylactoid reactions after the administration of daclizumab have not been observed but can occur after the administration of proteins. Medications for the treatment of severe hypersensitivity reactions should be available for immediate use. • The calculated volume of daclizumab should be mixed with 50 mL of sterile 0.9% sodium chloride solution and administered through a peripheral or central vein over a 15-min period. Once the infusion is prepared, it should be administered IV within 4 h. If it must be held longer, it should be refrigerated between 2°C–8°C (36°F–46°F) for up to 24 h. After 24 h, the prepared solution should be discarded. • No incompatibility between daclizumab and PVC or polyethylene bags or infusion sets has been observed. • No dosage adjustment is necessary for patients with severe renal impairment.
Infliximab (Remicade)	Monoclonal antibody against TNF-α Binds to soluble and membrane-bound TNF-α, producing reduction in serum IL-1 and reduced levels of nitric oxide synthase	Institutional protocols vary Usual dose: 10 mg/kg by IV administration Administer over at least 2 h Must be given with a low protein-binding filter of 1.2 mcm or less	Headache, nausea, abdominal pain, fatigue, fever, and coughing Infusion reactions, including fever, chills, chest pain, hypotension, headache, and urticaria can occur during the infusion and for up to 2 h after the infusion is complete. There is no increase in the incidence of reactions after the initial infusion. Delayed, serum sickness–like reactions including myalgias, arthralgias, fever, rash, sore throat, dysphagia, and hand and facial edema can be seen 3–12 d after infusion. Patients may develop human antichimeric antibody.	• Monitor patient for development of infusional toxicities. • Consider premedication with acetaminophen and diphenhydramine (Benadryl). • Initiate therapy at 10 mL/h × 15 min, increase to 20 mL/h × 15 min, and then increase to 40 mL/h × 15 min, then 80 mL/h × 15 min, then 150 mL/h × 30 min, and then 250 mL/h × 30 min to complete infusion in 2 h. • Stop or slow infusion and give diphenhydramine (Benadryl), acetaminophen, or Solu-Cortef to treat mild to moderate infusion reaction. Resume infusion at 10 mL/h once reaction is controlled or abates. • Medications for treating hypersensitivity reactions (eg, acetaminophen, antihistamines, corticosteroids, or epinephrine) and supplemental oxygen should be available for immediate use in the event of a reaction. • Incompatible with PVC equipment or devices. Use glass infusion bottles and polyethylene-lined administration sets.
Muromonab-CD3 (Orthoclone OKT3)	Febrile reactions; fever, chills, tremor Respiratory: dyspnea, chest pain, wheezing, pulmonary edema GI: nausea, vomiting, diarrhea Anemia, thrombocytopenia	2.5–5 mg/d IV bolus over 30–60 s, for 10–14 d	Reactions are greatest with first dose and occur within 30–60 min. To minimize first dose reaction, pretreat with methylprednisolone, acetaminophen, and diphenhydramine hydrochloride. Monitor vital signs every 15 min for 2 h, then every 30 min first two doses. Have emergency equipment and cooling blanket available. Repeat administrations may cause serious reactions if antibodies develop.	Muromonab-CD3 (Orthoclone OKT3)

(Continued on page 1076)

Table 47-7 Selected Immunosuppressive Drugs Used in Solid Organ and Hematopoietic Stem Cell Transplantation *(continued)*

Drug	Mechanism of Action	Dosing/Administration	Adverse Reactions	Comments
Alemtuzumab (Campath)	Monoclonal antibody directed against the cell surface antigen CD52, which is expressed on B and T lymphocytes	Institutional protocols vary Usual dose: 20 mg/d IV given over several hours for 5 d, beginning before transplantation	Infusional toxicities may be severe, and include fever and rigors in more than 80% of patients. Other adverse effects include neutropenia, anemia, thrombocytopenia, nausea, vomiting, rash, fatigue, and hypotension.	• Premedicate patient with acetaminophen and diphenhydramine • Medications for treating hypersensitivity reactions (eg, acetaminophen, antihistamines, corticosteroids, or epinephrine) and supplemental oxygen should be available for immediate use in the event of a reaction. • Consider treatment with meperidine to control infusional rigors. • Administer fluid bolus as ordered to treat hypotension. • Produces profound and rapid lymphopenia; therefore, patients require broad antifungal, antibacterial, antiviral, and antiprotozoal prophylaxis for at least 4 mo after treatment.
Antithymocyte globulin (ATG, Atgam, equine) (Thymoglobulin, rabbit)	Polyclonal immunoglobulin composed of horse or rabbit antibodies capable of destroying human leukocytes	Institutional protocols vary Usual dose: 10–40 mg/kg/d for equine ATG, and 2.5 mg/kg/d for rabbit ATG	Seizures, laryngospasm, anaphylaxis, pulmonary edema, leukopenia, and thrombocytopenia. ATG is a foreign xenogeneic protein and an antibody, which may cause serum sickness, including myalgias, arthralgias, fever, rash, sore throat, dysphagia and hand and facial edema.	• Skin test for hypersensitivity to animal serum may be performed before initial dose Monitor patient closely both during infusion and after infusion for signs of serum sickness and anaphylaxis. Consider premedication with corticosteroids, acetaminophen, and H_1 and H_2 blockers. Medications for treating hypersensitivity reactions (eg, acetaminophen, antihistamines, corticosteroids, or epinephrine) and supplemental oxygen should be available for immediate use in the event of a reaction. • Because transient and at times severe thrombocytopenia may occur after ATG administration, in patients with platelet counts <100,000, monitor platelet count 1 h after ATG administration, and transfuse platelets as indicated.
Cyclophosphamide (Cytoxan)	Leukopenia, thrombocytopenia Increased susceptibility to infections Metabolite of cyclophosphamide is a direct irritant to bladder mucosa and may cause hemorrhagic cystitis.	1–2 mg/kg	Given in place of azathioprine in patients with hepatotoxicity. Mesna may be administered to neutralize the toxic metabolite of cyclophosphamide (acrolein) Administer on awakening to avoid accumulation of metabolites in bladder while sleeping. Observe for hematuria. Urine output of at least 100 mL/h should be maintained for at least 72 h after Cytoxan is administered to promote adequate dilution of renally excreted metabolites that produce hemorrhagic cystitis.	Cyclophosphamide (Cytoxan)

Azathioprine (Imuran) (IV or PO)	Bone marrow suppression: leukopenia, thrombocytopenia, anemia, pancytopenia Rash Alopecia Liver damage, jaundice Increased susceptibility to infection	Regulated to keep WBC 5,000–10,000; drug usually stopped when WBC 3,000 or less Initial 2–5 mg/kg of body weight Maintenance: 2–3 mg/kg of body weight During rejection: maximum of 3 mg/kg of body weight dose not usually increased with rejection	Imuran dose is lowered when given concurrently with allopurinol as allopurinol delays metabolism of azathioprine	Azathioprine (Imuran) (IV or PO)
Sirolimus (Rapamune)	Structurally similar to tacrolimus and cyclosporine; however, it has a distinct immunosuppressant activity Inhibits response of B and T lymphocytes to cytokine stimulation by IL-2 and inhibits antibody production by B cells	Long half-life permits once-daily dosing Monitor trough blood levels	Hyperlipidemia, thrombocytopenia, leukopenia, headache, nausea, anorexia, dizziness	• May suppress hematopoietic recovery if used in patients who have recently undergone high-dose therapy. • Oral bioavailability is variable and is improved with high-fat meals. • Like tacrolimus and cyclosporine, sirolimus is metabolized through the cytochrome P-450 3A system. • Always administer doses in the evening to minimize impact of drowsiness on lifestyle and safety. • Teach patient to use caution when taking thalidomide with other drugs that can cause drowsiness or neuropathy. • Teach patient to rise slowly from a supine position to avoid lightheadedness. • Teach patient to report immediately signs or symptoms suggestive of peripheral neuropathy, including numbness or tingling in the hands or feet or the development of skin rash or skin lesion. These may require immediate cessation of the drug until the patient can be evaluated for the neuropathy or skin rash. • Teach patient to use protective measures (eg, sunscreens and protective clothing) against exposure to ultraviolet light or sunlight. • Control or manage constipation with a stool softener or mild laxative. • May impair wound healing
Methoxsalen (Oxsoralen)	When photoactivated by ultraviolet light, drug inhibits mitosis by binding covalently to pyrimidine bases in DNA	400 mcg/kg PO 1.5–2 h before exposure to ultraviolet light		• Patients who have received cytotoxic chemotherapy or radiation and who are taking methoxsoralen are at increased risk for skin cancers, and long-term use may increase the risk of skin cancer. • Toxicity increases with concurrent use of phenothiazines, thiazides, and sulfanilamides. • Severe burns may occur from sunlight or ultraviolet A exposure if dose or treatment frequency is exceeded. • Pretreatment eye examinations are indicated to evaluate for the presence of cataracts. Repeat eye examinations should be performed every 6 mo while patients are undergoing psoralen and ultraviolet A therapy.

These dosage ranges are general guidelines. Significant variations in dosages occur based on institutional practices, other drugs being used in combination, type of transplantation, and patient response to the drugs.

The cyclosporine preparations Neoral and Sandimmune are not bioequivalent and cannot be used interchangeably. Gengraf and Neoral are bioequivalent.

HTN, hypertension; WBC, white blood cell; ANC, absolute neutrophil count; GI, gastrointestinal; IFN, interferon; IL, interleukin; IV, intravenous; PO, oral; PVC, polyvinyl chloride; TNF, tumor necrosis factor.

▲ Complications of Transplantation

Complications after solid organ transplantation and HSCT are usually due to graft function, problems with immunosuppression, or the adverse effects of the transplantation preconditioning regimen. Other common complications after HSCT are GVHD and infection.

Organ Transplantation

Recipients of kidney, liver, heart, pancreas, and lung transplants are at risk for a number of complications, including acute and chronic organ rejection, infection, and bleeding.

Organ Rejection

The early recognition and management of organ rejection and its associated problems are key priorities for the critical care nurse. The transplanted organ represents a continuous source of HLA alloantigens capable of inducing a rejection response. This immunological response involves the recognition of HLA antigens of donor endothelial tissues cells by recipient lymphocytes or antibodies. The allograft continuously activates the immune response, resulting in lifelong overproduction of cytokines, constant cytotoxic activity, and sustained alteration in the graft vasculature. Transplantation of a vascular organ induces sensitization through direct stimulation of circulating host immune cells as they encounter donor antigens on allograft cell surfaces. Rejection leads to subsequent destruction of the antigen-bearing graft. The pathophysiological mechanisms of graft rejection are depicted in Figure 47-4.

Both donor and host factors contribute to the immune response of rejection. The major donor factor is the expression of antigens on the donor tissue and the presence of antigen-presenting cells within the transplanted graft. The major host factor is prior sensitization against ABO and HLA antigens expressed in the graft.[29]

Because the transplanted organ is not immunologically identical to the recipient, it acts as an antigen or foreign substance and triggers the immune system to reject it. Rejection can vary in degree from mild to severe and may be irreversible. Rejection may occur at any time, but the risk is highest in the first 3 months after transplantation. It is important to maintain therapeutic levels of immunosuppression and to provide patient and family education about the importance of taking all medications as instructed and the rationale for routine laboratory monitoring of the levels of immunosuppressive drugs. The earlier and more severe the rejection episode, the worse the prognosis for graft survival. Biopsy of the transplanted organ is usually needed to diagnose rejection definitively. Four types of rejection are defined: hyperacute, accelerated, acute, and chronic, although all types do not occur in all transplanted organs.

Hyperacute Rejection

Hyperacute rejection occurs in the operating room immediately after transplantation. It is a humoral immune response in which the recipient has preformed antibodies that immediately react against antigens of the donor organ. Vascular damage occurs, resulting in severe thrombosis and graft necrosis. In kidney and heart transplantation, hyperacute rejection always results in graft failure and the need for retransplantation. Fortunately, hyperacute rejection is uncommon and can usually be prevented by pretransplantation cross-matching.

Accelerated Rejection

Accelerated rejection is defined only in kidney transplantation, and it occurs within 1 week after transplantation. Clinically, the patient may have anuria, increased BUN and creatinine levels, and pain at the graft site. Accelerated rejection is due either to preformed antibodies against the donor antigens in the recipient's blood or to lymphocytes in the recipient that are already sensitized to some of the donor antigens. Like hyperacute rejection, accelerated rejection is seen infrequently because of improved tissue typing and cross-matching. It is treated aggressively with immunosuppressants and usually results in loss of the transplanted kidney.

Acute Rejection

Acute rejection occurs within the first 3 months after transplantation. This is the most common type of rejection, and most patients experience at least one episode. Acute rejection occurs when antigens on the donor organ trigger lymphocytes to mature into helper T cells. The helper T cells increase the production of cytotoxic killer T cells, which bind to the transplanted organ and damage it by secreting lysosomal enzymes and lymphokines. Acute rejection is also the type of rejection that responds best to immunosuppressive therapy.

Chronic Rejection

The pathophysiology of chronic rejection is not completely understood. Most likely it is a combination of a cell-mediated response and a response to circulating antibodies. Second in frequency to acute rejection, chronic rejection usually occurs from 3 months to years after transplantation and is accompanied by deteriorating organ function.

KIDNEY. Acute rejection occurs after the first postoperative week. It is the most frequently seen form of rejection and the type that responds best to therapy. Changes in laboratory values are the earliest and most reliable indicators that graft function is deteriorating. Clinical manifestations of rejection are more subtle and may not be seen. The patient may experience any, all, or none of the following laboratory findings during an acute rejection episode:

- Increased serum creatinine, BUN, serum β_2-microglobulin levels
- Decreased creatinine clearance
- Decreased urine creatinine level
- Possibly decreased urine sodium level
- Decreased blood flow identified by renal scan

Clinical manifestations of rejection include:

- Decreased urine output
- Weight gain

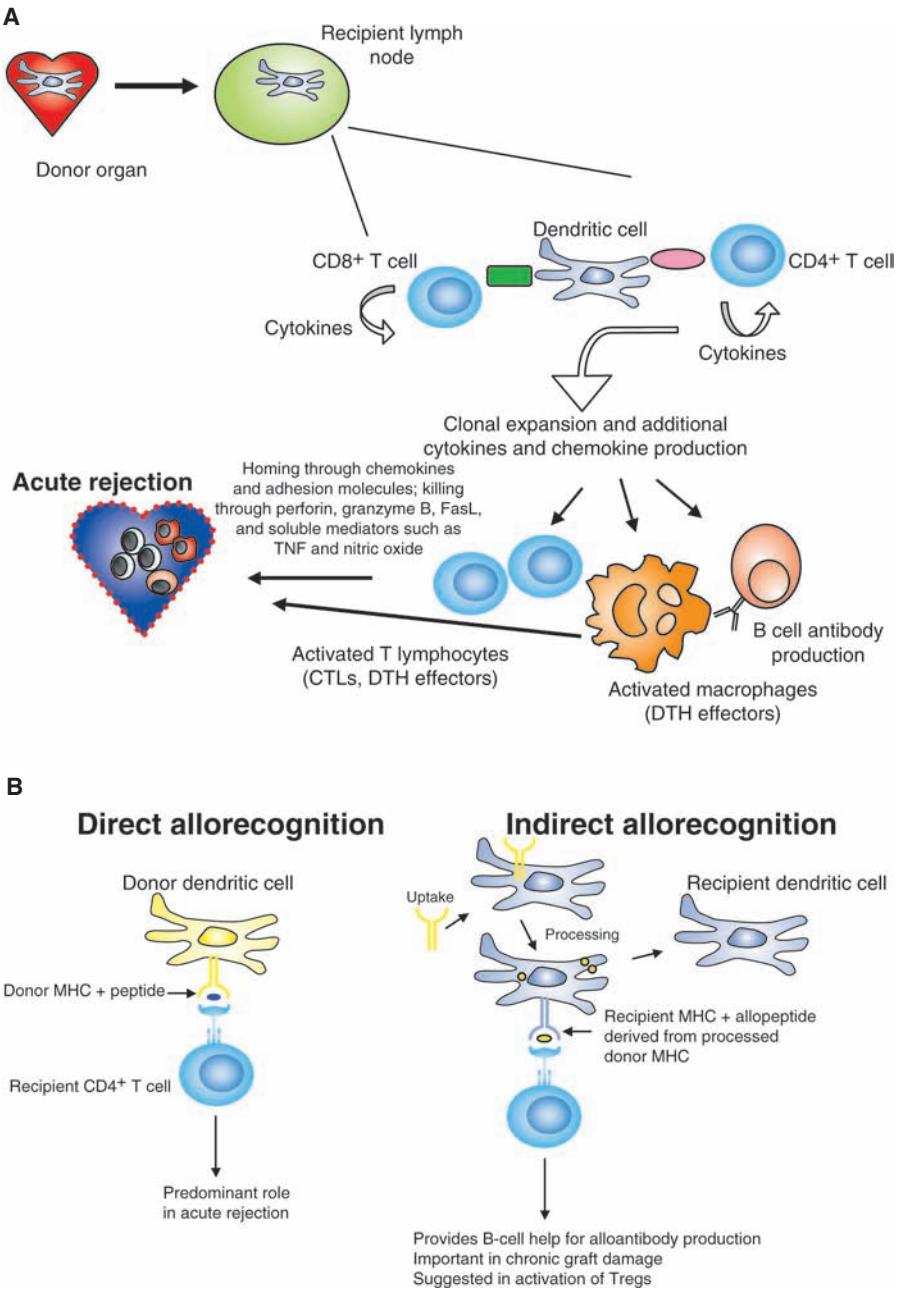

FIGURE 47-4 ▲ Mechanisms of graft rejection. **A:** Within 24 to 48 hours after engraftment, dendritic cells that normally reside within the donor organ migrate to regional recipient lymphoid tissue. In the lymph node, they stimulate alloreactive $CD4^+$ and $CD8^+$ T cells. Activated T cells, particularly $CD4^+$ cells, produce cytokines (eg, interleukin-2, interleukin-4, interferon-γ), and both populations respond by proliferating and differentiating. Activated T lymphocytes can cause graft destruction by direct lysis (cytotoxic T lymphocytes, or CTLs) or by local production of cytokines, a delayed-type hypersensitivity (DTH) reaction. Cytokines also promote macrophage and eosinophil activation and recruitment, and these cells can also secrete soluble inflammatory mediators that kill their targets. Last, activated T cells provide help for alloantibody production by B cells. **B:** There are two types of allorecognition. Direct allorecognition occurs when T cells recognize intact foreign major histocompatibility complex (MHC) molecules (as depicted in part *A*). This is thought to be the dominant initiator of acute graft rejection. T cells may also recognize peptide fragments derived from processing of donor antigens presented on self-MHC molecules. This is termed *indirect allorecognition*, and it is believed to be important in chronic graft dysfunction, in part perhaps because of its role in providing T-cell help for alloantibody production by B cells. Indirect allorecognition is also implicated in activating regulatory T cells, which may act to limit graft damage and promote tolerance. (From Lechler RI, Sykes M, Thomson AW, et al: Organ transplantation: How much of the promise has been realized? Nat Med 11(6):605–613, 2005.)

- Edema
- Temperature at least 100°F (37.8°C)
- Tenderness over the graft site, with possible swelling of the kidney
- General malaise
- Increased blood pressure

Chronic rejection is the result of repeated episodes of acute rejection in which the vessels become infarcted owing to the vasculitis, and the renal tissue becomes scarred. This gradually leads to deteriorating kidney function. The symptoms are similar to those of acute rejection except for fever and graft enlargement. Laboratory findings are similar to those of acute rejection but also include signs of chronic renal failure, such as a declining hematocrit and calcium–phosphorus imbalance. The rate of deterioration can vary from months to years. A transplant nephrectomy is not usually required unless the kidney becomes necrotic and life threatening.

LIVER. Acute rejection in liver transplantation is suspected when liver function tests, specifically PT/INR (most sensitive), aminotransferases, alkaline phosphatase, and total bilirubin, are increased. Clinical signs, such as decreased bile production and perigraft tenderness, may or may not occur.[20] Chronic rejection is believed to be due to multiple acute rejection episodes or a positive cross-match. A definitive diagnosis is made when a biopsy shows portal and bile duct inflammation and inflammatory cells, such as T lymphocytes.[20]

HEART. Although acute rejection is often asymptomatic, subtle signs and symptoms may include decreased cardiac output, atrial flutter or fibrillation, elevated WBC count, and low-grade fever. Endomyocardial biopsy is performed weekly for the first month and then less frequently to diagnose rejection. Acute rejection is a major cause of death in the first year after transplantation. Chronic rejection is the leading cause of death after the first year of cardiac transplantation. The prevalence within 5 years of transplantation is at least 60%. This cell-mediated rejection causes progressive myocardial fibrosis, leading to heart dysfunction. The lesions in allographic vasculopathy are concentric, not focal, unlike in typical atherosclerosis, and allographic vasculopathy can often be missed on standard cardiac catheterization. Angina cannot be used as a warning sign for coronary artery disease because the heart is denervated. Instead, decreased exercise tolerance during stress testing or intravascular ultrasonography is used for diagnosis.[30]

PANCREAS. Rejection is a major cause of graft loss in pancreas transplantation. This may be attributed to the difficulty in diagnosing rejection. Elevated blood glucose levels are a late sign and may occur too late to initiate successful treatment. When the bladder is used for exocrine drainage, urinary amylase levels reflect rejection before hyperglycemia becomes obvious. In combined kidney–pancreas transplantation, an elevated serum creatinine level may indicate rejection, although rejection can occur in one organ and not the other. Some experts state that chronic pancreas rejection may not occur in combined kidney–pancreas transplantation. The best pancreas transplant survival rate occurs when the procedure is performed simultaneously with kidney transplantation[10] (see Table 47-1, p. 1052). Needle biopsy during cystoscopy is used for definitive diagnosis.

LUNG. The signs and symptoms of lung transplant rejection are difficult to distinguish from pulmonary infection. Decreased lung function (ie, forced expiratory volume), dyspnea, cough, decreased breath sounds, fever, and tachypnea may occur in both rejection and infection. Immediately after surgery, rejection may also be confused with volume overload, reperfusion injury, or ischemic injury secondary to preservation. Chest radiographs showing interstitial and perihilar edema may be signs of rejection and signal the need for biopsy. Even so, biopsies must be carefully interpreted to rule out infectious complications, such as infection with CMV or *Pneumocystis carinii*, which can have histological findings similar to those of acute rejection.

Chronic rejection is known as obliterative bronchiolitis and occurs in approximately 15% to 25% of lung transplant recipients. Acute rejection and infection are believed to play a role in obliterative bronchiolitis. Acute rejection remains common, with 36% of lung transplant patients experiencing at least one episode of acute rejection in the first year after transplant.[30]

Infection

Infection is the most common posttransplantation complication. Alterations in the integrity of mucosal barriers and severe neutropenia from the pretransplantation conditioning regimen produce an environment conducive to serious bacterial and fungal infection.

The causative agents are often from the patient's own flora, particularly from the gastrointestinal tract and integumentary system. Pathogens may be bacteria, fungi, viruses, and even protozoa. The latter three groups of organisms are referred to as opportunistic pathogens. Normally harmless and found in humans and in the environment, they pose serious threats to patients with compromised immune systems. They take advantage of the decreased host defenses—hence the term "opportunistic." Examples of opportunistic infections include herpes simplex and herpes zoster viruses, CMV, *Candida albicans*, *P. carinii*, *Aspergillus* species, and *Cryptococcus* species.

All transplant recipients are at risk for bacterial infections from intravascular lines and urinary drainage catheters, but organ transplant recipients can also acquire postoperative wound and lung infections. Usually broad-spectrum antibiotics are given prophylactically for 48 hours after organ transplantation or until invasive lines and drains are removed. HSCT recipients receive antibiotics prophylactically for months after transplantation. Table 47-8 lists infections caused by bacteria and other organisms that commonly occur after allogeneic HSCT.

Recipients of organ transplants are at high risk for infection during the first 3 months after transplantation because they receive high dosages of immunosuppressants. Infections in the post–stem cell transplantation period usually follow a predictable pattern based on the recovery of the immune system. Therefore, recipients of HSCT are at high risk for infection during the first month, which is the pre-engraftment phase, because of neutropenia. HSCT recipients may receive colony-stimulating factors to reduce their risk for infection by accelerating WBC recovery. They remain at high risk for infection if they are receiving immunosuppressive medications to prevent or treat GVHD.

Table 47-8 Infections After Allogeneic Hematopoietic Stem Cell Transplantation

Period of Neutropenia (Days 0–30)	Period of Acute GVHD (Days 30–100)	Period of Chronic GVHD (Days 100+)
Gram-negative bacteria	Gram-negative bacteria	Encapsulated bacteria
Gram-positive bacteria	Gram-positive bacteria	Varicella-zoster virus
Herpes simplex	Cytomegalovirus (CMV)	CMV
Candida species	Polyomavirus (BK virus)	*P. carinii*
Aspergillus species	Adenovirus	*Aspergillus* species
	Varicella-zoster virus	
	Candida species	
	Aspergillus species	
	Pneumocystis carinii	
	Toxoplasma gondii	

Based on information from: Wingard JR, Hsu J, Hiemenz JW: Hematopoietic stem cell transplantation: An overview of infection risks and epidemiology. Infect Dis Clin North Am 24(2), 257–272, 2010.

During the first month, the predominant fungal infections in recipients of HSCT are *Aspergillus* species and *Candida* species, for which amphotericin B or fluconazole may be used prophylactically. The most frequent viral infection is herpes simplex, and 80% of the patients who were seropositive before transplantation experience a reactivation of herpes simplex unless they receive acyclovir prophylactically.[31]

After the first month, the most common infection in all transplant recipients is CMV. The consequences of CMV infection include enteritis, retinitis, pneumonitis, and marrow suppression. To prevent CMV infection, patients who are CMV seronegative should receive only CMV-negative blood products. Many centers require that all blood transfusions be filtered. Current recommendations are to treat solid organ transplant recipients, who are CMV negative and who receive a CMV-positive organ, prophylatically with oral valacyclovir (Valtrex) for 3 to 6 months after transplantation.[32] Ganciclovir may be appropriate for patients who are CMV seropositive and who are receiving increased immunosuppression for an episode of acute organ rejection. Close monitoring of HSCT recipients for CMV reactivation, as demonstrated by a rising level of CMV antigen by polymerase chain reaction in the blood, is imperative, with early preemption. Prevention is important in heart transplant recipients because there is a connection between CMV and coronary artery disease.[33] CMV may affect many organ systems; therefore, signs and symptoms of hepatitis, retinitis, enteritis, pneumonitis, fever, chills, and malaise may occur.[34]

A small number of HSCT recipients contract severe and potentially fatal infections 3 months or more after transplantation, during the late recovery phase, because of cellular and humoral immune deficiencies. The most frequent causes of these infections are *Pneumococcus* species, *Staphylococcus aureus*, *Candida* species, and varicella-zoster virus.

If infection develops in immunosuppressed patients, the usual signs and symptoms may be absent. In these patients, even a small increase in temperature (99°F [37.2°C]) may be significant. Daily monitoring of the WBC count is necessary. After organ transplantation, the leukocyte count is usually slightly elevated because of surgery and steroid treatment. However, infection may be present if the elevation persists, a rapid elevation occurs after a decline, or there is an increase in the percentage of immature WBCs (bands) noted on the differential.

It is essential to prevent infection in transplant recipients, who are immunosuppressed and may be neutropenic. Important nursing responsibilities include maintaining protective environments, practicing consistent and thorough provider handwashing and good oral and skin hygiene, monitoring vital signs frequently, and performing head-to-toe assessments. In some centers, additional protective measures include protective isolation systems, air filtration, gut and skin decontamination, and low-microbial diets. The benefit of these interventions has been debated, and their application is institution or protocol specific.[35,36]

In combined kidney–pancreas transplantation, immunosuppressive drugs may be discontinued in the presence of a severe infection to mobilize the patient's immune system. Consequently, the graft may be lost to save the patient. In heart, lung, and liver transplantation, immunosuppression may be decreased but must be continued.

Bleeding

Bleeding, oozing from the surface of the transplanted organ, or the presence of hematoma or lymphocele may occur after surgery. The heart transplant recipient is at risk for bleeding because the pericardial sac has stretched to accommodate an enlarged heart. When a smaller, healthy heart is implanted, the larger pericardial sac becomes a reservoir that can conceal postoperative bleeding. This may result in cardiac tamponade. Long-term coagulation therapy and liver congestion from pretransplantation heart failure also increase the risk for bleeding.

After liver transplantation, bleeding may occur as a result of coagulopathy because of liver dysfunction or from small vessels that continue to bleed after surgery. When the bladder drainage technique is used for exocrine drainage in pancreas transplantation, patients may have postoperative hematuria if the transplanted duodenal segment becomes ulcerated or if cystitis develops. Electrocautery using cystoscopy may be required for severe bleeding.

Gastrointestinal Complications Related to Steroid Therapy

Chronic steroid therapy increases the risk for peptic ulceration and erosive gastritis because it increases the secretion of hydrochloric acid and pepsinogen. Massive gastrointestinal bleeding may occur not only from steroid therapy but also from stress and decreased tissue viability caused by long-term protein restriction. For these reasons, patients usually are given histamine-2 (H_2) receptor antagonists (eg, nizatidine or ranitidine) or proton pump inhibitors (eg, omeprazole). The degree of renal function, together with concurrent medications, dictates which class of agent is selected for gastric cytoprotection.

Other serious gastrointestinal complications include acute pancreatitis, diverticulitis, *Candida* infection, esophagitis, obstruction from bowel adhesions, and ulcerative colitis. Infection becomes an added risk if the patient has an intestinal perforation. Ischemic bowel disease has been observed in the early posttransplantation period as a result of dehydration or ischemia resulting from low cardiac output.

More than one complication may occur simultaneously. In addition, signs and symptoms of gastrointestinal bleeding or perforation may be obscured by the anti-inflammatory effects of steroids. Therefore, complaints and changes in the patient's progress require thorough and prompt assessment.

The gastrointestinal tract of the patients who have had HSCT may also suffer the effects of the total-body irradiation and chemotherapy used in the preparatory regimen. Symptoms may include mucositis, nausea, vomiting, diarrhea, cramping, dyspepsia, anorexia, taste changes, and xerostomia.

Hematopoietic Stem Cell Transplantation

Graft Failure

Graft failure is usually defined precisely by institutional protocols. However, all definitions include a complete absence of engraftment or a seemingly initial hematopoiesis after transplantation, with later decreasing blood cell counts and an absence of hematopoiesis.[37] The clinical features of graft failure include neutropenia, anemia, and thrombocytopenia occurring beyond the initial period expected as a result of high-dose chemotherapy or chemoradiation therapy.

The overall incidence of graft failure is less than 5%, and it occurs most often in patients with aplastic anemia or those receiving unrelated donor transplants. The etiology is multifactorial. An important component in the evaluation is differentiating graft failure from disease recurrence or drug-induced myelosuppression. Table 47-9 describes graft failure in terms of its risk factors, possible causes, and therapeutic and preventive measures.

The HSCT recipient may be more susceptible to the myelosuppressive effects of various drugs after the transplantation. Drugs with a potential to cause myelosuppression should be used very cautiously, if at all, to minimize the risk for

Table 47-9 Graft Failure After Hematopoietic Stem Cell Transplantation: Risk Factors, Causes, and Preventive Measures

	Risk Factors	Causes	Preventive/Supportive Measures
Autologous stem cell transplants	• Patients with acute myelocytic leukemia, patients extensively pretreated • Low cell dose • Purged marrow • Marrow-suppressive drugs • Viral infection	• Defective marrow microenvironment with stromal cell damage • Collection of damaged stem cells due to extensive previous treatment • Drug-induced myelosuppression • Viral effects on stroma of bone marrow	• Harvest autologous stem cells early, before multiple cycles of potentially stem cell–toxic regimens have been given • Maximize number of infused cells (minimum number of autologous peripheral blood stem cells that results in consistent engraftment is at least 1×10^6 $CD34^+$ cells/kg of body weight, below which engraftment may be incomplete or there may be failure of engraftment) • Avoid myelosuppressive drugs after transplantation • Adjust doses of medications for renal dysfunction • Treat/prevent viral infections • Keep unmanipulated cells as backup in case or purged or manipulated grafts • Ensure that there is no folate or vitamin B_{12} deficiency • Administer G-CSF and rEPO as needed
Allogeneic stem cell transplants	• Diseases associated with a defective marrow microenvironment, including aplastic anemia and myelofibrosis • Stem cell source from HLA-mismatched, unrelated, or cord blood donor • Pretransplant transfusions, especially from a related donor • T-cell depletion, low cell dose, purging • Patients whose clinical condition precludes a sufficiently intensive conditioning regimen • Inadequate posttransplantation immunosuppression • Marrow-suppressive drugs • Viral infection, including infection with CMV	• Defective marrow microenvironment with stromal cell damage • Histocompatibility barriers • Allosensitization by transfusions • Damaged or inadequate number of stem cells infused • Persistence of host hematopoiesis • Persistence of immunocompetent host lymphocytes • GVHD-associated damage to bone marrow microenvironment • Drug-induced myelosuppression • Viral effects on stroma of bone marrow	• Avoid pretransplantation transfusions, especially from relatives • Select histocompatible donors • Ensure that the conditioning regimen is adequately immunosuppressive • Provide sufficient stem cell dose (minimum number of allogeneic peripheral blood stem cells that results in consistent engraftment is at least 2×10^6 $CD34^+$ cells/kg of body weight, below which engraftment may be incomplete or there may be failure of engraftment) • Use posttransplantation immunosuppression with cyclosporine, tacrolimus, or methotrexate • Avoid all myelosuppressive drugs after transplantation • Adjust doses of medications for renal dysfunction • Treat/prevent viral infections • Ensure that there is no folate or vitamin B_{12} deficiency • Administer G-CSF, rEPO as needed • Consider cryopreserving autologous peripheral blood stem cells preallograft for possible use in the event of graft failure and overwhelming clinical problems such as hemorrhage or life-threatening infection

rEPO, recombinant erythropoietin; G-CSF, granulocyte colony-stimulating factor.

Biol Blood Marrow Transplant 13(10):1121–1134, 2007.

drug-induced graft failure. In patients with delayed engraftment, it is prudent to review all medications and consider eliminating those that are not absolutely essential.

Veno-Occlusive Disease of the Liver

Veno-occlusive disease of the liver (also called sinusoidal obstructive syndrome) is a potentially fatal liver disease that occurs in 15% to 20% of recipients of HSCT. Veno-occlusive disease is a complication of the conditioning regimen and usually develops within 2 weeks of transplantation. The risk for veno-occlusive disease is increased in patients who have received total-body irradiation. Veno-occlusive disease may be severe; some studies report an incidence of 25% and a mortality rate close to 50%.[38–40]

Veno-occlusive disease occurs when fibrous material accumulates, resulting in obstruction of small venules in the liver. Subsequently, portal hypertension, acute liver congestion, and destruction of liver cells develop. Liver disease ranges from mild to severe, and severe liver failure may occur. In addition, veno-occlusive disease affects the kidneys; there is a decrease in renal blood flow, causing further water and sodium retention. Mild veno-occlusive disease persists until liver tissue heals and resumes normal function, usually 10 to 14 days after onset. Severe disease may result in multisystem failure.

Clinical manifestations of veno-occlusive disease usually begin during the first 3 weeks after transplantation and are characterized by hyperbilirubinemia, rapid weight gain, ascites, right upper quadrant pain, hepatomegaly, splenomegaly, and jaundice.[40] Treatment is supportive and focuses on maintaining intravascular volume and renal perfusion while minimizing fluid accumulation.[41] This may require central venous pressure monitoring and mechanical ventilation, as well as pulmonary artery pressure monitoring if excess fluids accumulate in the lungs. Sodium restriction is warranted, and spironolactone administration is necessary to decrease extravascular accumulation. Other supportive strategies may include renal-dose dopamine infusion, avoidance of diuretics that deplete intravascular volume, and chest physiotherapy to avoid pulmonary atelectasis.[40]

Strategies for preventing veno-occlusive disease of the liver are currently undergoing investigation. These include anticoagulation with heparin; fibrinolytics, such as tissue plasminogen activator or antithrombin III concentrates, defibrotide, prostaglandin E; and ursodeoxycholic acid (Actigall).[38–40,42,43]

Pulmonary Complications

Pulmonary complications develop in 30% to 60% of patients after HSCT.[44] Pulmonary complications may result from (1) infection, pulmonary edema, aspiration pneumonia, acute respiratory distress syndrome, and septic shock and (2) lung damage from total-body irradiation or pulmonary toxic chemotherapy agents.[41,44–48] Table 47-10 lists the pulmonary complications of HSCT.

Table 47-10 Pulmonary Complications of Hematopoietic Stem Cell Transplantation

Time Line	Complication
Acute (before day 30)	Pulmonary edema (secondary to fluid overload, cardiac dysfunction, or allergic reaction to medications/therapy) Oropharyngeal mucositis Aspiration pneumonia Pulmonary hemorrhage/diffuse alveolar hemorrhage Bacterial or fungal pneumonia Atelectasis Pleural effusion Recall radiation pneumonitis Allergic bronchospasm Transfusion-associated lung injury ARDS and septic shock
Early (before day 100)	Idiopathic interstitial pneumonitis Pulmonary embolism Viral pneumonia (CMV, herpes simplex virus, varicella-zoster virus, respiratory syncytial virus, adenovirus, parainfluenza, influenza) Protozoal pneumonia (*Pneumocystis carinii* pneumonia) Fungal pneumonia Bacterial pneumonia Transfusion-associated lung injury ARDS and septic shock
Late (after day 100)	Idiopathic interstitial pneumonitis Bacterial, fungal, or viral pneumonia Bronchiolitis obliterans/GVHD of lung

ARDS, acute respiratory distress syndrome.

Graft-Versus-Host Disease

GVHD, which is unique to allogeneic HSCT, results when the infused donor stem cells (graft) recognize the recipient (host) as foreign tissue. The graft then mounts an immunological response attacking the host tissues, resulting in a T-cell–mediated reaction in the skin (rash), gastrointestinal tract (enteritis), and liver (elevated liver function test results). Figure 47-5 shows examples of the skin and gastrointestinal tract manifestations that may occur in acute GVHD.

The incidence of GVHD is 30% to 60% in cases involving histocompatible, sibling-matched allografts, with more GVHD occurring when there is greater HLA mismatch between the donor and recipient.[49,50] The mortality rate due directly or indirectly to GVHD may reach 50%.[50] Risk factors other than histoincompatibility include sex mismatching; donor parity; older age; posttransplantation infectious complications, especially viral infections; the use of donor lymphocyte infusions after transplantation; and the type of GVHD prophylaxis used.[50]

GVHD is a serious complication, but it also has a beneficial effect in controlling the patient's malignancy in that immunocompetent donor cells are able to recognize the patient's malignant cells as foreign and eliminate them. This effect was originally identified in leukemia patients and was termed *graft-versus-leukemia effect*. Leukemia relapse was seen less often in patients with GVHD than in those without GVHD. The absence of GVHD in autologous transplant recipients is suspected to play a role in the higher disease relapse rates these patients experience. Recently, researchers are applying the graft-versus-malignancy effect to prevent disease recurrence after stem cell transplantation by the infusion of donor

FIGURE 47-5 ▲ Acute and chronic graft-versus-host disease (GVHD). **A:** GVHD of the skin is characterized by fine, discrete or confluent, erythematous macules and papules. Lesions may be pruritic or slightly tender with palpation. Earliest skin findings are usually seen on the face, palms and soles, and upper trunk. **B:** GVHD of the gastrointestinal tract. Images obtained during endoscopy demonstrate tissue edema, extensive erythema, and mucosal ulcerations. **C:** Oral lichen planus changes in a patient with chronic GVHD more than 130 days after allogeneic peripheral blood stem cell transplantation. Note the confluent, smooth, white papules that create a lacy pattern on the buccal mucosa. **D:** Chronic GVHD of the skin with irregularly shaped, deeply hyperpigmented macular lesions. Note the atrophy of the dermal and subcutaneous tissues with paper-thin skin giving an easily wrinkled or shiny appearance. The term *poikiloderma* is used to describe the classic features of patchy hypopigmentation and hyperpigmentation, dermal atrophy, and telangiectasias (small-diameter linear blood vessels seen on the skins surface.) **E:** Lichenoid chronic GVHD of the skin of the lumbar region with flat-topped, violaceous papules; the surface is shiny and has a lacy white pattern. The eruption is confluent in some areas, and hypertrophic plaques have developed. Postinflammatory hyperpigmentation may develop. (**B**, photo courtesy of Bruce Greenwald, MD, University of Maryland Medical System, Baltimore, MD; **C**, photo courtesy of Jane Fall-Dickson, RN, PhD, AOCN, National Institutes of Health, Bethesda, MD; **D** and **E**, photos courtesy of T. L. Diepgen and G. Yihune, Dermatology Online Atlas [http://www.dermis.net/doia].)

lymphocytes. This approach is called donor lymphocyte infusion. Research is also under way to devise strategies to induce GVHD in autologous recipients of HSCT.[51]

Acute Graft-Versus-Host Disease

Acute GVHD may occur as early as 7 to 21 days after transplantation but peaks 30 to 40 days after transplantation. Acute GVHD targets the skin, liver, and gastrointestinal system. Skin reactions, which often occur first, include an itchy maculopapular, erythematous rash on the palms, soles, ears, face, and trunk. This may resolve or progress to generalized erythroderma and desquamation. Gastrointestinal symptoms include nausea, vomiting, anorexia, abdominal cramping, and large-volume diarrhea that is green and watery. Stool may be guaiac-positive as a result of intestinal mucosa sloughing. An enlarged liver, right upper quadrant pain, jaundice, and elevated bilirubin and alkaline phosphatase levels may occur. The severity and extent of acute GVHD are evaluated using a grading system (Table 47-11).

Table 47-11 Staging and Grading System for Acute Graft-Versus-Host Disease

Clinical Staging of Individual Organ Manifestations		
Organ	**Stage***	**Description**
Skin†	+1	Maculopapular eruption over <25% of body area
	+2	Maculopapular eruption over 25%–50% of body area
	+3	Generalized erythroderma
	+4	Generalized erythroderma with bullous formation and often with desquamation
Liver	+1	Bilirubin 2.0–3.0 mg/dL
	+2	Bilirubin 3.1–6.0 mg/dL
	+3	Bilirubin 6.1–15 mg/L
	+4	Bilirubin >15 mg/dL
Gut	+1	Diarrhea <500 mL/d
	+2	Diarrhea 500–999 mL/d, or persistent nausea with histological evidence of GVHD in the stomach or duodenum
	+3	Diarrhea 1,500 or more mL/d
	+4	Severe abdominal pain, with or without ileus

Overall Grade			
Grade	**Skin‡**	**Liver**	**Gut**
I	+1 to +2	0	0
II	+1 to +3	+1 and/or	+1
III	+2 to +3	+2 to +3 and/or	+2 to +3
IV	+2 to +4	+2 to +4 and/or	+2 to +4

*Criteria for staging minimal degree of organ involvement required to confer that stage.

†Use rule of nines or burn chart to determine extent of rash.

‡If no skin disease is present, the overall grade is the highest single organ stage.

Chronic Graft-Versus-Host Disease

Chronic GVHD usually occurs in patients who have had acute GVHD, although it can occur in the absence of acute GVHD. Chronic GVHD typically occurs between 100 and 400 days after transplantation. Among patients who survived 150 days after allogeneic stem cell transplantation, researchers observed chronic GVHD in 33% to 49% of HLA-identical related transplants and in 64% of matched unrelated donor transplants.[52]

Risk factors for chronic GVHD include previous acute GVHD, older recipient age, and sex mismatching (female donor and male recipient).[53] The incidence of chronic GVHD may also be higher in recipients of peripheral blood stem cells than in recipients of bone marrow–derived stem cells.[52] Another significant risk factor for the development of chronic GVHD is a continuing need for corticosteroids for control of GVHD by day 100 after transplantation.[54]

Clinical manifestations of chronic GVHD, which may be limited or extensive, are present in the skin, liver, eyes, oral cavity, lungs, gastrointestinal system, neuromuscular system, and a variety of other body systems. Although the onset of chronic GVHD typically occurs much later than acute GVHD, generally 100 to 400 days after transplantation, there is a growing recognition that acute and chronic GVHD are best differentiated by their features, not their onset. Features of acute GVHD, including erythematous skin rash, liver function test abnormalities, nausea, vomiting, diarrhea, and abdominal pain, may occur after donor lymphocyte infusion. Similarly, pigmentary skin changes, sclerotic skin features, bronchiolitis obliterans, keratoconjunctivitis sicca, and oral dryness, all considered to be characteristics of chronic GVHD, may be observed in patients before day 100 after transplantation. A new paradigm for identifying acute and chronic GVHD and for diagnosing and staging chronic GVHD is evolving[55]; classification is based on the signs and symptoms of acute or chronic GVHD rather than on the number of days after transplantation. In addition, contemporary classification systems now identify an overlap syndrome in which diagnostic or distinctive features of chronic GVHD and acute GVHD appear together. Table 47-12 summarizes the clinical features, screening and evaluation, and interventions recommended for patients with chronic GVHD.[52,56–67]

Treatment and Prophylaxis of Graft-Versus-Host Disease

The first and most important way to limit GVHD is to find an HLA-matched donor. Despite such optimal matching of donor and recipient, further strategies to limit GVHD must be taken. The two major approaches to the prophylaxis of GVHD after HSCT are T-cell depletion of the graft and pharmacological therapy to prevent and treat GVHD.

T cells play a major role in the recognition of self from nonself proteins, and decreasing the number of T cells in the

Table 47-12 Chronic Graft-Versus-Host Disease: Clinical Manifestations, Screening/ Evaluation, and Interventions

Organ/System	Clinical Manifestations	Screening Studies/Evaluation	Interventions
Dermal	Dyspigmentation, xerosis (dryness), erythema, hyperkeratosis, pruritus, sclerosis, lichenification, onychodystrophy (nail ridging/ nail loss), alopecia	Clinical examination Skin biopsy—3-mm punch biopsy from forearm and posterior iliac crest areas	• Systemic Immunosuppressive therapy • PUVA; extracorporeal photopheresis • Topical tacrolimus ointment (Protopic) • Topical treatment with steroid creams, moisturizers/ emollient, antibacterial ointments to prevent suprainfection; aggressive lubrication of the skin • Because the sweat glands are affected, avoid overheating because heat prostration and heat stroke can occur • Avoid sunlight exposure, use sunblock lotion and wear a large hat that shades the face when outdoors
Oral	Lichen planus, xerostomia, ulceration	Oral biopsy from inner lower lip or buccal mucosa	• Steroid mouth rinses, oral PUVA, pilocarpine for xerostomia, fluoride gels/rinses to decrease caries • Careful attention to oral hygiene; regular dental evaluations
Ocular	Keratitis, sicca syndrome	Schirmer's test, ophthalmic evaluation	• Regular ophthalmological follow-up • Preservative-free tears • Temporary or permanent lacrimal duct occlusion • Fluid-ventilated, gas-permeable scleral lens prosthesis • Consider trial of cyclosporine ophthalmic emulsion (Restasis)
Hepatic	Jaundice, abdominal pain	Liver function tests (alanine and aspartate aminotransferases, alkaline phosphatase, bilirubin)	• Consider bile acid displacement therapy with ursodeoxycholic acid (Actigall) 300 mg PO three times a day
Pulmonary	Obstructive/restrictive pulmonary disease, shortness of breath, cough, dyspnea, wheezing, fatigue, hypoxia, pleural effusion	Pulmonary function studies, peak flow, ABG, chest CT	• Prevent and treat pulmonary infections, including *Pneumocystis carinii* and *Streptococcus pneumoniae* • Aggressively investigate changes in pulmonary function because these may represent chronic GVHD of lung/bronchiolitis obliterans • Encourage smoking cessation
Gastrointestinal	Nausea, odynophagia, dysphagia, anorexia, early satiety, malabsorption, diarrhea, weight loss	Stool cultures, esophagogastroduodenoscopy, colonoscopy, nutritional assessment, fecal fat excretion studies, serum amylase, D-xylose absorption test, CT of the abdomen	• Referral to gastroenterologist; consultation with nutritionist and nutrition support • Consider empirical trial of pancreatic enzyme supplementation • Aggressive management of gastrointestinal symptoms such as nausea and vomiting • Consider the use of cholestyramine (Questran) in the management of diarrhea • Consider a trial of oral beclomethasone, budesonide, or both
Nutritional	Protein and calorie deficiency, malabsorption, dehydration, weight loss, muscle wasting	Weight, fat store measurement, prealbumin	• Nutritional monitoring, supplementation, symptom specific interventions • Trial of megestrol (Megace) or other approaches to appetite stimulation (eg, mirtazapine [Remeron] or similar antidepressants; dronabinol [Marinol])
Genitourinary	Vaginal sicca, vaginal atrophy, stenosis, dyspareunia, vulvodynia	Pelvic examination; tissue biopsy	• Consider trial of mucosal application of corticosteroid ointment, cyclosporine ointment, or tacrolimus ointment • Vaginal dilators • Vaginal lubricants • Sexual counseling
Immunological	Hypogammaglobulinemia, autoimmune syndromes, development of autoantibodies	Quantitative immunoglobulin levels, CD4/CD8 lymphocyte subsets	• IV immunoglobulin supplementation as indicated, and prophylactic antimicrobials (rotating antibiotics for recurrent sinopulmonary infections, PCP prophylaxis, topical antifungals) • Screening for CMV and other opportunistic infections with frequent surveillance cultures and antigen detection • Consider vaccination against influenza and pneumococcus
Musculoskeletal	Myositis fascitis, contractures, debility, muscle cramps/ aches, carpal spasm	MRI measured range of motion, walk time, grip strength, creatine kinase, aldolase; performance status, formal quality-of-life evaluation (eg, FACT-BMT), formal evaluation of rehabilitation needs (CARES)	• Physical therapy for stretching and endurance • Correct electrolyte imbalances • Consider clonazepam, magnesium supplementation treatment for muscle cramping or myalgias

MRI, magnetic resonance imaging; CT, computed tomography; PCP, *Pneumocystis carinii* pneumonia; PUVA, psoralen and ultraviolet A.

graft before transplantation may decrease the incidence and severity of GVHD. Methods of T-cell depletion involve physical, immunological, and pharmacological techniques. The desired outcome is a reduction or elimination of T cells capable of initiating life-threatening GVHD. However, T cells also play a role in engraftment, and T-cell depletion carries greater risks for infection, graft failure, and disease relapse.

A variety of immunosuppressive agents, alone or in combination, have been used prophylactically for acute GVHD.[50] Immunosuppressive medications minimize the ability of the newly developing donor immune system to recognize the host or patient as foreign and limit the immune response. Immunosuppressive drugs may need to be taken for months or years after an allogeneic HSCT. Immunosuppression may involve a single drug (often tacrolimus or cyclosporine A) or a combination of drugs (methotrexate, tacrolimus, cyclosporine A, steroids, MMF, antithymocyte globulin [ATG]), sometimes in combination with T-cell depletion.[50,68] Table 47-7 on pages 1072–1077 presents the immunosuppressive agents commonly used in both HSCT and solid organ transplantation settings and the associated nursing implications.[67,69–77]

For patients at higher risk for GVHD, especially those undergoing matched unrelated HSCT, more intensive strategies for GVHD prevention are necessary. Many drug–drug interactions are associated with cyclosporine A and tacrolimus. Table 47-13 lists drugs that may interact with cyclosporine A and tacrolimus.[69] It is important to instruct patients to take their immunosuppressive medication exactly as directed and to contact their physician before starting any new medication.

Prospective, randomized trials have demonstrated that combination therapy is superior to single-drug therapy in preventing acute GVHD. However, to date, research has not shown that any one prophylactic regimen is superior in preventing acute GVHD or improving overall outcome.[50,68] The most widely used pharmacological regimen for the prophylaxis of acute GVHD is a combination of methotrexate and either cyclosporine A or tacrolimus.[78] Other drugs included in some GVHD prophylaxis regimens are corticosteroids, ATG, daclizumab, and MMF.[68,78–80] Table 47-14 presents several sample regimens for GVHD prophylaxis.

If grade II to IV acute GVHD develops, treatment is usually required.[56] Corticosteroids are the main component of therapy, along with continuing treatment with the immunosuppressive agent used for prophylaxis (tacrolimus or cyclosporine A). Corticosteroids are the main component of therapy, along with continuation of the immunosuppressive agents used for initial prophylaxis.[68,78–80] High doses of methylprednisolone (1 to 20 mg/kg/d) may be used. However, these high-dose regimens are associated with fatal infections and cannot be administered for more than a few days, and the dose of methylprednisolone is rapidly tapered to 2 mg/kg/d in divided doses. Once maximal improvement is achieved, the steroid dosage is tapered over 8 to 20 weeks, based on patient response.

For patients with GVHD in whom initial therapy has failed, a variety of salvage or secondary regimens, including MMF, infliximab, and daclizumab, are available. Once chronic GVHD develops, the usual therapy involves steroids, cyclosporine A, tacrolimus, and a variety of other immunosuppressive agents.[52,63,65,66,72,81] Gut rest, pain control, and antimicrobial prophylaxis coupled with hyperalimentation, if needed, are important aspects of the supportive care of patients with acute GVHD.[50] The outcome of treatment of acute GVHD is predicted by the overall grade of acute GVHD; higher overall grades are associated with poorer outcomes.[52,53] Response to treatment is another key deter-

Table 47-13 Drugs That May Alter Levels of Cyclosporine and Tacrolimus

Effects	Known Interactions	Suspected Interactions
Increase serum levels	Erythromycin Clarithromycin Itraconazole Fluconazole Ketoconazole Corticosteroids	H_2 antagonists Cephalosporins Thiazide diuretics Furosemide Acyclovir Warfarin Calcium channel blockers (ie, diltiazem, verapamil, nicardipine) Oral contraceptives Doxycycline Metoclopramide Coadministration with grapefruit juice
Decrease serum levels	Phenytoin or phenobarbital Rifampin or isoniazid Sulfadiazine + trimethoprim (IV)	Sulfinpyrazone Carbamazepine Anticonvulsants
Cause additive nephrotoxicity	Amphotericin B Aminoglycosides Melphalan Trimethoprim-sulfamethoxazole	Nonsteroidal anti-inflammatory drugs
Alter immunosuppressive effects		Propranolol Verapamil Etoposide

Based on information from Evans SO: The transplant pharmacopeia. In Treleaven J, Barrett AJ (eds): Hematopoietic Stem Cell Transplantation in Clinical Practice. Edinburgh, UK: Elsevier Limited, 2009, pp 331–342.

Table 47-14 Examples of Commonly Used Drug Regimens for Prophylaxis of Acute GVHD

Regimen	Dosing Schedule
Cyclosporine/steroids	Cyclosporine 3 mg/kg/d IV infusion from day –2, taper 10% weekly starting day +180* Methylprednisolone 0.25 mg/kg twice a day, days +7 to +14; 0.5 mg/kg twice a day, days +15 to +28; 0.4 mg/kg twice a day, days +29 to +42; 0.3 mg/kg twice a day, days +43 to +58; 0.25 mg/kg twice a day, days +59 to +119; and 0.1 mg/kg daily, days +120 to 180
Cyclosporine/ methotrexate/ steroids	Cyclosporine 5 mg/kg/d IV infusion from day –2, taper 20% every 2 wk starting day +84* Methotrexate 15 mg/m^2 on day +1, 10 mg/m^2 on days +3 and +6 Methylprednisolone 0.25 mg/kg twice a day, days +7 to +14; 0.5 mg/kg twice a day, days +15 to +28; 0.4 mg/kg twice a day, days +29 to +42; 0.3 mg/kg twice a day, days +43 to +58; 0.25 mg/kg twice a day, days +59 to +119; and 0.1 mg/kg daily, days +120 to 180
Tacrolimus/ minimethotrexate	Tacrolimus 0.03 mg/kg/d infusion from day –2, taper 20% every 2 wk starting day +180* Methotrexate 5 mg/m^2 on days +1, +3, +6, and +11
ATG/ cyclosporine/ methotrexate	ATG 20 mg/kg IV days –3, –2, and –1 Cyclosporine 5 mg/kg/d IV infusion from day –1, taper 10% weekly starting day +180* Methotrexate 10 mg/m^2 on days +1, +3, +6, and +11

*Either tacrolimus or cyclosporine has been used with this methotrexate or steroid dose schedule.

minant of outcome, and mortality is greatest in patients who do not achieve a complete response to the initial treatment strategy for acute GVHD.[54]

▲ Long-Term Considerations

Organ transplantation can lead to long-term survival. Increasing numbers of recipients lead healthier and longer lives. However, complications may occur long after transplantation.

Long-term care focuses on monitoring the patient's progress and adherence to the health care regimen. In solid organ transplant recipients, a major cause of graft loss in the long term is failure of patients to adhere to the medication regimen. Patients must also be monitored for the development of late complications, including infections, hypertension and cardiovascular disease, chronic rejection, and recurrence of the original disease, such as hepatitis in liver transplantation and recurrent glomerulonephritis in kidney transplantation. There is also increased incidence of posttransplantation lymphoproliferative disease in solid organ transplant recipients who are receiving long-term immunosuppression.[82,83]

Weight gain can be a significant complication after transplantation as a result of steroid use or because of general improved well-being related to the organ transplantation. Osteoporosis secondary to high steroid use is also a long-term issue for organ transplant recipients, more often for heart, liver, and stem cell transplant recipients than for kidney transplant recipients.

The refinement and success of HSCT has resulted in a large population of patients who have achieved control of their underlying disease. However, these patients must often deal with long-term sequelae and late effects of HSCT. In addition to chronic GVHD and infectious risks, they may experience a wide range of complications (Box 47-5).[67,84–102] Most transplantation centers have unique requirements for continued follow-up care that depends on protocols. The nature of the patient's complications determines the frequency of clinic visits. Patients and clinicians can use the guidelines provided at http://www.cibmtr. org/PUBLICATIONS/guidelines.html to direct long-term follow-up care after HSCT. Table 47-15 presents guidelines for screening and management of late effects in HSCT recipients.[67,84,86,87,89–92,94–102]

BOX 47-5 Early and Late Complications of Autologous and Allogeneic Hematopoietic Stem Cell Transplantation

Early (Occurring Before Day 1100)

Regimen-related toxicity
- Hemorrhagic cystitis
- Veno-occlusive disease of the liver
- Pulmonary complications
- Renal complications
- Neurological complications

Nutritional complications
Idiopathic pneumonitis
Graft failure
Infection
- Viral
- Bacterial
- Fungal

Graft-versus-host disease
Relapse

Late (Occurring After Day +100)

Regimen-related toxicity
- Cataracts
- Neurological conditions (peripheral and autonomic neuropathies)
- Gonadal dysfunction
- Endocrine dysfunction

Immunodeficiency
Infection
Musculoskeletal
- Osteoporosis
- Avascular necrosis

Chronic GVHD
Relapse of malignancy
Secondary malignancy

Table 47-15 Evaluation and Screening of Late Effects of Hematopoietic Stem Cell Transplantation

System/Dimension	Possible Late Effects	Evaluation and Screening
Disease status	Relapse/recurrence	Determined based on site of original disease, but may include CT scans, bone marrow aspirate and biopsy, lumbar puncture, cytogenetics, and engraftment studies Evaluation for minimal residual disease (if available)
Engraftment	Graft failure/marrow dysfunction with cytopenia	CBC with differential Bone marrow aspirate and biopsy Engraftment studies: to detect differences between DNA of donor and recipient and thus establish engraftment: variable nucleotide tandem repeats or restriction fragment length polymorphisms; cytogenetic studies may also be used to establish engraftment if the donor and recipient are of opposite sexes
Immunological function/recovery	Disorders of B- and T-lymphocyte quantity and function Hypogammaglobulinemia	CD4/CD8 lymphocyte subsets Quantitative immunoglobulin levels Vaccination titers
Cardiopulmonary effects	Interstitial pneumonitis Bronchiolitis obliterans Hypertension, cardiomyopathy, pericardial damage, peripheral vascular disease, coronary artery disease	Chest x-ray Pulmonary function tests with diffusing capacity of lungs for carbon monoxide Electrocardiogram (ECG) Echocardiogram History and physical examination
Neurological effects	Peripheral and autonomic neuropathies Cognitive changes, shortened attention span, difficulty with concentration Leukoencephalopathy Ototoxicity	Health history Neurological examination Neuropsychological testing Rehabilitation medicine Audiological testing
Gastrointestinal effects	Liver dysfunction Malabsorption syndromes	Liver function tests Hepatitis B serologies, hepatitis C polymerase chain reaction qualitative
Genitourinary effects	Renal dysfunction Radiation nephritis Hematuria, proteinuria Cancer of the bladder	BUN, creatinine Urinalysis with microscopy 24-h urine for creatinine clearance, total protein, if indicated
Endocrine		
Thyroid function	Hypothyroidism	TSH, T_3, T_4, free T_4
Gonadal function	Decreased production of gonadal hormones	LH, FSH, estradiol (women) Pelvic examination LH, FSH, testosterone (men)
Hypothalamic–pituitary	Abnormal pituitary gland function	Prolactin levels, FSH, LH, TSH
Ophthalmic	Cataracts	Ophthalmological examination to include slit-lamp examination and Schirmer's test
Dental/oral cavity	Sicca syndrome Caries Periodontal disease Xerostomia Oral malignancy	Regular dental evaluations Careful attention to oral hygiene Fluoride gels/rinses
Musculoskeletal	Osteoporosis Avascular necrosis Myopathy	Dual-energy x-ray absorptiometry scan MRI if pain in a joint, limited range of motion, or a limp MRI, neurological examination, electromyogram
Second malignancy	Nonmelanoma skin cancer	Complete physical examination with biopsy of suspect lesions; skin photographs may also help to monitor status
	Breast cancer	Mammogram, self-examination
	Thyroid cancer	History and physical examination, ultrasound, ^{131}I scan
	Acute leukemia	CBC with differential
	Myelodysplastic syndrome	Bone marrow aspirate and biopsy (if CBC abnormal)
	PTLD	CT scans if PTLD suspected
	Cancer of the uterine cervix	Gynecological examination with Papanicolaou smear
	Cancer of the bladder	Urinalysis with micro to detect microhematuria, urine cytology, follow-up cystoscopy

(continued on page 1090)

Table 47-15 Evaluation and Screening of Late Effects of Hematopoietic Stem Cell Transplantation (continued)

System/Dimension	Possible Late Effects	Evaluation and Screening
Integumentary	Increased incidence of benign and malignant nevi	Complete physical examination Skin biopsy of suspect lesions
Psychological/rehabilitation, quality of life	Changes in body image, roles, family relationships, lifestyle, occupation, discrimination, overcoming stigma, living with compromises, coping with symptoms	Assessment of individual adjustment, achievement of normal developmental tasks, marital stress, sexual function, body image, rehabilitation needs, symptom distress through systematic and structured evaluation

CBC, complete blood count; CT, computed tomography; FSH, follicle-stimulating hormone; LH, luteinizing hormone; MRI, magnetic resonance imaging; PTLD, posttransplantation lymphoproliferative disease; T_3, triiodothyronine; T_4, thyroxine; TSH, thyroid-stimulating hormone.

▲ Clinical Applicability Challenges

CASE STUDY

Mr. S. is a 25-year-old man who began experiencing shortness of breath 1 year ago. A chest radiograph revealed an enlarged cardiac silhouette. An echocardiograph demonstrated an ejection fraction of 15%, with dilated left and right ventricles, and no valvular abnormalities. The patient was diagnosed with idiopathic cardiomyopathy. The patient has no other medical problems. The patient was seen by a cardiologist and began medical management of his heart failure. The patient continued to have fatigue, shortness of breath at rest, and lower extremity swelling despite medical therapy (New York Heart Association Class IV failure). The patient was evaluated for heart transplantation and a left ventricular assist device (LVAD). The patient was deemed a candidate for heart transplantation, but because of the long waiting list and the continued failure of medical therapy, the decision was made to place an LVAD as a bridge to transplantation. The patient recovered well after placement of LVAD and was discharged home and was listed 1B on the heart transplant list.

Mr. S. was readmitted to the hospital after his LVAD placement for acute gastrointestinal bleeding secondary to gastritis. Since the patient was having complications from the anticoagulation that is needed for the LVAD, his transplantation status was upgraded to 1A. Fortunately, a suitable heart became available within a month.

Mr. S. underwent orthotopic heart transplantation. A standard biatrial approach was used. When he was separated from cardiopulmonary bypass, he was receiving dobutamine 6.0 mcg/kg/min, epinephrine 0.05 mcg/kg/min, vasopressin 0.04 units/min, and isoproterenol 5 mcg/min. After bypass, nitric oxide was introduced through the ventilator for an elevated pulmonary pressure of 48/26 mm Hg. He remained intubated from the operative procedure and was transferred to the cardiac surgery ICU. Mr. S. was extubated on postoperative day 1.

Mr. S. had no bleeding complications in the ICU. Weaning from the vasopressin and epinephrine occurred within the first 24 hours. He remained on dobutamine for right ventricular heart support, and he continued on isoproterenol for chronotropic support. After stable pulmonary pressures and adequate oxygenation were achieved, weaning from the nitric oxide occurred over 24 hours. Stable pulmonary pressures were maintained. Immediately after the operation, he was started on Solu-Medrol, 125 mg IV for three doses, as well as mycophenolate mofetil (MMF) (CellCept) for immunosuppression. After the IV therapy was completed, oral doses of steroids were given. Tacrolimus (Prograf) was held for the first 24 hours to ascertain that renal function was normalized. Tacrolimus was then initiated at low doses, with close attention to urinary output and renal indices. Blood urea nitrogen and creatinine values remained within normal limits, and the tacrolimus was increased with a goal level of 12 to 15 ng/mL. The transplant team had difficulty getting tacrolimus levels increased despite quickly increasing his doses. Because of cytomegalovirus (CMV) mismatch, he was started on prophylactic valganciclovir (Valcyte) 900 mg twice daily. CMV by polymerase chain reaction was checked weekly to evaluate for early CMV reactivation. Mr. S. was slowly weaned completely from dobutamine over the week after transplantation. He also had very high glucose levels and remained on an insulin drip and was also started on insulin glargine (Lantus).

One week postoperatively, the patient underwent endomyocardial biopsy and right heart catheterization. At this time, measurements of cardiac function were right atrial (RA) pressure, 8 mm Hg; right ventricular (RV) pressure, 31/14 mm Hg; pulmonary artery (PA) pressure, 21/11 mm Hg; pulmonary artery occlusion pressure (PAOP), 8 mm Hg; and cardiac index, 3.2 L/min/m^2.

(continued on page 1091)

CASE STUDY *(Continued)*

On the date of biopsy, the tacrolimus level was 8 ng/mL. The patient's immunosuppression medications included prednisone 30 mg twice daily, MMF (CellCept) 1,000 mg twice daily, and tacrolimus 6 mg twice daily. The endomyocardial biopsy was a grade 1A rejection. The transplant team increased the MMF (CellCept) to 1,500 mg twice daily, and the tacrolimus dose was aggressively titrated to maintain a level in the range of 12 to 15 ng/mL.

One week later, the patient underwent repeat right heart catheterization and endomyocardial biopsy. On the date of biopsy, the tacrolimus level was 12.6 ng/mL. The biopsy revealed a grade 0 rejection. The patient was discharged to home on a prednisone taper, MMF 1,500 mg twice daily, and tacrolimus 9 mg three times daily.

1. What are the unique priorities for care in a postoperative heart transplant recipient?.
2. How is CMV transmitted during transplantation procedures, and why is CMV an important consideration relative to transplantation outcomes? Also, what are the current treatment recommendations?
3. Why did the patient need an insulin drip postoperatively when he had no history of diabetes mellitus? What patient education would be important for this patient with regard to his newly diagnosed diabetes?
4. Why is it a priority to maintain tacrolimus levels of 12 to 15 ng/mL in the postoperative heart transplant recipient?

48 Common Immunological Disorders

Michael V. Relf, Brenda K. Shelton, and Kimmith M. Jones

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Utilize epidemiological evidence to describe the current human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) epidemics in the United States.
2. Describe the immunopathogenesis and natural history of HIV infection and AIDS.
3. Explain standard precautions and transmission-based precautions and their implementation in the intensive care unit.
4. Discuss the use of diagnostic testing and antiretroviral therapy in the management of HIV infection and AIDS.
5. Describe the pathophysiological processes of the oncological emergencies.
6. Discuss appropriate assessment data for each oncological emergency derived from patient history and physical examination, clinical manifestations, and diagnostic studies.
7. Explain the anticipated medical management and rationale for the treatment of selected oncological emergencies.
8. Describe relevant aspects of nursing management for each of the oncological emergencies.

Normally, an intact immune system provides protection from disease—both infectious and noninfectious diseases such as cancer. When one or more components of this system are weakened or adversely altered, a person becomes susceptible to a variety of diseases including opportunistic infections and some cancers. Primary immunodeficiency syndromes, typically single-gene disorders, mostly occur in males due to the fact that many are X-linked inherited syndromes.[1,2] The overall incidence of symptomatic primary immunodeficiency is estimated to be 1 in 10,000. Examples of primary immunodeficiencies include agammaglobulinemia (a failure of B-lymphocyte precursors to mature into B lymphocytes and ultimately plasma cells), X-linked agammaglobulinemia or Bruton's disease, Wiscott-Aldrich syndrome (involving both T and B lymphocytes and platelets), and severe combined immunodeficiency in which there is an absence of both T-lymphocyte and B-lymphocyte function. Spotlight on Genetics 48-1 focuses on the hematological condition, polycythemia vera, and Spotlight on Genetics 48-2 discusses ankylosing spondylitis, a form of chronic inflammatory arthritis.

An immunodeficiency is known as secondary if it is acquired later in life. Secondary immunodeficiencies have a variety of etiologies including malignancies (chronic lymphocytic leukemia, myeloma), drugs (cytotoxic agents, immunosuppressants used in organ transplantation, and steroids), viruses, nutritional deficits, metabolic disorders, and severe protein loss.[2]

This chapter is divided into two parts that focus on two areas of secondary immunodeficiency: (1) HIV infection and AIDS and (2) emergent situations precipitated by commonly occurring neoplastic disorders. The reader is encouraged to review Chapter 45, especially the material relating to the immune mechanisms (humoral and cell-mediated immunity, complement system, and phagocytosis/chemotaxis/opsonization). This review will help the reader appreciate the pathophysiological changes occurring in the conditions discussed in this chapter.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Impaired cellular immunity is the underlying pathophysiological consequence of AIDS, which is caused by the HIV. In 1981, the first case reports of the illness known today as AIDS were reported to the Centers for Disease Control and Prevention (CDC).[3] Since early in the HIV/AIDS epidemics, case surveillance definitions have been utilized by public health professionals and health care providers to diagnose,

SPOTLIGHT ON GENETICS 48-1

HEMATOLOGICAL SYSTEM–POLYCYTHEMIA VERA

- Polycythemia vera is a condition characterized by an increased number of red blood cells within the bloodstream and approximately 1 in 200,000 individuals are diagnosed each year.
- Mutations in the *JAK2* and *TET2* genes are associated with polycythemia vera. The function of the *TET2* gene is unknown. The *JAK2* gene provides instructions for making a protein that promotes the growth and division (proliferation) of cells.
- Polycythemia vera begins with one or more mutations in the DNA of a single hematopoietic stem cell, although it remains unclear exactly what initiates the disorder. A mutation in the *JAK2* gene seems to be particularly important for the development of polycythemia vera, as nearly all affected individuals have a mutation in this gene. *JAK2* gene mutations result in the production of a *JAK2* protein that is constantly turned on (constitutively activated), which improves the cell's ability to survive and increases production of blood cells
- Genetic and lab testing is available to diagnose Polycythemia Vera

SPOTLIGHT ON GENETICS 48-2

IMMUNE SYSTEM—ANKYLOSING SPONDYLITIS

- Ankylosing spondylitis is a form of chronic inflammatory arthritis that primarily affects the spine. It is part of a family of diseases called spondyloarthropathies, which affect between 3.5 and 13 per 1,000 people.
- A mutation in the *HLA-B* gene increases the risk of developing ankylosing spondylitis. Variations in several additional genes, including *ERAP1*, *IL1A*, and *IL23R*, have also been associated with ankylosing spondylitis.
- The *HLA-B* gene is part of a family of genes called the human leukocyte antigen (HLA) complex, which provide instructions for making a protein that plays an important role by helping the immune system distinguish the body's own proteins from proteins made by foreign invaders. Although *ERAP1*, *IL1A*, and *IL23R* influence immune system performance, it is unclear how variations affect risk of developing ankylosing spondylitis.
- Genetic testing such as targeted mutation analysis is available to diagnose ankylosing spondylitis.

Genetic Home Reference—http://ghr.nlm.nih.gov—Accessed July 14, 2011

Chen C-H, Lin K-C, Yu DTY, et al: Serum matrix metalloproteinases and tissue inhibitors of metalloproteinases in ankylosing spondylitis: MMP-3 is a reproducibly sensitive and specific biomarker of disease activity. Rheumatology 45(4):414–420, 2006

stage, and describe the natural history of HIV infection. In 2008, the HIV classification system and surveillance case definitions were revised and combined into a single case definition for HIV categorized by increasing severity—stage I, stage II, stage III (AIDS), or as stage unknown (Table 48-1).[4]

Since the 1980s, HIV infection has transformed from a life-limiting illness to a chronic illness manageable with strict adherence to antiretroviral therapy (ART) and other therapeutic interventions including the prophylaxis and treatment of opportunistic infections. Despite significant treatment advances, it remains an incurable disease that is highly stigmatized in the United States and around the world.[5] Without treatment, a person infected with HIV will progress to AIDS in about 10 years. However, with early diagnosis and treatment, survival for patients receiving ART and other therapies can be extended, on average, to 39 years.[6] Contemporary evidence across multisite studies demonstrates that the higher the $CD4^+$ T-cell lymphocyte count and the lower the viral load, there are decreased morbidity and mortality rates as well as a lower risk for progression to AIDS.

Caring for persons with HIV or AIDS requires collaborative, interdisciplinary care throughout the course of the illness.[5] Early in the AIDS epidemic, many believed it to be futile and a waste of resources to admit persons living with AIDS patients to an intensive care unit (ICU).[7] Today, however, as persons living with HIV and AIDS are living longer, they are being admitted to the ICU for management of AIDS-related opportunistic infections, complications associated with ART, and for medical problems unrelated to HIV infection.[8] When persons living with HIV or AIDS are admitted to the ICU, there are several challenging issues including legal statutes concerning HIV testing and disclosure, the administration of ART, risk for significant drug interactions between ART and medications commonly used in the ICU, and controversies surrounding the use of ART in the ICU.[9]

Critical care nurses need to be familiar with ART (1) to recognize life-threatening toxicities associated with this class of drugs, (2) to avoid drug interactions between ARTs and other classes of drugs that are common and potentially life-threatening, and (3) to avoid promoting ART drug resistance—a situation that could have profound negative consequences for the person living with HIV or AIDS after discharge from the ICU.[10] Physiological problems potentially experienced by persons living with HIV or AIDS requiring ICU care include immune reconstitution syndrome; acute respiratory distress syndrome from a variety of pathogens; atherogenic metabolic complications associated with ART; end-stage liver disease secondary to viral hepatitis; toxic effects, complications, and drug interactions associated with hepatitis C coinfection treatment (pegylated interferon and ribavirin); lactic acidosis associated with nucleoside reverse transcriptase inhibitors (NRTIs); and end-stage renal disease secondary to HIV-associated nephropathy; hepatitis B or C; diabetes; and hypertension.[9]

For some persons, a hospitalization or critical illness may result in them being diagnosed with HIV or AIDS. As many as 40% of patients with HIV are unaware of their status when they are admitted to the ICU.[9] To increase the rate

Table 48-1 Surveillance Case Definition for Human Immunodeficiency Virus (HIV) Infection Among Adults and Adolescents (Aged ≥13 years)—United States, 2008

Stage	Laboratory Evidence*	Clinical Evidence
Stage 1	Laboratory confirmation of HIV infection *and* $CD4^+$ T-lymphocyte count of ≥500 cells/mcL *or* $CD4^+$ T-lymphocyte percentage of ≥29	None required (but no AIDS-defining condition)
Stage 2	Laboratory confirmation of HIV infection *and* $CD4^+$ T-lymphocyte count of 200–499 cells/mcL *or* $CD4^+$ T-lymphocyte percentage of 14–28	None required (but no AIDS-defining condition)
Stage 3 (AIDS)	Laboratory confirmation of HIV infection *and* $CD4^+$ T-lymphocyte count of <200 cells/mcL *or* $CD4^+$ T-lymphocyte percentage <14†	*or* documentation of and AIDS-defining condition (with laboratory confirmation of HIV infection)†
Stage unknown‡	Laboratory confirmation of HIV infection *and* no information on $CD4^+$ T-lymphocyte count or percentage	*and* no information on presence of AIDS-defining conditions

*The $CD4^+$ T-lymphocyte percentage is the percentage of total lymphocytes. If the $CD4^+$ T-lymphocyte count and percentage do not correspond to the same HIV infection stage, select the more severe stage.

†Documentation of an AIDS-defining condition (Appendix A) supersedes a $CD4^+$ T-lymphocyte count of ≥200 cells/mcL and a $CD4^+$ T-lymphocyte percentage of total lymphocytes of ≥14. Definitive diagnostic methods for these conditions are available in Appendix C of the 1993 revised HIV classification system and the expanded AIDS case definition (CDC. 1993 Revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. MMWR Recomm Rep 41[No. RR-17], 1992) and from the National Notifiable Diseases Surveillance System. Available at: http://www.cdc.gob/epo/dphsl/casedet/case_definitions.htm.

‡Although cases with no information on $CD4^+$ T-lymphocyte count or percentage or on the presence of AIDS-defining conditions can be classified as stage unknown, every effort should be made to report $CD4^+$ T-lymphocyte counts or percentages and the presence of AIDS-defining conditions at the time of diagnosis. Additional $CD4^+$ T-lymphocyte counts or percentages and any identified AIDS-defining conditions can be reported as recommended. (Council of State and Territorial Epidemiologists. Laboratory reporting of clinical test results indicative of HIV infection: new standards for a new era of surveillance and prevention [Position Statement 04-ID-07]; 2004. Available at http://www.cste.org/ps/2004pdf/04-ID-07-final.pdf)

From Morb Mort Wkly Rep 57(RR10):1–8, 2008.

of HIV testing in health care settings, foster earlier detection of HIV infection, identify and counsel persons with unrecognized HIV infection while linking them to clinical and prevention services, and further reduce the rate of perinatal or vertical (mother-to-child) transmission, the CDC issued *Revised Recommendations for HIV testing of adults, adolescents, and pregnant women in health-care* settings in 2006 advocating the routine testing of all people who visit any health care setting.[11] On World AIDS Day 2010 (December 1, 2010), the Emerging and Infectious Diseases Expert Panel of the American Academy of Nursing endorsed the role of nursing in supporting routine HIV testing in all health care settings and increasing efficiencies in administrative operations for widespread testing.[12] Knowledge of an individual's HIV serostatus impacts the differential diagnosis and may influence the diagnostic and treatment options including patient outcome. Therefore, it is essential for critical care nurses to understand how HIV infection, as well as its sequelae and treatment, serves as a comorbid condition of the critically ill person or the primary admission diagnosis to the ICU.

▲ Epidemiology

In July 2010, CDC estimated that more than 1 million people were living with HIV in the United States.[13] One in five of those people was living with HIV but unaware of the infection. As a consequence of increased survival, the prevalence of HIV and AIDS is increasing in the United States while the number of new infections remains too high, with an estimated 56,000 Americans becoming newly infected with HIV annually. The majority of AIDS cases continue to occur in gay, bisexual, and other men who have sex with men (MSM). Half of new HIV infections annually and nearly half of the people living with HIV/AIDS are among MSM. However, heterosexuals and injection-drug users also continue to be diagnosed with HIV and AIDS. Like MSM, African Americans/Blacks are disproportionately affected by HIV and AIDS. Although African Americans/Blacks account for approximately 12% of the U.S. population, they account for nearly half of all new infections each year and half of the people living with HIV in the United States. The states and dependent areas with the highest rates (per 100,000) of adults and adolescents living with an AIDS diagnosis at the end of 2007 are, in descending order, the District of Columbia (1781.1), New York (456.9), Maryland (353.8), U.S. Virgin Islands (353.5), Puerto Rico (337.2), Florida (316), New Jersey (263.2), Delaware (261.6), Connecticut (253.7), and Georgia (250.8).[14]

▲ Immunopathogenesis of HIV

The immunocompromise associated with AIDS is caused by the viral agent HIV.[15,16] HIV is a single-stranded RNA virus that is part of the *Retroviridae* family in the genus *Lentivirus*. Two species of HIV are known to exist and include HIV-1 and HIV-2. HIV-1 and HIV-2 are human

primate lentiviruses while their genetic cousins, simian immunodeficiency virus 1 and 2 (SIV-1 and SIV-2), are nonhuman primate lentiviruses. Recent evidence documents extensive diversity of HIV-1 in the human primate population by 1960 and that the common ancestor to HIV-1 was spreading among humans 60 to 80 years before AIDS was first recognized in the 1980s.[17,18]

HIV is transmitted from person to person by blood and bodily fluids (semen, vaginal secretions, breast milk).[16] A variety of cells are susceptible to HIV infection including cells of the hematopoietic system, central nervous system (CNS), skin, gastrointestinal tract, myocardium as well as the dendritic cells, renal tubular cells, hepatocytes, Kupffer cells, pulmonary fibroblasts, cervix, prostate, testes, and dental pulp fibroblasts.[16] Influencing that transmission of HIV includes the biologic properties of the virus, its concentration in the bodily fluids, and the nature of the host's susceptibility at the cellular and immunological levels. Sexually transmitted infections (STIs) increase both the amount of infectious virus and the number of infected cells in the genitals and enhance HIV transmission. The lack of circumcision in males has been associated with an increased risk of infection related to the large number of dendritic cells in the foreskin and also with increased rates of transmission among uncircumcised men to their sexual partners.[16]

Viral Replication

HIV is composed of nine genes responsible for invading host cells and replicating. HIV is composed of a small outer envelope, an inner core of genetic material (RNA), and three enzymes necessary for reproduction: reverse transcriptase, integrase, and protease (controlled by the pol—or polymerase—gene). Like all RNA viruses, HIV cannot reproduce on its own. It must attach to and invade other cells to reproduce. Figure 48-1 illustrates the process of viral replication.

After HIV enters the bloodstream, infection occurs with transmission of HIV across a mucosal barrier attaching itself to dendritic cells or Langerhans cells.[15] Propagation of HIV occurs initially in partially activated $CD4^+$ T cells followed by massive propagation in activated $CD4^+$ T cells of the gut-associated lymphoid tissue. Then, dissemination of HIV to other secondary lymphoid tissues ensues with establishment of stable HIV viral reservoirs following.

Having an affinity for $CD4^+$ receptors, HIV attaches to the $CD4^+$ receptors on the T lymphocytes, fusing with the host cell, shedding its outer envelope and then integrating its viral core into the DNA of the host's cell. The viral RNA is incorporated into the DNA of the T-lymphocyte host with help from the enzyme integrase. After integration, viral RNA is transcribed into the host's DNA by way of the enzyme reverse transcriptase. After incorporation into the cell's DNA structure, the enzyme protease breaks the components down into functional pieces, which are then assembled into structurally intact, new infectious units called virions. This process tricks the host's cells into making components for more virions.

Eventually, the new virions undergo a process of coating and are then expelled from the host cell by budding.

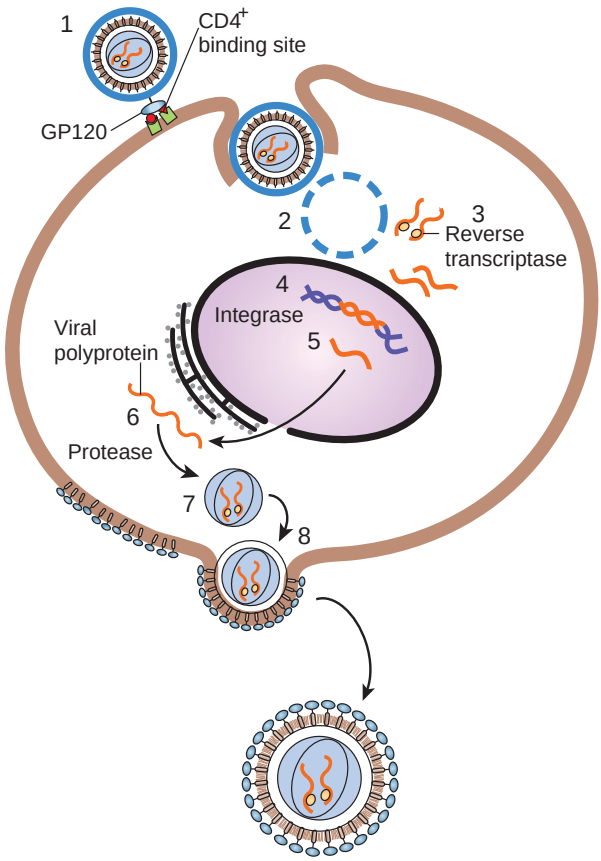

FIGURE 48-1 ▲ Process of human immunodeficiency virus (HIV) replication. (*1*) Attachment of HIV to a $CD4^+$ receptor. (*2*) Internalization and uncoating of the virus with viral RNA and reverse transcriptase. (*3*) Reverse transcription, which produces a mirror image of the viral RNA and double-stranded DNA molecule. (*4*) Integration of viral DNA into host DNA using the integrase enzyme. (*5*) Transcription of the inserted viral DNA to produce viral messenger RNA. (*6*) Translation of viral messenger RNA to create viral polyprotein. (*7*) Cleavage of viral polyprotein into individual viral proteins that make up the new virus. (*8*) Assembly and release of the new virus from the host cell. (Adapted from Porth C: Pathophysiology: Concepts of Altered Health States, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009.)

During budding, the parent cell releases a daughter cell with its cytoplasmic material, which begins existence as a separate cell. These daughter cells disseminate through the bloodstream and infect other cells. Approximately 30% of the viral burden in a person who is HIV positive is regenerated daily. This budding process—which weakens the cell wall of the original $CD4^+$ T cells leading to cellular instability in combination with the direct cytopathic effects of HIV on $CD4^+$ cells and progenitor cells, the effect of HIV on cell membrane permeability, induction of apoptosis (programmed cell death) associated with immune activation, destruction of the bone marrow and lymphoid tissues as well as cytokine dysregulation, anti-$CD4^+$ cell cytotoxic activity, and anti-$CD4^+$ autoantibodies—results in a decline in the number of circulating $CD4^+$ T-cell lymphocytes. Ultimately, these complex mechanisms destroy cellular immune functioning resulting in immunosuppresion.[16]

Immune Defects

Patients with HIV infection exhibit impaired activation of both cellular and humoral immunity.[15,16] HIV primarily infects the helper CD4+ T-cell lymphocytes of the immune system. As discussed in Chapter 45, these T cells play a major role in the overall immune response. Infection of the helper T cells with HIV results in profound lymphopenia with decreased functional abilities, including decreased response to antigens and loss of stimulus for T- and B-cell activation. In addition, the cytotoxic activity of the killer cells (CD8+ T cells) is impaired. Functional abilities of macrophages also are affected leading to decreased phagocytosis and diminished chemotaxis. In humoral immunity, there is diminished antibody response to antigens, along with dysregulation of antibody production. The total effect of these immune defects ultimately results in immunosuppression increasing susceptibility to opportunistic infections and neoplasms. Figure 48-2 presents a summary of the immune defects associated with AIDS.

HIV Transmission and Natural History

HIV is a fragile virus and cannot survive long outside the body. Survival time depends on the size of the liquid droplet in which it exists—the larger the droplet, the longer HIV can remain alive. As the droplet dries, HIV dies. HIV has been isolated from all types of body fluids and tissues. However, not all body fluids have been implicated in the transmission of HIV. The four fluids from which large amounts of virus have been isolated and have been implicated in transmission include blood, semen, vaginal fluid, and breast milk.

The infectiousness of a fluid depends on the amount of virus present (viral load) in the fluid and the ability of that fluid to reach the target cell. For HIV to cause infection, it must leave the body of the infected host, successfully enter the new host's bloodstream, and attach itself to a CD4+ receptor site. The likelihood that this series of events will occur is low, especially because a certain amount of virus is required to cause an infection. The notion that HIV does not transmit easily is based on evidence suggesting that the probability of transmission ranges from 0.0001 to 0.0040 per sexual contact.[15] Small tears in the anus or vagina provide a portal of entry for virus present in blood, semen, and vaginal fluid. The virus in breast milk can enter through cuts or irritation in the gastrointestinal tract of the infant.

There are three known modes of HIV transmission:[16]

- Unprotected vaginal or anal sexual contact with an infected person with unprotected receptive anal intercourse being the riskiest sexual behavior
- Inoculation with infected blood or blood products, which includes accidental needlestick injuries and risk for transmission with needle sharing by injection-drug users
- Vertical transmission from mother-to-child during delivery or through breast-feeding

After infection with HIV, a person does not immediately test positive for HIV. Seroconversion is the development of antibodies as a consequence of antigenic stimulation from HIV associated with exposure, which can be detected in the blood. In other words, seroconversion is the change from an HIV-negative result to an HIV-positive result. During the seroconversion process, the body recognizes HIV as an invader and develops antibodies, which are then detectable by enzyme-linked immunosorbent assay (ELISA). In most people, seroconversion occurs 2 to 8 weeks after exposure to HIV (average is 25 days).[19] During this time, a person can unknowingly transmit the virus and may falsely test negative by an ELISA screening test. In 97% of persons, seroconversion occurs within 3 months, but in extremely rare cases, it can take up to 6 months for antibodies to develop.[19]

Once infected with HIV, manifestations of acute or primary HIV infection, also known as acute antiretroviral syndrome, occurs 2 to 4 weeks later. The manifestations of acute HIV infection can present like other infectious viral disease including mononucleosis and influenza. The most frequent manifestations associated with acute HIV infection include fever (96%), adenopathy (74%), pharyngitis (70%), rash (70%), myalgias (54%), and, less frequently, diarrhea (32%), headache (32%), nausea/vomiting (27%), hepatosplenomegaly (14%), weight loss (13%), thrush (12%), and neurological symptoms (12%).[20] During this acute HIV infection phase, there is usually a high viral load. During this phase of HIV infection, it is not uncommon for an individual to be unaware of his/her HIV serostatus and to test negative or indeterminate for HIV. Several studies suggest that during

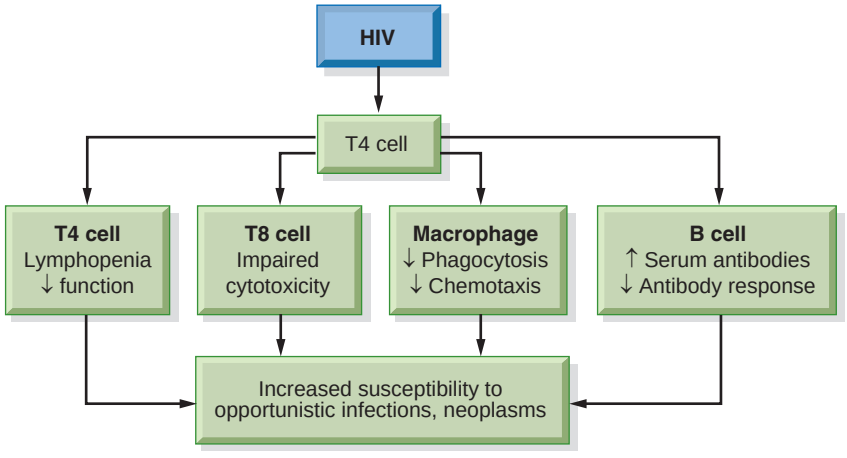

FIGURE 48-2 ▲ Summary of immune defects in AIDS.

BOX 48-1 Summary of Isolation Precautions

Standard Precautions: "Based on the principle that all blood, bodily fluids, secretions, excretions except sweat, non-intact skin and mucous membranes may contain transmissible infectious agents"

Common Organisms

Hepatitis A virus
Hepatitis B/D virus
Hepatitis C virus
Human immunodeficiency virus (HIV)
Pneumocystis jiroveci

Key Elements

Hand Hygiene

- Before direct care contact
- Wash hands after touching blood, body fluids, secretions, excretions, and contaminated items, regardless of whether gloves are worn.
- Wash hands immediately after gloves are removed, between patient contacts, and whenever indicated to prevent transfer of microorganisms to other patients or environments. Use plain soap for routine handwashing and an antimicrobial or waterless antiseptic agent for specific circumstances.
- Wear clean, nonsterile gloves when touching blood, body fluids, excretions or secretions, contaminated items, mucous membranes, and nonintact skin. Change gloves between tasks on the same patient as necessary, and remove gloves promptly after use.
- Restrict use of artificial nails and nail polish.

Use of Personal Protective Equipment

- Wear mask, eye protection, or face shield during procedures and care activities that are likely to generate splashes or sprays of blood or body fluids. Use gown to protect skin and prevent soiling of clothing.

Health Care Delivery System

- Ensure that used patient care equipment that is soiled with blood or identified body fluids, secretions, and excretions is handled carefully to prevent transfer of microorganisms or cleaned and appropriately reprocessed if used for another patient.
- Use adequate environmental controls to ensure that routine care, cleaning, and disinfection procedures are followed.
- Handle, transport, and process linen soiled with blood and body fluids, excretions, and secretions in a manner that prevents skin and mucous membrane exposures, contamination of clothing, and transfer of microorganisms.

Safe Injection Practices

- Use previously identified techniques and equipment to prevent injuries when using needles, sharps, and scalpels and place these items in appropriate puncture-resistant containers after use.

Airborne Precautions: Used in addition to standard precautions for "patients known or suspected with organisms transmitted by airborne droplets that remain suspended in the air and can be widely dispersed by air current"

Common Organisms

Mycobacterium tuberculosis
Varicella
Measles
SARS

Key Elements

- Place the patient in private room with an isolation sign on the door that has monitored negative air pressure in relation to surrounding areas, 6–12 air changes per hour, and appropriate discharge of air outside or monitored filtration if air is recirculated.
- Keep the door closed to the patient room at all times and the patient in the room whenever possible.
- Use respiratory protection when entering room of patient with known or suspected TB. If patient has known or suspected rubeola (measles) or varicella (chickenpox), respiratory protection should be worn unless person entering room is immune to these diseases.
- Transport the patient out of the room only when necessary, and place a surgical mask on the patient if possible.
- Consult Centers for Disease Control and Prevention Guidelines for additional prevention strategies for TB.

Droplet Precautions: Used in addition to standard precautions for "patients known or suspected to be infected with microorganisms transmitted by droplets generated during coughing, sneezing, talking, or during cough producing procedures"

Common Organisms

Meningitis
Pertussis
Influenza (A, B, C, Avian, H1N1)
Mumps
Rubella
Mycoplasma

Key Elements

- Place the patient in private room with an isolation sign on the door, if available, or cohort patients if necessary. Door closed at all times.
- Spatial separation of at least 3 ft from other patients/visitors. Health care providers should wear a mask when working within 3 ft of the patient.
- Transport the patient out of the room only when necessary, and place a surgical mask on the patient if possible.

(*continued on page 1100*)

BOX 48-1 Summary of Isolation Precautions (continued)

Contact Isolation: Used in addition to standard precautions for "patients known or suspected to be infected or colonized with epidemiologically important microorganisms that can be transmitted by direct contact with the patient when performing care activities or indirect contact (touching) with environmental surfaces or patient care items"

Common Organisms	Key Elements
Clostridium difficile	• Place the patient in private room with an isolation sign on the door, if available, or cohort patients if necessary. Door closed at all times.
Respiratory syncytial virus	
Pediculosis	• Change gloves after having contact with infective material. Remove gloves before leaving the patient environment, and wash hands with an antimicrobial or waterless antiseptic agent.
Scabies	
Multidrug resistant staphylococcus aureus (MRSA)	• Wear a gown if contact with infectious agent is likely or patient has diarrhea, ileostomy, colostomy, or wound drainage not contained by a dressing.
Vancomycin resistant enterococcus (VRE)	• Limit movement of the patient out of the room.
Gram-negative bacteria	• When possible, dedicate the use of noncritical patient care equipment to a single patient to avoid sharing equipment.

Adapted from Siegel JD, Rhinehart E, Jackson M, et al; the Healthcare Infection Control Practices Advisory Committee: 2007 Guideline for Isolation Precautions: Preventing Transmission of Infectious Agents in Healthcare Settings, June 2007. Available at: http://www.cdc.gov/ncidod/dhqp/pdf/isolation2007.pdf

this acute HIV infection phase, as many as 40% of lifetime transmissions occur. As previously stated, over 20% of all HIV-infected persons in the United States are not aware of their current serostatus and therefore have the potential to transmit the virus to another person. Although ELISA plays a valuable role in screening, it is not a confirmatory test for the diagnosis of HIV. Later in this chapter, other diagnostic tests used in HIV testing will be discussed.

The risk for HIV transmission to health care workers is low if standard precautions are followed[21] (Box 48-1). Occupational exposure can occur through a percutaneous injury (needlestick), contact with mucous membrane, or contact with nonintact skin (chapped, abraded, or affected by dermatitis).[22] The estimated average risk for HIV transmission after a percutaneous injury is 0.3%. The estimated average risk for HIV transmission after a mucous membrane exposure is 0.09%.[22] To provide a mechanism for comparison, if a health care worker were to receive a percutaneous needlestick from a host who was antigen positive for hepatitis B virus (HBV), hepatitis C virus (HCV), and HIV, the health care worker would have a 37% to 62% risk for acquiring HBV if previously not vaccinated and a 1.8% risk for acquiring HCV in comparison to only a 0.3% risk for acquiring HIV. Factors that can influence HIV transmission in a health care setting include contact with a device that is visually contaminated with blood, exposure to a large quantity of blood, participating in a procedure in which a needle is placed in an artery or vein, and deep injuries.[22]

For many years, occupational and nonoccupational postexposure prophylaxis (PEP) has been offered to health care workers and persons with exposure to HIV. PEP should be started as soon as possible after exposure to HIV, preferably within hours but no later than within 72 hours.[22] After 72 hours, PEP is not recommended. The decision about when to initiate PEP is based on the type of exposure, risk assessment of the incident, and risk assessment for HIV. Combination therapy using two or three medications is recommended in PEP; the number of medications depends on the type of exposure and the risk status of the source. Whether an occupational or nonoccupational exposure, PEP is prescribed for 28 days and requires the person to maintain strict adherence, which may be difficult if toxicities or side effects develop. Laboratory tests for toxicity should occur at the time of exposure and 2 weeks later and consist of a complete blood count (CBC) and renal and hepatic function tests. At the time of the exposure, persons exposed should have serological testing followed by repeat testing at 6 weeks, 12 weeks, and 6 months after exposure.[22] The National HIV/AIDS Clinicians' Consultation Center is a 24-hours-a-day, 7-days-a-week resource to all health care professionals and includes a PEP hotline to help manage exposure not only to HIV but also to HBV and HCV (see http://www.nccc.ucsf.edu/home for more information).

Since there has not been a decline in the number of new infections in the United States, scientists, clinicians, public health specialists, and advocacy groups have debated the value of preexposure chemoprophylaxis as a mechanism to prevent HIV infection. In a large, multisite clinical trial reported in December 2010, scientists identified that use of oral ART provided protection against the acquisition of HIV infection among MSM study participants.[23] Although not current standard of care, findings from this study may change prevention guidelines for high-risk populations in the future.

Regardless of the etiology of HIV infection, once infected with HIV, individuals will progress from the acute primary HIV infection phase to an asymptomatic phase. During this period, HIV viral replication continues resulting in a decline of immune functioning. As the number of $CD4^+$ T cells declines, a number of infectious and noninfectious diseases begin to present. Table 48-2 describes the complications common at various $CD4^+$ T-cell counts. If not treated, the cellular immune system will continue to decline and the person living with HIV will continue to be at risk for or experience an increased number of infectious and noninfectious diseases. Once the $CD4^+$ T-cell count reaches 200 cells/mm^3, the infected person is considered immunosuppressed and at very high risk for a number of opportunistic infections and other problems (Box 48-2 provides a list of AIDS-defining conditions).

Table 48-2 Correlation Between CD4⁺ T-Cell Count and HIV Complications

CD4⁺ T-cell count* (as cells/mm³)	Infectious Complications	Noninfectious† Complications
>500	Acute retroviral syndrome Candidal vaginitis	Persistent generalized lymphadenopathy Guillain-Barré syndrome Myopathy Aseptic meningitis
200–500	Pneumococcal and other bacterial pneumonia Pulmonary tuberculosis (TB) Herpes zoster Oropharyngeal candidiasis (thrush) Cryptosporidiosis, self-limited Kaposi's sarcoma Oral hairy leukoplakia	Cervical intraepithelial neoplasia Cervical cancer B-cell lymphoma Anemia Mononeuronal multiplex Idiopathic thrombocytopenic purpura Hodgkin's lymphoma Lymphocytic interstitial pneumonitis
<200	*Pneumocystis jiroveci* pneumonia Disseminated histoplasmosis and coccidioidomycosis Miliary/extrapulmonary TB Progressive multifocal leukoencephalopathy	Wasting Peripheral neuropathy HIV-associated dementia Cardiomyopathy Vacuolar myelopathy Progressive polyradiculopathy Non-Hodgkin's lymphoma
<100	Disseminated herpes simplex Toxoplasmosis Cryptococcosis Cryptosporidiosis, chronic Microsporidiosis Candidal esophagitis	
<50	Disseminated cytomegalovirus Disseminated *Mycobacterium avium* complex	Primary central nervous system (CNS) lymphoma

*Most complications occur with increasing frequency at lower CD4⁺ T-cell counts.

†Some conditions categorized as noninfectious are often microbially mediated, such as lymphoma (Epstein-Barr virus), and cervical carcinoma (human papillomavirus).

▲ Assessment

History and Physical Examination

The spectrum of clinical findings associated with acute HIV infection, HIV and AIDS ranges from flulike symptoms, to a period of no symptoms, to a variety of infections and symptoms associated with decreasing immunocompetence, to unquestionable AIDS. Patients with HIV infection may become seriously ill, requiring frequent hospitalizations and care in the ICU. In the past, critical care nurses frequently encountered patients with AIDS experiencing life-threatening opportunistic infections. Today, as patients with HIV and AIDS are living longer, critical care nurses are more frequently caring for this population as they experience other critical illnesses associated with aging including cardiovascular disease, renal problems, trauma, or consequences of ART in addition to the complications of AIDS.

Pneumocystis pneumonia (PCP), which is caused by *Pneumocystis jiroveci* (formerly known as *Pneumocystis carinii*), is the most common opportunistic infection requiring admission to the ICU.[24] The organism is considered a fungus based on its genetic makeup. Even though the name has changed, the abbreviation PCP is still used to describe the pathogen. The most common presenting symptoms include fever, exertional dyspnea, nonproductive cough, and a normal chest radiograph progressing to severe hypoxemia and respiratory failure.

The major indication for critical care of patients with PCP is impending or actual respiratory failure. Symptoms of respiratory compromise often are more severe than diagnostic studies, such as chest radiographs and blood gas values, indicate. Therefore, early aggressive therapy for PCP using intravenous (IV) trimethoprim and sulfamethoxazole (Bactrim, Septra) and corticosteroids is the treatment of choice. Corticosteroids are given to reduce the inflammation caused by the death of *P. jiroveci* in the lungs. Even with urgent, aggressive treatment, many patients require mechanical ventilation for progressive alveolar hypoventilation. Adverse reactions to trimethoprim and sulfamethoxazole, including nausea and vomiting, maculopapular rash, bone marrow suppression, anorexia, headache, crystalluria, and fever, reportedly occur in more than 50% of patients.

Patients with AIDS may also experience complex neurological conditions including cryptococcal meningitis, toxoplasmosis, histoplasmosis, Creutzfeldt-Jakob disease (CJD) leading to progressive multifocal leukoencephalopathy, and CNS lymphomas. Like PCP, a priority is to reduce immunosuppression by initiating ART so that these opportunistic

BOX 48-2 Case Definition of AIDS for Surveillance Purposes: Indicator Conditions

- Candidiasis of bronchi, trachea, or lungs
- Candidiasis, esophageal
- Cervical cancer, invasive
- Coccidioidomycosis, disseminated or extrapulmonary
- Cryptococcosis, extrapulmonary
- Cryptosporidiosis, chronic intestinal (>1 month duration)
- Cytomegalovirus (CMV) disease (other than liver, spleen, or nodes)
- CMV retinitis (with loss of vision)
- Encephalopathy, HIV-related
- Herpes simplex: chronic ulcer(s) (>1 month duration); or bronchitis, pneumonitis, or esophagitis
- Histoplasmosis, disseminated or extrapulmonary
- Isosporiasis, chronic intestinal (>1 month duration)
- Kaposi's sarcoma
- Lymphoma, Burkitt's (or equivalent)
- Lymphoma, immunoblastic (or equivalent)
- Lymphoma, of brain, primary
- *Mycobacterium avium* complex or *Mycobacterium kansasii*, disseminated or extrapulmonary
- *Mycobacterium tuberculosis*, any site (pulmonary or extrapulmonary)
- *Mycobacterium*, other species or unidentified species, disseminated or extrapulmonary
- *Pneumocystis jiroveci* pneumonia
- Pneumonia, recurrent bacterial
- Progressive multifocal leukoencephalopathy (PML)
- *Salmonella* septicemia, recurrent
- Toxoplasmosis of brain
- Wasting syndrome due to HIV
- $CD4^+$ count 200 cells/mL or less

Source: Centers for Disease Control and Prevention. Revised surveillance case definitions for HIV infection among adults, adolescents, and children <18 months and for HIV infection and AIDS among children aged 18 months to less than 13 years—United States, 2008. Morb Mortal Wkly Rep 57(RR10):1–8, 2008.

infections can be avoided. For the critical care nurse, treatment is usually associated with managing the neurological compromise that includes increased intracranial pressure, seizures, and hemiparesis.

Although the early research related to HIV and AIDS was originally conducted in men, the body of knowledge examining HIV and AIDS in women is significant—partially as a result of the natural history study of HIV in women also known as the Women's Interagency HIV Study.[25] Many recent studies, which have included women, suggest that men and women do not differ in terms of the general characteristics of HIV disease, except for the HIV-infected woman's increased risk for cervical dysplasia.[6] The clinical course of infection, including time from HIV infection to AIDS, risk factors for HIV seroconversion, number and type of opportunistic illnesses, protection against infections, and the effectiveness of potent antiretroviral agents, all appear similar in both men and women.

No organ system escapes involvement in HIV infection. Single infections may develop in critically ill patients with AIDS, but patients often have multiple infections simultaneously that require a variety of treatment strategies. The decrease in immune system functioning causes the multisystem manifestations to develop, resulting in an increase in opportunistic infections. Figure 48-3 presents manifestations of HIV infection and AIDS. Box 48-3 lists examples of nursing diagnoses for patients with HIV infection.

Laboratory and Diagnostic Studies

Tests Used to Detect HIV

Several serological tests are used to determine whether a person has been exposed to HIV. The most widely used test for screening is the ELISA, which determines the presence of antibodies for HIV. The results of this rapid and inexpensive test are available in usually less than 1 hour. ELISA screening tests can be performed on either blood/plasma/serum or oral fluid.[20] Results are reported as either reactive (positive) or nonreactive (negative) and have a sensitivity (true positive) rate of 99.5% and specificity (true negative) rate of 99.994%.[20] Unfortunately, the presence of other antibodies may lead to a false-positive result, which means that the test result was HIV positive, but the person is actually HIV negative. With ELISA, a positive/reactive ELISA is always repeated, and if the second ELISA is positive, confirmatory testing with Western blot is required.

Due to the "window period" associated with seroconversion, during the acute HIV infection phase, low production of antibodies at the time the test is performed or recency of infection may lead to a false-negative result. A false-negative result means that the test result was HIV negative but that the person is actually HIV positive; therefore, persons should not be considered HIV negative until there are repeated negative results in a 6-month period. During this "window period," if a person engages in high-risk behaviors associated with HIV, another 6-month window is required to determine the individual's HIV status.

Rapid HIV testing is based on ELISA technology. Instead of sending the specimen to the laboratory and then obtaining results days later, as was standard procedure in the past, rapid HIV testing with ELISA yields results within 20 minutes. Frequently, this type of testing is done in emergency departments (EDs) and primary health care environments including clinics. Current rapid HIV tests can be performed with either serum or saliva samples. Any positive ELISA, regardless of specimen type, still requires confirmatory testing with Western blot. In June 2010, the FDA approved a fourth-generation HIV test. This contemporary HIV test incorporates p24 antigen testing with standard antibody testing and enables earlier and more accurate HIV detection—particularly during the window period.

All positive ELISAs are confirmed by a Western blot. The Western blot analysis is the most widely used confirmatory test and is highly sensitive and specific. The Western blot identifies the presence of antibodies to HIV-1 and/or HIV-2 proteins (depending on the specific assay). The Western blot screens for the following proteins: core (p17, p24, p55), polymerase (p31, p51, p66), and envelope (gp41, gp120, gp160).[20] In analyzing test results from a Western blot, the test is considered to be negative if no bands are present. To be positive, the Western blot results must include gp120/160 and either gp41 or p24. An indeterminate Western blot is the presence of any band not meeting positive criteria.

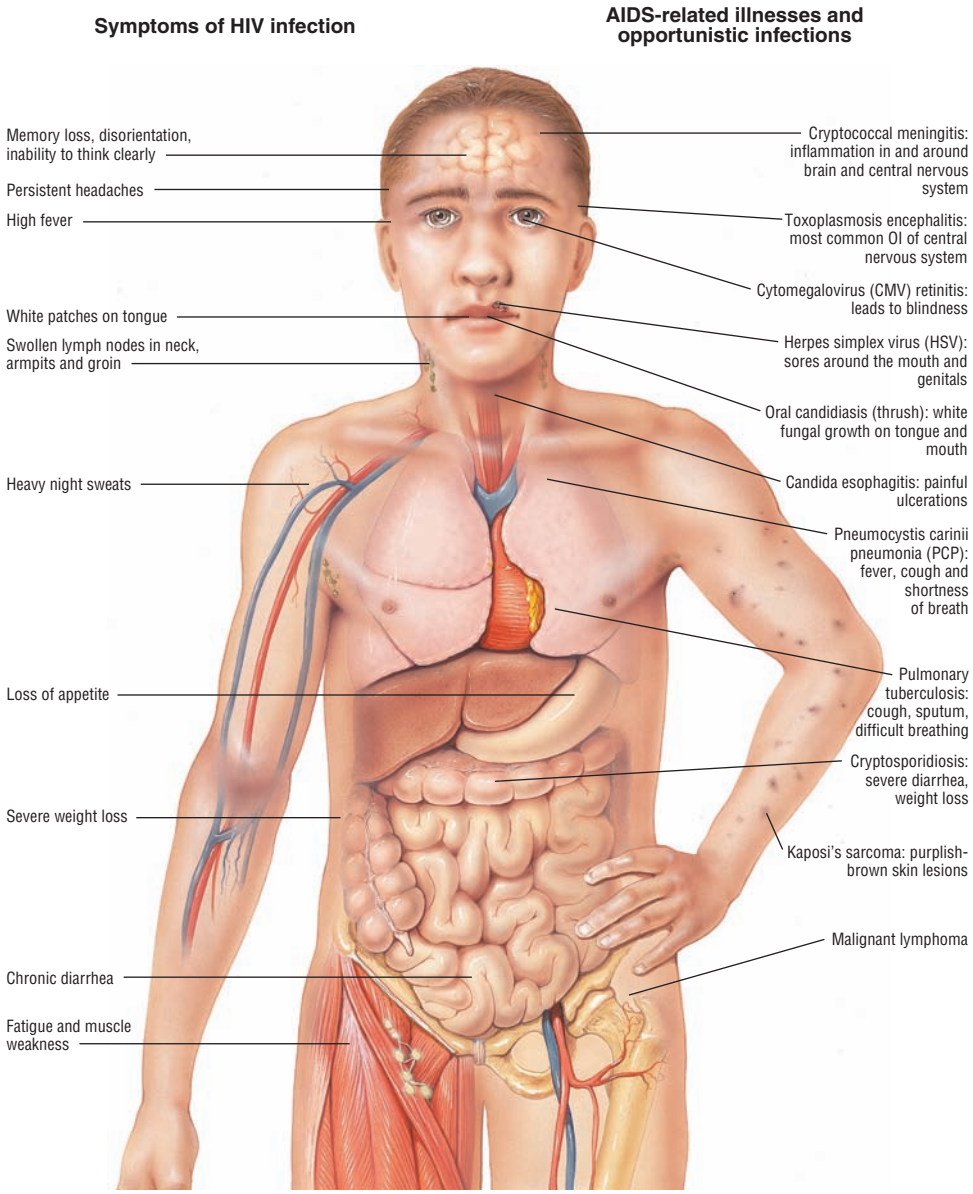

FIGURE 48-3 ▲ Manifestations of HIV infection and AIDS. (From Anatomical Chart Company: Atlas of Pathophysiology, 3rd ed. Springhouse, PA: Springhouse, 2010, p 267.)

Several alternative FDA-approved HIV detection methods are available, but usually are not routinely used in screening adults. The polymerase chain reaction (PCR) test is frequently used in newborns and children to screen for HIV infection. Because it tests for genetic material of HIV rather than antibodies to the virus, it can identify HIV infection at a much earlier stage. Therefore, in adults, this test is frequently done when there has been a high-risk occupational or nonoccupational exposure.

As a consequence of the 2006 CDC recommendations, screening for HIV should be routinely performed in all health care settings for persons between the ages of 13 and 64. Further, all patients initiating treatment for tuberculosis (TB) or seeking treatment for STIs should be routinely screened. All persons likely to be at high risk for HIV should be tested annually. According the CDC, "persons likely to be at high risk include injection-drug users and their sex partners, persons who exchange sex for money or drugs, sex partners of HIV-infected persons, and MSM or heterosexual persons who themselves or whose sex partners have had more than one sex partner since their most recent HIV test."[20](p 7)

Tests Used to Evaluate Progression of HIV Infection

HIV nucleic acid testing, also called viral load testing, in combination with the $CD4^+$ T-cell lymphocyte count is currently the best method available to determine progression on the HIV disease continuum. The viral load measures the amount of viral particles in a cubic mm (mm^3) of blood. The higher the viral load, the more HIV present to cause immune destruction and the more rapid the progression to AIDS.[20] Three methods can be used to determine the viral load: HIV RNA PCR, branched-chain DNA (bDNA), and nucleic acid sequence–based amplification. PCR is the most common method. The test results are used to determine the best time to begin ART and when a change in therapy may be indicated.

BOX 48-3 EXAMPLES OF NURSING DIAGNOSES

For the Patient With HIV or AIDS

- Risk for Infection related to immunodeficiency
- Risk for Impaired Gas Exchange related to
  - Alveolar–capillary membrane changes with *Pneumocystis jiroveci* infection
  - Infectious processes (TB, pneumococcal pneumonia)
  - Acute respiratory distress syndrome
  - Pneumothorax
- Risk for Deficient Fluid Volume related to diarrhea, dysphagia, sepsis
- Anxiety related to critical illness, fear of death
- Social Isolation related to family/community/health care provider knowledge deficit about risk for transmission and HIV-related stigma
- Deficient Knowledge related to antiretroviral therapy, prophylactic medications
- Risk for Decreased Cardiac Tissue Perfusion related to HIV-associated cardiomyopathy, nephropathy
- Risk for Activity Intolerance related to anemia, HIV-associated fatigue
- Risk for Bleeding related to thrombocytopenia, coagulopathy, intracranial hemorrhage

The $CD4^+$ T-cell count and percentage is another important evaluation tool used to stage HIV disease and to make decisions concerning the initiation of ART and prophylactic treatment for opportunistic organisms.[26] The normal $CD4^+$ T-cell count is around 1,000 cells/mm^3 in adults, and the count declines over time in the person with HIV not on treatment (Fig. 48-4). There is an inverse relationship between the viral load and $CD4^+$ T-cell count (Fig. 48-5). As HIV/AIDS progresses, the number of $CD4^+$ T cells declines, and the amount of HIV in the blood increases.

Other tests used to evaluate HIV infection include CBC, rapid plasma reagin (to screen for syphilis), chest radiograph, serum chemistries, Papanicolaou (Pap) tests to screen for cervical cancer in women and to screen for anal carcinoma in both men and women, purified protein derivative skin test (to screen for TB), hepatitis serology (to screen for HBV and HCV), toxoplasmosis serology, and cytomegalovirus (CMV) antibody serology.

▲ Management

Management of patients with HIV disease involves a complex, multisystem assessment, including diagnostic tests that establish a baseline and determine the appropriateness of therapy. Prognosis is based on the type and number of opportunistic infections that occur and the degree of immunocompromise. Patients with multiple opportunistic infections tend to be more seriously immunosuppressed and have a poorer prognosis.

Control of Opportunistic Infection

The primary goal of management in critically ill HIV-infected patients is the prevention or resolution of infections whether opportunistic, community-acquired, and/or health care associated. Opportunistic infections are the leading cause of death in patients with HIV infection; therefore, prevention is the cornerstone of treatment. Treatment of opportunistic infections is aimed at support of the involved system or systems. Treatment guidelines have been developed for prophylaxis against several organisms associated with HIV and AIDS. In April 2009, the *Guidelines for Prevention and Treatment of Opportunistic Infections in HIV-Infected Adults and Adolescents* were published.[26] The current organisms for which prophylaxis is strongly recommended include *P. jiroveci*, *Mycobacterium tuberculosis*, and *Toxoplasma gondii*. Organisms that should be considered for prophylaxis include CMV, *Mycobacterium avium* complex, and varicella-zoster.

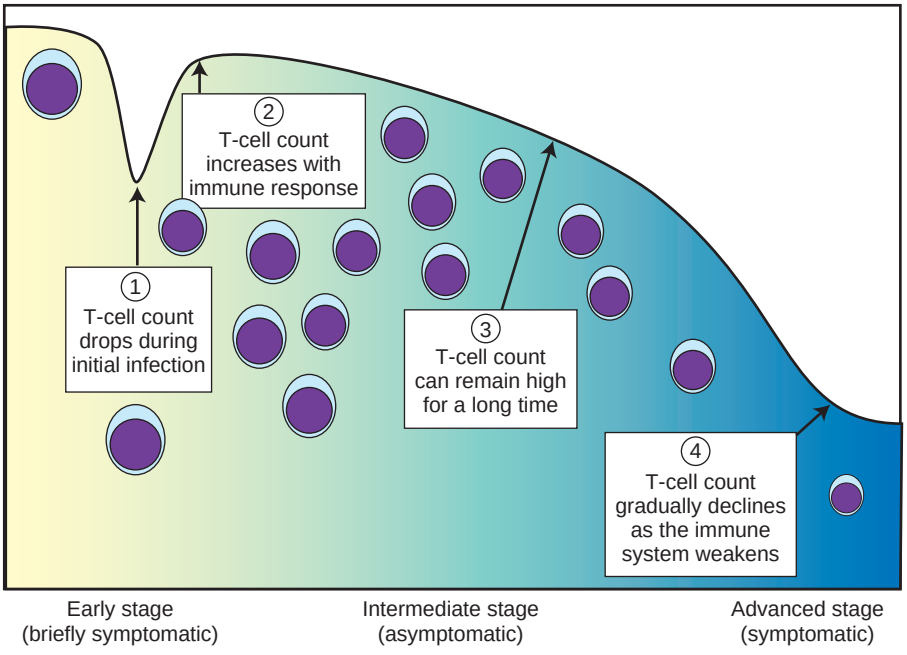

FIGURE 48-4 ▲ Use of T-cell count (CD4) to stage HIV infection. (*1*) The T-cell count drops during initial infection because the virus is destroying the T cells. (*2*) Once the immune system starts to fight back, the T-cell count increases. T-cell counts can go up and down at different times during HIV disease, but they do not return to where they were before infection. (*3*) T-cell counts can remain fairly high for a long time—sometimes for years—but steadily lose ground. (Redrawn from Glaxo Wellcome: HIV: Understanding the Disease. Research Triangle Park, NC: Author, 1995.)

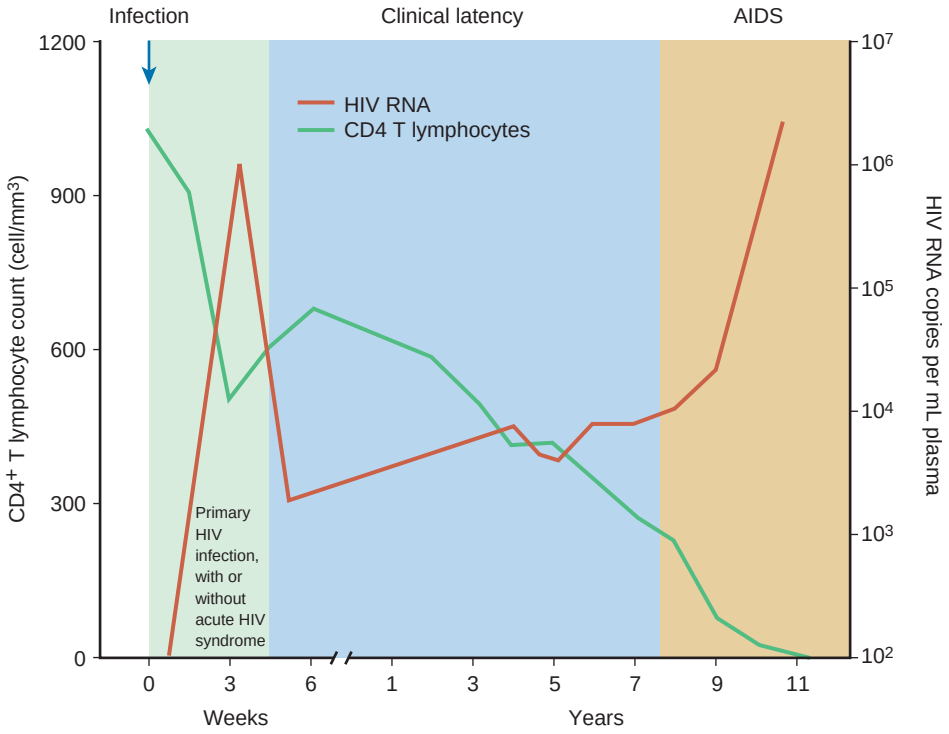

FIGURE 48-5 ▲ Typical course of HIV infection. (From Understanding Disease and Management. Available at: http://www.Roche-hiv.com; modified from Fauci AS, Pantaleo G, Stanley S, et al: Immunopathogenic mechanisms of HIV infection. Ann Intern med 124(7):654–663, 1996.)

Further, vaccination guidelines should be implemented to prevent vaccine preventable diseases including hepatitis A, hepatitis B, seasonal influenza, and *S. pneumoniae*.

Maintenance of safe infection control measures to prevent unnecessary contamination and complications in the ICU are essential when working with patients with HIV infection and AIDS. For current treatment guidelines associated with prophylaxis against common opportunistic infections associated with HIV and AIDS, critical care nurses are encouraged to collaborate with the interdisciplinary team and review data published on the HIV/AIDS pages of the CDC Web site (please refer to http://www.cdc.gov/hiv/default.htm for more information).

The use of ART has had a significant impact on the treatment of opportunistic infections. The number of opportunistic infections has significantly decreased because of advances in ART.[25,26] Prophylactic or suppressive treatment for PCP, toxoplasmosis, CMV infection, M. *avium* complex infection, leishmaniasis, cryptococcosis, and candidal thrush may be discontinued if the patient's $CD4^+$ T-cell count increases sufficiently and is sustained, usually above 200 cells/mm^3.[26] Administration of ART also can rapidly reduce viral load, thereby decreasing the incidence of complications.

Antiretroviral Therapy

Persons living with HIV or AIDS who receive ART and maintain strict adherence can survive for many years (average is 39 years) after being infected with the virus.[6] The classes of antiretrovirals used to treat HIV include the nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), fusion inhibitors (FIs), integrase strand transfer inhibitors (INSTIs), and entry inhibitors/CCR5 antagonists.[27] These drug groups act by blocking the fusion of HIV with $CD4^+$ receptors (FIs) or work at different points along the replication cycle (INSTIs, NRTIs, NNRTIs) or inhibit the development of new virions (PIs). Many FDA-approved medications in these classes are available for use (Table 48-3).[15]

The decision to initiate or change a person's therapy is determined by the presence or absence of symptoms along with the degree of immunosuppression that the patient is experiencing and the viral burden. The guidelines are based on the virological, immunological, and clinical status of the patient.[27] In the critical care environment, there is considerable debate about the appropriateness of initiating ART as well as using ART because of the potential for significant adverse effects (Table 48-4) and drug interactions (Table 48-5). Therefore, it is important for critical care nurses to collaborate with the interdisciplinary team, especially the infectious diseases specialist, to obtain parameters for initiating and withholding ART medications when caring for critically ill persons living with HIV or AIDS. In regard to ART, either therapy needs to be fully administered or entirely withheld. If not, there is significant potential for viral resistance to develop.

For some persons with advanced AIDS, initiation of ART can lead to immune reconstitution inflammatory syndrome (IRIS). In this syndrome, an increase of symptoms consistent with an acute inflammatory or infectious process are present but not explained by a new infectious diagnosis. Clinically, a paradoxical worsening or new onset of infectious manifestations usually occurs as a result of improved immune functions and renewed inflammatory responses, an increase in the production of memory and naïve T cells, enhanced lymphoproliferation, increased interleukin-2 responses, and reduced production of some cytokines. The most

frequent infectious processes associated with IRIS are TB, *Mycobacterium avium* complex, cryptococcosis, CMV, herpes zoster, HBV/HCV, and CJD. During IRIS, supportive therapy is indicated and aggressive treatment of the infectious diseases is indicated until the patient is clinically stabilized.

Potent Combination Antiretroviral Therapy

Potent combination ART, also known as highly active ART, became the standard of practice in 1996. According to guidelines published by CDC in October 2011,[27] ART should be initiated in all patients with a history of an AIDS-defining illness (see Box 48-2, p. 1102) or with a $CD4^+$ T-cell count below 350 cells/mm^3. For patients with a $CD4^+$ T-cell count between 350 and 500 copies/mm^3, ART is recommended. In patients with HIV-associated nephropathy and HBV coinfection, regardless of the $CD4^+$ T-cell count, ART should be initiated. For patients with $CD4^+$ T-cell counts about 500 cells/mm^3, the panel was equally divided with 50% favoring starting ART and 50% recommending ART as optional at this stage.

Contemporary evidence indicates that monotherapy with single NRTI, dual-NRTI, and triple-NRTI regimens are not recommended.[27] The three preferred ART regimens for treatment-naïve patients (those who have not previously taken ART) recommended by CDC in October 2011 include:

- Nonnucleoside reverse transcriptase inhibitor + 2 nucleoside reverse transcriptase inhibitors
- Protease inhibitor (preferably boosted with ritonavir) + 2 nucleoside reverse transcriptase inhibitors

Table 48-4 Adverse Events Associated With Antiretroviral Therapy Requiring Intensive Care Unit

Adverse Event	Associated ART
Bleeding events	TPV/r: Reports of intracranial hemorrhage PIs: increased bleeding in hemophiliac patients
Bone marrow suppression	Zidovudine (ZDV)
Cardiovascular effects	Myocardial infarction (MI) and cerebrovascular accident: associated with PI but not NNRTIs use in cohort study MI only: association between recent ABC and didanosine (ddI) use found in observational cohort; association not seen in randomized studies of ABC
CNS effects (may include one or more of the following: drowsiness, somnolence, insomnia, abnormal dreams, dizziness, impaired concentration and attention span, depression, hallucination, exacerbation of psychiatric disorders, psychosis, suicidal ideation)	Efavirenz (EFV)
Hypersensitivity with hepatic failure	Nevirapine (NVP)
Hepatotoxicity	All NNRTIs; all PIs; most NRTIs; maraviroc
Hyperlipidemia	All PIs (except unboosted atazanavir [ATV]); stavudine (d4T); EFV > NVP
Hypersensitivity	ABC
Insulin resistance/diabetes mellitus	Thymidine analogs (ZDV, d4T); some PIs linked to insulin resistance and diabetes mellitus (but unclear if a class effect)
Lactic acidosis/hepatic steatosis ± pancreatitis (severe mitochondrial toxicities)	NRTIs, especially d4T, ddI, ZDV
Nephrolithiasis/ urolithiasis/crystalluria	Indinavir (IDV), ATV, fosamprenavir (FPV)
Nephrotoxicity	IDV, tenofovir (TDF)
Neuromuscular weakness syndrome (ascending)	Stavudine (d4T)
Pancreatitis	ddI alone; ddI + d4T, hydroxyurea (HU), ribavirin (RBV), or TDF; rare reports with Lopinavir/r (LPV/r)
Stevens-Johnson syndrome (SJS)/toxic epidermal necrosis (TEN)	NVP more than DLV, EFV, ETR; also reported with APV, FPV, ABC, DRV, ZDV, ddI, IDV, LPV/r, ATV

- Integrase strand transfer inhibitor + 2 nucleoside reverse transcriptase inhibitors

In regard to the treatment-experienced person living with HIV, or those who have previously taken ART, the current understanding of viral dynamics during treatment suggests that "most first-line antiretroviral regimens should be able to suppress virus indefinitely, assuming that the optimal regimen is selected and assuming that the patient can adhere to that regimen indefinitely."[27] (p 65)

Regardless of the combination selected, ART has numerous treatment goals.[27] First, it is essential to maximally and durably suppress the HIV viral load to undetectable levels for as long as possible. Second, with viral suppression, it is then possible to restore and preserve immunological function. Third, with the suppression of the viral load, it is also possible to reduce HIV disease transmission by positive persons. Fourth, with viral suppression and immune reconstitution, it is possible to reduce HIV-associated morbidity and mortality ultimately improving survival. Finally, and equally important, ART can help to improve the quality of life of the person living with HIV or AIDS.

The decision to initiate ART or modify the regimen is complex and based on many factors. It is these issues, as well the significant risk for drug interactions and low trough levels associated with poor absorption, that ARTs are carefully considered in the critical care environment. According to the CDC,[27] (p 38) decisions about ART regimen selection should also be individualized in collaboration with the patient partner and should critically examine a number of factors, including:

- Comorbid conditions (eg, cardiovascular disease, chemical dependency, liver disease, psychiatric disease, renal diseases, or TB)
- Potential adverse drug effects
- Potential drug interactions with other medications
- Pregnancy or pregnancy potential
- Results of genotypic drug resistance testing
- Gender and pretreatment CD4 T-cell count if considering nevirapine
- HLA-B*5701 testing if considering abacavir

- Coreceptor tropism assay if considering maraviroc
- Patient adherence potential
- Convenience (eg, pill burden, dosing frequency, and food and fluid considerations)

The $CD4^+$ T-cell count is one of the most important markers in determining whether to start treatment.[27] The most recent treatment guidelines recommend initiating ART in all patients with a $CD4^+$ T-cell count less than 350 cells/mm^3 and to those patients who have a history of an AIDS-defining illness (see Box 48-2, p. 1102). ART therapy should also be initiated, regardless of $CD4^+$ T-cell count, in patients who are pregnant, have HIV-associated nephropathy, or are infected with HBV warranting treatment. For patients with a $CD4^+$ T-cell count between 350 and 500 cells/mm^3, ART is recommended.

HIV viral load levels are used to evaluate the effectiveness of ART. Once therapy has begun, a decrease in HIV viral load should occur within 2 to 8 weeks. According to the CDC, "the minimal change in viral load considered to be statistically significant (two standard deviations) is a threefold, or a 0.5 $\log_{10}$ copies/mL change."[27, p. C-6] One key goal of therapy is suppression of viral load to below the limits of detection (below 40 to 75 copies/mL by most commercially available assays). For most individuals who are adherent to their antiretroviral regimens and who do not harbor resistance mutations to the prescribed drugs, viral suppression is generally achieved in 12–24 weeks.[27] Viral load assessment should be repeated every 3 to 4 months to monitor effectiveness.

There are times when the treatment does not achieve the desired effect. This is termed antiretroviral treatment failure. There are three types of treatment failure: virological failure, immunological failure, and clinical progression. Virological failure is defined as a viral load that fails to decrease to nondetectable levels. Immunological failure is defined as a lack of the immune system to increase the $CD4^+$ T-cell count by 25 to 50 cells/mm^3 over the patient's baseline within the first year of treatment or a drop in the $CD4^+$ T-cell count to below the patient's baseline. Clinical progression is defined as the occurrence or recurrence of an opportunistic illness after 3 months of receiving treatment with antiretroviral agents.[27] When failure occurs, virological failure is most commonly the first to develop. Virological failure is typically followed by immunological failure and then clinical progression. The time interval between each is extremely varied and may be several years.

Drug Resistance Testing

Genotypic and phenotypic resistance assays are frequently used in the provision of HIV care to assess viral strains and inform treatment decisions.[27] Genotypic assays assess mutations in relevant sections of the viral genome while phenotypic assays determine the ability of HIV to grow in the presence of different drug concentrations. Genotypic resistance testing is the most commonly used resistance assay in clinical practice. Genotypic assay results can be obtained within a few days after obtaining a blood sample, are more affordable, and have an increased sensitivity for detecting mixtures of wild-type virus and resistant virus.[27] A genotype assay should not be obtained if the viral load is less than 1,000 copies/mm.[27] Genotypic resistance testing helps to reduce the chance that antiretroviral treatment failure will occur since ART is based on identified mutations and individual drug/class resistance profiles.

ONCOLOGICAL COMPLICATIONS AND EMERGENCIES

Oncological emergencies are potentially life-threatening complications that occur as a result of malignancy or its treatment.[1,2] As many as 20% of people diagnosed with cancer have at least one oncological emergency during the course of their disease.[2,3] The incidence of these emergencies increases as patients with cancer live longer and develop complications that relate to progressive or advanced disease.[4,5] The nurse must recognize disease-related and patient-specific risk factors for the development of critical illness and plan appropriate assessment and intervention strategies for the most common oncological emergencies. These emergencies are classified by pathophysiological mechanisms: hematological, anatomical–structural, and metabolic. Hematological complications involving bone marrow dysfunction, such as engraftment syndrome and leukostasis, commonly occur in neoplastic disorders. Disorders related to tumor or treatment-related bone marrow suppression include anemia, bleeding, and infections. Anatomical–structural disorders, such as cardiac tamponade, carotid artery rupture, hepatic veno-occlusive disease, obstruction of the superior vena cava, pleural effusion, spinal cord compression (SCC), and tracheobronchial obstruction, are the result of tumor invasion or treatment-related destruction of normal anatomical structures. Metabolic disruptions from cancer or its treatment, such as hypercalcemia, syndrome of inappropriate antidiuretic hormone (SIADH) secretion, and tumor lysis syndrome, may involve hormone stimulation, procoagulant activity, and electrolyte imbalances.[6]

▲ General Principles in the Critical Care of Patients With Cancer

Patients with cancer present unique concerns for the critical care nurse. A knowledge of preexisting illness, nature of the malignancy, treatment-related considerations, and prognostic implications must be incorporated into patient care.[1,5,7] In addition, it is necessary to appreciate the psychosocial factors related to caring for patients with a chronic disease.[1] Box 48-4 provides guidelines for evaluating an oncological emergency.[1,8,9] Ideally, before any acute event, the oncologist or primary care physician has discussed end-of-life care and the oncological crises that should be treated and those that should not be treated with the patient and family members.[5,10] However, if this is not the case, the critical care nurse is an important liaison between the primary care physician and the intensive care physician. Each time a patient with cancer presents with

BOX 48-4 Guidelines for Evaluating an Oncological Emergency

Symptoms and Signs
1. Are the symptoms and signs related to the tumor or to complications of treatment?
2. How quickly are the symptoms of the oncological emergency progressing?

Natural History of the Primary Tumor
1. Is there a previous diagnosis of malignancy?
2. What is the disease-free interval between the diagnosis of the primary tumor and onset of the emergency?
3. Has the emergency developed in the setting of terminal disease?

Efficacy of Available Treatment
1. Has there been no prior therapy or extensive pretreatment?
2. Should treatment be directed at the underlying malignancy or the urgent complications?
3. Will the patient's general medical condition influence the ability to administer effective treatment?

Treatment and Goals
1. What is the potential for cure?
2. Is prompt palliation required to prevent further debilitation?
3. What is the risk versus benefit ratio of treatment?
4. Should treatment be withheld if there is a minimal chance of response to available antitumor therapies?

Used with permission from Murphy GP, Lawrence W, Lenhard RE: Clinical Oncology. Atlanta, GA: American Cancer Society, 1995, p 597.

critical illness, malignancy-associated prognostic variables and information regarding treatment of the presenting condition should be used to advise the patient of the best course of action.[1,8,9] Clearly there are times when the risk/benefit ratio of a lifesaving measure does not warrant its use, yet there are also many other situations in which a lifesaving intervention in a hopelessly ill patient may significantly enhance the quality of remaining life.[1,8–11] For example, a patient with advanced cancer may present with a potentially life-threatening pericardial effusion that can be effectively treated with insertion of a pericardial catheter. This patient may require a limited amount of intensive care after catheter insertion and fluid drainage, but the symptom relief may be advantageous in enhancing the quality of the last few months of the patient's life. Aggressive management of most oncological emergencies is indicated if a histological diagnosis of cancer has not been established, if the patient has a good prognosis or can achieve prolonged palliation with treatment, or if there is the possibility of restoring functional status.[1,5,7,8,11,12] The guidelines in Box 48-4 are presented as a list of clinical questions that should be considered when deciding whether to provide critical care interventions for the patient with cancer.[8,13]

To provide high-quality, individualized care to patients with oncological emergencies, the critical care nurse should know a few facts regarding critical illness and the patient with cancer. Box 48-5 presents important conclusions drawn from multiple studies of critical illness in patients with cancer.[1,5,7–9,12,14–16] Box 48-6 lists nursing diagnoses for patients with oncological emergencies.

BOX 48-5 Critical Care of Cancer Patients: Conclusions From the Literature

Incidence of Critical Illness
- Affects about 20% of patients
- More common in patients with hematological malignancy
- Most common critical illnesses include respiratory distress, refractory hypotension, and oncological emergencies.

Prognostics of Critical Illness
- Survival is better in the newly diagnosed patient who has not yet received antineoplastic therapy.
- Survival from specific interventions:

Cardiac arrest:	<2% alive to discharge
Mechanical ventilation:	12%–45% alive to discharge (worst prognosis in patients receiving blood and marrow transplant; best prognosis in patients with a newly diagnosed solid tumor)
Dialysis:	21%–40% alive to discharge (prognosis has been improving with use of continuous renal replacement therapies)

- Most important predictor of survival: status of the underlying malignant disease
- Other poor prognostic variables: age extremes, concomitant health problems, severity of cancer, aggressiveness/potency of treatment, and reversibility of the specific crisis.

▲ Hematological Complications

Bone Marrow Suppression

Cancer and its treatment often cause suppression of hematopoietic cell production or differentiation. Causes of bone marrow suppression are commonly associated with cancerous invasion of the bone, chemotherapy and some radiation treatments, or hematopoietic stem cell transplantation. The clinical consequences are symptoms related to decreased red blood cell production (anemia), decreased platelet production (thrombocytopenia), and decreased white blood cell (WBC) production (leukopenia). Table 48-6 is a summary of the key clinical features of these three types of bone marrow suppression.[1,17–19] These disorders are

BOX 48-6 EXAMPLES OF NURSING DIAGNOSES

For Patients With Oncological Emergencies
- Risk for Infection related to impaired or deficient leukocytes
- Risk for Injury related to thrombocytopenia and bleeding
- Risk for Ineffective Peripheral Tissue Perfusion due to reduced erythrocytes, or vascular disruption by tumor
- Impaired Gas Exchange due to cancer involvement of the lungs or alterations in fluid status
- Risk for Imbalanced Fluid Volume due to disease or treatment
- Fatigue due to malignant illness or its treatment
- Impaired Physical Mobility due to disease complications
- Anxiety related to fear of disease or treatment
- Deficient Knowledge related to disease or anticancer therapies
- Ineffective Coping related to severity of illness or prognosis
- Ineffective Role Performance due to chronic serious illness

not uniquely oncological, but they are common in patients with cancer and influence the patient's response to other critical illnesses.

Other causes of bone marrow suppression must be considered if cancer-related etiological factors are not present. When serum tests are unclear in elucidating the etiology of bone marrow suppression, a bone marrow aspirate or biopsy may be performed to confirm whether the pathophysiological process arises in the cell production phase. This test may require sedation and a local anesthetic before a large coring needle is used to remove the liquid red bone marrow from either the hip or sternum. Bone marrow biopsy determines whether the bone marrow defect is present during the cellular production phase, and it may be a basis for clinical management.[1,19] Management of bone marrow suppression as a cluster involves determining whether the cause is time-limited and ascertaining the amount of supportive therapy required. Treatment may include administration of bone marrow growth factors specific to the deficient cellular component,[20] infusion of blood components,[17] or prophylactic clotting enhancement, and antimicrobial therapy to prevent life-threatening bleeding or infectious complications.[17,21]

Engraftment Syndrome

Engraftment syndrome, also known as cytokine release syndrome, cytokine storm, hemophagocytic syndrome, and macrophage activation syndrome, is a recently identified disorder that occurs infrequently in association with the return of bone marrow growth after treatment of hematological malignancies and hematopoietic stem cell transplantation.[22–24] Patients most at risk for engraftment syndrome are women, those with acute leukemia (especially lymphocytic subtype), those who have just had allogeneic hematopoietic stem cell transplantation (especially with human leukocyte antigen (HLA)-mismatched donors), and those who have had transplantation for autoimmune disorders or solid tumors.[22–28]

Table 48-6 Key Clinical Features of Bone Marrow Suppression

Feature	Anemia	Thrombocytopenia	Leukopenia
Definition	General criteria • Hemoglobin <12 mg% • RBC count < 3.0 × 10^6/mm^3 • Hematocrit < 32% Specific to types of anemia • Aplastic anemia • Nutritional anemia • Hemolytic anemia	Classified according to severity of thrombocytopenia and risk of bleeding: • Mild: <100,000/mm^3 • Mild: <1,000/mm^3 • Moderate: <50,000/mm^3 • Severe: <20,000/mm^3	Classified according to severity of leukopenia and risk for infection Decreased granulocytes (granulocytopenia) classified by severity of ANC • Moderate: <500/mm^3 • Severe: <100/mm^3 Decreased lymphocytes (lymphocytopenia) classified by severity of absolute lymphocyte count • Mild: <250 cells/mm^3 • Moderate: <100 cells/mm^3 • Severe: <50 cells/mm^3
Pathophysiology			
Etiology/contributing factors	General • Bone marrow suppression (eg, chemotherapy, radiation to axial skeleton) • Nutritional deficits—iron, protein, B vitamins • Medications (estrogens, allopurinol [Zyloprim]) Aplastic anemia • Congenital disorders (eg, Fanconi's syndrome, maternal ingestion of thiazides) • Viral infection • Medications Nutritional anemia • Iron deficiency • B-vitamin deficiency Hemolytic anemia • Immune hemolysis (viral illness, autoimmune disease) • Sickle cell anemia • PNH	• Bone marrow suppression (eg, chemotherapy, radiation to axial skeleton) • Medications (nonsteroidal anti-inflammatory drugs) • Large-bore intravenous lines (eg, IABP) • High metabolic rate (eg, fevers)	• Bone marrow suppression (eg, chemotherapy, radiation to axial skeleton) • Nutritional deficits • Medications

(continued on page 1112)

Table 48-6 Key Clinical Features of Bone Marrow Suppression (continued)

Feature	Anemia	Thrombocytopenia	Leukopenia
Clinical manifestations	• Due to decreased oxygen carrying and tissue delivery: fatigue, oliguria, chest pain, decreased bowel sounds, and constipation • Due to decreased body insulation and vascular volume: hypothermia, hypotension, orthostasis • Due to compensation for inadequate oxygen delivery to the tissue: tachycardia, tachypnea, cool extremities	• Due to decreased platelet plugging for normal vascular wear and tear: gum oozing, petechiae, occult blood in urine and stool • Related to inadequate platelet response to injury: ecchymoses, hematomas, bleeding around procedure sites, frank hematuria, or gastrointestinal bleeding	Granulocytopenia • Due to decreased phagocytic properties and recognition of invading microbes: fever, pain at site of potential infection, bacterial and fungal infecting organisms (after 7–10 d of granulocytopenia) • Related to diminished inflammatory response: lack of localized erythema, swelling, or exudates Lymphocytopenia • Due to decreased cellular immune responses and recognition of foreign tissue or proteins: tissue anergy to pathogens, (opportunistic and viral infections more common)
Diagnostic tests	General • RBC count • Hematocrit and hemoglobin • RBC morphology Aplastic anemia • Bone marrow aspirate and biopsy Nutritional anemia • Ferritin level • Transferrin level • Total iron-binding capacity • Folate level • Vitamin B_{12} level Hemolytic anemia • Total and direct bilirubin • Erythrocyte sedimentation rate • RBC morphology • Hemoglobin electrophoresis (sickle cell, PNH) • Indium-tagged RBC survival studies	• Platelet count • Bleeding time tests platelet quality to identify whether symptoms may be partly related to platelet function rather than number	• White blood cell count is initial screening tool, but analysis of actual cell count may be helpful • ANC demonstrates the true number of granulocytes available for phagocytic activity • Absolute lymphocyte count demonstrates the true number of lymphocytes available for recognition of foreign tissue and proteins
Common nursing problems	• Fatigue • Activity intolerance • Hypoxemia • Digestion disorders	• Bleeding • Altered body image	• Infection • Risk for hemodynamic instability
Medical management	• Erythropoietin injections • RBC transfusions • Energy conservation	• Interleukin-11 (Oprelvekin) injections • Platelet transfusions • Bleeding precautions • Thrombopoietin (Nplate®)	• Granulocyte colony-stimulating factor (G-CSF) or granulocyte–macrophage colony-stimulating factor (GM-CSF) injections • Broad-spectrum antimicrobial therapy

ANC, absolute neutrophil count; PNH, paroxysmal nocturnal hemoglobinuria; IABP, intra-aortic balloon pump; RBC, red blood cell.

Patients who have had early engraftment after high-dose marrow-ablative treatment are also at risk for engraftment syndrome.[27]

Pathophysiology

Regrowth of bone marrow cells, particularly myelocytes, results in release of inflammatory cytokines that produce vasodilation and capillary leaking similar to sepsis.[27] Lymphocytes and myelocytic precursors engraft the bone marrow earliest, and patients often still appear leukopenic at the onset of symptoms. Patients with engraftment syndrome often present with signs and symptoms similar to infection at a time when their blood counts are still low, and they are equally at risk for engraftment syndrome and severe infection. Therefore, it is extremely difficult to distinguish the two disorders.

Assessment

HISTORY. Engraftment syndrome often begins with fever, total-body erythema or rash, and symptoms of respiratory distress,[27,29] and these symptoms may be the only manifestations. However, many patients exhibit additional signs or symptoms of cytokine effects, such as oliguria or hematuria with elevated creatinine, abdominal discomfort with elevated aminotransferases, and gastrointestinal bleeding.[27–30] The Spitzer criteria for diagnosis includes these symptoms and the presence of the inflammatory marker of increased C-reactive protein.[27] The onset of symptoms is rapid, usually occurring over 24 to 48 hours, and symptoms dissipate after the neutrophils engraft and the WBC count reaches about 2,500 to 3,000/mm.[4,26,27,29] Box 48-7 outlines key clinical manifestations that distinguish sepsis and engraftment syndrome.

DIAGNOSTIC STUDIES. There is no clearly definitive diagnostic test that can differentiate engraftment syndrome from sepsis, which it closely resembles. Even elevations of C-reactive protein are more reflective of inflammation than a true diagnostic test of differentiation.[27] The cornerstones of diagnosis are the constellation of clinical symptoms, subsequent increase in WBC count in patients with previous leukopenia, and absence of a positive microbial culture. New markers for bacterial of fungal pathogens such as beta-D-glucan and procalcitonin are inconclusive at this time.

Management

Engraftment syndrome is managed supportively and conservatively. Patients are presumed septic and treated with broad-spectrum antimicrobial agents. Acetaminophen and diphenhydramine are administered as needed for erythema and pruritus. Hepatic dysfunction requires cautious monitoring and adjustment of fluids and medication doses as appropriate. IV fluids are used to prevent vasodilatory hypotension, but, occasionally, vasoconstricting agents such as phenylephrine or norepinephrine are necessary.[23] Rapid-acting IV corticosteroids have been used effectively when clinical symptoms are strongly suggestive of this disorder.[29] Mechanical ventilation and renal replacement therapy are initiated as indicated, with the understanding and presumption that the syndrome is usually very short-lived.

Complications

The long-term outcome for most patients with engraftment syndrome is excellent, and there are no significant clinical sequelae.[23,26,27,29] Rarely do patients die or have long-term ischemic organ damage. In situations in which negative sequelae have occurred, it has been difficult to determine whether engraftment syndrome or sepsis was the primary pathophysiological process. For example, patients with a rapid onset and progression of respiratory distress syndrome may die of refractory hypoxemia, yet whether this has been caused by undiagnosed and untreated infection or engraftment syndrome cannot be determined.

Leukostasis

Leukostasis is a disorder of excess circulating immature WBCs, resulting in hyperviscosity and microvascular occlusions.[31–34] Cancers such as acute leukemias are the primary cause of leukostasis, although the similar proliferative lymphomas, such as Burkitt's and lymphoblastic lymphoma, have also been reported as triggering malignancies.[31,32] The incidence of symptomatic leukostasis in acute leukemia is estimated to be 5% to 30%,[2,34,35] and its association with high circulating immature WBCs confers a poor prognosis.[31,35,36] Initial mortality in patients with this syndrome is estimated to be approximately 40%.[33,37]

Pathophysiology

Excess numbers of circulating WBCs, such as commonly occur in patients with acute leukemia, can cause a hyperviscosity syndrome that may lead to microcirculatory occlusion with ischemia and vessel rupture. Several types of leukemia can cause elevated WBC counts, with greatest risk with

BOX 48-7 Distinguishing Between Sepsis and Engraftment Syndrome

Sepsis	Engraftment Syndrome
• Fever, variable clinical features	• Fever, sudden onset, often high and continuous
• Variable symptom onset	• Sudden symptom onset over 24–48 h near engraftment period
• Variable skin manifestations	• Erythema with or without pruritic total-body rash
• Dyspnea, often with distinct infiltrates on chest radiography	• Dyspnea; bilateral diffuse alveolar infiltrates on chest radiography
• Thrombocytopenia; occasional mucous membrane bleeding	• Gastrointestinal bleeding
• Hypotension-related oliguria and elevated creatinine	• Unprecipitated oliguria, elevated creatinine, hematuria
• Hypotension-related hepatomegaly, elevated aminotransferases	• Unprecipitated hepatomegaly, elevated aminotransferases

acute monocytic leukemias of the M3v, M4, M5 subtypes, or acute lymphoblastic leukemia with 11q23 chromosome abnormality.[2,38] The immature myelocytes (blasts) found in acute nonlymphocytic leukemia have the greatest propensity for "stickiness" due to adhesion molecules and their interaction with endothelial vessel linings and are most likely to cause leukostasis.[2,33,35] Risk for leukostasis is considered greatest when the WBC count is greater than 100,000/mm^3, although significant clinical symptoms may be present even when counts are in the 50,000/mm^3 range, especially if the WBC count is increasing rapidly or the cells are immature.[2,31,33] Vascular occlusion of the lungs and brain is most common, although coronary artery occlusion, renal failure, and splenic or bowel infarctions have been reported.[32,33,39] Hypoxic vasodilation is thought to worsen the clinical effects of vascular occlusions in the brain.[39,40]

Assessment

HISTORY. Patients with leukostasis usually first present with respiratory or neurological symptoms.[31,34,35] Onset of symptoms is acute (several hours to 1 day). Severe respiratory distress with hypoxemia and inflammatory alveolar infiltrates are the hallmarks of pulmonary involvement. It is difficult to determine the severity of hypoxemia because the immature WBC blasts consume the oxygen in the arterial blood gas (ABG) specimen, making the arterial blood oxygen level appear even lower than suspected based on clinical evidence. Oxygen saturation may be low (eg, 82% to 90%), but ABG oxygen levels may be only 30 mm Hg.[2,34,41] It is believed that immediate icing and rapid transit may reduce but not eliminate this testing problem. Neurological leukostasis presents as mental status changes with clear focal deficits; vascular occlusions cause thrombotic or embolic strokes.[35,39,40] Other clinical findings also associated with a poorer outcome in these patients include older age, monocytic cell line, bilirubin greater than 1.5 mg/dL, serum creatinine greater than 1.2 mg/dL, lactic dehydrogenase more than 2,000 IU, and thrombocytopenia less than 50,000/mm^3.[35]

DIAGNOSTIC STUDIES. Leukostasis may be suspected in high-risk groups, but the diagnosis is primarily made on the basis of clinical manifestations. In many instances, the existence of pathophysiological complications such as infarction or stroke may validate the presumed diagnosis. Patients have specific diagnostic tests performed to assess their presenting symptoms. Chest radiography is often sufficient to diagnose pulmonary leukostasis. A head computed tomography (CT) scan may reveal neurological leukostasis. Ultrasonography and magnetic resonance imaging (MRI) may also be performed. In pulmonary leukostasis, ABG results are used with a clear understanding of their diagnostic limitations.[2,31,38]

Management

In leukostasis, the preferred management is to identify high-risk or early symptomatic patients and perform rapid cytoreduction, such as leukapheresis or high-dose chemotherapy, before the cells cause organ damage.[2,31,32,36,37] Some clinicians have noted that although leukapheresis does not have an impact on mortality, it does notably affect the number of WBCs and their influence on end-organ damage.[32,37,42] Therapeutic leukapheresis removes 20,000 to 40,000 WBCs per treatment, and once- or twice-daily treatments are often required until the WBC count is less than 30,000 to 40,000/mm.[31,33,37,38,42] If leukapheresis cannot be performed immediately, large amounts of IV fluids should be administered to dilute the blood and enhance renal excretion of metabolic toxins.[2] If leukapheresis is still not possible within a 12- to 24-hour period, and the patient's symptoms continue to worsen, exchange transfusions may be necessary.[33,42]

Many patients also receive immediate concomitant chemotherapy to prevent rapid cell regrowth or spontaneous tumor lysis syndrome with renal failure.[31,34] If possible, it is preferred to complete the necessary leukapheresis cycles before starting chemotherapy; however, many patients are too sick for such treatment. When this occurs, the critical care nurse must administer antimicrobial agents or chemotherapy between leukapheresis treatments. Despite some early controversies, chemotherapy may be administered concomitantly with continuous renal replacement therapy (CRRT) as the clearance rate with this dialysis therapy is less than normal kidney clearance so there are no worries that the chemotherapy is being removed by the dialysis treatment.[43] This is not the case with hemodialysis, which does remove many chemotherapy agents. Low-dose cranial radiation (100 to 300 Gy) was once believed to stabilize cell membranes and destroy malignant cells, but this practice is now not recommended.[2,43] Patients with leukostasis receive supportive drug therapy with agents such as antimicrobials, diuretics, bronchodilators, phosphate-binding agents, rasburicase, and allopurinol, which are aimed at stabilizing their symptoms.

It is important to recognize interventions that worsen the hyperviscosity of leukostasis and avoid these actions. Patients with acute leukemia are often anemic, but blood products should be administered with extreme caution and in combination with crystalloid fluids to avoid increased blood viscosity.[2,43] Diuretics may be given to enhance renal excretion of uric acid associated with tumor cells lysis, but also only in combination with crystalloid fluids to maintain normal vascular osmolarity. Supportive interventions to reduce intracranial hemorrhage may include elevating the head of the bed and administering corticosteroids. Definitive treatment requires administration of chemotherapy directed against the leukemia. Box 48-8 lists nursing interventions aimed at reducing the risk for leukostasis-related complications.

BOX 48-8 Nursing Interventions for Leukostasis

- Recognize patients at risk for leukostasis—acute myelocytic leukemia (with circulating blasts), white blood cell count more than 100,000/mm^3, renal dysfunction, dehydration.
- Administer large volumes of intravenous fluids to dilute cells and aid excretion of lysis components.
- Perform cytoreduction with leukapheresis or rapid-acting chemotherapy (eg, cyclophosphamide) as soon as possible.
- Treat organ system–specific leukostatic symptoms (eg, elevation of head of bed, bronchodilators).
- Administer drugs to reduce effects of tumor lysis: phosphate-binding drugs, allopurinol, rasburicase.
- Administer blood components cautiously early in the disease when hyperviscosity is problematic.
- Plan assessment interventions aimed at monitoring for ischemia or infarction of the body organs.

Complications

Even in the face of appropriate, definitive treatment, patients with leukostasis may experience stroke, respiratory failure, bowel infarction, renal failure, or myocardial infarction. In many, some degree of reversible organ ischemia develops, requiring supportive treatment.[31,33]

Typhlitis/Necrotizing Enterocolitis

Pathophysiology

Patients with severe or prolonged neutropenia are at risk for acute gastrointestinal symptoms related to the presence and activity of microbes within the gastrointestinal tract.[21] Resident Gram-negative organisms can produce serious clinical disease in patients without granulocytes. Microbial infiltration of less perfused areas of the bowel, such as the cecum and appendix, produces an acute inflammation of the bowel wall, edema, and paralytic ileus.[21] This has been named neutropenic enterocolitis, which is interchangeable with the term typhlitis.[44] Gases produced by these bacteria can also lead to air in the bowel wall, ischemia, and possible infarction, which is then termed necrotizing enterocolitis or pneumatosis intestinalis. While reported more frequently in children, high-dose marrow suppressing therapy in any individual can lead to typhlitis.[45,46] Although older studies describe incidence rates of 20% to 40% of patients treated for leukemia or undergoing hematopoietic stem cell transplantation, recent reports suggest the incidence may vary from less than 1% to approximately 6% of such cases.[21,45,47] Despite a serious clinical presentation of acute abdominal infection, more than half of patients had negative blood cultures.[45]

Assessment

HISTORY. Patients with prolonged and/or severe neutropenia are at risk for developing typhlitis, although other specific risks include presence of an appendix and prior bowel surgery.[44] Medications that have been linked to increased incidence of typhlitis include carboplatin, cyclophosphamide, cytosine arabinoside, daunomycin, docetaxel, doxorubicin, idarubicin, methotrexate, paclitaxel, pegylated asparaginase, topotecan, and vincristine.[45] Unusual incidents of its occurrence with alemtuzumab,[48] interferon alfa,[49] and pemetrexed[50] have also been reported. Since the consistent administration of oral antimicrobials to sterilize the gut, nonadherence with these medications has also been associated with development of this disorder. Patients present with diffuse abdominal pain that is semilocalized in the right upper or middle quadrant of the abdomen.[51–53] Guarding, abdominal distention, diarrhea, and reduced bowel sounds are common, and rebound tenderness or gastrointestinal bleeding signals a more severe disease that has progressed to bowel ischemia and infarction.[21] Most patients demonstrate symptoms of acute abdominal sepsis such as fever, fluid shifting with oliguria, weight gain, and hypotension, although in antibiotic-controlled disease, these septic symptoms may be intermittent.[21,52,53]

DIAGNOSTIC STUDIES. Initial screening tests include an abdominal flat plate x-ray to detect possible air under the diaphragm, and a CT scan with contrast, while also evaluating lactic acid and amylase levels for signs of bowel ischemia.[21,44,54] An enlarged and edematous cecum is considered diagnostic, although other tests are better at predicting the severity of bowel wall injury or ischemia.[42,52,54]

Management

Since recognition of this complication and its pathophysiological origin, many clinicians have undertaken two primary preventive measures. First, high-risk patients are administered oral antimicrobial antibiotics (usually in liquid form) that destroy intestinal bacteria, producing sterile conditions within the bowel.[44] Secondly, patients with anticipated severe neutropenia are administered prophylactic hematopoietic growth factors, unless acute myeloid leukemia where there is concern the growth factors may enhance tumor growth.[21] These patients may perhaps then have reduced neutropenia. In patients who develop less severe typhlitis, potent broad-spectrum antimicrobials aimed to destroy a variety of both Gram-positive and Gram-negative bacteria, gut rest, and observation may be warranted and adequate until the patient's own WBCs repopulate their bone marrow and can destroy an existing infection.[44,45,53] Throughout the continuum of this complication, lactic acid levels are followed and IV fluids are administered to maintain gut perfusion.[49,55] Vasopressor agents are avoided if at all possible. In more serious cases, granulocyte transfusions have been administered in an attempt to boost the patient's immune activity.[21] In severe, sepsis-related disease or pneumatosis, emergent surgical resection may be necessary.[49,51,55]

Complications

This continuum of bowel wall abnormalities may lead to acute bowel perforation, bowel infarction or gastrointestinal bleeding.[51,55] These serious consequence often herald poor outcomes as the patients are also too high of risk to consider surgical resection of the bowel, even though this intervention may be the only potentially effective measure to arrest the sepsis.

▲ Anatomical–Structural Complications

Cardiac Tamponade

Cardiac tamponade is the result of accumulation of excess pericardial fluid or the presence of a tumor that compresses the heart. At autopsy, as many as 20% of people with cancer are found to have cardiac or pericardial metastases.[56]

Pathophysiology

The pericardium is a double-walled sac that surrounds the heart and great vessels. A visceral layer lines the surface of the heart, and the parietal layer (or outer layer) moves freely. The pericardium supports the heart in a stable position and provides a frictionless sac for cardiac contractions. The pericardial cavity lies between the two layers and contains 10 to 50 mL of serous fluid.

Neoplastic cardiac tamponade results from the formation and accumulation of excessive amounts of fluid in the pericardial sac. This emergent condition may also be caused by encasement of the heart by tumor or postradiation

pericarditis. The severity of the tamponade is in direct proportion to the rate of fluid formation and the volume of fluid accumulated. Slow accumulation may stretch the pericardium so that cardiac contractility is not adversely affected for months.[56,57] Normal diastolic filling is impaired by elevated pericardial pressures, and stroke volume is reduced. As stroke volume continues to fall, hypotension, compensatory tachycardia, and equalization and elevation of the mean left atrial, pulmonary arterial and venous, right atrial, and vena caval pressures occur. In an attempt to maintain arterial pressure, increase blood volume, and improve venous return, tachycardia and peripheral vasoconstriction develop. If the tamponade goes undiagnosed or untreated, circulatory collapse ensues.

Cancers of the esophagus or lung grow by direct extension into the pericardium, whereas distant primary cancers (eg, renal cell) metastasize to the pericardium through the bloodstream. Large chest tumors may also cause pericardial effusion due to lymphatic obstruction of pericardial fluid recirculation. The primary tumors most commonly associated with pericardial effusion are tumors of the breast, lung, or esophagus; lymphoma; gastrointestinal carcinomas; melanoma; sarcoma; and leukemia.[58–60] Radiation pericarditis may be a causative factor, especially if the patient's heart was in the treatment field and if the total dose of radiation to this field exceeded 4,000 rad (40 Gy).[61] Biotherapeutic agents such as interleukin-2 (Aldesleukin) and interferon-alpha cause increased capillary permeability and clinically significant pericardial effusions.[62] Pericardial effusion has also been reported in patient receiving arsenic trioxide,[57,63,64] cyclophosphamide,[64] and cytosine arabinoside.[57]

Assessment

HISTORY. Signs and symptoms reflect the rapidity with which the fluid accumulates in the pericardial sac and, in the patient with cancer, are mainly those of right-sided heart failure due to slow accumulation.[20] Signs of tamponade include rapid, weak pulse; distant heart sounds; distended neck veins during inspiration (Kussmaul's sign); pulsus paradoxus (inspiratory decrease in arterial blood pressure of >10 mm Hg from baseline); ankle or sacral edema; edema; ascites; hepatosplenomegaly; hepatojugular reflex; lethargy; and altered level of consciousness.[56,65–67] The patient may complain of dyspnea, cough, and retrosternal pain that is relieved by leaning forward. On occasion, a patient with a large effusion experiences epigastric pain, hiccups, hoarseness, nausea, and vomiting.[56]

DIAGNOSTIC STUDIES. A variety of studies are used to determine the presence and severity of cardiac tamponade. A chest film is used to determine the presence of cardiac enlargement, mediastinal widening, or hilar adenopathy.[68] The electrocardiogram (ECG) may show nonspecific abnormalities, including low QRS complex voltage in limb leads, sinus tachycardia, precordial ST-segment elevations, and T-wave changes.[56] Echocardiography is the most sensitive and most specific noninvasive test for the presence of tamponade and is used routinely in most settings.[65,69] Two distinct echoes may be identified, one from effusion and the other from the posterior heart border. Spaces between these echoes indicate the size of the effusion or the thickness of the pericardium. Catheterization of the right side of the heart reveals pericardial tamponade or constriction but is performed infrequently because echocardiograms are routinely available.[70] Clarification of specific pathological features and tumor involvement of the pericardium itself cannot be determined by echocardiogram and may require CT or MRI imaging.[65,71,72] Pericardiocentesis gives a positive cytological result in the patient with metastatic cancer.[73,74]

Management

First, volume expansion is necessary because it increases venous pressure so that it is greater than the pericardial pressure, allowing increased venous return and improved cardiac output.[56] Oxygen administration is required, although assisted or mechanical ventilation may increase thoracic pressures, further impeding venous return and worsening the tamponade.

The definitive treatment for pericardial effusion is fluid drainage. Acute or life-threatening symptoms are indications for emergent pericardial drainage by needle or catheter pericardiocentesis (Box 48-9). Without definitive treatment to alleviate the fluid in the pericardium, cardiac arrest occurs. Tamponade is likely to recur in 24 to 48 hours if treatment to prevent pericardial fluid reaccumulation is not initiated quickly.

Factors that clinicians should consider when selecting a therapeutic option include the sensitivity of the primary tumor to specific treatment modalities, previous treatment, and the patient's life expectancy.[58] If effective drugs are available (eg, as in lymphoma and small cell lung cancer), systemic chemotherapy may be initiated after the patient is clinically stable.[62] This treatment may also be effective in patients with leukemia, lymphoma, and breast cancer who have pericardial effusion. In radiosensitive tumors such as lymphoma and breast cancer, radiation therapy may be the treatment of choice.[68] Research has shown that radiation therapy may control more than 50% of malignant pericardial effusions.[75] Insertion of a pericardial catheter guided by fluoroscopy or echocardiography to permit rapid fluid drainage is often the preferred immediate treatment.[71,75] The catheter may remain in place while anticancer therapy begins. Pericardial sclerosis through the pericardial catheter, which is rarely used, can control tamponade by causing adherence of the two pericardial layers and inhibiting fluid accumulation.[58,75,76] Intrapericardial chemotherapy with agents such as cisplatin[74] and bleomycin[60] has also been infrequently reported. Intraoperative fluid drainage or shunting has been used with moderate success in extensive malignant disease.[77,78] In patients with a longer life expectancy and adequate performance status, an inferior pericardiotomy may be performed thoracoscopically. In this procedure, a pleural–pericardial window is created, which provides immediate relief of cardiac compression and tissue specimens for histo-

BOX 48-9 PATIENT SAFETY

Signs and Symptoms of Neoplastic Cardiac Tamponade

- Cyanosis, dyspnea with hypoxemia, impaired consciousness, or shock
- Pulsus paradoxus exceeding 50% of the pulse pressure
- Decrease of more than 20 mm Hg in pulse pressure
- Central venous pressure exceeding 13 mm Hg

logical diagnosis. Fewer than 5% of patients have recurrence of symptoms after this procedure. Pericardectomy is necessary if radiation-induced pericardial disease is not responsive to conservative medical management. This procedure should not take place if an extensive pericardial tumor is present because surgical morbidity and mortality rates are high.[79]

Carotid Artery Rupture

Causes of a carotid artery rupture (or "blowout") are tumor erosion and rupture of the carotid artery. Such rupture results in the loss of large amounts of blood that, without rapid intervention, becomes life-threatening hemorrhage. Patients at risk for this oncological emergency are primarily those with cancer of the head and neck, especially after surgery or radiation, or with a wound infection.[80–82] Affected patients occasionally have thyroid cancer, lymphoma, or melanoma.[80,81] Patients with a palpable pulse on top of a tumor, or in close proximity to it, have a greater risk for carotid vessel erosion.[80,81]

Pathophysiology

Rupture of a carotid artery is likely to occur when that vessel is weakened by invasion of tumor or by surgical manipulation. Other causes of vessel weakness include simultaneous infection or skin flap necrosis.

Assessment

The rupture of the artery may occur suddenly with forceful expulsion of large volumes of blood from the damaged vessel; however, the first sign of erosion or rupture usually is a small trickle of blood from the neck area or unexplained oral bleeding.[80] If the skin over the artery is intact, the patient may have darkened or ecchymotic skin changes, swelling, difficulty swallowing or breathing, retrosternal or high epigastric chest pain, and mental status changes. A unilateral headache or visual disturbance may also signal carotid artery bleeding. Box 48-10 lists the cardinal signs and symptoms of carotid artery rupture.

Management

Patients identified at high risk for carotid artery rupture may have vascular stents placed during surgery as a preventive measure. In addition, IV access should be in place, and blood should be typed and available for immediate transfusion.[81,83] Gauze, irrigation saline solution, and vascular clamps should be readily available at all times. The first emergency intervention in cases of suspected carotid artery rupture is constant digital pressure with saline-soaked cotton dressing wrapped around the two middle fingers and applied directly to the area over the artery.[84] The nurse must not lessen pressure to see whether the bleeding has stopped or attempt to apply a hemostat. Either of these steps increases the likelihood of further blood loss. Maintenance of the airway is essential. Only after the patient is in the operative suite and the operative area has been prepared should the pressure be released. The surgical treatment of choice is ligation of the damaged artery. Embolization or stent placement may be alternatives.[84,85] Chapter 22 contains a detailed discussion of carotid artery surgery with assessment and nursing care.

BOX 48-10 PATIENT SAFETY

Cardinal Signs and Symptoms of Carotid Artery Rupture

- Oozing blood from neck wound
- Unexplained oral bleeding
- Ecchymoses over neck region
- Sudden neck edema
- Retrosternal or epigastric chest pain
- Sense of impending doom, anxiety, or restlessness

Complications

The overall mortality rate of carotid artery rupture is 40% to 60%.[80] About 60% of patients who survive this complication have long-term neurological deficits, the most common of which is hemiparesis. The risk for hemiparesis is reduced by the prevention of shock and replacement of fluid for adequate perfusion of the brain through the opposite internal carotid artery.[80]

Hepatic Veno-Occlusive Disease (Sinusoidal Obstruction Syndrome)

Hepatic veno-occlusive disease, also known as sinusoidal obstruction syndrome, is occlusion of the venous vessels of the liver. The disease is a complication of high-dose radiation therapy and chemotherapy.[86,87] Its incidence is as low as 5% to 10% in patients receiving some chemotherapy[88] and monoclonal antibody regimens but as high as 30% to 40% in some receiving hematopoietic stem cell transplants.[88,89] Although sinusoidal syndrome is most likely to develop in patients receiving high-dose alkylating agents (eg, cyclophosphamide, busulfan) or abdominal radiation, it also occurs in patients receiving the leukemic monoclonal antibody gemtuzumab (Mylotarg)[86,90] and oxaliplatin (Aloxatin).[91] Other risk factors in patients with cancer are extensive pretreatment, older age, and previous history of hepatitis.[90]

Pathophysiology

Through uncertain mechanisms, etiological agents cause fibrotic changes in the endothelial layer that lines the walls of the veins and sinusoids in the liver, resulting in narrowed and stiff-walled venules that have a tendency for thrombosis. Venous flow through the liver is reduced, and there is congestion and eventual pressure-related hepatic damage.[87,88]

Assessment

HISTORY. The earliest manifestations of hepatic veno-occlusive disease are fluid retention, elevated serum bilirubin, and nonspecific abdominal pain.[88,89] The onset of these symptoms occurs an average of 8 to 20 days after therapy; the time varies with the causative agent.[88] The clinical course begins primarily as one of portal hypertension with ascites, painful hepatomegaly, and right-sided heart failure; it progresses over 1 to 3 weeks to include hepatic destruction with coagulopathies, thrombocytopenia, hyperammonemia, metabolic alkalosis, increased vagal tone, and hepatorenal failure.[88,89] Box 48-11 lists early and late clinical findings in hepatic veno-occlusive disease. Most patients with hepatic veno-occlusive disease have mild, reversible disease, and only 10% to 20% have severe, life-threatening manifestations.[88]

BOX 48-11 PATIENT SAFETY

Signs and Symptoms of Hepatic Veno-Occlusive Disease

Early Findings

- Weight gain
- Fluid retention, edema
- Painful hepatomegaly
- Increased total and direct bilirubin
- Increased aspartate aminotransferase and alkaline phosphatase

Late Findings

- Coagulopathies, thrombocytopenia
- Hyperammonemia
- Metabolic alkalosis
- Hepatorenal syndrome
- Right-sided heart failure
- Elevated aminotransferases
- Increased vagal tone

DIAGNOSTIC STUDIES. The first and most specific diagnostic test is the elevation of total and indirect bilirubin.[88] Aspartate transaminase (previously known as serum glutamic oxaloacetic transaminase) and alkaline phosphatase also increase early, and when progressive liver failure develops, hepatic aminotransferases also increase. Abdominal ultrasonography confirms hepatic enlargement and is used to rule out causal conditions, such as cholestasis and hepatic abscess.[88] The new addition of ultrasonographic Doppler technology can provide more conclusive evidence of hepatic veno-occlusive disease with validation of venous wall turgidity and estimated portal pressures.[89]

In late or severe disease, the platelet count decreases, and coagulation studies such as prothrombin time or partial thromboplastin time are prolonged. A definitive diagnosis may be made only on the basis of liver biopsy. When it is necessary to differentiate hepatic veno-occlusive disease from other clinically similar processes, such as graft-versus-host disease, liver biopsy shows venule fibrosis.[92]

Management

Because the pathological mechanisms of hepatic veno-occlusive disease are uncertain, therapy is still presumptive and not clearly effective. Once hepatic veno-occlusive disease is suspected, supportive therapies, such as balancing fluid administration and diuresis, are implemented.[93] Transjugular intrahepatic portosystemic shunt procedures have been used in an attempt to enhance portal blood outflow.[93] Patients may require platelet and fresh frozen plasma transfusions, vasopressors, and ammonia-lowering therapies, such as lactulose.[94] Researchers have noted modest reports of successful symptom resolution with high-dose methylprednisolone, glutamine with high-dose vitamin E, ursodiol, activated factor VII, defibrotide, and tissue plasminogen activator.[93,95] Defibrotide, an oligonucleotide derived from porcine intestinal mucosa that demonstrates simultaneous antithrombotic properties with microvascular protective features, producing minimal hemorrhagic risk, is the most promising and well-studied agent.[96,97] Renal replacement therapy is often required; continuous venovenous hemofiltration is often the preferred method of therapy because these patients exhibit increased vagal tone and a tendency for vasodilatory hypotension. Some experts advocate early implementation to preserve renal function and reduce the need for respiratory support.[87] Before the advent of CRRT, mechanical ventilation to control fluid imbalance–induced respiratory distress was often necessary.

No methods to prevent hepatic veno-occlusive disease have yet proved successful. Results of studies of low-dose heparin (subcutaneously or intravenously), prostaglandin E_1, and defibrotide as potential preventive agents have so far been inconclusive.[88,98,99]

Complications

Patients with mild to moderate hepatic veno-occlusive disease experience complete reversal of the pathological process. It is uncertain whether supportive therapies have any influence on this outcome. Well-controlled studies clearly show that mortality is high in patients with total bilirubin levels greater than 15 to 18 mg/dL, renal dysfunction, high fibrinogen D-dimers, or a hepatic pressure gradient of greater than 20 mm Hg.[90,93]

Superior Vena Cava Syndrome

Superior vena cava syndrome (SVCS)—obstruction of the superior vena cava—results in venous blockage that produces pleural effusion and facial, chest, arm, and neck edema.[100,101] Severe obstruction results in impaired cardiac filling, and the venous congestion has also been associated with tracheal obstruction and cerebral edema.

Pathophysiology

The superior vena cava is a thin-walled, low-pressure blood vessel in the mediastinal cavity that collects blood from the venous vessels that drain the head and neck and the upper thoracic cavity. The mediastinum is a rigid anatomical structure that contains the trachea, the vertebral column, the sternum and ribs, and the lymph nodes.

Most cases of SVCS result from mediastinal malignancies or involved lymph nodes that cause extrinsic compression or invade the vessel.[100–102] More than 75% of cases are secondary to small cell or squamous cell lung cancers, and 10% to 15% are secondary to mediastinal lymphomas.[100–104] Obstruction of the vessel lumen by a thrombus may also occur; it is most commonly caused by a central venous catheter or a hypercoagulability syndrome due to cancer.[100–102,105] Box 48-12 summarizes the risk factors for SVCS.

BOX 48-12 Risk Factors for Superior Vena Cava Syndrome

- Chest, neck, or epigastric tumors (eg, lung cancer, breast cancer, lymphoma, head and neck cancer, thyroid cancer, gastric cancer, esophageal cancer, pancreatic cancer, metastatic renal cell cancer, metastatic colorectal cancer, melanoma)
- Devices in the superior vena cava (eg, large-bore, multilumen central lines, especially if placed in the subclavian site)
- Hypercoagulability syndromes (disseminated intravascular coagulation, hypercoagulability of malignancy [eg, mucin-producing adenocarcinomas, brain tumors, Trousseau's syndrome])

Assessment

HISTORY. Signs and symptoms of SVCS depend on the rapidity of compression of the superior vena cava. If it is compressed gradually and collateral circulation develops, indications of SVCS may be more subtle.[102,104] Initial symptoms are most prominent in the early morning and include periorbital and conjunctival edema, facial swelling, and Stokes' sign (tightness of the shirt collar).[101] These signs may disappear after the patient has been upright for a few hours. The patient may also complain of visual disturbances and headache. Altered consciousness and focal neurological signs may result from brain edema and impaired cardiac filling. Late signs and symptoms include distention of the veins of the thorax and upper extremities[104] dysphagia, dyspnea, cough, hoarseness, and tachypnea. All patients, including children, most commonly visit health care providers because of dyspnea.[101,103] Pleural effusions are present in approximately 60% of cases, compounding respiratory symptoms and providing a complex dimension for treatment planning.[106] Most pleural effusions are transudative and related to obstruction of pleural and lymphatic outflow.

DIAGNOSTIC STUDIES. Until recently, diagnostic evaluation of SVCS required multiple tests to validate the location, size, and vena cava involvement of tumors or thrombus. Conventional chest CT with IV contrast, venography, angiography, and radionuclide scans were necessary. Currently, the spiral CT scan with contrast, which provides accurate information about tumor location and involvement of the vena cava, may be the only diagnostic test performed.[107] However, biopsy or cytological tests may be required to establish a diagnosis in many patients because this syndrome is the presenting symptom at the time of diagnosis of cancer.[108]

Management

The primary treatment of choice for SVCS caused by a tumor is radiation therapy. Dosage depends on the size of the tumor and its radiosensitivity. Radiation therapy is initially given in high daily fractions (total dose of 30 to 50 rad) for 14 to 21 days, and symptom relief occurs in 7 to 14 days.[101] Radiation therapy is palliative for SVCS in 70% of patients with lung cancer and for more than 95% of patients with lymphoma.[103] Radiation of the mediastinal, hilar, and supraclavicular lymph nodes and any adjacent parenchymal lesions is appropriate in patients with locally advanced non–small cell lung cancer.

Patients who receive radiation therapy experience increased cough within 3 days of the start of therapy. During the initial 7 to 10 days, secretions are increased because of inflammation, but a dry irritation then develops, resulting in a dry, hacking cough with few secretions but possible bleeding.[100] Chemotherapy may be the treatment of choice for SVCS in patients with disseminated disease, such as small cell anaplastic carcinoma or lymphoma. The agents used most often include high-dose regimens containing cyclophosphamide, cisplatin or carboplatin, bleomycin, etoposide, and doxorubicin.[100,103] The most common adverse effects of these agents include bone marrow suppression, cardiac toxicity, and renal dysfunction.

Treatment of SVCS caused by a thrombus around a central venous catheter may include antifibrinolytics or anticoagulants and possibly surgical removal of the catheter.[109] In any case, chest and neck central venous catheter placements should be avoided until effective treatment has been delivered.

In some circumstances, the placement of stents or vascular grafts in the superior vena cava provides immediate symptomatic relief while patients receive definitive therapy.[108,110–112] It is unclear whether long-term anticoagulation is required. Caution must be taken and intensive observations are made to enhance early detection of bleeding as the tumor shrinks.[113] Supportive care is essential. Maintenance of a patent airway is of the highest priority.[100] Because many patients have severe dyspnea, they are unable to lie flat for their radiation therapy, and short-term airway intubation may be necessary. Clinicians may prescribe oxygen therapy, diuretics, steroids, and heparin, and their administration requires careful observation of patient response. If necessary, administration of corticosteroids for 3 to 7 days to decrease the edema associated with the disease and treatment is warranted.[108] The nurse teaches the patient not to bend over and to avoid Valsalva maneuvers. When the patient is in bed, the head should be at least in a semi-Fowler's position. Elevation of the arms on pillows helps alleviate swelling; however, elevation of the legs is not helpful because this increases fluid volume in the torso.

Complications

Several complications may occur in patients with SVCS. Right-sided heart failure is the most common.[100] Such heart failure is usually self-limiting and is treated symptomatically with fluid restrictions, diuretics, and digoxin. Vessel rupture in SVCS when a tumor invades the vena cava is a great risk because the tumor shrinks with treatment. The incidence of vessel rupture is highest in patients with esophageal and lung cancer; peak incidence is 3 to 4 weeks after initiation of therapy.[100] Warning signs of vessel rupture are acute and sudden dyspnea, hypoxia, cough, and vascular collapse. Radiation pneumonitis, an inflammatory response in the radiation field that correlates with breath sound and radiographic changes reflective of alveolar capillary permeability, may occur 2 to 8 weeks after start of therapy in patients who receive chest radiation for SVCS.[100] Treatment of radiation pneumonitis involves corticosteroids and supportive therapy. SVCS recurs in 10% to 30% of patients.[101]

Pleural Effusion

Pathophysiology

There is normally 30 to 150 mL of fluid between the visceral and parietal pleura that helps maintain a negative pleural pressure to facilitate lung expansion with minimum work of breathing. A pleural effusion is excess accumulation of fluid in the pleural space with subsequent impaired lung expansion and hypoxemia. When lymphatic obstruction (particularly of the thoracic duct), venous congestion, pleural inflammation, or excess capillary permeability occurs, the amount of fluid increases or does not drain properly.[114]

Although many nonmalignant conditions (eg, congestive heart failure, hypothyroidism) may cause pleural effusion, malignant conditions involving lymphatic obstruction or infiltration with malignant cells may also have the same result. Pleural effusions that result from volume overload, capillary permeability, or lymphatic obstruction produce a transudate characterized by the presence of albumin and the

absence of cell fragments or enzymes in the pleural fluid.[115,116] Malignant cell infiltration or pleuritic infection causes pleural inflammation and exudates characterized by the release of red blood cells, WBCs, and lactate dehydrogenase into the pleural fluid.[116] As many as 50% of patients with cancer experience pleural effusions during the course of their disease, particularly in cancers of the lung or breast.[114,117,118] The presence of pleural effusion is associated with a shorter life expectancy, averaging 3 to 12 months after diagnosis.[117,119,120] Predictors for better outcome include specific types of cancer and patients with higher performance status at diagnosis of effusion.[120]

Accumulation of pleural fluid leads to increased (more positive) pleural pressure. Higher pleural pressures increase the work of breathing, and collapsed alveoli cause decreased gas exchange and hypoxemia.[114]

Assessment

HISTORY. The clinical findings in pleural effusion are related to the two major physiological mechanisms: increased work of breathing and alveolar collapse. Excess pleural pressures decrease lung compliance ("stiff lungs"). Patients feel short of breath and must use their accessory muscles to breathe, and chest excursion on the affected side is reduced. When patients are in an upright position, the force of gravity pulls down the fluid, and breath sounds are diminished to the level of fluid. The pleural fluid takes up space in the chest, impeding lung expansion with consequent alveolar collapse. Symptoms that relate to this pathological process are diminished breath sounds, unequal chest excursion, tracheal shift away from the effusion, and signs of hypoxemia (eg, dyspnea, anxiety, confusion, oliguria, decreased bowel sounds).[114,118]

DIAGNOSTIC STUDIES. The first diagnostic test performed to confirm the presence of pleural effusion is an upright chest radiograph or CT.[121,122] The fluid accumulates in the lower lung, causing a blunted diaphragmatic dome and decreased radiolucence in the lower lung. Fluid accumulation often produces a meniscus of decreased radiolucence and a thickened lateral pleural lining, indicating fluid tracking up the side.[121] When alternative diagnoses such as hemothorax, infection, or tumor infiltrates are possible, the CT scan may be more accurate. After a pleural effusion is confirmed, a cytological evaluation, which involves extraction of a sample of fluid and sending it for fluid chemistry and cytology, is necessary. Pleural fluid is categorized as transudative or exudative, which provides clues to the cause of the effusion. Cytological studies require at least 50 mL fluid to confirm the presence or absence of malignant cells; the results of which influence treatment decisions.[123,124] Multiple specimens may be necessary to confirm malignancy; it is estimated that cytology may be positive only 30% of the time when malignant cells are present.[122,123] When fluid cytology is inconclusive, pleural biopsy may be helpful in diagnosis of malignant infiltration.[125]

Management

The treatment of pleural effusion depends on the etiological mechanism, rapidity of symptom onset, and degree of respiratory compromise.[114,126] Because many patients with malignant pleural effusion have limited survival, the selection of treatment that enhances quality of life with minimal time required for recovery is optimal. When pleural effusions are small or have a nonmalignant cause, observation without definitive treatment may be indicated. Aggressive antineoplastic therapy may be indicated when a large tumor causes lymphatic obstruction, heart failure, or pneumonitis that in turn causes pleural effusion.

When malignant cells are present in the pleural fluid, management may be determined by overall treatment goals. Repeated therapeutic thoracenteses are often the preferred initial choice; this assumes that the ultimate cause of the pleural effusion is being treated or that the patient's life expectancy does not warrant more interventional measures.[114,118,122,126] When the patient's life expectancy is longer, and pleural effusions do not resolve with anticancer therapy and intermittent thoracenteses, treatment includes long-term chest catheter drainage or pleurodesis. Long-term pleural drainage via a soft tunneled catheter (eg, Pleurex® catheter) allows patients to have a means of draining excess fluid while remaining at home.[127–131] When drainage slows and patients become a good candidate for pleurodesis, they are admitted to the hospital for this procedure. Alternatively, patients may be admitted for placement of a traditional chest catheter and once drainage slows, pleurodesis may be performed. Pleurodesis, also called pleural sclerosing, involves intrapleural administration of a chemical (eg, doxycycline, bleomycin) or a mechanical agent (eg, talc slurry) to alter the pH of the pleural fluid and cause inflammatory adherence of the visceral and parietal pleura to each other.[123] Sclerosed pleura do not have the normal lubricating pleural fluid, and restrictive lung disease is the long-term consequence. Pleurodesis is successful only about 67% of the time, necessitating the availability of additional treatment options. Box 48-13 presents nursing interventions related to managing pleurodesis.

Pleurectomy is a thoracic surgical procedure that removes the entire pleura. Pleurectomy is effective but can be difficult to perform when long-term inflammation and pleurodesis attempts cause a friable pleura that

BOX 48–13 NURSING INTERVENTIONS

For Pleurodesis

- Be certain pleural drainage from chest tube in previous 24 hours is less than 150 mL.
- Obtain sclerosing agent (bleomycin, doxycycline, or talc slurry) and postsclerosing flush solution (preservative-free sterile water or normal saline solution or lidocaine [Xylocaine] 1% or 2%).
- Plan to inject sclerosing agent into the chest drainage tube.
- Set up an extra chest drainage system with tubing to connect if tubing leaks after injecting sclerosing agent.
- Clamp tubing for 4 to 6 hours after instillation of sclerosing agent.
- Have patient be as mobile as possible, but scheduled body rotation is not necessary to ensure distribution of the agent throughout the pleura.
- Unclamp chest tube and observe drainage (effective 67% to 70% of time). If effective, drainage is minimal to absent.
- Assist with removal of chest tube and monitor patient for air tracking and pneumothorax, or reaccumulation of fluid.

is not easily separated. Chronic, long-term pleuroperitoneal shunts or implanted access devices have been used, but development of fibrin sheaths on the catheters often causes occlusion.[118,126] In cases where catheter drainage is unsuccessful, intracavitary chemotherapy with cisplatin, interferon, or pemetrexed have been used with moderate success[122,123,126,132]

Complications

Untreated pleural effusions that continue to accumulate lead to clinically significant alveolar collapse and respiratory failure, which may be caused by loss of gas-exchanging airways or mediastinal shifting with major airway obstruction. Progressive hypoxemia leads to profound respiratory acidosis and ischemic organ failure. Evacuation of an extensive and long-standing pleural effusion may result in reexpansion pulmonary edema or hypotension from fluid shifts.[133]

Spinal Cord Compression

Spinal cord compression (SCC) occurs when tumor cells or collapsed vertebrae in the epidural space exert pressure on the spinal cord, which may result in permanent dysfunction (including paralysis) if not diagnosed and treated promptly. Epidural tumors are found in more than 5% of patients with metastatic disease at autopsy.[134] The most common cause of SCC is compression fracture and vertebral collapse.[135] Factors associated with effective local control and long-term survival after SCC include favorable histological diagnosis, no visceral metastases, and a long-course radiation therapy schedule.[134,135]

Pathophysiology

Two major pathophysiological mechanisms are likely to result in SCC: (1) tumors arising within the epidural space through vertebral or lymphatic spread and (2) bony metastasis causing vertebral collapse with spinal cord and nerve root compression.[134,135] Permanent neurological damage from proximal tumors may also occur if spinal circulation is compromised such as in prolonged ischemia or hemorrhage.[136] Other disorders producing signs and symptoms of cord compression are paraneoplastic syndromes, radiation myelopathy, herpes zoster, pain from a pelvic or long bone metastasis, or cytotoxic drug effects.[136] Table 48-7 presents the tumors most likely to cause cord compression and the location of compression.

Assessment

HISTORY. When a primary tumor presses on the spinal cord, signs and symptoms usually develop slowly. Problems develop more rapidly with metastatic disease. Most patients with SCC complain of progressive central or radicular back pain that often is aggravated by weight bearing, lying down, coughing, sneezing, or performing the Valsalva maneuver. Sitting relieves the pain.[137,138]

The earliest neurological symptoms are sensory changes, such as numbness, paresthesia, and coldness.[138,139] Compression occurs most often in the thoracic section of the spinal cord, causing neurogenic bladder with urinary retention and incontinence. Patients may also lose the urge to defecate and are unable to bear down. Men on occasion lose the ability to have or maintain an erection. Metastases to the cauda equina frequently produce impaired urethral, vaginal, and rectal sensations; bladder dysfunction; decreased

Table 48-7 Spinal Cord Compression: Etiology and Clinical Presentation

Location of Lesion	Common Malignant Etiologies	Physical Symptoms	Autonomic Symptoms
Cervical spine	• Head and neck cancers • Melanoma	• Radicular pain in the neck, occipital region, and shoulders (pain is often provoked by neck movement) • Quadriplegia • Upper extremity weakness (may be spastic or atrophic) • Sensory loss in area of weakness • Weakness or paralysis of the diaphragm may occur with lesion at or above C4 (may be unilateral or bilateral)	• Hypotension • Bradycardia • Loss of temperature autoregulation • Autonomic hyperreflexia • Gastric hypersecretion and paralytic ileus • Reflex bowel, bladder, and penile erection • Hoffman's sign (flicking of the middle finger induces flexion of the ipsilateral thumb or index finger)
Thoracic spine	• Breast cancer • Gastric cancer • Lung cancer • Lymphoma • Pancreatic cancer	• Pain (may be local, radicular, or both) • Paraplegia • Sensory loss below the level of the lesion • Reflex abnormalities distal to the lesion	• Venous stasis and associated complications • Reflex bowel, bladder, and penile erection
Lumbar spine	• Ovarian cancer • Renal cell cancer • Prostate cancer	• Bowel and bladder dysfunction • Extensor plantar response	• Venous stasis and associated complications • Reflex bowel, bladder, and penile erection
Cauda equina	• Bladder cancer • Prostate cancer	• Pain (may be local, referred, or radicular) • Sphincter disturbances • Loss of buttock and leg sensation • Lower extremity weakness/paralysis	• Areflexic bowel, bladder, and penile erection

BOX 48-14 CONSIDERATIONS FOR THE OLDER PATIENT

Spinal Cord Compression

Signs and symptoms of SCC often begin as subtle and nonspecific back pain and sensory changes. The older patient may have concomitant diabetes mellitus or osteoarthritis that produces overlapping symptoms, delaying diagnosis of the oncological complication. In addition, older persons often have bowel and bladder changes causing constipation or urinary incontinence, mimicking the more serious autonomic changes that occur in later SCC. People at high risk for SCC, such as those with known bone metastases, should be taught the importance of reporting and having evaluated all back pain and sensory changes, especially in the lower extremities. In SCC, palpable vertebral tenderness is more often present than with other nononcological disorders.

sensation in the lumbosacral dermatomes; and saddle anesthesia.[139] Box 48-14 describes spinal cord considerations in the older adult.

It is possible to determine the level of cord compression by the patient's report of pain during straight leg raising, neck flexion, or vertebral percussion. The upper limit of the sensory level is usually one or two vertebral bodies below the site of compression.[139] Lessened rectal tone and perineal sensation are observed with autonomic dysfunction. Deep tendon reflexes can be brisk with cord compression and diminished with nerve root compression.

Once patients experience pain, motor weakness and ataxia often follow.[139] They may complain that the arms or legs feel heavy. Some patients lose the ability to sense light touch, pain, and temperature. Over time, weakness may progress to spasm, paralysis, and muscle atrophy; sensations of deep pressure and position may disappear.

DIAGNOSTIC STUDIES. A screening spinal radiograph will detect up to 80% of vertebral fractures and high risk for SCC and may be used for initial, rapid evaluation in high-risk patients, particularly when an MRI is not readily available.[140] MRI is the diagnostic test of choice due to high sensitivity for neurological tissues. MRI examinations can clearly demonstrate all epidural deposits as well as complete or partial block of the spinal cord.[141,142] A myelogram or CT scan may reveal spinal tumors, but these studies are less sensitive for diagnosing the presence and extent of cord compression. Lumbar puncture, which is used to obtain cerebrospinal fluid, reveals malignant cells in the presence of epidural disease.[141]

Management

Factors considered in the selection of the best therapeutic option are the level of cord compression, the rate of neurological deterioration, and previous use of radiation therapy.[134] Corticosteroids decrease peritumoral edema and neurological dysfunction. Dexamethasone, 10 mg as an initial dose, is administered to patients with neurological symptoms before emergency diagnostic procedures are performed and is continued during radiation therapy (4 to 20 mg every 6 hours) and then tapered.[134,135,140,143] It is not clear whether such steroid therapy affects final patient outcome.

Radiation therapy is appropriate when the tumor is determined to be radiosensitive and should be initiated as soon as the diagnosis of cord compression has been confirmed.[137] Radiation portals include the entire area of blockage and two vertebral bodies above and below this area. More than 50% of patients with rapid neurological deterioration improve with radiation therapy; however, patients with autonomic dysfunction or paraplegia have a poor prognosis with any therapy.[140,143] Laminectomy, with or without placement of stabilization rods in the nearby vertebral bodies, may result in immediate decompression of the spinal cord and nerve roots.[144,145] The posterior approach is preferred but is often difficult because most metastases arise in the vertebral bodies anterior to the spinal cord.[141,145] The anterior approach is warranted for people with tumors that are believed to be resectable, making the clinical risks worth the aggressive surgical intervention.[144] Postoperative radiation therapy is used to shrink residual tumor, relieve pain, and improve the patient's functional status. Surgery is usually contraindicated if there is a collapsed vertebral body or if there are several areas of cord compression. If there is no previous histological diagnosis of cancer, or if infection or epidural hematoma must be ruled out, then laminectomy can be used for both diagnosis and treatment. If high cervical cord compression precludes surgery, a neurologist should stabilize the patient's neck in halo traction to prevent respiratory paralysis.[145] If the patient continues to deteriorate neurologically despite high doses of steroids and radiation therapy, then emergency decompression may be necessary.[144] In some people, stabilization of the spine with vertebroplasty with or without kyphoplasty represents a less invasive and equally effective short-term resolution for acute cord compression and its associated pain.[145–147] Injection of physiological cement (kyphoplasty) to reexpand collapsed vertebrae has been used to successfully prevent progression to SCC.[147] If the tumor is chemosensitive, chemotherapy concurrently with or soon after completion of radiation therapy or surgery may be appropriate. Chemotherapy may also be effective in patients with multiple myeloma who have had previous radiation therapy.[145] Systemic chemotherapy or hormonal therapy may be useful in certain types of tumors, such as lymphoma or prostatic cancer.

Pain management includes the administration of appropriate analgesics, bed rest, and patient support during position changes and transfer. Range-of-motion exercises are useful in patients with motor and sensory deficits. Bowel retraining and intermittent urinary catheterization may be necessary. Frequent skin care is essential. Surgical wounds are particularly susceptible to skin breakdown (with possible wound dehiscence) because of limited mobility and the effects of concomitant corticosteroid therapy.[138]

Tracheobronchial Obstruction

Pathophysiology

Obstruction of the trachea or major branches of the bronchi with tumor results in respiratory distress and hypoxemia. The severity of symptoms depends on the rapidity of obstruction and degree of closure.[148,149] Tumors most likely to cause airway obstruction are lung cancer and lymphoma, although other metastatic tumors (eg, head and neck cancer, melanoma, renal or breast cancer) and nonmalignant disorders (eg, amyloidosis, bronchomalacia) may also cause airway obstruction.[149] Rare instances of leukemia and lymphomatous infiltrates causing airway obstruction have also been reported.[150]

Assessment

HISTORY. Patients with tracheobronchial obstruction present with varying degrees of dyspnea depending on the amount and location of the obstruction and the rapidity of onset. Some patients with slowly developing tumors have compensated respiratory acidosis and minimal symptoms even with nearly complete obstruction. Other patients, especially those with lymphoma or small cell lung carcinoma, have rapidly growing tumors and severe symptoms even when the airway is less than 75% obstructed. Stridor is present in tracheal obstruction, and wheezing with unequal chest excursion is seen with bronchial obstruction.[149] Some patients presenting with severe respiratory distress actually have only partial airway obstruction, but the resultant narrowed airway leads to concomitant atelectasis or trapped secretions with pneumonia that may be mistaken as more severe tumor obstruction.[151]

DIAGNOSTIC STUDIES. Bronchoscopy makes it easy to detect tracheal or bronchial obstruction and grade its severity. However, bronchoscopy does not always reveal whether the airways are compressed extrinsically or invaded with tumor.[148] Bronchoscopy is used with spiral CT scans to provide a comprehensive description of the obstructive process that is used to guide therapy.[152]

Management

Clinically significant obstruction of the major airways always necessitates immediate treatment, although the therapeutic plan varies according to tumor-specific factors and therapeutic goals. Emergent treatment of airway occlusion–induced hypoxemia or hypercapnia may require nasal inhalation or heliox-based nebulizer treatments. A combination of oxygen and helium that is lighter than pure oxygen, heliox enhances movement of the air beyond the area of obstruction and provides palliative relief until more aggressive operative measures are possible.[153] If air movement is adequate, bronchodilators and corticosteroids are administered to enhance ventilation, and if simultaneous pneumonia is suspected, antimicrobial therapy is instituted.[149]

Effective treatment for endobronchial tumors includes laser, cautery, photodynamic therapy, and endobronchial brachytherapy.[154–157] These therapies for tumors invading the major airways are highly successful for prolonging life as well as improving its quality. Most procedures entail use of a rigid bronchoscope under anesthesia, and patients usually experience a rapid recovery with little more than a sore throat and annoying cough for a few days afterward.[156,157] Endobronchial brachytherapy involves endotracheal intubation with precisely directed radiation therapy through an endobronchial catheter.[158] In laser therapy, electrocautery, photodynamic therapy, and endobronchial brachytherapy, close observation for airway bleeding is necessary, and clinicians may prescribe cough suppressants or low-dose corticosteroids to reduce the incidence of bleeding.[155,156] Airway opening with tracheal or bronchial stents may provide temporary symptomatic relief while definitive anticancer treatment is implemented for palliative relief of symptoms.[154,159–162] For insertion of an airway stent, a rigid bronchoscope and light anesthesia are necessary, and multiple bronchoscopic procedures to assess or adjust placement are required. The most common problem with stents, especially if placed before shrinking the tumor, is displacement because the airway naturally opens with the reduction of tumor. Displaced stents usually cause severe and sudden respiratory distress and require immediate interventional adjustment. In rare circumstances, or when stenting is not possible, patient positioning to shift the chest tumor off the major airway (eg, prone positioning) may provide temporary symptomatic relief while cancer therapy is used to shrink the tumor.[159,160]

Complications

Two severe complications that may occur are total airway occlusion and hemorrhage caused by tumor erosion into the nearby pulmonary vessels. Treatment of total obstruction is the same as that of partial obstruction when an improvement in symptoms can be reasonably expected as a result of therapy. Emergent extracorporeal membrane oxygenation (ECMO) has also been used to bridge until the tumor shrinks. Treatment of hemorrhage, when recognized before massive bleeding occurs, may involve embolization. If severe hemorrhage occurs, it is necessary to insert a dual-lumen endotracheal tube or single-sided intubation and occlude the bleeding lung while ventilating the good lung until surgical repair can be performed. Airway obstruction may also lead to erosion through the airway and accompanying pneumothorax. In these circumstances, supportive therapy, such as chest tube insertion, may be used but is rarely helpful.

▲ Metabolic Complications

Hypercalcemia

Hypercalcemia exists when the corrected serum calcium level is above 11 mg/dL (normal range, 8.5 to 10.5 mg/dL). This is the most common metabolic oncological emergency that develops when the bones release more calcium into the extracellular fluid than can be filtered by the kidneys and excreted in the urine.[163–166]

Pathophysiology

Ninety-nine percent of the calcium in the body is in an insoluble form in the bones. The remaining 1% is freely exchangeable calcium. The calcium of importance is the ionized calcium, which must be maintained within a precise range. Serum calcium levels are regulated by parathyroid hormone and calcitonin.[163,167] The release of parathyroid hormone from the parathyroid glands stimulates an increase in serum calcium levels, whereas the release of calcitonin produces a decrease in serum calcium levels.[164]

Destruction of the bone by metastatic invasion is believed to be the most common cause of malignant hypercalcemia; however, 20% of patients with solid tumors usually associated with hypercalcemia do not show evidence of bony involvement.[163,168] In some cancers, tumor cells secrete certain humoral substances, such as parathyroid hormone–like substances or osteolytic prostaglandins. In patients with multiple myeloma, the abnormal plasma cells produce osteoclast-activating factor (OAF); however, hypercalcemia does not develop in these patients unless they have inadequate renal function.[169] Patients with T-cell lymphoma have severe hypercalcemia related to the ectopic production of OAF, colony-stimulating factor, interferon-γ, and an active vitamin D metabolite.[170] Additional causes of hypercalcemia in the presence of malignancy include immobilization,

BOX 48-15 Causes of Hypercalcemia in Malignancy

- Bone demineralization due to bone metastases (most common in breast, colorectal, lung, and renal cell cancer)
- Tumor production of a parathormone-like substance (thyroid cancer, multiple myeloma, leukemia, lymphoma, gastric cancer, pancreatic cancer, lung cancer)
- Renal insufficiency
- Immobilization
- Dehydration

renal insufficiency, thiazide diuretics, high dietary calcium or vitamin D intake, and low phosphate levels.[164,167,171] Box 48-15 lists causes of hypercalcemia in malignancy.

Hypercalcemia develops in as many as 40% to 50% of women with metastatic breast cancer. There is a risk for bone metastasis, and estrogen and antiestrogens stimulate breast cancer cells to produce osteolytic prostaglandins and to increase bone resorption.[167] In cases of nonbone sources of hypercalcemia, it is often viewed as a hallmark of the presence of tumor. The incidence and severity may dramatically decrease when the patient's tumor is quiescent and become severe or difficult to manage when the tumor is active.[169]

Assessment

HISTORY. The severity of signs and symptoms of hypercalcemia often correlates with the serum calcium level. Common presenting symptoms include nausea, constipation, polyuria, and mental status changes. Most patients present with somnolence, combativeness, or confusion.[172]

DIAGNOSTIC STUDIES. Elevated serum calcium and elevated ionized calcium are the hallmark diagnostic findings in hypercalcemia. The serum calcium measurement is often reported as an absolute number without considering that only the calcium bound to albumin is counted. The serum calcium may be corrected for a low albumin by subtracting the patient's albumin from low normal, multiplying this number by a correction factor of 0.8, and adding this number to the reported calcium.[173,174] Serum ionized calcium levels are accurate, but because the normal value is 1.0 mEq/L (± 0.02), it is a less sensitive indicator of clinically significant hypocalcemia.[174]

In addition to increased calcium levels, there are also elevations in alkaline phosphatase and immunoreactive parathyroid hormone.[173,174] Serum phosphate and serum potassium are decreased. Symptomatic patients usually have ECGs that show a bradycardia and prolonged PR, QRS, and QT intervals.[172,174]

Management

Medical management of hypercalcemia involves the use of IV fluids and drug therapy to enhance renal excretion of calcium and to decrease bone resorption. Acute hypercalcemia is initially treated with IV normal saline (0.9% NaCl) solution to dilute calcium levels and increase urinary calcium excretion.[165,175] When hypercalcemia is life-threatening, aggressive hydration (250 to 300 mL/h) and IV loop diuretics such as furosemide are necessary.[175] Hemodialysis with calcium-free dialysate has been used successfully for emergency management of life-threatening hypercalcemia.[176]

In most patients, treatment with hydration, diuretics, appropriate antitumor therapy, and mobilization is effective. Patients who do not respond to these therapies require hypocalcemic therapy indefinitely. Bisphosphonates are most frequently used. Currently, the most potent bisphosphonate available is zoledronic acid. It is administered as an 8-mg 15-minute IV infusion daily for 3 days unless serum calcium levels decrease before that time.[175] Until recently, the mainstay of bisphosphonate therapy was pamidronate, and some clinicians may still prefer it. It is licensed to be given as a 90-mg, 24-hour infusion with continued hydration, possibly diuretics, and careful monitoring of calcium levels. However, because of clinical safety and efficacy studies, many clinicians give this dose over 90 to 120 minutes. An FDA-licensed monoclonal antibody targeting rank ligand for prevention of bone breakdown, denosumab, is also available, but its use in hypercalcemia has been limited.[177] In cases unresponsive to bisphosphonates, calcitonin, corticosteroids, or strontium-98 may be useful.[81,164,165,175,178] If possible, patients should ambulate to prevent osteolysis. It is necessary to eliminate constipation, which is usually caused by an increased level of calcium in the blood. Reduced oral intake of calcium or increased salt intake may be of some help. Patients should not take medications, such as thiazide diuretics and vitamins A and D, because they elevate the calcium level.[179] Close monitoring of fluid status is essential. Patients may receive up to 10 L of IV fluids daily, and the nurse should carefully measure intake and output. In addition, careful observation for overhydration is important. Potassium supplements may be necessary. Hypercalcemia is a common oncological emergency that can be prevented or diminished in a large number of patients with the appropriate prophylactic bisphosphonates, education, and precautions.[81,165,172,179] Box 48-16 presents a teaching guide for patients with hypercalcemia.

BOX 48-16 TEACHING GUIDE Malignancy-Associated Hypercalcemia

Patients at high risk for malignancy-associated hypercalcemia include those with:

- Bone metastases (most common in breast, lung, and colon cancer)
- Lung cancer
- Gastrointestinal cancers (gastric, pancreatic, colon)
- Hematological cancers (leukemia, lymphoma, multiple myeloma)
- Renal (kidney) cancer
- Thyroid cancer

Patients with the risk factors below need to be instructed that additional factors increase their risk for developing hypercalcemia. These factors include:

- Lack of physical activity
- Low fluid status
- Poor kidney function

Critical care nurses can teach patients methods for preventing hypercalcemia as follows:

- Drink at least six to eight glasses of water every day.
- Eat salty foods.
- Remain physically active.
- Limit dairy products and vitamin D–enriched foods, such as milk, cheese, and yogurt.

Complications

Permanent renal tubular abnormalities may develop in patients with prolonged hypercalcemia.[171] Sudden death from cardiac dysrhythmias may result from an acute increase in serum calcium. Long-term bisphosphonate use has been associated with severe osteonecrosis of the jaw. Specific risk factors for this complication are not yet clear.[180]

Syndrome of Inappropriate Antidiuretic Hormone (SIADH) Secretion

SIADH secretion is a clinical disorder characterized by excess stimulation of pituitary excretion of antidiuretic hormone (ADH). Under normal circumstances, the posterior pituitary gland releases ADH in response to changes in plasma osmolality (concentration of solutes) and circulating blood volume. ADH release causes decreased urine production and volume and increased water resorption. SIADH has several specific causes related to cancer and its treatment.[181] The clinical consequences of SIADH and its management strategies are discussed in Chapter 44.

Pathophysiology

When thoracic or mediastinal tumors press on major cardiac vessels, the obstruction may impede cardiac output. The posterior pituitary gland perceives this to be a fall in circulatory volume and compensates by inappropriately secreting ADH, which in turn suppresses urinary output. The resulting volume expansion improves cardiac output but leaves the patient with a relative sodium deficiency (dilutional hyponatremia).

In addition to the pressure of thoracic or mediastinal tumors on cardiac vessels, cancers and treatment-related factors can also precipitate SIADH. Small cell lung cancers or mixed cellularity lung cancers, pancreatic, renal, gastric, head and neck, thyroid cancer, neuroendocrine, and melanoma release an ADH-like substance.[181–185] Certain chemotherapeutic agents, such as cyclophosphamide, ifosphamide, imatinob, vincristine, vinorelbine and alemtuzumab, as well as morphine, may stimulate ADH release or potentiate its effects on the kidneys.[181,182,186–189] One study views ongoing evidence of SIADH after antineoplastic treatment as a poor prognostic sign, often a subtle indicator of persistent tumor.[190] Enhancing this confusing clinical picture may be that brain injury, pulmonary infection and HIV disease also cause SIADH.[191]

Management

Treatment of the underlying malignancy is of primary importance in cancer-related SIADH.[187] Clinical evidence of excess ADH is present until the primary tumor stops compressing the major cardiac vessels or producing ADH-like substances. Antineoplastic therapy may include chemotherapy, radiation therapy, or corticosteroids. Fluid intake limited to 500 to 1,000 mL/d should result in a corrected fluid balance in 7 to 10 days.[182,184,192] Demeclocycline, an antibiotic that inhibits ADH secretion, may be effective; patients with chronic SIADH may receive demeclocycline, 900 to 1,200 mg/d.[192] Adverse effects include diarrhea, nausea, dysphagia, and photosensitivity. New specific vasopressin-receptor antagonists, called vaptans, enhance water diuresis without sodium loss and show promise in the treatment of this disorder.[192]

Diuretics are not necessary except in severe circumstances because they may produce additional electrolyte imbalances. However, the patient who is comatose or convulsing should receive 3% IV hypertonic saline solution and a potent loop diuretic, such as furosemide.[182,184] Fluid imbalances and hyponatremia may be severe enough to warrant initiation of mechanical ventilation; the need for this aggressive respiratory support is the most predictive of a mortality rate of 22% to 40%.[190]

Tumor Lysis Syndrome

Tumor lysis syndrome is a metabolic imbalance caused by rapid cancer cell death occurring with clinical significance in 2% to 4% of high-risk patients.[193] Most patients experience this complication 1 to 5 days after initiation of therapy in patients with chemosensitive or radiosensitive tumors.[194,195] However, there are documented instances of tumor lysis syndrome in rapidly proliferating disease such as acute leukemia or high-grade lymphoma even before treatment initiation.[195]

Patients at greatest risk for tumor lysis syndrome are those with bulky tumors having a high growth rate (eg, acute leukemia or Burkitt's lymphoma) and those with highly radiosensitive or chemosensitive tumors, such as small cell lung cancer and most malignant lymphomas.[194–197] Patients with preexisting renal dysfunction may be at greatest risk owing to their difficulty in clearing the metabolic waste products fast enough to prevent clinical complications.[195,198] Other patients at high risk are those with Merkel's tumor, testicular cancer, hepatoblastoma, and medulloblastoma.[195]

Pathophysiology

Rapid cell death causes the release of intracellular contents (potassium, phosphorus, and nucleic acids) into the circulating serum. The normal filtration mechanisms in the kidneys should immediately detect the levels of metabolic waste products and attempt to excrete them. If production is more rapid than excretion or renal insufficiency is present, accumulation of electrolytes and uric acid occurs in the serum. The most common abnormalities include hyperkalemia, hyperphosphatemia, and hyperuricemia.[195] High phosphorus causes the kidneys to excrete calcium, causing hypocalcemia. Hyperuricemia causes deposition of uric acid crystals in the urinary tract and may lead to renal failure.[43,195,197,198]

Assessment

HISTORY. Signs and symptoms of tumor lysis syndrome are related to the specific electrolyte imbalances involved and renal dysfunction. Hyperkalemia, hyperphosphatemia, hypocalcemia, hyperuricemia, and acidosis may occur. Box 48-17 lists the typical clinical signs and symptoms associated with the metabolic abnormalities of tumor lysis syndrome.[195]

BOX 48-17 PATIENT SAFETY

Signs and Symptoms of Tumor Lysis Syndrome

Hyperkalemia
- Peaked T waves on electrocardiogram (ECG)
- Dysrhythmias (tachycardia, ventricular ectopy/torsade de pointes [especially when potassium levels are >6.8 mEq/L])
- Muscle flaccidity, weakness
- Hyperactive bowel sounds, abdominal cramping, and diarrhea

Hyperphosphatemia
- Muscle weakness
- Bone marrow suppression (thrombocytopenia, leukopenia)
- Bone demineralization with tendency for pathological fractures
- Renal dysfunction

Hypocalcemia
- Muscle tetany
- Seizures
- Short PR and QT intervals on ECG
- Dysrhythmias (tachycardia, ventricular ectopy/torsade de pointes)
- Hyperactive bowel sounds, abdominal cramping, and diarrhea

Hyperuricemia
- Uric acid crystals in urine
- Hematuria
- Oliguria, anuria
- Flank pain
- Renal failure

Acidosis
- Tachypnea
- Hypotension

DIAGNOSTIC STUDIES. The electrolyte panel analysis is used to identify key abnormalities in patients at risk for tumor lysis syndrome. Elevated serum potassium, phosphate, uric acid, blood urea nitrogen, and creatinine, with low calcium, are reported. Acidosis may be present in patients with severely compromised renal function. The urinary uric acid/creatinine ratio is greater than 1. Renal ultrasonography is used to exclude ureteral obstruction.[199]

Management

Treatment involves recognition of high-risk patients and promoting prevention through aggressive hydration, as well as administration of phosphate-binding agents and allopurinol for at least 48 hours before beginning chemotherapy. It is necessary to avoid agents that block tubular reabsorption of uric acid (eg, aspirin, radiographic contrast, probenecid, thiazide diuretics). The goal is to keep the serum uric acid level within normal limits. Electrolyte disturbances are specifically treated as needed.[193,200]

IV fluids are given to ensure a urine volume of more than 3 L/d. In the past, IV sodium bicarbonate (4 g initially, then 1 to 2 g every 4 hours) has been administered to alkalinize the urine and reduce uric acid crystallization in the kidney tubules. Clinicians are now less likely to initiate alkalinization if the phosphate is high because calcium phosphate precipitation is equally likely to cause renal failure.[196,197,200] To measure urine output more accurately, insertion of a Foley catheter into the bladder is usually necessary. If oliguria or anuria develops, ureteral obstruction must be excluded. Phosphate-binding agents such as aluminum hydroxide are given every 2 to 4 hours in an effort to keep phosphate levels below 4 mg/dL.[195] Concomitant diuresis or medications such as Kayexalate that enhance gastrointestinal excretion of potassium may effectively manage elevated serum potassium levels not prevented with hydration. Allopurinol, a xanthine oxidase inhibitor that blocks uric acid production, is administered in doses ranging from 300 to 900 mg/d. Because it is now available in an IV form given as 200 to 400 mg/m^2/d, rapid normalization of uric acid levels is an achievable objective.[195] Its greatest limitation is that it cannot assist in breakdown or clearance of already existing uric acid.[201] Rasburicase (Elitek), acts like the natural enzyme urate oxidase to oxidize uric acid to allantoin for excretion.[201,202] Rasburicase is used cautiously in patients at risk for glycoprotein deficiency (GPD) because of increased risk for hemolytic anemia. Severe hypersensitivity reactions have also been reported and warrant careful observation during infusion. The uric acid serum blood levels drawn on patients receiving rasburicase must be placed in an iced blood tube and transported to the laboratory on ice to ensure accurate levels.[200–203] If diuresis does not occur within a few hours after the initiation of treatment, renal replacement therapy is needed. An initial hemodialysis treatment usually reduces the patient's uric acid levels by 50%, but most patients then receive several additional days of CRRT until electrolyte abnormalities and hyperuricemia resolve.[43,193] A low-calcium dialysate is used to prevent calcium phosphate precipitation. If peritoneal dialysis is used, albumin is added to the dialysate to increase uric acid protein binding and removal.

The focus of nursing care is on careful monitoring of fluid therapy, intake and output, and electrolyte balance. The use of prophylactic allopurinol, aggressive hydration, and early intervention with CRRT has reduced the incidence and severity of tumor lysis syndrome.[195]

▲ Clinical Applicability Challenges

CASE STUDY

M.S. is a 62-year-old woman, with a 2-month history of intermittent dyspnea, occurring with increasing frequency and less provocation. She is currently presenting to the ED with acute exacerbation of symptoms and new onset of epigastric pain. Her medical history reveals past mild hypertension controlled by diet and exercise. She also has a history of light smoking of less than two packs of cigarettes per week for 15 years.

On presentation, the patient has visible respiratory distress. She is diaphoretic, has circumoral cyanosis, is using her accessory muscles to breathe, has better chest excursion on the left, and is sitting upright on the Gurney. Physical examination reveals:

Neurological assessment: M.S. is anxious but oriented to person, place, and time and has equal limb movement and sensation with some stiffness and aching of the right arm. She also reports epigastric pain rating 4 on a 1 to 10 scale (with 10 the greatest pain) radiating to the back.

Respiratory assessment: Labored respirations at 34/min, greatly diminished breath sounds throughout the right lung field, bilateral wheezes in upper lobes, egophony auscultated on the right side, and tracheal shift to the left. A small, approximately 2-cm mass is palpated in the right supraclavicular area.

Cardiovascular assessment: Muffled heart sounds, with point of maximal impulse shifted to the sixth intercostal space, lateral one third of the clavicular line. There is global edema of the upper extremities and neck and right-sided jugular vein distention. Pulse is 132 beats/min and irregular, and the blood pressure is 160/96 mm Hg in the right arm and 142/88 mm Hg in the left.

Gastrointestinal/genitourinary assessment: Abdomen is soft and nontender other than the epigastric distress. Patient reports moderate nausea and anorexia that has become more pronounced within the past week. Bowel sounds are diminished but active in all four quadrants. No urinary distress is reported and last urine output was 4 hours ago.

Chest x-ray shows a right mediastinal lung mass measuring approximately 4 × 4 cm with moderate pleural effusion, venous congestion, and enlarged cardiac silhouette.

Arterial blood gas values on 100% nonrebreather mask: pH 7.31, pCO_2 54, pO_2 56, and HCO_3 28.

M.S. is transferred to the ICU after peripheral IV insertion, verification of normal 12-lead electrocardiogram, initiation of the cardiac monitor showing atrial fibrillation at a rate between 120 and 134 beats/min, initiation of ipratropium bromide (Atrovent) bronchodilator therapy, and indwelling catheter after administration of furosemide (Lasix) 40 mg. She was also febrile at presentation and specimens for culture were obtained followed by administration of acetaminophen (Tylenol) and piperacillin–tazobactam (Zosyn).

Upon arrival in the ICU, the nurse confirms these findings and verifies that the only other laboratory abnormalities are white blood cell count 18,500, Hgb 11.0, Na 132, Cl 95, K 3.4, and Mg 0.9.

A chest computed tomography (CT) with contrast is ordered but delayed because the patient is unable to lie flat for the procedure. Electrolyte replacement of potassium and magnesium is initiated. The ICU nurse suggests insertion of a central line for blood drawing, and potential multiple medications, but physicians are reluctant at this time suspecting probable superior vena cava syndrome (SVCS).

Discussion of best management of the atrial fibrillation is debated. It is decided that the rhythm disturbance is likely acute in onset and anticoagulation is considered risky until more diagnostic tests are performed. After diuresis, electrolyte replacement, and antibiotics have been in place for 12 to 24 hours, they will reevaluate the patient unless her condition dramatically worsens. If her condition improves, the CT scan for assessment of SVCS, pleural effusions, possible pulmonary embolism, and tracheobronchial obstruction will be performed. If her condition does not improve, it is likely that endotracheal intubation with mechanical ventilation and sedation will be used for stabilization. An echocardiogram is ordered to assess the clinical impact of the pericardial effusion, and a bronchoscopy is planned for the following day to assess the degree of airway obstruction and accessibility for tissue biopsy diagnosis.

1. In a patient with a known large mediastinal tumor, several oncological emergencies may occur. Describe the emergent conditions M.S. is experiencing in the case study as well as the physiological basis of these emergencies.

2. Patients and families often are surprised by the sudden occurrence of an oncological emergency. Develop a teaching plan for M.S. and her family.

3. Explore the psychosocial challenges of treating a patient with newly diagnosed cancer presenting initially in the ICU.

4. M.S. requires additional evaluation for cytopathological diagnosis and even potential treatment. How can the nurse best assist in achieving the CT scan and potential emergent radiation or chemotherapy?

49 Common Hematological Disorders

Debby Greenlaw

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Describe the pathophysiology, assessment, and management of patients with disorders of red blood cells.
2. Discuss the pathophysiology, assessment, and management of patients with disorders of white blood cells.
3. Explain the pathophysiology, assessment, and management of patients with disorders of hemostasis.

Critically ill patients are at high risk for developing complications from a variety of hematological disorders. Anemia is common in the critical care unit; the causes are multifactorial and include preexisting disease, blood loss from multiple sources, and suppressed erythropoiesis. Critically ill patients are also highly susceptible to overwhelming infections from severe neutropenia as well as hemorrhagic complications secondary to severe thrombocytopenia and other clotting disorders.

This chapter presents an overview of the pathophysiology, assessment, and management of hematologic disorders in the critically ill patient. Red blood cell, white blood cell, platelet, and coagulation disorders are discussed.

▲ Disorders of Red Blood Cells

Polycythemia

Polycythemia Vera

Polycythemia vera is a myeloproliferative disorder of increased red blood cell (RBC) production resulting in a high hematocrit and an increased RBC mass. Increased RBC production causes decreased tissue oxygenation, increased blood viscosity, vascular insufficiency, and risk for thrombosis. As the disease progresses, some patients may develop bone marrow fibrosis, splenomegaly, and pancytopenia. Acute leukemia may develop in a small percentage of these patients.

Secondary Polycythemia

Secondary polycythemia is a disorder of increased RBC production that can develop as a normal response to chronic hypoxia. Conditions causing chronic hypoxia include living at high altitudes, cardiopulmonary disease, sleep apnea, obesity hypoventilation syndrome, and exposure to carbon monoxide. Secondary polycythemia may also result from an inappropriate increase in erythropoietin production as a result of renal disease or, in rare cases, hepatic disease.

Assessment

Arterial and venous thrombosis resulting from the blood's hyperviscosity is the major concern. The patient with polycythemia is at increased risk for thromboembolic events such as myocardial and cerebral infarction, deep venous thrombosis, and pulmonary embolism.

It is important to review the patient's medical history for cardiac or pulmonary disease. Also, any history of arterial or venous thrombosis is pertinent. Smoking history is relevant because cigarette smokers may have high carboxyhemoglobin levels. Patients with polycythemia often complain of itching after a hot shower or bath. Table 49-1 lists additional clinical findings in polycythemia vera.

Management

Serial phlebotomy is the first-line treatment for polycythemia vera. Generally 500 mL of blood is removed weekly until a hematocrit of less than 45% is achieved. Most patients managed by serial phlebotomy develop iron deficiency, which limits their ability to make RBCs and thus decreases the frequency of phlebotomy. The disadvantage of phlebotomy is that it stimulates bone marrow production, which leads to increased numbers of defective, sticky platelets. Antiplatelet aggregating agents, such as aspirin and dipyridamole, do not reduce thrombotic events and may increase the risk for bleeding.

Older patients with vascular disease are at high risk for thrombosis and require bone marrow suppression in addition to phlebotomy. Hydroxyurea is the medication of choice. Long-term therapy with bone marrow–suppressing agents has been associated with an increased risk for acute leukemia, so the potential benefits must be weighed against the anticipated duration of therapy. Measures to prevent thromboembolic complications, such as lower extremity compression

Table 49-1 Clinical Findings and Related Causes in Polycythemia Vera

Clinical Finding	Cause
Dizziness, headache	Increased blood viscosity
Thrombosis	Increased blood viscosity, thrombocytosis, platelet defects
Pruritus	Elevated blood levels of histamine and/or increased skin mast cells
Bleeding tendency	Increased red blood cell (RBC)/fibrin ratio; engorged capillaries and venules due to increased blood volume
Epigastric distress	Engorgement of gastric mucosa; increased blood histamine levels
Numbness and burning of toes	Peripheral vascular insufficiency
Cardiovascular insufficiency	Impaired tissue oxygenation due to increased blood viscosity

devices or facilitating ambulation if the patient's condition permits, should be instituted.

Treatment of secondary polycythemia focuses on correcting the underlying cause with long-term oxygen therapy, smoking cessation, weight loss, or surgical intervention as indicated. If these measures are ineffective, serial phlebotomy to maintain a hematocrit of 45% or less is required.

Anemia

Anemia may be seen in the intensive care unit (ICU) as an incidental condition in a patient admitted to the unit for another acute illness or as an acute condition requiring intensive monitoring and intervention. Typically, anemias are classified as blood loss, hemolytic (increased destruction of RBCs) or hypoproliferative (decreased production of RBCs). In addition, anemias can be classified by RBC size as microcytic, normocytic, or macrocytic.

Anemia is prevalent in critically ill patients. Acute blood loss, especially from intraoperative and gastrointestinal hemorrhage, is a frequent cause of anemia in critically ill patients. Phlebotomy for diagnostic tests has also been implicated as a cause for anemia cases in the ICU. It is estimated that for every 100 mL of blood drawn, there is an associated decrease in hemoglobin of 0.7 g/dL and in hematocrit of 1.9%. Even with a conservative measurement of blood loss of 100 mL/d from phlebotomy, the impact is significant, especially in the patient who is hospitalized for several weeks in the ICU.

In addition to blood loss, disseminated intravascular coagulation (DIC) and a variety of hemolytic disorders can decrease the survival of RBCs, causing anemia in the critically ill. Nutritional deficiencies, inflammation, and sepsis all contribute to anemia as well.

Types of Anemia

The following discussion gives a brief review of the different types of anemia. Because the workup and treatment of many of these anemias does not take place in the critical care setting, the discussion is limited. The main focus of the material presented is specific to anemia in the critically ill.

BLOOD LOSS ANEMIA. Blood loss anemia is probably the most common anemia requiring admission of the patient to the ICU. Blood loss should always be ruled out in any acute anemia. The primary focus of patient management is to identify and treat the underlying source of blood loss.

Stress gastritis can be the source of significant blood loss. This complication is easier to prevent than it is to treat. All critically ill patients should be considered at risk, and prophylactic therapy with H_2-blockers, proton pump inhibitors, or sucralfate should be initiated. Endoscopy may be performed to evaluate for a potential gastrointestinal source of blood loss.

HEMOLYTIC ANEMIAS. Hemolytic anemias result from the destruction of RBCs. They may be congenital or acquired and can vary greatly in the severity of the anemia.

Congenital Hemolytic Anemia. The most common types of congenital hemolytic anemias are caused by enzyme defects or RBC membrane defects (Table 49-2). Most congenital RBC enzymatic deficiencies are glucose-6-phosphate

Table 49-2 Congenital Hemolytic Anemias and Primary Interventions

Type of Defect	Primary Interventions
Enzyme Defects	
Glucose-6-phosphate dehydrogenase	Avoidance of agents that trigger hemolysis; hydration
Pyruvate kinase deficiency	Transfusion; splenectomy
Red Blood Cell Membrane Defects	
Hereditary spherocytosis	Splenectomy; folic acid supplements
Hereditary elliptocytosis	Usually no treatment required; folic acid supplements
Paroxysmal nocturnal hemoglobinuria	Corticosteroids, androgens, recombinant erythropoietin (rEPO), iron therapy; transfusion as needed; anticoagulation therapy if thrombotic events; possible bone marrow transplantation

BOX 49-1 Substances That May Cause Hemolytic Anemia in Susceptible Individuals

Congenital Hemolytic Anemia (glucose-6-phosphate dehydrogenase [G6PD] Deficiency)

- Norfloxacin
- Methylene blue
- Chloramphenicol
- Phenazopyridine

- Cephalosporins

dehydrogenase (G6PD) and pyruvate kinase deficiencies. Enzyme defects cause the RBCs to lyse when exposed to certain stressful conditions, such as drugs, chemicals, infections, surgery, or pregnancy. Substances to which people with G6PD deficiency may be susceptible are listed in Box 49-1.

Acquired Hemolytic Anemia. Acquired hemolytic anemias can be caused by several different factors (Table 49-3). In microangiopathic hemolytic anemia, RBCs are fragmented by vasculitis, collagen vascular disease, abnormal cardiac valves, arteriovenous (AV) malformations, thrombotic thrombocytopenic purpura (TTP), or DIC. Patients who experience hypothermia or cold cardioplegia with cardiac surgery may have RBCs with shortened life spans owing to membrane damage. Patients with RBCs recovered from the "cell saver" also experience significant membrane damage and hemolysis. Treatment focuses on removing the causative factor, such as replacing the abnormal heart valve or repairing the AV shunt. If this is not possible, the patient may be maintained on iron and folate supplements and periodic transfusions of RBCs.

Infectious agents may cause hemolytic anemia indirectly by causing splenomegaly or directly by invading the RBC and destroying its membrane. Malaria is an example of the latter. These patients are treated with transfusion support and anti-infective agents to address the underlying cause.

Abnormally shaped RBCs are frequently noticed in patients with liver disease. These patients may also have congestive splenomegaly, which causes sequestration and destruction of RBCs. In severe hemolysis, splenectomy and supportive RBC transfusions may be required.

Some patients can experience autoimmune hemolytic anemias. Warm autoimmune hemolytic anemia is the most common of these types. Approximately one half of all cases are idiopathic; known causative factors include collagen diseases, lymphoproliferative disorders, and drug reactions (see Box 49-1). Primary therapy is oral glucocorticoids to suppress the immune system. Additional treatments for patients who do not respond to glucocorticoids may include splenectomy, immunosuppressive agents, and intravenous immunoglobulin (IVIG).

Cold-reactive autoimmune hemolytic anemia is a disorder in which exposure to cold triggers complement-fixing immunoglobulin M antibodies to attach to RBCs in susceptible people, causing agglutination (clumping) and hemolysis (destruction). Often, these patients have an underlying lymphoproliferative disorder; others may have *Mycoplasma pneumoniae* infection, infectious mononucleosis, or hepatitis. If these patients require blood transfusion, use of a blood warmer and measures to keep the patient warm are recommended. Steroids and splenectomy are ineffective; intervention focuses on avoiding exposure to cold.

DEFICIENCY ANEMIAS. Deficiency anemias include iron deficiency anemia, megaloblastic anemia, anemia of chronic disease, and aplastic anemia. Table 49-4 lists common interventions for these anemias.

Table 49-3 Acquired Hemolytic Anemias and Potential Interventions

Acquired Hemolytic Anemia	Interventions
Microangiopathic	Removal of causative factor; iron and folate supplements; transfusion
Infectious agents	Treatment of underlying infection; transfusion
Liver disease	Splenectomy; transfusion
Autoimmune	
Warm antibody	Glucocorticoids; splenectomy; immunosuppressive agents; transfusion
Cold-reactive	Avoidance of exposure to cold; transfusion; plasma exchange
Drug-induced	Discontinuation of drug; transfusion

Table 49-4 Common Deficiency Anemias and Primary Interventions

Type of Anemia	Primary Interventions
Iron deficiency anemia	Iron supplements; correction of underlying stressor
Megaloblastic anemia	Vitamin B_{12} replacement; folic acid supplement
Anemia of chronic	Transfusion; rEPO; correction of underlying disorder
Aplastic anemia	Transfusion; immunosuppression; bone marrow transplantation

BOX 49-2 Drugs That Interfere With Folate Metabolism

- Alcohol
- Cholestyramine
- Metformin
- Phenobarbitol
- Phenytoin
- Pyrimethamine

Iron Deficiency Anemia. Iron deficiency is the most common cause of anemia in adults. It is usually caused by chronic blood loss, but it may be due to inadequate iron intake or absorption. It is imperative in chronic blood loss to search for the underlying cause and correct it. Oral iron replacement theory is typically administered. In patients with malabsorption disorders or poor tolerance of oral iron, however, parenteral iron may be considered.

Megaloblastic Anemias. Megaloblastic anemias are a group of anemias, most of which are caused by a deficiency of vitamin B_{12} (cobalamin), folate, or both. Drugs that interfere with folate metabolism are listed in Box 49-2. Treatment entails correcting the deficiency.

Vitamin B_{12} is poorly absorbed from the gut; therefore, intramuscular or subcutaneous injection is required. Most patients require maintenance injections monthly for the remainder of their lives. Body stores of folate can be restored with an oral folate supplement given daily for approximately 4 weeks. Once the deficiency is corrected, maintenance therapy is rarely necessary unless underlying factors, such as chronic alcoholism, are present.

Anemia of Chronic Disease. Finally, anemia is seen with a number of chronic disorders, such as renal failure, infections, malignancies, and connective tissue diseases including rheumatoid arthritis. Anemia of chronic renal failure generally starts to occur when the creatinine clearance is less than 45 mL/min and continues to worsen with increasing renal failure. Several mechanisms cause anemia of chronic disease. One factor is suppression of RBC production. Other factors are a decreased RBC survival time and low serum erythropoietin levels. Aspects of anemia in older patients are presented in Box 49-3. Treatment involves correcting the underlying cause, if possible. Transfusion may be of temporary benefit, although the survival of the transfused RBCs is reduced. Recombinant erythropoietin (rEPO) may be the treatment of choice for many people. rEPO is typically given as 50 to 100 units/kg intravenously or subcutaneously three times a week, with adjustments based on response. Complications of rEPO therapy are infrequent and are seen mostly in patients on renal dialysis. They may include hypertension, seizures, AV shunt thromboses, and increased blood viscosity.

Aplastic Anemia. In aplastic anemia, there is deficiency of RBCs as well as white blood cells (WBCs) and platelets (in other words, aplastic anemia is a condition of pancytopenia). In many cases, the cause of aplastic anemia is unknown. Possible factors include drugs, chemicals, viruses, and immunological and congenital disorders (Box 49-4). In some patients, aplastic anemia is thought to result from replacement of normal cells by clones of cells that are incapable of normal hematopoiesis. Clinical features of aplastic anemia are related to the underlying pancytopenia and include anemia, infections, and bleeding.

Severe aplastic anemia is treated with transfusion support, immunosuppressive agents, and bone marrow transplantation. Drugs that stimulate bone marrow function are of no benefit in this condition. Bone marrow transplantation, preferably from a human leukocyte antigen–matched sibling donor, should be considered for patients younger than age 60. These patients should be considered for immediate transplantation and should not receive any transfusions or drug therapy before transplantation, if possible. Immunosuppressive therapy with antithymocyte globulin, cyclosporine, or methylprednisolone

BOX 49-3 CONSIDERATIONS FOR THE OLDER PATIENT

Anemia

Anemia is common in the elderly, and its prevalence increases with age. As with other cells, the body's capacity for red cell replacement decreases with aging, typically with a greater decline seen in men than women. Although most elderly people are able to maintain their hemoglobin and hematocrit levels within a normal range, they are unable to replace their red cells as promptly in situations such as bleeding.

In the elderly, anemia is usually the result of bleeding, infection, malignancy, or chronic disease. Combined deficiencies are common in older adults. Undiagnosed and untreated anemia is associated with decreased functional and self-care abilities and depression. It can also cause neurologic and cognitive disorders, cardiovascular complications, and increased risk for mortality. Orally administered iron is poorly used in older adults.

BOX 49-4 Causative Factors in Aplastic Anemia

Congenital (20% of Cases)
- Fanconi's anemia
- Familial aplastic anemia

Acquired (80% of Cases)
- Idiopathic
- Irradiation
- Drugs
  - Chloramphenicol
  - Carbamazepine
  - Sulfonamides
  - Cimetidine
  - Gold salts
  - Acetazolamide

  - Mycobacteria
- Immunological
  - Graft-versus-host disease
  - Systemic lupus erythematosus
- Pregnancy

may be of benefit for older patients or those without a compatible donor for bone marrow transplantation.

Assessment

The history of the patient with anemia includes assessment of blood loss (including perioperatively, in the stool, and from the menses) as well as a thorough diet history. General symptoms of anemia include weakness, depressed mood, impaired cognitive function, and easy fatigability. Signs and symptoms indicative of decreased perfusion secondary to anemia are tachycardia, chest pain, dyspnea, and dizziness. Clinical consequences of anemia are impaired tissue oxygenation, impaired organ function, impaired susceptibility to thrombocytopenic bleeding, increased risk for postoperative mortality, increased probability of transfusion, and decreased survival.[1] Anemia in critically ill patients is similar in clinical presentation to the anemia of chronic disease, both of which lead to underproduction of RBCs.

Physical examination findings of anemia include pallor, tachycardia, hypotension, and signs of high-output heart failure. Patients with hemolytic anemia may have splenomegaly, jaundice, and dark urine owing to the excretion of bilirubin. It is necessary to review the intake and output records for fluid balance because hemodilution is common, particularly in the postoperative patient, because of aggressive intravenous hydration. All patients should have a stool guaiac test performed to look for occult gastrointestinal blood loss.

Typically, critically ill patients have low serum iron and total iron-binding capacity with elevated serum ferritin. When the iron studies are abnormal, serum erythropoietin levels are only mildly elevated, with little evidence of a reticulocyte response to endogenous erythropoietin. Further laboratory assessment to evaluate anemia is discussed in Chapter 46.

Management

The treatment of anemia starts with identifying the underlying cause. Iron sulfate, 325 mg by mouth two to three times per day, may be indicated. Parenteral iron may be administered when the patient is unable to take oral medications, or in the case of malabsorption or severe renal failure. Intramuscular iron injection may be painful and stain the patient's skin. Instead, intravenous injection is recommended. Close patient observation is necessary because severe anaphylactic reactions may occur with this treatment (Box 49-5). Vitamin C is often given to aid in the absorption of iron. Folic acid and vitamin B_{12}, if needed, should be considered.

BOX 49-5 PATIENT SAFETY

Parenteral Administration of Iron Dextran

- Anaphylactic reactions, including fatalities, have followed the parenteral administration of iron dextran injection.
- Have resuscitation equipment and personnel trained in the detection and treatment of anaphylactic reactions readily available.
- Administer a test dose prior to the first therapeutic dose.
- Use only in patients in an iron deficient state not amenable to oral iron therapy.

From FDA Warning/Alert, October 16, 2009, Iron dextran injection –938, 2008.

BLOOD TRANSFUSION. The risk versus benefit of blood transfusion in the critically ill patient continues to be an area of scrutiny and study. In the past, hemoglobin transfusion triggers varied between 7 and 10 g/dL, most often between 8 and 9 g/dL. However, this practice is changing because of a number of factors associated with worse clinical outcomes occurring in patients receiving blood transfusions.

Therapeutic Considerations. Currently, it is believed that transfusion of packed RBCs should be reserved for management of severe, active bleeding or for the patient who is experiencing serious symptoms from anemia. In other words, the practice should be to transfuse when the risks of decreased oxygen-carrying capacity outweigh the risks of transfusion, rather than relying on a specific hemoglobin or hematocrit trigger. Evidence-based guidelines have been developed to guide transfusion decisions in specific critical care populations, such as patients with sepsis, acute lung injury, and neurologic injury and diseases.[1]

The normal compensatory mechanisms in response to the decreased oxygen supply of anemia (increased heart rate, increased cardiac output and index, decreased systemic vascular resistance) may not work efficiently or at all in critically ill patients. This deficit in compensatory mechanisms is particularly relevant in patients with cardiac disease and in those at high risk for myocardial infarction. For example, a patient with coronary stenosis may not have the normal response of vasodilation as a compensatory mechanism to the anemia. Likewise, increased cardiac output may not be achievable in patients with cardiomyopathy or pulmonary edema. Other patients who may have a poor prognosis if they do not receive a transfusion include those with sepsis and higher APACHE II (disease severity) scores.

Complications. Complications of blood transfusion may be noninfectious, infectious, or immunologic. A common noninfectious complication of transfusion is volume overload, particularly in the patient with pulmonary edema or cardiomyopathy. Patients can have a transfusion-related acute lung injury resembling acute respiratory distress syndrome (ARDS) with dyspnea, hypoxia, and noncardiogenic pulmonary edema. Febrile reactions are associated with white cell antigens present in units of packed RBCs. Unfortunately, preventable fatal hemolytic reactions result from transfusion of ABO-incompatible blood.

Viral screening of blood products and careful selection of donors have certainly decreased the risk for transfusion transmission of viruses, such as human immunodeficiency virus (HIV) and hepatitis C. However, there is still a risk posed by donors who donate during the infectious period before seroconversion occurs. In addition to viral contaminants that can be tested, blood screening methods do not exclude other infectious agents, such as hepatitis A virus, human parvovirus B19, cytomegalovirus (CMV), malaria, and disease-causing bacteria.

Multiple published studies report an increased risk for infection and an increased mortality rate associated with transfusions. Exposure to the donor's leukocytes in transfusion may trigger an immune system response. Potential adverse outcomes include exacerbation of infections, earlier

recurrence of malignancy, impaired wound healing and other postoperative complications, and increased likelihood of mortality.

To avoid some of these complications, consideration may be given to leukoreduced blood transfusion for critically ill patients. Leukoreduction is the process of removing WBCs from the blood product by filtration. Leukoreduced blood is less likely to cause antibodies to develop against specific blood types and less likely to cause febrile transfusion reactions. Also, leukoreduced blood greatly reduces the chance of CMV transmission.

ERYTHROPOIETIC-STIMULATING PROTEINS. Administration of erythropoietic-stimulating proteins, such as epoetin and darbepoetin, may be a safer method of increasing hemoglobin and reducing the need for transfusion in many patients. Contraindications include uncontrolled hypertension and hypersensitivity to albumin. The optimal effective dose and timing of administering erythropoietic-stimulating proteins in critically ill patients have not yet been determined, and this is a topic of ongoing clinical trials.

Nursing Care of the Patient With Anemia

Nursing interventions in all anemias support treatment protocols and measures to identify the underlying cause. Other important actions include assessing for adverse effects of replacement therapy and for signs and symptoms indicative of decreased perfusion. If transfusion therapy is prescribed, vigilance in identifying the correct patient and ensuring ABO compatibility is of utmost importance to prevent adverse and potentially fatal outcomes. In addition, measures to decrease metabolic needs and reduce oxygen demand should be instituted, including promotion of a restful environment, adequate pain control, and minimization of agitation. Supplemental oxygen may be needed to assist in maintaining adequate oxygen supply to the tissues.

Critical care nurses are in an ideal position to identify when phlebotomy appears excessive or unnecessary and to question the clinical justification for testing. Strategies to reduce phlebotomy blood loss should be instituted. These include eliminating standing orders for laboratory tests, organizing blood draws to eliminate duplicate testing, consolidating multiple collections, using smaller collection tubes, and using devices that return waste blood to the patient. The frequency of arterial blood gas collection can often be decreased by using noninvasive monitoring techniques, such as pulse oximetry and capnography.

Sickle Cell Disease

Pathophysiology

Sickle cell disease (SCD) is a chronic hereditary hemolytic anemia that occurs almost exclusively in blacks; however, a variety of other ethnic groups can be affected. The sickle cell gene results in abnormal hemoglobin, usually hemoglobin S (HbS). When oxygen and pH levels fall, HbS RBCs become elongated, sickle or crescent shaped, and rigid. These sickled cells are unable to pass through small blood vessels, causing inflammation, obstruction of the vessels, and decreased delivery of oxygen that perpetuates the cycle with more sickling. The cells are hemolyzed or destroyed when the body recognizes their abnormal structure.

Clinical Presentation

The most common clinical picture in SCD is painful vaso-occlusive crisis. The crisis begins suddenly, sometimes as a consequence of infection or a change in temperature or for no identifiable reason. Severe deep pain is present in the long bones of the extremities. Sometimes, the abdomen is affected by severe pain resembling an acute abdomen. The pain may be accompanied by fever, malaise, and leukocytosis.

SCD also results in organ damage with microinfarctions of the heart, skeleton, spleen, and central nervous system (CNS). Repeated splenic infarctions result in splenic failure, predisposing the patient to overwhelming infection, especially Gram-negative sepsis. Other manifestations of SCD that may be seen in the critical care patient are stroke, cardiac chamber enlargement, pulmonary hypertension, renal failure, and chronic leg ulcers.

Acute chest syndrome is caused by pulmonary infarction from fat embolism; bacterial infections likely contribute to its development as well. Symptoms include chest pain, fever, tachypnea, leukocytosis, and pulmonary infiltrates. Acute chest syndrome is a medical emergency, and if not treated properly, complications, such as ARDS, may develop.

Management

Treatment of sickle cell crisis includes aggressive intravenous fluid hydration to decrease blood viscosity and maintain renal perfusion. The patient must be evaluated for infection, and if this is suspected, prompt treatment with broad-spectrum antibiotics is instituted until the causative organism is identified, and the therapy can be tailored to the patient's needs. Oxygen administration may be needed to maintain adequate tissue perfusion. RBC transfusions are not usually required. Patients with SCD take folic acid supplementation and may take hydroxyurea, which helps prevent sickling (see Evidence-Based Practice Highlight 49-1). Although activity is usually not restricted, the patient may not be able to tolerate exercise because of pain.

The pain experienced by patients in sickle cell crisis is intense. Patients require around-the-clock dosing with a strong narcotic, such as intravenous morphine. Frequent, lower doses of narcotics avoid the erratic levels of analgesia caused by infrequent doses of stronger narcotics. Time-release narcotics and patient-controlled analgesia are two methods

EVIDENCE-BASED PRACTICE HIGHLIGHT 49-1

Treatment of Sickle Cell Disease

Hydroxyurea is an important advance in the treatment of sickle cell disease. Strong evidence supports its use. It decreases severe painful episodes, hospitalizations, number of blood transfusions, and the acute chest syndrome, particularly in adults.

From Brawley OW, Cornelius LJ, Edwards LR, et al: National Institutes of Health consensus development conference statement: hydroxyurea treatment for sickle cell disease. Ann Intern Med 148(12):932–938, 2008.

of delivering steady doses of pain medication. Patients with sickle cell crisis may not display overt signs of pain, as is typical for patients who experience chronic pain. The patient's report of pain, as well as clinical indicators, should be used in assessing pain.

Nursing care of the patient with sickle cell crisis includes close monitoring for response to interventions to promote tissue perfusion, treat infection, and effectively manage pain. A multidisciplinary approach may include input from pain management experts, social workers, psychiatrists, physical and occupational therapists, and infectious disease specialists.

▲ Disorders of White Blood Cells

Leukopenia

Leukopenia refers to an abnormally low number of WBCs. The most common type of WBC deficiency is neutropenia, defined as a neutrophil count of less than 1,500 cells/mm^3. Severe neutropenia, in which the neutrophil count is less than 200 cells/mm^3, is referred to as agranulocytosis. Neutropenia can be seen as a result of a wide variety of conditions (Table 49-5). The most common cause of leukopenia is drug related.

Clinical Presentation

Because the neutrophil is essential to defense against bacterial and fungal infections, patients with neutropenia are susceptible to overwhelming infection and life-threatening sepsis. The risk for infection is related to the severity of the neutropenia. Untreated infections can be rapidly fatal, particularly if the neutrophil count is less than 250/mm^3. In severe neutropenia, the usual signs of the inflammatory response to infection may be absent.

Neutrophils provide the first line of defense against organisms that inhabit the skin and gastrointestinal tract. Thus, skin infections and ulcerative lesions of the mouth are common infections in the neutropenic patient. The most frequent site of serious infection is the respiratory tract, a result of bacteria or fungi that frequently colonize the airways.

Assessment

The history should include presence of viral infection or autoimmune diseases, such as systemic lupus erythematosus or rheumatoid arthritis. A thorough medication history, including over-the-counter preparations, should be obtained. Patients with neutropenia may present with mouth ulcers, fever, shaking chills, and systemic infection. Physical examination may reveal splenomegaly.

The presence of abnormal RBCs or WBCs suggests a primary bone marrow process. Laboratory studies should include viral serology for hepatitis and HIV as well as antinuclear antibody (ANA). Bone marrow aspiration and biopsy may be needed if the neutropenia is severe or the cause is not apparent.

Management

Neutropenia is treated by removing or managing the underlying cause if known. If the patient is febrile, appropriate cultures and a chest radiograph should be obtained, followed by immediate broad-spectrum intravenous antibiotic therapy to prevent progression to septic shock and death. Signs and symptoms of infection without fever should also prompt administration of antibiotics in patients with neutropenia. If evidence of infection persists despite adequate antibiotic therapy, antifungal agents may be added to provide coverage for potential *Candida* or *Aspergillus* infections.

If the neutropenia is severe, treatment may include a hematopoietic growth factor (filgrastim, pegfilgrastim, or sargramostim) that stimulates bone marrow production of new neutrophils and enhances the activity of already circulating neutrophils. Additionally, patients with severe neutropenia or those with recurrent or serious infections may benefit from steroids. IVIG may improve the neutrophil count. Transfusions are used cautiously in patients who may require bone marrow transplantation.

Table 49-5 Causes of Neutropenia

Cause	Mechanism
Accelerated removal (eg, inflammation and infection)	Removal of neutrophils from the circulation exceeds production
Drug-induced granulocytopenia	
Cytotoxic drugs used in cancer therapy	Depressed bone marrow function with decreased production of all blood cells.
Phenothiazines, propylthiouracil, and others	Toxic effect on bone marrow precursors
Aminopyrine, certain sulfonamides, phenylbutazone, and others	Immune-mediated destruction
Periodic or cyclic neutropenia (occurs during infancy and later)	Unknown
Neoplasms involving bone marrow (eg, leukemias and lymphomas)	Overgrowth of neoplastic cells, which crowd out granulopoietic precursors
Idiopathic neutropenia that occurs in the absence of other disease or provoking influence	Autoimmune reaction
Felty's syndrome	Intrasplenic destruction of neutrophils

From Porth CM: Essentials of Pathophysiology, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2007, p 183.

Neoplastic Disorders

Neoplastic disorders refer to those disorders characterized by new and abnormal growth of cells that may be benign or malignant. The clinical features of neoplastic disorders are determined largely by their site of origin. Lymphoproliferative disorders (disorders in which lymphoid tissue increases by reproducing) may originate in the bone marrow or in the lymph nodes and thymus. Lymphoproliferative disorders of the bone marrow are leukemias and multiple myeloma; lymphoproliferative disorders of the lymph nodes and thymus are lymphomas. Because blood cells circulate throughout the body, these neoplasms are systemically disseminated from the onset.

Lymphoma

HODGKIN'S LYMPHOMA. Hodgkin's lymphoma is a cancer of the lymphatic system, beginning as a malignancy in a single lymph node and then spreading to surrounding lymph nodes. A diagnosis of Hodgkin's disease is confirmed by the presence of abnormal Reed-Sternberg cells in biopsied tissue.

NON-HODGKIN'S LYMPHOMA. Non-Hodgkin's lymphoma (NHL) is a diverse group of malignancies that originate in the lymphoid cells. NHL can occur as a discreet mass, such as a single lymph node, or as a widespread disease that affects multiple organ systems, including the bone marrow.

CLINICAL PRESENTATION. Symptoms of both types of lymphoma are related to the body area affected by the rapid growth of abnormal lymphoid cells. Constitutional symptoms include fever, fatigue, and weight loss. In the advanced stages, patients may have extensive chest disease and experience increasingly severe dyspnea. Bulky chest disease can cause superior vena cava syndrome. Abdominal disease can cause obstruction of the bowel or the ureters. Bone marrow involvement can lead to decreased production of RBCs, WBCs, and platelets. Extensive involvement of the lymphatic system can lead to impaired immune function and frequent, severe infections. Lymphoma of the CNS can cause headaches, visual disturbances, motor dysfunction, and increased intracranial pressure.

MANAGEMENT. The diagnosis, staging, and treatment of lymphomas are typically performed entirely on an outpatient basis. The care of a critically ill patient with lymphoma is usually for the management of complications that arise from the disease or its treatment. Oncological complications and their management are discussed in detail in Chapters 47 and 48.

Leukemia

The leukemias are hematologic malignancies that affect the bone marrow and the lymph tissues. They are characterized by proliferation of hematopoietic stem cells, resulting in the accumulation of abnormal (leukemic) cells in the bone marrow and a decreased production of normal blood cells. These abnormal leukemic cells circulate in the blood stream and infiltrate many body organs. Leukemias commonly are classified according to their predominant cell type (lymphoblastic or myelogenous) and whether the condition is acute or chronic. The chronic leukemias are not discussed in this chapter.

ACUTE LYMPHOBLASTIC LEUKEMIA. Acute lymphoblastic leukemia (ALL) is a disorder in which a clone of immature lymphocytes proliferates and replaces the normal cells of the bone marrow. The leukemic clones proliferate and infiltrate other normal tissues, such as the liver, spleen, and lymph nodes. Anemia, thrombocytopenia, and granulocytopenia are common. The spleen, liver, thymus, and lymph nodes are usually enlarged.

ACUTE MYELOGENOUS LEUKEMIA. A malignant disorder of hematopoietic stem cells, acute myelogenous leukemia (AML) causes abnormal production of the myeloid cell lines (erythrocyte, neutrophil, megakaryocyte, and macrophage). The malignant clones proliferate but do not differentiate into mature, functional cells. The blood, bone marrow, or both contain more than 30% immature blast cells. The proliferation of immature cells and bone marrow infiltration results in anemia, neutropenia, and thrombocytopenia. The patient's symptoms are related to these conditions. Splenomegaly is present in approximately one third of patients. Patients may require immediate interventions at the time of diagnosis for infections or anemia or to achieve hemostasis.

CLINICAL PRESENTATION. Although ALL and AML are distinct disorders, they typically present with similar clinical features. These manifestations and their pathologic basis are summarized in Table 49-6.

Patients with leukocyte counts greater than 100,000 cells/mm^3 are at risk for leukostasis, a condition in which the high number of blasts increase blood viscosity, develop leukoblastic emboli, and aggregate in the capillaries. Manifestations include headache, confusion, CNS infarctions, acute respiratory insufficiency, and pulmonary infiltrates.

MANAGEMENT. Leukostasis requires immediate treatment to lower the blast count rapidly. Initial treatment involves emergent leukapheresis (removal of WBCs from the circulation) along with hydroxyurea. Chemotherapy should be initiated to stop leukemic cell production in the bone marrow.

A comprehensive discussion of diagnosis and treatment of leukemia is beyond the scope of this text. As in the patient with lymphoma, the patient with leukemia will typically be seen in the critical care unit as a result of complications of the disorder or its treatment. Refer to discussions of anemia, granulocytopenia, and thrombocytopenia in this chapter, as well as Chapters 47 and 48, for coverage of bone marrow or stem cell transplantation and oncological emergencies.

Nursing Care of the Patient With a White Blood Cell Disorder

The goals of nursing care of the patient with a WBC disorder are vigilant assessment for and prevention of infection, delivery of therapy, and management of disease and treatment-associated complications. Nursing interventions are guided

Table 49-6 Clinical Manifestations of Acute Leukemia and Their Pathologic Basis*

Clinical Manifestations	Pathologic Basis
Bone marrow depression	
Malaise, easy fatigability	Anemia
Fever	Infection or increased metabolism by neoplastic cells
Bleeding	Decreased thrombocytes
Petechiae	
Ecchymosis	
Gingival bleeding	
Epistaxis	
Bone pain and tenderness upon palpation	Subperiosteal bone infiltration, bone marrow expansion, and bone resorption
Headache, nausea, vomiting, papilledema, cranial nerve palsies, seizures, coma	Leukemic infiltration of central nervous system
Abdominal discomfort	Generalized lymphadenopathy, hepatomegaly, splenomegaly due to leukemic cell infiltration
Increased vulnerability to infections	Immaturity of the white cells and ineffective immune function
Hematologic abnormalities	Physical and metabolic encroachment of leukemia cells on RBC and thrombocyte precursors
Anemia	
Thrombocytopenia	
Hyperuricemia and other metabolic disorders	Abnormal proliferation and metabolism of leukemic cells

*Manifestations vary with the type of leukemia.

From Porth CM: Essentials of Pathophysiology, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2007, p 189.

by the treatment modality (eg, chemotherapy, radiation, bone marrow transplantation).

Meticulous attention to infection control procedures and vigilant surveillance of invasive therapeutic lines and equipment are mainstays of care. Attention must be paid during daily oral care to ensure that superinfection with *Candida* or herpesvirus has not developed. Antibacterial mouthwashes decrease the risk for infection. Severe mucositis may require opiates for pain control. Assessment for early indications of infection (eg, fever, chills, tachycardia, and tachypnea) may allow for prompt and aggressive initiation of pharmacological therapies to reduce morbidity and mortality associated with infection in patients with WBC disorders.

Diarrhea may be a side effect of chemotherapy, neutropenia, or secondary causes. *Clostridium difficile* infection must be considered and treated if present. Digital rectal examinations should not be performed on neutropenic patients.

▲ Disorders of Hemostasis

The term hemostasis refers to the stoppage of blood flow.[2] The hemostatic system is a finely balanced network of coagulation factors and endothelial and platelet components. Hemostasis may be impaired by disruption of numerous interactions in the coagulation pathways or deficiencies or dysfunction in the required components for coagulation. Disorders of hemostasis include hypercoagulable states and bleeding disorders, whether from platelet defects (thrombocytopenia) or coagulation defects. Disorders of hemostasis are often seen in critically ill patients.

Platelet Disorders

Normally, approximately two thirds of platelets are circulating in the blood, and one third are sequestered or stored in the spleen. The life span of circulating platelets is 7 to 10 days. Thrombocytopenia occurs when there is decreased production or increased destruction of platelets or increased sequestration of platelets in the spleen. Common causes of thrombocytopenia are listed in Table 49-7. The most common causes seen in critical care patients are discussed here. A complete etiological discussion is beyond the scope of this chapter.

Table 49-7 Causes of Thrombocytopenia

Decreased Platelet Production	Splenic Sequestration of Platelets	Increased Destruction of Platelets
Marrow infiltration	Splenic enlargement	Nonimmune
Malignancy	Tumor infiltration	Vascular prostheses
Myelofibrosis	Infection	Disseminated intravascular coagulation (DIC)
Granulomatous disease	Splenic congestion	Sepsis
Marrow failure	Portal HTN or liver disease	Vasculitis
Medication		Thrombotic thrombocytopenic purpura (TTP)
Chemotherapy		Immune
Aplastic anemia		Autoantibody (idiopathic thrombocytopenic purpura)
Severe iron deficiency		Drug-associated*
Infection (HIV, Epstein-Barr virus, TB)		Circulating immune complexes (systemic lupus erythematosus, viral, bacterial sepsis)
Alcohol use		Posttransfusion ab (PLA1)
Nutritional deficiency		
Iron, folate, vitamin B_{12}		

*One of most common causes of thrombocytopenia.

From Kwoh C, Buch E, Quartarolo J: The Washington Manual General Internal Medicine Consult. Philadelphia, PA: Lippincott Williams & Wilkins, 2004, p 167.

Types of Thrombocytopenia

DRUG-INDUCED THROMBOCYTOPENIA. The most common cause of thrombocytopenia in hospitalized patients is drug induced. The confirmation of this diagnosis occurs when the thrombocytopenia resolves after withdrawal of the causal medication. Medications commonly associated with thrombocytopenia include antineoplastic agents, heparin, histamine$_2$-blockers, trimethoprim-sulfamethoxazole, rifampin, vancomycin, amiodarone, and valproic acid; however, this list is not complete.

HEPARIN-INDUCED THROMBOCYTOPENIA. After antineoplastic agents, heparin is the next most common drug associated with thrombocytopenia. Heparin-induced thrombocytopenia (HIT) is interesting in that thrombosis, rather than bleeding, may accompany the low platelet count. HIT places patients at risk for life-and limb-threatening consequences, including deep venous thrombosis, arterial occlusion, ischemic stroke, limb gangrene, myocardial infarction, and pulmonary embolism.

It is important to be aware that subcutaneous unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH) delivered at treatment or prophylaxis dosing, by arterial or venous line flushes, through heparin-coated catheters, and intermittent heparin administered during dialysis may lead to HIT. Although HIT typically occurs 4 to 14 days after initiation of heparin therapy, it can occur as early as 10 hours after administration if the patient has been exposed to heparin within the previous 100 days. For patients who are starting heparin therapy, whether UFH or LMWH, the recommendation is to obtain a baseline platelet count and then repeat a platelet count within 24 hours of starting heparin. Clinical guidelines also suggest platelet count monitoring at least every 2 or 3 days up to 14 days or until heparin therapy is stopped[3].

The hallmark of HIT is a decrease in platelet count to less than 50% of baseline or to fewer than 150,000/mm^3 or the occurrence of an unexplained thromboembolic event. Blood testing should be done for HIT antibodies.

For patients with confirmed or strongly suspected HIT, whether or not complicated by thrombosis, national guidelines recommend using a nonheparin anticoagulant (see Box 49-6).[3] Even if there is no clinical evidence of deep vein thrombosis, ultrasonography of the leg veins should be performed. Warfarin therapy should not be started until after the platelet count has substantially recovered, usually to at least 100,000/mm^3. Nonheparin anticoagulant should be continued until the platelet count has reached a stable plateau, the international normalized ratio (INR) has reached the intended target range, and after a minimum overlap of at least 5 days between nonheparin anticoagulation and warfarin therapy. Platelets are generally not transfused unless the patient is actively bleeding.

BOX 49-6 Nonheparin Anticoagulants

- lepirudin (renally adjust dose; APTT monitoring)
- argatroban (APTT monitoring)
- fondaparinux
- bivalirudin

THROMBOTIC THROMBOCYTOPENIC PURPURA. Thrombotic thrombocytopenic purpura (TTP) is an acute disorder with a mortality rate of 30% to 40%. Patients with TTP have absent or decreased levels of platelet-aggregating factor inhibitor, which is normally present in plasma. As a result, platelets become sensitized and clump in blood vessels, causing occlusion.

A presentation of five classic findings suggests TTP. Not every patient exhibits all five findings; however, the first two of the following conditions must be present for the diagnosis to be considered:

- Thrombocytopenia and bleeding from increased consumption of platelets
- Microangiopathic hemolytic anemia from rupture of RBCs as they try to pass through partially occluded blood vessels
- Fever, possibly from hemolysis or vascular infarction of the hypothalamus
- Neurologic abnormalities, including fluctuating and often bizarre neurological abnormalities, transient ischemic attacks, strokes, seizures, and coma from interrupted blood flow to the brain
- Renal dysfunction caused by obstruction of intraglomerular capillaries and infarction of the renal cortex

Clinical features of TTP are described further in Table 49-8. Initiation of the disease process may be related to endothelial damage, autoimmune disorders, viral and bacterial infections, toxic agents, and genetic predisposition.

IMMUNE THROMBOCYTOPENIC PURPURA. Immune thrombocytopenic purpura (ITP) is an immune-mediated disorder of platelet destruction. Historically, ITP stood for idiopathic thrombocytopenic purpura because the mechanism of thrombocytopenia was not understood. However, now the pathophysiology of the disease is clearer, and some have suggested that the name auto ITP might be more accurate.

There are two distinct forms of ITP. Acute ITP typically occurs in childhood and may resolve spontaneously in several

Table 49-8 Clinical Manifestations of Thrombotic Thrombocytopenic Purpura

Abnormality	Findings
Thrombocytopenia	Bleeding, ecchymosis, purpura at various sites
Hemolytic anemia	Schistocytes, reticulocytosis, elevated serum lactate dehydrogenase and bilirubin, jaundice, pallor, weakness
Neurological abnormalities	Headache, mental changes, confusion, visual problems, seizures, coma, aphasia, dysphasia, paresthesias
Renal dysfunction	Proteinuria, microscopic hematuria, elevated blood urea nitrogen (BUN) and creatinine, renal failure
Fever	Persistent elevation of temperature during acute phase
Other	Abdominal pain, malaise, nausea, vomiting, weakness, ECG changes

weeks. Autoimmune platelet destruction appears to be stimulated after a viral illness, even mild infections. Chronic ITP usually occurs in adults, more often in women than men. The platelet membrane is coated with an autoantibody (usually IgG), and the sensitized platelets are destroyed in the spleen and liver. Therefore, platelet survival in the circulation is decreased. In at least 50% of patients with ITP, no known causative agent is identified; other patients may have underlying autoimmune, rheumatic, or lymphoproliferative diseases or HIV infection. ITP is diagnosed when other disorders of platelet destruction are ruled out.

Assessment

The history, physical examination, and initial laboratory data help differentiate between the mechanisms of thrombocytopenia.

The patient history includes assessment of symptoms associated with any of the risk factors or associated disorders (see Table 49-8). A patient or family history of bleeding may help differentiate between acquired and congenital disorders. Critical to the assessment is an accurate medication and alcohol history. Fatigue, fever, weight loss, or night sweats may be associated with infection or malignancy. It is also important to note a history of platelet transfusion.

The physical examination includes a thorough examination of the skin for petechiae and bruising. It is important to also include the oropharynx in this examination as well as checking the stool for guaiac. Hypotension, tachycardia, and fever are suggestive of sepsis. A fever is also frequently present in TTP. An enlarged spleen suggests splenic sequestration of trapped blood from portal hypertension. In this setting, patients are likely to exhibit signs of liver disease, including jaundice, ascites, and extremity muscle wasting.

Laboratory examination is also significant. Signs and symptoms of low platelets vary depending on the platelet count. Platelet counts greater than 100,000/mm^3 should result in normal hemostasis. Platelet counts less than 50,000/mm^3 may lead to prolonged bleeding after procedures, easy bruising, and bleeding from the oral or gastrointestinal mucosa. Platelet counts less than 20,000/mm^3 are associated with an exponential increase in the risk for bleeding The nurse carefully assesses the patient for petechial rash or spontaneous bleeding such as epistaxis or bleeding gums. Platelet counts less than 10,000/mm^3 are associated with possible intracranial hemorrhage.

The complete blood count with differential is the most important first step to identifying the etiology of thrombocytopenia. It is important to check for accompanying anemia and leukopenia. If pancytopenia is present, bone marrow failure may be the cause of the problem. If this is suspected, a bone marrow biopsy may be performed. The presence of microcytosis or macrocytosis suggests vitamin deficiency. Severely decreased ferritin, folate, or vitamin B_{12} levels also support this as an etiology. The presence of schistocytes on the differential may indicate TTP or DIC.

It is important to rule out artifactual thrombocytopenia caused by clumping of the platelets in a test tube containing ethylenediamine tetraacetic acid (lavender top). A report of platelet clumping should raise this suspicion. If the platelets are clumped, the automatic counter may inaccurately measure the number of platelets resulting in a falsely low count. In this case, the sample should be redrawn in a citrate tube (blue top) or heparinized tube (green top).

Bleeding time is a test of platelet function. When the platelet count drops below 50,000/mm^3, the bleeding time is significantly prolonged and is not useful. The bleeding time is a helpful test when a patient has mucosal bleeding but a normal platelet count. Evaluating prothrombin time (PT), partial thromboplastin time (PTT), and fibrin degradation products (FDPs) may help identify DIC and distinguish a hemolytic anemia from TTP. Additional studies that may be ordered to assist in determining the underlying etiology include HIV and ANA screening as well as liver function tests.

Management

The initial step in management of thrombocytopenia is to review the patient's medication list, placing on hold any drugs that may be suspected to induce thrombocytopenia. In addition, medications that inhibit platelet function should be avoided, including aspirin, antiplatelet agents, and nonsteroidal antiinflammatory drugs. Avoidance of trauma is essential and may even preclude the placement of central venous catheters and other invasive procedures. Evaluation of continued blood loss and assessment of daily laboratory data for adequacy of the platelet count and other parameters of hemostasis are important measures.

Patients with mild to moderate thrombocytopenia without bleeding require no treatment. Platelet transfusions are indicated when the platelet count is below 20,000/mm^3 or in the case of spontaneous bleeding. A single donor unit of platelets is equivalent to six random donor platelets and should increase the platelet count by 30,000/mm^3. The patient must be monitored for allergic reactions, anaphylaxis, and volume overload.

In sequestration or destruction-mediated thrombocytopenia, the response to platelet transfusion is typically very poor. Transfused platelets are destroyed very quickly by the same mechanism that causes the disease. Platelet transfusion should be used only for major life-threatening bleeding. In these patients, because the platelets may not last long, platelets need to be administered shortly before performing any invasive procedures.

TTP is an emergency because of its extremely high mortality rate. Early recognition and prompt initiation of treatment are imperative to improve patient survival. Acutely ill patients require plasma exchange in which plasmapheresis is used to remove 2 to 3 L of the patient's plasma, with an equal amount of fresh plasma given as replacement. Plasmapheresis is initiated as quickly as possible and repeated daily until the platelet count is greater than 150,000/mm^3. This may take 5 to 10 days or more. Plasma exchange is superior to simple plasma infusion. However, because some patients do respond to simple plasma infusions, all patients should be infused immediately with fresh frozen plasma until plasma exchange can be arranged. Antiplatelet agents and prednisone may be used, although the effectiveness of these therapies is controversial. Platelet transfusion is contraindicated even in severe thrombocytopenia because the transfused platelets may aggregate, resulting in myocardial infarction, stroke, coma, or death. Patients with TTP may be "cured," may relapse years later or may have a chronic relapsing course.

Immunosuppression with corticosteroids is the initial therapy for ITP. Prednisone therapy usually takes a few days

before the count begins to rise. When the platelet count is critically low (5,000/mm^3 or less) or the patient shows signs of serious bleeding, prednisone alone may not raise the platelet count rapidly enough. When a rapid increase in the platelet count is needed, IVIG, in addition to steroids, is highly successful. A typical treatment regimen is IVIG at 1 g/kg/d and prednisone 1 mg/kg/d. Patients with chronic ITP who fail to respond to steroids or are steroid dependent may require splenectomy. These patients should receive pneumococcal, meningococcal, and *Haemophilus influenzae* type B vaccines.

Coagulation Disorders

Coagulation disorders can result from deficiencies or impairment of one or more of the clotting factors. These disorders of coagulation may be congenital or acquired. The most common congenital bleeding disorders are von Willebrand's disease and hemophilia A. These disorders are caused by a deficiency in a specific factor. Numerous complications can occur as a result of these bleeding disorders (Table 49-9).

Management involves correcting the coagulation factor deficiency and treating sequelae that occur as a result of abnormal bleeding. Patients with mild hemophilia A and mild von Willebrand's factor deficiency may respond to intravenous or nasal spray administration of desmopressin acetate, a hormone that temporarily stimulates the release of factor VIII to control bleeding. More severe cases of hemophilia A or active bleeding require intravenous infusion of factor VIII concentrate. More severe bleeding in von Willebrand's disease requires factor VIII concentrate that contains von Willebrand's factor. von Willebrand's factor is also found in cryoprecipitate, and factors VIII and IX are in fresh frozen plasma.

Disseminated Intravascular Coagulation

Pathophysiology

Disseminated intravascular coagulation (DIC) is defined as the inappropriate triggering of the coagulation cascade and a breakdown in the normal feedback mechanisms in the body that allow for the dissolution of clots. Instead of a localized response to tissue damage or vascular injury, there is systemic coagulation activity, resulting in diffuse intravascular fibrin formation and widespread intravascular clotting. Eventually, coagulation factors become depleted as the body attempts to dissolve the newly formed clots. Because of the rapidity of intravascular thrombin formation, clotting factors are used up at a rate exceeding factor replenishment. In essence, there is an imbalance between the natural procoagulant and anticoagulant systems in the body. The result is unregulated thrombin activity, microvasculature thrombi, platelet consumption, and microangiopathic hemolytic anemia.

Activation of coagulation mechanisms also activates the fibrinolytic system. The breakdown of fibrin and fibrinogen results in FDPs and d-dimers. These products interfere with platelet function and the formation of the fibrin clot. In addition, plasmin can activate the complement and kinin systems, leading to increased vascular permeability, hypotension, and shock. Thus, the patient has a simultaneous, self-perpetuating combination of diffuse clotting and simultaneous hemorrhage occurring in response to the precipitating event as well as the potential for hemodynamic instability (Fig. 49-1).

Table 49-9 Complications in Coagulation Disorders

Bleeding Site	Complication
Abdomen	Hypotension, hypovolemic shock
Muscle	Compartment syndrome
Joint	Hemarthrosis with destruction of bone and cartilage in joint capsule
Intracranial	Increased intracranial pressure
Retropharyngeal	Airway obstruction
Gastrointestinal	Anemia, melena
Urinary tract	Clots in ureters (especially after factor administration)

Etiology

DIC is a secondary complication that requires an underlying condition that serves as the initial triggering event for the inappropriate stimulation of clotting. This involves the activation of any of the coagulation pathways. The extrinsic pathway is activated by damage to the endothelial lining of blood vessels. Common causes include surgery, burns, heat stroke, bacterial endotoxin, and malignant tumors. The intrinsic pathway is activated when subendothelial tissue is exposed to the bloodstream and circulating factor XII comes in contact with the exposed tissue. The exposure may follow vascular injury or damage from immune complexes or bacterial endotoxins. The result is clot formation and activation of the coagulation cascade. Endotoxins released by Gram-negative bacteria and the resulting sepsis are significant triggers of DIC, accounting for approximately 20% of cases.

Shock or low-flow states can result in metabolic acidosis, tissue ischemia, and necrosis, which may also lead to clot formation. In cancer, a common etiology of DIC, the condition is caused by tumors eroding tissue with subsequent release of thromboplastin or stimulation of factor XII from vascular injury, as well as by the autolysis of tumor cells in rapidly proliferating tumors. In cancers that are able to autolyse (eg, acute leukemia, Burkitt's lymphoma, small cell lung cancer), the cell fragments that result from the lysis are seen as "foreign bodies" and stimulate clotting. Still other cancers release procoagulants that enhance clotting (eg, mucin-producing adenocarcinomas, prostate and renal cancer, promyelocytic leukemias, and brain tumors).[4] Box 49-7 outlines some malignant and nonmalignant states of physiological disequilibrium that can be precipitating factors for DIC.

Clinical Presentation

Clinical consequences include systemic ischemia from the thrombi formation as well as minor or major hemorrhage from ongoing fibrinolysis and depletion of clotting factors. A patient with DIC is vulnerable to a wide variety of complications resulting from the thrombotic or hemorrhagic disease processes. Thrombosis may result in ischemia or infarction in any organ, with concomitant loss of function. With depletion of clotting factors and platelets, bleeding into subcutaneous

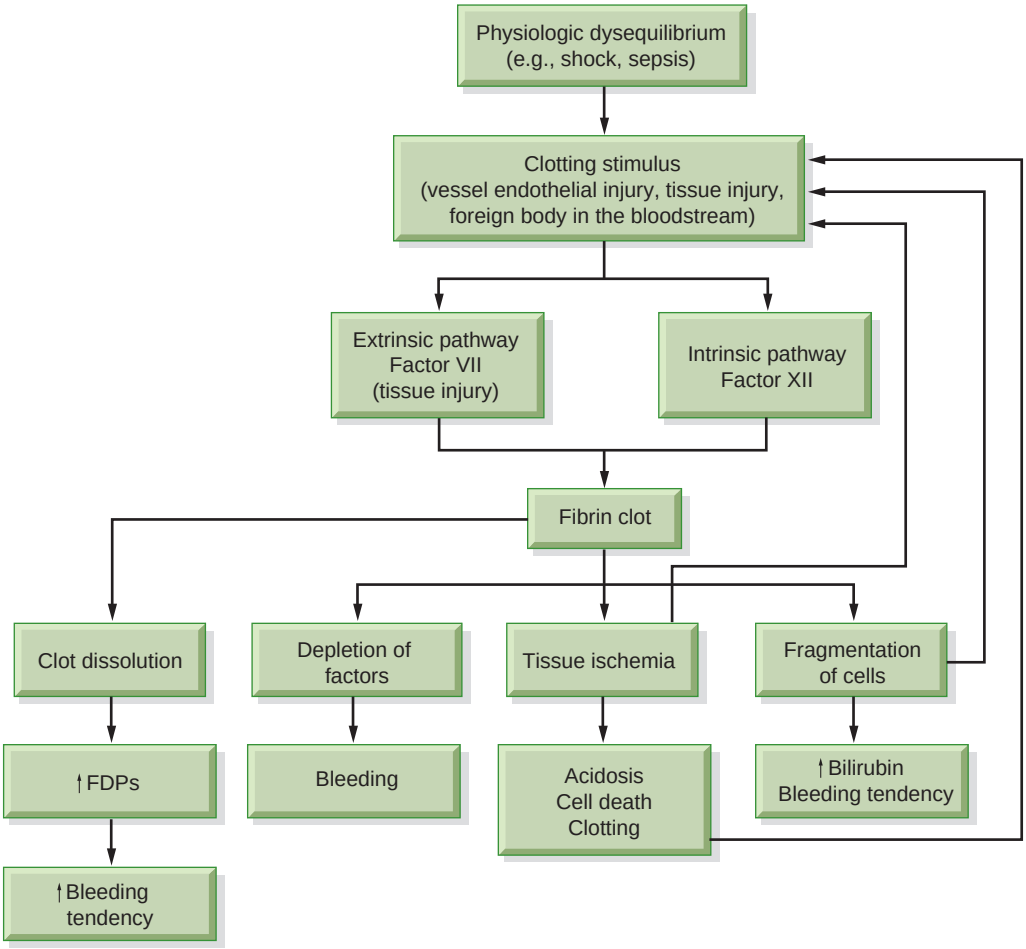

FIGURE 49-1 ▲ Self-perpetuating cycle of thrombosis and bleeding in disseminated intravascular coagulation (DIC).

tissues, skin, and mucous membranes, or more serious hemorrhage, may result.

Assessment

All critically ill patients are at risk for developing DIC because many are in the state of physiological disequilibrium characterized by hypovolemia, hypotension, hypoxia, and acidosis, all of which have procoagulant effects. In addition, the patient's critical illness may have been triggered by an injury that itself could result in the development of DIC. Increased awareness of DIC as a potentially catastrophic complication in the critically ill patient has resulted in earlier recognition and intervention. The critical care nurse who is armed with knowledge of physiological norms and who uses a systemic approach to assessment may be the first person to identify the early signs of coagulation dysfunction and its probable trigger.

BOX 49-7 Selected Disease States Associated With DIC

Nonmalignant

- Bacterial infections
- Viral infections (HIV, cytomegalovirus, hepatitis)
- Burns
- Heat stroke
- Brain injury
- Crush injuries and necrotic tissue
- Obstetrical complications (amniotic fluid embolism, missed abortion, eclampsia, retained dead fetus, abruptio placentae)
- Intravascular hemolysis (hemolytic transfusion reactions, massive blood replacement therapy)
- Acute liver disease
- Intravascular prosthetic devices
- Prolonged low-cardiac output states (cardiac failure, prolonged cardiopulmonary bypass, hemorrhagic shock, cardiopulmonary arrest)
- Vasculitis
- Immunological disorders (immune complex disorders, allograft reaction, incompatible blood transfusion)
- Surgery
- Other (snake venom, vascular malformations, fat embolism)

Malignant

- Leukemias
- Solid tumors (adenocarcinoma, lung cancer, breast cancer, hepatic cancer, colon cancer, prostate cancer, brain cancer)
- Chemoradiation therapy

HISTORY AND PHYSICAL EXAMINATION. DIC may be acute in presentation, evidenced by severe clinical deterioration, or chronic in presentation, evidenced by mildly abnormal laboratory values and minimal, varied clinical symptoms. In chronic DIC, thrombosis is the prevalent disorder, and the degree of symptomatology is related to the ability of the liver and bone marrow to compensate for the disorder. Affected patients may have low-grade bleeding if factors become depleted, unexpected thrombotic events (including large vessel thrombi), or both. Chronic DIC must be ruled out in patients with multiple thrombotic sites developing simultaneously, serial thromboses, superficial venous thromboses, or arterial thromboses, especially in the presence of malignancy.[4]

However, most critical care nurses care for patients with acute DIC. It is important to realize that the assessment varies as the disease state evolves. Clinical assessment is organized according to the basic pathological process of DIC: clot formation with resulting emboli and perfusion defects or unchecked clot dissolution with resultant bleeding. The nurse evaluates the patient for signs and symptoms of inappropriate clotting: cyanosis, gangrene, mental status changes, altered level of consciousness, cerebrovascular accident, pulmonary embolus, bowel ischemia and infarction, and renal insufficiency or failure. Thrombosis may involve both arteries and veins, and clinical examination may reveal demarcation cyanosis (total occlusion of microvessels, most common in digits but may be evident in earlobes). In addition, the nurse evaluates the patient for signs of bleeding: bleeding from the nose, gums, lungs, gastrointestinal tract, surgical sites, injection sites, and intravascular access sites; hematuria; petechial rashes; and purpura fulminans. Bleeding is a manifestation of later disease because it is evidence of depletion of clotting factors, bleeding diathesis, or both.

Care of the patient with possible DIC requires constant reassessment and interpretation of findings. For example, the patient with a dull headache is likely to have a thrombotic defect, whereas a sudden and acute headache is more likely to be hemorrhagic. Dyspnea can be from a thrombotic disorder (pulmonary embolism) or from a hemorrhagic disorder (bleeding in the lungs). Either condition may present with hemoptysis and blood with suctioning. Hypotension may result from myocardial infarction (a thrombotic disorder) or cardiac tamponade (a hemorrhagic disorder). Ischemic bowel is characterized by decreased bowel sounds and a crampy and painful abdomen, with potential gastrointestinal bleeding when the mucosal layer sloughs, whereas gastrointestinal bleeding presents with heme-positive to melanotic stool and hyperactive bowel sounds. Nurses must monitor patients with DIC closely for signs and symptoms of the onset of shock, either hypovolemic or ischemic in origin. When caring for patients at risk for DIC, constant assessment of all body systems and critical thinking are necessary.

LABORATORY STUDIES. Regardless of the inciting event, four basic diagnostic components of DIC can be appreciated: excessive rate of clot formation; increased rate of clot dissolution; consumption of essential clotting factors; and end-organ damage resulting from the excessive clotting process.

Table 49-10 outlines studies that are commonly used to assess DIC. These studies, unfortunately, are neither specific nor sensitive, and results vary throughout the course of the disease. For the average patient, thrombocytopenia occurs as platelets are consumed during the unchecked clotting, followed by hypofibrinogenemia. Normal fibrinogen levels do not preclude DIC because it is an acute-phase reactant. Serial measurements of platelet count, PT, PTT, and fibrinogen levels help gauge disease progression. Peripheral smears

Table 49-10 Laboratory Findings in Acute DIC

Test	Normal Value	Value in DIC
Massive Intravascular Clotting		
Platelet count	150,000–400,000/mm^3	Decreased
Fibrinogen level	200–400 mg/100 mL	Decreased
Thrombin time	7.0–12.0 s	Prolonged
Protein C level	4 mcg/mL	Decreased
Protein S level	23 mcg/mL	Decreased
Secondary Depletion of Essential Clotting Factors		
Prothrombin time	11–15 s	Prolonged
Activated partial thromboplastin time	30–40 s	Prolonged
International normalized ratio	1.0–1.2 times normal	Prolonged
Excessive/Accelerated Fibrinolysis		
Fibrin degradation products	<10 mg/mL	Increased
D-dimer assay	<50 mcg/dL	Increased
Antithrombin III level	89%–120%	Decreased
Clinical Effects of Microvascular Clotting/Cell Destruction		
Schistocytes on peripheral smear		Present
Bilirubin level	0.1–1.2 mg/dL	Increased
Blood urea nitrogen	8–20 mg/dL	Increased

may reveal the presence of schistocytes reflecting fragmentation of RBCs moving through clots or partially occluded vessels.

Management

The backbone of therapy for DIC is eliminating the causative agent. The culprit that activates the clotting factors must be eliminated, whether through antibiotic or antifungal therapy for sepsis, antineoplastic therapy, rehydration, increasing oxygenation, or resolution of low-flow states. Unfortunately, some causes (such as burns, crush injury, and brain injury) cannot be as easily eliminated. General treatment principles include avoiding vasoconstriction that may worsen perfusion defects, maintaining adequate fluid volume status, and screening for and eliminating all medications that may enhance bleeding. Attention is also directed to correcting hypotension, hypoxia, and acidosis, all of which have procoagulant effects (Box 49-8).

Patients *at risk for* DIC as a result of sepsis may be given activated protein C (drotrecogin alfa [activated], marketed as Xigris) to slow the development of uncontrolled clotting that may result from the septic process. There are stringent criteria for using activated protein C. The argument for use is that with aggressive treatment of the causative agent (sepsis), it may be possible to decrease the rate of clot formation, slow the clotting cascade, and reclaim the balance between clotting and fibrinolysis. This agent has not been investigated, however, for its potential benefit in patients with confirmed DIC.

Heparin therapy may be initiated to minimize further clotting by increasing neutralization of thrombin. However, the risk for increased bleeding is always a major concern. In acute DIC, few clinical studies have shown heparin's effectiveness in slowing the coagulation cascade.

Replacement therapy and repletion of clotting factors are the focus of the treatment for significant hemorrhage. Fresh frozen plasma contains components of both the coagulation

BOX 49–8 *COLLABORATIVE CARE GUIDE for the Patient With DIC*

Outcomes	Interventions
Oxygenation/Ventilation	
Arterial blood gases are within normal limits.	• Monitor pulse oximetry and/or arterial blood gases. • Transfuse as necessary to increase oxygen carrying capacity. • Maintain oxygen delivery whether noninvasive or mechanical ventilation.
Breath sounds are clear bilaterally.	• Suction oropharynx and trachea carefully when necessary (see Chapter 25, Box 25-7, p. 516) • Turn, cough, deep-breathe, and use incentive spirometer every 2 h.
Circulation/Perfusion	
Patient will achieve/maintain tissue perfusion.	• Monitor tissue perfusion: color, temperature, pulses, level of consciousness, urinary output, and SaO_2/PaO_2. • Monitor vital signs every 1–4 h based on clinical condition. • Monitor cardiac output, systemic vascular resistance, and pulmonary artery pressure every 4 h if pulmonary artery catheter in place. • Administer blood products, positive inotropic agents, intravenous (IV) infusions as ordered.
Hematological	
Patient will not experience bleeding related to coagulopathies.	• Monitor PT, PTT, and complete blood count daily; more frequently if monitoring for acute changes or response to therapy. • Assess every 2–4 h for thrombotic and hemorrhagic manifestations. • Quantify degree of bleeding (count dressing changes, measure bodily drainage; test stool, urine, and emesis for heme). • Assess organ systems for signs and symptoms: change in mental status with cerebral hemorrhage or thrombotic event; decreased SaO_2 and hemoptysis with pulmonary bleeding; visual changes (diplopia, blurred vision, visual field deficit) with retinal thrombosis/hemorrhage; back pain, flank pain, abdominal pain consistent with visceral organ bleeding. • Administer blood products and coagulation factors as indicated. • Maintain strict adherence to bleeding precautions. • Minimize invasive procedures and treatments • Avoid medications that inhibit coagulation or promote thrombosis.
Fluids/Electrolytes	
Patient is euvolemic.	• Trend daily weight. • Monitor intake and output; replace/diurese as required. • Maintain IV access and fluid replacement therapy.
Mineral and electrolyte levels are within normal limits.	• Monitor and replace electrolytes daily and PRN.

(*continued on page 1148*)

BOX 49–8 COLLABORATIVE CARE GUIDE for the Patient With DIC (continued)

Outcomes	Interventions
Mobility/Safety	
There is no evidence of bleeding due to preventable injury.	• Institute bleeding precautions (soft toothbrush, electric razor, no rectal temperatures). • Provide safe physical environment. • Apply pressure to puncture sites for 3–5 min, and then use pressure dressing.
Skin Integrity	
Skin will remain intact.	• Turn patient every 2 h and assess skin each time patient is repositioned for pressure areas, petechiae, and ecchymosis. • Assess injection sites and incisions for bleeding. • Consider pressure relief/reduction mattress, avoid shearing forces. • Use Braden scale to assess risk for skin breakdown.
Nutrition	
Caloric and nutrient intake meets metabolic requirements per calculation (eg, basal energy expenditure).	• Provide parenteral feeding if patient is NPO. • Assess for gastrointestinal bleeding and report. • Consult dietitian or nutritional support service.
Comfort/Pain Control	
Patient will be as comfortable as possible as evidenced by stable vital signs or cooperation with treatments or procedures.	• Objectively assess comfort/pain using a pain scale. • Correlate pain ratings with sites of potential ischemia or hemorrhage. • Provide analgesia and sedation as indicated by assessment. • Monitor patient response to medication.
Psychosocial	
Patient demonstrates decreased anxiety.	• Provide areas of control to patient and family as possible (eg, performance of ADLs, visitors) • Provide explanations and reassurance before procedures. • Consult social services and pastoral care as appropriate. • Provide for adequate rest and sleep.
Teaching/Discharge Planning	
Patient/significant others understand procedures and tests needed for treatment.	• Educate patient and family regarding disease process, need for intensive monitoring, and actions taken to correct disorder. • Prepare the patient and family for procedures, such as blood transfusions and laboratory studies. • Educate the patient and family regarding clinical parameters and patient presentation required for safe discharge from unit/hospital.

and fibrinolytic systems and can be given to normalize the INR. The recommended dose is 10 to 20 mL/kg. Platelet transfusions are usually used only for patients with active bleeding or a platelet count of less than 20,000/mm^3. Cryoprecipitate may be used for patients with plasma fibrinogen levels below 100 mg/dL. A single unit provides 200 mg of fibrinogen, as well as factor VIII, factor XII, and von Willebrand's factor. The usual adult dose is 5 to 10 units, with each unit raising the fibrinogen level by 5 to 10 mg/dL. Depleted antithrombin III (necessary to balance clot production) can be replaced using heat-treated pooled plasma concentrates; this has been shown to shorten the duration of DIC. RBC transfusions, although not useful for repleting coagulation factors, may be given to increase hemoglobin and oxygen-carrying capacity.

Localized bleeding can be minimized when possible. With venipuncture or removal of vascular access from compressible sites, pressure is applied for a minimum of 15 to 30 minutes or until bleeding has stopped. Sites are reassessed frequently for rebleeding because the initial clot may dissolve if the patient lacks the factors required to maintain hemostasis. Topical hemostatics may be used to provide superficial hemostasis.

▲ Clinical Applicability Challenges

CASE STUDY

Mrs. K. is a 63-year-old African American female with a known history of chronic kidney disease. She was hospitalized 6 weeks ago and had a left arm arteriovenous (AV) fistula placed in anticipation of eventual hemodialysis. The morning of this admission, she presents to her primary care physician's office complaining of worsening shortness of breath, dizziness, and generalized weakness. Mrs. K. is directly admitted to a telemetry unit on the hospitalist service. Physical examination findings include a markedly elevated blood pressure 222/118, generalized edema, but clear breath sounds. Initial laboratory work includes an elevated blood urea nitrogen, 141 mg/dL and creatinine, 15.9 mg/dL; hemoglobin, 7.1 mg/dL and platelet count, 306,000/mm^3. Admission orders include increasing her antihypertensive agents, transfusion of 2 units of packed red blood cells (PRBCs), a nephrology consult, and unfractionated heparin (UFH) 5,000 units subcutaneously every 8 hours for deep vein thrombosis (DVT) prophylaxis. A ventilation/perfusion scan is also performed with the finding of low probability for pulmonary embolism.

The nephrologist assesses that Mrs. K. has progressed to end-stage renal disease and recommends initiation of hemodialysis. Because Mrs. K's AV fistula is not mature, a Perma-Cath is placed. In addition to PRBC transfusion, the nephrologist recommends intravenous iron and erythropoietic-stimulating protein administration (eg, epogen, darbepoetin).

Mrs. K. gradually responds to treatment and on hospital day 12 is preparing for discharge. On rounds, the nurse practitioner notes that Mrs. K's last platelet count on hospital day 9 had dropped to 137,000/mm^3, and a complete blood count is ordered to be drawn by the dialysis nurse before the day's hemodialysis treatment. The dialysis nurse immediately pages the nurse practitioner noting that the platelet count is 13,000/mm^3. Heparin-induced thrombocytopenia (HIT) is strongly suspected. All heparin as well as any platelet-affecting medications are stopped, blood is drawn for a heparin-induced antibody (HITA) screen, and a hematology consult is requested. A nonheparin anticoagulant (see Box 49-6) is started. Even though Mrs. K. has no lower extremity edema or discomfort, lower extremity venous ultrasonography is performed, and a right common femoral vein thrombus is detected.

The following morning, laboratory results include a positive HITA and a platelet count of 36,000/mm^3. On hospital day 19, Mrs. K.'s platelet count is 102,000/mm^3. She is started on warfarin 5 mg each evening. On day 5 of warfarin therapy, her international normalized ratio (INR) is 1.36, and platelet count is 112,000/mm^3. Mrs. K. has been hospitalized a total of 23 days and is anxious to go home. She is taught how to self-administer the nonheparin anticoagulant injection.

Mrs. K. is discharged home and instructed to take warfarin 10 mg daily. She will have her INR checked with each dialysis treatment until her INR is stable between 2 and 3 at which time the nonheparin anticoagulant can be stopped. The nurse instructs Mrs. K. and her daughter to inform health care providers that she is not to be given UFH or low-molecular-weight heparin because of this episode of HIT. The nurse suggests Mrs. K. wear a medical identification bracelet with this information.

1. The nurse is concerned about Mrs. K.'s platelet count of 137,000/mm^3. Why is the platelet count important?

2. Mrs. K. is treated for HIT before the diagnosis is confirmed by laboratory testing. Why?

3. Despite Mrs. K. having no clinical evidence of DVT, bilateral lower extremity venous Doppler studies are ordered. What is the rationale?

PART 12

INTEGUMENTARY SYSTEM

50

Anatomy and Physiology of the Integumentary System

Joan M. Davenport

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Describe the features of the epidermis, dermis, and hypodermis.
2. Describe the appendages of the skin and state the purpose of each.
3. Discuss the homeostatic functions of the skin.
4. Explain the mechanism of infection resistance afforded by the integument.

The skin is described as protective, sensitive, reparative, and capable of maintaining a person's homeostasis. These physiological features are explored in this chapter as functions of the anatomy of the skin and its appendages. The skin, which covers 1.2 to 2.3 m^2 of area, is the largest organ of the body and is supplied with one third of the circulating blood volume.[1] The three layers of the skin are the outer epidermis, the middle dermis, and the underlying hypodermis, or subcutaneous tissue. The appendages include the hair, nail, eccrine and apocrine sweat glands, and sebaceous glands. Figure 50-1 pictures the structures and layers of the skin. The functions of the skin include protection, sensation, water balance, temperature regulation, and vitamin production.

▲ Epidermis

This outer layer of the skin serves to protect underlying structures from invasion by microbes and other foreign substances. The cornified, external layer of the epidermis helps in the body's regulation of water loss. The innermost sublayer bends into the dermis and serves as the basis for the glands, nails, and hair roots. The epidermis does not have vascular supply; it depends on the dermal level for its nourishment.

Melanin and keratin are formed in the inner cellular layer of the epidermis. Melanocytes provide melanin, a pigment for both the skin and hair. This pigment provides the color for the skin and, more important, protects the underlying structures from ultraviolet light exposure by absorbing and scattering the radiation.[2]

Keratin is a tough protein that makes up hair, nails, and the tough, outer epidermal surface. These flattened scales of the skin slough continually and are replaced every 2 to 4 weeks.[2] The epidermis is actually made up of five distinct layers; the keratinocytes move from inner to outer sublayers as they mature. At the top, outermost layer, the keratinocytes are dead and are arranged in various thicknesses depending on the area of the body. In parts of the face, there is a thin stratum made up of a layer 15 cells deep. This contrasts with the thicker soles of the feet and palms of the hands, with at least 100 layers of keratinized cells.[2] It is these tough protein cells that serve to protect the underlying structures of the body.

▲ Dermis

The middle layer of the skin, the dermis, provides support for the outer epidermal layer. It is a very vascular connective tissue, and the blood vessels are integral to regulation of body temperature and blood pressure. The arteriovenous anastomoses, under control of the sympathetic nervous system and found in the dermal layer, are able to dilate or constrict in

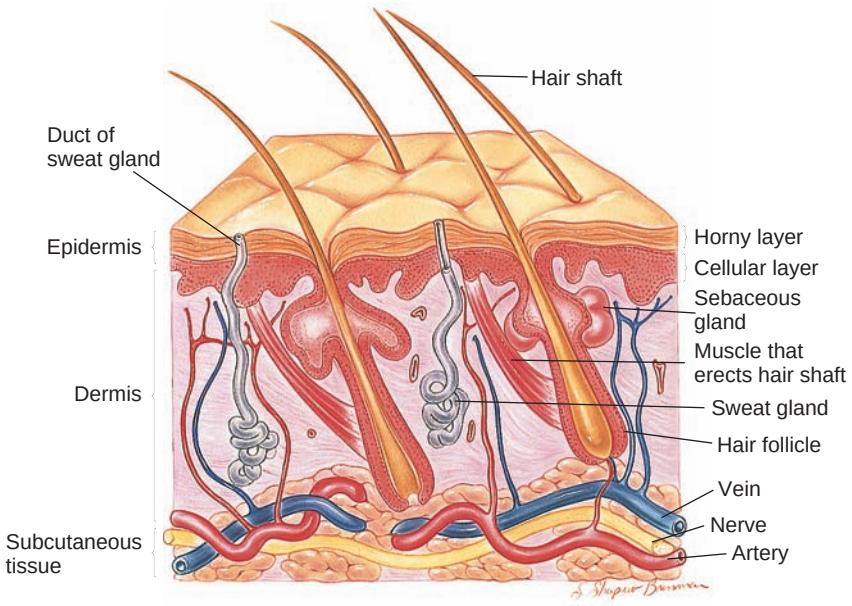

FIGURE 50-1 ▲ Layers of the skin. (From Bickley LS: Bates Guide to Physical Examination and history Taking, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 163.)

response to environmental conditions of heat and cold and to internal stimulation from anxiety or blood volume loss.

The sensory function of the skin includes receptors for heat, cold, touch, pressure, and pain; these are located in the dermal layer. There is a great variety in the function of the nerve endings. Multiple stimuli are mediated centrally and result in patterned responses.[2]

The dermis is composed of two distinct layers. The papillary dermis is the more superficial of the two layers, lying just beneath the epidermis. This layer provides the attachment for the epidermis as the epidermal basal cells project into the papillary dermis.[3]

The thicker underlayer of the dermis is the reticular dermis. Collagen is organized in a three-dimensional mesh pattern in this portion of the dermis. It is this mesh arrangement that allows the dermis to stretch with movement. Immune system components of the skin are found in the dermal layer and include macrophages, mast cells, T cells, and fibroblasts.[2]

▲ Hypodermis

The hypodermis or subcutaneous skin layer consists of connective tissue interspersed with fat. The fat of the hypodermis has the protective functions of heat retention and cushioning the underlying structures. In addition, the fat of the subcutaneous skin layer serves as storage for calories.[2]

▲ Skin Appendages

The hair, nails, and sebaceous and sweat glands are considered a part of the skin. These structures arise from or extrude through the epidermal or dermal skin layers.

Sweat Glands

Eccrine sweat glands are distributed throughout the surface of the skin. These glands arise from the dermis and open at the skin surface. These specialized glands secrete sweat for the purpose of internal body temperature regulation.

Apocrine sweat glands are not as widespread as the eccrine glands, are larger than eccrine glands, and open through a hair follicle of the axillae, nipples, areolae, groin, eyelids, and external ears.[2] Another difference between the two types of sweat glands is that the larger, less abundant apocrine glands secrete an oily substance with a particular odor. This odor is used by animals to recognize the presence of other animals. In humans, the odor, known as body odor, is produced when the secretions come in contact with bacteria and when the fluid begins to decompose.[2]

Sebaceous Glands

The sebaceous glands secrete sebum, a combination of triglycerides, cholesterol, and wax, through the hair follicle. These glands are situated over the entire surface of the skin except for the palms and soles of the feet. Sebaceous glands are inactive until puberty. At this time, they enlarge and are stimulated to secrete sebum by a rise in sex hormones. The sebum serves to keep the skin and hair from drying out.[2] By protecting the outer layer of the epidermis from undue drying, the sebum helps to conserve body heat. Table 50-1 summarizes the location and function of the eccrine, apocrine, and sebaceous glands.[4]

Hair

Epidermal cells in the dermis form the hair. Together with the sebaceous gland, the hair follicle forms the pilosebaceous unit. Vellus hair is unobtrusive, soft, and less pigmented than terminal hair. Terminal hair is darker, coarser, and more obvious. The follicular bulb is the site of vascular papilla, which nourishes and maintains the hair follicle. Hair color is determined by the melanocytes also found at the bulb. Under the sebaceous gland, adjacent to the hair follicle, are the arrector pili muscles. Contraction of the arrector pili causes gooseflesh, a

Table 50-1 Sweat and Sebaceous Glands

Type of Gland	Location	Function
Eccrine sweat glands	All over body	Regulate body temperature
	Numerous in thick skin	Respond to emotional distress
	Extended from dermis to epidermis	Respond to physiological stimuli
Apocrine sweat glands	Axillae	Respond to hormonal influences
	Nipples, breasts	Respond to emotional distress
	Anogenital region	
	External ear canal	
	Eyelids	
Sebaceous glands	All over body except palms of hands, dorsum, and soles of feet	Produce sebum to lubricate hair and skin

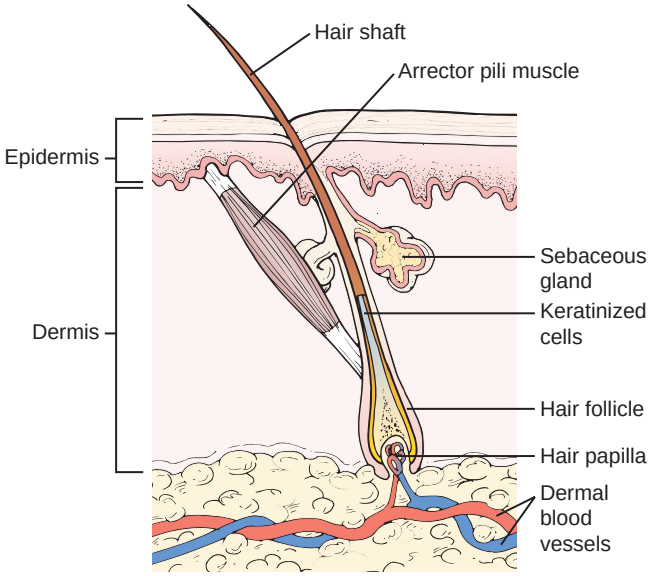

FIGURE 50-2 ▲ Structures of hair. (From Porth MP, Matfin G (eds): Pathophysiology, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 1551.)

reduction of skin surface area, and reduced surface area for heat loss (Fig. 50-2).

Nails

Hardened plates of epidermal keratin cells grow from a curved groove over the distal dorsal fingertips. These nails serve to protect the fingers and toes and increase physical dexterity. Approximately one fourth of the nail is covered by the proximal nail fold; the cuticle extends from the fold and serves to waterproof the space between the plate and the fold. The lunula is the white, "half-moon"–shaped edge distal to the cuticle. The angle between the proximal nail fold and the nail plate is expected to be less than 180 degrees (Fig. 50-3).

▲ Functions of the Skin

The epidermal layer of the integument provides protection against microbes, ultraviolet light exposure, and countless other threats. This tough, hardened outer layer also restricts water loss and thus helps to maintain organism homeostasis. The vascular dermis, with its rich supply of blood vessels, provides blood pressure and temperature-regulatory features. Immune functions performed by macrophages, mast cells, T cells, and fibroblasts are also housed in the dermis. Nerve endings here supply receptors for heat, cold, touch, pressure, and pain. Within this vascular dermal area, a potential space exists. This space, with its extracellular and extravascular fluid, may serve as a fluid reservoir to replace intravascular or intracellular fluid loss. This is also the place for fluid to migrate toward when intravascular hydrostatic pressure increases above the hydrostatic pressure with the dermal layer. This process produces the edema seen in patients. The skin's ability to stretch with movement is also provided by the dermal collagen's mesh formation. The underlying hypodermal layers of connective tissue and fat serve to retain heat and to cushion the underlying structures. The appendages of the skin, the hair, nails, and glands, contribute to the homeostatic function primarily by controlling heat loss with the hair's arrector pili muscles and secretions by the sebaceous and sweat glands. The integument is vital to an individual's survival.

During critical care hospitalizations, there are many insults to the skin. Surgical wounds, vascular catheter insertions,

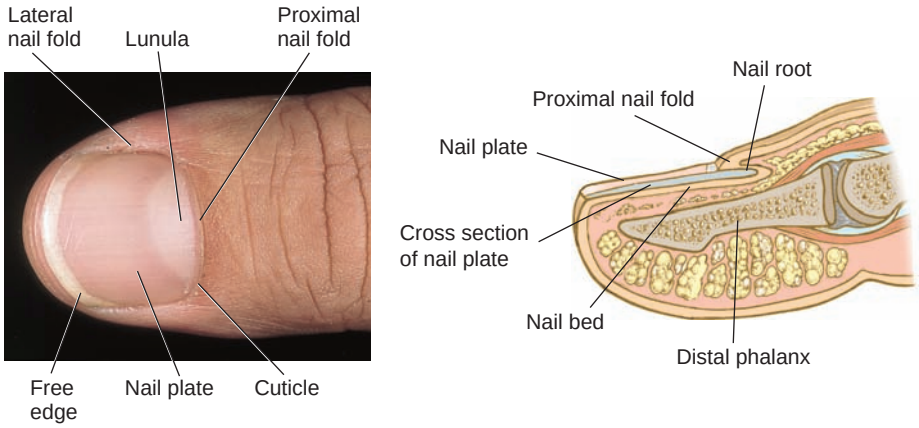

FIGURE 50-3 ▲ The normal nail. (From Bickley LS: Bates Guide to Physical Examination and history Taking, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 164.)

BOX 50-1 Anatomical and Physiological Changes in the Integumentary System That Occur With Aging

- The skin becomes thinner, and there is a decrease in skin flexibility, placing the person at risk for epidermal tearing.
- The skin loses dermal elasticity, collagen, and mass, resulting in fine wrinkling, looseness, and sagging.
- The number of dermal blood vessels decreases; the vessels become thinner and more fragile, thus increasing the risk for bruising and hemorrhage.
- There is decreased density and activity of the eccrine and apocrine glands and decreased sebum production, resulting in dryness, itching, and decreased perspiration.
- Decreased peripheral circulation leads to slowed nail growth and brittle nails that split easily.
- Reduced hormone levels lead to thinning of the hair and transition from terminal to vellus hair.
- Decreased melanin leads to graying of the hair.
- Sun exposure over a long period of time leads to yellowing and thickening of the skin and the development of old age spots (solar lentigo).

opportunistic infections of the skin, nutritional compromise, and persistent pressure that leads to reduced blood flow are only a few of the challenges faced by the patient's integument. In older patients, age-related changes (Box 50-1; see also Chapters 12 and 51) leading to increased fragility of the skin and slower healing magnify the effects of these insults. Attention to the skin and appendages by the nurse maximizes this organ's functioning and results in protection of the patient.

▲ Clinical Applicability Challenges

SHORT ANSWER QUESTIONS

1. What does the integument system do to maintain physiological homeostasis?
2. What are the physiological changes that occur to cause the pitting edema seen often in the critically ill adult patient?
3. In what ways are the expected physiological changes of the skin of the older adult exacerbated or worsened during critical illness?

51 Patient Assessment: Integumentary System

Joan M. Davenport and Janet A. Wulf

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Discuss the health history and physical assessment when evaluating a patient's skin.
2. Explain expected differences in skin color related to racial or skin tone characteristics.
3. Describe and recognize abnormal changes in skin color.
4. Explain and identify skin lesions resulting from increased vascularity.
5. Describe the significance of rashes related to infection or to allergic reaction.
6. Compare and contrast pitting and nonpitting edema.
7. Explain the cause of pressure ulcers and the Braden scale used to assess a patient for pressure ulcer development.
8. Discuss the features of malignant skin diseases.

The skin of a critically ill person is exposed to insults ranging from diminished blood flow and the resultant risk for pressure ulceration to rashes from hypersensitivity drug reactions and opportunistic infections. There is often ample opportunity for the critical care nurse to assess the skin—the intimacy involved in providing care to someone who is critically ill, the relative level of undress of the patient, and the attention to detail implicit in critical care nursing make integument assessment an ongoing and vital process.

▲ History

When caring for patients with skin disorders, it is important to obtain information from the health history (Box 51-1). The information is useful in guiding the physical examination and in determining appropriate interventions.

▲ Physical Examination

The assessment techniques necessary for an evaluation of the integument involve inspection and palpation.

Inspection

Inspection of the general appearance of the skin includes assessment of color; determination of the presence of lesions, rashes, or increased vascularity; and assessment of the condition of the nails and hair.

Color

Skin color is expected to be uniform over the body, except for the areas with greater degrees of vascularity. The genitalia, upper chest, and cheeks may appear pink or have a reddish tone in people with light skin. These same areas may appear darker in people with dark skin. Additional normal variations in skin color include those listed in Table 51-1.

Skin color is determined by the presence of four pigments: melanin, carotene, hemoglobin, and deoxyhemoglobin. The amount of melanin is genetically determined and produces varying degrees of dark skin tone. Carotene, a yellow pigment, is in subcutaneous fat and is most evident in those areas with the most keratin, the palms and soles of the feet. Skin color abnormalities, such as pallor, cyanosis, jaundice, and erythema, manifest differently depending on the person's normal skin tone (Table 51-2).

The degree of oxygenation affects skin color. Hemoglobin, attached to red blood cells, transports oxygen to the tissues. A diminished flow of oxyhemoglobin through the cutaneous circulation results in pallor. In people with light skin, the skin appears very pale, without the usual pink undertones. In people with darker skin, pallor manifests as a yellowish-brown or ashen appearance (again, because the usual pink undertones are lost).

As hemoglobin gives up its oxygen to the tissues, the hemoglobin changes to deoxyhemoglobin. When deoxyhemoglobin is present in the cutaneous circulation, the skin

BOX 51-1 HEALTH HISTORY for Integumentary Assessment

Chief Complaint
- Patient's description of the problem

History of the Present Illness
- Complete analysis of the following signs and symptoms (using the NOPQRST format; see Box 17-1, p. 207)
- Changes in skin color, pigmentation, temperature, or texture
- Changes in a mole
- Excess dryness or moisture
- Skin itching
- Excess bruising
- Delay in healing
- Skin rash or lesions
- Hair loss or increased growth
- Changes in hair texture
- Changes in nails

Past Health History
- Relevant childhood illnesses and immunizations: impetigo, scabies or lice exposure, measles, chickenpox, scarlet fever
- Past acute and chronic medical problems including treatments and hospitalizations: diabetes, peripheral vascular disease, Lyme disease, Parkinson's disease, immobility, malnutrition, trauma, skin cancers, radiation treatments, HIV/AIDS
- Risk factors: age, ultraviolet sun exposure, tanning beds, exposure to dyes, toxic chemicals, insect bites, contact with some poisonous plants, autoimmune disease, exposure to extremes of temperature
- Past surgeries: skin biopsy
- Past diagnostic tests and interventions: allergy testing
- Medications: aspirin, antibiotics, barbiturates, sulfonamides, thiazide diuretics, oral hypoglycemic agents, tetracycline, antimalarials, antineoplastic agents, hormones, metals, topical steroids
- Allergies and reactions: foods, medications, contrast dyes, latex, soaps
- Transfusions

Family History
- Health status or cause of death of parents and siblings: skin cancer, autoimmune diseases

Personal and Social History
- Tobacco, alcohol, and substance use
- Family composition
- Occupation and work environment: farmers, roofers, creosote or coal workers, furniture repair and refinishing, gardeners
- Living environment: ability for self-care and hygiene, exposure to insects and pests, availability of indoor sleeping in environmental temperature extremes
- Diet
- Sleep patterns
- Exercise
- Cultural beliefs
- Spiritual/religious beliefs
- Coping patterns and social support systems
- Leisure activities
- Sexual activity
- Recent travel

Review of Systems
- Psychiatric/emotional: increased anxiety, nervousness, sleeplessness
- Neurologic: loss or decrease in sensation, numbness, pain or neuropathy, stroke
- Cardiovascular: swelling of extremities, cold extremities, varicose veins
- Gastrointestinal: change in diet, recent weight loss or gain, loss of appetite
- Musculoskeletal: immobility, weakness
- Metabolic: altered glucose levels

takes on a blue cast, and the person is said to be cyanotic.[1] In light-skinned people, cyanosis may be seen as a grayish-blue color, especially in the palms and soles of the feet, the nail beds, the earlobes, the lips, and the mucous membranes. In those with darker skin, cyanosis appears as an ashen-gray color seen in the same areas.[2]

The yellowish hue of jaundice is indicative of liver disease or of hemolysis of red blood cells. In dark-skinned people, jaundice is seen as a yellowish-green color in the sclera, palms of the hands, and soles of the feet. In light-skinned people, jaundice is seen as a yellow coloration of the skin, sclera, lips, hard palate, and underside of the tongue. Bickley and Szilagyi[1] recommend using a transparent slide pressed against the lips to "blanch out the red color," making the yellow of jaundice more easily seen.

Table 51-1 Normal Variations in Skin Color

Normal Variation	Description
Moles (pigmented nevi)	Tan to dark brown; may be flat or raised
Stretch mark (striae)	Silver or pink; may be caused by weight gain or pregnancy
Freckles	Flat macules anywhere on the body
Vitiligo	Unpigmented skin area; more prevalent in people with dark skin
Birthmarks	Generally flat marks anywhere on the body; may be tan, red, or brown

Another skin color abnormality is erythema. Erythema manifests as a reddish tone in light-skinned people and a deeper brown or purple tone in dark-skinned people. It is indicative of increased skin temperature caused by inflammation. The process of inflammation increases vascularity of the tissues, and this, in turn, produces the color alteration seen with erythema. Erythema may be expected when associated with a surgical wound, due to the inflammatory process inherent in any tissue trauma. It is also seen in disease processes affecting the skin, such as cellulitis. In either case, the erythema is indicative of inflammation.

Lesions

Skin lesions are variously described by their color, shape, cause, or general appearance (Table 51-3, p. 1157; Table 51-4, p. 1160). They are considered abnormal conditions and arise from many factors (see Spotlight on Genetics 51-1, p. 1160). In general, it is important to note the anatomical location, distribution, color, size, and pattern of any abnormal skin lesion (Fig. 51-1). In addition, details about the lesion's borders or edges, as

Table 51-2 Skin Color Abnormalities

Skin Color Abnormality	Underlying Cause	Manifestation in Light-Skinned People	Manifestation in Dark-Skinned People
Pallor	Decreased blood flow (decreased oxyhemoglobin flow to tissues)	Excessively pale skin	Yellowish-brown or ashen color to the skin
Cyanosis	Increased deoxyhemoglobin in the cutaneous circulation	Grayish-blue color of the palms and soles of the feet, the nail beds, the lips, the earlobes, and the mucous membranes	Ashen-gray color of the conjunctiva, oral mucous membranes, and nail beds
Jaundice	Increased red blood cell hemolysis, liver disease	Yellow color of the sclera, lips, and hard palate	Yellow-green color of the sclera and palms and soles of the feet
Erythema	Inflammation	Reddish tone	Deeper brown or purple tone

well as whether the lesion is flat, raised, or sunken, should be noted. Finally, the length of time the lesion has been present and any environmental or medication exposure that may be considered contributory should also be noted.[3]

Vascular lesions can be either a normal variation or an abnormal finding. Vascular changes considered to be normal variants include nevus flammeus (port-wine stain), immature hemangioma (strawberry mark), telangiectasis, cherry angioma, and capillary hemangioma (Table 51-5, p. 1161). Abnormal vascular findings include petechiae, purpura, ecchymoses, spider angiomas, and urticaria (hives). These findings may indicate disease or injury and warrant further investigation by the critical care nurse.

Petechiae are purple or red, small (1- to 3-mm) lesions easily seen on light-skinned people and more difficult to see on those with dark skin (Fig. 51-2A, p. 1161). These tiny

Table 51-3 Primary Skin Lesions

Type	Description	Examples	Illustration
Macule	<1 cm in diameter, flat, nonpalpable, circumscribed, discolored	Brown: freckle, junctional nevus, lentigo, melasma Blue: Mongolian spot, ochronosis Red: drug eruption, viral exanthema, secondary syphilis Hypopigmented: vitiligo, idiopathic guttate hypomelanosis	 Macule
Patch	>1 cm in diameter, flat, nonpalpable, irregular shape, discolored	Brown: larger freckle, junctional nevus, lentigo, melasma Blue: Mongolian spot, ochronosis Red: drug eruption viral exanthema, secondary syphilis Hypopigmented: vitiligo, idiopathic guttate hypomelanosis	 Patch
Papule	<1 cm in diameter, raised, palpable, firm	Flesh, white or yellow: flat wart, milium, sebaceous hyperplasia, skin tag Blue or violaceous: venous lake, lichen planus, melanoma Brown: seborrheic keratosis, melanoma, dermatofibroma, nevi Red: acne, cherry angioma, early folliculitis, psoriasis, urticaria, and eczema	 Papule

(continued on page 1158)

Table 51-3 Primary Skin Lesions (continued)

Type	Description	Examples	Illustration
Nodule	>1 cm, raised, solid	Wart, xanthoma, prurigo nodularis, neurofibromatosis	 Nodule
Plaque	>1 cm, raised, superficial, flat-topped, rough	Psoriasis, discoid lupus, tinea corporis, eczema, seborrheic dermatitis	 Plaque
Tumor	Large nodule	Metastatic carcinoma, sporotrichosis	 Tumor
Vesicle	<1 cm, superficially raised, filled with serous fluid	Herpes simplex, herpes zoster, erythema multiforme, impetigo	 Vesicle
Bulla	>1-cm vesicle	Pemphigus, herpes gestationis, fixed drug eruption	 Bulla

(continued on page 1159)

Table 51-3 Primary Skin Lesions (continued)

Type	Description	Examples	Illustration
Pustule	Raised, superficial, filled with cloudy, purulent fluid	Acne, candidiasis, rosacea, impetigo, folliculitis	 Pustule
Wheal	Raised, irregular area of edema, solid, transient, variable size	Hives, cholinergic urticaria, angioedema, dermatographism	 Wheal
Cyst	Raised, circumscribed, encapsulated with a wall and lumen, filled with liquid or semisolid	Digital mucus, epidermal inclusion, pilar	 Cyst

From Rhoads J: Advanced Health Assessment and Diagnostic Reasoning. Philadelphia, PA: Lippincott Williams & Wilkins, 2006, pp 81–83.

hemorrhages in the dermal or submucosal layers may be seen anywhere on the body including oral mucosa and conjunctiva. They are caused by extravasated blood and do not disappear when pressure is applied to them.[3] Purpura are very similar to petechiae, only larger. Purpura may appear brownish-red.

Ecchymoses are bruises. They may appear as purple to yellowish-green rounded or irregular lesions and are more easily seen in people with light skin (see Fig. 51-2B). Ecchymoses occur as a result of trauma, when blood leaks from damaged blood vessels into the surrounding tissue.

Spider angiomas are fiery red lesions that are most often located on the face, neck, arms, or upper trunk (see Fig. 51-2C). Spider angiomas are seldom seen below the waist. They have a central body that is sometimes "raised and surrounded by erythema and radiating legs."[1] These lesions are most often associated with liver disease and vitamin B deficiency but also occur normally in some people.[1]

Urticaria is a reddened or white, raised, nonpitting plaque that often occurs as a result of an allergic reaction. The lesion often changes shape and size during the course of the reaction. The edema associated with urticaria is a result of local vasodilation and inflammation, which is followed by transudation of serous vascular fluid into the surrounding tissue.

Rashes

Rashes identified during inspection may indicate infection or a reaction to drug therapy. Some of these rashes are identified by the names listed in Table 51-3. Identifying the type of lesion may help in identifying the cause of the rash. Attention to the development of a rash in association with a change in pharmacotherapy is essential to help identify the occurrence of an allergic hypersensitivity reaction.[4] The development of urticaria is often associated with food or drug reactions. Urticaria usually resolves completely over days to several weeks as the excess local fluid is reabsorbed. These lesions are often pruritic, and patient scratching may precipitate secondary skin abrasions, which can place the patient at risk for localized skin infections.

Skin infections are most often caused by fungi or yeasts and may range from superficial tinea pedis (athlete's foot)

Table 51-4 Secondary Skin Lesions

Type	Description
Crust	Dried exudates over a damaged epithelium; may be associated with vesicles, bullae, or pustules. Large adherent crust is a scab.
Erosion	Loss of superficial epidermis; does not extend to the dermis; may be associated with vesicles, bullae, or pustules.
Fissure	Crack in the epidermis usually extending into the dermis.
Keloid	Hypertrophied scar tissue; secondary to collagen formation during healing; elevated irregular and red; more common in African Americans.
Lichenification	Thickening and roughening of the skin; accentuated skin markings; may be secondary to repeated rubbing irritation and scratching.
Scale	Skin debris on the surface of the epidermis secondary to desquamated, dead epithelium. Color and texture vary.
Scar	Skin mark left after healing of wound or lesion that represents replacement by connective tissue of the injured tissue. Young scars are red or purple. Mature scars are white or glistening.
Ulceration	Loss of epidermis, extending into dermis or deeper. Bleeding and scarring are possible.

Adapted from Weber J, Kelley J: Health Assessment in Nursing, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 199.

to intermediate yeast infections (eg, moniliasis resulting from *Candida albicans* infection) to deep fungal infections (eg, aspergillosis) that invade the underlying tissues. Most often in the critical care setting, fungal and yeast infections are of the intermediate type and are the result of an opportunistic infection by normal flora. Antibiotics, corticosteroids, poor nutrition, and diabetes mellitus place the patient at risk for these infections. Candidiasis presents in the groin and under the breasts of female patients with erythema, a whitish pseudomembrane, and macropapular satellite lesions.[5] Oral candidiasis, also known as thrush, manifests as a whitish coating of the oral mucosa, especially the tongue. This painful condition may produce fissures on the tongue and often restricts a patient's oral intake, further compromising the patient from a nutritional perspective.

SPOTLIGHT ON GENETICS 51-1

Focal Dermal Hypoplasia

- Focal dermal hypoplasia is characterized by skin abnormalities present from birth, such as streaks of very thin skin with 90% of affected individuals being female.
- Mutations in the *PORCN* gene cause focal dermal hypoplasia. This gene provides instructions for making a protein that is responsible for modifying other proteins.
- Mutations in the *PORCN* gene appear to prevent the production of any functional PORCN protein. Researchers believe Wnt proteins cannot be released from the cell without the PORCN protein. When Wnt proteins are unable to leave the cell, they cannot participate in the chemical signaling pathways that are critical for normal development
- Genetic testing via sequence analysis of the entire coding region is available for the diagnosis of focal dermal hypoplasia.

Genetic Home Reference-http://ghr.nlm.nih.gov, accessed July 14, 2011.

Garavelli L, Wischmeijer A, Rosato S, et al: Focal dermal hypoplasia (Goltz syndrome): A new case with a novel mutation in the PORCN gene and unusual spinal anomaly. Genetic Counseling 21(1):126–128, 2010.

Condition of the Hair

The patient's terminal hair is inspected daily, noting the hair's quantity, distribution, and texture. Scalp hair should be resilient and evenly distributed.

Alopecia refers to hair loss and can be diffuse, patchy, or complete. Hair loss in the critical care setting can be associated with pharmacotherapy. Chemotherapy used in oncology treatment produces alopecia. Other drugs, such as heparin, used for a prolonged time may also be responsible for hair loss.[6,7] Hirsutism or increased facial, body, or pubic hair growth is an abnormal finding in the examination of women and children. Hirsutism has a familial pattern and is associated with menopause, endocrine disorders, and certain pharmacotherapies (eg, corticosteroids and androgenic medications).[2]

FIGURE 51-1 ▲ Inspecting for lesions. (From Rhoads J: Advanced Health Assessment and Diagnostic Reasoning. Philadelphia, PA: Lippincott Williams & Wilkins, 2006, p 76.)

Table 51-5 Vascular Lesions: Normal Variations

Normal Variation	Description
Nevus flammeus (port-wine stain), immature hemangioma (strawberry mark)	Range from dark red to pale pink and are considered birthmarks
Cherry angioma	Small, slightly raised, bright red lesions on the face, neck, and trunk; increase in size and number with advancing age
Capillary hemangioma	Red, irregular patch caused by capillary dilation in the dermis of the skin
Telangiectasis	Irregular, fine red lines caused by permanent dilation of a group of superficial vessels

A change in the hair's texture may indicate ongoing health concerns. Hair that is thin and brittle occurs in hypothyroidism. In those with severe protein malnutrition, the hair color may appear reddish or bleached, and the hair texture is described as brittle and dry.[7]

Also not to be overlooked is the presence of infection or infestation of the scalp and hair. The patient's scalp and body hair are inspected regularly for evidence of flaking, sores, lice, louse eggs, scabies, and ringworm. During the inspection, the hair is parted in several areas to reveal the underlying scalp (Fig. 51-3).

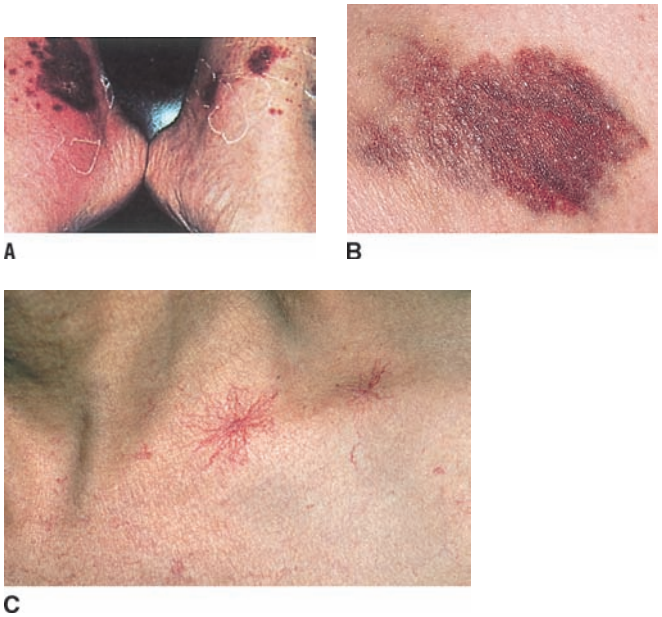

FIGURE 51-2 ▲ A–C: Abnormal vascular lesions. (**A**, from Smeltzer SC, Bare BG. Textbook of Medical-Surgical Nursing, 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2000. **B**, from Bickley LS: Bates' Guide to Physical Examination and History Taking, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 184. **C**, from Goodheart HP. Goodheart's Photoguide of Common Skin Disorders, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2003.)

FIGURE 51-3 ▲ Inspecting the scalp and hair. (From Weber J, Kelley J: Health Assessment in Nursing, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 191.)

Condition of the Nails

Nails, like hair, can be overlooked in the rush of critical care nursing; however, a careful inspection as part of the routine assessment can reveal information about the patient's general state of health. The nail bed is very vascular and is an excellent location for assessing the adequacy of the patient's peripheral circulation. The capillary refill test, done by blanching the nail beds and then releasing the pressure, should indicate a return of the pink tones in less than 3 seconds. Nail beds that are tinted bluish or purplish may indicate cyanosis; nail beds that are pale may indicate reduced arterial blood flow.

When the angle of the nail is 180 degrees or greater, clubbing is said to be present (see Chapter 24, Fig. 24-2). Clubbing is attributed to chronic hypoxemia. Other shapes that the nail takes on may provide clues to deficient nutritional states of the patient (Fig. 51-4). A spoon-shaped nail, called koilonychias, is associated with iron deficiency anemia.

Chronic disease states, such as cirrhosis, heart failure, and type II diabetes mellitus, may affect the nails by producing Terry's nails.[1] These nails are whitish with a distal band of dark reddish-brown color, and the lunulae may not be visible (Fig. 51-5). Bands across the nails, especially in the older adult, may indicate protein deficiency. However, in dark-skinned individuals, lengthwise, linear, dark stripes or diffuse brown, blue, or black pigmentation may be a normal finding.[5] Hyperkeratotic, dull, discolored, and distorted nails may be onychomycosis, a fungal infection of the nails seen frequently in critically ill patients. It is more common in toenails than fingernails. Risk factors include diabetes, poor venous and lymphatic drainage, poorly fitting shoes, history of athlete's foot, and increasing age.[8]

Palpation

The skin is palpated for texture, moisture, temperature, mobility and turgor, and edema (Fig 51-6). In addition, any evidence of discomfort arising from the areas palpated is noteworthy.

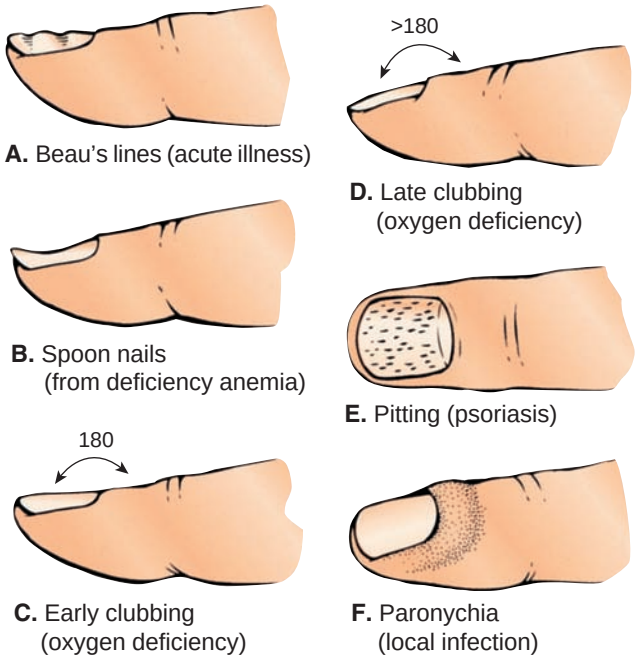

FIGURE 51-4 ▲ **A–F:** Common nail disorders. (From Weber J, Kelley J: Health Assessment in Nursing, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 203.)

Texture

Texture refers to the smoothness of the skin surface. It requires gentle palpation to assess. Rough skin occurs in patients with hypothyroidism.

Moisture

The skin may be described as dry, oily, diaphoretic, or clammy. Dry skin may be seen in the patient with hypothyroidism. Skin is oily with acne and with increased activity of the sebaceous glands, as in Parkinson's disease. Diaphoresis may be a response to increased temperature or increased metabolic rate. Hyperhidrosis is the term given to excessive perspiration. Bromhidrosis refers to foul-smelling perspiration. Low cardiac output states may produce skin that is referred to as clammy.

FIGURE 51-5 ▲ Terry's nails, seen in people with chronic diseases such as cirrhosis, congestive heart failure, and type II diabetes mellitus. (From Bickley LS: Bates' Guide to Physical Examination and History Taking, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 193.)

FIGURE 51-6 ▲ Palpating to assess skin turgor and mobility. (From Weber J, Kelley J: Health Assessment in Nursing, 4th ed. Philadelphia, PA: Lippincott Williams &Wilkins, 2010, p 190.)

Temperature

Temperature is usually assessed with the dorsal surface of the hand to identify the general skin temperature as warm or cool. The skin's temperature can also be used to assess the possibility of reduced blood flow from an arterial insufficiency. In this case, the skin may be noticeably cooler distal to an occluding lesion.

Mobility and Turgor

Mobility and turgor provide information about the health of the skin and may yield information about the patient's fluid volume balance. When assessed centrally, over the clavicles, the skin is expected to lift up easily and quickly return into place. Skin mobility may be decreased in scleroderma or in a patient with increased edema. Skin turgor is decreased in the patient with dehydration.[1]

Edema

Edema is classified as either nonpitting or pitting. Nonpitting edema is that which does not depress with palpation. Nonpitting edema is seen in patients with a local inflammatory response and is caused by capillary endothelial damage. In addition to the edema, the skin is usually red, tender, and warm. Pitting edema is usually in the skin of the extremities and in dependent body parts. Pitting edema is identified as edema that retains the depression made when palpated. This type of edema can be further classified by the depth of the depression and, occasionally, by the amount of time it takes the pit to rebound (Table 51-6).

Table 51-6 Pitting Edema Scale

Scale	Description	Depth of Indentation (mm)	Return to Baseline
4+	Severe	8	2–5 min
3+	Moderate	6	1–2 min
2+	Mild	4	10–15 s
1+	Trace	2	Disappears rapidly

▲ Assessment of Pressure Ulcers

The development of pressure ulcers in the critically ill patient is a preventable complication. The difficulty arises in the patient with multiple-system dysfunction with concomitant fluid, electrolyte, and nutritional deficiencies. Common pressure ulcer points include the occiput, scapula, sacrum, buttocks, ischium, heels, and toes. Pressure applied by the weight of the body causes a reduction in arterial and capillary blood flow, leading to these ischemic events. Therefore, frequent position changes are required to prevent the development of pressure ulcers. Pressure ulceration on the toes occurs as a result of the pressure of the bed linen on the feet. Dressing devices and wound appliances can place pressure on underlying skin, resulting in reduced blood flow. The back of the neck of the patient with a tracheostomy tube must be assessed because the tube holder may be applied too tightly. The tape securing a nasogastric tube must be regularly removed and the condition of the tip of the nose and nares assessed for changes resulting from pressure from the tube.

Assisting the patient with frequent position changes is crucial in preventing pressure ulcers from developing. In addition, keeping the skin clean and dry is requisite in preventing pressure ulceration. Moisture increases the risk for maceration of the skin and promotes its breakdown. Infectious matter in wound drainage or feces increases the risk that an ulcer will progress and become a major source of sepsis.

Patients with decreased sensation or awareness (eg, from brain or spinal cord injury or from a peripheral neuropathy, such as that caused by diabetes) are at greater risk for ulceration because they do not recognize the discomfort from being in one position for extended periods. Similarly, patients with sedation or frequent analgesic dosing are at increased risk for problems related to their immobility. Patients with poor circulation, such as that caused by hypotension, heart failure, or peripheral vascular insufficiency, are also at higher risk because of the underlying possibility of tissue hypoxia. Lack of movement then serves only to accelerate the process of pressure ulcer development.

Identifying those people most at risk for pressure ulcer development is a focus of assessment. The National Pressure Ulcer Advisory Panel recommends assessment on admission or change of status and at least every 24 hours in the intensive care unit.[10] Recognizing that there are certain features that increase a patient's risk for development of pressure ulcers allows the critical care nurse to increase surveillance and implement preventive treatment modalities. Problems with sensory perception, moisture, incontinence, activity, mobility, nutrition, and friction and shearing forces increase the patient's risk of developing pressure ulcers, which are debilitating and expensive to treat. Critically ill patients are among those with the most significant limitations of these parameters, and therefore are at very high risk for the development of pressure ulcers.

Many tools for assessing pressure ulcer risk use a point system.[9,10] The Braden Scale for Predicting Pressure Sore Risk, recommended in the guidelines set forth by the U.S. Agency for Health Care Policy and Research and widely used in hospital settings, requires the daily assessment of six parameters and provides a numerical score ranging from a very high-risk score of 6 to a very limited risk or minimal-risk score of 23[9] (Fig. 51-7). Adults with a score below 16 (18 for older adults) are considered at risk, and specific interventions to prevent the development of ulceration are recommended.

Studies suggest that stage 1 pressure ulcers are less likely to be identified in dark-skinned people, leading to higher incidence of stage 2 pressure ulcers in black patients than in white patients.[11,12] Bates, McCreath, and Pongquan[12] propose that difficulties with accurate visual assessment may contribute to this disparity when "lack of early recognition results in failure to institute preventive interventions." They further suggest that a nonvisual assessment technique, such as subepidermal moisture assessment, may offer a more objective method for assessing skin integrity.

During assessment of the skin, the nurse must be vigilant for signs of skin breakdown. The formation of pressure ulcers is illustrated in Figure 51-8. See Chapter 52 for the management of skin integrity.

▲ Assessment of Skin Tumors

Benign nevus and seborrheic keratosis are common, benign skin lesions. The benign nevus or mole appears in the first two to three decades, and its appearance remains unchanged over time. These lesions have clearly defined borders, are uniform in color, and are round or oval. The nevus is periodically assessed for changes because a change may indicate dysplasia of the tissue and the risk for melanoma. Seborrheic keratoses are common, yellow to brown lesions that are described as velvety when touched (Fig. 51-9A, p. 1166). These lesions are often multiple and often symmetrically distributed on the trunk and face. Precancerous lesions (actinic keratoses) are thick, rough patches that develop on sun-exposed areas of the skin, especially in fair-skinned people (see Fig. 51-9B, p. 1166). They are described as dry, scaly, and rough textured; however, not all actinic keratoses look alike.[13] The color may vary from brown to red to yellowish-black, or they may appear as red bumps or scaly patches. They are often described as feeling like sandpaper. These lesions require attention because there is a risk for development of squamous cell carcinoma.[13]

Skin cancer is the most common type of cancer in the United States. It is estimated that one in five people will be diagnosed with skin cancer in their lifetimes.[14] Basal cell and squamous cell cancers are often grouped as nonmelanoma skin cancers. Basal cell carcinomas are found exclusively in light-skinned people and arise from the hair follicles on the head and neck. Prolonged and cumulative exposure to the sun is recognized as the cause of basal cell carcinoma. These tumors are slow growing and rarely metastasize but do cause local skin destruction and disfigurement. Basal cell carcinomas appear with pearly, raised borders and depressed centers[1] (see Fig. 51-9C, p. 1166).

Squamous cell carcinomas affect the skin and the mucous membranes. Like basal cell cancers, the primary cause is exposure to ultraviolet light. Radiation and tissue damage from scars, ulcers, and fistulas may give rise to squamous cell carcinomas. These cancers can be invasive and are more malignant than basal cell cancers if not treated promptly. As it develops, the carcinoma takes on a hyperkeratotic appearance and may ulcerate and bleed[14] (see Fig. 51-9D, p. 1166).

Malignant melanomas are highly metastatic lesions that come from the melanin-producing cells of the body. The

Braden Scale

FOR PREDICTING PRESSURE SORE RISK

Patient's Name_____ Evaluator's Name_____ Date of Assessment

SENSORY PERCEPTION Ability to respond meaningfully to pressure-related discomfort	**1. Completely Limited:** Unresponsive (does not moan, flinch, or grasp) to painful stimuli, due to diminished level of consciousness or sedation. OR limited ability to feel pain over most of body surface.	**2. Very Limited:** Responds only to painful stimuli. Cannot communicate discomfort except by moaning or restlessness. OR has a sensory impairment which limits the ability to feel pain or discomfort over 1/2 of body	**3. Slightly Limited:** Responds to verbal commands, but cannot always communicate discomfort or need to be turned. OR has some sensory impairment which limits ability to feel pain or discomfort in 1 or 2 extremities.	**4. No Impairment:** Responds to verbal commands. Has no sensory deficit which would limit ability to feel or voice pain or discomfort.	
MOISTURE Degree to which skin is exposed to moisture	**1. Constantly Moist:** Skin is kept moist almost constantly by perspiration, urine, etc. Dampness is detected every time patient is moved or turned.	**2. Very Moist:** Skin is often, but not always, moist. Linen must be changed at least once a shift.	**3. Occasionally Moist:** Skin is occasionally moist, requiring an extra linen change approximately once a day.	**4. Rarely Moist:** Skin is usually dry, linen only requires changing at routine intervals.	
ACTIVITY Degree of physical activity	**1. Bedfast:** Confined to bed	**2. Chairfast:** Ability to walk severely limited or nonexistent. Cannot bear own weight and/or must be assisted into chair or wheelchair.	**3. Walks Occasionally:** Walks occasionally during day, but for very short distances, with or without assistance. Spends majority of each shift in bed or chair.	**4. Walks Frequently:** Walks outside the room at least twice a day and inside room at least once every 2 hours during waking hours.	
MOBILITY Ability to change and control body position	**1. Completely Immobile:** Does not make even slight changes in body or extremity position without assistance.	**2. Very Limited:** Makes occasional slight changes in body or extremity position but unable to make frequent or significant changes independently.	**3. Slightly Limited:** Makes frequent though slight changes in body or extremity position independently.	**4. No Limitations:** Makes major and frequent changes in position without assistance.	
NUTRITION Usual food intake pattern	**1. Very Poor:** Never eats a complete meal. Rarely eats more than 1/3 of any food offered. Eats 2 servings or less of protein (meat or dairy products) per day. Takes fluids poorly. Does not take a liquid dietary supplement. OR is NPO and/or maintained on clear liquids or IVs for more than 5 days.	**2. Probably Inadequate:** Rarely eats a complete meal and generally eats only about 1/2 of any food offered. Protein intake includes only 3 servings of meat or dairy products per day. Occasionally will take a dietary supplement. OR receives less than optimum amount of liquid diet or tube feeding.	**3. Adequate:** Eats over half of most meals. Eats a total of 4 servings of protein (meat, dairy products) each day. Occasionally will refuse a meal, but will usually take a supplement if offered. OR is on a tube feeding or TPN regimen which probably meets most of nutritional needs.	**4. Excellent:** Eats most of every meal. Never refuses a meal. Usually eats a total of 4 or more servings of meat and dairy products. Occasionally eats between meals. Does not require supplementation.	
FRICTION AND SHEAR	**1. Problem:** Requires moderate to maximum assistance in moving. Complete lifting without sliding against sheets is impossible. Frequently slides down in bed or chair, requiring frequent repositioning with maximum assistance. Spasticity, contractures or agitation leads to almost constant friction.	**2. Potential Problem:** Moves feebly or requires minimum assistance. During a move skin probably slides to some extent against sheets, chair, restraints, or other devices. Maintains relatively good position in chair or bed most of the time but occasionally slides down.	**3. No Apparent Problem:** Moves in bed and in chair independently and has sufficient muscle strength to lift up completely during move. Maintains good position in bed or chair at all times.		
					Total Score

Braden Scale Scores
1 = Highly Impaired
3 or 4 = Moderate to Low Impairment
Total Points Possible: 23
Risk Predicting Score: 16 or Less

NPO: Nothing by Mouth
IV: Intravenously
TPN: Total parenteral nutrition

worldwide frequency of malignant melanomas is growing more rapidly than for any other cancer except lung cancer. Those at highest risk include those with fair complexions, those prone to sunburn, and those with a family history of melanoma.[14] The most common location for the development of these lesions is on the trunk in men and on the legs in women. The tumors have irregular borders, are dark brown or black, and are usually larger than 6 mm (see Fig 51-9E). The American Cancer Society[14] recommends a monthly self-assessment for melanoma using the "ABCDs." A is for asymmetry; B is for borders (are they irregular, ragged, notched, or blurred?); C is for color (dark brown or black, red, white, or blue?); and D is for diameter.

Figure 51-9 provides pictures and descriptions of these benign, premalignant, and malignant lesions. While in a critical care setting, it is possible to perform a thorough assessment for suspect skin lesions that may be cancerous, refer the patient to a dermatologist or oncologist, and have treatment initiated much sooner than would otherwise be the case.

▲ Clinical Applicability Challenges

CASE STUDY

Mr. P., a 74-year-old man, came in for coronary artery bypass graft 4 weeks ago and was unable to be weaned from the ventilator. He was moved to surgical intensive care unit during a 2-week period of hemodynamic instability that required intravenous norepinephrine (Levophed) to support his blood pressure, and during that time he was sedated. Mr. P. subsequently developed acute renal failure and pneumonia. His medical history includes chronic obstructive pulmonary disease, obesity, chronic renal insufficiency, and diabetes mellitus. He also has a history of alcohol abuse. Mr. P. is oriented to person reliably and sometimes to place. He was on continuous enteral feedings through a nasogastric tube until a week ago when a percutaneous endoscopic gastrostomy tube was placed. He has a right-arm peripherally inserted central catheter line, through which he is receiving antibiotics for pneumonia.

Mr. P. is scheduled for a tracheostomy tomorrow. He has a continuous bladder catheter and an incontinence fecal bag in place draining liquid stool. Physical therapy consultation was made on day 3, and once each day, he is transferred by three care givers to a stretcher chair for 4 to 6 hours. He cannot hold a pencil to write and has difficulty communicating.

1. What factors place Mr. P. at increased risk for developing pressure ulcers?
2. What are Mr. P.'s risk factors related to compromised integument that may lead to infection?
3. What nursing interventions would you use to reduce the risk to integument?

52 Patient Management: Integumentary System

Susan Luchka

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Define specific terms related to wounds: *acute wound, chronic wound, partial thickness, full thickness, stages of wound healing*.
2. Explain the normal healing process.
3. Describe what is meant by *primary intention*, *secondary intention*, and *tertiary intention*.
4. Describe nursing care for the patient with a wound.
5. Discuss the influence of nutrition and pharmacotherapy on wound healing.

Nursing management of wounds is both challenging and rewarding. Effective wound care requires a sound knowledge base and meticulous method. This chapter discusses wounds, such as pressure ulcers and skin tears, the healing process, and nursing assessment, management, and patient teaching related to caring for serious wounds that need ongoing care.

▲ Types of Wounds

A wound is simply a break in skin integrity. Wounds may be acute or chronic. An acute wound is a wound that follows an orderly, sequential healing process, resulting in an area that has anatomical and functional integrity.[1,2] Acute wounds are caused by surgery or trauma. Conversely, a chronic wound fails to yield an area that has anatomical and functional integrity. Chronic wounds fail to follow an orderly, sequential process because of precipitating factors, such as diabetes, pressure, malnutrition, peripheral vascular disease, immune deficiencies, and infection.[1,2] An acute wound may become a chronic wound at any time.

Acute and chronic wounds may be defined as partial- or full-thickness wounds. Partial-thickness wounds involve the epidermis and may involve the dermis. A partial-thickness wound is a shallow wound that is usually moist and painful (because the loss of the epidermis exposes the nerve endings). Full-thickness wounds involve the loss of the epidermis, dermis, and subcutaneous tissue, and they may involve muscle, tendons, ligaments, and bone. A full-thickness wound involves a large amount of tissue loss and appears as a crater or crevice.

Pressure ulcers and leg ulcers are two specific types of wounds that may be seen in the critical care setting. Critically ill patients are at risk for developing pressure ulcers related to hemodynamic factors, disease processes, immobility, and nutritional deficits. Leg ulcers are due to specific disease processes. Both pressure ulcers and leg ulcers may complicate the critically ill patient's overall recovery.

Pressure Ulcers

Pressure ulcers are wounds caused by pressure, shearing, and friction. Pressure ulcers start as acute wounds but become chronic in patients with other risk factors. Risk factors for the development of pressure ulcers include prolonged and impaired mobility, incontinence, malnutrition, diabetes, spinal cord injuries, metastatic cancers, decreased level of consciousness, impaired mental status, and peripheral vascular disease.[1–3] A patient teaching guide for pressure ulcers is shown in Box 52-1.

Pressure ulcers are the only type of wound that is staged. Staging occurs when the wound is assessed and documented.

- Stage I is defined as nonblanchable erythema of intact skin. In patients with darker skin, the stage I pressure ulcer may be red, blue, or purple. It may be accompanied by hardness, induration, and edema.
- Stage II involves partial-thickness tissue loss and presents as a fluid-filled blistered or denuded area (a shallow open wound).
- Stage III is a full-thickness wound involving the subcutaneous tissue and presents as a crater.
- Stage IV is also a full-thickness wound involving a large amount of tissue loss. A stage IV wound extends through the subcutaneous tissue and deep into the fascia, involving muscle, bone, ligament, or tendon.
- Unstageable is a pressure ulcer covered by eschar (black, brown, tan) or slough (yellow, brown, grey, green, or tan), which prevents assessment of the wound bed. The wound must be débrided prior to staging.
- Suspected deep tissue injury is a localized maroon or purple discolored area of intact skin or a blood-filled blister. The area is usually tender, mushy, or boggy.[3]

BOX 52-1 TEACHING GUIDE Pressure Ulcers

- Pressure ulcers are also known as *pressure sores* or *bed sores*.
- Pressure ulcers occur in people who have trouble moving around easily.
- At first, a pressure ulcer is just a reddened, tender area. If pressure is not relieved, the skin in this area may break down (open up or pull off, forming a blistered area). Pressure ulcers can destroy the underlying muscles, bone, ligaments, and tendons if they are not treated.
- Risk factors for pressure ulcers include difficulty moving around, medical problems (such as diabetes), spinal cord injury, incontinence of urine and stool, surgeries that limit mobility for an extended period (such as hip or knee replacement surgery), poor nutrition, and poor hydration (decreased fluid intake).
- Pressure ulcers occur most frequently over bony prominences (eg, heels, sacral area, hips, and shoulder blades), but they can occur anywhere on the body where there is constant pressure that is unrelieved.
- Many times, pressure ulcers can be prevented by turning the person in bed at least every 2 hours and by placing a pillow under the person's ankles to keep the heels off the bed, thus relieving pressure. A specialty bed may also be used to decrease pressure.
- *Not all pressure ulcers can be prevented*. The person's medical condition, nutrition and hydration status, immune status, and overall health status are all factors that affect the person's risk for developing pressure ulcers.
- Treatment depends on the type of pressure ulcer and the person's health status.

Reverse staging is inappropriate. The tissue that fills in the wound bed is not the same as the tissue that has been lost. Lost muscle or subcutaneous tissue cannot be replaced. Therefore, it is appropriate to document "healing stage IV wound," but it is not appropriate to document "stage IV wound now stage III."

Pressure ulcers covered by eschar or slough are considered unstageable. Eschar prevents the assessment of the wound bed. Documentation is "unstageable, wound covered by eschar/slough." If the wound is débrided, it may then be staged.

The standards of care for pressure ulcers are established by the Agency for Healthcare Research and Quality (AHRQ), the Wound Ostomy and Continence Nurses (WOCN), the National Pressure Ulcer Advisory Panel (NPUAP), and the European Pressure Ulcer Advisory Panel (EPUAP).

The most recent standards of care were set by the NPUAP and the EPUAP in 2009 and are considered the gold standard at this time. These standards guide institution policy and procedure and are supported by evidence-based practice.

The Wound Ostomy and Continence Nurses Society (WOCN) have expanded the AHRQ standards through evidence-based practice. The WOCN issues clinical practice guidelines that apply evidence-based practice, new research and drugs, and the AHRQ standards. Guidelines specific to wound care are:

- Guidelines for Management of Wounds in Patients with Lower Extremity Arterial Disease (2002)
- Guideline for the Prevention and Management of Pressure Ulcers (2003)
- Management of Wounds in Patients with Lower-Extremity Neuropathic Disease (2004)
- The V.A.C. Therapy Clinical Guidelines (2007)
- NPUAP-EPUAP Guidelines for Pressure Ulcer Prevention and Treatment (2009)

Leg Ulcers

Leg ulcers are chronic wounds seen frequently in critically ill patients with underlying health problems, such as venous stasis ulcers, arterial ulcers, and diabetic foot ulcers. Although patients with leg ulcers may have a high risk for pressure ulcers, leg ulcers are not pressure ulcers and are not staged.

Venous Stasis Ulcers

Venous stasis ulcers are usually found on the medial aspect of the lower leg, superior to the medial malleolus.[1,2] The wound margins are irregular and present as shallow craters, and the wound margins and lower leg may have a ruddy appearance or hemosiderin staining.[1,2] The drainage from venous stasis ulcers may vary from mild to heavy. The primary treatment for venous stasis ulcers is compression therapy using an Unna boot or a multiple-wrap dressing.[1,2] Multiple-wrap dressings have the advantage of continuous compression, which may not be achieved with the Unna boot. The affected leg is elevated above heart level to decrease edema (edema impedes the healing process).

Arterial Ulcers

Arterial ulcers (ischemic ulcers) are usually found on the distal leg, medial malleoli, and dorsal aspect of the foot and toes.[1,2] The wound margins of arterial ulcers are round, smooth (*not* irregular), and frequently described as having a punched-out appearance.[1,2] Arterial ulcers have pale wound beds and may be shallow or deep. The affected leg may be cool to the touch, cyanotic, and pale with minimal hair distribution. The patient experiences increased pain to the affected area if the leg is elevated.[1,2] The primary dressing for arterial leg ulcers is an occlusive dressing. Healing does not occur unless the vascular deficit is addressed surgically.

Diabetic Foot Ulcers

Diabetic foot ulcers are found in patients with diabetes and are frequently not recognized early, owing to the patient's accompanying neuropathy. The primary locations for diabetic foot ulcers are the plantar aspect of the foot, heels, and metatarsals.[1,2] To promote wound healing, a dressing that provides a moist environment is used most often. The ulcer area usually needs débridement and must be assessed carefully for infection. Other treatment modalities include off-loading the patient's weight using special shoes. Osteomyelitis is always a concern in patients with diabetic foot ulcers. Healing is prolonged because of the diabetes. Therefore, it is important to aggressively manage the diabetes to promote an optimal healing environment.

Skin Tears

Skin tears (partial-thickness wounds) are acute wounds secondary to the removal of tape or transparent occlusive dressings. Skin tears occur when the skin is thin and fragile. Fragile skin may be due to age, disease process, nutritional status, drug therapy (ie, steroids), or a combination of these factors. The skin is so fragile that it literally tears as tape or plastic film dressings are removed.

It is a common misconception that plastic film dressings, wound closure strips (Steri-Strips), or wound adhesives should

be applied to skin tears. Plastic film dressings and Steri-Strips potentiate more skin tears as they are removed or become dislodged. Because it is difficult to approximate the wound margins in a skin tear, wound adhesive frequently drips into the wound bed, prolonging healing and promoting infection.

Skin tears are cleansed gently with normal saline solution (or other institution-approved cleanser). Care is taken not to create a larger skin tear. After the wound area is cleansed, a hydrogel is applied to the wound and covered with a nonadherent dressing. Then the wound is wrapped with a self-adherent wrap, such as Kling or Coban, to hold the dressing in place without using tape on the skin. It is important to minimize the use of adhesives in all forms for patients prone to skin tears.

▲ Wound Healing

Optimal wound healing occurs in a moist (not extremely wet or dry) environment. The wound-healing process consists of three phases (Fig. 52-1).

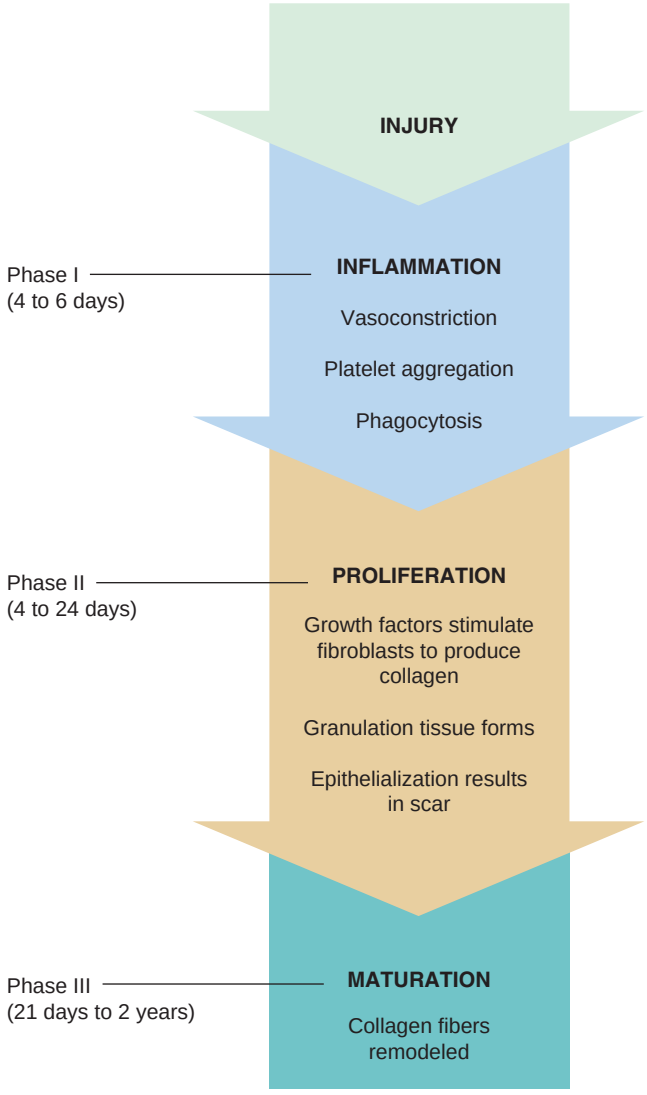

FIGURE 52-1 ▲ The stages of wound healing.

Phases of Wound Healing

The first phase is the *inflammatory phase*, which occurs immediately after the wound occurs. At the time of injury, there is immediate vasoconstriction; this is the body's way of controlling bleeding. Once vasoconstriction occurs, platelets collect at the site and deposit fibrin to form a clot. The vasoconstriction holds the wound together, and the platelets with their fibrin clot formation essentially "plug the hole." Phagocytosis also occurs during the inflammatory phase. Phagocytosis is the release of macrophages at the site of injury to destroy any bacteria that may be present and to remove the wound's cellular debris. This is the body's way of providing the optimal environment for wound healing (ie, a clean wound bed). It is at this time that growth factors are also present at the site of the injury. Overall, the inflammatory phase is estimated to last between 4 and 6 days. Visual assessment of the wound during the inflammatory phase reveals a wound with erythema, edema, and pain.

The second phase of wound healing is the *proliferation phase*. Growth factors stimulate the fibroblast to produce collagen. Collagen, along with new blood vessels and connective tissue, creates granulation tissue. Visual assessment of the wound at this point reveals a wound that is beefy red and shiny with a grainy or bumpy appearance. The appearance of granulation tissue prompts the wound margins to contract. Pulling together of the wound edges decreases the overall size of the wound. The last step of the proliferation phase is *epithelialization* or *reepithelialization*. Epithelialization results in a scar. The estimated overall duration of the proliferation phase is anywhere from 4 to 24 days.

The final and third phase of wound healing is the *maturation phase*. During the maturation phase, the collagen fibers are remodeled. The goal is to increase the tensile strength of the scar tissue. It has been estimated that only 70% to 80% of the skin's original strength is attained when the wound is healed. The maturation phase can extend from 21 days to 2 years. The outcome is always an area of tissue that is at greater risk for breakdown and more fragile than undamaged tissue.

If the wound becomes extremely wet or dry, the phases of wound healing occur, but at a slower rate. This may affect the final quality of the scar tissue with respect to anatomical and functional integrity as well as tensile strength. The patient's age and physical status also have an impact on the healing process (Box 52-2). Other factors that affect wound healing are listed in Table 52-1.

BOX 52-2 CONSIDERATIONS FOR THE OLDER PATIENT

Factors That Affect Wound Healing

- Less subcutaneous tissue
- More fragile skin secondary to age and drug therapy
- Increased number of precipitating risk factors for pressure ulcers
- Increased number of precipitating risk factors for chronic wounds
- Nutrition: less than or more than body requirements
- Decreased ability to care for self with age
- Decreased immune system function
- Decreased pulmonary and cardiovascular function
- Increased potential for incontinence (urine and stool)

Table 52-1 Factors Affecting Wound Healing

Factors	Rationale	Nursing Interventions
Age of patient	The older the patient, the less resilient the tissues.	Handle all tissues gently.
Handling of tissues	Rough handling causes injury and delayed healing.	Handle tissues carefully and evenly.
Hemorrhage	Accumulation of blood creates dead spaces as well as dead cells that must be removed. The area becomes a growth medium for organisms.	Monitor vital signs. Observe incision site for evidence of bleeding and infection.
Hypovolemia	Insufficient blood volume leads to vasoconstriction and reduced oxygen and nutrients available for wound healing.	Monitor for volume deficit (circulatory impairment). Correct by fluid replacement as prescribed.
Local Factors		
Edema	Reduces blood supply by exerting increased interstitial pressure on vessels.	Elevate edematous part; apply cool compresses.
Inadequate Dressing Technique Too small Too tight	 Permits bacterial invasion and contamination Reduces blood supply carrying nutrients and oxygen	 Follow guidelines for proper dressing technique.
Nutritional deficits	Protein–calorie depletion may occur. Insulin secretion may be inhibited, causing blood glucose level to rise.	Correct deficits; this may require parenteral nutritional therapy. Monitor blood glucose levels. Administer vitamin supplements as prescribed.
Foreign bodies	Foreign bodies retard healing.	Keep wounds free of dressing threads and talcum and powder from gloves.
Oxygen deficit (tissue oxygenation insufficient)	Insufficient oxygen may be due to inadequate lung and cardiovascular function as well as localized vasoconstriction.	Encourage deep breathing, turning, controlled coughing.
Drainage accumulation	Accumulated secretions hamper healing process.	Monitor closed drainage systems for proper functioning. Institute measures to remove accumulated secretions.
Medications		
Corticosteroids	May mask presence of infection by impairing normal inflammatory response	Be aware of action and effect of medications patient is receiving.
Anticoagulants	May cause hemorrhage	
Broad-spectrum and specific antibiotics	Effective if administered immediately before surgery for specific pathology or bacterial contamination. If administered after wound is closed, ineffective because of intravascular coagulation.	
Patient overactivity	Prevents approximation of wound edges. Resting favors healing.	Use measures to keep wound edges approximated: taping, bandaging, splints. Encourage rest.
Systemic disorders Hemorrhagic shock Acidosis Hypoxia Renal failure Hepatic disease Sepsis	These depress cell functions that directly affect wound healing.	Be familiar with the nature of the specific disorder. Administer prescribed treatment. Cultures may be indicated to determine appropriate antibiotic.
Immunosuppressed state	Patient is more vulnerable to bacterial and viral invasion; defense mechanisms are impaired.	Provide maximum protection to prevent infection. Restrict visitors with colds; institute mandatory hand hygiene by all staff.
Wound stressors Vomiting Valsalva maneuver Heavy coughing Straining	Produce tension on wounds, particularly of the torso.	Encourage frequent turning and ambulation and administer antiemetic medications as prescribed. Assist patient in splinting incision.

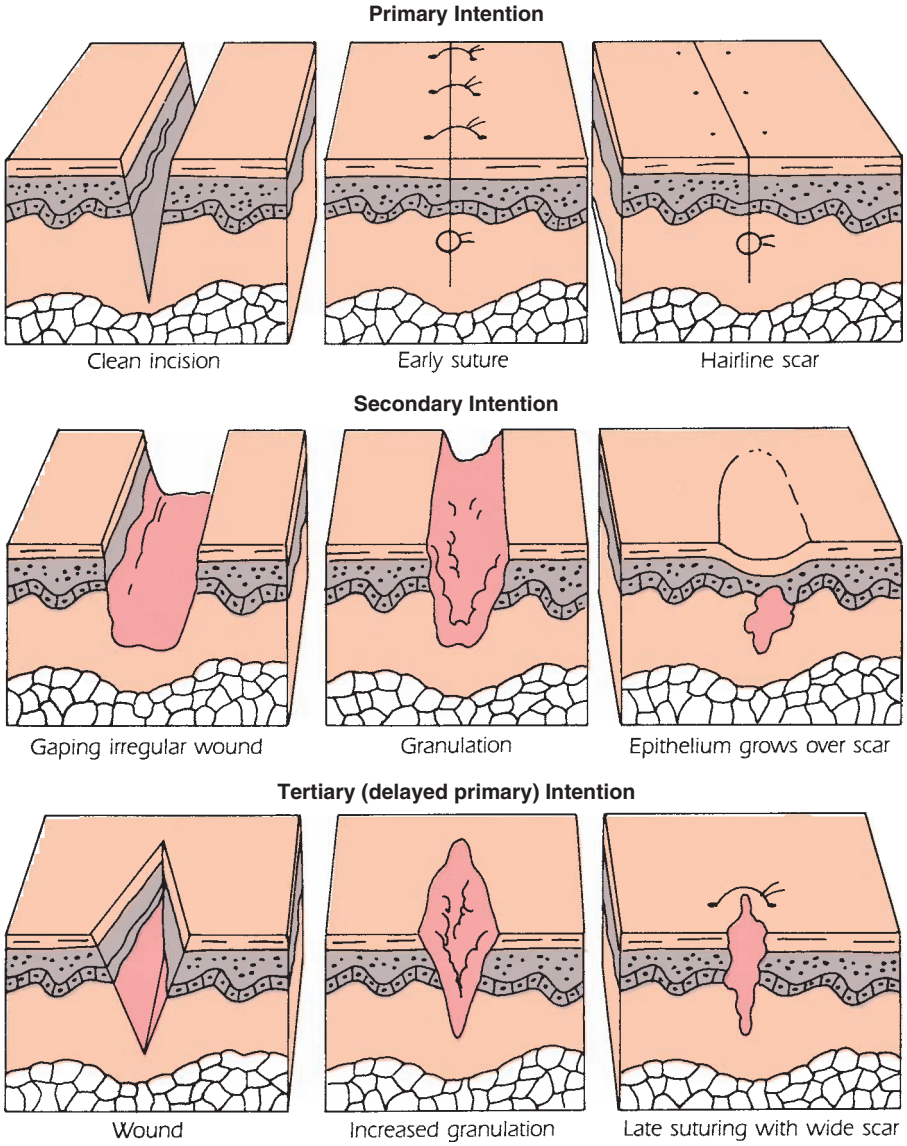

FIGURE 52-2 ▲ Types of wound healing: primary intention healing, secondary intention healing, and tertiary intention healing. (Adapted from Smeltzer SC, Bare BG, Hinkle JL, et al: Brunner & Suddarth's Textbook of Medical–Surgical Nursing, 12th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 474.)

Methods of Wound Healing

Wounds can heal through primary intention, secondary intention, or tertiary intention (Fig. 52-2). *Intention* is used for acute or surgical wounds. The edges of the wound are drawn together (approximated), shortening the time required for the wound to heal to about 4 to 14 days overall. Primary intention is associated with a decreased risk for infection and minimal scarring. With primary intention, not only is scarring minimal and the risk for infection decreased, but the amount of tissue loss is decreased.

Secondary intention is seen most frequently in chronic wounds but can occur in acute wounds, when the wound edges cannot be approximated to each other because of a significant tissue loss. An example of secondary intention is a pressure ulcer or a venous stasis ulcer. The potential for infection is increased because of the inability to approximate the edges, thus leaving the area open to bacteria. Scarring may also be significant, depending on the amount of tissue loss.

The last form of wound repair is *tertiary intention*, which may also be called *delayed primary intention*. Tertiary (delayed primary)intention should not be confused with primary intention. With this type of wound healing, the wound is not closed for a period (usually 3 to 5 days) to allow infection, edema, or both, to resolve. During this time, the wound is packed or irrigated to remove exudate and cellular debris. When the edema and risk for infection have decreased, the wound edges are approximated, and the wound is closed as it is in primary intention. Scarring is usually greater than that seen with primary intention but less than that seen with secondary intention.

▲ Wound Assessment

Wound assessment is performed in an orderly, sequential manner (Box 52-3). The location of the wound is defined as precisely as possibly using anatomical terminology

BOX 52-3 Wound Assessment

Location: Document the location, using anatomical positions.
Size: Document the size, in centimeters or millimeters. Measure the length (by clock positions) from the 12- to 6-o' clock position. Measure the width from the 9- to 3-o' clock position.
Depth: Use a sterile swab to determine the depth of the wound (see Fig. 52-4).
Undermining or tunneling: Document the presence or absence of undermining or tunneling (see Fig. 52-5).
Tissue type: Describe the wound bed. If the wound bed is not visible, document the presence and condition of the eschar (scab), sutures, staples, or other wound closure.
Drainage: Note the presence or absence of drainage. If drainage is present, describe its odor, color, amount, and consistency.
Wound margins: Describe the wound margins (approximation, condition, and appearance of surrounding tissue).
Drains and tubes: Note the type of drain or tubing and its location (using anatomical or clock positions).
Condition of dressing: Describe the amount and type of drainage on the dressing, as well as the ease with which the dressing was removed.
Pain: Evaluate on a 0 to 10 scale (or other institution-approved assessment scale). Provide pain relief as needed before, during, and after wound assessment or dressing change.

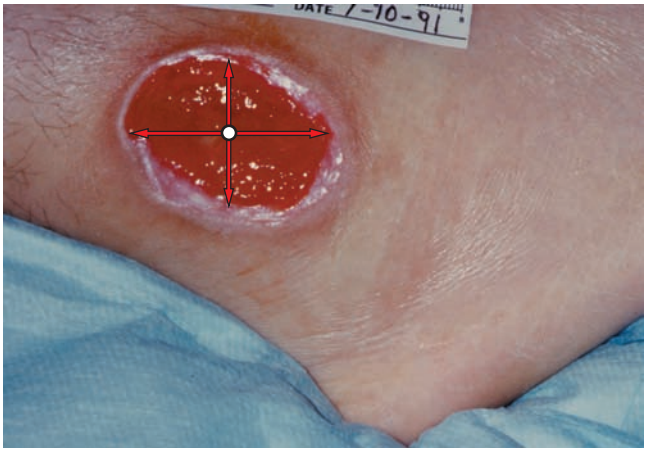

FIGURE 52-3 ▲ Wound measurement. Linear measurements of a wound should be taken at the greatest length and width perpendicular to each other, as shown. (From Baranoski S, Ayello EA: Wound Care and Essentials Practice Principles, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2008, p 84.)

(eg, "medial aspect of the left lower leg, 10 cm distal to the knee"). Using correct anatomical terminology allows other health care professionals to visualize the location of the wound. Correct location is especially important if the patient has more than one wound. Photography may be used, more frequently in chronic wounds than in acute wounds. Factors to consider when using photography are lighting consistency and distance. To portray the wound accurately, room lighting and distance from the wound must be as identical as possible from one photograph to another.

The size of the wound should always be measured in centimeters, millimeters, or both.[2,3] Terminology such as "the size of a half dollar" should be avoided. This leads to inconsistent and inaccurate documentation. Linear measurements of a wound are taken at the greatest length and width perpendicular to each other (Fig. 52-3).

Depth of the wound is measured by placing a sterile swab in the deepest area of the wound and marking the location of the wound's margin on the swab.[2] The sterile swab is dipped in normal saline solution before inserting it into the wound to minimize the potential of leaving cotton fibers in the wound. After removing the swab, measure from the distal tip of the swab to the area that was marked. Documentation includes the depth in centimeters and also the location where the assessment was made (eg, "depth 5.8 cm in the distal wound bed in the 9-o' clock position") (Fig. 52-4). Clear, concise documentation allows other health care professionals to reassess the wound depth in the same area with each reevaluation.

Undermining and tunneling do not occur in acute wounds, but the nurse always assesses the wound for their presence. Undermining occurs when there is the loss of tissue along the wound margins, the "lip of tissue."[2] Tunneling is exactly what it implies, a tunnel opening somewhere in the wound bed.

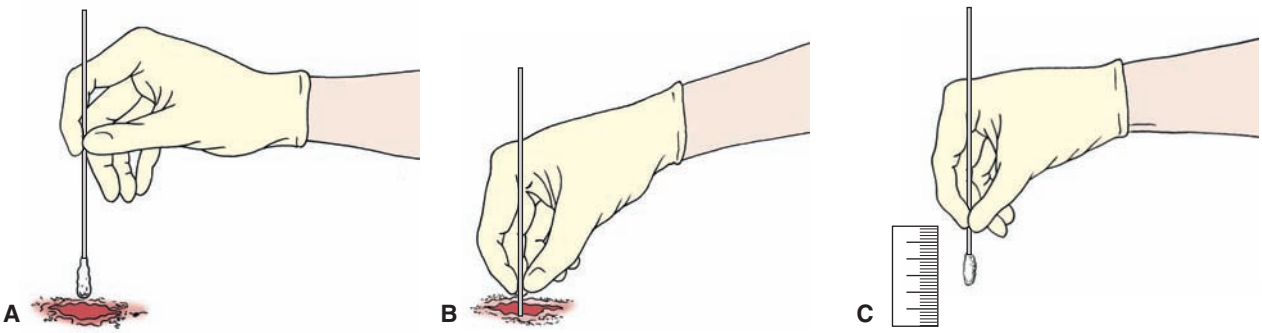

FIGURE 52-4 ▲ Procedure for measuring wound depth. **A:** Put on gloves. Gently insert the swab into the deepest portion of the wound that you can see. **B:** Grasp the swab with your thumb and forefinger at the point corresponding to the wound margin. **C:** Carefully withdraw the swab while maintaining the position of your thumb and forefinger. Measure from the tip of the swab to that position. (From Thomas Hess C: Clinical Guide: Wound Care, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2008, p 25.)

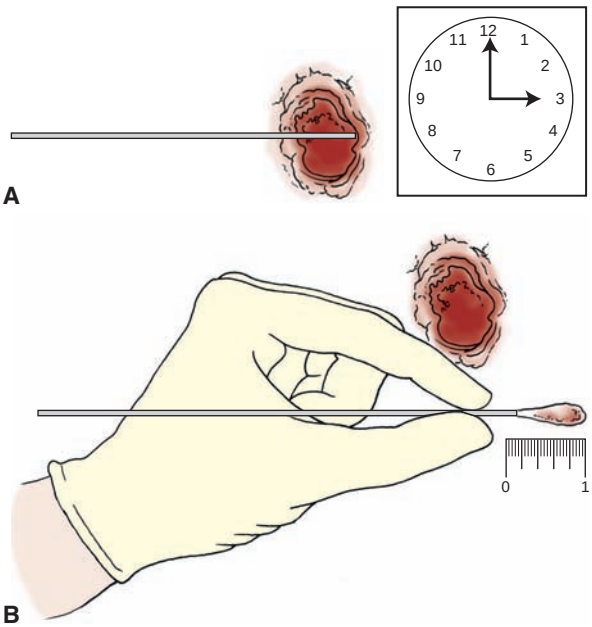

FIGURE 52-5 ▲ Procedure for determining the direction and depth tunneling. **A:** To assess the direction of tunneling, put on gloves and insert the swab into the sites where tunneling occurs. Progressing in a clockwise direction, document the deepest sites where the wound tunnels. (Twelve o'clock points in the direction of the patient's head, so in this example, tunneling occurs at three o'clock.) **B:** To assess the depth of tunneling, insert the swab into the tunneling areas, and grasp the swab where it meets the wound margin. Remove the swab, place it next to a measuring guide, and document the measurement centimeters. (From Thomas Hess C: Clinical Guide: Wound Care, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2008, p 27.)

Tunneling can begin in acute wounds in which there are drains. (Note that if tunneling occurs, the wound is not an acute wound but has become a chronic wound.) A sinus tract is an opening somewhere in the wound bed that extends into the tissue ending with a "small pocket" of open area. The process for assessing the direction and depth of tunneling is shown in Figure 52-5.

Determining the tissue type entails visual assessment of the wound bed. The tissue in the wound bed should be beefy red (as opposed to pale). The presence or absence of granulation tissue (shiny red, grainy, or bumpy tissue) is noted. The nurse assesses for necrotic tissue, which presents as black or brown tissue. Slough may also be present in the wound bed. Slough is yellow and stringy. If the wound bed is not visible, the presence or absence of eschar (scab), sutures, staples, Steri-Strips, wound adhesives, or negative pressure dressings is documented.

The presence or absence of drainage is also important to note, along with the location of the drainage or exudate (eg, "drainage/exudate noted at the proximal end of the wound"). The drainage or exudate needs to be assessed for odor, color, consistency, and amount (eg, "abdominal dressing of ten 4″ × 4″ gauze pads is saturated with serosanguineous drainage every 2 hours").

The wound margins are also assessed when performing a wound assessment. Are the edges well approximated? Is the surrounding tissue clean, dry, reddened, edematous, pale, intact, or blistered? Again, it is important to be as exact as possible to paint an accurate picture of the wound margins for the next health care professional.

Drains or tubes may be present in or near the wound bed. Drains or tubes are assessed for location, the appearance of the surrounding tissue, and the characteristics of the drainage. Consider the insertion site of a drain or tube as an acute wound in itself.

The dressing is assessed after it is removed. The soiled dressing's condition (eg, "saturated"), the ease with which the dressing was removed (eg, "sticking"), and the location and type of drainage on the dressing are described. If the dressing came off without being removed by the nurse, this is noted as well (eg, "dressing found lying in bed—wound uncovered").

Pain is assessed using an institution-approved standardized scale, such as the 0 to 10 scale. The patient should never be in pain while a wound is being assessed. If the patient experiences pain during wound assessment, the assessment should be stopped, and the patient should be medicated before continuing. Management of pain as it relates to wound assessment and care is discussed in more detail later in this chapter.

Wound documentation includes all descriptions and measurements, the presence and absence of pain during the procedure, and the type of dressing applied.[1–3] Many institutions use special wound measurement tools, wound assessment tools, and documentation tools (eg, flow sheets or computerized documentation) for wound documentation. The presence or absence of wounds must be documented upon admission per Medicare guidelines by both the physician and the nurse. Pressure ulcers are considered preventable; therefore, if the patient develops a pressure ulcer during hospitalization, the hospital will not be reimbursed for the care.

▲ Wound Care

Nursing diagnosis for patients with wounds revolves around a few basic themes[4] (Box 52-4). Wound care seeks to address these problems.

Wound Cleansing

The goal of cleansing the wound is to remove bacteria and cellular debris without damaging the wound bed or granulating tissue. The periwound area must also be cleansed

BOX 52-4 NURSING DIAGNOSES

For the Patient With an Acute or Chronic Wound

- Acute Pain related to acute débridement and wound care
- Ineffective Peripheral Tissue Perfusion related to immobility, edema, infection decreased cardiac output
- Impaired Tissue Integrity related to etiology/contributing factors of wound development
- Imbalanced Nutrition: Less Than Body Requirements
- Risk for Infection related to altered skin integrity
- Disturbed Body Image related to dysfunctional open wound, scarring, or amputation
- Risk for Imbalanced Fluid Volume related to metabolic changes
- Risk for Electrolyte Imbalance related to metabolic changes
- Impaired Physical Mobility related to wound

to prevent bacteria from migrating into it. All wounds are cleansed before reapplying the dressing. Normal saline solution is the safest wound cleanser. Some commercial cleansers are also safe for the wound bed. Solutions to be avoided when cleansing wounds are povidone-iodine, acetic acid, sodium hypochlorite (Dakin's solution), and hydrogen peroxide. These solutions are toxic to epithelial cells and thereby impede granulation and wound healing.

Open wounds are cleansed starting in the middle and moving outward in a circular motion to include the periwound area. Incisions are cleansed from top to bottom, again starting in the middle and moving outward to include the periwound area.

Wound Closure

The goal of all wound care is ultimately the closure of the wound and restoration of skin integrity. Wound closure is usually promoted by various types of treatments and dressings.

Vacuum-Assisted Wound Closure (Negative Pressure Therapy)

Vacuum-assisted wound closure (VAC) is a system that assists wound closure by providing localized negative pressure to the wound bed and wound margins. The occlusive dressing promotes a moist environment for healing, and the negative pressure removes excessive wound drainage, which assists in pulling the wound margins together (Fig. 52-6).[5]

Tubing, similar to that of suction tubing, is placed into a special foam dressing. The foam dressing is shaped in wedges that are cut to fit the wound. The sponge wedge and tubing are then covered with an occlusive transparent dressing. The tube is then connected to the vacuum unit at low suction levels (as directed by the manufacturer). The negative pressure draws the wound edges together by collapsing the foam dressing and removing wound fluids while maintaining a moist wound environment that promotes healing. If the dressing is not collapsed, there is a leak in the system, and the dressing must be replaced with attention given to the transparent occlusive dressing application. The transparent occlusive dressing must be securely in place to maintain negative pressure in the wound. Dressings have the appearance of being "vacuum packed" when the dressing is secure and occlusive.

With the VAC system, granulation tissue is stimulated, infection and bacterial colonization are decreased, and wound closure occurs in a moist "vacuum" environment. In addition, the VAC system decreases the frequency of dressing changes, thus decreasing patient discomfort and nursing time.[5]

The VAC system can be used in both acute and chronic wounds.[5] The VAC system may be indicated for chronic wounds (including diabetic and nonhealing stage III and IV pressure ulcers); flaps and grafts (both acute surgical wounds); dehisced incisions; acute and traumatic wounds; and burns. Dehisced incisions are ones that split open along natural or sutured lines. The VAC system should be used with extreme caution in patients with active bleeding, those who are on anticoagulant therapy, or patients with a history of uncontrolled bleeding.[5] The VAC system is contraindicated for any patient with untreated osteomyelitis, necrotic tissue with eschar, malignancies of the wound, or nonenteric and unexplored fistulas. The foam wedge dressing is not to be placed in direct contact with exposed blood vessels, organs, or nerves. VAC sponges must be positioned on viable tissue; therefore, if necrotic tissue or devitalized tissue is present, the wound needs to be débrided before the VAC sponges can be placed. The VAC system may be used in an infected wound but only with appropriate antibiotic therapy.[5] Patients at risk for bleeding must be monitored carefully, and if bleeding occurs, the VAC therapy must be discontinued.[5]

The use of the VAC system continues to increase as clinical case studies show positive patient outcomes in grafts, flaps, and orthopedic surgeries. The use of wound irrigations or instillations (antibiotics or anesthetic agents) in conjunction with this type of wound therapy is another promising area.

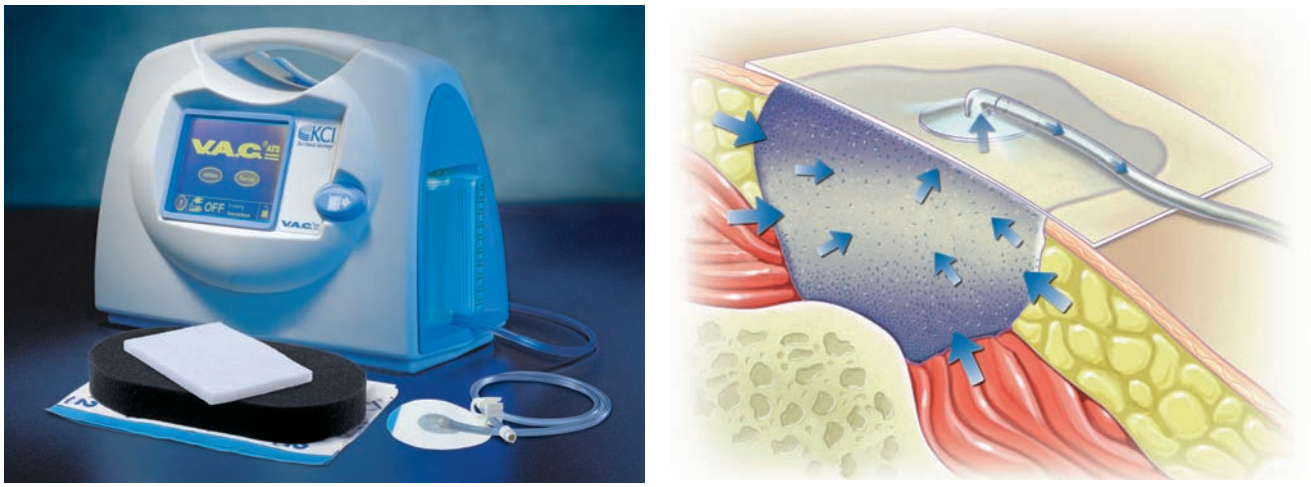

FIGURE 52-6 ▲ A vacuum-assisted wound closure device, such as the V.A.C. ATS device shown here, assists wound closure by providing localized negative pressure to the wound bed and wound margins. (Courtesy of KCI Licensing, Inc., 2007.)

VAC therapy also has made an economic impact. It decreases the length of wound healing, nursing labor, supplies, length of stay, complications, and hospital readmission, while it promotes the salvage of limbs.[5] In addition, this therapy has an emotional impact that can be directly related to the nursing diagnosis of Disturbed Body Image related to dysfunctional open wounds, scarring, or amputation.[4]

It is the nurse's responsibility to be familiar with the operation and maintenance of the VAC system. Nursing responsibilities include wound assessment and documentation, along with placing the patient on the VAC system, changing the canister, and maintaining the system. The wound should demonstrate progressive healing. If documentation fails to demonstrate progressive wound healing within 30 days, then alternative therapies must be considered.

Sutures, Staples, and Wound Adhesives

Sutures or staples must be cleaned with sterile normal saline solution or a wound cleanser. Immediately after surgery, the wound needs to be covered with a dry sterile dressing. Frequently after the initial postoperative period, the staples or sutures are left open to air.

Wound adhesives may be used on surgical or traumatic wounds to approximate the wound margins, in which case sutures are used to close the underlying tissue, and the wound adhesive is applied topically to the wound margins as they are drawn together. Wound adhesives are not to be placed in the wound bed (only on the margins) because this may lead to delayed wound healing or infection. The wound adhesive appears like a shiny, clear coating over the incision. Caution is needed when applying wound adhesives because of their liquid status. Wound adhesives may inadvertently spread to other areas. Extreme caution must be exercised when using wound adhesives near the eyes. Incisions in which wound adhesives are used are not rubbed or soaked with any wound cleaner. They may be gently rinsed. Steri-Strips should not be used in conjunction with wound adhesives. Wounds in which a wound adhesive has been used are left uncovered.

Wound Drainage

Often, a drain is inserted in the wound to prevent the pooling of exudate in the wound bed. Pooling of exudate in the wound bed decreases healing and increases the potential of infection or tunneling. The most common types of drains are Hemovac drains, Penrose drains, Jackson-Pratt drains, and chest tubes. Basic care of all drains and chest tubes includes cleansing with sterile normal saline solution and applying a dressing. The dressing stabilizes the drain and prevents the drain insertion site from coming in contact with drainage and other potentially infectious surfaces. Drain and tube insertion sites are never left open to air because of the risk for infection. If drainage from another source may potentially saturate the dressing (over the drain site), the dressing also needs to be occlusive. Drain tubing is stabilized with tape to decrease the potential for inadvertent dislodgment, removal, and pain. Inadvertent removal of a drain potentiates pain and infection, and an acute wound may become a chronic one.

Antibiotic preparations (eg, bacitracin or Neosporin) may be applied, although hydrogen peroxide and povidone-iodine (Betadine) ointment are always avoided because they destroy granulation tissue and prolong the healing process. Normal saline solution causes no damage to the wound bed and is physiologically normal and cost-effective. Some institutions may use prepared wound cleansers. Most wound cleansers have some potential to destroy granulating tissue (compared with normal saline solution) but are less toxic to granulating tissue than hydrogen peroxide or Betadine. Prepared wound cleansers are improving rapidly, becoming less cytotoxic and more time-efficient and cost-effective.

Impregnated gauzes for packing and various solutions (eg, Betadine and Dakin's solution) may be used in the event that the wound is infected; however, they should not be used as a routine wound treatment for a prolonged time because they destroy granulating tissue and inhibit the normal healing process. Remember that the use of these products signals that the wound is not an acute wound but has become a chronic wound.

Wound Dressings

The goal of wound dressings is to protect the wound from infection and promote a moist environment. There are hundreds of dressing products available. The dressing of choice depends on the wound.

Wet-to-Dry Dressings

A wound healing by secondary or tertiary intention is frequently packed with wet-to-dry dressings. The use of wet-to-dry dressings is not recommended. Although wet-to-dry dressings are frequently used in clinical practice, evidence-based practice has shown they are actually detrimental to the wound. Wounds need a moist environment to heal without impediment. Changing a wet-to-dry dressing every 8 or 12 hours leads to the dressing becoming exceptionally dry. Thus, when it is removed, indiscriminate débridement of both necrotic and granulating tissue occurs. This constant débriding of the wound increases the patient's discomfort, promotes infection (caused by frequent dressing changes), slows the healing process, and may enlarge the wound. Wet-to-dry dressings affect not only wound healing but also health care costs by prolonging the healing time and increasing nursing labor and supply expenses.

Calcium Alginates and Foam Dressings

Wound healing by secondary or tertiary intention may also be promoted with calcium alginates or foam dressings (as opposed to wet-to-dry dressings). Calcium alginates are made from brown seaweed. They come in ropelike or flat pieces that must be "fluffed" and packed into the wound bed. Calcium alginates have an absorptive quality and can hold up to 20 times or more their weight in wound drainage. As the calcium alginate absorbs the wound drainage, its appearance changes from dry, fluffed strands to that of a gel that is easily removed from the wound. Calcium alginates may be covered with a hydrocolloid or a transparent dressing.

Foam dressings have the advantage of being highly absorptive. They are available in various shapes and sizes and are placed over the wounds. When it is time to remove the foam dressing, it is simply lifted off the wound. Minimal trauma occurs to the wound bed and surrounding tissue. Foam dressings, like calcium alginates, provide a moist wound environment.

Contraindications to calcium alginates and foam dressings vary according to the manufacturer. Caution should always be used if the wound is infected.

Hydrocolloids

Hydrocolloids are most frequently used in the care and treatment of stages I and II pressure ulcers. Hydrocolloids are occlusive, self-adhesive, and absorptive, although their absorptive capacity is not as great as that of calcium alginates or foam dressings. The advantage of hydrocolloids is that they need changing only every 3 to 5 days or if they are inadvertently removed. Contraindications to hydrocolloids depend on the manufacturer's recommendations. Again, caution is always used if the wound is infected.

Hydrogels

Hydrogels are most frequently used for dry wounds. They help maintain a moist wound environment, promoting granulation, epithelialization, and autolytic débridement. Hydrogels have a water or glycerin base.

Absorptive Wound Dressings

Absorptive dressings vary in construction; they are composed of hydrofibers, cellulose, rayon, or cotton. Absorptive dressings can contain larger amounts of exudates than calcium alginate dressings. Absorptive dressings may be used as primary or secondary dressings.

Silver (Ag) Dressings

Silver dressings are dressings that have been impregnated with silver. They may be topical dressings, such as Acticoat, which has the appearance of a 4″ × 4″ gauze pad and is placed against the wound bed, or hydrofiber dressings, such as Aquacel Ag, which is highly absorptive and can be packed into the wound. Many silver-impregnated dressings may be left in place for prolonged periods, which is advantageous for nursing care and patient teaching.

The silver has a bactericidal effect. Before the advent of antibiotics, silver was the treatment of choice for wound infections. The potential for bacteria to develop a resistance to silver is negligible; to date, only one possible case has been reported. Silver dressings work well in conjunction with other medical and pharmacotherapeutic treatments.

Bilayered Dressings

Bilayered dressings are engineered dressings that are applied as "grafts" to wounds that fail to progress with other treatment plans. These graft materials may be composed of fibroblast, collagen, and growth factors depending on the type and brand. They act by giving the (noninfective) chronic wound a "jump start." Examples of these dressings are Apligraf, Integra, and Oasis. They are frequently used on venous stasis ulcers and diabetic foot ulcers or on exposed bone, tendon, or joints. The cost of these graft materials is much more than conventional treatments; however, by "jump-starting" the process of wound healing, they may actually be more cost-effective in difficult cases.

Wound Débridement

At times, both acute (ie, grafts) and chronic wounds need to be débrided. Débridement is the removal of necrotic (dead) or devitalized tissue. Necrotic or devitalized tissue presents as dark brown, black, yellow, pale, cyanotic, or crusty eschar. To promote optimal wound healing, this tissue needs to be removed from the wound. Débridement creates an "acute wound," and the three phases of wound healing are initiated. Débridement may be performed in several ways: autolytic, chemical, mechanical, or laser. Occasionally, a combination of débridement methods may be used throughout the healing process. Combination therapy depends on the type of wound and its location, the patient's status, and physician preference.

Autolytic Débridement

In autolytic débridement, the body breaks down necrotic or devitalized tissue. Hydrocolloid dressings are frequently used to promote autolytic débridement. Autolytic débridement is not the optimal choice in wounds that have large amounts of necrotic tissue. Autolytic débridement takes time for the body to use its own ability to lyse and dissolve necrotic tissue.

Chemical Débridement

Chemical débridement is accomplished using collagen-based drugs applied topically to the wound. An example of a chemical débridement medication is Collagenase Santyl. Chemical débridement agents dissolve nonviable tissue. Product instructions must be reviewed before use.

Mechanical Débridement

Mechanical débridement can be accomplished by wet-to-dry dressings (which are not recommended), whirlpool procedures, or ultrasound treatment. Although wet-to-dry dressings are an effective method of débridement, care must be taken to change to another method of wound care when the wound bed is débrided. Use of the whirlpool procedure is controversial because although it does débride (but not effectively), the potential for infection is increased with multiple patients using a static number of whirlpools (even though they are cleaned between patients). Use of whirlpool procedures also leaves the wound margins macerated, which increases tissue loss, impeding wound closure. The use of ultrasound treatment for débridement requires more research/evidence-based practice to determine its effectiveness.

Sharps Débridement

In sharps débridement, using a scalpel or scissors, the wound bed is cleared of all necrotic and devitalized tissue surgically. This surgical procedure may require anesthesia, intravenous

conscious sedation, a local anesthetic, or a combination of the three.

Laser Débridement

Laser débridement may also be used to provide a clean wound bed. Currently, laser débridement is not performed as frequently as autolytic, chemical, and mechanical débridement. As technology advances, the use of laser débridement will become more common.

Biosurgical Débridement

Biosurgical débridement is the instillation of sterile larvae (maggots) into a wound. These sterile larvae selectively digest necrotic or devitalized tissue. However, they may not be accepted well by the patient.

Wound Cultures

Routine wound cultures are not recommended unless there are signs and symptoms of infection, such as fever, erythema, edema, induration, foul odor, purulent exudates, increased amount of exudate, abscess, cellulitis, discoloration of granulation tissue, friable granulation tissue (bleeds easily), increased or unexpected pain or tenderness, or an elevated white blood cell count. All wounds are considered contaminated and have the potential to become infected. Several methods may be used to culture a wound, including fluid biopsy, wound (tissue) biopsy, and surface culture (culture swab).

A surface culture is usually done first. The wound is cleansed or irrigated with sterile normal saline solution before swabbing the wound. Exudate and necrotic tissue are not cultured—doing so provides invalid results. After the wound is cleansed, the swab is gently rolled or rotated, starting at the 12-o'clock position and moving in a zigzag pattern from side to side down the wound to the 6-o'clock position.[2] Optimally, there should be 10 points of contact (Fig. 52-7).[2] A colony count of 100,000 organisms/mL indicates an infection that needs to be treated with the appropriate antibiotic.[6] At colony counts of greater than 100,000 organisms/mL, normal wound healing is inhibited, and the wound becomes a chronic wound.[2] Wounds that do not respond to antibiotic treatment need to be recultured. The most appropriate form of culture in this scenario is a wound biopsy. Wounds that contain necrotic tissue or tunneling need both aerobic and anaerobic cultures.

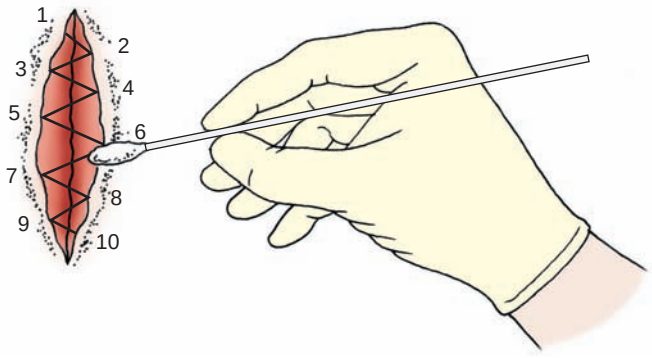

FIGURE 52-7 ▲ Procedure for collecting a wound culture. The wound edges are swabbed using 10-point coverage. (From Thomas Hess C: Clinical Guide: Wound Care, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2008, p 101.)

Use of Pressure-Relieving Devices

Pressure relief is a major component of wound care. A variety of methods may be used, ranging from low to high technology.[1–3,7] Programs that use both high- and low-technology solutions and adapt to meet the patient's needs at various stages in the recovery process tend to be the most successful.

The easiest and most effective treatment for pressure ulcers on the heels is to keep the heels off the bed by placing a pillow under the lower legs (a low-technology, cost-effective treatment). A schedule for turning and positioning the patient is an effective, easily implemented, and cost-effective intervention for relief of pressure. Critically ill patients may require specialty beds that are designed to reduce pressure. Many specialty beds inflate, deflate, alternate pressures, and laterally rotate. To prevent the occurrence of additional pressure ulcers, it is necessary to follow manufacturer's recommendations when positioning patients on specialty beds. Although these beds do relieve some pressure, they do not eliminate all pressure, as turning the patient from side to side does. Another pressure-relieving device is the Vollman-Turner device, which places the patient in the prone position (thus relieving all pressure on the patient's back). The Vollman-Turner device is not a specialty bed; rather, it is a device that is attached to the bed frame. The advantage of the Vollman-Turner device is that only a minimal number of people are needed to turn the patient.

Pain Management

In all areas of wound care (assessment, cleansing, dressing changes, and positioning), the nurse needs to focus on pain assessment and control. No procedure should occur without assessing for pain and then medicating the patient as needed. Once the pain is controlled, the nurse may proceed with the wound care. The choice of pain medication and the delivery method used (eg, continuous drip, epidural, patient-controlled analgesia pump, local anesthesia) depends on the patient's status.

Pharmacotherapy

Pharmacotherapy in wound care entails the use of pain medications and, in some cases, growth hormones and steroids. Pain medications are used to control pain during wound assessment, cleansing, and dressing changes. Growth hormones, for example, becaplermin (Regranex Gel 0.01%), may be used to stimulate wound healing. Regranex is applied topically to the wound in measured doses that are recalculated weekly or biweekly. The gel is spread evenly over the wound and covered with gauze moistened with saline solution. Topical steroid creams, such as clocortolone pivalate (Cloderm) and doxepin hydrochloride (Prudoxin), may be prescribed for wound care to relieve surface

inflammation and pruritus of the wound margins. Chemical débridement agents (discussed earlier) are also considered pharmacotherapy.

Although silver-impregnated dressings are referred to as antimicrobials, they are considered a dressing and not a pharmacotherapeutic agent. Silver gels such as SilvaSorb can be used instead of a silver-impregnated dressing. SilvaSorb gel is a combination of silver and a hydrogel applied into the wound and is a controlled-release formula.

Xenaderm is a protective ointment composed of balsam Peru, castor oil, and trypsin. This ointment increases blood flow to partial-thickness wounds while acting as a barrier in incontinent patients.

▲ Care of Specific Wounds

Pressure Ulcers

Pressure ulcer treatment depends on the stage of the wound. Stage I and II pressure ulcers are usually treated with hydrocolloid dressings. Stage III and IV pressure ulcers may be dressed using absorptive hydrofiber dressings in the wound bed or with calcium alginates fluffed and placed into the wound bed and then covered with hydrocolloid or occlusive transparent dressings. Although they are used, wet-to-dry dressings are not optimal, as previously discussed. Other options for stage III and IV pressure ulcers are foam dressings and the VAC system.

Burns

Burns are acute wounds, graded as first, second, or third degree and described as partial or full thickness. Wound care goals in burns are a clean wound, free from infection. Burns are cleaned with sterile normal saline solution or a mild soap and water. Topical ointments, such as bacitracin, polymyxin, or silver sulfadiazine, may be applied. After cleansing the wound, a dressing is applied. The type of dressing depends on the type of burn, the amount of tissue involved, institutional policy, and physician preference. Care of the patient with burns is discussed thoroughly in Chapter 53.

High-Volume Draining Wounds

Some wounds may have high volumes of exudate (drainage). Exudate is the response of the body to the inflammatory phase. Wound drainage is composed of neutrophils, macrophages, cellular debris, proteins, and toxins. High-volume draining wounds generate more drainage than traditional gauze pad dressings can manage, in which case hydrocolloids, calcium alginates, hydrogels, or foam dressings may be used. A composite dressing may also be used. These dressings combine the physical attributes of two or more dressings to enhance the absorptive capability.

If the exudate cannot be controlled with these measures, alternatives must be considered. The goal of wound care in this instance is to contain the drainage and protect the surrounding tissue from breakdown. Frequently, the wound maybe "pouched" or "bagged." The same supplies used for ostomy pouching are used for pouching a wound, or a product designed specifically for pouching high-volume draining wounds may be used. Pouching the high-volume draining wound allows for accurate measurement of output from the wound and protects the surrounding wound margins.

To pouch a wound, the skin is first cleaned with saline solution or an antibacterial soap and water, then dried. The skin may then be prepared with a protective skin barrier wipe, which protects the skin and enhances the adherence of the wafer. The wound is measured or traced, and a wafer is cut to fit. Stoma paste is applied around the cut-out area to prevent leakage of the drainage onto the skin. A one- or two-piece pouching system may be used. With a one-piece pouching system, the wafer with pouch is applied to the wound. With a two-piece system, the wafer is applied first, and then the pouch is attached. Both systems need a closure device at the end of the pouch. A benefit of a two-piece system is that it allows for pouch removal so that the wound can be assessed without disturbing the wafer. The wound margins need to be assessed for skin breakdown when the system is changed and may be protected by a variety of skin wipes or protective ointments.

▲ Nutrition and Wound Healing

In critical care, monitoring nutritional status is as important as monitoring hemodynamics. Nutrition needs to be addressed early in the patient's admission to promote the optimal opportunity and environment for healing. One study showed that patients who receive a nutritional assessment within the first 48 hours of admission to the hospital setting have a lower incidence of pressure ulcer development during their hospital stay.[8] Nutrition is paramount in critically ill patients or patients with wounds, whether the wounds are acute or chronic. To heal properly, the body needs adequate carbohydrates, fats, proteins, minerals, calories, vitamins, and hydration (Table 52-2).[1,2,8]

Protein is a basic and key component of all cellular activity. Without proteins, the inflammatory process is impaired, and the risk for infection increases. Proteins also affect oncotic pressure, which predisposes the patient to edema. Wound edema decreases the diffusion of oxygen and nutrients, impeding the healing process even more.

Although protein is a key component in the healing process, other nutrients play major roles. Carbohydrates are the body's fuel source and spare the proteins, so they can be used in cellular construction. Fats maintain cell membrane function and assist with the movement of minerals and fat-soluble vitamins in and out of the cell. Vitamins act as catalysts in the body's chemical reactions and are also needed for protein and cellular replication. Minerals are needed in the body's biochemical reactions and control the movement of fluids into and out of the cell, through the process of osmosis.

An adequate caloric intake is required for a wound to heal. Normal adult caloric intake is 25 to 30–40 kcal/kg/d, and the normal adult protein intake is 0.8 g/kg/d.[1,2] In a critically ill or critically injured patient, caloric and protein intakes must be dramatically increased. Caloric intake requirements

Table 52-2 Necessary Nutrients for Wound Healing

Nutrient	Function	Results of Deficiency
Proteins	• Wound repair • Clotting factor production • White blood cell production and migration • Cell-mediated phagocytosis • Fibroblast proliferation • Neovascularization • Collagen synthesis • Epithelial cell proliferation • Wound remodeling	• Poor wound healing • Hypoalbuminemia and generalized edema, which slows oxygen diffusion and metabolic transport mechanisms from the capillaries and cell membranes • Lymphopenia • Impaired cellular immunity
Carbohydrates	• Supply cellular energy • Spare protein	• Body uses visceral and muscle proteins for energy
Fats	• Supply cellular energy • Supply essential fatty acids • Cell membrane structure • Prostaglandin production	• Inhibited tissue repair • Use of visceral and muscle proteins for energy
Vitamin A	• Collagen synthesis • Epithelialization	• Poor wound healing • Impaired immunity
Vitamin C	• Membrane integrity • Antioxidant	• Impaired immunity • Poor wound healing • Capillary fragility
Vitamin K	• Normal blood clotting	• Increased risk for hemorrhage and hematoma formation
Iron	• Collagen synthesis • Enhances leukocytic bacterial activity • Hemoglobin synthesis	• Anemia, leading to increased risk for local tissue ischemia • Impaired tensile strength
Zinc	• Cell proliferation • Cofactor for enzymes • Vitamin A utilization	• Impaired collagen cross-linkage • Slow healing • Alteration in taste • Anorexia • Impaired immunity
Copper	• Collagen cross-linkage • Red blood cell synthesis	• Decreased collagen synthesis • Anemia
Pyridoxine, riboflavin, and thiamine	• Energy production • Cellular immunity • Red blood cell synthesis	• Decreased resistance to infection • Impaired wound healing
Arginine	• Increases local wound immune system • Nitrogen-rich (32% nitrogen, whereas the average amino acid is 16% nitrogen) • Precursor to proline, which is converted to hydroxyproline and then to collagen	• Decreased local wound immune system
Glutamine	• Primary fuel for fibroblasts • Preservation of lean body mass	• Less fuel for fibroblasts

From Hess CT: Clinical Guide: Wound Care, 5th ed. Ambler, PA: Lippincott Williams & Wilkins, 2005, p 28.

increase to 35 to 40 kcal/kg/d, and protein requirements increase to 1.5 to 2 g/kg/d (Table 52-3).[2] Optimal nutritional care for the patient with wounds can be achieved by consulting a dietitian and monitoring laboratory test results along with the patient's basic intake, output, daily weights, anthropometrics, calorie count, and social history.

Serum albumin and prealbumin levels are of particular interest in that they are a key indicator of protein available for cellular construction and replication. Table 52-4 demonstrates the various albumin requirements at specific ages.[6] In each case, if the albumin level is less than the minimal parameter, replacement therapy is needed to provide the optimal wound-healing environment. Normal serum albumin is defined as 3.8 to 5 g/dL. In an adult, a serum albumin level of less than 3.5 g/dL necessitates replacement therapy.

Serum total protein levels are also monitored. Normal levels for serum total protein are 6 to 8 g/dL (see Table 52-4).[6] As stated earlier, protein also affects the oncotic pressure, and levels less than 6 g/dL lead to edema. Note that the serum total protein level, like the albumin level, varies according to age.

Table 52-3 Nutrient Needs Based on Body Weight

Nutrient	Requirements
Calories	
Normal	25–30 kcal/kg/d
Protein–calorie malnutrition (PCM)*	30–35 kcal/kg/d
Critically ill or injured*	35–40 kcal/kg/d
Protein	
Recommended daily allowance (RDA)	0.8 g/kg/d
PCM	1.5 g/kg/d
Critically ill or injured*	1.5–2.0 g/kg/d
Fat	<30% kcal
Water	30 mL/kg body weight or 1 L/1,000 kcal

*Nutrient supplementation required.

From Hess CT: Clinical Guide: Wound Care, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2008, p 31.

Along with electrolytes, complete blood count (CBC), serum albumin, and serum total protein, two other laboratory tests that may be assessed are serum transferrin and the total lymphocyte count (TLC). The serum transferrin level is an indicator of the body's ability to transfer iron through the plasma. The normal serum transferrin level is 180 to 260 mg/dL.[6,7] Decreased serum transferrin levels lead to anemia, as demonstrated by the CBC. TLC normal parameters are 1,500 to 3,000 cells/mcL.[6] A TLC assists in the assessment of the patient's immune status and may be decreased in states of malnutrition.

Micronutrients, vitamins, and minerals also affect wound healing. Zinc is needed in the structure of collagen and production of protein. Ascorbic acid is also a component of collagen synthesis. Vitamin A plays a role in cellular proliferation and increases the tensile strength of healing wound tissue. Therefore, use of a high-potency daily multivitamin and mineral supplement is recommended for patients with altered skin integrity.[8]

Patients who are on nothing by mouth (NPO) status for longer than 24 to 48 hours are at risk for slowed healing owing to the lack of an adequate supply of protein, carbohydrates, and other nutrients. Nutritional management includes monitoring laboratory test results; documenting intake and output and daily weights; having a nutritional assessment performed by a dietitian; feeding by total parental or peripheral parental nutrition or enteral means; and making calorie counts.

Adequate hydration is paramount to ensure oxygen delivery to the tissues. If the patient is hypovolemic, oxygen transport to the peripheral tissues is impaired. The optimal goal is to maintain hemodynamic stability. (For a thorough discussion of hemodynamic assessment, see Chapter 17.) In the critically ill patient, tissue perfusion must be addressed based on the symptom and cause. For example, if the cardiac output is decreased, systolic blood pressure is decreased, the heart rate is tachycardic, and the pulmonary artery wedge pressure is decreased, the patient is hypovolemic. To improve tissue perfusion for this critically ill patient, fluids are given. The hemoglobin and hematocrit must also be assessed, and if values are low, the patient should receive a blood transfusion. By improving hydration and correcting the anemia, the circulating volume and the oxygen-carrying capacity of the blood are increased, thus improving tissue perfusion. This enhances the environment for wound healing.

▲ Patient Teaching and Discharge Planning

Patient teaching and discharge planning are ongoing processes that occur throughout the patient's hospital stay. Discharge planning for patients with wounds is a multidisciplinary challenge. An important part of discharge planning is ensuring that the patient or a family member knows how to care for the wound after the patient leaves the hospital. Examples of patient teaching guides for wound care are given in Boxes 52-5 and 52-6.

Table 52-4 Normal Values for Serum Total Protein and Serum Albumin

Age of Patient	Total Protein	Albumin
Adult	6.0–8.0 g/dL or 60–80 g/L	3.5–5.0 g/dL or 38–50 g/L
10–19 y	6.3–8.6 g/dL or 68–86 g/L	3.7–5.6 g/dL or 37–56 g/L
7–9 y	6.2–8.1 g/dL or 62–81 g/L	3.7–5.6 g/dL or 37–56 g/L
4–6 y	5.9–7.8 g/dL or 59–78 g/L	3.5–5.2 g/dL or 35–52 g/L
1–3 y	5.9–7.0 g/dL or 59–70 g/L	3.4–4.2 g/dL or 34–42 g/L
<5 d	5.4–7.0 g/dL or 54–70 g/L	2.6–3.6 g/dL or 26–36 g/L

BOX 52-5 TEACHING GUIDE Wound Care (Sutures, Staples, and Wound Adhesives)

Wound Closure
- Sutures are thread-like. They are placed using a needle to pull the skin together. You may see "knots."
- Staples are special surgical staples. They are placed using a special staple gun to pull the skin together.
- Wound adhesives are a type of glue that holds the edges of the skin together.

Patient Activity
- Keep your sutures/staples/wound adhesive clean and dry.
- Wash your hands before you start.
- Do not rub or pull the area.
- Clean the wound gently with mild soap and water and rinse, or use a wound cleanser as directed by your physician. Do not "soak" the sutures/staples/wound adhesive. Gently pat the area dry.
- A dry gauze dressing may be applied to keep your wound clean or pad the area if your clothes rub.
- Wash your hands when you are done.

When To Call Your Physician
- Call if you find any redness, tenderness, pus-type drainage, swelling, missing sutures or staples, or increased pain, or if the area is warm or hot to the touch.
- Call if you have a fever of more than 101°F.
- Call immediately and go to the emergency department if your incision "pulls open."

Medications
- Take your medications as prescribed.
- If you are taking an antibiotic, take all pills prescribed. Do not stop taking them when you feel better.

Safety
- You may drive, climb stairs, work, begin sexual activity, and lift when instructed by the physician.

BOX 52-6 TEACHING GUIDE Wound Care (Dry Dressing, Calcium Alginate, Hydrocolloid, or Hydrofiber)

Patient Activity
Always wash your hands before and after changing your dressing.

Dry Dressing
- Change your dressing every day.
- Clean your wound with normal saline solution, mild soap and water, or a wound cleanser as directed.
- Cover the wound with a dry gauze dressing.

Calcium Alginate
Calcium alginate is a dressing that can be packed (lightly) into your wound. It is made of a special type of seaweed that has healing properties. Calcium alginate looks similar to "angel hair" when "fluffed."

- Change your dressing every 3 days unless otherwise directed by your physician.
- Remove the old dressing (it will appear to be a gelatinous mass, not the fibrous "angel hair" you put in.)
- Clean your wound with normal saline solution or with a wound cleanser as directed.
- Take the calcium alginate out of the package and gently fluff it (pull it apart slightly so that it has a light, fluffy look).
- Place the fluffed calcium alginate into the wound.
- Cover the wound and calcium alginate with the type of covering you were directed to use.

Hydrocolloid
Hydrocolloid is a thicker type of wound covering that can be placed over open wounds, such as bedsores (pressure ulcers). Hydrocolloid may also be placed over a wound in which calcium alginate has been packed. Hydrocolloid comes in various shapes and sizes. It has an adhesive (sticky) side. The adhesive side goes over the wound.

- Change your dressing every 3 to 7 days unless otherwise directed by your physician, or when it comes off.
- Gently peel the old hydrocolloid off, being careful not to peel too quickly or too roughly.
- Clean your wound with normal saline or with a wound cleanser as directed.
- If you are packing the wound with calcium alginate, do it at this time.
- Peel the paper off the adhesive side of the hydrocolloid.
- Place the hydrocolloid adhesive side down over the wound.
- Press gently and smooth the hydrocolloid over the wound.
- Place your hand on top of the hydrocolloid for about 1 minute. This helps the adhesive to stick better.

Hydrofiber
Hydrofiber is a dressing that is absorbent, interacting with wound drainage by forming a soft gel that is easily removed from the wound while maintaining a healing environment. Hydrofiber may or may not have silver added to the dressing. Silver has an antimicrobial effect that helps to keep the wound free of bacteria.

- Change your dressing when it is saturated with drainage, or after 7 days.
- Remove the old dressing (it will appear to be a gelatinous mass).
- Clean your wound with normal saline solution or with a wound cleanser as directed.
- Take the hydrofiber out of the package and place it in the wound.
- Cover the wound and hydrofiber with the type of covering you were directed to use.

When to Call Your Physician
- Call if you have any redness, tenderness, pus-type drainage, swelling, missing sutures or staples, or increased pain, or if the area is warm or hot to the touch.
- Call if you have a temperature higher than 101°F.

Medications
- Take your medications as prescribed.
- If you are taking an antibiotic, take all pills prescribed. *Do not stop taking them* when you feel better.

Safety
- You may drive, climb stairs, work, begin sexual activity, and lift when instructed by the physician.

▲ Clinical Applicability Challenges

CASE STUDY

Mr. B. is a 75-year-old Japanese American with a history of diabetes mellitus, chronic obstructive pulmonary disease, hypertension, and smoking. He was active and still working 4 days per week when he suffered a cerebral vascular accident. He was found lying on the kitchen floor; estimated time down was 24 hours or slightly more. He is intubated on FIO_2 (fraction of inspired oxygen) 70%, tidal volume of 700 ml, assist control of 16, and pressure support of 5 cm H_2O. He is nonresponsive, except to pain, and no movement on his right side is noted. Vital signs are blood pressure 140/82 mm Hg; temperature 100°F; heart rate 110 bpm; and respiratory rate 16 bpm (not assisting the ventilator, in that the patient is unable to initiate or attempt any spontaneous triggering of the ventilator). Glascow Coma Scale is 9. He has an 8-cm maroon-purple area on his right hip, a blood-filled blister on the right heel, and a fluid-filled blister on the left heel present upon admission to the intensive care unit.

1. Compare and contrast the fluid-filled blister and the blood-filled blister.
2. Discuss the staging/classification of the right hip wound.
3. Explain the importance of "present on admission."

53 Burns and Common Integumentary Disorders

Louis R. Stout and Lisa M. Johnson

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Discuss the classifications of a burn injury.
2. Describe the pathophysiology of a burn injury.
3. Review the physiological changes associated with each organ system in relation to a burn injury.
4. Discuss the initial priorities of caring for a patient with a burn injury.
5. Formulate a plan of care for a patient who has sustained a burn injury.
6. Discuss other types of injured patients who are cared for in the burn unit.

The past two decades have witnessed a significant decline in the number of burn injuries, hospitalizations, and deaths. Total burn injuries in the United States have decreased more than 50%, from 2.5 million to approximately 1 million per year. Burn injuries account for 500,000 emergency department (ED) visits per year, with about 40,000 patients being hospitalized; nearly 70% of burn patients are men.[1] The average size of a burn is about 10% of the total body surface area (TBSA).[2]

Of the patients with burns who are hospitalized, about half are treated at specialized burn centers.[1] Burn treatment centers are composed of nurses, physicians, physical therapists, occupational therapists, recreational therapists, nutritionists, psychologists, social workers, and spiritual support staff. The American Burn Association (ABA) has established guidelines for transfer and referral of these patients to burn centers.

Great strides have been made in the technological and pharmacological care of the burned patient. In the 1940s and 1950s, a patient with a 30% to 40% TBSA burn had a 50% chance of survival (LD_{50}).[3] Over the decades, survivability increased as the result of penicillin and broad-spectrum antibiotics, the burn center concept, and aggressive nutrition and excision. Today, a patient with a 78% TBSA burn has a 50% chance of survival. The trend toward outpatient management has contributed to the decreased number of hospitalized patients. Acute hospitalization resulting from a burn injury has declined 50% since the 1970s. From 1995 to 2005, the average length of stay for inpatient hospitalization declined from 13 to 8 days, and the mortality rate decreased from 6.2% to 4.7%.[1,2] Most recent mortality rates have declined further to 3.7%.[2]

Despite the dramatic reductions in incidence, an acute burn injury remains the third leading cause of death in children between the ages of 1 and 9 years, although it has decreased to the sixth leading cause of death in the remainder of the population. The advocacy of several national organizations has helped introduce increased fire-resistant products, fire prevention programs, and legislation (eg, flame-retardant children's sleepwear, smoke alarms, fire suppression systems).[4] Nevertheless, there are an estimated 4,000 fire and associated burn deaths per year.[1,2] Measures for safely preventing burns are given in Box 53-1.

▲ Classification of Burn Injuries

Burn injuries are described in terms of causative agent, depth, and severity.

Causative Agent

A burn injury usually results from energy transfer from a heat source to the body. The heat source may be thermal, chemical, electrical, or radiation producing. Skin is a great resistor; injury occurs when the agent exceeds the threshold for resistance.

Thermal Burns

Thermal burns account for 70% of all burn injuries.[2] They may be caused by a flame source such as a house fire, a cooking accident, or a fiery explosion. Scald burns from steam or contact with a hot object, such as a cooking pan or hot steel, may also cause thermal injury.

Chemical Burns

Chemical injuries are commonly encountered after exposure to acids and alkali, including hydrofluoric acid, formic acid, anhydrous ammonia, and organic compounds. Other specific chemical agents that cause chemical burns include

BOX 53-1 TEACHING GUIDE Preventing Burns

Prevent Accidents in the Home

- Install a smoke detector on each floor of your house; change the batteries twice a year.
- Plan an exit route in your house in the event of a fire and have routine fire drills once a month.
- Exercise caution with cooking. Avoid wearing clothes with sleeves that may dangle and accidentally ignite clothing.
- Exercise caution with foods that are cooked in a microwave.
- Keep pot and skillet handles turned inward on the stove.
- Never allow children to stand on an open oven door, as this may cause the entire stove to collapse.
- Never leave children unattended in a bathtub.
- Set your hot water heater no higher than 120°F.
- Never leave candles unattended and always be sure candles are fully extinguished.
- Have your furnace serviced once a year.
- Install a carbon monoxide detector.
- Never use the oven or barbeque grill as a heating source.

Prevent Accidents Outside the Home

- Only a responsible adult should handle fireworks. Never leave fireworks out where children can have access.
- Exercise caution with campfires and grills.
- Do not pour accelerant (gasoline, lighter fluid) on a lighted fire.
- If an electrical wire is found in a tree, do not touch! Call the local electric company and police/fire company as soon as possible.
- Use sunscreens! Choose a sunscreen with ultraviolet A and ultraviolet B protection and a sun protection factor of 30. Apply every 2 to 3 hours.

Should a Burn Occur

- Stop the burning process by removing the source (refer to Box 53-2 for immediate treatment based on burn depth and size).

white phosphorus, certain elemental metals, nitrates, and hydrocarbons.

Contact time is a critical element in determining the severity of injury. Removal of contaminated clothing and water irrigation is crucial to limit the effects of the chemical. Regardless of the causative agent, the irrigation must continue once the patient arrives at the ED. Forego identification of a specific agent to neutralize the acid or alkali agents because a neutralizing agent will also cause a chemical reaction in the neutralizing process thereby risking further burn injury. For all chemical burns, hydrotherapy treatment should continue until the pain resolves, taking 1 to 3 hours or longer. Chemicals to the eyes should be flushed continuously until a full evaluation can be completed by an ophthalmologist. Some agents such as hydrofluoric acid require specific treatments to stop tissue destruction. Calcium chloride topical gels or dermal injections are used.[5,6]

Electrical Burns

The effects of electricity on the body are determined by the type of current (alternating or direct), the pathway of the current, the duration of contact, the resistance of the body tissue, and the amount of voltage. Because of their highly developed nervous system, humans are sensitive to very small electric currents. Electricity travels the path of least resistance; therefore, tissue, nerves, and muscle are easily damaged, whereas bone is not.

Low-voltage injuries are considered to be caused by 1,000 V or less. Low-voltage injuries tend to occur at home and involve the hands and oral cavities. The most common cause of low-voltage electric burns of the hand is contact with an extension cord in which the insulating material has worn off, either from wear or misuse. A low-voltage burn of the hand usually consists of a small, deep burn that may involve vessels, tendons, and nerves. Although these burns involve a small area of the hand, they may be severe enough to require amputation of a finger. Low-voltage electricity can also damage the oral cavity, leaving a permanent scar. These injuries occur most frequently in children between the ages of 1 and 2 years.[6] Most are caused by sucking on, or biting, an extension cord socket. Whereas low-voltage current usually follows the path of least resistance (nerves, blood vessels), high-voltage current takes a direct path between entrance and ground. Current is concentrated at its entrance to the body, then diverges centrally, and finally converges before exiting. Unfortunately, the most severe damage to tissue occurs at the sites of contact, which are commonly referred to as entrance and exit wounds. High-voltage electric entry wounds are charred, centrally depressed, leathery in appearance, and local muscle flexion (ie, contact with the hand is likely to present with the hand and forearm in a fixed, almost fully flexed position, often described as a "claw-like" position). Exit wounds are more likely to "explode" as the charge exits. They are usually caused by lightning.

Depth

Many factors alter the response of body tissues to heat. The degree or depth of burn depends on (1) the temperature of the injuring agent, (2) the duration of exposure to the injuring agent, and (3) the areas of the body that are exposed to the injuring agent. Whereas the body can sustain prolonged exposure to moderate temperatures such as a hot tub of water (110°F or 43°C), significant damage can occur in as little as 1 second when the temperature exceeds 150°F (68°C). Hot water heaters are often installed with the setting at 140°F (60°C).[1,5,6] A safer setting would be 120°F (49°C) especially in homes with children or elderly family members. Damage to the skin is frequently described according to the depth of injury and is defined in terms of superficial, partial-thickness, and full-thickness injuries, which correspond to the various layers of the skin (Table 53-1; Fig. 53-1).

Superficial Burns

Superficial burn injuries are commonly known as first-degree burns. Superficial burns affect the epidermal layer and heal with minimal intervention. Sunburn is a familiar example of a first-degree superficial burn injury; others may be very brief exposure to hot liquid, flash, flame, or chemical agent. The burned skin is painful at first and later itches because of the stimulation

Table 53-1 Characteristics of Burns of Various Depths

Depth	Tissues Involved	Usual Cause	Characteristics	Pain	Healing
Superficial (first-degree)	Epidermis	Sun Scalds	Dry Pinkish red Blanches Typically don't blister	Painful	About 3–5 days No scarring
Superficial partial-thickness (second-degree)	Epidermis into papillary dermis	Flash Scalds	Moist, blisters Pinkish to redden Blanches	Hypersensitive Very painful	2–3 weeks Minimal scarring
Deep partial-thickness (second-degree)	Epidermis into reticular dermis (epidermal-lined hair and sweat glands intact)	Above plus hot solids, flame, and intense radiant injury, chemical	Slightly moist to dry Mottled, pink and white Slow to no blanching	Discomfort to pressure	3 or more weeks Late hypertrophic scarring; marked contracture formation
Full-thickness (third-degree)	Entire dermis into subcutaneous fat; may involve connective tissue, muscle, bone	Sustained flame, electrical, chemical, and steam	Dry, leathery, cracked White, cherry red, or black, thrombosed vessels No blanching	Typically no pain, pressure with palpation	Cannot self-regenerate; needs grafting

of sensory receptors. Because of the continuous replacement of epidermal epithelial cells, this type of injury heals spontaneously without scarring in 3 to 5 days. Care of superficial burns is minimally supportive and is summarized in Box 53-2.

Partial-Thickness Burns

Partial-thickness burns (second-degree burns) are differentiated into superficial and deep partial-thickness burns. Superficial partial-thickness burns affect the epidermal and superficial dermal layers and usually heal with minimal intervention in 10 to 14 days (see Box 53-2). Deep partial-thickness burns affect the entire epidermal layer and more deep dermal layers. Fluid resuscitation, nutritional status, and premorbid conditions may affect the healing potential of a deep partial-thickness burn injury. Deep partial-thickness burn injuries may have some spontaneous healing in 3 to 4 weeks but require surgical intervention (excision and skin grafting) if the burn is of any significant size. Delayed healing may result in scarring and loss of function.

Full-Thickness Burns

Prolonged exposure to flame, a hot object, a chemical agent or contact with high-voltage electricity can result in full-thickness burns (third-degree burns). These burns extend into the poorly vascularized adipose tissue. All epidermal and dermal elements, sweat glands and hair follicles, are

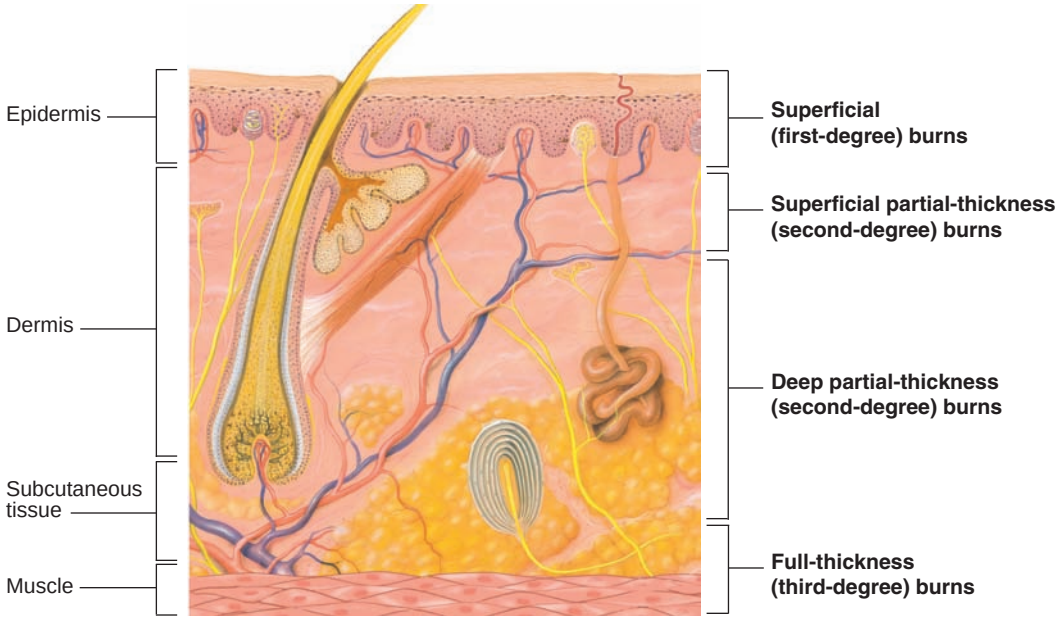

FIGURE 53-1 ▲ Classification of burns by depth of injury. (Adapted from Anatomical Chart Company: Atlas of Pathophysiology. Springhouse, PA: Springhouse, 2010, p 385.)

BOX 53-2 Care of Superficial (First-Degree) Burns and Superficial Partial-Thickness (Second-Degree) Burns

Superficial (First-Degree) Burns

- Apply ice packs or cold compresses.
- No dressing is required.
- Aloe gel with lidocaine can be applied topically as necessary for localized relief.
- Acetaminophen, aspirin, or ibuprofen can be taken as necessary for generalized discomfort.

Superficial Partial-Thickness (Second-Degree) Burns

- If the skin or blister is broken, wash the area with water and mild antiseptic soap.
- Apply a layer of silver sulfadiazine or bacitracin.
- Apply a layer of nonadherent gauze and secure with a gauze roll.
- Dressings should be changed twice a day.
- Wrap fingers and toes individually to prevent "webbing" of healing granulation tissue.
- The patient may continue his or her usual activity depending on the burned site.
- Dependent extremities should be elevated above the level of the heart to prevent excessive edema and promote venous return.
- The patient should be aware of signs and symptoms of infection, including fever, marked tenderness and erythema surrounding the burn wound, purulent drainage of pus, red streaks radiating from the wound, or pain that cannot be controlled with analgesics.
- The patient should follow up in 2 days with a primary care provider.

destroyed. These burns may appear white, red, brown, or black. Reddened areas do not blanch in response to pressure because the underlying blood supply has been interrupted. Thrombosed blood vessels and capillaries may be visualized.[6,7] These burns are insensate because the sensory receptors have been completely destroyed, and the patient may feel deep pressure only. In addition, the burns may appear sunken because of the destruction of underlying fat and muscle.

The loss of the hair follicle eliminates the ability of the skin to regenerate. A small wound (<4 cm) may be allowed to heal by granulation and migration of healthy epithelium from the wound margins. However, extensive, open full-thickness wounds leave the patient highly susceptible to overwhelming infection and malnutrition. Wound closure by skin grafting restores the integrity of the skin.

Severity

Burn severity is determined by the extent and depth of the burn and the causative agent, time, and circumstances surrounding the burn injury. To assess the severity of the burn, several factors must be considered:

- The percentage of body surface area burned
- The depth of the burn
- The anatomical location of the burn
- The person's age (Box 53-3)
- The person's medical history
- The presence of concomitant injury
- The presence of inhalation injury

BOX 53-3 CONSIDERATIONS FOR THE OLDER PATIENT

Burns

Older patients respond differently to burn injuries because of age-related changes and diminished physiological reserve. Preexisting medical conditions and complications as a result of injury are significant factors leading to mortality of the older burn patient. The adverse effects of trauma, including burns, can persist for an extended period after injury. Once injured, elderly patients may never regain their preinjury level of health. Postdischarge destination and care are challenging obstacles in discharge planning. Family interest in assuming caregiver responsibility, ability of the patient to render self-care, insurance, and financial limitations must be considered in planning for discharge. Many independent elderly patients will no longer be able to return home alone after a burn injury. Rehabilitation and long-term care facilities can create an emotional and financial burden on the family. In addition, acute rehabilitation requires the patient to participate in 3 hours of therapy each day. Many elderly patients are unable to meet this requirement, and thus may not be eligible for acute rehabilitation.

Several methods using percentages of TBSA may be used to estimate the extent of a burn. The "rule of nines" or "rule of palms" allows for quick estimation until a detailed Lund and Browder assessment can be done. The rule of nines divides the body into parts in multiples of 9% (see Fig. 53-2). When estimating burn size, burns may involve only one surface of a body part or they may be circumferential. For example, if only the anterior surface of the arm is burned, then the TBSA is estimated to be 4.5%. However, if the burn circles the entire arm, then the value is 9%. The rule of palms can be used for estimating small scattered burns (eg, scald or grease burns). The patient's palmar surface (including the fingers) equals 1% of the patient's TBSA.

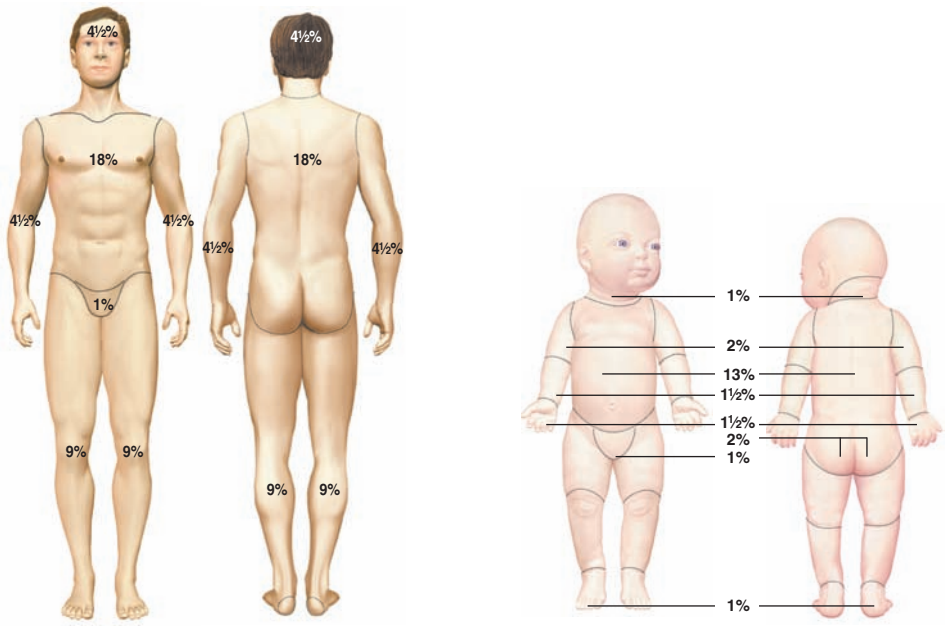
The Lund and Browder method (see Fig. 53-2) is highly recommended because it corrects for the large head/body ratio of infants and children. Surface measurements are assigned to each body part in terms of the age of the patient. However, because this method of measuring burn size is time consuming, it should be done after resuscitation efforts are well established.

A burn injury may range from a small blister to a massive full-thickness burn. Recognizing the need for a clear description of terms, the ABA developed the Injury Severity Grading System, which is used to determine the magnitude of the burn injury and to provide optimal criteria for hospital resources for patient care. The severity of burn injury is categorized into minor, moderate, and major, as outlined in Box 53-4. Minor burn injuries can be treated in the ED with outpatient follow-up every 48 hours, until the risk for infection is reduced and wound healing is underway. Patients with moderate, uncomplicated burn injuries or major burn injuries should be referred to a regional burn center and, if appropriate, transferred for specialized care.

▲ Pathophysiology

Localized Tissue Response

Cellular injury starts when tissues are exposed to an energy source (thermal, chemical, electrical, or radiation). The depth of the thermal injury is demonstrated by the extent of injury



A. Rule of Nines

AREA	PERCENT OF BURN					SEVERITY OF BURN		TOTAL PERCENT

FIGURE 53-2 ▲ **A:** The "rule of nines" method for determining percentage of body area with burn injury. **B:** Lund and Browder method for determining percentage of body area with burn injury. (**A,** Adapted from Anatomical Chart Company: Atlas of Pathophysiology. Springhouse, PA: Springhouse, 2010, p 385.)

BOX 53-4 Classification of Severity of Burn Injury

Minor Burn Injury
- Second-degree burn of less than 15% TBSA burn in adults or less than 10% TBSA in children
- Third-degree burn of less than 2% TBSA not involving special care areas (eyes, ears, face, hands, feet, perineum, joints)
- Excludes all patients with electrical injury, inhalation injury, or concurrent trauma; all poor-risk patients (ie, extremes of age, intercurrent disease)

Moderate, Uncomplicated Burn Injury
- Second-degree burns of 15% to 25% TBSA in adults or 10% to 20% in children
- Third-degree burns of less than 10% TBSA not involving special care areas
- Excludes all patients with electrical injury, inhalation injury, or concurrent trauma; all poor-risk patients (ie, extremes of age, intercurrent disease)

Major Burn Injury
- Second-degree burns of more than 25% TBSA in adults or 20% in children
- All third-degree burns of 10% or more TBSA
- All burns involving eyes, ears, face, hands, feet, perineum, joints
- All patients with inhalation injury, electrical injury, or concurrent trauma; all poor-risk patients

down through the layers of skin. Figure 53-3 represents the concentric zones of a burn injury.[6] The zone of coagulation is the area where the most damage has been sustained; temperatures have reached 113°F (45°C). The tissues are black, gray, khaki, or white and have undergone protein coagulation and cell death. This area has lost the ability to recover and requires surgical intervention. The zone of stasis immediately surrounds the zone of coagulation. This area contains cells that are at the most risk during burn resuscitation. They can recover or become necrotic in the initial 24 to 72 hours, depending on the conditions and course of resuscitation. The zone of hyperemia is the area of increased blood flow in an effort to bring the needed nutrients to the tissue for recovery (*active hyperemia*) and to remove the metabolic waste products (*reactive hyperemia*). This area heals rapidly and has no cell death.

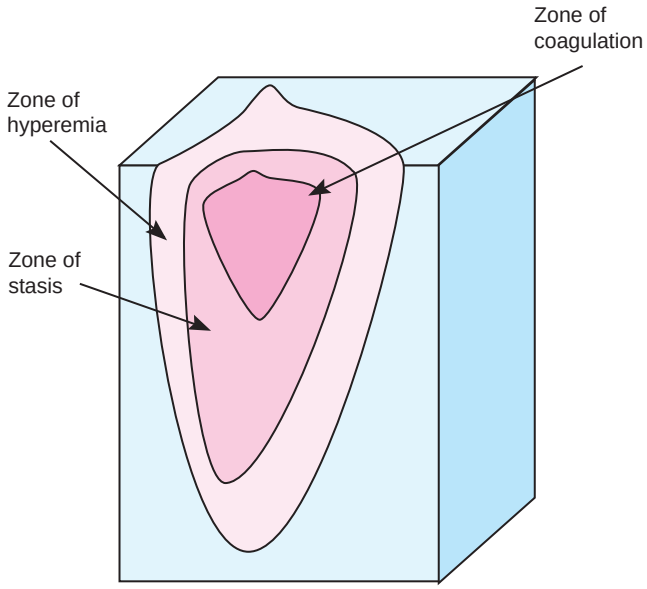

FIGURE 53-3 ▲ The concentric zones of a burn injury.

Systemic Response

Major changes at the cellular level are responsible for the tremendous systemic response noted in a patient with burns. The localized response causes a coagulation of cellular proteins, leading to irreversible cell injury with local production of complement, histamine, and oxygen free radicals (ie, byproducts of oxidative processes). Oxygen free radicals alter cell lipids and proteins, affecting the integrity of the cell membrane. This is particularly problematic in the endothelium of the microvascular circulation because disruption of the cell membrane leads to increased vascular permeability.[8] Increased vascular permeability leads to loss of plasma proteins into the interstitium and results in a marked decrease in circulating volume. Complement activation and histamine release contribute to the increased vascular permeability by increasing production of oxygen free radicals.[8,9] Increased vascular permeability leads to the formation of interstitial edema, which usually peaks within 24 to 48 hours of injury. It is hypothesized that the microvasculature takes weeks to restore itself completely to its premorbid state. The pulmonary vasculature is not spared, and pulmonary interstitial edema forms, with intraalveolar hemorrhages; this initial pulmonary insult is thought to be a precursor to the development of acute respiratory distress syndrome (ARDS).[8]

Systemically, a burn injury causes a release of vasoactive substances, such as histamine, prostaglandins, interleukins (ILs), and arachidonic acid metabolites. These substances initiate the systemic inflammatory response syndrome (SIRS). The potent mediators and cytokines (nitric oxide, platelet-activating factor [PAF], serotonin, thromboxane A_2, and tumor necrosis factor [TNF]) deplete the intravascular volume, decreasing blood flow to the kidneys and the gastrointestinal (GI) tract. If left uncorrected, hypovolemic shock, metabolic acidosis, and hyperkalemia may occur. Intestinal mucosal permeability also markedly increases and can become the primary source of bacterial infection. Early enteral feeding is one step to help prevent the translocation of bacteria.[10,11]

Nitric oxide relaxes smooth muscle and produces vasodilation and hypotension. It may also depress myocardial function and block platelet aggregation and adhesion. PAF initiates neutrophil and white blood cell (WBC) activation and produces tissue inflammation. PAF increases permeability of vessels, thereby decreasing myocardial contractility, causing vasodilation and hypotension. Some prostaglandins, and its activation, cause vasoconstriction, increased blood flow, and fever. Serotonin causes vasodilation, hypotension, and increased vessel permeability. TNF is responsible for numerous cellular responses, including increased formation of oxygen free radicals, which leads to injury of the lungs, GI tract, and kidneys; increased cytokine production; initial hyperglycemia followed by hypoglycemia; hypotension; metabolic acidosis; coagulopathy; and activation of the coagulation cascade.[8]

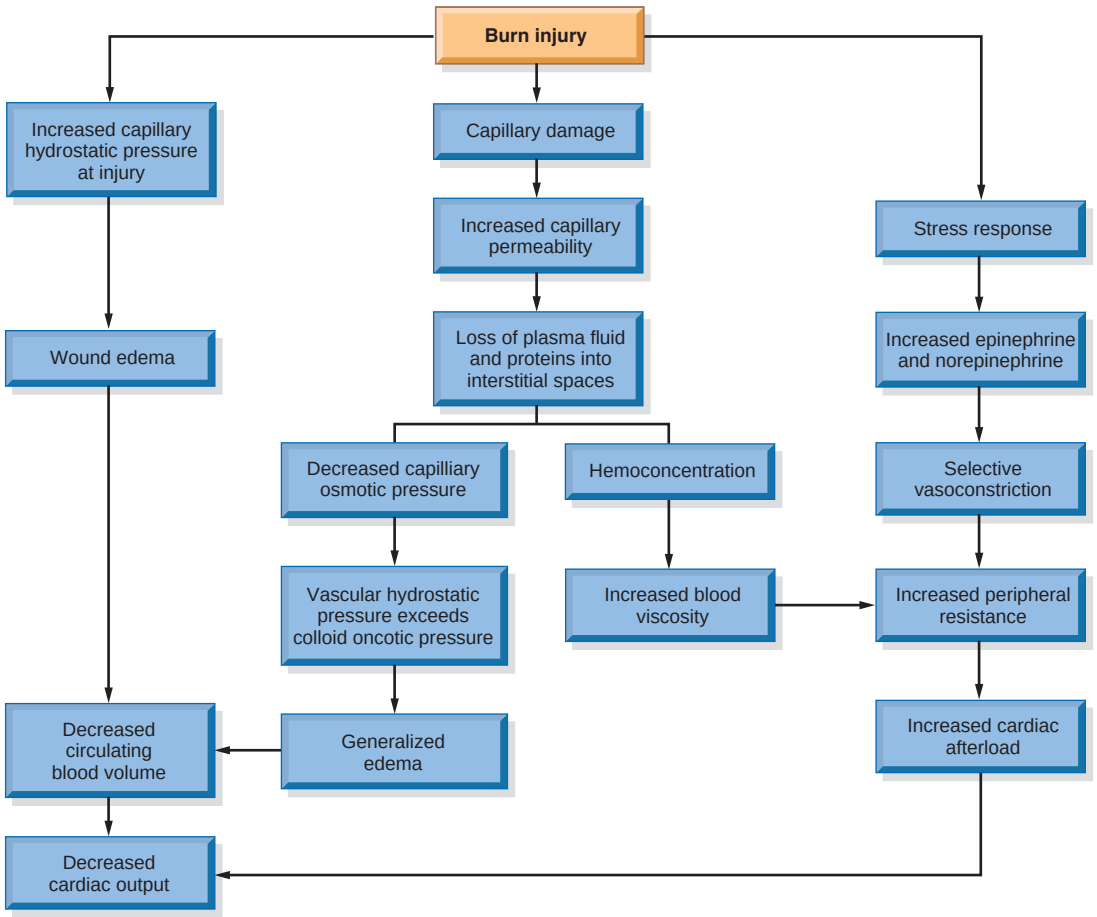

FIGURE 53-4 ▲ Fluid shifts in burn shock.

The end results of the local and systemic responses are dramatic if the burn covers more than 20% of the TBSA. The person with a major burn injury experiences a form of hypovolemic shock known as burn shock (Fig. 53-4). Within minutes of thermal injury, a marked increase in capillary hydrostatic pressure occurs in the injured tissue, accompanied by an increase in capillary permeability. This results in a rapid shift of plasma fluid from the intravascular compartment across heat-damaged capillaries, into interstitial areas (resulting in edema), and to the burn wound itself. The loss of plasma fluid and proteins results in a decreased colloid osmotic pressure in the vascular compartment. As a result, fluid and electrolytes continue to leak from the vascular compartment, resulting in additional edema formation in the burned tissue and throughout the body.

This "leak," which consists of sodium, water, and plasma proteins, is followed by a decrease in cardiac output, hemoconcentration of red blood cells, diminished perfusion to major organs, and generalized body edema. The pathophysiological response after burn injury is biphasic. In the early postinjury (ebb) phase, generalized organ hypofunction develops as a consequence of decreased cardiac output. Peripheral vascular resistance increases as a result of the neurohumoral stress response after trauma. This increases cardiac afterload, resulting in a further decrease in cardiac output. The increase in peripheral vascular resistance (selective vasoconstriction) and the hemoconcentration resulting from plasma fluid loss may cause the blood pressure to appear normal at first. However, if fluid replacement is inadequate, and plasma protein loss continues, hypovolemic shock soon occurs.

In patients receiving adequate fluid resuscitation, the cardiac output usually returns to normal in the latter part of the first 24 hours after burn injury. As plasma volume is replenished during the second 24 hours, the cardiac output increases to hypermetabolic levels (hyperfunction phase) and slowly returns to more normal levels as the burn wounds are closed.[8,10,12]

In some instances, with burns exceeding 60% of the TBSA, depressed cardiac output does not respond to aggressive volume resuscitation. A myocardial depressant factor capable of depressing ventricular contractility by 60% has been identified. Myocardial depression in the early postburn period may also be the result of reduced coronary blood flow.[8,10]

The response of the pulmonary vasculature is similar to that of the peripheral circulation. However, pulmonary vascular resistance is greater and lasts longer. Immediately after burn injury, the patient may experience a mild, transient pulmonary hypertension. A decrease in oxygen tension and lung compliance may also be evident.

The loss of fluid throughout the body's intravascular space results in a thickened, sluggish flow of the remaining circulatory blood volume. The effects reach all body systems. This slowing of circulation permits bacteria and cellular material to settle in the lower portions of blood vessels, especially in the capillaries, which results in sludging.

The antigen–antibody reaction to burned tissue adds to circulatory congestion by the clumping or agglutination of cells. Coagulation problems occur as a result of the release of

thromboplastin by the injury itself and the release of fibrinogen from injured platelets. If thrombi occur, they may cause ischemia of the affected part and lead to necrosis. Although of limited incidence in patients with burns, the increased coagulation process may develop into disseminated intravascular coagulation.

▲ Concomitant Problems

Pulmonary Injury

Pulmonary damage usually occurs within 24 to 48 hours of the injury and is secondary to the inhalation of combustible products or may be the result of inhaled superheated air. In an incident involving large amounts of steam, the risk for injury is far greater because water has a heat-carrying capacity 4,000 times greater than air and has the ability to be inhaled deeply in the pulmonary system.[1,6] Pulmonary injury may also be the result of a systemic process related to SIRS.

Fiberoptic bronchoscopy permits direct visualization of the airways (facilitating evaluation of erythema, edema, ulceration, and enlarged vessels) as well as the removal of debris by lavage. Fiberoptic bronchoscopy should be completed when feasible and repeated as indicated during the acute phase to document the extent of the pulmonary injury and complete direct lavage when necessary.

Carbon Monoxide Toxicity

Carbon monoxide is a nonirritating, odorless, colorless gas that is formed as a result of incomplete combustion of any carbon fuel. This gas is found in a variety of sources, including exhaust from vehicles, hot water heaters, furnaces and tobacco smoke. Carbon monoxide poisoning produces its effect on the body by competing with oxygen for uptake on hemoglobin, thereby acting as an asphyxiant. Because carbon monoxide affinity for hemoglobin is 200 to 300 times higher than oxygen, carbon monoxide readily displaces the oxygen, leading to the formation of carboxyhemoglobin and a reduction in systemic arterial oxygen content.[13–15] Carboxyhemoglobin shifts the oxyhemoglobin dissociation curve to the left, further decreasing the ability of the red blood cells to release oxygen to body tissues.[15] This may lead to severe anoxia and related brain injury.

The patient with a clear history of exposure to carbon monoxide is usually found in a closed environment in the presence of combusted gases, such as smoke, automobile exhaust, or fumes from a faulty furnace.[6] The signs of carbon monoxide poisoning depend on the carboxyhemoglobin present in the patient's blood (Table 53-2).[13]

When carbon monoxide poisoning is suspected, 100% high-flow oxygen is administered. Carbon monoxide has a half-life of 4 hours if the patient breathes room air and 45 minutes if the patient is breathing 100% oxygen. Hundred percent oxygen should be continued until the carboxyhemoglobin level is less than ten percent and neurological symptoms resolve.[6,13,14] Serial carboxyhemoglobin level measurements are the most accurate way to assess responsiveness to oxygen therapy.[13] Pulse oximetry is inaccurate when the carboxyhemoglobin level is elevated because pulse oximetry cannot distinguish between oxygen and carbon monoxide on the hemoglobin. The analysis and trending of arterial blood gas (ABG) levels for acid–base balance, lactate levels, and bicarbonate are helpful to manage carbon monoxide poisoning with lactic or metabolic acidosis.[13]

Table 53-2 Signs and Symptoms of Carbon Monoxide Poisoning

Carboxyhemoglobin Saturation (%)	Clinical Presentation
10	No symptoms
20	Headache, nausea/vomiting, dyspnea on exertion
30	Confusion, lethargy, tachypnea
40–60	Seizure, coma, changes on electrocardiogram
More than 60	Death

Inhalation Injury

Besides carbon monoxide poisoning, smoke inhalation can result in thermal injury to the airway. Pulmonary damage, primarily as a result of inhalation injury, is historically seen in less than 10% of the total cases but accounts for 20% to 84% of burn mortality and is a significant factor in increasing the hospital length of stay.[16] Three stages of injury have been described:

1. Acute pulmonary insufficiency may occur during the first 36 hours.
2. Pulmonary edema occurs in 5% to 30% of patients with burns between 6 and 72 hours after injury.
3. Bronchopneumonia appears in 15% to 60% of patients with burns 3 to 10 days after injury.

Upper airway injury is the result of inhalation of superheated air, which may cause blisters and edema in the supraglottic area around the vocal cords. This situation may cause airway obstruction and edema. Hoarseness, stridor, dyspnea, carbonaceous sputum, and tachypnea indicate airway compromise, which must be addressed immediately. Early intubation may thwart such disastrous occurrences.

Tracheobronchial and parenchymal lung injuries are usually a result of incomplete combustion of chemicals (eg, aldehyde, acrolein) or noxious gases which in a chemical pneumonitis. Pathophysiologic changes associated with lower lung injuries include impaired ciliary activity, hypersecretion, edema, inflammation, and bronchospasm.[6,14,16] Inflammatory changes in the trachea and alveoli occur within 24 hours of injury. The pulmonary tree becomes irritated and edematous. The alveoli may collapse, causing a decreased compliance, which leads to atelectasis. ARDS may develop rapidly. However, changes may not become apparent until the second 24 hours. Pulmonary edema is a possibility any time from the first few hours to 7 days after the injury. Subtle changes in the patient's sensorium may indicate hypoxia.

History and physical assessment findings that should alert the nurse to the potential for inhalation injury are given in Box 53-5. Serial ABG evaluations show a decreasing arterial oxygen tension (PaO_2). Usually, the admission chest film appears normal because changes are not reflected until 24 to 48 hours after the burn. A sputum specimen is obtained for culture and sensitivity studies. Laryngoscopy and

BOX 53-5 PATIENT SAFETY

History and Physical Examination Findings Suggestive of Inhalation Injury

- History of incident occurring in a confined area
- Singed nasal or facial hairs
- Burns of the oral or pharyngeal mucous membranes
- Burns in the perioral area or neck
- Carbonaceous sputum
- Change in voice
- Change in level of consciousness

bronchoscopy may be of value in determining the presence of extramucosal carbonaceous material (the most reliable sign of inhalation injury) and the state of the mucosa (blistering, edema, erythema). More specific confirmation of inhalation injury is achieved with the use of fiberoptic bronchoscopy, which permits direct examination of the proximal airway, and xenon-133 scintigraphy (ventilation–perfusion scanning).[6,14] Xenon-133 scintigraphy is helpful in establishing a diagnosis of injury to small airways and lung parenchyma.

Infection

There is no greater problem for the patient with burns than infection. Infection is the most common cause of death in patients with burns after the first 7 days.[17] Loss of the mechanical barrier between the human body and the environment is the first step in the weakening of defenses. All aspects of the immune system, including phagocytosis, soluble mediators of innate immunity such as complement, antibody production, and cellular (T-cell) defense systems, are compromised by severe burn injury.

Actions of the health care team can compromise patient survival. All catheters invading the body, including endotracheal tubes, central venous catheters, and bladder catheters, must be handled with as clean a technique as possible. Although the skin and gut are the source of endogenous bacteria, a greater threat to the patient is colonization with antibiotic-resistant pathogens carried by the burn team from other patients. The hands must be washed without fail before and after handling the patient, the patient's bed, or equipment. When dressings are removed and wounds exposed, sterile gloves must be worn. Frequent and meticulous hand washing alone probably prevents infection more than any other single action. Infection control policies vary from burn center to burn center, but the philosophy remains the same: Make every effort to minimize the transmission of bacteria from patient to patient.

Diagnosis of invasive infection in the patients with burns is unusually difficult. Most patients with burns meet two or more of the SIRS criteria because they are constantly and chronically exposed to the environment thus releasing inflammatory mediators. The ABA Consensus developed *triggers* that should prompt the health care team to look for an infection in the burn patient (see Table 53-3). Manifestations of multisystem organ dysfunction, such as hypotension, hypoxia, decreased pulmonary compliance, renal failure, or hepatic dysfunction, are almost certain signs of septic shock.

Qualitative wound cultures done by swabbing the wound yield no new information other than the nature of the bacterial species colonizing the surface of the wound. A biopsy of the burn wound permits a quantitative assay of the number of colony-forming units (CFUs) of bacteria per gram of tissue. Burn wound sepsis is likely if the colony count is greater than 105 CFU/g, and the quantitative culture also allows isolation and identification of the invading organism.

Table 53-3 American Burn Association (ABA) Consensus: Sepsis and Infections in Burns Versus Systemic Inflammatory Response Syndrome (SIRS)

ABA Consensus	SIRS
Temperature > 39°C or <36.5°C	Temperature > 38°C or <36°C
Heart rate > 110 bpm	Heart rate > 90 bpm
Respiratory rate > 25 bpm or minute ventilation > 12 L/min ventilated	Respiratory rate > 20 bpm or $PaCO_2$ < 32 mm Hg
Thrombocytopenia < 100,000/mcl	WBC > 12,000/mm^3 or <4,000/mm^3 or left shift > 10% bands
Hyperglycemia (no preexisting diabetes) or insulin resistance	
Enteral feeding intolerance	

Concern for infection if at least three of the above.

bpm, breaths per minute.

From Greenhalgh DG, Saffle JR, Holmes JH, et al: American Burn Association consensus conference to define sepsis and infection in burns. J Burn Care Res 28(6):776–790, 2007.

Trauma

Concomitant injuries such as fractures and head trauma pose significant risk for the patient with burns. Ensuring adequate airway, breathing, and circulation takes precedence over caring for specific injuries. Cervical spine injuries should be stabilized and cleared. If head trauma is suspected, a computed tomography scan is obtained. The history of the burn injury is critical to assisting with the evaluation of the patient. The burn wounds may mask some of the classic signs of underlying injuries, such as ecchymosis or swelling. The burn event may include events, such as an explosion, the patient being thrown or falling, or a motor vehicle crash. Patients with electrical injuries must also be evaluated for fractures secondary to the violent muscular contraction after exposure; special focus should be placed on the cervical spinous process and long bones.

▲ Assessment and Management

The initial assessment of the patient with burns is like that of any trauma patient. The ABA has identified criteria for referral to a burn center (Box 53-6). Patients with these burns should be treated in a specialized burn facility after initial assessment and treatment at an ED. Whether the patient

BOX 53-6 Criteria for Referral to a Burn Center

- Partial-thickness burns more than 10% of TBSA
- Burns that involve the face, hands, feet, genitalia, perineum, or major joints
- Third-degree burns in any age group
- Electrical burns, including lightning injury
- Chemical burns
- Inhalation injury
- Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality
- Concomitant trauma, in which the burn injury poses the greatest risk for morbidity or mortality*
- Children with burns in hospitals without qualified personnel or equipment for the care of children
- Patients with burns who will require special social, emotional, or long-term rehabilitative intervention

*In such cases, if the trauma poses the greater immediate risk, the patient may be initially stabilized in a trauma center before being transferred to a burn unit. Physician judgment is necessary in such situations and should be in concert with the regional medical control plan and triage protocols.

Data from the American Burn Association Burn Center Referral Criteria.

stays at the initial hospital or is transferred to a burn center facility, the resuscitation phase begins immediately after the burn insult has occurred. The primary and secondary surveys are completed before transfer. Proper stabilization of the patient is crucial for successful transfer. As with any major trauma, the first hour is crucial, and the next 24 to 36 hours are also important. The management of fluid balance, the respiratory system, and nutrition is vital, and all systems have a major impact on the patient's survival.

Resuscitative Phase

Primary Survey

The following parameters are assessed in the primary survey:

- Airway maintenance with cervical spine protection
- Breathing and ventilation
- Circulation with hemorrhage control
- Disability (assess neurological deficit)
- Exposure (completely undress the patient, but maintain temperature)

Airway

On initial assessment of the patient with burns, the airway must be assessed immediately. The compromised airway may be controlled by a chin lift, jaw thrust, insertion of an oropharyngeal airway in an unconscious patient, or endotracheal intubation. It is crucial not to hyperextend the neck in patients with suspected cervical spine injuries.

Breathing and Ventilation

Ventilation requires adequate functioning of the lungs, chest wall, and diaphragm. To assess for breathing and ventilation, the nurse must listen to the chest and verify breath sounds in each lung, assess adequacy of rate and depth of respiration, administer high-flow oxygen at 15 L/min using a nonrebreathing mask, and assess for circumferential full-thickness burns of the chest that may impair ventilation.

Circulation

Assessment of the circulation includes a measurement of blood pressure and heart rate. Special attention should be paid to the distal pulses of any extremity with circumferential burns. Intravenous (IV) cannulation is performed by inserting two large-bore catheters into the skin that is unburned, if possible. A central venous catheter should be inserted when indicated. Doppler ultrasonography can be used to assess for pulses. Box 53-7 lists risk factors for impaired circulation.

Disability

Typically, the patient with burns is alert and oriented. If not, associated injuries, such as inhalation injury, head trauma, substance abuse, or preexisting medical conditions, should be considered. The assessment is initiated by determining the patient's level of consciousness using the AVPU (Alert, responds to Verbal stimuli, responds to Painful stimuli, Unresponsive) method.

Exposure

All the patient's clothing and jewelry are removed to complete the primary and secondary survey. Ensure the environment is warmed as the burn patient is poikilothermic. After examination, the patient is covered with a clean, dry sheet and warm blankets to prevent evaporative cooling. If possible, IV fluids are warmed at 98.6°F (37°C) to 104°F (40°C).

Secondary Survey

The secondary survey is completed after resuscitative efforts are well established and consists of a detailed history and physical examination of the patient as well as a complete history of the accident. Every attempt is made to determine exactly what happened (Box 53-8). A detailed neurological examination is completed, and initial radiographic and laboratory studies are done. Resuscitative measures are ongoing and constantly evaluated.

A complete history and physical examination are the hallmarks of the secondary survey. It is not uncommon for patients to have comorbid diseases. Preexisting diseases, such as diabetes, hypertension, asthma, cancer, and stroke, should be documented. A medication list is obtained from the patient if possible, or a family member is asked to provide the information. In addition, any allergies, the person's tetanus immunization history, and the time of the person's last meal should be documented. Burn depth and burn size are assessed.

BOX 53-7 *PATIENT SAFETY*

Risk Factors for Impaired Circulation

- Progressive diminution of pulses despite adequate resuscitation
- Decreased capillary refill
- Decreased sensation
- Progressive worsening of pain
- Paresthesias
- Pallor of extremity

BOX 53-8 Questions to Ask During a Secondary Survey

Thermal Burns
- How did the burn occur?
- Did the burn occur inside or outside?
- Did the clothes catch fire?
- How long did it take to extinguish the fire?
- Were there any explosions?
- Was the patient found in a smoke-filled room?
- How did the patient escape?
- Did the patient jump out of a window?
- Were there other people injured or killed at the scene?
- Was the patient unconscious at the scene?
- Was there a motor vehicle crash?
- Was the car severely damaged?
- Was there a car fire?
- Are the purported circumstances of the injury consistent with the burn characteristics (is there possibility of abuse)?

Scald Injuries
- How did the burn occur?
- What was the temperature of the liquid?
- What was the liquid; how much liquid was involved?
- What was the burn cooled with?
- Who was present when the burn took place?
- Where did the burn take place? Is there possibility of abuse?

Chemical Burns
- What was the agent?
- How did the exposure occur?
- What was the duration of contact?
- Did contamination take place?

Electrical Burns
- What kind of electricity was involved?
- Did the patient lose consciousness?
- Did the patient fall?
- What was the estimated voltage?
- Was cardiopulmonary resuscitation administered at the scene?

Burn injuries require a global assessment. The following laboratory and diagnostic studies are indicated for patients with burns:

- Complete blood count (CBC)
- Comprehensive chemistry panel, including blood urea nitrogen
- Creatinine level
- Urinalysis
- ABG values to include carboxyhemoglobin determination
- Electrocardiogram
- Chest radiograph

After the primary and secondary surveys are complete, the burned area is usually covered with a dry sheet. This reduces the risk for infection and keeps the patient warm. A cool compress can be applied to small superficial burns. If the patient has a high-voltage electrical burn or cardiac changes are noted, continuous cardiac monitoring is provided. If the patient has a chemical burn, the area is immediately flushed with large amounts of water to remove the chemical, and all contaminated clothing is removed and bagged. If the patient is going to be transferred to a burn center, initiation of fluid resuscitation, insertion of a nasogastric tube (NGT), and insertion of an indwelling urinary catheter may be carried out during the secondary assessment.

Providing Hemodynamic Support

Therapy for burn shock is aimed at supporting the patient through the period of hypovolemic shock until capillary integrity is restored. Fluid resuscitation is the primary intervention in the resuscitative phase in the intensive care unit (ICU) to maintain tissue perfusion and end organ function. Goals in fluid resuscitation are as follows:

- Correct fluid, electrolyte, and protein deficits.
- Replace continuing losses and maintain fluid balance.
- Prevent excessive edema formation.
- Maintain an hourly urinary output in adults of 30 to 50 mL/h (approximately 0.5 mL/kg/h).[6]

Formulas for Fluid Administration

Numerous formulas have been developed for fluid resuscitation (Box 53-9). Each has advantages and disadvantages. They differ primarily in terms of recommended volume administration and salt content. In general, lost crystalloid and colloid solutions must be replaced rigorously. Free water, given as dextrose 5% in water (D_5W) with or without added electrolytes, is regulated so that insensible fluid loss is covered. Lactated Ringer's solution is the crystalloid of choice because it is a balanced salt solution that closely approximates the composition of extracellular fluid.

The ABA recommends the use of the ABA consensus formula for the resuscitation of patients with burns. The formula is a combination of the modified Brooke formula and the Baxter (commonly called Parkland) formula. The ABA consensus formula requires 2 to 4 mL of lactated Ringer's solution per kilogram of body weight per percentage TBSA burn. The total amount calculated is administered in the first 24 hours after injury. One half is given in the first 8 hours *from the time of the burn*, one fourth is given during the next 8 hours, and the remaining one fourth is given over the next 8 hours. The ABA consensus formula and the other fluid resuscitation formulas are guidelines, and individual patients may require more or less than 2 to 4 mL/kg per percentage TBSA during the first 24 hours. Patients who often require more fluid than the formula predicted include those with electrical injuries, inhalation injuries, delayed resuscitation, prior dehydration at time of injury, and concomitant trauma.

Other formulas contain various amounts of hypertonic saline or colloid. Hypertonic saline resuscitation lowers the amount of fluid that needs to be given to selected patients; however, it can cause severe hypernatremia and must be used cautiously. The argument against colloid administration within 12 hours of injury is that during this time, the diffuse postburn capillary leak allows colloids to extravasate through endothelial junctions. Therefore, colloid administration does not produce any demonstrable oncotic benefit over administration of a crystalloid while the capillary leak is present. The postinjury time at which capillary integrity is restored varies among people but usually is between 12 and 14 hours. Many physicians administer colloids at this point to restore albumin levels to 2.0 to 3.0 mg/dL. Controversy exists over the type of colloid to be administered, with some centers using salt-poor albumin, and others using fresh frozen plasma.

BOX 53-9 Fluid Resuscitation Formulas

Baxter (Parkland) Formula
- First 24 hours: Lactated Ringer's solution (4 mL/kg/% TBSA); half given over first 8 hours, remaining half given over next 16 hours
- Second 24 hours: Dextrose in water, plus potassium- and colloid-containing fluid (0.3 to 0.5 mL/kg/%TBSA)

Brooke Formula
- First 24 hours: Lactated Ringer's solution (1.5 mL/kg/% TBSA) plus colloid solution (0.5 mL/kg/%TBSA); half given over first 8 hours, remaining half given over next 16 hours
- Second 24 hours: Lactated Ringer's solution (0.5 to 0.75 mL/ kg/%TBSA), plus 5% dextrose in water (D_5W) (2 L)

Modified Brooke Formula
- First 24 hours: Lactated Ringer's solution (2 mL/kg/% TBSA); half given over first 8 hours, remaining half given over next 16 hours
- Second 24 hours: Colloid solution (0.3 to 0.5 mL/kg/% TBSA), plus D_5W to maintain adequate urine output

Consensus Formula
- First 24 hours: Lactated Ringer's solution (2 to 4 mL/ kg/% TBSA in adults; 3 to 4 mL/kg/%TBSA in children); half given over first 8 hours, remaining half given over next 16 hours
- Second 24 hours: Colloid-containing fluid (0.3 to 0.5 mL/ kg/%TBSA), plus electrolyte-free fluid (in adults) or half-normal saline solution (in children) to maintain adequate urine output

Dextran Formula
- First 8 hours: Dextran 40 in saline (2 mL/kg/h), plus lactated Ringer's solution infused to maintain urine output at 30 mL/h
- Second 8 hours: Fresh-frozen plasma (0.5 mL/kg/h) for 18 hours, plus additional crystalloid to maintain adequate urine output

Evans Formula
- First 24 hours: 0.9% normal saline solution (1 mL/kg/%TBSA), plus colloid solution (1 mL/kg/%TBSA); half given over first 8 hours, remaining half given over next 16 hours
- Second 24 hours: 0.9% normal saline solution (0.5 mL/kg/% TBSA), plus D_5W (2 L)

The challenge is to balance resuscitation since under or over resuscitation have significant consequences. Care must be taken to avoid fluid overload and pulmonary edema. This is often difficult because large amounts of fluids are given over a short period during fluid resuscitation immediately after the burn. For example, using the high range of the ABA consensus formula, a male patient weighing 75 kg who received burns over 50% of his body would require up to 15,000 mL of fluid (4 mL × 75 kg × 50% TBSA = 15,000 mL). Of this, 7,500 mL is to be administered during the first 8 hours, and 3,750 mL is to be administered in the second and third 8-hour periods. It is extremely difficult to avoid fluid overload and pulmonary edema when it is necessary to infuse large amounts of fluids so rapidly.

After the first 24 hours after injury, replacing the massive evaporative water loss is a major consideration in fluid management. The primary solution given at this time is D_5W, with the goal of keeping the patient's sodium concentration at 140 mEq/L. The fluid volume depends on the severity of injury, the age of the patient, the physiological status of the patient, and any associated injuries. Consequently, the volume recommended by a resuscitation formula must be modified according to the person's response to therapy (Fig. 53-5).

Urine output is the single best indicator of fluid resuscitation in patients with previously normal renal function. The onset of spontaneous diuresis is a hallmark indicating the end of the resuscitative phase. Infusion rates can be decreased by 20% to 30% for 1 hour if the urine output is satisfactory and can be maintained for 2 hours; the reduction may then be repeated. It is essential that urinary outputs be maintained within normal limits of 30 to 50 mL/h (0.5 mL/kg/h) in the adult. Other indications of adequate fluid replacement are listed in Box 53-10.

Patients are usually weighed daily. A gain of 15% of admission weight may be expected with large fluid resuscitation. Intake and output must be monitored meticulously. Patients who sustain deep muscle injury (ie, second- or third-degree burns or electrical injuries) are at risk for development of acute renal insufficiency. This renal dysfunction may be the result of inadequate fluid resuscitation, or it may be the consequence of the liberation of the myoglobin and hemoglobin from damaged cells. These compounds, sometimes called hemochromogens, may precipitate in renal tubules, resulting in acute tubular necrosis. Hemochromogens produce a clear reddish-brown color in the urine. Should hemochromogens appear in the urine, acidosis should be corrected promptly and IV fluids increased to maintain a brisk urine output (75 to 100 mL urine/h) until the urine returns to its normal clear yellow and there is no urinary myoglobin.

Providing Pulmonary Support

Inhalation injury is the leading cause of death in the first 24 hours after burn injury. It increases the mortality rate by 20% alone and by as much as 60% when combined with pneumonia.[16,18] Goals for the successful treatment of inhalation injury include improving oxygenation and decreasing interstitial edema and airway occlusion.

The conventional treatment for inhalation injury is largely supportive because direct intervention is difficult. Humidified oxygen is administered to prevent drying and sloughing of the mucosa. Upper airway edema peaks 24 to 48 hours after injury. If the injury is mild or moderately severe, placing the patient in a high Fowler's position and administering aerosolized racemic epinephrine may be sufficient to limit further edema formation. Severe upper airway obstruction may require endotracheal intubation to protect the airway until the edema subsides.

In patients with mild tracheobronchial injury, atelectasis may be prevented by frequent pulmonary toilet, using a high Fowler's position, coughing and deep breathing, chest physiotherapy, repositioning, frequent tracheal suctioning, and incentive spirometry.[13,14] In patients with more severe inhalation injury, more frequent suctioning may be necessary, and bronchoscopic removal of debris may be appropriate. These patients usually require endotracheal intubation and mechanical ventilatory support. The objective of ventilatory support is to provide adequate gas exchange at the lowest possible inspired oxygen concentration and airway pressure, in an attempt to reduce the incidence of oxygen toxicity and pulmonary barotrauma. The use of volumetric diffusive

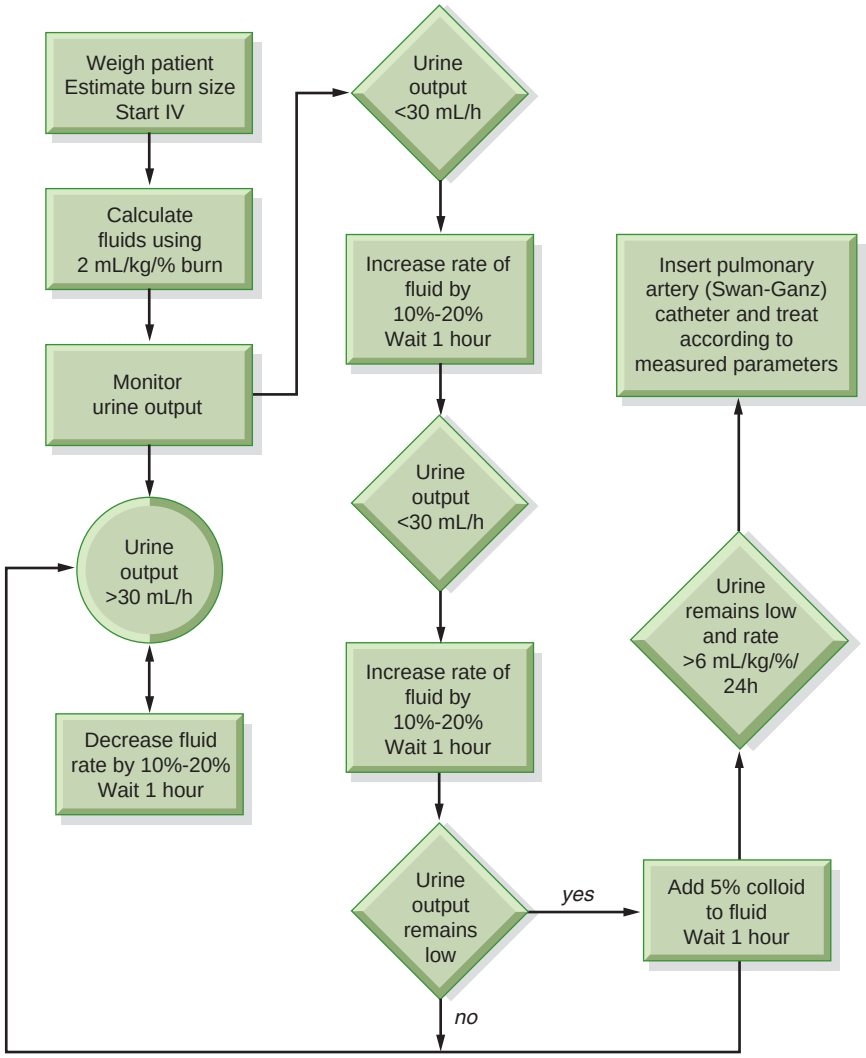

FIGURE 53-5 ▲ Initial 24-hour fluid management. (From Rue LW, Cioffi WG: Resuscitation of thermally injured patients. Crit Care Nurs Clin N Am 3(2):186, 1991.)

respiration (VDR) appears to offer advantages over conventional mechanical ventilation.[14,18] In VDR, subtidal volume breaths accumulate and build to a set airway pressure, which is then followed by passive exhalation. Throughout the ventilatory cycle, high-frequency pulsations of air are continuously administered. This method of inspiration appears to aid in ventilation and recruitment of partially obstructed alveoli.

Patients with bronchospasm are treated with aerosolized or intravenously administered bronchodilators. Respiratory parameters are monitored closely, and constant attention is paid to breath sounds and vital signs to detect fluid overload as early as possible.

Bronchopneumonia may be superimposed on other respiratory problems at any time and may be hematogenous or airborne. Airborne bronchopneumonia is most common, with onset occurring soon after injury. It is often associated with a lower airway injury or aspiration. Hematogenous, or miliary, pneumonia begins as a bacterial abscess secondary to another septic source, usually the burn wound. The time of onset usually is 2 weeks after injury.

Prophylactic antibiotics and steroids have not been demonstrated to prevent the common complications of infection encountered in patients with inhalation injury. New methods to decrease the incidence of nosocomial pneumonia in critically ill patients that are currently under investigation include selective decontamination of the orodigestive tract.

Escharotomy

Any circumferential burn to an arm or leg may mimic compartment syndrome. Edema formation in the tissues under the tight, unyielding eschar of a circumferential burn of a deep partial-thickness or full-thickness injury produces significant vascular compromise in the affected limb.

To minimize the risk for circulatory compromise, the patient's rings, watch, and other jewelry are removed during the initial examination. Elevation and range of motion of the injured extremity may alleviate minimal degrees of circulatory distress. Skin color, sensation, capillary refill, and peripheral pulses are assessed and documented hourly in an extremity with a circumferential burn. Doppler ultrasonography is the most reliable means of assessing arterial blood flow and the need for an escharotomy. In the upper extremity, the radial, ulnar, and palmar arch pulses are checked hourly. In the lower extremity, the posterior tibial and dorsalis pedis pulses are checked hourly. Loss—or a progressive diminution (decrease)—of the ultrasonic signal is an indication for escharotomy.[19] In circumferential chest burns, respiration and ventilatory effort needs

BOX 53-10 Indications of Adequate Fluid Replacement*

Urinary output	30–70 mL/h (0.5 mL/kg/h)
Pulse rate	100–120 bpm
Central venous pressure (CVP)	<12 cm H_2O
Pulmonary artery occlusion pressure (PAOP)	<18 mm Hg
Lungs	Clear
Sensorium	Clear
Gastrointestinal tract	Absence of nausea and adynamic ileus
Arterial base deficit and lactate	Normalizing values

*Central lines and Swan-Ganz catheters are not inserted routinely because of the danger of sepsis; however, they are used in selected instances.

to be continuously assessed. Escharotomy may be necessary to relieve chest wall restriction and improve ventilation.[19]

The escharotomy is carried out as a bedside procedure, using a sterile field and scalpel, an electrocautery device, or both. Taking the patient to the operating room is not necessary and causes unacceptable delay. Local anesthesia is rarely needed because full-thickness injuries are insensate. However, small doses of narcotics and benzodiazepines assist in patient comfort. Patients with this severity of injury are often already intubated and therefore receiving sedatives and analgesics.

The incision should be placed along both the mid-medial and mid-lateral aspect of the extremity and should extend through the eschar down to the subcutaneous fat to permit adequate separation of the cut edges for decompression (Fig. 53-6). The incisions should be made from an area of unburned tissue and extended to unburned tissue if possible.

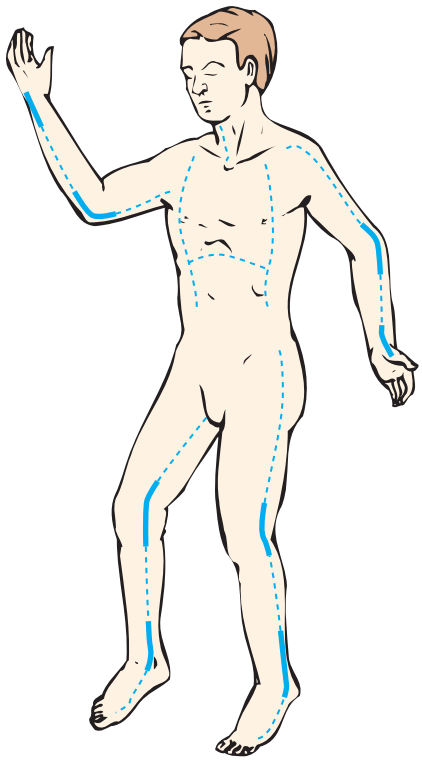

FIGURE 53-6 ▲ Preferred sites of escharotomy incisions.

The procedure should be completed with the patient in the anatomically correct position to minimize the risk for damage to major blood vessels and nerve bundles, especially when incisions cross joints.

Reparative Phase

Once the patient stabilizes, measures are taken to promote healing and prevent infection. As noted earlier, burn wounds can have profound effects on nearly every organ system. Box 53-11 lists nursing diagnoses for patients with burns, and Box 53-12 contains a collaborative care guide for the patient with burns.

Ensuring Optimal Nutrition

Before the unique nutritional needs of patients with burns were fully recognized in the late 1970s, those who had severe burn injuries, and who survived, languished in a hospital ward with minimal oral intake until they became severely cachectic. It is currently clear that appropriate nutrition plays a significant role in improving outcome for patients with severe burn injuries.

Although early parenteral feeding has been associated with increased mortality because of an increase in the risk for infection, early enteral feeding has been proposed because it may reduce the translocation of bacteria from the intestinal lumen.[10,11] Passage of bacteria from the gut into the intestinal lymphatics or portal venous system probably occurs in all healthy people. However, the intestinal edema that accompanies the burn resuscitation period and the

BOX 53-11 EXAMPLES OF NURSING DIAGNOSES

For the Burn Patient

- Ineffective Airway Clearance related to impaired cough, oropharyngeal and tracheal swelling, or artificial airway
- Impaired Gas Exchange related to inhalation injury, atelectasis, ARDS, or carbon monoxide poisoning
- Ineffective Breathing Pattern related to circumferential chest burn, upper airway obstruction, or ARDS
- Impaired Peripheral Tissue Perfusion related to edema or circumferential burn (eschar syndrome)
- Deficient Fluid Volume related to altered capillary permeability, insensible, and third-spacing losses
- Fluid Volume Excess related to fluid resuscitation and subsequent fluid mobilization 3 to 5 days postburn
- Impaired Skin Integrity related to burn injury or surgical interventions
- Hypothermia related to impaired integument
- Imbalanced Nutrition: Less Than Body Requirements related to hypermetabolic response to burn injury, paralytic ileus
- Impaired Urinary Elimination related to indwelling urinary catheter
- Risk for Infection related to loss of integument, invasive procedures, and immunocompromise
- Acute Pain related to exposure of nerve endings, invasive procedures, surgical procedures, and dressing changes
- Ineffective Coping related to altered body image and fear
- Anxiety related to traumatic injury, fear of dying, fear of disfigurement, change in body image, and change in role relationships

BOX 53-12 COLLABORATIVE CARE GUIDE for the Patient With a Burn

Outcomes	Interventions
Oxygenation/Ventilation	
Patent airway is maintained. Lung is clear on auscultation.	• Auscultate breath sounds every 2–4 h and as needed (PRN). • Assess for inhalation injury, and anticipate intubation. • Assess quantity and color of tracheal secretions. • Suction endotracheal airway when appropriate (see Chapter 25, Box 25-16, pp. 538–539). • Hyperoxygenate and hyperventilate before and after each suction pass.
Peak, mean, and plateau pressures are within normal limits for a patient on a ventilator.	• Monitor airway pressures every 1–2 h. • Monitor lung compliance every 8 h (see Chapter 24). • Administer bronchodilators and mucolytics. • Perform chest physiotherapy every 4 h. • Monitor airway pressures and lung compliance for improvement after interventions. • Calculate PaO_2/FiO_2 ratio and oxygen index, monitoring trends.
There is no evidence of atelectasis or infiltrates.	• Turn side to side every 2 h. • Consider kinetic therapy or prone positioning. • Daily chest x-ray.
Arterial blood gases (ABGs) are within normal limits.	• Initial and serial carboxyhemoglobin (carbon monoxide) levels until <10% • Monitor ABGs monitor acid-base balance, lactate and bicarbonate levels. (Pulse oximeter and calculated SaO_2 are inaccurate measures in the presence of carbon monoxide.) • Provide humidified oxygen. • Consider hyperbaric therapy.
Circulation/Perfusion	
Blood pressure, heart rate, CVP, and pulmonary artery (PA) pressures are within normal limits.	• Assess vital signs every 1 h. • Assess hemodynamic pressures every 1 h if patient has PA catheter. • Administer intravascular volume as ordered to maintain preload (see below).
Temperature is within normal limits.	• Monitor temperature every 1 h. • Maintain a warm environment, and use warming lights or blankets to prevent hypothermia. • Treat fever by cooling the environment, antipyretics and cooling blankets.
Perfusion to extremities is maintained; pulses are intact.	• Monitor perfusion using Doppler and palpation every 1 h. • Elevate burned extremities. • Prepare for escharotomy or fasciotomy.
Fluids/Electrolytes	
Restore and maintain fluid balance: Urine output 30–70 mL/h or 0.5 mL/kg/h. CVP 8–12 mm Hg; PAOP 12–18 mm Hg; blood pressure, within normal limits; heart rate 100–120 bpm.	• Assess intake and output every 1 h. • Give lactated Ringer's 2–4 mL/kg/TBSA%, divided into first 24-h postburn. • Monitor for spontaneous diuresis, and reduce intravenous infusion rate as indicated. • Take daily weight.
Electrolytes, mineral, and renal function values are within normal limits.	• Monitor and replace minerals and electrolytes. • Monitor blood urea nitrogen, creatinine, myoglobin, and urine electrolytes and glucose. • Monitor neurological status. • Monitor and treat dysrhythmias. • Monitor and limit water consumption, burn patients have extreme thirst and if allowed drastically decrease sodium level.
Mobility/Safety	
Patient is free of joint contractures.	• Provide passive and active range-of-motion exercises every 1–2 h. • Apply positioning splints as needed.
There is no evidence of complications related to immobility.	• Turn and reposition every 2 h. • Consider kinetic therapy. • Consider deep venous thrombosis prophylaxis.

(*continued on page 1199*)

BOX 53-12 *COLLABORATIVE CARE GUIDE for the Patient With a Burn (continued)*

Outcomes	Interventions
There is no evidence of infection.	• Maintain strict sterile technique, and monitor technique of others. • Maintain sterility of invasive catheters and tubes. • Per hospital protocol, change dressings and invasive catheters. Culture wounds, blood, urine, as necessary. • Monitor for changes in sputum or wounds. • Monitor SIRS/ sepsis using burn criteria: temperature, tachycardia, tachypnea or ↑minute ventilation, feeding intolerance, elevated glucose/insulin resistance.
Skin Integrity	
Unburned skin will remain intact.	• Assess skin every 4 h and each time patient is repositioned. • Turn every 2 h. • Consider pressure relief/reduction mattress and devices.
Burns begin healing without complications.	• Treat burns per hospital protocol; apply topical medications and débride as indicated. • Monitor skin graft viability. • Protect grafted areas (eg, bed cradle, dressings). • Consider air fluidized bed to enhance healing and relieve pressure from burned surface.
Nutrition	
Caloric and nutrient intake meets metabolic requirements per calculation (eg, Basal Energy Expenditure).	• Provide enteral or parenteral nutrition within 24 h of injury. • Consult dietitian or nutritional support service to assess nutritional requirements with team. • Monitor protein and calorie intake. • Monitor albumin, prealbumin, transferrin, cholesterol, triglycerides, glucose, nitrogen balance.
Comfort/Pain Control	
Patient will have minimal pain (<5 on pain scale) and discomfort.	• Assess pain and discomfort using objective pain scale every 4 h, PRN, and following administration of pain medication. • Administer analgesics before procedures and monitor patient response. • Use nonpharmacological pain management techniques (eg, music, distraction, touch).
Psychosocial	
Patient demonstrates decreased anxiety.	• Assess vital signs during treatments, discussions, and so forth. • Administer anxiolytics before treatments/procedures. • Consult social services, clergy, and so forth as appropriate. • Provide for adequate rest and sleep. • Encourage discussion regarding long-term effects of burns, available resources, and coping strategies.
Teaching/Discharge Planning	
Patient/significant others understand procedures and tests needed for treatment.	• Prepare patient/significant others for procedures, such as débridement, escharotomy, fasciotomy, intubation, and mechanical ventilation.
Significant others understand the severity of the illness, ask appropriate questions, and anticipate potential complications.	• Explain the potential effects of burns and the potential for complications, such as infection, respiratory or renal failure. • Encourage significant others to ask questions related to the management of burns, disfigurement, coping, and so forth.

immunosuppression that follows make it difficult for the body to clear these microorganisms effectively. Microbial products—either live organisms or cell wall fragments—disseminate through the body, prompting the release of cytokines such as TNF, interleukin-1 (IL-1), and interleukin-6 (IL-6). These cytokines exacerbate the hypermetabolic response and may initiate SIRS.

The rationale for enteral feeding within the first 24 hours of injury is that the presence of food in the gut lumen reduces the rate of microbial translocation. Although not proved definitively in the clinical setting of patients with burns, safety and simplicity of early feeding have been demonstrated. One approach is to slowly infuse tube feedings through the NGT at a rate of 10 to 20 mL/h. Although this

clearly does not meet the nutritional needs of adult patients, it is enough to protect the gut mucosa. Long feeding tubes can be placed into the small bowel using endoscopy or fluoroscopy and the rate steadily increased to meet the estimated calculated caloric requirements. The advantages of such tubes are higher and earlier rates of infusion and continuous feeding of patients during surgical procedures requiring general anesthesia. Patients with minor burns may be able to satisfy their caloric needs and fluid resuscitation through oral intake only.

Despite the theoretical advantages and need for the calories provided by enteral feeding, difficulties exist, and the technique cannot be used in all patients. Patients receive, on average, only 80% of the goal rate for enteral feedings because of frequent interruptions for patient care, including radiological procedures and surgery. This deficit increases when patients develop intestinal ileus, as typically occurs with major infection. Osmotic diarrhea is troublesome, particularly when the patient's feces soil the burn dressings. A variety of techniques combat diarrhea, including replacement of intestinal flora with lactobacillus granules and nonpasteurized yogurt, as well as retardation of small bowel motility with diphenoxylate hydrochloride.

The estimated caloric and protein needs of a patient may be met more reliably with parenteral than enteral feeding. The central venous catheter, which predisposes the patient to invasive infections (particularly infections with *Candida* species), is a disadvantage. Reports suggest that the rate of bacterial translocation is increased with the use of parenteral nutrition compared with enteral nutrition and that infection rates are higher.[10,20] Long-term use of parenteral nutrition alone is associated with hepatobiliary dysfunction, including cholestatic hepatitis and acalculous cholecystitis. Nevertheless, parenteral nutrition can be used for patients who do not tolerate enteral feedings because of paralytic ileus of the intestine or prolonged diarrhea.

Burn injury results in an increase in the metabolic expenditure. Initial investigative work performed in the 1970s demonstrated that some patients with burns needed as many as 7,000 or 8,000 kcal/d to maintain weight. Although patients with burns still become hypercatabolic after injury, they do not become so to the same degree because of changes in management. Because of the effect of earlier enteral feeding and the introduction of procedures that promote early wound closure (early and aggressive excision and grafting and the use of biological dressings), the increase in metabolic rate has diminished; healing does not fully begin until the wounds are closed. Indirect calorimetry has shown that the most severe injuries require no more calories than twice the resting energy expenditure (REE) as described in the Harrison-Benedict formula. The REE calculated by the Harrison-Benedict formula is multiplied by a stress factor in direct proportion to the size of the burn (Box 53-13). The stress factor is judged conservatively to avoid overfeeding, which is associated with increased susceptibility to infection. Although indirect calorimetry prevents gross underestimation or overestimation of the patient's caloric needs, in most patients, it is probably not superior to estimating their needs from a formula (such as the Harrison-Benedict formula) alone.

Wound repair depends on amino acids, which are the building blocks of proteins. The type of amino acids used in enteral feedings varies. The amino acids arginine and glutamine have immune-enhancing properties, improve nitrogen retention, and maintain lean body mass. Formulas containing arginine supplements have been reported to reduce infections in trauma patients and to reduce length of stay of critically ill patients.

BOX 53-13 Stress Factors for Energy Expenditure Related to Burn Size (Harrison-Benedict Equations)

Women:REE = 655 + [4.3 × Wt(lb)] + [4.3 × Ht(in)] – [4.7 × age]
Men:REE = 65 + [6.2 × Wt(lb)] + [12.7 × Ht(in)] – [6.8 × age]

TBSA (%)	Stress Factor
0–10	1.4
11–20	1.5
21–30	1.6
31–40	1.7
41–50	1.8
51–60	1.9
>60	2.0

REE, resting energy expenditure.

Judging the amount of protein necessary for recovery from burn injuries is difficult. Massive and unquantified loss of protein from the burn wound exudates precludes nitrogen balance studies based on urine excretion alone. Sequential measurements of serum proteins, such as transferrin and prealbumin, are a better index of the body's response to the amount and type of dietary protein given; however, few clinical studies show a correlation between an increase in serum proteins and improved clinical outcome. It is important to avoid overfeeding of protein because it predisposes patients to sepsis. Amounts of protein greater than 3 g/kg/d in adults are usually not tolerated because of azotemia. Dietary protein should be started at an administration rate of 1.2 g/kg/d and should be increased if there is not a subsequent increase in serum protein markers. A patient's diet can also be supplemented with vitamins A and C, and with the trace element zinc, all of which improve wound healing.

Successful weaning of patients from nutritional supplements sometimes occurs earlier than expected. A regular diet with liquid supplements is offered within 24 hours of extubation. The increased thirst of patients with burns is used to encourage the intake of protein-containing solutions, either soy- or milk-based supplements, or protein-containing fruit drinks. Using supplements, patients can take up to 2,000 kcal each day. It is preferable to feed patients or allow them to feed themselves because of the inherent risks of feeding tubes and central lines.

Providing Musculoskeletal Support

Physical and occupational therapy begins on day 1 of a burn injury. Independent of the patient's general condition, injured upper and lower extremities can be elevated to allow adequate venous drainage and reduce edema. Passive exercises are initiated and, if alert and cooperative, the patient should participate in these exercises. Active and passive exercises to maintain joint range of motion are continued throughout hospitalization and the outpatient rehabilitation period.

Two important axioms influence rehabilitation. First, the burn wound will shorten by contraction until it meets an opposing force. Across a flexor surface, this may result in a contracture. Second, the position of comfort is the position of contracture. Range-of-motion exercises prevent tendon shortening and restriction of joint motion by burn scar contractures. As patients begin to recover and participate actively in therapy, exercises are designed to increase muscle strength and endurance. A return to activities of daily living frequently takes months.

An unfortunate consequence of contractures and immobility is heterotopic ossification. Heterotopic ossification develops when there is an abnormal deposition of calcium phosphate crystals in joint spaces or along tendons. Heterotopic ossification restricts the motion of joints, particularly in elbows and knees. Unlike the heterotopic ossification seen in patients with spinal cord injuries, the heterotopic ossification seen in patients with burns does not respond to treatment with etidronate disodium, and early surgical removal is not indicated. Resolution occurs with time in most patients, and few need surgical removal of the ossified crystals in the joints.

Managing Pain

The pain associated with burns is managed aggressively. All narcotics are given intravenously because absorption of the drug is unpredictable when given intramuscularly or subcutaneously secondary to the hypermetabolic response and the fluid shifts.[6,19,21] Patients are given anxiolytics for anxiety related to appearance, procedures, and fear.[22] Patient-controlled analgesia (PCA) is ideal for patients who are awake, sufficiently oriented, and physically able to use the pump. PCA pumps can provide a continuous pain medication, with a "dose" available every 6 to 8 minutes for intermittent pain. The nurse can give the patient a "bolus" dose before procedures, such as dressing changes and physical therapy. Recommended narcotics include morphine, fentanyl, and hydromorphone.[21,22]

Caring for the Wound

CLEANSING. The wound protocols of all burn centers and hospitals vary, but the most common wound cleansing involves water and chlorhexidine or saline solution and povidone-iodine (Betadine). Wounds are cleansed at each dressing change and are observed for signs of infection and rate of healing.

Hydrotherapy is the preferred approach of most burn centers because the warm, flowing water is beneficial to help loosen exudates, clean and assess the wound, and provide range-of-motion exercise. The solutions used vary and may contain salt, povidone-iodine, and bleach. Because the procedure is usually painful, patients should receive an analgesic 20 to 30 minutes before beginning and small, frequent doses throughout as needed. In addition, the patient should receive a complete explanation of, and assistance with, pain-controlling techniques (eg, imagery, music therapy). Additional support should be offered by providing ongoing explanations of what is to be done and why and by permitting the patient to participate in care as much as possible. Limiting the time the procedure takes is important to the patient's pain tolerance and temperature control. Hydrotherapy should be limited to 20 minutes to prevent extreme chilling, which increases metabolic demand.

Care must be taken to avoid cross-contamination of wounds during bathing procedures. For this reason, many centers no longer immerse patients in Hubbard tanks. Portable shower trolleys with disposable liners can provide hydrotherapy without the risk for contamination. These may be used in a central shower room or in facilities so equipped, or used directly in the patient's room, reducing the risk for transporting the critically ill. Clean or healing wounds should be cleaned separately from contaminated ones.

APPLICATION OF TOPICAL ANTIMICROBIAL MEDICATIONS. The choice of topical antimicrobial medications depends on the wound depth, location, and condition and on the presence of specific organisms. Common antimicrobial drugs used from time of admission to a burn unit include silver sulfadiazine (Silvadene), mafenide acetate (Sulfamylon), 0.5% silver nitrate, nitrofurazone, povidone-iodine, bacitracin, gentamicin, and nystatin (Table 53-4). No single drug is totally effective against all burn wound infections. Treatment is guided by in vitro testing or in vivo results. Eschar and granulating wound surfaces may be cultured three times weekly to identify contaminating organisms and determine antibiotic sensitivity.

Silver sulfadiazine is the primary topical drug of choice on admission. The most common adverse reaction is transient leukopenia; therefore, serial CBCs must be monitored. If the WBC count falls below 3,000 cells/mm^3, the physician will probably prescribe another topical agent. When the leukocyte count returns to normal (4,000 to 5,000 cells/mm^3), silver sulfadiazine therapy may be reinstituted.[23]

If the colony counts increase, the topical agent of choice is usually mafenide acetate cream, an effective broad-spectrum bacteriostatic agent. Mafenide acetate diffuses through third-degree eschar to the burn wound margin within 3 hours of application. Patient discomfort is common because mafenide acetate may cause a burning sensation as it penetrates the eschar tissue, lasting 20 to 30 minutes after application. This agent inhibits carbonic anhydrase, resulting in metabolic acidosis. This acidosis initially is compensated for by hyperventilation. Oral administration of sodium citrate dihydrate (Bicitra) or IV sodium bicarbonate usually corrects this acid–base imbalance.

The application of topical antimicrobial drugs inhibits the rate of wound epithelialization and may increase the metabolic rate. Electrolyte imbalances (eg, sodium leaching by silver nitrate) and acid–base abnormalities may occur. The best topical drugs are water soluble because they do not hold in heat and macerate the wound. With the application of any topical drug, it is important to use sterile technique. Antimicrobial creams should be applied to a thickness recommended by the manufacturer and reapplied at the necessary frequency to maintain consistent coverage.

DÉBRIDEMENT. Eschar covers the burn wound until it is excised or has separated spontaneously. Small burn wounds may be allowed to separate on their own if the wound shows no signs or symptoms of infection, the patient is hemodynamically stable, or the situation does not allow for excision. In theory, burn wound management is simple. It calls for débridement of the eschar and skin graft closure before the eschar becomes infected. However, the sometimes serious

Table 53-4 Medications for Burn Wound Management

Agent	Advantages	Disadvantages	Nursing Considerations
Mafenide acetate	Broad-spectrum, penetrates eschar	Painful application, acid–base imbalances	Apply twice a day, leave open to air
Silver nitrate	Painless application, broad-spectrum, rare sensitivity	No eschar penetration, discolors wound and environmental surfaces, must be kept moist	Wet-to-wet dressing with nonadhering layer, followed by a gauze layer every 24 h
Silver sulfadiazene	Painless application, broad-spectrum, easy application	May cause transient leukopenia, minimal eschar penetration	Apply a moderate layer and wrap in a gauze dressing every 12 h
Bacitracin	Painless application, nonirritating	No eschar penetration, antimicrobial spectrum not as wide as above medications	Apply a thin layer and nonadhering dressing; if used on face, leave open to air
Mupirocin	Antimicrobial spectrum broader than bacitracin	Expensive	Apply a thin layer and nonadhering dressing; if used on face, leave open to air
Neomycin	Painless application	Antimicrobial spectrum not as wide as above medications	Apply a thin layer and nonadhering dressing; if used on face, leave open to air

systemic complications of burn injury, such as hypovolemia and sepsis, may delay this course of action significantly.

Mechanical Débridement. Mechanical débridement may be accomplished using forceps and scissors to gently lift and trim loose necrotic tissue. Another form of mechanical débridement is dressing the wound with coarse gauze in the form of wet-to-dry or wet-to-wet dressings. Wet-to-dry dressings consist of layers of moistened coarse mesh gauze. As the inner layer dries, it adheres to the wound, entrapping exudate and wound debris. The dressing should be removed at a 90-degree angle, and every effort should be made to avoid damaging fragile, newly granulating tissue. As the wound forms increasing amounts of granulation tissue, wet-to-wet dressings may be used to prevent desiccation and trauma. These dressings remain moist until the next dressing change. The dressing should be removed by first gently lifting from the edges toward the center of the wound and then removing the dressing at a 180-degree angle. This procedure prevents detachment of newly formed epithelial tissue.

Enzymatic Débridement. Enzymatic débridement involves the application of a proteolytic substance to burn wounds to shorten the time of eschar separation. Travase and Elase are the most commonly used agents. The wound is first cleaned and débrided of any loose necrotic material. The agent is then applied directly to the wound bed and covered with a layer of fine-mesh gauze. A topical antimicrobial agent is applied next, and the entire area is covered with saline-soaked gauze. The dressing is changed two to four times per day.

Enzymatic débridement has the advantage of eliminating the need for surgical excision; however, certain complications must be considered. Hypovolemia may occur as a result of excessive fluid loss through the wound. Hence, no more than 20% TBSA should be treated in this manner. Cellulitis and maceration of normal skin may occur around the wound periphery, and patients often complain of a burning sensation lasting 30 to 60 minutes after enzyme application.

Surgical Débridement. In surgical excision, the wound is excised to viable bleeding points while minimizing the loss of viable tissue. Early excision has contributed significantly to the survival of people with major burns. The open burn causes hypermetabolism and a stress response that is not corrected until wound closure occurs. Surgical excision should be done as soon as the patient is hemodynamically stable, usually within 72 hours.[24]

After excision is complete, hemostasis must be achieved. This may be accomplished by topical thrombin sprayed on the wound or application sponges soaked in a 1:10,000 epinephrine solution.[24] After removal of necrotic tissue, the exposed underlying structures must be dressed with a temporary or permanent covering to provide protection and prevent infection.

GRAFTS. The ideal substitute for lost skin is an autograft of similar color, texture, and thickness from a close location on the body. Sheets of the patient's epidermis and a partial layer of the dermis are harvested from unburned locations using a dermatome. These grafts, referred to as split-thickness skin grafts, can be applied to the wound as a sheet graft or mesh grafts.

In a sheet graft, the harvested skin is applied to the surgically excised area. It is usually covered with a petrolatum-based gauze dressing. Overexposed areas such as the face and hands, a sheet graft gives a more natural appearance than a mesh graft.

Grafts must be inspected frequently to ensure that fluid is not collecting underneath them. Fluid accumulation is prevented by rolling a cotton-tipped applicator over the graft to express any trapped fluid. The sheet graft should be "pie-crusted" to allow for the expression of fluid through the closest opening; this avoids rolling the fluid to the edge of the graft, increasing the risk for dislodging the grafted tissue. After adherence has begun, usually after 24 hours, the fluid may be removed with a very small-gauge needle (26-gauge) to avoid disrupting the adherence of graft.

In a mesh graft, the harvested skin is slit, and the graft is then placed on the burn site. The slits (or interstices) allow the skin to expand, providing for greater coverage and drainage and facilitating draping over uneven surfaces. Mesh grafts frequently have to be expanded to obtain maximal coverage from each piece of autograft. An expansion ratio of 1:2 or 1:4 is often practical. Sometimes ratios such as 1:6 or 1:7 are used to cover large burns when donor tissue is limited. With these larger ratios, the expanded autograft is covered with either cadaver skin allografts, synthetic skin (Biobrane, Winthrop Pharmaceuticals), or negative pressure dressings.[25] In addition to physically stabilizing the fragile mesh, the cover decreases evaporation, heat loss, and bacterial contamination.

Dressings are used after surgery to immobilize the grafted area and prevent shearing and dislodging of the graft. Postoperative dressings also provide a degree of compression to minimize hematoma and seroma formation, but they may be a source of vascular compression in the extremities. Pulse checks distal to the dressings are documented every 4 hours for 24 hours after surgery. The dressings are usually left in place until the third postoperative day. Until that time, the dressings are moistened every 6 hours with a solution containing normal saline and polymyxin. The antibiotic solution keeps the fragile meshed grafts moist and protects against infection. On postoperative day 3, the dressings are removed and evaluated by the physician, who determines the success of the grafting. This is expressed in terms of percentages. The grafted area is then covered with a nonadherent dressing and a gauze layer, which are secured with a gauze roll. All components of the dressing are moistened with the antibiotic solution.

Donor site care can vary with a variety of products used at burn centers and sometimes between burn surgeons. The donor site is covered during surgery with a single layer of fine-mesh gauze (eg, Scarlet Red, Biobrane, Acticoat).[25] Most products are kept in place until separation from the donor site begins. Positioning to prevent pressure on the site and to allow for drying is important. Daily inspection of the donor site is essential to detect early signs of infection or cellulitis.

A new technique that involves the growth and subsequent graft placement of cultured epithelial autografts has become an important adjunct to permanent coverage of extensive burn wounds. Biopsies are taken from unburned skin, and cells are cultured in the laboratory. Sheets of cultured epithelial cells are attached to petrolatum-impregnated gauze and applied to the wound. The cultured cells are highly fragile, and the surgeon may elect to place the patient in traction for increased protection of the grafted tissue. After 7 to 10 days, the gauze application is removed, and a nonadherent dressing is applied to prevent mechanical trauma.

Providing Psychological and Familial Support

Providing psychological support for the newly admitted patient with burns and the family is not the least of the many tasks facing the critical care nurse. The patient most often is awake and alert, although anxious and overwhelmed by the suddenness and magnitude of injuries. With high anxiety levels and lack of knowledge pertaining to burns, the family approaches the burn unit with fear, hesitancy, and sometimes hysteria. The physical appearance of the patient and the high-technology atmosphere of the burn unit are frightening. Preparing the family for the initial visit by explaining what to expect and escorting them to the bedside is extremely important. Visitors often are overwhelmed on the first visit and stand silently with increasing feelings of anxiety and hopelessness. Burn injuries are dramatic and are psychologically traumatic for the patient and for those who witnessed the accident. Counseling for the patient and the family begins on the day of admission. Families require constant support, and the burn team should plan weekly family meetings to discuss the patient's care plan and progress. This is often the all-important basis for establishing a trusting relationship for the long months of rehabilitation ahead. The trusting relationship that is established initially provides a strong base for patient and family teaching and rehabilitation in the months to follow. Critically ill patients with burns are likely to experience a series of small gains combined with intermittent setbacks, and this pattern does not stop until the burn wounds are closed, which can be 2 to 3 months after injury. The family needs to be informed and provided with the means to care for their own physical and psychological needs. Families of patients who were transferred from a great distance and who lack nearby support systems find the entire situation particularly stressful. The need to provide support for families cannot be overemphasized.

Patients with burns often become depressed and withdrawn, asking to be left alone and not to be made uncomfortable. The nurse should respond by making certain expectations of the patient clear. That is, the nurse should make it clear to the patient that he or she is to feed himself or herself, go to the bathroom, or do as much as his or her physical condition permits, while communicating to the patient that the situation is not hopeless and that recovery is expected.

The best way to handle regression in a patient with burns is to acknowledge it. First, the nurse must accept the fact that the patient may be unable to cope on an adult level and that the patient may be unstable emotionally and physically. Second, the nurse must devise ways to help the patient cope on an appropriate level. Interventions that usually help include following a regular schedule so that the patient knows what is expected, rewarding the patient for adult behavior, and permitting the patient as much control and choice as possible.

It is not uncommon for severely burned patients, and sometimes family members, to transfer their fears to a specific caregiver (physician, nurse, therapist) and to complain that they are being treated unjustly or unkindly. Working with a psychiatric liaison nurse may help the burn survivor recognize and deal with his or her fears more effectively and help the caregiver support the patient by responding therapeutically.

Hallucinations, confusion, and combativeness are common in severely burned patients for physical and mental reasons. Exhaustion, pain, and medications may distort reality and produce psychotic-like behavior.

Although the patient tends to concentrate on the present, the family members look to the future and want to know what to expect. Information about the patient's condition and treatments should be shared with them using an honest and open approach.

Rehabilitative Phase

Patients with extensive burns require many months for recovery and rehabilitation. Physical and psychological rehabilitation measures are begun in the ICU and continued throughout the recovery period.

Physical Rehabilitation

The diet of the patient with burns should remain high in protein until all wounds have healed. As healing takes place, the diet should be tapered to meet normal caloric requirements. The patient with burns may become accustomed to eating frequently and in large amounts. After healing is complete, metabolism returns to normal, and weight will be gained if eating habits are not controlled properly.

Prevention of Scarring and Contractures

Once regarded as inevitable, hypertrophic scarring and joint contractures are now largely preventable. Preventive measures start when the person is admitted to the hospital and continue for at least 12 months or until the scar is fully mature.

These preventive measures (ie, positioning the body and helping the patient perform range-of-motion exercises) are not new to the nurse. Positioning the body with the extremities extended is extremely important. Although tightly flexed positions are preferred by patients for comfort, they result in severe contractures. The range-of-motion exercises should be carried out with each dressing change or more often if indicated. Special splints are used to maintain arm, legs, and hands in extended, yet functional, positions. Later, when the wounds have healed sufficiently, the person is custom-fitted for a special pressure garment. By applying continuous uniform pressure over the entire area of the burn, the garment prevents hypertrophic scarring. The garment must be worn almost 24 hours a day for approximately 1 year. The smooth elastic garment forms a shield that permits the person to wear normal clothing and resume ordinary activities much sooner.

Healed and grafted skin is dry and tight. Itching is a major patient complaint as healing occurs. Massaging a mild, nonirritating lotion into the healed skin provides lubrication, aids in range of motion, and promotes circulation.

Psychological Rehabilitation

The burn survivor may have many psychological issues once discharge is nearing. The patient may have posttraumatic stress disorder, anxiety, depression, or a combination of these. To ensure that these issues are effectively managed, the multidisciplinary team caring for the patient with burns must include mental health professionals.

▲ Other Types of Injuries Treated in Burn Centers

Burn center referrals are not limited to the traditional burn injuries (thermal, chemical, electrical, or radiation). Patients with disease processes that primarily involve the integumentary system have had better outcomes in burn centers because the unit is structured with the high levels of necessary resources for patient care. Patients who are referred to burn centers may have such conditions as toxic epidermal necrolysis syndrome (TENS), erythema multiforme minor, and extensive Stevens-Johnson syndrome, as well as diseases that may result in the loss of large amounts of tissue, such as necrotizing fasciitis, staphylococcal scalded skin syndrome, bullous pemphigoid, or pemphigus vulgaris. Patients with significant cold injuries may also be routinely referred to regional burn centers in some areas of the country.

Toxic Epidermal Necrolysis Syndrome

Toxic epidermal necrolysis syndrome (TENS) is a superficial, exfoliative dermatitis that has been related to multiple sources, the most common being an adverse reaction to medications, the staphylococcal toxin, or viral infections.[26] The source may be undeterminable. TENS can involve the entire mucosal surface of the body to include the oral mucosa and conjunctiva as well as the vaginal or urethral linings. The immediate concern is the oral lesions and the possible occlusion of the respiratory system; intubation may be indicated as a supportive measure. The definitive diagnosis is made by sending a biopsy from the involved tissue for microscopic examination where an epidermal split is observed at the junction of the epidermis and dermis.

Patients with TENS are often described by the percentage of their body surface area that is currently open, requiring fluid and electrolyte replacement for evaporative water loss through the open wounds. This disease is similar in its effects to the body as a partial-thickness injury seen with a thermal burn. The lesions in TENS tend to be hypersensitive and extremely painful, with the nerve endings exposed to the environment. If the soles of the feet are involved, ambulation is extremely painful and may lead to debilitation if physical activity is not maintained. Nutritional support is also important to assist with the healing process; the insertion of a small-bore feeding tube may be indicated if caloric intake cannot be maintained secondary to oral lesions.

To increase patient survival, patients with TENS should be admitted to a burn center because of the complexity of wound care and the need for meticulous infection control standards. Historically, these patients have been treated with silver nitrate dressings, but more recently, a variety of products, such as Acticoat or biological dressings, have been used. The primary concern of wound care is that the dressings remain moist, not wet, at all times to decrease the desiccation of the dermal layer. Steroids are not indicated, and antibiotics used only for specific infections.

Necrotizing Fasciitis

Necrotizing fasciitis is a rapid and progressive inflammatory infection of the soft tissue that presents a diagnostic and therapeutic challenge. The pathogens enter the tissue through an open wound and spread rapidly in the extracellular space between the subcutaneous tissue and the fascia. It is classified into two types based on the culture findings. Type I is polymicrobial and accounts for 90% of the cases. Risk factors include postoperative status, obesity, diabetes, or older adulthood.[26] Type II accounts for 10% of all cases and typically affects the upper and lower extremities. The infecting agent is Group A beta-hemolytic streptococcus, with or without *Staphylococcus aureus*.[26,27] Diagnosis may be difficult initially because the external cutaneous damage may not be readily appreciated and the signs and symptoms may be diffuse. Early diagnosis is paramount, with timely and radical surgery being the definitive intervention. Necrotic tissue

must be completely excised and explored to clean tissue borders. Broad-spectrum antibiotics are started preoperatively, and culture and Gram stain are used to provide guidance for the antibiotic regimen. Local and systemic infection must be completely controlled before wound closure is addressed.[11]

As in burn injuries, infection control is the primary component of wound management in necrotizing fasciitis. The need for extensive excision of tissue to the depth of the fascial compartments can result in extreme contractures and the loss of the protective mechanisms of the subcutaneous tissue (eg, protection from shearing and blunt forces, fat storage, temperature regulation).[26]

Cold Injuries

Environmental exposure without appropriate protection may result in a cold injury. Although these injuries are more common in temperatures below freezing, their onset may occur also at relatively moderate temperatures depending on the length of the exposure and the person's condition at the time. Injuries may range from a localized frostbite to systemic lowering of the body's core temperature with hypothermia.

Frostbite is most often seen of the fingers, toes, and nose because they tend to be the most exposed to the environment with outdoor activity, and circulation is the most difficult to maintain in the microvasculature. With prolonged exposure, the intracellular and extracellular fluids of the body tissue become chilled and may eventually form ice crystals, impeding the blood flow to the area and leading to tissue destruction.[6]

Mild cases involve only the skin and subcutaneous tissues, whereas the more severe cases involve deeper structures. The symptoms range from numbness and itching to paresthesia and decreased motion.[6]

Tissue should not be rewarmed until the patient is in a controlled environment where the warmth can then be maintained. Rewarming the tissue also contains risks because this may release a shower of microemboli. In addition, it is also extremely painful. Purplish or bluish blisters are left intact, whereas clear or white blisters are débrided, similar to burn blisters. To preserve as much length as possible for functionality, amputation is discouraged until definitive demarcation occurs, which can take weeks to months.[6,9]

▲ Clinical Applicability Challenges

CASE STUDY

Mr. R. is a 35-year-old man who sustained burns while making repairs to his car. While parked in the garage during the repairs, the car engine caught fire. Mr. R. was able to get out from under the car and out of the garage unassisted. A neighbor witnessed the event and used the garden hose to extinguish the fire on the patient. The neighbor drove Mr. R. to the hospital. They arrived 25 minutes after the fire.

Mr. R. walked into the emergency department (ED) and the ED staff noted burns to chest, abdomen, bilateral circumferential arms, face, neck, and upper back. They estimated 55% total body surface area (TBSA) burned using the Rule of Nines. Mr. R. is a well-nourished, well-developed man in relatively good health. His preburn weight is 154 pounds (70 kg). He denies allergies and reports no significant past medical or surgical history. His only significant family medical history is a mother with type 2 diabetes mellitus. Mr. R denies using tobacco products or recreational drugs but reports drinking one case of beer per week for the past 5 years. He is unsure of having a tetanus vaccine. He is married with two young children.

The ED staff conducts a primary and secondary survey in a warmed trauma room and places 100% humidified oxygen by nonrebreather mask on the patient. Since the accident Mr. R. complains of severe pain to the skin of his face and arms. It is noted he is becoming hoarse and has burnt facial hair.

Based on his examination (facial burns, singed facial hair) and airway protection, Mr. R. is intubated. Two large-bore intravenous (IV) catheters are placed in bilateral upper extremities and an indwelling catheter is inserted. Fluid resuscitation is started, tetanus immunization is given, and analgesics are given in frequent small IV doses for pain.

The regional burn center is contacted and transportation arranged. Mr. R. is wrapped in clean, dry dressings with additional blankets to help insulate and maintain body temperature during the transport. Copies of all documents are sent with Mr. R. who arrives 3 hours after the burn occurred and he is directly admitted to the burn ICU. The airway is confirmed. All pulses are immediately assessed and present. The upper extremities are of concern due to circumferential burns and they are slightly diminished.

Mr. R.'s vital signs are heart rate 138 bpm, blood pressure 105/56 mm Hg, respirations (assisted by ventilator) 12 breaths/min, temperature 96.8°F (36.0°C). Breath sounds are auscultated and coarse rhonchi are heard. Heart sounds are normal and rapid. The monitor displays sinus tachycardia without ectopy. At admission, samples are obtained and sent to the laboratory for study. A chest

(continued on page 1206)

CASE STUDY (Continued)

x-ray is taken. Distal pulses on extremities with circumferential burns are assessed at least every hour. The upper extremities are checked more frequently because the pulses are diminished, and these are confirmed with Doppler ultrasound when not palpable. Bronchoscopy is performed, revealing erythema to the bilateral upper airways and no carbonaceous material; the bilateral lower airways appear to be uninjured. A fentanyl infusion and scheduled doses of lorazepam (Ativan) are given for analgesic relief and sedation, with additional dosing ordered for wound care and breakthrough pain.

Once stabilized, Mr. R. is taken to the warm shower room, and all wounds are manually débrided. Shower time is minimized to reduce the risk for hypothermia, a significant contributor to the mortality of trauma patients; a nasogastric tube is inserted and arterial lines and central lines are placed.

When resuscitation is well underway, the Lund-Browder chart is completed, and a burn size of 40% TBSA is calculated. Full-thickness burns (third-degree) account for 24% of the injuries; the burn area texture is leathery, and the surface is dry with thrombosed vessels. Prior to intubation, Mr. R. denied pain in these areas when touched or exposed to the air. The remaining partial-thickness burns are reddened, moist, and weeping serous fluid where thin-walled blisters have ruptured. When these are touched, Mr. R. has facial grimacing and blood pressure rises. To determine estimated fluid requirements in the first 24 hours from the time of the burn, the burn resuscitation formula is calculated:

$$2\text{mL} \times 70\text{kg} \times 40\%\,\text{TBSA} = 5{,}600 \text{ in first 24 hours;}$$
$$2{,}800 \text{ mL in first 8 hours}$$

Mr. R. received 900 mL fluid at the transferring facility and 560 mL fluid while in transport and arrival to the burn center, which means that he needs an additional 1,350 mL of fluid in the first 8 hours from the time of the burn. It is now 4 hours since the time of the burn, so the fluid is divided for the remaining 4 hours, or 340 mL/h. Since the placement of the urinary catheter at the transferring facility, urine output has been 180 mL, or an average of 45 mL/h. Although this is currently adequate, it will be closely monitored because it has been trending down.

After Mr. R. returns from the shower, the following topical agents are applied: silver sulfadiazine (Silvadene) cream to all partial-thickness and full-thickness burns, bacitracin ophthalmic ointment around eyes and bacitracin ointment to the rest of the face, and mafenide acetate (Sulfamylon) cream to the ears. The patient is placed on a pressure relief mattress to decrease the risk for pressure ulcers, with particular concern for the occiput, sacrum, and heels. The head of the bed is elevated to 30 degrees, and the bilateral upper extremities are placed in airplane slings to elevate hands and abduct the axilla.

Selected initial laboratory results are as follows: sodium, 146 mEq/L; potassium, 3.5 mEq/L; chloride, 107 mEq/L; blood urea nitrogen, 19.0 mg/dL; creatinine, 0.9 mg/dL; WBC count, 10,100 cells/mm^3; and hematocrit, 53.6%. Urine outputs for hours 6 and 7 from the time of the burn are 23 and 17 mL, respectively, and the IV rate of fluid administration is increased by 20% to 408 mL/h. Urine output for hour 8 is 25 mL and the IV rate of fluid infusion is increased by 20% to 490 mL/h.

Twelve hours after the burn, Mr. R.'s forearms are tight and edematous, and pulses in the upper extremities are faint and confirmed with a Doppler. Fluid resuscitation appears controlled; the patient is not hypotensive, with a blood pressure of 112/63 mm Hg. The heart rate has decreased within the expected range (122 bpm), and urinary output is adequate (43 mL in the last hour). Escharotomies are performed to the medial and lateral aspects of both arms and the dorsum of the hands. Pulses are immediately palpable at the conclusion of this procedure. A small-bore feeding tube is placed, and a nutrient-dense tube feeding is started and increased slowly as tolerated.

Albumin 5% is added to Mr. R.'s fluid resuscitation during the second 24 hours at 39 mL/h (0.3 mL/70 kg/44% TBSA for 30%–49% TBSA burn). The burn wounds are to be cleansed twice a day with 4% chlorhexidine gluconate (Hibiclens) soap. Alternating solutions are applied to all burn wounds except the face, with mafenide acetate (Sulfamylon) in the morning and silver sulfadiazine in the evening. Mafenide acetate is always applied to the ears, with bacitracin to the face and bacitracin ophthalmic around the eyes. Nursing and rehabilitative personnel provide passive range of motion to all major joints frequently, with particular attentiveness to the hands.

Mr. R. is taken to the operating room on postburn day 3 for a full excision and grafting. The donor sites are the areas of bilateral thighs that were not burned and the bilateral calves. These are covered with fine mesh (Xeroform) gauze. The arms, right thigh, and posterior torso are covered with 3:1 autograft and wrapped with a veil dressing and 5% mafenide acetate solution-moistened gauze. The posterior torso is bolstered to protect from shearing forces. The dressings are moistened with mafenide acetate solution every 6 hours and whenever necessary to avoid tissue desiccation. To maximize donor tissue, the anterior torso is excised and covered with the template Integra to close the wounds. The dorsa of the hands are covered with a split-thickness sheet graft and left open, and the palms are covered with Integra. The hands are splinted in a position of function. The sheet graft is observed hourly for the first 24 hours postoperatively; blebs are rolled to ensure that grafts adhere. After this time, small hematomas are aspirated via a tuberculin

(continued on page 1207)

CASE STUDY *(Continued)*

syringe. Donor sites are elevated on leg nets for exposure to the air. Heat lamps are used at low settings to assist with drying.

Mr. R. is weaned from the ventilator postoperatively and extubated the morning of postburn day 5. Aggressive pulmonary toileting is initiated to reduce the risk for pneumonia. He is started on vancomycin for burn wound cellulitis, which is stopped after 5 days when the cellulitis resolves. He is assisted to the bedside chair on postoperative day 5 (postburn day 8), and diet is advanced as tolerated. He is assisted to walk on postoperative day 6 (postburn day 9). When he tolerates 50% of his daily caloric needs orally, enteral feedings are changed to only night feedings and stopped when he tolerates more than 75%. He begins ambulating on postoperative day 11 (postburn day 14) and is transferred to the ward.

Mr. R. returns to the operating room on two more occasions for additional excision and grafting procedures and to cover the Integra templates when donor sites are ready for reharvesting. His wounds are healing with minimal graft loss and without difficulty. On postburn day 37, he is discharged to an inpatient rehabilitation facility with compression garments, for continued strengthening and stretching of contracted tissue. He is discharged from rehabilitation on postburn day 50. He is seen in the outpatient burn clinic for periodic followup and is readmitted to the burn center 6 months after the burn for surgical intervention of contracted tissue.

1. Discuss the pathophysiology of why fluid boluses are contraindicated and therefore not used during the resuscitation phase to treat marginally low hourly urine outputs. If the hourly urine output is exceeding the 0.5 mL/kg/h, how would you adjust the resuscitation infusion?

2. Discuss the different types of pain Mr. R. may be experiencing and how they may be treated.

3. Discuss how you would secure Mr. R.'s medical devices: endotracheal tube, NGT, and peripheral IVs inserted through partial thickness burns.

4. Discuss the signs and symptoms of ventilator compromise that would indicate the need for a chest escharotomy.

PART 13

MULTISYSTEM DYSFUNCTION

54 Shock, Systemic Inflammatory Response Syndrome, and Multiple Organ Dysfunction Syndrome

Kathryn T. Von Rueden, Emily Smith Des Champs, and Karen L. Johnson

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Describe common pathophysiological processes involved in the generalized shock response.
2. Compare and contrast the etiology and clinical manifestations of the major types of shock.
3. Explain the anticipated management and rationale for treatment of the various shock states.
4. Describe patients at risk for development of shock and complications associated with the various shock states.
5. Discuss nursing management principles for patients with shock, systemic inflammatory response syndrome, and multiple organ dysfunction syndrome.

Under normal conditions, oxygen delivery to the cells is sufficient to meet metabolic needs. Under stress, oxygen requirements of cells, tissues, and organs increase. Oxygen is consumed more rapidly, and compensatory mechanisms are initiated to meet the increased oxygen demands and restore perfusion to cells. The compensatory mechanisms are the same, regardless of the clinical condition causing the cellular hypoperfusion. Clinical conditions that result in cellular hypoperfusion are often referred to as shock states.

▲ Pathophysiology of Shock

Although shock states have different causes and different clinical presentations, some features, such as hypoperfusion, hypercoagulability, and activation of the inflammatory response, are common to all shock states. Once a shock state develops, the subsequent course may have more to do with the physiological response to shock, including activation of the sympathetic nervous system, the inflammatory response, and the immune system, rather than with the initial cause of the shock. Thus, shock can be considered as a derangement of compensatory mechanisms that results in further circulatory and respiratory dysfunction with subsequent multiple organ damage.

Tissue Oxygenation and Perfusion

Oxygenation of all organs and tissues is directly related to the cellular oxygen demands, adequacy of oxygen supply to

meet demand, cellular extraction of oxygen from the blood, and the ability of the cells to use oxygen. The pulmonary system functions to provide for the diffusion of oxygen into the blood. Oxygen binds with hemoglobin in the pulmonary capillaries to form oxyhemoglobin to carry oxygen to tissues. This is measured as arterial oxygen saturation (SaO_2). The cardiovascular system transports oxygenated blood to the cells for metabolism. Typically, cells consume about 25% of the oxygen delivered; this utilization of oxygen is referred to as oxygen consumption (VO_2). Oxygen delivery (DaO_2) is the amount of oxygen transported to the cells every minute. Chapter 17 reviews how these oxygen parameters are calculated.

Under normal conditions, VO_2 is independent of DaO_2. This means that when cells need to consume additional oxygen to produce energy, they can extract the necessary amount required to produce energy in the form of adenosine triphosphate (ATP). However, during times of physiological stress, VO_2 becomes dependent on DaO_2.[1,2]

Initial respiratory, endocrine, and circulatory compensatory mechanisms respond to the cells' need for oxygen by increasing DaO_2 (eg, by increasing respiratory rate, cardiac output (CO), antidiuretic hormone (ADH) release, and renin–angiotensin aldosterone activity). If additional oxygen is required, and the cells cannot extract the oxygen, they must use anaerobic metabolism to produce ATP. Anaerobic metabolism is not an efficient method of energy production, and the ATP produced is insufficient to meet cellular demands. Moreover, anaerobic metabolism produces lactic acid as a by-product and can result in metabolic acidosis. If oxygen continues to be insufficient to meet cellular demands for energy, cell death ensues. As more cells die, tissues and organs become progressively dysfunctional.[2]

During shock states, oxygen is consumed at a much greater rate than it is delivered. Oxygen supply is insufficient to meet oxygen demand, resulting in cellular hypoxia and dysfunction. To meet the increased need for cellular VO_2, the DaO_2 must be increased. Although it is not possible to manipulate cellular VO_2 directly, many interventions can be implemented to manipulate and increase DaO_2. In shock states, the primary goal is to maximize DaO_2 to meet cellular oxygen requirements in an ongoing effort to prevent tissue and cell death and maintain end-organ perfusion.

Compensatory Mechanisms

Cellular perfusion depends on the synergy of multiple physiological processes. The pulmonary, endocrine, and circulatory systems maintain an intricate balance of oxygen exchange and delivery to the cells by generation of an adequate oxygenated blood supply and CO (Fig. 54-1). The autonomic nervous system assists in the orchestration of this delicate balance.

During states of hypoxia, activated compensatory mechanisms increase the depth and rate of respiration. The

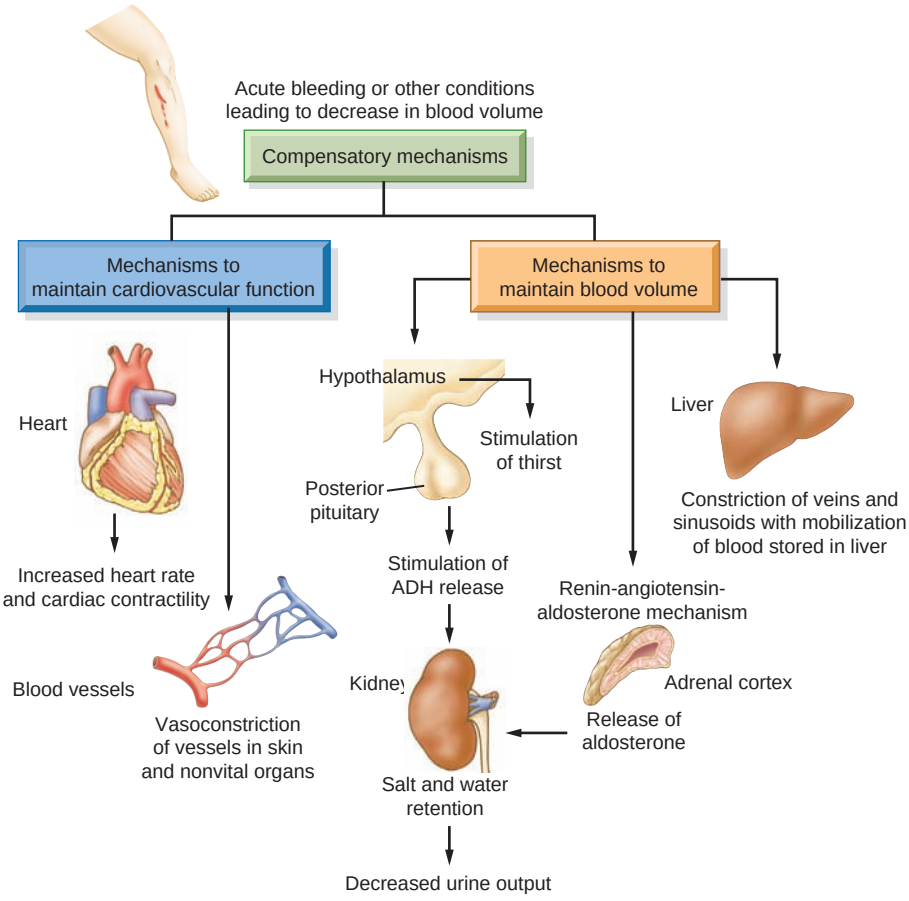

FIGURE 54-1 ▲ Compensatory mechanisms used to maintain circulatory function and blood volume in hypovolemic shock. ADH, antidiuretic hormone. (From Porth CM: Essentials of Pathophysiology: Concepts of Altered Health States, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2011, p 503.)

cardiovascular system increases CO to increase oxygen delivery to the cells. During states of low perfusion (low blood pressure), compensatory mechanisms are initiated and result in increases in heart rate, systemic vascular resistance (SVR), preload, and cardiac contractility in an effort to restore appropriate circulatory volume. Chapters 16 and 17 provide a discussion of these terms. The fall in systemic blood pressure activates a series of neurohormonal responses aimed at reestablishing sufficient CO and perfusion to vital organs. The fall in blood pressure results in decreased stimulation of baroreceptors and eventually an increase in sympathetic response.

Continued sympathetic stimulation causes an increased heart rate and contractile force, increasing the CO. Arteriolar vasoconstriction (increased SVR) increases blood pressure and also shunts blood from less vital organs such as the stomach and intestines to vital organs, such as the heart, lungs, and brain. Preload and subsequently stroke volume and CO are increased by venoconstriction. The kidneys respond to sympathetic stimulation and local hypoperfusion by activating the renin–angiotensin system, which increases vasoconstriction of the arterioles and veins, increasing SVR and blood pressure. Activation of the renin–angiotensin system also stimulates the adrenal cortex to release aldosterone, which acts on the kidney to conserve sodium and water, increasing circulating volume. A drop in blood pressure also causes the pituitary gland to release ADH. ADH stimulates water and sodium retention by the kidney, further increasing preload. An increase of preload (from multiple sources) increases stroke volume, thereby increasing CO and blood pressure. Collective compensatory responses act together to increase the body's circulating volume, blood pressure, and CO to provide perfusion and oxygen to the cells[2] (Fig. 54-2).

The goal in treating patients in shock states is to reestablish perfusion to provide adequate oxygen to meet the needs to the cells as quickly as possible. Early recognition of signs of shock and ongoing assessments guide therapeutic interventions. The nurse plays a key role in the ongoing assessment of shock. The patient's clinical presentation depends on the cause of the shock state and degree of compensation as discussed later in this chapter. Clinical assessment parameters should be evaluated frequently to monitor the progression of shock state and the effectiveness of interventions. Traditional assessment parameters include altered level of consciousness, tachypnea, arterial blood gases (PaO_2, $PaCO_2$, SaO_2), tachycardia, hypotension, decreased urine output, and metabolic acidosis (base deficit and serum lactate levels), which are commonly found in all states of hypoperfusion. Recent advances in technology provide methods for earlier assessment of the patient's tissue oxygenation and perfusion using measures of gastric pH, sublingual end-tidal carbon dioxide, and central mixed venous oxygen saturation ($ScvO_2$) (refer to Chapter 17). These technologies allow for earlier assessment and detection of shock and metabolic acidosis.[3]

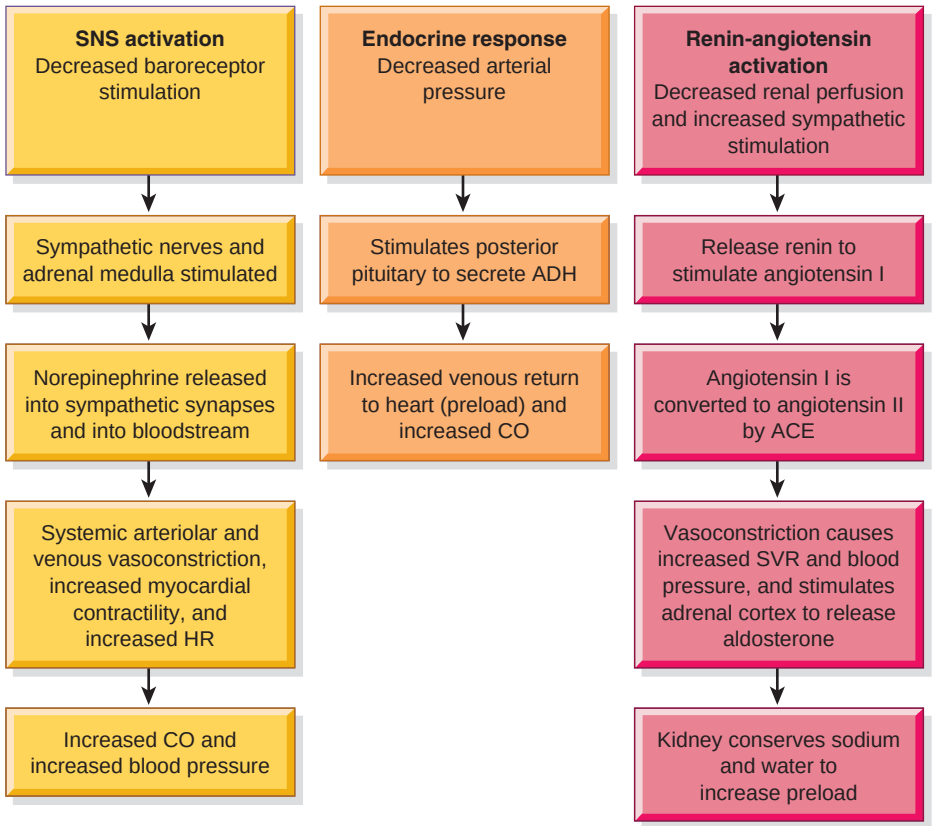

FIGURE 54-2 ▲ Compensatory mechanisms in shock. ACE, angiotensin-converting enzyme; ADH, antidiuretic hormone; CO, cardiac output; HR, heart rate; SNS, sympathetic nervous system.

▲ Systemic Inflammatory Response Syndrome

The progression of shock states involves systemic activation of the inflammatory response. The inflammatory response has both protective and potentially detrimental effects. The latter results in damage to tissues and organs. The term systemic inflammatory response syndrome (SIRS) is used to describe patients in whom the inflammatory response is fully and systemically activated. Efforts have been made to identify patients in whom this systemic reaction is occurring, with the thought that prompt, effective intervention might prevent progression of the shock to the irreversible stage. SIRS is manifested by two or more conditions listed in Box 54-1.[4] The SIRS criteria are sometimes used as the triggers for initiating rapid response teams. (Refer to Chapter 14.)

Etiology

SIRS may be caused by any type of shock or other insults such as massive blood transfusion, traumatic injury, brain injury, surgery, burns, and pancreatitis and typically precedes septic shock.[5] Thus, SIRS criteria should be evaluated in any patient with shock or any condition that might lead to shock. Normally, the inflammatory response is an essential, tightly regulated, and controlled protective mechanism of local response to invasion by microorganisms or to local tissue damage. However, in SIRS, this usually local inflammatory response becomes a systemic response that results in an unregulated inflammatory response with widespread involvement of endothelial cells and a generalized activation of inflammation and coagulation.

BOX 54-1 Clinical Terminology: SIRS, Sepsis, and Organ Failure

Bacteremia: The presence of viable bacteria in the blood

Hypotension: A systolic blood pressure (SBP) of less than 90 mm Hg or a reduction of more than 40 mm Hg from baseline in the absence of other causes for hypotension

Infection: Pathological process caused by the invasion of normally sterile tissue, fluid, or body cavity by pathogenic or potentially pathogenic organisms.

Systemic inflammatory response syndrome: The systemic inflammatory response that can be triggered by a variety of infectious and noninfectious conditions. The response is manifested by two or more of the following conditions:

- Temperature greater than 38°C or less than 36°C (>100.4°F or <96.8°F)
- Heart rate more than 90 beats/minute
- Respiratory rate more than 20 breaths/min or $PaCO_2$ less than 32 mm Hg (<4.3 kPa)
- WBC count greater than 12,000 cell/mm^3, less than 4,000 cells/mm^3, or greater than 10% immature (band) forms

Sepsis: SIRS plus a known or suspected infection

Severe sepsis: Sepsis associated with organ dysfunction, hypoperfusion, or hypotension. Hypoperfusion and perfusion abnormalities may include, but are not limited to, lactic acidosis, oliguria, or an acute alteration in mental status.

Septic shock: Sepsis with hypotension, despite adequate fluid resuscitation, along with the presence of perfusion abnormalities that may include, but are not limited to, lactic acidosis, oliguria, or an acute alteration in mental status. Patients who are on inotropic or vasopressor agents may not be hypotensive at the time that perfusion abnormalities are measured.

Multiple organ dysfunction syndrome: Presence of altered organ function in an acutely ill patient such that homeostasis cannot be maintained without intervention.

From Levy MM, Fink MP, Marshall JC, et al: 2001 SCCM/ESICM/AACP/ATS/SIS International sepsis definitions conference. Crit Care Med 31: 1250–1256, 2003.

Pathophysiology

Activation of the inflammatory response causes the release of various cytokines from macrophages. Examples of proinflammatory cytokines include tumor necrosis factor-α (TNF) and interleukin-1 (IL-1). Under normal circumstances, there are tight junctions between the endothelial cells that line blood vessels. However during proinflammatory states, these cytokines break these tight junctions, causing endothelial cells to separate. This increases capillary permeability and allows plasma to leak into the interstitial spaces. As a result of endothelial cell separation and exposure of the subbasement membrane, coagulation processes are stimulated. Platelets aggregate and adhere to endothelial cells and the subbasement membrane to form platelet plugs. The coagulation cascade is also activated. Fibrin, the end product of the coagulation cascade, forms strands around the clot to give it stability and strength. Proinflammatory cytokines also attract phagocytic white blood cells (WBCs) to the area and activate the complement cascade. The combination of activity of WBCs and complement proteins may result in elimination of the invading microorganism.[2]

Endothelial cells that line blood vessels are central to the development of a local inflammatory response. Important functions of endothelial cells include providing an anticoagulant surface and controlling permeability of vessels.[6] In a local inflammatory response, endothelial cells near the site of inflammation become activated as a result of mediators released by injured tissue cells. The activated endothelial cells express cell surface proteins that attract platelets and neutrophils. A procoagulant endothelial surface is formed in the area. Microthrombi form in the capillaries and obstruct blood flow.[6]

WBCs, platelets, and activated endothelial cells release vasodilating substances such as nitric oxide (NO), histamine, and bradykinin. These substances also promote additional capillary leak from blood vessels, resulting in additional extravasation of plasma and coagulation factors.

In SIRS, the inflammatory response is systemic; it occurs throughout the body. The result is an overwhelming, unregulated inflammation with uncontrolled coagulation, disruption of capillaries and intravascular volume loss, maldistribution of circulating volume, and oxygen supply and demand imbalance.[2] Endothelial cells are activated in many vessels throughout the body, causing widespread extravasation of fluid into the interstitial compartment and systemic activation of the immune system and coagulation cascade (Fig. 54-3).

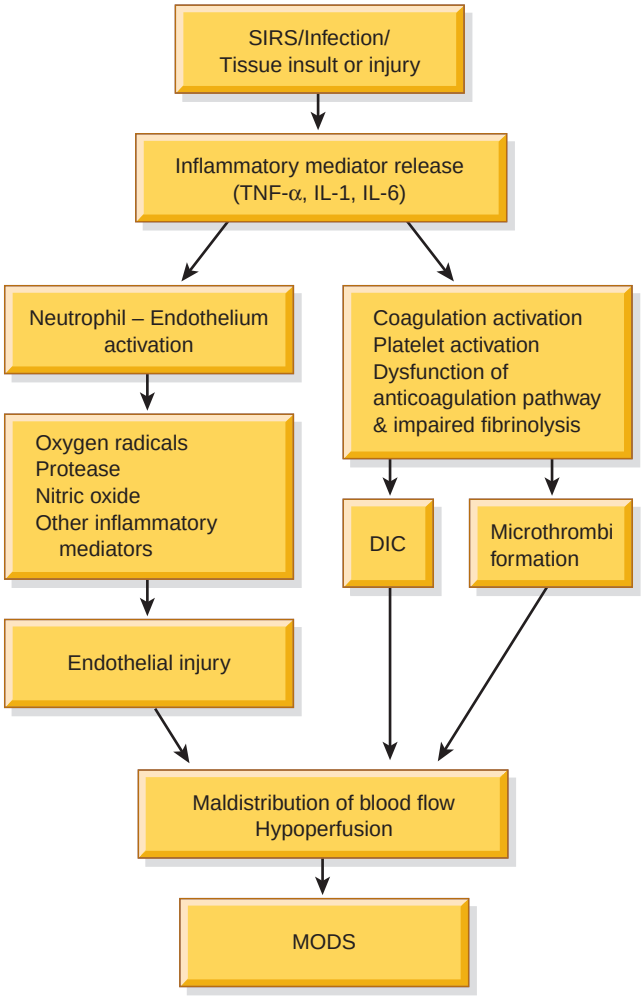

FIGURE 54-3 ▲ Inflammation, coagulation, and impaired fibrinolysis in systemic inflammatory response syndrome and multiple organ dysfunction syndrome. TNF-α, tumor necrosis factor-alpha; IL, interleukin; DIC, disseminated intravascular coagulation; MODS, multiple organ dysfunction syndrome.

There are substantial extravascular fluid accumulation and microthrombi formation in capillaries and in the interstitium. The combination of intravascular coagulation and decreased circulating blood volume results in reduced perfusion of vital organs, increasing the likelihood of multiple organ dysfunction syndrome (MODS) and death.

Events surrounding the complex interactions of the mediators of SIRS remain an active area of clinical research. Several mediators are believed to play a key role in the maldistribution of blood flow and oxygen delivery and consumption imbalance associated with SIRS and sepsis. Table 54-1 lists the key mediators of SIRS and summarizes their activity.

▲ Stages of Shock

Shock is believed to progress through three increasingly severe stages, the last of which cannot be reversed by known means. It is difficult to determine the stage of shock in a particular person at a particular time for three reasons: (1) shock has diverse causes, (2) the exact time of onset is unknown in many cases, and (3) diagnostic tests that give a clear-cut measurement of the extent of shock at a given time are lacking. Nevertheless, the stages are useful because they allow shock to be viewed as a progressive, rather than a static, process. Timely reversal of the shock state can prevent development of multiple organ failure and death.[2]

In the initial, nonprogressive stage (stage 1), the previously described compensatory mechanisms are effective in maintaining relatively normal vital signs and tissue perfusion. During stage 1, shock is poorly diagnosed and frequently goes unrecognized. However, if the cause of the shock is successfully recognized and treated, the patient may make a full recovery.

In the intermediate, progressive phase (stage 2), compensatory mechanisms that maintain normal perfusion begin to fail, metabolic and circulatory derangements become more pronounced, and activation of the inflammatory and immune responses may fully develop. At this point, interventions that target both the cause of the shock and the resultant metabolic, circulatory, and inflammatory responses may result in salvage of the patient. At this time, signs of failure in one or more organs may become apparent.

In the final, irreversible stage (stage 3), cellular and tissue injury is so severe that correction of metabolic, circulatory, and inflammatory derangements is difficult or impossible, and cellular hypoxia and death ensue. MODS develops, often resulting in the demise of the patient. This is discussed in the latter section of this chapter.

As previously mentioned, any shock state can trigger SIRS and if left unrecognized and untreated, can cause MODS. Understanding the classification, etiology, and clinical presentation of shock enables clinicians to more rapidly identify and manage shock, thus improving the patient's likelihood of survival.

▲ Classification of Shock

The causes of shock can be classified as hypovolemic, cardiogenic, and distributive. Hypovolemic and distributive shock result in inadequate venous return to the heart, while cardiogenic shock is caused by the failure of the heart to pump effectively. Inadequate venous return may result from hypovolemia (dehydration, hemorrhage) or widespread vasodilation (sepsis, anaphylaxis, or loss of sympathetic tone with a spinal cord injury), which cause a relative hypovolemia. Pump failure may result from myocardial infarction, abnormal heart rate or rhythm, or impaired diastolic filling.[7]

Hypovolemic Shock

Etiology

Hypovolemic shock is a result of inadequate circulating volume. Most commonly, hypovolemic shock is caused by sudden blood loss or severe dehydration. Some injuries, such as burns, cause significant fluid shifts from the intravascular space to the interstitial space, resulting in hypovolemia. See Chapter 53 for a discussion of care for patients with burns. Volume disorders in critically ill patients may be classified as either depletion or expansion disorders and involve both

Table 54-1 Mediators of the Inflammatory/Immune Responses

Mediator	Description of Activity	Clinical Response
Endotoxin	• Activates complement system and coagulation cascades • Activates macrophages, which release TNF and IL-1	• Increased microvascular permeability, vasodilation, third spacing, microthrombi formation • Inflammatory response
Tumor necrosis factor (TNF)	• Released by monocyte–macrophages • Multiple effects locally and systemically • Stimulates other mediator activity	• Hypotension, tachycardia, myocardial depression, tachypnea, hyperglycemia, metabolic acidosis, third spacing, fever, microvascular vasoconstriction
Interleukin-1 (IL-1)	• Released by monocyte–macrophages • Stimulates leukocytosis • Triggers production of acute phase proteins and release of amino acids from skeletal muscle • Activates procoagulant activity • Decreases vascular responsiveness to catecholamines	• Increased white blood cells (WBCs) • High urinary nitrogen excretion and muscle wasting • Elevated coagulation laboratory values • Decreased systemic vascular resistance, which is not as responsive to low dosages of vasopressor or synthetic catecholamine agents
Interleukin-6 (IL-6)	• Released by monocytes, helper T cells, and macrophages • Increases inflammatory response • B-cell stimulation and differentiation • Synergistic with IL-1	• Fever • Antibody secretion
Complement cascade	• Inflammatory process • Opsonization and lysis of foreign particles and cells • Stimulates neutrophils (and oxygen radicals) and IL-1 • Degranulation of mast cells and basophils	• Edema formation, vasodilation, vascular permeability, third spacing • All effects of IL-1
Platelet aggregating factor	• Released by mast cells, basophils, macrophages, neutrophils, platelets, and damaged endothelium • Increases platelet aggregation • Increases neutrophil adhesion • Increases vascular permeability and bronchoconstriction • Negative inotropic effects on the heart	• Microthrombi formation interfering with perfusion • Third spacing • Bronchoconstriction, rhonchi and wheezes, increased pulmonary airway pressures • Decreased heart contractility and force, which is not as responsive to low dosages of vasopressor and inotropic agents
Arachidonic acid (AA) metabolites	• Stimulation of AA causes the release of metabolites prostaglandins (PG), thromboxanes (TX), and leukotrienes (LT). • PGF and TXA2 cause pulmonary hypertension, vasoconstriction, and platelet activation and aggregation. • PGE, PGD, and prostacyclin cause vasodilation and decreased platelet aggregation. • Leukotrienes increase neutrophil chemotaxis, vascular constriction, and vascular permeability. • Increase gastric permeability to Gram-negative bacteria • Inhibits leukocyte adhesion and platelets	• Oxygenation and ventilation difficulties, increased airway resistance, wheezing • Third spacing and edema formation • Vasodilation, increased capillary permeability, and hypotension
Oxygen radicals	• Generate metabolites (O_2-, H_2O_2, OH-) during the respiratory burst of the neutrophils • Damage cell structure and interfere with cell activities • Damage endothelial cells, which stimulate the coagulation system • Increase permeability	• Inflammatory response, edema formation, fever • Microthrombi formation • Third spacing

intracellular and extracellular compartments. Acute fluid volume loss does not allow the normal compensatory mechanisms to restore an appropriate circulating volume rapidly enough. If left untreated, hypovolemia may lead to a variety of secondary complications, such as hypotension, electrolyte, and acid–base disturbances, and organ dysfunction resulting from hypoperfusion (Fig. 54-4).

Pathophysiology

A sudden loss of intravascular volume decreases venous return to the heart and results in reduced CO. Compensatory mechanisms are initiated to increase the circulating volume through the activation of the sympathetic nervous system and neurohormonal responses (see Fig. 54-1, p. 1210). If the condition persists, existing blood volume is shunted to the vital organs (heart, lungs, and brain), causing hypoperfusion to such organs as the liver, stomach, and kidneys. If volume is not replaced, compensatory mechanisms eventually become ineffective. The failure of the compensatory mechanisms to restore adequate circulating volume causes cellular hypoperfusion and inability to meet cellular oxygen requirements for metabolism. The cells must use anaerobic metabolism in an effort to meet their ATP requirements; this results in lactic acidosis.

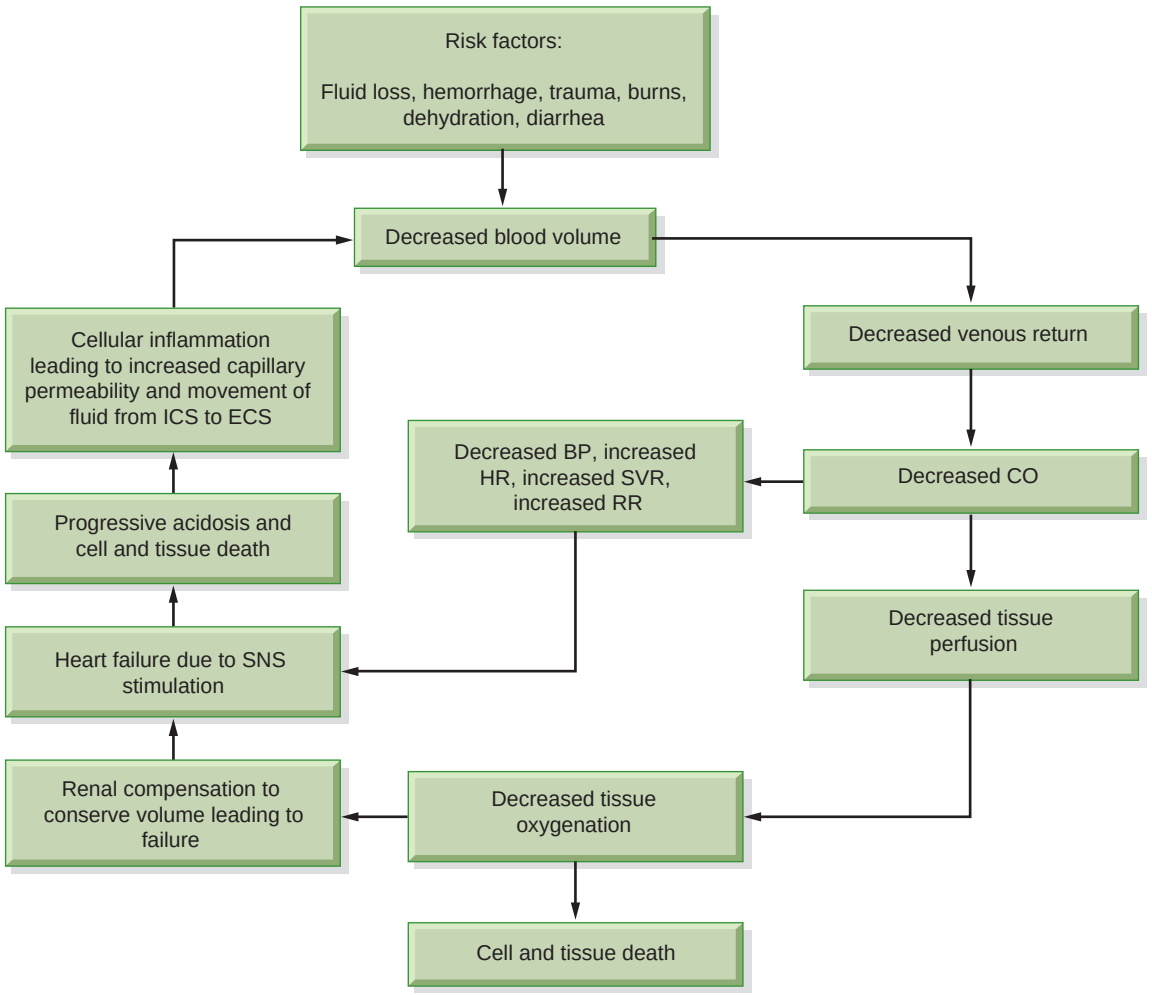

FIGURE 54-4 ▲ Hypovolemic shock. BP, blood pressure; CO, cardiac output; ECS, extracellular space; HR, heart rate; ICS, intracellular space; RR, respiratory rate; SNS, sympathetic nervous system; SVR, systemic vascular resistance.

Failed compensatory mechanisms, which were initiated to restore CO, eventually cause the myocardium to fatigue. Sympathetic stimulation to increase heart rate, contractility, and SVR escalates the workload of the heart. Ejection of a higher volume of blood against a higher SVR requires utilization of more oxygen and energy. Such stress on the heart causes an increase in myocardial metabolism and myocardial oxygen consumption ($M\dot{v}O_2$). The continued lack of circulating volume prevents appropriate oxygen delivery to the heart, creating a vicious cycle. Inability of the circulatory system to provide end-organ perfusion with enough oxygen forces conversion to anaerobic metabolism to meet cellular energy needs. Anaerobic metabolism cannot provide enough ATP to meet energy demands; thus, ischemic damage may ensue. If the situation continues, end-organ failure may occur (see Fig. 54-4).

Assessment

Clinical findings are directly related to the severity and acuity of volume loss (Table 54-2). Some patients, especially older patients or those who have chronic diseases, have more subtle compensatory responses, which may be overlooked. Box 54-2 lists considerations in older patients. Serial assessments of physical and laboratory findings may uncover trends that guide treatment and prevent vascular collapse.

HISTORY. A thorough history of the patient's presenting problem may reveal risk factors for hypovolemic shock. Patients experiencing significant blood loss because of gastric hemorrhage or liver or splenic rupture from trauma require a rapid replacement of circulating volume to prevent the consequences of hypovolemia.

PHYSICAL FINDINGS. Patients with hypovolemic shock have the following signs and symptoms caused by poor organ perfusion:

- Altered mentation, ranging from lethargy to unresponsiveness
- Rapid and deep respirations, which gradually become labored and shallower as the patient's condition deteriorates
- Cool and clammy skin, with weak and thready pulses
- Tachycardia from activation of the sympathetic nervous system
- Hypotension
- Decreased urine output; urine is dark and concentrated because the kidneys are conserving fluid.

Table 54-2 Correlation of Clinical Findings Associated With Volume Loss in Hypovolemic Shock

Estimated Blood Loss	Clinical Findings
<500 mL	None
500–1,000 mL	• Tachycardia (↑HR > 20% of patient's baseline) • Hypotension (↓SBP > 10% of patient's baseline) • ↓Urine output • Pulses weaker • Skin and extremities cool to touch • Hemodynamics: within normal limits CO, ↑SVR • Mild acidosis (↑base deficit, ↑lactic acid, ↓gastric pH)
1,000–2,000 mL	• Tachycardia (↑HR > 20%–30% of patient's baseline) • Hypotension (↓SBP > 10%–20% of patient's baseline) • Tachypnea (↑RR > 10% of patient's baseline) • Oxygen saturation may not be altered dependent on the percentage of exogenous oxygen the patient is receiving • SvO_2 < 60% • ↓Urine output (<30 mL/h) • Altered level of consciousness: restlessness, agitation, confusion, or obtunded • Cool, diaphoretic skin • Poor peripheral pulses • Hemodynamics: ↓CO, ↑SVR • Progressive acidosis (↑base deficit, ↑lactic acid, ↓gastric pH)
2,000–3,000 mL	• Tachycardia (↑HR > 20%–30% of patient's baseline) • Hypotension (↓SBP > 10%–20% of patient's baseline) • Tachypnea (↑RR > 10%–20% of patient's baseline) • ↓Oxygen saturation • SvO_2 < 55%–60% • Oliguria → anuria • Mental stupor • Marked peripheral vasoconstriction: cold extremities, poor peripheral pulses, pallor • Hemodynamics: ↓CO, ↑SVR • Severe acidosis (↑base deficit, ↑lactic acid, ↓gastric pH)

SBP, systolic blood pressure; SVR, systemic vascular resistance; CO, cardiac output; RR, respirations; HR, heart rate.

LABORATORY STUDIES. Useful laboratory studies include determinations of serum lactate, arterial pH, and base deficit to assess the presence of anaerobic metabolism. Test results can be used to measure the effectiveness of fluid replacement therapy. A serum lactate level that remains elevated after initial resuscitation is a poor prognostic indicator.[8,9] Metabolic laboratory studies and electrolyte determinations assist with adjustment of fluid and electrolytes. Serial hemoglobin and hematocrit determinations and coagulation panels may be drawn to assess the need for blood product replacement. However, the hemoglobin and hematocrit may not directly reflect the severity of blood loss from either hemoconcentration caused by dehydration or hemodilution caused by IV fluid therapy.

Management

Management focuses on restoring circulating volume and resolving the cause of volume loss. Composition of volume replacement therapy depends on what was lost. Crystalloid solutions are used primarily as first-line therapy. Isotonic solutions, such as lactated Ringer's solution or 0.9% normal saline solution, are preferred over hypotonic solutions (5% dextrose solution). Blood products and other colloid solutions (albumin and synthetic volume expanders) may be used to assist in the resuscitation process, especially if blood loss is the primary cause. Packed red blood cells are administered to maximize oxygen-carrying capacity.

The use of colloids in the early phase of fluid replacement is controversial. Because colloids stay within the intravascular space better than crystalloids, patients generally require smaller volumes of colloids for resuscitation. However, capillary membrane permeability is increased in shock, which allows colloids to "leak" from the blood vessels into the extravascular space, further shifting fluids from the intravascular space to interstitial tissues and thereby worsening the hypovolemia. Current research suggests that colloids are not superior to crystalloids in treating hypovolemia in critically ill patients.[10–12] Table 54-3 summarizes some of the known complications of fluid resuscitation.

Nursing management of hypovolemic shock focuses on the restoration of circulating volume through volume administration. Obtaining and maintaining adequate IV access is essential. Ideally, large-bore (16-gauge or larger) IV catheters are inserted in the antecubital space or central venous system to assist with the rapid infusion of fluids. Care must be taken to administer fluids as rapidly as possible without compromising the pulmonary system. Fluids given too rapidly may cause pulmonary congestion and inhibit adequate oxygenation, further compromising oxygen delivery

BOX 54-2 CONSIDERATIONS FOR THE OLDER PATIENT

Response to Shock States

As a person ages, normal physiological changes may limit the ability of the body to respond efficiently to shock states. The nurse should be aware of physiological changes of aging and monitor closely for changes in the older patient's baseline assessment(s). The patient's medical history may reveal other chronic diseases or conditions that further compromise normal physiological changes seen with aging. (See also Chapter 12, The Critically Ill Older Patient)

Cardiovascular system: Increased dysrhythmias, increased atrial size and irritability, left ventricular myocardial thickening leading to decreased compliance and lower ejection fraction; thickened heart valves that interfere with forward flow; decreased response to sympathetic nervous system; decreased sensitivity of baroreceptors; generalized stiffening of arterial vessels, including aorta

Pulmonary system: Decreased tidal volume and respiratory muscle strength, decreased alveolar surface area, increased dead space at end expiration, decreased elastic recoil of lungs, increased resting respiratory rate, increased risk for infection as a result of decreased number of cilia, blunted response to hypoxemia, decreased gag and cough reflex leading to increased risk for infection, aspiration

Hematological system: Decreased ability of bone marrow to produce cells (red blood cells, white blood cells [WBCs], platelets), increased anemia, decreased immune function (decreased production of T and B lymphocytes) leading to increased infections, lower baseline temperature, gradual changes in temperature in the elderly versus spikes (101.3°F [38.5°C]), increased risk for adverse drug reactions

to the tissues. Fluids should also be warmed during infusion to limit the negative effects of hypothermia. Frequent documentation of vital signs, heart rate, respiratory rate and depth, oxygen saturation, urine output, and mentation, as well as laboratory results and interventions, is essential.

Cardiogenic Shock

Etiology

Cardiogenic shock is actually extreme congestive heart failure and therefore results from loss of critical contractile function of the heart. Usually, cardiogenic shock is diagnosed by the presence of systemic and pulmonary hemodynamic alterations, which result from inadequate CO and tissue perfusion. Typically, this occurs when greater than 40% of ventricular mass is damaged. The most common cause of cardiogenic shock is an extensive left ventricular myocardial infarction. In-hospital mortality rates are 40% to 60%, having declined somewhat after the introduction of early revascularization procedures such as cardiac catheterization, percutaneous coronary intervention, and open heart surgery.[7] Although cardiogenic shock may develop within a few hours after the onset of myocardial infarction symptoms, it often occurs after hospitalization. Other causes of cardiogenic shock include papillary muscle rupture, ventricular septal rupture, cardiomyopathy, acute myocarditis, valvular disease, and dysrhythmias.

Box 54-3 shows independent predictors for development of cardiogenic shock. Patients with all five risk factors have a greater than 50% chance of developing cardiogenic shock. Identifying patients at risk for development of cardiogenic shock and formulating strategies for prevention is extremely important.

Table 54-3 Complications of Volume Resuscitation

Fluid Type	Complications
Crystalloid and colloid	Dilutional coagulopathy Dilutional thrombocytopenia Hypothermia Increased hemorrhage Decreased blood viscosity Pulmonary edema Intracranial hypertension (patients with traumatic brain injury)
Packed red blood cells	Acidosis (banked blood has pH 6.9–7.1) Left shift on the oxyhemoglobin dissociation curve (banked blood is deficient in 2,3-DPG) Hyperkalemia Immunological and infectious complications Dilutional coagulopathy Dilutional thrombocytopenia Hypothermia

Pathophysiology

Cardiogenic shock is caused by loss of ventricular contractile force, which results in decreased stroke volume and decreased CO (Fig. 54-5). Neuroendocrine compensatory mechanisms, which are discussed in detail in the section on hypovolemic shock, are activated to increase preload through retention of sodium and water (see Fig. 54-1, p. 1210). Vasoconstriction also increases afterload (SVR). Ventricular filling pressures increase because of the increased preload, but lack of contractility prevents complete ejection. The ventricle becomes distended, further impairing effective contraction, and CO continues to decrease. Compensatory mechanisms continue the vicious cycle of elevated ventricular filling pressures and SVR in combination with an inability of the heart to eject an adequate volume of blood into circulation. Blood pools in the pulmonary circulation, resulting in pulmonary congestion. Pulmonary capillaries are under increased pressure and leak fluid into the interstitium and alveoli, preventing the diffusion of oxygen from alveoli into the pulmonary capillaries and reducing oxygen tension in the blood.

BOX 54-3 PATIENT SAFETY

Risk Factors for Inpatient Development of Cardiogenic Shock

- Increased age (elderly)
- Left ventricular ejection fraction less than 35% on hospital admission
- Large myocardial infarction
- History of diabetes mellitus
- Previous myocardial infarction

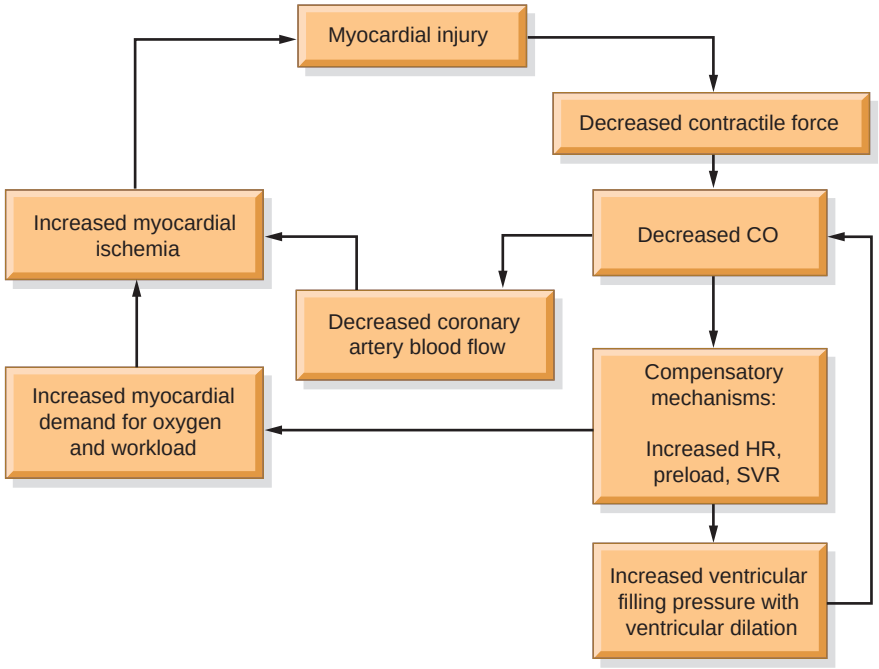

FIGURE 54-5 ▲ Cardiogenic shock. CO, cardiac output; HR, heart rate; SVR, systemic vascular resistance.

Cells become ischemic because of the decreased CO, adding to an already tenuous state of myocardial functioning by further stimulating compensatory mechanisms to increase perfusion to the cells. Increased sympathetic stimulation increases the heart rate even more, further escalating myocardial oxygen demands and compounding the crisis. Associated hypotension prevents adequate oxygenation of myocardial tissue, exacerbating the anaerobic metabolism of the myocardial tissue and further decreasing the contractile state of the heart. These stressors placed on the failing heart may result in extension of a myocardial infarction.

Assessment

Patients who are at high risk of cardiogenic shock require close monitoring. Assessment parameters are similar to the signs and symptoms of congestive heart failure but are more extreme. Assessment findings should be followed over time to allow the nurse to perceive the subtle changes that signal the beginning of cardiogenic shock.

HISTORY. A thorough history provides the information necessary to predict patients at risk for developing cardiogenic shock. Cardiogenic shock frequently occurs in people who have suffered an extensive myocardial infarction, have an admission ejection fraction of less than 35%, have diabetes mellitus, or are elderly (see Boxes 54-2 and 54-3). The existence of these predisposing factors should alert the clinician to assess for the initial phases of shock, allowing for rapid, life-saving intervention. It is important to rule out other causes of decreased CO before initiating therapy. Patients with acute myocardial infarction may require rapid revascularization with thrombolytics (see Chapter 21), percutaneous coronary intervention (see Chapter 18), or cardiac surgery (see Chapter 22).

PHYSICAL FINDINGS. Clinical manifestations associated with cardiogenic shock are outlined in Box 54-4. In addition to the signs and symptoms listed in the box, patients with cardiogenic shock often experience recurrent chest pain, which may indicate extension of the infarction. Other clinical findings are directly related to the decrease in CO.

LABORATORY STUDIES. Presence of elevated myocardial tissue markers, accompanied by progressive hemodynamic compromise and clinical deterioration, is often a hallmark of extensive myocardial necrosis, which may precipitate

BOX 54-4 Clinical Manifestations of Cardiogenic Shock

Hemodynamic Findings
SBP less than 90 mm Hg
Mean arterial pressure (MAP) less than 70 mm Hg
Cardiac index less than 2.2 L/min/m^2
Pulmonary artery occlusion pressure (also known as pulmonary artery wedge pressure) greater than 18 mm Hg
Systemic vascular resistance greater than 1,400 dynes/s/cm^{-5}

Noninvasive Findings
Thready, rapid pulse
Narrow pulse pressure
Distended neck veins
Dysrhythmias
Chest pain
Cool, pale, moist skin
Oliguria
Decreased mentation

Pulmonary Findings
Dyspnea
Increased respiratory rate
Inspiratory crackles, possible wheezing
Arterial blood gas measures show a decrease in PaO_2
Respiratory alkalosis

Radiographic Findings
Enlarged heart
Pulmonary congestion

cardiogenic shock. Laboratory studies suggesting myocardial tissue death reveal a continuous release of myocardial bands of creatine phosphokinase (MB-CPK) and cardiac troponin I into the circulation. These cardiac markers are released into the bloodstream by dying cardiac cells into the bloodstream. Each marker has a time course for its peak level indicative of myocardial injury. Brain natriuretic peptide (BNP), another cardiac marker that may be assessed by laboratory analysis, is produced and released by the ventricle when it is stretched due to pressure overload. The BNP can be used to help determine both the presence and severity of heart failure.[13]

Management

Management is aimed at increasing myocardial oxygen delivery, maximizing CO, and decreasing left ventricular workload. The first goals of treatment are to correct reversible problems, protect the ischemic myocardium, and improve tissue perfusion. Early treatment is imperative to preserve myocardial muscle. Reversing the hypoxemia and acidosis can improve the response to other therapies. Fluids should be managed to provide adequate filling pressure without overdistention of the ventricle. Left ventricular filling pressures are often elevated; therefore, diuresis or nitrate infusion may be indicated to achieve optimal preload. Electrolytes, specifically potassium, calcium, and magnesium, may need to be replaced to provide optimal conditions for the damaged myocardial muscle.

Nursing management for the patient with cardiogenic shock centers on conserving myocardial energy and decreasing the workload of the heart. Use of opioid analgesics and sedatives to minimize the sympathetic nervous system response can increase venous capacitance and decrease resistance to ejection. Opioids also relieve ischemic pain. Increasing the oxygen concentration of inspired air is a simple but important step and may require initiation of mechanical ventilation. Nurses need to provide physical care and periods of rest to minimize myocardial energy expenditure.

Dysrhythmias often occur with acute myocardial infarction, ischemia, or acid–base imbalances and can further decrease CO. Correcting these problems with antiarrhythmic agents, cardioversion, or pacing can help restore a stable heart rhythm and enhance CO. The critical care nurse must obtain, follow, and carefully interpret the patient's hemodynamic parameters to achieve the goal of optimal CO. Optimal filling pressures assist in restoring CO but must be attained cautiously. As mentioned, left ventricular filling pressures may be elevated, and diuresis should be used to reduce these pressures. If the left ventricular filling pressure is too low, fluids may be used, but they must be stopped when filling pressures increase without a subsequent increase in CO. In general, a preload (left ventricular end-diastolic pressure [LVEDP]) of 14 to 18 mm Hg should be maintained. Achieving an "optimal filling pressure" by administering fluids and diuretics is not always an easy task. Slow fluid administration or diuresis requires diligent assessment of the effectiveness of the interventions. Invasive measures of fluid status may be used in patients with pulmonary artery catheters, central venous catheters, or specialized sensors on arterial catheters. Although these technologies provide a wealth of information, at this time there is little evidence to show that their use improves patient outcomes. For this reason, excellent clinical examination skills are essential and noninvasive measures such as blood pressure, mental status, and urine output are very important.[7,14,15]

Pharmacological agents can be used to augment CO, but they too must be used cautiously. Many agents can increase myocardial oxygen consumption ($M\dot{v}O_2$) without having an appreciable effect on CO. Decisions to use some pharmacological agents are based on overall risk–benefit considerations. The sympathomimetic drugs norepinephrine and epinephrine hydrochloride may enhance CO by increasing contractility, heart rate, or SVR but simultaneously increase cardiac work. In addition, stimulation of beta-2 receptors by epinephrine may produce dilation in peripheral vascular beds that robs vital organs of blood. Agents with positive inotropic effects that have less activity on vascular tone, such as low-dose dopamine hydrochloride, dobutamine hydrochloride, amrinone, and milrinone, are frequently used with success.[7,16] Table 54-4 lists pharmacological agents used in treating patients in shock states.

Decreasing the workload of the left ventricle can be accomplished through pharmacological afterload reduction or mechanical support devices. It is recommended that vasodilators, such as sodium nitroprusside, nitroglycerin, or angiotensin-converting enzyme (ACE) inhibitors, be administered to reduce SVR and LVEDP in an effort to increase CO and improve left ventricular function.[16] Mechanical support for the failing ventricle includes the intra-aortic balloon pump and left ventricular assist device. Both devices reduce the workload of the left ventricle by supplementing pumping ability (see Chapter 18).

Distributive Shock States

Distributive shock states can be caused by anaphylaxis (anaphylactic shock), loss of sympathetic tone (neurogenic shock), or sepsis (septic shock). The underlying mechanism is decreased venous return resulting from displacement of blood volume away from the heart because of enlargement of the vascular compartment and loss of blood vessel tone (Fig. 54-6). Loss of blood vessel tone occurs as a consequence of a loss of sympathetic innervation to blood vessels (neurogenic shock) or because of vasodilating substances in the blood (anaphylactic and septic shock). Distributive shock states can occur in a variety of settings, although the most common is sepsis.[17]

Anaphylactic Shock

Anaphylaxis results from an allergic reaction to a specific allergen that evokes a life-threatening hypersensitivity response. While foods are the most common cause of anaphylaxis in children, medication and insect-sting allergies are more common causes in adults.[18] If left untreated, vascular collapse can occur, resulting in greatly decreased tissue perfusion and death. Prompt intervention is critical.

ETIOLOGY. Antigens, the substances that elicit the response, can be introduced through injection or ingestion, or through the skin or respiratory tract. Substances capable of evoking anaphylaxis in humans include a multitude of factors (Box 54-5).

Table 54-4 Pharmacological Drugs Used in the Treatment of Shock*

Drug	Heart Rate	Effects on Contractility	Systemic Venous Resistance	Nursing Considerations
Dopamine (Intropin)	↑	↑↑	↑	Hemodynamic effects are dose dependent May increase $M\dot{V}O_2$ demands
Epinephrine (Adrenaline)	↑↑	↑↑	↑	May induce ventricular dysrhythmias May increase $M\dot{V}O_2$ demands β_2 Activity may dilate peripheral beds
Norepinephrine (also known as levarterenol [Levophed])	↑	↑	↑↑↑	Monitor peripheral circulation closely; may increase $M\dot{V}O_2$
Phenylephrine (Neo-Synephrine)			↑↑	May induce dysrhythmias
Vasopressin (Pitressin)		↑	↑↑	Monitor peripheral circulation closely; may increase $M\dot{V}O_2$
Sodium nitroprusside (Nipride)	↑		↓↓	Hemodynamic effects are dose dependent; adjust dosage slowly
Nitroglycerine (Tridil)	↑		↓	Hemodynamic effects are dose dependent; adjust dosage slowly; tolerance may develop
Angiotensin-converting enzyme (ACE) inhibitors	↑		↓	
Amrinone (Inocor)	↑	↑	↓	May increase $M\dot{V}O_2$ demands
Milrinone (Primacor)	↑	↑↑	↓	May increase $M\dot{V}O_2$ demands Monitor for tachyarrhythmias
Dobutamine (Dobutrex)	↑	↑↑	↓	May increase $M\dot{V}O_2$ demands Monitor for tachyarrhythmias

$M\dot{V}O_2$, myocardial oxygen consumption.

*All agents should be administered through a central venous catheter and using a volumetric pump.

Anaphylaxis may be either immunoglobulin E (IgE) or non-IgE mediated. Non-IgE responses occur without the presence of IgE antibodies and are called anaphylactoid reactions. It is thought that direct activation of mediators causes this response. Anaphylactoid reactions are commonly associated with nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin. If there has been an anaphylactoid reaction to one agent, restrictions should include all NSAIDs because any of them could elicit a second reaction.

IgE-mediated anaphylaxis occurs as a result of the immune response to a specific antigen. The first time the immune system is exposed to the antigen, a very specific IgE antibody is formed and circulates in the blood. When a second exposure to this antigen occurs, the antigen binds to this circulating IgE, which then activates mast cells and basophils, triggering release of histamine, prostaglandins, leukotrienes, and other biochemical mediators that initiate anaphylaxis.

Pathophysiology

The antibody–antigen reaction causes antibody-specific mast cells and basophils to secrete substances such as histamine, leukotrienes, eosinophil chemotactic substance, heparin, prostaglandins, neutrophil chemotactic substance, and platelet-activating factor 2 (Fig. 54-7). These substances, particularly histamine, prostaglandins, and leukotrienes, cause systemic vasodilation, increased capillary permeability, bronchoconstriction, coronary vasoconstriction, and urticaria (hives). Some of the other substances precipitate a continued downward spiral by causing myocardial depression, inflammation, excessive secretion of mucus, and peripheral vasodilation.[19] The diffuse arterial vasodilation creates a maldistribution of blood volume to tissues, and venous dilation decreases preload, decreasing CO. Increased capillary permeability leads to loss of vascular volume, further decreasing CO and subsequently impairing tissue perfusion. Initial symptoms include itching, urticaria, and some difficulty breathing due to bronchoconstriction. Death from circulatory collapse or extreme bronchoconstriction may occur within minutes or hours.

Assessment

Anaphylactic shock may have no predisposing factors. Therefore, avoiding known allergens is usually the best way to prevent anaphylactic shock.

HISTORY. It is necessary to obtain a thorough history of allergies and responses to drugs, foods, blood products, or anesthetic agents. Moreover, it is important to recognize the various clinical presentations.

PHYSICAL FINDINGS. The earlier the symptoms of anaphylaxis appear after exposure to the antigen, the more severe the response. Initially, generalized erythema,

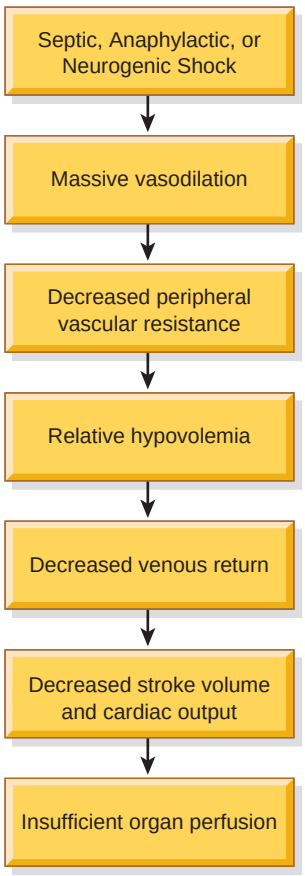

FIGURE 54-6 ▲ Distributive shock states are caused by decreased venous return as a result of displacement of blood volume away from the heart due to enlargement of the vascular compartment and loss of blood vessel tone.

urticaria, and pruritus may occur in response to the antigen. Other symptoms may include anxiety and restlessness, dyspnea, wheezing, chest tightness, a warm feeling, nausea and vomiting, angioedema, and abdominal pain. As the episode progresses, severe respiratory manifestations, such as laryngeal edema or severe bronchoconstriction with stridor, may develop. Hypotension from vasodilation soon occurs and leads to circulatory collapse. As circulatory collapse or hypoxia related to severe bronchoconstriction progresses, the level of consciousness deteriorates to unresponsiveness.

Management

Early recognition and treatment of anaphylaxis is essential. Therapeutic goals include removal of the offending antigen, reversal of effects of the biochemical mediators, and restoration of adequate tissue perfusion. Regardless of the cause of the anaphylactic reaction, treatment depends on clinical symptoms. If the symptoms are mild, immediate therapy includes oxygen and subcutaneous or IV administration of an antihistamine, such as diphenhydramine, to block the effects of histamine. Any patient with life-threatening changes in airway, breathing, or circulation should immediately receive epinephrine to reverse the vasodilation and bronchoconstriction (Box 54-6). If the patient is severely hypotensive or does not respond promptly to epinephrine, rapid infusion (over 1 to 3 minutes) of crystalloid fluids is essential. Other pharmacotherapy includes corticosteroids, bronchodilators, and, if absolutely necessary, vasoconstrictors and positive inotropic agents to combat circulatory collapse.[20,21]

Nursing care involves maintaining an adequate airway and monitoring patient response to the antigen. The nurse also monitors respirations, heart rate, blood pressure, and level of anxiety, and institutes comfort measures related to the dermatological manifestations. If the agent causing the anaphylaxis is unknown, evaluation for allergies and future risk for anaphylaxis should be completed. Patient education regarding prevention and treatment is critical for any person who experiences a significant anaphylactic or anaphylactoid reaction.

Neurogenic Shock

ETIOLOGY. Neurogenic shock results from loss or disruption of sympathetic tone, which causes peripheral vasodilation and subsequent decreased tissue perfusion. The disturbance of sympathetic tone may be caused by any event

BOX 54-5 PATIENT SAFETY

Drugs Commonly Implicated in Anaphylactic and Anaphylactoid Reactions

Antibiotics	Penicillin and its synthetics, cephalosporins, erythromycin, streptomycin, tetracyclines
Anti-inflammatory agents	Salicylates, aminopyrine, ibuprofen, naproxen, and others
Narcotic analgesics	Morphine, codeine
Anesthetics	Procaine, lidocaine, cocaine, thiopental
Anesthetic adjuncts	Succinylcholine, tubocurarine
Other medications	Protamine, chlorpropamide, parenteral iron, iodides, thiazide diuretics
Blood products	Red blood cell, WBC, and platelet transfusions; gamma globulin
Immune sera	Rabies, tetanus, diphtheria antitoxin, snake and spider antivenom
Diagnostic agents	Iodinated radiocontrast agents
Venoms	Bees, wasps, hornets, spiders, snakes, jellyfish
Hormones	Insulin, corticotropin, pituitary extract
Enzymes and other biologicals	Acetylcysteine, pancreatic enzyme supplements
Extracts used in desensitization	Food, pollen, venoms
Foods	Eggs, fish, shellfish, milk, nuts, legumes
Textiles	Latex

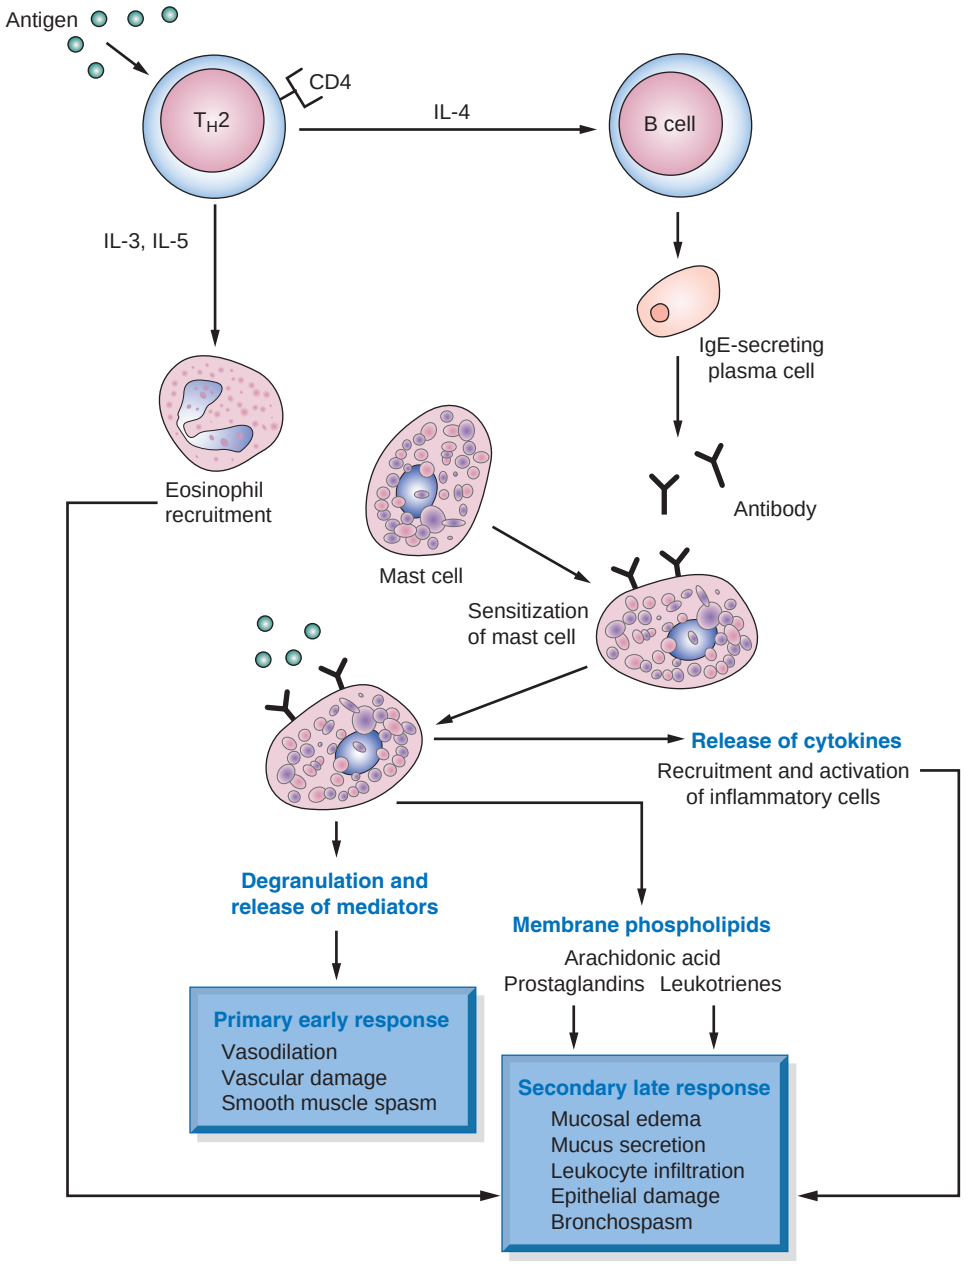

FIGURE 54-7 ▲ IgE-mediated hypersensitivity reaction. IL-3, interleukin 3; IL-4, interleukin 4; IL-5, interleukin 5. (From Porth CM: Concepts of Altered Health States, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 412.)

that disrupts the sympathetic nervous system. The most common cause of neurogenic shock is a spinal cord injury above the level of T6 because sympathetic innervation occurs above this level. Other causes include spinal analgesia, emotional stress, pain, drugs, or other central nervous system problems.

BOX 54-6 Epinephrine Dosage in Anaphylaxis (Adults)

Epinephrine 1:1,000 dilution (1 mg/mL), 0.2 to 0.5 mL intramuscularly or subcutaneously every 5 minutes, as necessary, should be used to control symptoms and increase blood pressure in patients experiencing anaphylaxis.

From Joint Task Force on Practice Parameters, American Academy of Allergy, Asthma and Immunology, American College of Allergy, Asthma and Immunology, Joint Council of Allergy, Asthma and Immunology: The diagnosis and management of anaphylaxis: An updated practice parameter. J Allergy Clin Immunol 115(3 Suppl 2):S483–S523, 2005

PATHOPHYSIOLOGY. Neurogenic shock is characterized by hypotension, bradycardia, and hypothermia. When sympathetic tone is lost, unopposed parasympathetic tone results in uncontrolled arterial vasodilation and a decrease in SVR. Simultaneous venous vasodilation results in blood pooling and decreases preload. Unopposed parasympathetic stimulation leads to bradycardia, even in the presence of falling blood pressure, which would normally lead to increased heart rate through stimulation of baroreceptors in the aortic arch and carotid sinus. The decrease in both stroke volume (from decreased preload) and heart rate leads to decreased CO, resulting in inadequate tissue perfusion. Hypothermia results from uncontrolled heat loss resulting from excessive vasodilation.[22,23]

ASSESSMENT. Physical findings in the patient with neurogenic shock are largely related to excessive vasodilation and the impaired response to this process. Patients demonstrate decreased central venous pressure (CVP), CO, and SVR combined with bradycardia. Unlike many shock states in which the patient may feel cold and clammy, often the skin is warm due to the uncontrolled vasodilation. In the trauma patient, it is important to exclude hypovolemia before attributing hypotension to neurogenic shock.

MANAGEMENT. Prevention and treatment of hypotension through careful fluid resuscitation is a high priority. The patient's effective circulating volume may be dramatically decreased because of venous pooling. In general, the systolic blood pressure (SBP) should be kept over 90 mm Hg. If fluid administration alone is not adequate to restore the blood pressure, vasopressors may be added. The use of agents with alpha-adrenergic activity promotes vasoconstriction, while beta-adrenergic agonists increase heart rate and contractility.[22] (Refer to Chapter 37 for detailed information on spinal cord injury and associated complications such as neurogenic shock.)

Septic Shock

Septic shock is a complex and generalized process that involves all organ systems. Sepsis, severe sepsis, and septic shock represent progressive stages of the same illness. In 1991, the Society of Critical Care Medicine and the American College of Chest Physicians established universal definitions for the term sepsis and other associated clinical conditions[4] to promote earlier detection of and intervention for these states, improve outcomes, and standardize the terminology used in research protocols. In 2001, a second consensus conference was held to modify the existing definitions for accuracy, reliability, and clinical utility of the diagnosis of sepsis[24] (Box 54-1, p. 1212).

ETIOLOGY. In the United States, it has been estimated that there are as many as 750,000 cases of severe sepsis annually, and that incidence is increasing.[25] The incidence is rising for several reasons: an aging population, increasing number of infections associated with antibiotic-resistant organisms, an increasing number of immunocompromised patients who present with critical illness, more patients undergoing high-risk surgery, and possibly improved identification. The mortality rate for sepsis is approximately 20% and can be as high as 70% in severe sepsis and septic shock. Survivors are often left with a profoundly different quality of life.[25] Risk factors for the development of septic shock include host factors and treatment-related factors (Box 54-7). Approximately one in four patients who present to the emergency department in sepsis will progress to septic shock within 72 hours.[26] Risk factors for progression from sepsis to severe sepsis are listed in Box 54-8.

Septic shock is initiated by an infection. Infections may be due to invading Gram-negative or Gram-positive bacteria, fungi, and viruses. In some patients, multiple causative organisms are identified, but in many patients the causative organism is never identified. Bacteria may be introduced through the pulmonary system, urinary tract, or gastrointestinal system; through wounds; or through invasive devices.

BOX 54-7 PATIENT SAFETY

Risk Factors for the Development of Septic Shock

Host Factors
- Extremes of age
- Malnutrition
- General debilitation
- Chronic debilitation
- Chronic illness
- Drug or alcohol abuse
- Neutropenia
- Splenectomy
- Multiple organ failure

Treatment-Related Factors
- Use of invasive catheters
- Surgical procedures
- Traumatic or thermal wounds
- Invasive diagnostic procedures
- Drugs (antibiotics, cytotoxic agents, steroids)

PATHOPHYSIOLOGY. Septic shock results from complex interactions among invading microorganisms and immune, inflammatory, and coagulation systems, which results in a proinflammatory and procoagulation state (Fig. 54-8). Both Gram-negative and Gram-positive organisms may directly stimulate the inflammatory response and other aspects of the immune system that activate cytokines, complement, and coagulation systems. In response to the presence of microorganisms, macrophages and helper (CD4+) type 1 helper T (Th1) cells secrete the proinflammatory cytokines, such as TNF-α and IL-1β. As previously discussed, these cytokines induce endothelial dysfunction and result in increased capillary permeability. In addition to proinflammatory cytokines, anti-inflammatory cytokines are also released. Type 2 helper T cells (Th2) secrete the anti-inflammatory cytokines IL-4 and IL-10, which balance the proinflammatory response. But in some patients, these proinflammatory cytokines fail to shut down or control the proinflammatory cytokines, and the "out of control" proinflammatory response activates the coagulation cascade.[27]

Another important aspect of sepsis is the imbalance between procoagulant and anticoagulant factors. Endotoxins

BOX 54-8 PATIENT SAFETY

Risk Factors for Progression From Sepsis to Severe Sepsis
- SBP less than 110 mm Hg
- Temperature more than 38.2°C
- Sodium more than 145 mmol/L
- Platelets less than 150 × 10^9/L
- Bilirubin more than 30 mcmol/L
- Mechanical ventilation
- Presence of infection
  - Primary bacteremia
  - Aerobic Gram-negative bacilli
  - Gram-positive cocci
  - Peritonitis
  - Pneumonia

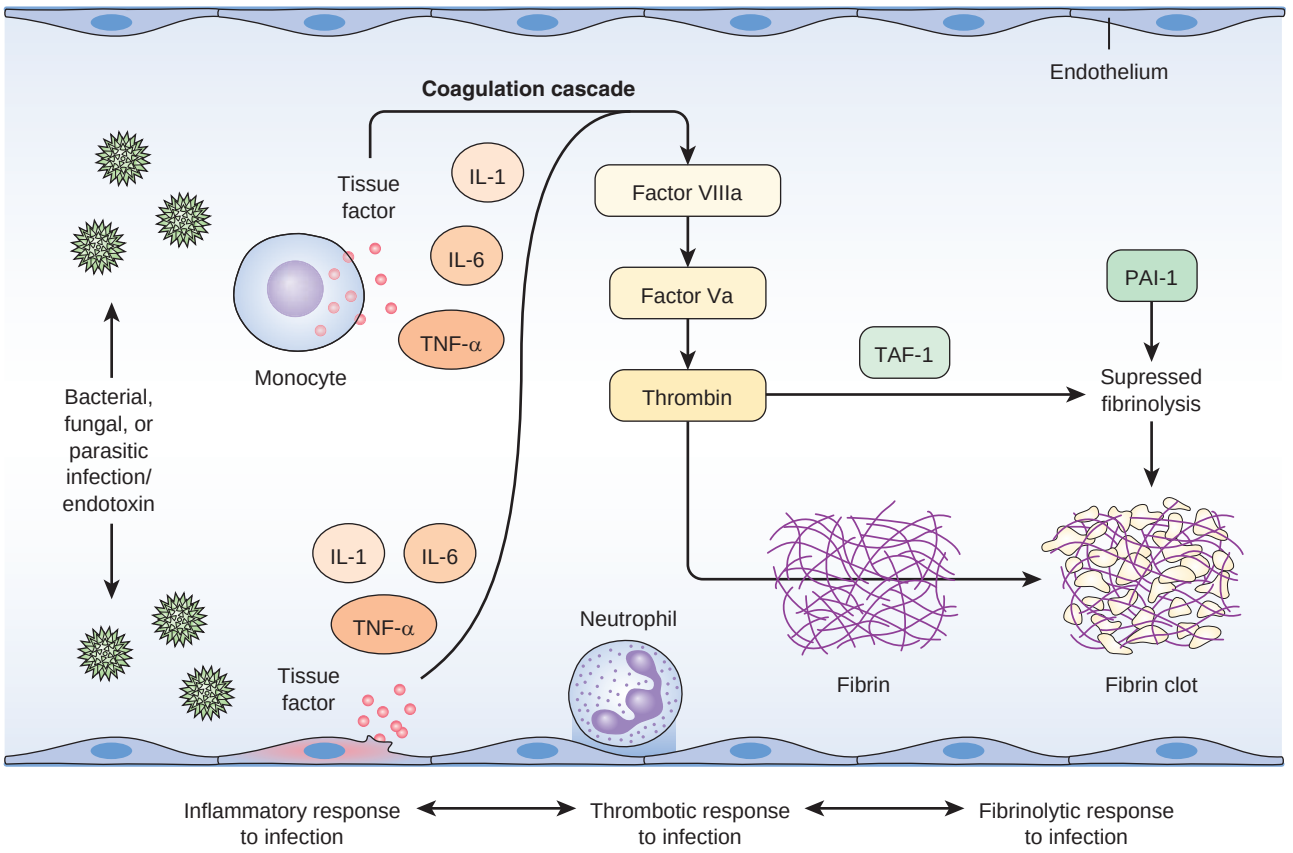

FIGURE 54-8 ▲ Inflammatory/immune response in septic shock. IL-1, interleukin 1; IL-6, interleukin 6; TNF-α, tumor necrosis factor-α; TAFI, thrombin-activated fibrinolysis inhibitor; PAI-1, plasminogen-activator inhibitor-1. (Copyright © 2001, Eli Lilly and Company. All rights reserved.)

stimulate endothelial cells to release tissue factor, which activates the coagulation cascade causing the conversion of fibrinogen to fibrin. Fibrin binds to platelet plugs that have adhered to damaged endothelial cells, forming a stable fibrin clot. These clots form throughout the microvasculature and cause additional injury and ischemia to distal tissues. Normally, anticoagulant factors (protein C, protein S, antithrombin III, tissue factor pathway inhibitor) modulate coagulation, preventing widespread microthrombi formation. Thrombin binds with thrombomodulin on endothelial cells, "activating" protein C. Activated protein C then inactivates factors V and VIII and inhibits the synthesis of plasminogen-activator inhibitor, which then allows plasmin to break down the fibrin–platelet clots.[28] Unfortunately, sepsis lowers the levels of these anticoagulant factors, and the net result is a procoagulant state that contributes to further inflammation.[27] Recognition that the proinflammatory and procoagulant responses result in a loss of homeostasis of almost every organ system is key to understanding sepsis.

Cardiovascular Alterations. In general, septic shock is associated with three major pathophysiological effects on the cardiovascular system: vasodilation, maldistribution of blood flow, and myocardial depression.

Proinflammatory cytokines stimulate the release of NO from endothelial cells. NO is a potent vasodilator and causes widespread vasodilation. Because of this vasodilation, there is decreased venous return to the heart, decreased CO, and decreased SVR. Other inflammatory mediators, including endothelin, are released from endothelial cells and cause vasoconstriction in other vascular beds. This situation of mixed vasodilation and vasoconstriction produces maldistribution of blood flow, particularly in the microcirculation.[29]

In septic shock, myocardial depression is evident in a decreased ventricular ejection fraction, dilation of the ventricles, and a flattening of the Frank-Starling curve after fluid resuscitation. Myocardial depressant factors, such as the cytokines TNF-α, IL-1β, and IL-6, are released as part of the inflammatory cascade. NO also contributes to dysfunction by impairing the ability of cells to utilize available oxygen for ATP production. The heart demonstrates functional impairment of contractility and ventricular performance.[30]

Early in septic shock, activation of the sympathetic nervous system and release of vasodilatory substances such as NO promote development of a hyperdynamic state with high CO and low SVR. Later, as circulating cardiac depressants increase, the heart becomes hypodynamic, with low CO and increased SVR. Hemodynamic parameters, including $ScvO_2$/SvO_2 and measures of metabolic acidosis, should be followed over time to recognize early and progressive cardiac failure.

Pulmonary Alterations. Events initiated by activation of the inflammatory response and its mediators affect the lungs both directly and indirectly. Activation of the sympathetic nervous system and release of epinephrine from the adrenal medulla produce bronchodilation. However, this may be overridden by activity of cytokines, and the net result is bronchoconstriction. More importantly, inflammatory mediators and activated neutrophils cause capillary leak into the pulmonary interstitium, resulting in interstitial edema, areas of

poor pulmonary perfusion (shunting), pulmonary hypertension, and increased respiratory work. As fluid collects in the interstitium, pulmonary compliance is reduced, gas exchange is impaired, and hypoxemia occurs.

The pulmonary alterations described previously may culminate in acute respiratory distress syndrome (ARDS), which is frequently associated with septic shock.[31] Continued fluid accumulation in the pulmonary interstitium may finally spill over into the alveoli, producing alveolar infiltrates that provide fertile areas for bacterial growth. Mechanical ventilation, which is common in patients with ARDS, may provide an avenue of entry for lung infections. Therefore, a secondary pneumonia may develop, possibly caused by a different organism than that which produced the sepsis. See Chapter 27 for more information about ARDS.[31]

Hematological Alterations. Platelet abnormalities also occur in septic shock because endotoxin indirectly causes platelet aggregation and subsequent release of more vasoactive substances (serotonin and thromboxane A_2). Circulating platelet aggregates have been identified in the microvasculature of septic patients. These obstruct blood flow and compromise cellular metabolism. Overactivation of the coagulation cascade without the counterbalance of adequate fibrinolysis compromises tissue perfusion both regionally and globally. Over time, clotting factors are depleted, and a coagulopathy results, with the potential of progressing to disseminated intravascular coagulation (DIC).[28]

Metabolic Alterations. Septic shock induces a hypermetabolic state characterized by an increase in resting energy consumption, extensive protein and fat catabolism, negative nitrogen balance, hyperglycemia, and hepatic gluconeogenesis. Excessive catecholamine release stimulates gluconeogenesis and insulin resistance, which both result in hyperglycemia in critically ill patients who do not have diabetes. Cells are progressively unable to use glucose, protein, and fat as energy sources. Hyperglycemia that is resistant to insulin therapy is a frequent finding in early shock. Eventually, all glycogen energy stores are depleted, cells lack ATP, and cellular pumps fail, progressing to tissue and organ death.

In response to lack of effect of insulin, proteins break down, leading to high blood urea nitrogen and urinary nitrogen excretion. Muscle protein is broken down to amino acids, some of which are used as energy sources for the Krebs cycle or as substrates for gluconeogenesis. In later stages of shock, the liver is unable to use the amino acids because of its own metabolic dysfunction. Amino acids then accumulate in the bloodstream.

As shock progresses, adipose tissue is broken down (lipolysis) to furnish the liver with lipids for energy production. Hepatic triglyceride metabolism produces ketones, which circulate to peripheral cells that can use them in the Krebs cycle for ATP production. As liver function decreases, triglycerides are not broken down; they collect in the mitochondria, inhibit the Krebs cycle, and result in increased anaerobic metabolism and lactate production. The ability of cells to extract and use oxygen is impaired as a result of mitochondrial dysfunction. Oxidants are normally produced as a by-product of oxidative phosphorylation. However, in critical illness, an accumulation of oxidants occurs that results in oxidative stress. Oxidative stress causes lipid peroxidation, protein oxidation, and mutations in mitochondrial DNA, thereby contributing to cell death.

The net effect of these metabolic derangements is that cells become energy starved. This energy deficit is implicated in the emergence of multiple organ failure that frequently develops regardless of interventions designed to support the circulatory and organ systems.[32,33]

ASSESSMENT. A thorough understanding of the mediator responses that occur during sepsis aids in assessing and evaluating the response to treatment.

Physical Findings. Some of the earliest signs of septic shock include changes in mental status (confusion or agitation), increased respiratory rate as compensation for the metabolic acidosis, and either fever or hypothermia. Because of the exaggerated inflammatory response with release of vasoactive mediators, the clinical presentation of the patient is complex. The patient is edematous yet intravascularly depleted, and areas of microthrombi and vasoconstriction obstruct perfusion. As fluid replacement occurs, the leaking capillary beds shift the fluid interstitially, requiring more fluid resuscitation, which may further exacerbate interstitial edema. Because of the inappropriate systemic activation of the coagulation system, clotting factors are depleted, and spontaneous bleeding may occur. Perfusion imbalances cause ischemia in some vascular beds, such as the splanchnic circulation, skin, and extremities, which may lead to necrosis. Consistent with the hyperdynamic state, CO may initially be high; however, it is insufficient to maintain adequate perfusion due to the inappropriately low SVR.

Laboratory Studies. Laboratory and diagnostic studies that may help to identify sepsis are summarized in Box 54-9. Despite the use of such testing, the early diagnosis of sepsis and septic shock is usually made on the basis of patient risk factors and clinical findings (see Box 54-7).

MANAGEMENT. Septic shock requires a prompt, aggressive, multidisciplinary team approach with monitoring and treatment facilities found in an intensive care unit. The primary treatment goals are to maximize oxygen delivery above cellular oxygen consumption requirements and to halt the exaggerated inflammatory response. The treatment of sepsis involves early, goal-directed therapy. See the Evidence-Based Practice Highlight 54-1. Initiating therapy promptly (within the first 6 hours), with specific hemodynamic goals for resuscitation, has been shown to slow the decompensation of patients in a septic state and decrease the risk for cardiovascular collapse.[34] The Surviving Sepsis Campaign Guidelines,[35] developed in 2003 and revised in 2007 by an international team, outline the evidence-based care of patients with sepsis (Table 54-5, p. 1228). The use of a sepsis protocol or sepsis bundle improves interdisciplinary management of septic shock and is associated with improved survival.[36,37]

Prevention. Because morbidity and mortality from septic shock are so high, it is imperative that preventive infection control measures be in place. In critically ill patients, defense mechanisms are often impaired, and protection from hospital-acquired (nosocomial) infections is essential. Nosocomial infections increase length of hospital stay and are associated with substantial costs, ranging from $5,800 to $12,700 for a case of sepsis and $11,100 to $22,300 for a case of pneumonia.[38] Therefore, a critical aspect of nursing care involves meticulous adherence to aseptic technique, thorough hand washing, and a continuing awareness of potential sites and causes of infection. Sources of equipment-related infections are listed in Box 54-10.

Identification and Treatment of Infection. Immediately on presentation, blood cultures should be drawn and then empiric

BOX 54-9 Physiological Data Helpful in Diagnosing Sepsis

- Cultures: blood, sputum, urine, surgical or nonsurgical wounds, sinuses, and invasive lines; positive results are not necessary for diagnosis.
- CBC: WBCs usually will be elevated and may decrease with progression of shock.
- Chemistry panel: hyperglycemia may be evident, followed by hypoglycemia in later stages.
- Arterial blood gases: metabolic acidosis with mild hypoxemia (PaO_2 < 80 mm Hg) and possibly compensatory respiratory alkalosis ($PaCO_2$ < 35 mm Hg) is present in sepsis.
- CT scan may be needed to identify sites of potential abscesses.
- Chest and abdominal radiographs may reveal infectious processes.
- SvO_2 or $ScvO_2$ can assist in the assessment of adequacy of oxygen delivery and consumption.
- Lactate level: decreasing levels of lactate in the serum indicate aerobic metabolism is able to meet cellular energy requirements. Elevated levels indicate inadequate perfusion and anaerobic metabolism to meet cellular energy requirements.
- Base deficit: elevated levels indicate inadequate perfusion and anaerobic metabolism.
- $EtCO_2$: may detect early indications of inadequate regional and global tissue perfusion

broad-spectrum antibiotic therapy with coverage against Gram-negative and Gram-positive bacteria and anaerobes must be initiated. Once the infectious organism has been isolated, antibiotic therapy should be narrowed to antibiotics effective against that specific organism to try to minimize development of antibiotic resistance. Source identification and control is of paramount importance. If a source is identified, definitive measures to alleviate the cause of sepsis might include resection or drainage of purulent tissues or secretions.[35]

However, antimicrobial treatment of sepsis is not sufficient to treat the generalized inflammatory reactions seen with septic shock. Supportive measures establish and maintain adequate tissue perfusion, and other therapies aim to block or interfere with the action of the various mediators implicated in shock. Aspects of supportive care include the following:

- Restoring intravascular volume
- Maintaining an adequate CO
- Ensuring adequate ventilation and oxygenation
- Restoring balance between coagulation and anticoagulation
- Providing an appropriate metabolic environment

Restoration of Intravascular Volume. Adequate volume replacement is important for reversing hypotension. Patients may require several liters or more of fluid because

EVIDENCE-BASED PRACTICE HIGHLIGHT 54-1

Severe Sepsis: Initial Recognition and Resuscitation

△ Expected Practice

- Assess all patients and immediately notify physician when a patient presents with clinical findings suggestive of sepsis.
- Clinical findings for severe sepsis include:
  - Documented or suspected infection

AND

  - Two or more of the following systemic inflammatory response syndrome (SIRS) criteria:
    - Heart rate greater than 90 beats/min
    - Temperature less than 36°C (96.8°F) or greater than 38.3°C (101°F)
    - Respiratory rate greater than 20 breaths/min or $PaCO_2$ less than 32 mm Hg
    - White blood cell count greater than or equal to 12,000/mm^3 or less than or equal to 4,000 mm^3 or a left shift in the immaturation of granulocytes (bands) greater than 10%

AND

  - At least one of the following indicators of tissue hypoperfusion or sepsis-related acute organ dysfunction:
    - Acute altered mental status
    - Systolic blood pressure less than 90 mm Hg or mean arterial pressure less than 70 mm Hg or a SBP decrease of 40 mm Hg
    - Blood glucose greater than 140 mg/dL in patients without diabetes.
    - Arterial hypoxemia (PaO_2/FiO_2 < 300)
    - Acute oliguria (<0.5 mL/kg/h for at least 2 hours)
    - Creatinine increase greater than 0.5 mg/dL above baseline
    - Coagulation abnormalities (INR > 1.5 or a PTT > 60 seconds)
    - Ileus
    - Thrombocytopenia (platelet count < 100,000/mL)
    - Hyperbilirubinemia (plasma total bilirubin > 2 mg/dL) Lactate greater than 2 mmol/L
- Obtain serum lactate measurements. Hyperlactatemia is defined as lactic acid level greater than 4 mmol/L. (Level D)
- Obtain blood cultures as well as cultures from all potential sites of infection prior to initiating broad spectrum antibiotics. Blood cultures should be drawn prior to initiation of antibiotic therapy and within 1 hour of sepsis diagnosis. (Level D)
- Evaluate for and remove potential sources of infection (eg, obviously infected invasive devices). (Level D)
- Maintain the following therapeutic endpoints during resuscitation: mean arterial pressure at greater than 65 mm Hg, central venous pressure (CVP) 8 to 12 mm Hg, and central venous or mixed venous oxygen saturation greater than 70%. (Level D)
  - Administer fluids to attain a CVP of 8 to 12 mm Hg or greater than or equal to 12 mm Hg if on a ventilator. (Level D)
  - Administer vasopressors if necessary to achieve a mean arterial pressure of 65 mm Hg if fluid replacement is not successful. (Level D)
  - If venous oxygen saturation goal not attained, consider additional fluids, blood transfusion, and/or dobutamine administration. (Level D)
- Maintain blood glucose levels at less than 150 mg/dL. (Level D)
- Consider administration of human recombinant activated protein C (drotrecogin alfa activated) for patients at risk for dying and presenting with septic shock, sepsis with multiple organ failure, and sepsis-induced acute respiratory distress syndrome. (Level D)

Note: Administration of human recombinant activated protein C (drotrecogin alfa activated) is no longer recommended. The FDA sent out notification on October 25, 2011 that Eli Lilly has withdrawn this drug from the market. In a recently completed clinical trial (PROWESS-SHOCK trial), the drug failed to show a survival benefit for patients with severe sepsis and septic shock.

EVIDENCE-BASED PRACTICE HIGHLIGHT 54-1 (continued)

Severe Sepsis: Initial Recognition and Resuscitation

△ Supporting Evidence

- More than 750,000 cases of severe sepsis occurred annually (year 2000) and mortality ranges from 28% to 50% with an overall hospital mortality of about 30%.[1] Sepsis (infection and two of the SIRS criteria) can rapidly progress to severe sepsis (infection + SIRS criteria + organ dysfunction) to septic shock (persistent hypotension and tissue hypoperfusion despite sufficient fluid resuscitation) within 24 hours.[1–4]
- Treatment should be initiated regardless of where the patient is located within the hospital. A prospective randomized study of 263 emergency department patients diagnosed with severe sepsis or septic shock showed that patients treated aggressively with a goal direction toward tissue oxygenation within the first 6 hours of presentation had a 16% improvement in mortality. Another small retrospective study showed a decrease in mortality in patients identified with signs of severe sepsis and treated within the first 6 hours.[3,5–8]
- Serum lactate levels can be elevated in the setting of a normal or increased cardiac output. The measurement of serum lactate can reflect occult decreases in global tissue perfusion, and as such, may be an indicator of organ malperfusion. The presence and the clearance rate of lactate are associated with increases in patient morbidity and mortality.[3,9]
- Early administration of appropriate antibiotics decreases mortality in patients with Gram-positive and Gram-negative bacteremias. Empiric broad spectrum antibiotics should be initiated when possible after obtaining appropriate cultures but prior to identification of the infecting organism and reassessed after 48 to 72 hours based on culture results and clinical data.[10]
- According to the Surviving Sepsis Campaign guidelines, during the first 6 hours of treatment, the goal is to achieve and maintain a CVP of 8 to 12 mm Hg or 12 to 15 mm Hg for patients receiving mechanical ventilation and a MAP of at least 65 mm Hg with fluid resuscitation.[9] Dobutamine is identified as the medication of choice to increase cardiac output to normal levels or to improve lactate clearance when cardiac output is not being measured. Two large clinical trials did not show a benefit from increasing cardiac output above physiologic normal levels in order to increase oxygen delivery to the tissues.[11–13] Available data do not support the use of low-dose dopamine for renal protection.[14]
- Colloids have not been shown to be of more benefit than crystalloid for fluid resuscitation. One large randomized controlled trial comparing 4% albumin with normal saline in the treatment of patients requiring volume resuscitation found no significant difference in mortality between the groups. Several literature reviews have concluded that choice of fluids does not appear to change outcomes.[15,16]
- In the setting of hypotension, fluid replacement should be optimized before vasopressors are started. No high-level evidence exists to identify the most appropriate vasopressor to use for the treatment of septic shock and selection is based on multiple clinical parameters. However, in the Surviving Sepsis Campaign Guidelines for the Management of Severe Sepsis and Septic Shock, norepinephrine or dopamine are identified as the initial vasopressors of choice to increase vascular tone and blood pressure.[9]
- Two meta analyses concluded that administration of high-dose corticosteroids are of no benefit or may be detrimental to patients with septic shock.[17,18] In vasopressor-dependent shock, the addition of low-dose exogenous cortisol has been shown to improve the uptake of the patient's own and the exogenously administered sympathetic stimulants when serum cortisol levels are low.[19]
- Maintaining glucose levels within normal range (80 to 110 mg/dL) but at least less than 150 mg/dL has been shown to decrease morbidity and mortality in a surgical population but did not focus on septic patients. Maintaining glucose levels less than 150 mg/dL showed reduced morbidity but not mortality in critically ill medical patients with sepsis.[20,21]
- In a large double-blind study, human recombinant activated protein C (drotrecogin alfa activated) decreased mortality by 6% in patients with severe sepsis and decreased mortality by 13% for patients at high risk for death (ie, patients having an APACHE II score of 25 or greater).[22,23]

Note: Administration of human recombinant activated protein C (drotrecogin alfa activated) is no longer recommended. The FDA sent out notification on October 25, 2011 that Eli Lilly has withdrawn this drug from the market. In a recently completed clinical trial (PROWESS-SHOCK trial), the drug failed to show a survival benefit for patients with severe sepsis and septic shock.

AACN Evidence Leveling System

Level A Meta-analysis of quantitative studies or metasynthesis of qualitative studies with results that consistently support a specific action, intervention, or treatment.
Level B Well-designed, controlled studies with results that consistently support a specific action, intervention, or treatment.
Level C Qualitative studies, descriptive or correlational studies, integrative review, systematic reviews, or randomized controlled trials with inconsistent results.
Level D Peer-reviewed professional organizational standards with clinical studies to support recommendations.
Level E Multiple case reports, theory-based evidence from expert opinions, or peer-reviewed professional organizational standards without clinical studies to support recommendations.
Level M Manufacturer's recommendations only.

Excerpted from American Association of Critical-Care Nurses Practice Alert. Available online at http://aacn.org. All references cited in this alert are available with the associated resources related to this chapter. Visit: http://thepoint.lww.com

of mediator-induced vasodilation and capillary leak. Fluid replacement should be guided by hemodynamic parameters, urine output, and indicators of metabolic acidosis (end-tidal carbon dioxide, base deficit, lactic acid levels). The Surviving Sepsis Campaign Guidelines recommend fluid resuscitation with crystalloids or colloids to a target CVP of at least 8 mm Hg (12 mm Hg or higher if the patient is receiving mechanical ventilation).[35] Invasive monitoring devices, such as arterial catheters, some of which can provide CO information, and central venous catheters that can monitor CVP and venous oxygen saturation ($ScvO_2$ or SvO_2), are helpful in guiding fluid resuscitation.[39] A downward trend in the markers of metabolic acidosis is a good indicator of improvement in tissue perfusion. Blood products may be administered even in the absence of bleeding to enhance the delivery of oxygen to cells. Administering the fluid and closely monitoring the response to fluid therapy are important nursing responsibilities (see Table 54-5).

Table 54-5 Surviving Sepsis Campaign Guidelines

Collaborative Care Focus	Surviving Sepsis Guidelines	Interventions and Patient Care Considerations
Oxygenation, ventilation	**Mechanical Ventilation** • For patients requiring mechanical ventilation, a tidal volume of 6 mL/kg should be used, with an upper limit plateau pressure of 30 cm H_2O or less. • Permissive hypercapnia may be tolerated in patients with elevated plateau pressures and tidal volumes. • A minimum amount of positive end-expiratory pressure should be used to prevent lung collapse at end expiration. • The head of bed should be raised to at least 30 degrees unless contraindicated to prevent ventilator-associated pneumonia. • Prone position may be considered in patients with acute respiratory distress syndrome requiring high levels of FiO_2 or plateau pressure. • A weaning protocol for severe and refractory hypoxemia with spontaneous breathing trial should be in place to promote ventilator weaning in patients who are arousable, hemodynamically stable, who have no new life-threatening conditions, and who are not requiring high levels of FiO_2 or ventilatory support.	• Maintain a patent airway. • Auscultate breath sounds every 2–4 h and PRN. • Suction endotracheal airway when appropriate (see Chapter 25). • Hyperoxygenate and hyperventilate before and after each suction pass. • Monitor pulse oximetry and end-tidal CO_2. • Monitor arterial blood gases as indicated by changes in noninvasive parameters. • Monitor intrapulmonary shunt (Qs/Qt and PaO_2/FiO_2). • Monitor airway pressures every 1–2 h. • Consider kinetic therapy. • Consider a daily chest x-ray (see Chapter 27).

Circulation, perfusion	**Initial Resuscitation**
	• Resuscitation should begin as soon as sepsis is identified.
	• Fluid resuscitation should initially begin with boluses of crystalloids.
	• Goals of resuscitation in the initial 6-h period after identifying sepsis should include:
	  • Central venous pressure: 8–12 mm Hg (12 mm Hg or higher if mechanically ventilated)
	  • Mean arterial pressure (MAP) of at least 65 mm Hg
	  • Urine output 0.5 mL/kg/h or more
	  • $ScvO_2$ 70% or higher or SvO_2 65% or higher
	• If venous oxygen saturation target not achieved:
	• Consider additional fluid
	  • Transfuse packed red blood cells to achieve a hematocrit of 30% or higher and/or
	  • Start dobutamine infusion (to a maximum of 20 mcg/kg/min)
		• Administer intravascular fluids and vasopressors per protocol.
		• Lactate level may be used to confirm hypoperfusion in patients who are not hypotensive. Monitor serum lactate level on admission and then at least once daily.
		• Assess vital signs hourly.
		• Assess hemodynamic pressures hourly if patient has a pulmonary artery catheter in place.
		• Monitor SvO_2 via a specialty pulmonary artery catheter or $ScvO_2$ via central venous catheter.
		• Administer red blood cells or inotropic agents as ordered to increase oxygen delivery.

	Ongoing Hemodynamic Management
	• Continue to use fluid challenge techniques as long as associated with clinical improvement.
	• Vasopressors should be considered for patients unresponsive to fluid challenges (inadequate blood pressure and organ perfusion).
	  • Norepinephrine or vasopressin should be used.
	  • Low-dose dopamine should not be used for renal protection as a part of the treatment for severe sepsis.
	  • Epinephrine is recommended as the first alternative agent in septic shock that responds poorly to norepinephrine or vasopressin.
		• Monitor for response to fluid challenge with increases in blood pressure or urine output.
		• Monitor for evidence of intravascular volume overload.
		• Vasopressors should be administered through central venous access whenever possible.
		• For patients on vasopressors, an arterial catheter should be placed as soon as possible for accurate monitoring of blood pressures.

	• Inotropic therapy may be initiated for patients with low cardiac output (CO) despite adequate fluid resuscitation.
	  • Dobutamine may be used to increase CO/index to normal levels.
	  • Patients with hypotension should also receive a vasopressor to maintain MAP.
		• Monitor CO and cardiac index per hospital protocol.
		• Monitor hemoglobin and hematocrit.

	• Blood products: After the initial resuscitation is complete, administer red blood cells only when the hemoglobin is <7 g/dL.
	  • The target hemoglobin is 7–9 g/dL for patients without significant coronary artery disease, acute hemorrhage, or lactic acidosis.
	  • Erythropoietin is not recommended for anemia related to severe sepsis but may be used for anemia of other etiologies (such as renal failure).
	  • Fresh frozen plasma is not routinely used to correct altered coagulation unless there is active bleeding or invasive procedures are planned.
		• During transfusion, observe for signs of transfusion reaction.
		• Monitor coagulation parameters.

(continued on page 1229)

Table 54-5 Surviving Sepsis Campaign Guidelines (continued)

Collaborative Care Focus	Surviving Sepsis Guidelines	Interventions and Patient Care Considerations
Sedation, analgesia, and neuromuscular blockade	• A sedation protocol should be used in conjunction with a standardized sedation scale for patient evaluation. • Intermittent bolus sedation or continuous sedation is recommended. • Avoid neuromuscular blocking agents whenever possible.	• Monitor sedation level per sedation scale. • Continuous infusion of sedative agents should be interrupted daily for assessment of patient status while awake, with subsequent retitration as indicated by sedation protocol and assessment.
Steroid therapy	• Consider IV corticosteroids (hydrocortisone) in patients with septic shock who respond poorly to adequate fluid resuscitation and vasopressors.	• Monitor for elevated glucose levels, gastric ulcers, and other complications of steroid administration.
Fluids, electrolytes, and glycemic control	• Blood glucose: After initial stabilization, blood glucose level should be maintained at <150 mg/dL.	• Monitor intake and output every 1 h. • Monitor electrolytes daily and PRN. • Replace electrolytes as ordered. • Monitor blood urea nitrogen (BUN), creatinine, serum osmolality, and serum electrolyte values daily.
	• Renal replacement therapy with intermittent hemodialysis and continuous renal replacement therapy (CRRT) are considered equivalent. CRRT may be preferable in the hemodynamically unstable patient.	• Monitor fluid balance and hemodynamic stability of patients receiving renal replacement therapy.

Identifying and treating the cause of sepsis	• Cultures should be obtained before antimicrobial therapy is initiated. At least two blood cultures should be obtained:
	  • At least one culture specimen drawn percutaneously
	  • At least one culture specimen from each vascular access device inserted >48 h prior
	  • Culture other sites as clinically indicated (urine, cerebrospinal fluid, wounds, respiratory secretions, or other body fluids).
		• Obtain urine, sputum, and blood cultures as ordered.

	• The patient should be formally evaluated for a focus of infection. Any known or suspected source of infection (ie, necrotic tissue, abscesses, or infected vascular access devices) should be removed or treated. • IV antibiotics should be started as early as possible and always within the first hour of recognizing severe sepsis or septic shock. • Initial therapy should include medications with activity against the likely pathogen, with consideration of patterns of resistance in the hospital and community.	• Obtain wound and central vascular line tip culture specimens as ordered. • Administer antibiotics as ordered. • Monitor serum antibiotic levels as ordered. • Consider infectious disease consult. • Monitor systemic inflammatory response syndrome criteria: increased WBCs, increased temperature, tachypnea, and tachycardia.
Preventing new infection	• The antimicrobial regimen should be reassessed daily to optimize activity and prevent development of resistance.	• Adjust antibiotics based on culture results. • Use strict aseptic technique during procedure, and monitor technique of others. • Maintain sterility of invasive catheters and tubes.

Deep venous thrombosis (DVT) prophylaxis	• Patients with sepsis should receive prophylaxis against DVT.
	  • Low-dose unfractionated heparin or low-molecular-weight heparin is preferred.
	  • For patients with a contraindication to pharmacological prophylaxis, mechanical therapy should be used (graduated compression device or intermittent compression device).
	  • For patients at high risk, both pharmacological and mechanical prophylaxis should be considered.
		• Monitor for signs and symptoms of deep venous thrombosis (redness, swelling, tenderness, or pain in calf).

Stress ulcer prophylaxis	• All patients with sepsis should receive stress ulcer prophylaxis. • The preferred agents are H_2 blockers or proton pump inhibitors.	• Monitor for signs and symptoms of peptic ulcer disease (abdominal pain, gastrointestinal bleeding).
Consideration for limitation of support	• Communicate likely outcomes and realistic goals of treatment to patients and family. • Consider less aggressive support or withdrawal of support if in the best interest of the patient.	• Consult social services, clergy, and palliative care team as appropriate. • Provide for adequate rest and sleep.

BOX 54-10 *PATIENT SAFETY*

Equipment-Related Sources of Infections

- Intravascular catheters (arterial and venous)
- Endotracheal/tracheostomy tubes
- Indwelling urinary catheters
- Surgical wound drains
- Intracranial monitoring devices and catheters
- Orthopedic hardware
- Nasogastric tubes
- Gastrointestinal tubes

Maintenance of Adequate Cardiac Output. In the early phase of septic shock, CO may be normal or elevated. However, the CO is not adequate to maintain tissue oxygenation and perfusion because of decreased SVR and peripheral vasodilation. As septic shock progresses, CO begins to decrease because of cardiac dysfunction. Because oxygen delivery is dependent on CO, maintenance of CO is a primary therapeutic goal.

If adequate volume replacement does not improve tissue perfusion, vasoactive drugs are administered to support circulation. The Surviving Sepsis Campaign Guidelines recommend the catecholamines norepinephrine and dopamine as first-line vasopressors for patients in septic shock. Vasopressin or epinephrine may be used as second-line agents.[17,35] For patients with a low CO or SvO_2 despite adequate fluid resuscitation, dobutamine is the recommended first-line inotropic agent[35] (see Table 54-5).

Maintenance of Adequate Ventilation and Oxygenation. Maintaining a patent airway, augmenting ventilation, and ensuring adequate oxygenation in the patient with septic shock usually requires endotracheal intubation and mechanical ventilation. Because of the ARDS-like picture, low tidal volume (known as lung-protective) ventilation strategies are frequently necessary (for nursing management of patients on mechanical ventilation, see Chapter 25). Assessment of circulatory support, ventilation, and oxygenation is essential. The patient's DaO_2 and VO_2 needs are evaluated frequently. The goal is to maximize DaO_2 to ensure that VO_2 remains independent of DaO_2. Aerobic metabolism is maintained, and tissue energy needs are satisfied through the delivery of adequate oxygen to the cells.

Restoration of Balance Between Coagulation and Anticoagulation. There has been intense investigation of drugs aimed directly at the bacterial toxins and mediators implicated in the inflammatory response seen in sepsis and SIRS. Drotrecogin alfa (activated) (Xigris), a form of human recombinant activated protein C, is not recommended for use in patients with sepsis based on a recently completed clinical trial (PROWESS-SHOCK trial). The drug failed to show a survival benefit for patients with severe sepsis and septic shock.[40] Currently research does not show improved outcomes in patients who receive these medications.

Maintenance of Metabolic Environment. The many and varied metabolic derangements associated with septic shock necessitate frequent monitoring of hematological, renal, and hepatic function. Nutritional stores are depleted, and the patient requires supplemental nutrition to prevent malnutrition and to optimize cellular function. Enteral nutrition is the preferred route of nutritional support because it maintains the integrity of the gastrointestinal tract, decreases infection, and decreases mortality in patients with a septic or hypotensive event.[41]

Intolerance of enteral feeding may necessitate the use of total parenteral nutrition, but ideally, a small amount of enteral nutrition can still be delivered. Recent research suggests that specific nutrients, such as glutamine, omega-3 fatty acids, antioxidants, nucleic acid, and arginine, may help support the immune system during states of stress.[41,42] (See Chapter 40 for a discussion of nutritional support.)

▲ Multiple Organ Dysfunction Syndrome

MODS is defined as a progressive physiological failure of several organ systems in acutely ill patients following an acute threat to systemic homeostasis such that homeostasis cannot be maintained without intervention.[4] MODS can result from SIRS or any type of shock as a consequence of the inability to maintain end-organ perfusion and oxygenation.

Etiology

The exact etiology of MODS is unknown. Release of systemic inflammatory mediators found in SIRS (see Table 54-1, p. 1214) may play a role in the etiology of MODS.[2] In addition, a loss of integrity of mucosal barrier function may liberate bacterial toxins from the gut. These toxins circulate systemically, damaging multiple organs. Finally, tissue hypoxia caused by microvascular thromboses probably also contributes to MODS.[6]

Pathophysiology

Several mechanisms may contribute to the pathophysiology of MODS; it appears to result from a cascade of bacterial factors, endothelial injury, inflammatory mediators, disturbed hemostasis, and microcirculatory failure (see Fig. 54-3, p. 1213). Mitochondrial dysfunction and reduced ATP production is implicated in organ failure.[43] It is suggested that MODS may even be an adaptive state allowing organs time to recover from injury and insult.[44]

Damage to organs may be primary or secondary and cause organ failure. A primary insult refers to a direct injury to an organ that results in organ dysfunction. For example, severe blunt chest trauma injures the lungs and may cause ARDS. Secondary insult is due to mechanisms operable in shock states. For example, a wound infection may cause sepsis, but the resultant SIRS and septic shock may cause ARDS (ARDS is discussed in Chapter 27).

In MODS, there is "crosstalk" between tissue and organ systems; dysfunction and the inflammatory response in one organ may trigger dysfunction in another.[45,46] Therefore, failure of a particular organ makes the failure of a second or third organ more likely. MODS has been described as a "continuum of physiologic derangements"[47] (p 369).

Usually, the first organs to manifest signs of dysfunction are the lungs, heart, and kidneys. Liver failure tends to occur later because the liver has a considerable compensatory capacity. If hypoperfusion persists, all vital organs may fail. It is paramount that interventions increase end-organ perfusion and oxygenation and lessen the inflammatory response during the clinical management of shock states to prevent or limit MODS.

The lungs are typically the first organ system to fail.[45] They are particularly vulnerable to failure because the capillary beds act as a filter that is exposed to cytokines, mediators, and activated neutrophils. Capillary leakage causes interstitial edema, which impairs pulmonary gas exchange. The epithelial cells lining the alveoli are affected by inflammatory mediators. The disruption of the epithelium allows fluid, mediators, and coagulation factors to flood the alveoli, further impairing pulmonary gas exchange.[31] Respiratory failure associated with MODS is not different than ARDS and is discussed in detail in Chapter 27.

The cardiovascular system dysfunction includes reduced CO secondary to dysrhythmias and myocardial depression, as well as abnormalities in the peripheral vascular system, including vasodilation and hypotension that is unresponsive to fluid administration, increased capillary permeability, and maldistribution of blood flow. The most common hematological dysfunction is thrombocytopenia, which is due to increased consumption of platelets due to microthrombi formation and sequestration of platelets in the spleen, as well as impaired thrombopoiesis as a result of bone marrow suppression. This increases the risk for DIC in MODS. (See Chapter 49 for a discussion of DIC.)

Neurological dysfunction can be manifested by altered levels of consciousness, confusion, and delirium. The dysfunction may be secondary to poor cerebral perfusion or an increase in metabolic substances that are neurotoxic (ammonia), or they can be due to electrolyte imbalances. Renal dysfunction can occur secondary to poor renal perfusion and prolonged ischemia to renal tubular cells or intrarenal causes such as nephrotoxic drugs. Renal failure may also be a direct result of mechanical ventilation from altered cardiovascular function or to ventilator-induced lung injury and resultant cytokine release.[46] Progressive liver dysfunction results in hepatic failure. Hepatic failure affects multiple body systems because the liver has so many functions, including synthesis of albumin, clotting factors, and drug metabolism. And, as previously discussed, hepatic failure can lead to impaired mitochondrial function and the ability of cells to use oxygen.

Assessment

Early recognition and management of MODS is essential to improve the likelihood of survival.[48]

Assessment of vital signs for signs of SIRS including hypotension, tachycardia, tachypnea, hypothermia, and hyperthermia is crucial in all hospitalized patients, particularly those at risk for developing shock and MODS. Close surveillance of laboratory values for changes in coagulation parameters, platelet count, WBCs, lactate, renal function, and other studies discussed in this chapter provides early indicators that a patient may be developing organ dysfunction. Several scoring systems exist to determine the extent of MODS, but to date there has not been uniform acceptance of one tool over another.[49] Nursing diagnoses for shock states, SIRS, and MODS are shown in Box 54-11.

BOX 54-11 EXAMPLES OF NURSING DIAGNOSES

For the Patient With Shock States, Systemic Inflammatory Response Syndrome, and Multiple Organ Dysfunction Syndrome

- Risk for Decreased Cardiac Tissue Perfusion
- Risk for Ineffective Cerebral Tissue Perfusion
- Decreased Cardiac Output
- Deficient Fluid Volume
- Ineffective Breathing Pattern
- Impaired Gas Exchange
- Impaired Spontaneous Ventilation
- Impaired Physical Mobility
- Imbalanced Nutrition: Less Than Body Requirements
- Acute Pain
- Fear
- Anxiety

Management

Nurses have a key role in preventing, recognizing, and managing patients with MODS. Prevention strategies include enforcement of measures to prevent nosocomial infections, such as proper positioning (head of bed elevated during mechanical ventilation), oral care, turning and skin care, invasive catheter care, and wound care. Unfortunately, no specific medical treatment for MODS, other than supportive care, is available. Management focuses on treating hemodynamic and metabolic derangements as described in the above management of sepsis (see Table 54-5). Treatment directed at specific organ systems, other than supportive measures such as continuous renal replacement therapy and low tidal volume ventilation, has not been shown to result in improved survival in patients with MODS. This may reflect the interdependence of organ systems and the systemic character of MODS. However, evidence suggests that early identification of patients with a high likelihood of developing MODS and early normalization of $ScvO_2$, arterial lactate concentration, base deficit, and pH lead to a more benign hospital course with decreased inpatient mortality.[39,47]

▲ Clinical Applicability Challenges

CASE STUDY

Ms. H., an 81-year-old female, is brought to the emergency department one afternoon in an ambulance from her skilled nursing facility. Her care givers report that Ms. H., who is normally alert, oriented, and communicative, has been becoming increasingly drowsy and lethargic over the past 24 hours. She has had no fever. She has a history of type 2 diabetes, hypertension, coronary artery disease, and an ischemic stroke 5 years ago that left her with some residual right-sided weakness. Her medications include metoprolol, lisinopril, atorvastatin, aspirin, metformin, and a multivitamin.

(*continued on page 1232*)

CASE STUDY *(Continued)*

On physical examination, Ms. H. is pale, diaphoretic, and lethargic. She arouses to voice but is able only to state her first name. Her vital signs on arrival in the emergency department are as follows: blood pressure, 84/52 mm Hg; heart rate, 130; respiratory rate, 26; temperature, 36.9°C; and oxygen saturation by pulse oximetry is 89% on room air. She is placed on 2 L/min of oxygen via nasal cannula, with improvement in saturation to 95%. Two large-bore intravenous (IV) catheters are started, and specimens are sent immediately for laboratory analysis, including two sets of blood cultures. She is given a liter bolus of normal saline solution. Meanwhile, a Foley catheter is inserted, yielding 40 mL of concentrated urine that is sent for immediate analysis and culture if indicated. Her laboratory results are as follows: sodium, 143 mmol/L; potassium, 3.9 mmol/L; blood urea nitrogen, 32 mg/dL; creatinine, 0.9 mg/dL; glucose, 104 mg/dL; lactate, 2.1 mmol/L; hemoglobin, 11.1 g/dL; hematocrit, 33.5%; and white blood cell (WBC) count, 14.2 1,000/mcl. Her urinalysis reveals 58 WBCs and is positive for nitrites and leukocyte esterase. Chest x-ray findings are normal.

After the first liter of fluid, her blood pressure is 88/54 mm Hg, and a second liter bolus of normal saline solution is given. She is also given ceftriaxone 1 g IV and ampicillin 2 g IV and is admitted to the medical intensive care unit. A central line is inserted for fluid and medication administration and monitoring of central venous pressure (CVP) and superior vena cava oxygen saturation ($ScvO_2$). An arterial line is inserted for continuous blood pressure monitoring. She receives an additional liter of normal saline solution to achieve CVP between 8 and 12 mm Hg, but her mean arterial pressure (MAP) hovers around 55 to 60 mm Hg and urine output remains about 20 mL/h. Norepinephrine is started at 1 mcg/min and titrated to 8 mcg/min to achieve a MAP of 65 mm Hg or greater.

Six hours into her intensive care unit stay, Ms. H develops a fever at 38.7°C. At this time, her $ScvO_2$ is 64% and the lactate level has increased to 3.4 mmol/L. Dobutamine is started at 5 mcg/kg/min, her urine output begins to improve, and her $ScvO_2$ rises to 71%. Her heart rate decreases to 105 beats/min. She is started on subcutaneous heparin for venous thromboembolism prophylaxis as well as famotidine for stress ulcer prophylaxis, and antibiotic therapy is continued. Her glucose level has risen to 160 mg/dL, so an insulin drip is started to maintain glucose level between 110 and 140 mg/dL. Overnight, she remains on norepinephrine and dobutamine, receives an additional liter of normal saline solution to maintain CVP at 8 to 12 mm Hg, and makes 30 to 60 mL/h of urine.

The next morning, Ms. H.'s lactate level has decreased to 1.8 mmol/L, and $ScvO_2$ remains 70% to 75%. Other laboratory results include hemoglobin 10.1 g/dL, hematocrit 30.2%, and WBC count 13.6 1,000/mcl. The nurse is able to decrease the norepinephrine incrementally without a drop in MAP. The laboratory reports growth of Gram-negative rods in the urine sent for culture, and antibiotic therapy is narrowed to a fluoroquinolone. On examination, Ms. H. is more alert and is oriented to place and person. Her heart rate is 85 to 90; respiratory rate 16, and temperature 36.5°C. In the afternoon, her lactate level is 1.4 mmol/L and $ScvO_2$ 72%. The dobutamine is discontinued. Close monitoring of her MAP, CVP, and $ScvO_2$ is continued. She remains stable overnight and is transferred to the step-down unit for continuing care the following day.

1. Discuss some of the challenges encountered in trying to deliver timely antibiotic therapy to patients presenting in the emergency department with severe sepsis.
2. Discuss why steroid therapy was not indicated for Ms. H. based on the Surviving Sepsis Campaign Guidelines.
3. Discuss the serum lactate level as a measure of tissue perfusion and prognostic indicator in shock states.

55 Trauma

Carla A. Aresco

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Compare and contrast mechanisms of trauma injury.
2. Describe phases of initial assessment and related care of the trauma patient.
3. Discuss the assessment of patients with thoracic, abdominal, musculoskeletal, and maxillofacial trauma.
4. Explain the management and nursing care of patients with thoracic, abdominal, musculoskeletal, and maxillofacial trauma.
5. Describe early and late complications of trauma and the impact of these complications on mortality.

Trauma is defined by the *American Heritage Dictionary* as "a wound, especially one produced by sudden physical injury."[1] Injury is defined by the National Committee for Injury Prevention and Control as "unintentional or intentional damage to the body resulting from acute exposure to thermal, mechanical, electrical, or chemical energy or from the absence of such essentials as heat or oxygen."[2] Unintentional injuries include motor vehicle crashes (MVCs), poisonings, falls, drownings, fires, and burns. Intentional injuries (eg, suicide attempts, assaults, and homicides) include injuries from poisoning, hanging, drowning, firearms, cutting, and jumping. This chapter specifically discusses mechanical injury.

Trauma is one of the leading causes of critical illness and death in the United States. In 2007, unintentional injury was the number one cause of death in age groups 1 through 44 years and the fifth leading cause of death in all age groups.[3] At present, MVCs, with the increased number of cars and drivers, have made civilian trauma an international epidemic; globally, the war on terror has increased the importance and incidence on military trauma.[4]

▲ Mechanism of Injury

Knowing the mechanism of injury is important because this information can help explain the type of injury, predict the eventual outcome, and identify common injury combinations. In addition, an injury may exist in a trauma patient without the classic signs. The mechanism of injury may indicate the need for additional diagnostic workup and reassessment.

The mechanism of injury is related to the type of injuring force and the subsequent tissue response. Injury occurs when the force deforms tissues beyond their failure limits. Wounds vary depending on the injuring agent.[5] The effect of injury also depends on personal and environmental factors, such as the person's age and sex, the presence or absence of underlying disease process, and the geographic region.

Force may or may not be penetrating. The injury delivered from force depends on the energy delivered and the area of contact. In penetrating injury, the concentration of force is to a small area. In blunt or nonpenetrating injury, the energy is distributed over a large area. The predominant feature affecting the impact is speed, or acceleration:

$$\text{Force} = \text{mass} \times \text{acceleration}$$

Blunt Injury

Mechanisms of blunt injury include MVCs, falls, assaults, and contact sports. Multiple injuries are common with blunt trauma, and these injuries are often more life threatening than penetrating injuries because the extent of the injury is less obvious and the diagnosis can be more difficult.

Blunt injury is caused by a combination of forces. These forces include acceleration, deceleration, shearing, crushing, and compressive resistance:

- Acceleration is an increase in the velocity (or speed) of a moving object.
- Deceleration, on the other hand, is a decrease in the velocity of a moving object.
- Shearing occurs across a plane when structures slip relative to each other.
- Crushing occurs when continuous pressure is applied to a body part.
- Compressive resistance is the ability of an object or structure to resist squeezing forces or inward pressure.

In blunt trauma, it is the direct impact that causes the greatest injury. Injury occurs when there is direct contact between the body surface and the injuring agent. Indirect forces are transmitted internally with dissipation of energy to the internal structure. The extent of injury from an indirect force depends on transference of energy from an object to the body. Injury occurs as a result of energy released and the tendency for the tissues to be displaced on impact. Acceleration–deceleration injuries are the most common causes of blunt trauma.

In an MVC, the vehicle size and design change injury patterns. Small cars are involved in more crashes per mile and cause more deaths than larger vehicles. Before the crash, the occupant and the car are traveling at the same speed. During the crash, both the occupant and the car decelerate to zero, but not necessarily at the same rate. There are actually three collisions involved in one crash. The first is the car with another object; the second is the occupant's body with the interior of the car; and the third is the internal tissues with the rigid body surface structure. For example, rapid deceleration in an MVC can cause direct injury to tissue. Subsequently, injury occurs as internal organs impinge on bony internal structures and cause major vessels to undergo stretching and bowing.

Wearing shoulder and lap restraints reduces the incidence and severity of injury by reducing the force with which a person strikes a surface, thereby preventing the occupant from striking multiple surfaces and being ejected from the vehicle[4] (Fig. 55-1). The occupant's position in the vehicle also makes a difference in the blunt injury received. When a vehicle strikes a pedestrian, it is important to visualize the size of the vehicle and the size of the pedestrian. The area of impact can vary depending on these factors (Fig. 55-2).

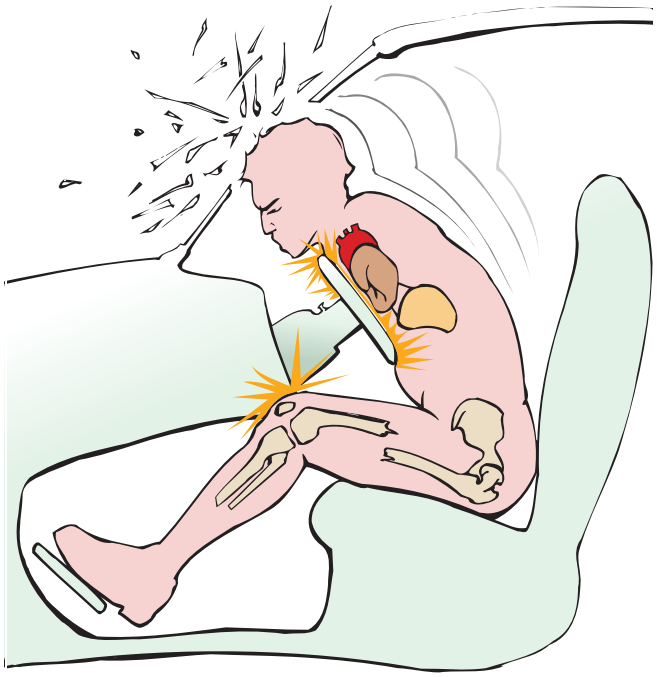

FIGURE 55-1 ▲ In a motor vehicle crash, if the driver is not wearing a seat belt, damage may occur in various sections of the body. Common injuries occur to the skull, scalp, face, sternum, ribs, heart, liver, or spleen. Bones of the pelvis and lower extremities also may be damaged.

Penetrating Injury

Penetrating trauma refers to an injury produced by foreign objects penetrating the tissue. The severity of the injury is related to the structures damaged. The mechanism of injury is caused by the energy created and dissipated by the penetrating object into the surrounding areas. The amount of tissue damaged by a bullet is determined by the amount of energy that transfers into the tissue along with the amount of time it takes for the transfer to occur. It is important to note that the external appearance of the wound does not reflect the extent of internal injury.

Velocity determines the extent of cavitation and tissue damage (Fig. 55-3). Low-velocity missiles localize the injury to a small radius from the center of the tract and have little disruptive effect. They cause little cavitation and blast effect, essentially only pushing the tissue aside. High-velocity missiles can cause more serious injury because of the amount of energy and cavitation produced.[6] The damage depends on three factors: the density and compressibility of the tissue injured, the missile's velocity, and the fragmentation of the primary missile. High-velocity bullets compress and accelerate tissue away from the bullet, causing a cavity to form around the bullet and its entire tract.[6]

Shotguns are short-range, low-velocity weapons that use multiple lead pellets encased in a larger shell for ammunition. Each pellet is a missile (Fig. 55-4). It is important to obtain a brief description of the mechanism of gunshot injuries, including the weapon, the ammunition, and ballistics. This essential information is used to guide the assessment of patients who sustain injuries from these weapons. All trauma patients must be undressed and inspected for entrance and exit wounds during the assessment process.

A stab wound or impalement is a low-velocity injury. The main injury determinants are length, width, and trajectory of the penetrating object and the presence of vital organs in the area of the wound. Although the injuries tend to be localized, deep organs and multiple body cavities can be penetrated.

▲ Initial Assessment and Management

When a trauma patient is brought to the emergency department or the trauma resuscitation unit, it is imperative to obtain a thorough history of the preceding events. This initial evaluation aids in assessment and treatment and can decrease morbidity and mortality. During this initial assessment, it is important to obtain as much detail as possible about the circumstances surrounding the injury, including the mechanism of injury. To facilitate initial assessment, intervention, and triage of the trauma victim, the American College of Surgeons (ACS) Committee on Trauma has developed guidelines. These guidelines provide an organized, standardized approach to the initial assessment of trauma patients, increasing the speed of the primary assessment and minimizing the risk that injuries will be overlooked.

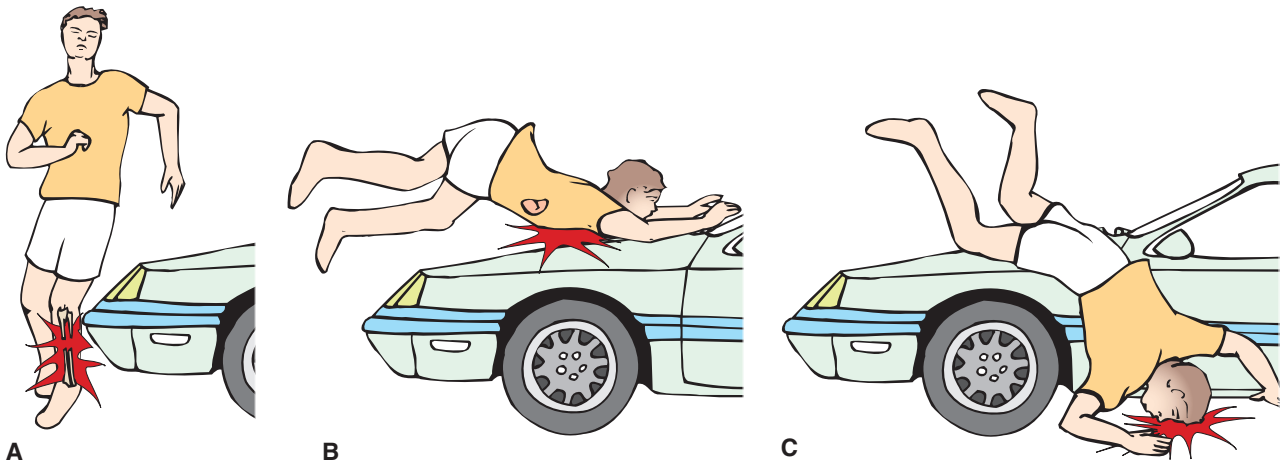

FIGURE 55-2 ▲ Pedestrians may be hurt critically when hit by a moving vehicle. **A:** A common injury is the fracture of the tibia and fibula at the time of impact. **B:** Impact when the pedestrian strikes the hood of the car may cause fractured ribs and a ruptured spleen. **C:** Injuries to the head and additional fractures of the extremities may occur as the pedestrian rolls off the braking car or is thrown by the impact.

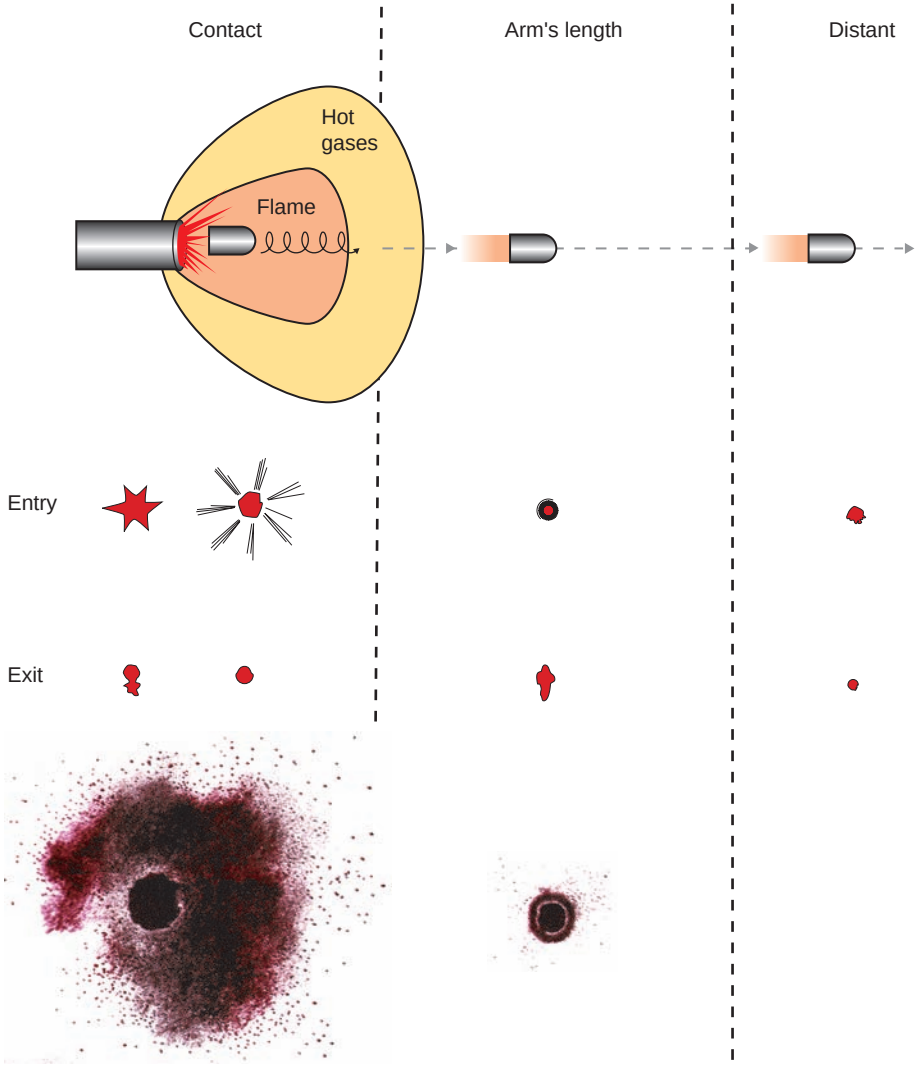

FIGURE 55-3 ▲ Diagrammatic views of the effects of gunshot wounds on the body surface. Kinetic energy is dependent on the distance from which the weapon is fired and the tissue involved. Entry and exit wounds are shown when in direct contact, at arm's reach, and at a distance. The bottom illustrations show entry wounds of .22 rifle at 5-cm range (**left**) and at 20-cm range (**right**). The drilled-in entry wound and faint powder markings are indicated.

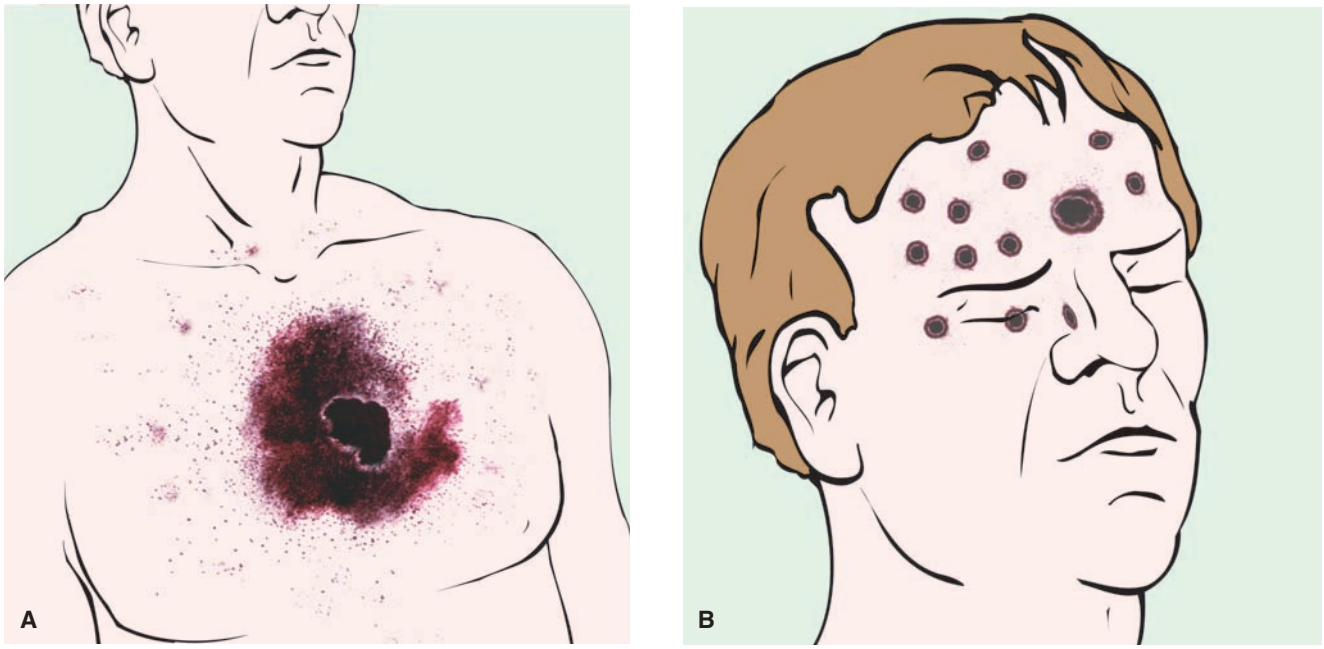

FIGURE 55-4 ▲ Damage is caused by shotguns at two different distances. **A:** At close range, opening is extensive and is surrounded by blood splatters and powder burns. **B:** At medium range (8 to 10 ft), the larger entry wound is surrounded by individual pellet wounds.

Prehospital Management

The trauma patient has a greater chance of a positive outcome if admission to a trauma center and definitive care are initiated within 1 hour of injury. Care begins in the prehospital arena and is continued throughout the hospital stay. Many current studies discuss the prehospital management of trauma patients and seem to conclude that the principal factor influencing prehospital care is the transport time to the trauma center. The swift transport of trauma patients to the most appropriate facility and the appropriate identification and treatment of injuries are essential components of modern trauma systems.[7]

The advanced trauma life support guidelines state that the emphasis for assessment and management in the prehospital phase should be placed on maintaining the airway, ensuring adequate ventilation, controlling external bleeding and preventing shock, maintaining spine immobilization, and transporting the patient immediately to the closest appropriate facility.[8] The prehospital priority of maintaining adequate airway, breathing, and circulation (ABC) may be difficult because of the mechanism of injury. It is imperative that cervical spine immobilization be maintained at all times during airway management and transport to definitive care. After assessing and managing the ABCs, the trauma patient's neurological status is assessed, including level of consciousness and pupil size and reaction. Once this primary assessment is complete, a secondary assessment is performed to determine any other injuries.

The prehospital providers must consider the facility that will receive the patient (Table 55-1). Transporting the patient to a level I facility allows definitive care to be initiated earlier in the process, thereby reducing patient mortality. Trauma systems have been designated to get the "right patient to the right resources in the right time frame." Creation of trauma centers and trauma programs has a positive effect on outcomes in severely injured patients.[9] Transport of the patient to a lesser facility for "stabilization," followed by transport to the definitive care setting later on, is associated with higher patient mortality. For select severe injuries, level I trauma centers have significantly better survival and functional outcomes than level II, III, or IV centers.

Research has shown that injury-related mortality is significantly reduced with organized systems of trauma care, including prehospital care, acute care, and rehabilitation.[10] Inclusive trauma systems have been designed to care for all injured patients and involve all acute care facilities to the extent that their resources allow.[10]

In-Hospital Management

In-hospital patient management entails a rapid primary evaluation and resuscitation of vital functions, a more detailed secondary survey, a tertiary survey to identify specific injuries, and initiation of definitive care. Table 55-2 shows the process, the initial assessment and management of the patient with trauma, commonly referred to as the "ABCDEs" of trauma care. According to the ACS, adhering to this sequence allows for the efficient identification of life-threatening conditions.[7] Optimal care of the trauma patient includes a preplanned emergency phase involving a predetermined response team with defined roles and expectations. This is necessary so that multiple procedures can be performed simultaneously. The team leader is a physician. It is the leader's responsibility to assess the patient, order and interpret the diagnostic studies, and prioritize the diagnostics and therapeutic concerns.

Table 55-1 Trauma Center Designation

	Level I	Level II	Level III	Level IV
Admission requirements	1,200 patients per year; 20% with an Injury Severity Score (ISS) 15 or more or 35 patients per surgeon with an ISS of 15 or more	Varies depending on geographical area, population, resources available, and system maturity	No requirement	No requirement
Surgeon availability	24-h in-house attending surgeon	Rapidly available	Promptly available	24-h emergency coverage
Research center	Required	Not required	Not required	Not required
Education, prevention, and outreach	Required	Required	Required	Required

Source: Scalea TM, Boswell SA: Initial management of traumatic shock. In McQuillan KA, Von Rueden KT, Hartsock RL, et al (eds): Trauma Nursing, 3rd ed. Philadelphia, PA: WB Saunders, 2002.

Primary Survey

During the primary survey, each priority of care is dealt with in order. The patient's assessment does not continue to the next phase until each preceding priority is effectively managed. For example, if a patient does not have a patent airway, breathing and ventilation cannot be established. Therefore, it is during this initial phase that life-threatening injuries are identified and managed. So, if the patient does not have a patent airway, endotracheal intubation, chest tube insertion, and central vascular line access may be initiated and intravenous (IV) fluid and blood products may be administered to maintain life-sustaining vital signs before moving on to the next phase of the evaluation. Initial radiographs and procedures are dependent on the findings in the primary survey. However, chest, abdomen, and pelvis imaging is generally completed at this time.

Assessing the patient for evidence of hypovolemia is essential. Blood loss can result from an external injury, associated with obvious bleeding, or from an internal injury, where bleeding may not be obvious. Any of these injuries can lead to inadequate tissue perfusion, which equals traumatic shock. It is necessary to first stop the bleeding with compression or surgery and then replace the lost intravascular volume. Some signs of hypovolemia include pallor, poor skin integrity, diaphoresis, tachycardia, and hypotension. Usually, trauma patients arrive at the trauma center with a large-bore IV line already in place, with IV fluid running in rapidly.

During the resuscitation period, electrocardiography (ECG) is performed. The patient is placed on a monitor with pulse oximetry and end-tidal carbon dioxide monitoring. A Foley catheter and a nasogastric or orogastric tube are

Table 55-2 Initial Assessment and Management of the Patient With Trauma

Parameter	Assessment	Interventions
Airway	Air exchange Airway patency	Jaw thrust, chin lift Removal of foreign bodies Suctioning Oropharyngeal or nasopharyngeal airway Endotracheal intubation (orally or nasally) Cricothyrotomy
Breathing	Respirations (rate, depth, effort) Color Breath sounds Chest wall movement and integrity Position of trachea	Supplemental oxygen Ventilation with bag–valve device Treatment of life-threatening conditions (eg, tension pneumothorax)
Circulation	Pulse, blood pressure Capillary refill Obvious external bleeding Electrocardiogram	Hemorrhage control: direct pressure, elevate extremity, pneumatic antishock garment Intravenous therapy: crystalloids, blood transfusion Treatment of life-threatening conditions (eg, cardiac tamponade) Cardiopulmonary resuscitation
Disability	Level of consciousness Pupils	—
Exposure	Inspection of body for injuries	—

placed, and blood specimens are sent to the laboratory for evaluation. Blood work includes evaluation of electrolytes, hemoglobin and hematocrit, blood type and crossmatch, and arterial blood gases (ABGs), if the patient is believed to have a high level of injury.

The nurse also assesses the patient for hypothermia. The trauma patient is often subjected to environmental factors, which, along with his or her altered physiological state and possibly wet clothing, predispose the patient to hypothermia. Some measures, such as the infusion of room-temperature IV fluids or exposure of the patient's body to inspect for injuries, can exacerbate hypothermia. Warm fluids and blankets are used whenever possible to increase body temperature or maintain normothermia.

Secondary Survey

Once the primary survey is completed, a more detailed secondary survey is initiated. This survey begins at the head and works down to the patient's feet. Non-life-threatening injuries are revealed during this survey. During this time, a plan is developed and the appropriate diagnostic tests (eg, radiographs, ultrasound studies, computed tomography [CT] scans, angiographic studies) are ordered. This is also the time when a more detailed patient history can be obtained, as well as important information regarding the mechanism of injury. The nurse asks the field providers for information regarding the incident because the patient may not be able to speak or may not remember the event. Family and friends might be helpful in providing additional information about the patient.

Questions the nurse asks before or during the trauma patient's arrival to the hospital include the following:

- Was the person involved in an MVC? Was the person wearing a restraining device? If the person was hit by a vehicle, was the person on foot or on a bike? What kind of vehicle was involved? Where was the person at the time of impact? What was the speed, point of impact, type of impact? Was there a fatality at the scene?
- Is blunt or penetrating trauma the main concern?
- Did the patient fall? How far? Was the fall off a ladder or down a flight of stairs?

Based on the information obtained from field providers or family members of the patient, other injuries may be suspected, and further investigation may be warranted. This is especially true in intubated, comatose, or paralyzed patients who are unable to verbalize their complaints. The nurse continuously reassesses the trauma patient because injuries often go undetected.

Tertiary Survey

The tertiary survey is completed on all trauma patients admitted to the intensive care unit (ICU). It is necessary to identify all of the patient's injuries completely. To do this, another head-to-toe examination is completed, an assessment of the patient's response to resuscitation is made, films are reviewed with the radiologist, laboratory values are reviewed, and every effort is made to obtain or complete a preinjury medical history. Delays in injury identification are common. However, if the injury is found within 24 hours of admission, it is not considered a missed injury.

Fluid Resuscitation

Most trauma patients have a fluid volume deficit that must be corrected. The goal of fluid resuscitation is to maintain perfusion to the vital organs, especially the heart and the brain, by restoring circulating volume.[11,12] It is essential to have adequate intravascular volume and oxygen-carrying capacity to transport needed nutrients to the tissues.[8] Fluid administration is one of the most basic concepts in resuscitation and is also a part of the daily routine of medically managed patients in the hospital.[11,12] To guide fluid resuscitation, the nurse uses physical assessment and hemodynamic parameters. Two factors affect the choice of fluid: how the volume loss occurred and which solutes need to be replaced.[13] It is important to address the underlying problem causing the loss of fluids, electrolytes, or both. With aggressive fluid resuscitation, many patients have total-body edema and ascites. The two main complications of aggressive fluid resuscitation are hypothermia and coagulopathy.[13]

Crystalloids

Typically, crystalloids are used for the trauma patient. Crystalloids contain water and other electrolytes that are premixed into the fluid. These electrolytes include sodium, potassium, and chloride. Crystalloids closely mimic the body's extracellular fluid and can be used to expand both intravascular and extravascular fluid volume. There tends to be a larger requirement for crystalloid replacement compared with the amount of blood lost. Crystalloids can be further broken down by their tonicity. The tonicity is based on the amount of sodium in the solution. Crystalloids can be classified as isotonic, hypotonic, and hypertonic (Table 55-3).

Hypertonic saline has been shown to enable a more rapid restoration of cardiac function with a smaller volume of fluid. It is supplied either in a 3%, 7.5%, or 23.4% sodium chloride (NaCl) solution. As little as 4 mL/kg, if given rapidly, may have the same hemodynamic effect as several liters of isotonic crystalloid. Hypertonic saline solution has the effect of shifting water into the plasma. This water comes from the red blood cells, interstitial space, and tissue.[14] The result is a rapid increase in blood volume, which supports and improves hemodynamics. Hypertonic saline solution increases the mean arterial pressure and cardiac output, which then leads to peripheral vasodilation. Some studies have indicated that

Table 55-3 Intravenous Fluid

Isotonic	• Example: 0.9 normal saline solution • Equivalent to the tonicity of the human body • Causes minimal shifts between intracellular and extracellular fluid
Hypotonic	• Example: 5% dextrose in water (D_5W) • Tonicity is less than that of human body • May cause swelling, pulls into extracellular space
Hypertonic	• Example: 3% saline solution • Tonicity is more than that of human body • Pulls fluid into the intravascular space

Modified from American Association of Critical-Care Nurses: Clinical Reference for Critical-Care Nursing, 4th ed. Aliso Viejo, CA: American Association of Critical-Care Nurses, 1998.

no change in survival rates were demonstrated in patients given hypertonic saline solution versus lactated Ringer's solution.[13]

The initial management of trauma patients often requires the infusion of 2 L of isotonic crystalloid as rapidly as possible, while trying to achieve a normal heart rate and blood pressure.[12] However, research has shown that the infusion of crystalloids in patients with hypotension can cause more harm by displacing a hemostatic clot, only to cause more bleeding.[11–13] The infusion of crystalloid also further dilutes the patient's hemoglobin and can increase intraperitoneal blood loss. Makley et al suggest that "conventional fluid resuscitation may prime the inflammatory response for the development of organ injury and late complications including ARDS." This is thought to be related to hemorrhagic shock with tissue ischemia, and subsequent reperfusion injury promotes a systemic inflammatory response, which contributes to the development of late complications.[15]

Colloids

Colloids can also be given to resuscitate a trauma patient. Colloids, such as albumin, dextran, and hetastarch, create oncotic pressure, which encourages fluid retention and movement of fluid into the intravascular space. Colloids have a longer duration of action because they are larger molecules and stay in the intravascular compartment longer.[14] They are also more efficient in expanding plasma volume, use a smaller volume, and increase colloid osmotic pressure.[14]

Proponents of colloid use have argued that less volume of fluid is necessary to achieve hemodynamic stability and that the fluid is retained in the intravascular space longer. Despite possible advantages, there is no clear evidence that colloids are superior to crystalloids for resuscitation of the trauma patient. Potential complications, such as anaphylaxis and coagulopathy, have been reported with certain colloids. These potential adverse affects, together with higher costs, make colloids less desirable than crystalloids for use in resuscitation of trauma patients.

Blood Products

Blood products are considered an excellent resuscitation fluid. Red blood cells increase oxygen-carrying capacity and allow for volume expansion.[12] It is well known that the maintenance of adequate oxygen delivery is critical in the bleeding trauma patient; therefore, packed red blood cells are the mainstay of treatment. Blood also stays in the intravascular space for longer periods of time compared with the other resuscitation fluids.[12] Although there is some concern about blood-borne pathogens and transfusion reactions, it is essential to understand the advantages offered by blood transfusion.

Blood should be transfused when patients are hemodynamically unstable or are showing signs of tissue hypoxia despite crystalloid infusion. Crossmatched blood is preferred but may not be available if emergent transfusion prohibits type and crossmatching of the patient's blood. O-negative blood is the preferred type of uncrossmatched blood, especially in women of childbearing age. O-positive blood may be used in male and postmenopausal female patients. If the patient requires large amounts of blood, transfusion of fresh frozen plasma and platelets is initiated. It is important to replace coagulation factors and platelets not contained in blood. In the event of massive blood transfusions, the risk for acute respiratory distress syndrome (ARDS) and disseminated intravascular coagulation (DIC) is heightened. An extended period of hypotension increases the possibility of renal failure.

Autotransfusion is another common modality used in the hemorrhaging trauma patient. Obviously, the nature of trauma prevents patients from donating their own blood, as they may in an elective surgery. However, sometimes blood is salvaged. Most often, blood is saved from a chest tube underwater seal device. A cell saver is connected into the system, and the blood from the wound collects there. Once full, the cell saver is disconnected from the underwater seal device, and this blood is then transfused into the patient using a macroaggregate filter.

Blood Substitutes

Blood substitutes have been developed but have not been approved for use in all countries. These agents do not require crossmatching and do not carry the risk for blood-borne pathogen transmission. Blood substitutes have a long shelf life and are not immunosuppressive. Blood substitutes have oxygen-carrying capacity and oxygen dissociation capability of natural hemoglobin, and in addition, they have the ability to maintain hemodynamic stability and intravascular perseverance.[13] Some examples of blood substitutes are perfluorocarbons and hemoglobin solutions.[13]

Damage Control

Damage-control surgery avoids widespread procedures on unstable patients, stabilizes potentially fatal problems at initial operation, and utilizes staged surgery after initial resuscitation.[16] It is designed to avoid or correct the lethal triad of hypothermia, acidosis, and coagulopathy before definitive management can be performed. Uncontrolled bleeding and iatrogenic interventions ultimately result in hypothermia, coagulopathy, and acidosis. Each of these exacerbates the other, causing a spiraling cycle with death as the ultimate result.[16–18]

Damage control involves using a staged approach to patients with multiple injuries. The stages are as follows:

- Stage 1: Stop hemorrhage, control contamination, and perform closure methods to close wounds temporarily.
- Stage 2: Correct physiological abnormalities in the ICU by warming and ensuring adequate resuscitation as well as correcting coagulopathy.
- Stage 3 (final stage): Definitive operative management

The philosophy of damage control is to abbreviate surgical interventions before the development of irreversible physiological end points.[16–18] Traditionally, damage control was used for abdominal trauma, but it is now used for all types of trauma that require immediate surgery.

Definitive Care

Increasingly, trauma care consists of nonoperative management of stable patients. Traditionally, solid organ injuries, both blunt and penetrating, were treated with surgery. Today, many trauma surgeons are choosing nonoperative management for their patients whenever possible. Ever more sophisticated techniques for visualization of internal structures,

BOX 55-1 EXAMPLES OF NURSING DIAGNOSES

For the Person With Trauma

- Deficient Fluid Volume related to hemorrhage, third spacing
- Impaired Gas Exchange related to pulmonary trauma, respiratory complications (eg, acute respiratory distress syndrome [ARDS], pain)
- Impaired Tissue Integrity related to trauma, surgery, invasive procedures, immobility
- Anxiety related to critical illness, fear of death or disfigurement, role changes within social setting, or permanent disability
- Risk for Decreased Cardiac Tissue Perfusion, Risk for Ineffective Cerebral Tissue Perfusion: Multiple organs related to decreased cardiac output, decreased oxygenation, decreased gas exchange
- Risk for Infection related to trauma, invasive procedures
- Acute Pain related to trauma
- Dysfunctional Gastrointestinal Motility related to intra-abdominal trauma, ileus, or both
- Ineffective Coping, Compromised Family Coping related to trauma

such as CT, ultrasonography, and angiography, have reduced the need for immediate surgical exploration in many cases. Without question, CT offers improved accuracy and high sensitivity and specificity.[19] It provides more information to aid in diagnosing injuries that may have been missed without it. Using CT to discharge a patient earlier, or clear him or her for an earlier surgery with another service, makes sense from a patient care and economic perspective. In addition, many of these techniques can be used for management, as well as diagnosis. For example, angiographic interventions may be used to embolize a hemorrhaging internal vessel, obviating the need for invasive surgical intervention. Patients who are treated nonoperatively require frequent assessment and are admitted to the ICU to facilitate this.

To observe the patient effectively, the nurse must be aware of potential injuries and associated signs and symptoms. Examples of nursing diagnoses are given in Box 55-1. Attention is also given to the management of preexisting medical conditions and the identification of injuries missed during treatment of life-threatening problems. Once again, knowledge regarding the mechanism of injury is necessary. Finally, the patient is monitored for the development of complications. The critical care nurse must be aware of potential complications and related risk factors associated with various injuries. Certain situations, such as prolonged extrication, prolonged hypothermia, respiratory or cardiac arrest, massive fluid resuscitation, or massive blood transfusions, suggest an increased likelihood of severe injuries and a greater chance of complications and death after trauma. A collaborative care guide for the patient with multisystem trauma is given in Box 55-2.

▲ Assessment and Management of Specific Injuries

Although this section discusses traumatic injuries related to specific areas of the body, the nurse must keep in mind that head-to-toe assessment is required for each trauma patient. Physical assessment of each organ system is indicated, as described in previous chapters throughout this text.

Thoracic Trauma

Thoracic injuries range from simple abrasions and contusions to life-threatening insults to the thoracic viscera. Although these injuries are associated with a high mortality rate, most can be managed with simple chest tube insertion, mechanical ventilation, aggressive pain control, and other supportive care. Great vessel injuries or disruption to the heart usually result in immediate death. Early deaths (30 minutes to 3 hours after injury) are related to cardiac tamponade, tension pneumothorax, aspiration, or airway obstruction.[20]

Immediate life-threatening injuries require evaluation and treatment during the primary survey. Examples of these include airway obstruction, tension pneumothorax, cardiac tamponade, open pneumothorax, massive hemothorax, and flail chest (Fig. 55-5). Potentially life-threatening injuries, such as thoracic aortic disruption, tracheobronchial disruption, myocardial contusion, traumatic diaphragm tear, esophageal disruption, and pulmonary contusion, should be addressed during the secondary survey.[20]

In thoracic injury, the first priority is always airway management. This includes immediate airway control as well as adequate oxygenation and protection from aspiration. Airway obstruction may be the result of another injury or the primary problem. The most common causes of airway obstruction are the tongue, avulsed teeth, dentures, secretions, and blood. Other causes of airway obstruction include injuries to the trachea, thyroid cartilage, or cricoid process.

Tracheobronchial Trauma

Injuries to the trachea or bronchi can be caused by blunt or penetrating trauma and frequently are accompanied by esophageal and vascular damage. Ruptured bronchi often are present in association with upper rib fractures and pneumothorax. Severe tracheobronchial injury is associated with a high mortality rate; however, with continued improvements in prehospital care and transport, more of these patients are surviving.

Airway injuries often are subtle. Presenting signs include dyspnea (occasionally the only sign), hemoptysis, cough, subcutaneous emphysema, anxiety, hoarseness, stridor, air hunger, hypoventilation, use of accessory muscles, sternal and subscapular retractions, diaphragm breathing, apnea, and cyanosis. Cyanosis may be a late sign. Often, trauma patients are anemic and do not have enough hemoglobin to develop cyanosis. A chest radiograph can alert the physician to a possible injury; however, diagnosis usually is made with bronchoscopy or during surgery. Tracheobronchial injury is considered whenever a persistent air leak accompanies a pneumothorax.

Small lung lacerations or pleural tears can be managed conservatively with mechanical ventilation delivered through an endotracheal tube or tracheostomy. Larger injuries may require surgical repair. Simultaneous independent lung ventilation, in which each lung is ventilated

BOX 55-2 *COLLABORATIVE CARE GUIDE for the Patient With Multisystem Trauma*

Outcomes	Interventions
Oxygenation/Ventilation	
The patient will maintain a patent airway.	• Auscultate breath sounds. • Perform frequent assessments. • Intubate if needed. • Provide supplemental oxygen PRN.
The patient will maintain an SaO_2 of 95% or more and have adequate ABG values.	• Provide pulmonary toilet (chest physiotherapy and incentive spirometry). • Intubate. • Monitor ABGs.
The patient will be able to take deep breaths and will be free of anxiety.	• Use mechanical ventilation if necessary to support adequate ventilation. • Provide adequate pain medication to promote deep breathing (patient-controlled analgesia [PCA], epidural, around-the-clock medications) • Medicate before pain increases. • Use antianxiety drugs as necessary.
Circulation/Perfusion	
The patient will maintain an adequate blood pressure, heart rate, and respiratory rate.	• Monitor respiratory rate and depth. • Use ECG monitor. • Administer intravenous (IV) fluids and packed red blood cells to ensure adequate intravascular volume and oxygen-carrying capacity. • Administer medications, such as vasoactive and inotropic agents, after intravascular volume is restored. • Install pulmonary artery catheter/A-line. • Assess skin color and capillary refill time.
The patient will not experience deep venous thrombosis.	• Use prophylactic anticoagulants unless contraindicated. • Apply antiembolic stockings. • Use pneumatic compression devices.
Fluids/Electrolytes	
The patient will maintain an adequate intake and output.	• Monitor blood pressure, heart rate, central venous pressure, pulmonary capillary wedge pressure, IV fluid. • Use Foley catheter to monitor urine output. • Consider insensible fluid loss in output. • Monitor laboratory values.
The patient will maintain electrolyte balance.	• Replace electrolytes PRN. • Monitor ECG.
Mobility/Safety	
The patient's range of motion will be maintained.	• Consult physical/occupational therapist. • Use splints PRN. • Do range-of-motion exercises every 8 h. • Out of bed as tolerated.
Skin Integrity	
The patient will not experience skin breakdown.	• Monitor skin every 4 h. • Turn patient every 2 h and PRN. • Use pressure-relieving devices. • Remove splints to monitor skin. • Provide prescribed wound care. • Monitor wound for evidence of infection.
Nutrition	
The patient will maintain an adequate calorie intake to meet metabolic needs.	• Arrange dietary/nutrition consult. • Use total parenteral nutrition/lipids if enteral nutrition contraindicated. • Tube feeds: Encourage enteral nutrition when possible. • Check prealbumin and electrolytes. • Monitor for weight loss.

(*continued on page 1243*)

BOX 55-2 COLLABORATIVE CARE GUIDE for the Patient With Multisystem Trauma (continued)

Outcomes	Interventions
Comfort/Pain Control	
The patient will maintain a pain score of <5.	• Administer adequate pain medication. • Use PCA/epidural PRN. • Arrange pain consult if needed. • Use sedation as needed. • Monitor vital signs.
Psychosocial	
The patient will maintain as much control as possible.	• Inform patient of procedures. • Establish a schedule with the patient if possible. • Provide an alternate means of communication if necessary, such as lip reading, writing, and a communication board.
The patient and family will cope effectively with the traumatic event.	• Provide repeated information. • Encourage use of appropriate coping. • Encourage use of support systems. • Arrange social work consult.
Teaching/Discharge Planning	
The patient will be involved in discharge planning.	• Discuss discharge with patient. • Allow patient to make decisions if possible.
The patient will understand injuries and complications of injuries.	• Provide discharge instructions accordingly with injury. • Provide patient with list of injuries.

separately (each with a dedicated ventilator), may also be used.

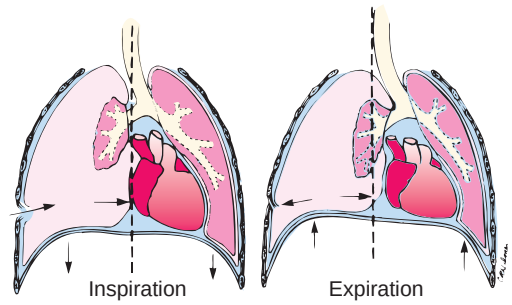
Nursing care involves the assessment of oxygenation and gas exchange, along with appropriate pulmonary care. During the first few days, the physician may perform a bronchoscopy to visualize the repair site and provide more effective secretion removal. Pneumonia is a potential short-term complication, whereas tracheal stenosis may occur later.

Bony Thorax Fractures

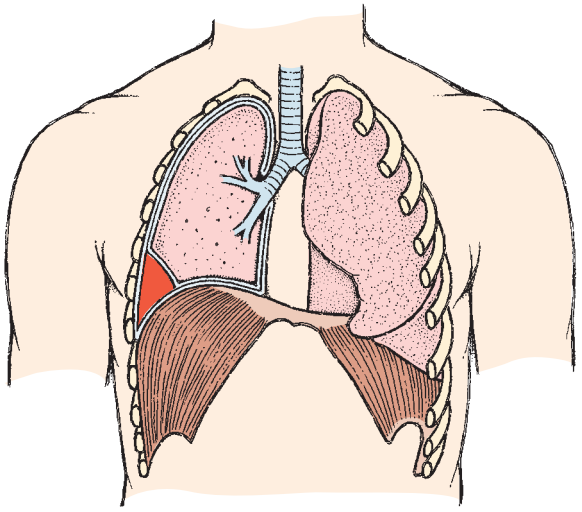
Rib fractures, sternal fractures, and flail chest are thoracic fractures commonly seen in trauma patients. They occur when the applied force exceeds the strength of the thoracic cage. Rib fractures are common injuries. They are clinically significant as (1) markers of serious intrathoracic and abdominal injuries, (2) sources of significant pain, and (3) predictors of pulmonary deterioration. With rib fractures, the most common associated thoracic injuries are pneumothorax, hemothorax, and pulmonary contusion, and the most frequently injured abdominal organs are the liver and the spleen.[21] The greatest concerns for nurses caring for patients with such injuries are pain, ineffective ventilation, and secretion control. Ribs 1 and 2 are usually protected by the clavicle, scapula, humerus, and surrounding muscles. If these ribs are fractured, it often signifies that high-impact trauma and other injuries, for example, to the aorta, the thorax, and the spine, are very likely and should be investigated. Ribs 4 through 10 are most commonly fractured in blunt trauma. If these ribs are fractured, there are often associated underlying lung injuries. Fractures of the lower ribs (8 through 12) can also be associated with injury to the liver or other abdominal structures.[21] Sternal fractures are associated with blunt trauma.

Flail chest is an injury that involves multiple rib fractures. These fractures can be anterior, posterior, or lateral, and usually a sternal fracture is present as well. The stability of the thorax is disrupted, and the rib cage no longer moves in unison. The diagnosis of flail chest is made on the basis of a fracture of two or more ribs, in two or more separate locations, causing an unstable segment. This creates a free-floating segment of rib or sternum.[21] The injured area does not respond to the action of the respiratory muscles; rather, it moves in accordance with the changes in intrapleural pressure. The flail segment movement is paradoxical, hence the term paradoxical breathing. The flail segment causes a decrease in the normal negative pressure of the chest, thereby decreasing ventilation and causing some degree of hypoxia. The flail segment follows pleural pressure instead of respiratory muscle activity. As the patient's pulmonary status worsens, the paradoxical movement of the flail segment increases. Initially, muscular splinting may mask the injury until the patient becomes fatigued. This patient may require intubation and mechanical ventilation.[21]

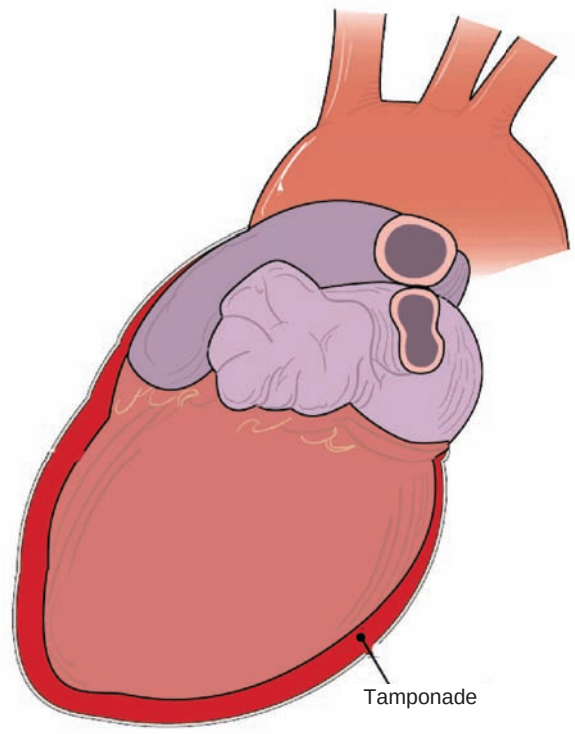
Initial management of patients with bony thorax fractures includes airway management, pain management, and oxygen therapy to maintain adequate saturation. The nurse must consider the underlying structures and the possible injury to them. Treatment of flail chest includes turning the patient with the injured side down to improve oxygenation. This is often difficult because of the need to maintain cervical spine immobilization. Other treatment modalities include internal splinting, accomplished by placing the intubated patient on positive-pressure ventilation. Sometimes, surgical repair is



A. Tension pneumothorax



B. Hemothorax



C. Cardiac tamponade

performed, especially if a thoracotomy is necessary for other reasons. Surgical repair may help decrease the need for prolonged mechanical ventilation.

Pleural Space Injuries

For the purpose of this chapter, the term pleural space injuries is used in reference to pneumothorax (intrapleural air collection), hemothorax (intrapleural blood collection), and hemopneumothorax (interpleural air and blood collections). Pleural space injuries are caused by disruption of an intrathoracic structure that allows air or blood to build up in the pleural layers, thereby leading to a decrease in negative intrathoracic pressure. Sometimes, air and blood continue to build up in the pleural cavity, causing increased tension, which leads to a tension pneumothorax or a tension hemothorax. Either blunt or penetrating trauma may result in a pleural space injury.

The mechanism of injury may lead the nurse to suspect a pleural space injury. For example, an unrestrained driver whose chest hits the steering wheel has a great potential for this injury. When assessing the patient, respiratory distress may be evident along with altered ventilation, which leads to impaired gas exchange. Impaired gas exchange may be evidenced by restlessness, anxiety, tachypnea, decreased oxygenation, poor color, and diaphoresis. The nurse continuously reassesses the patient because even if the original injury is small, it can expand, causing a life-threatening emergency.

Chest radiography is usually used to diagnose pleural space injuries. Sometimes, if the pneumothorax is less than 20% of the chest cavity, it may not be seen initially on chest film. A chest CT scan often shows the smaller pleural space injuries.

Treatment of pleural space injuries includes appropriate management of the patient's airway, ventilation, and oxygenation. A large-bore chest tube, such as a 40-French tube, is often inserted to reexpand the lung and drain the air or blood. This tube is inserted in the fourth or fifth intercostal space at the midaxillary line. For trauma patients with a simple pneumothorax, a chest tube may be placed in the second intercostal space at the midclavicular line. Once the tube is inserted, it is attached to an underwater seal system and then attached to suction. The effects of treatment are assessed by chest radiograph, physical examination, and noting of improved oxygenation. Often, there is an air leak in the underwater seal system of the chest tube drainage device that ceases within a few days.

The nurse monitors the amount of blood that drains into the chest tube drainage device. Drainage of more than 250 mL/h for 2 consecutive hours may indicate a missed injury or the need for further exploration and should be reported.[5]

A massive hemothorax is defined as 1.5 to 4 L of intrathoracic blood loss and truly constitutes a life-threatening injury. A massive hemothorax is often caused by severe thoracic injuries, and the source of bleeding is a large systemic blood vessel or mediastinal structure. Patients with massive hemothorax often arrive at the emergency department or trauma resuscitation unit in cardiopulmonary arrest. These patients require immediate thoracotomy to control bleeding. The patients who are not in cardiopulmonary arrest present

with signs of hypovolemic shock (see Chapter 54), dyspnea, tachypnea, and cyanosis. Initial management of these patients includes treatment of the shock state. Two large-bore IV lines should be established and resuscitation fluid administered. The amount of fluid administered depends on the patient's response.[5,21]

A left massive hemothorax is more common than a right one and is often associated with aortic rupture. The chest cavity is large enough to hold most of the patient's circulating blood volume. Because of this, the bleeding stops only when the pressure in the pleural cavity is equal to or greater than the pressure in the damaged vessel. Placement of a chest tube in a patient with massive hemothorax could lead to exsanguination by eliminating the tamponade caused by a closed chest injury. If a chest tube is inadvertently placed, it should be clamped until exploratory thoracotomy can be performed.

Tension pneumothorax is a life-threatening condition that requires immediate recognition. It may be the result of a primary injury to the thorax or a delayed complication related to tracheobronchial injury or mechanical ventilation. Tension pneumothorax is caused by air entering the pleural space and becoming trapped without an exit. A one-way valve closed system is formed. This causes a compression of one or more of the intrathoracic structures (trachea, heart, lungs, and great vessels) and prohibits them from functioning adequately. The outcome is ventilation failure, compromised venous return, and insufficient cardiac output.[21]

Tension pneumothorax is often difficult to diagnose in the trauma patient because of other injuries the patient may have, as well as the presence of a shock state. It may not be diagnosed until the patient has decompensated. The nurse may notice that it is difficult to ventilate the patient, despite an open airway. There is often a drop in the patient's oxygenation. Other signs of tension pneumothorax include chest asymmetry, tracheal shift, neck vein distention (unless the patient is hypovolemic), decreased breath sounds on the affected side, and evidence of decreased cardiac output (eg, decreased blood pressure and poor tissue perfusion).

Treatment of tension pneumothorax requires immediate decompression of the trapped air. This is done initially by placing a 14- or 16-gauge needle into the pleural space, usually between the second to fourth anterior intercostal space. An immediate rush of air should escape, and the patient's ventilation should improve. Supplemental oxygen is provided to the patient before decompression. After emergent decompression, the needles are changed to chest tubes. This is done to allow the lungs to expand as well as to prevent a reoccurrence. Lastly, additional assessment is necessary to determine the cause of tension pneumothorax. The nurse must continue to assess and reassess the patient.

Pulmonary Contusion

A pulmonary contusion is a bruising of the lung parenchyma, often caused by blunt trauma. It is the most common lung injury.[20,21] It is often apparent on the chest radiograph and CT as ill-defined, patchy, ground-glass density regions of opacification in mild contusion to widespread areas of consolidation in more severe injury. CT is more sensitive in diagnosing pulmonary contusions because it may take up to 24 hours for the pulmonary contusion to show up on chest radiograph.[21] However, the presence of a scapular fracture, rib fractures, or a flail chest should lead to the suspicion of a possible underlying pulmonary contusion. In fact, pulmonary contusion should be anticipated in any patient who sustains significant high-energy blunt chest trauma. The most common mechanism for pulmonary contusion is MVCs.

Pulmonary contusion occurs when rapid deceleration ruptures capillary cell walls, causing hemorrhage and extravasation of plasma and protein into alveolar and interstitial spaces. This results in atelectasis and consolidation, leading to intrapulmonary shunting and hypoxemia. Presenting signs and symptoms include dyspnea, rales, hemoptysis, and tachypnea. Severe contusions also result in increasing peak airway pressures, hypoxemia, and respiratory acidosis. Pulmonary contusion may mimic ARDS; both are poorly responsive to high fractions of inspired oxygen (FiO_2). ARDS is discussed in detail in Chapter 27. The greater the degree of pulmonary contusion, the greater the degree of ventilatory impairment.[21]

Treatment of pulmonary contusion is supportive. Patients with a mild contusion require close observation with frequent ABG measurements or pulse oximetry monitoring. Additional nursing interventions include frequent respiratory assessment, pulmonary care, and pain control. Chest physiotherapy and continuous epidural analgesia also may be beneficial. An oximetric pulmonary artery catheter and arterial line usually are placed to facilitate monitoring of ABGs, hemodynamics, and respiratory parameters (oxygen delivery, oxygen consumption, intrapulmonary shunt).

Severe pulmonary contusion may require ventilatory support with positive end-expiratory pressure (PEEP). Although alveolar ventilation improves as PEEP is added, blood flow to alveoli may diminish, leading to an increased intrapulmonary shunt. To optimize tissue perfusion and oxygenation, each change in PEEP requires assessment of the status of the shunt, oxygen delivery, and other indicators of tissue perfusion (cardiac output, blood pressure, and urine output). Adequate pain control is necessary and may require epidural or intrapleural infusions of analgesics or an intracostal nerve block. In severe cases of respiratory compromise, increased sedation or paralysis may be indicated to decrease energy expenditure and oxygen requirements. A rotation bed also may be considered to promote pulmonary toilet and respiratory gas exchange. Positioning the patient with the injured side up is beneficial in the case of a severe unilateral contusion. In rare instances, when the patient does not respond to traditional mechanical ventilation, prone positioning and high-frequency jet ventilation may be used. Another mode of ventilation commonly used is airway pressure-release ventilation.

Fluid management also is important. Intake and output, daily weights, central venous pressure, and pulmonary artery and capillary wedge pressures are monitored to guide fluid administration. Medications may need to be more concentrated to compensate for excess fluid intake, and diuretics may be required periodically. Severe fluid restriction is not indicated. Instead, fluid balance should be maintained at a normal level (euvolemia) to support optimal cardiac output and oxygen delivery. The contused lung should show radiographic signs of improvement within 72 hours. The

presence of persistent infiltrates may indicate complications, such as pneumonia or superimposed ARDS. Long-term sequelae include prolonged reduced functional residual capacity, dyspnea, and fibrosis.

Blunt Cardiac Injuries

Blunt cardiac injuries encompass a wide spectrum of clinical manifestations ranging from asymptomatic myocardial bruise to cardiac rupture and death.[21] These injuries include cardiac wall rupture, valvular disruption, coronary artery dissection, and cardiac contusions. Table 55-4 describes the blunt cardiac injury (BCI) classification according to the sequelae of the injury. There are few clinical signs and symptoms of BCI. Chest pain is usually the most common, and others secondary to thoracic injuries often occur (eg, dyspnea, chest wall ecchymosis, flail chest).[21]

Cardiac contusions, the most common form of blunt cardiac injuries, are usually caused by blunt trauma as the heart hits the sternum during rapid deceleration. A contusion can also develop if the heart is compressed between the sternum and the spine. Symptoms vary from none (common) to severe congestive heart failure and cardiogenic shock.[22] Complaints of chest pain must be evaluated carefully after trauma. Nonspecific ECG changes, which can include any type of dysrhythmia, are frequently seen. A dysrhythmia always indicates a cardiac contusion until proven otherwise. Atrial dysrhythmias and conduction disturbances may be seen with right-sided cardiac injuries; ventricular disturbances are more likely after left-sided cardiac injuries.

A cardiac contusion is suspected when there is a history of severe anterior blunt trauma and the patient has chest wall bruising and fractures of the ribs or sternum. A 12-lead ECG is performed to detect any electrical abnormalities. Most patients with cardiac contusions have ECG abnormalities on admission.[22] However, there is no correlation between the complexity of the dysrhythmia and the degree of the cardiac contusion. These patients are placed on continuous cardiac monitoring, and blood is drawn for cardiac isoenzyme and troponin studies. Although cardiac enzymes lack specificity in terms of diagnosis, they are used to guide therapy.

Controversy exists over the standard of care for patients with cardiac contusion. Because there is no standard in diagnosing this injury, there is also no standard in treatment.[22]

Table 55-4 Blunt Cardiac Injury (BCI) Classification According to the Sequelae of the Injury

Classification	Description
1	BCI with cardiac free wall rupture
2	BCI with septal rupture
3	BCI with coronary artery injury
4	BCI with cardiac failure
5	BCI with complex dysrhythmias
6	BCI with minor electrocardiographic or cardiac enzymes abnormalities

From Schultz JM, Trunkey DD: Blunt cardiac injury. Crit Care Clin 20:57–70, 2004.

Continuous monitoring must be done to evaluate for symptomatic dysrhythmias, especially ventricular irritability and conduction defects. Echocardiography or multigated angiography may be helpful in determining any muscle defect or damage. In general, patients are treated to relieve their symptoms.

Penetrating Cardiac Injury

In most cases, a penetrating injury to the heart results in prehospital death. Those who survive do so because of cardiac tamponade. Cardiac tamponade and hypovolemic shock are the common presenting signs.[20] The right ventricle is injured most often because of its anterior location.[5] Occasionally, small stab wounds to the ventricles seal themselves because of the thick ventricular musculature. Treatment of hemodynamically stable patients remains controversial. In some instances, monitoring with serial CT scanning or with pericardial and pleural ultrasonography is acceptable. In other cases, surgery to create a thoracoscopic pericardial window may be necessary to aid in the diagnosis of ongoing hemorrhage and to drain pericardial fluid collections. In the presence of ongoing hemorrhage and shock, lost blood volume is replaced, and the patient is immediately transported to the operating room for a median sternotomy and exploration. In severe cases, a thoracotomy in the emergency department may be required as a lifesaving measure.

After surgical repair, appropriate central lines and arterial line are placed to facilitate careful hemodynamic monitoring. Vasopressors or inotropic agents may be necessary to maintain adequate blood pressure and cardiac output. Fluid and electrolyte balance, along with cardiac rhythm, must be monitored closely. Heart sounds are assessed to detect murmurs, indicating valvular or septal defects, and for signs of congestive heart failure. Chest and mediastinal tube drainage are recorded frequently. Fresh frozen plasma and platelets are administered, as indicated, to correct coagulopathies. Complications include continued hemorrhage and postcardiotomy syndrome.

Cardiac Tamponade

Cardiac tamponade, known as both a symptom and injury, can result from both penetrating and blunt trauma. It is a life-threatening injury that needs to be immediately assessed and treated. Cardiac tamponade is caused by blood filling the pericardium and compressing the heart, causing decreased cardiac filling, which leads to reduced cardiac output and eventually shock.[23] Bleeding into the pericardial sac (hemopericardium) or a small pericardial rupture may or may not cause cardiac tamponade, depending on the amount of pressure in the pericardium.[23]

The pericardial sac normally holds about 25 mL of fluid, which serves to cushion and protect the heart. Only a small amount of pericardial blood (50 to 100 mL) is necessary to increase intrapericardial pressure. Continued bleeding increases the pressure rapidly, and the patient presents with signs and symptoms of cardiac tamponade.

Classic symptoms include decreased blood pressure, muffled heart sounds, and increased central venous pressure manifested by distended neck veins (Beck's triad).[22] Another key sign to cardiac tamponade is pulsus paradoxus, "an inspiratory

systolic fall in arterial pressure of 10 mm Hg or more during normal breathing."[23] This is caused by a fall in cardiac output. Because these signs may be obscured in the hypovolemic trauma victim, patients with a history of precordial trauma must be treated with a high index of suspicion. Diagnosis of cardiac tamponade is not easy. An echocardiogram is most useful in the diagnosis and is readily available, but the cardiac tamponade is a clinical diagnosis.[23] Treatment of cardiac tamponade includes airway control, oxygenation, hemodynamic support, and rapid transport to a definitive care center. The rapid transfusion of IV fluids increases venous pressure and ultimately improves cardiac output as well as provides the needed time to prepare for interventions. Ultimately, the treatment of cardiac tamponade is drainage of blood from the pericardial sac (pericardiocentesis).[22] This is the only life-sustaining intervention.[23] Nursing management of a patient with cardiac tamponade includes airway protection and ventilatory support, hemodynamic support, and assistance with interventions provided to the patient.

Aortic Injuries

Death from aortic disruption occurs immediately in 75% to 90% of cases.[24] Disrupting the blood flow in the aorta inhibits perfusion to vital organs and extremities. The location and size of the disruption determine its significance.[24] Blunt aortic injury is usually associated with sudden deceleration or compression forces. MVCs are the primary causes of this injury.[20] Of the patients who make it to the hospital alive, 75% are hemodynamically unstable and 50% die before repair. Many of these patients have other significant injuries. Aortography is the gold standard for diagnosis of aortic injuries, although transesophageal echocardiography and chest CT play an increasingly important role.[20]

There are three common locations of vessel rupture. Because the thoracic aorta is very mobile, the tears occur at points of fixation. The most common is at the aortic isthmus, just distal to the left subclavian artery, where the vessel is attached to the chest wall by the ligamentum arteriosum. The two other sites of rupture are in the ascending aorta, where the aorta leaves the pericardial sac, and at the entry to the diaphragm. The inner layers of the vessel tear on impact from deceleration. The outer layers remain intact and balloon out into a pseudoaneurysm. A partial circumferential hematoma may also be tamponaded by surrounding tissues. Both of these mechanisms may prolong survival, but only for a limited time.

An understanding of the injury history can raise the suspicion of aortic injury. Penetrating mediastinal injuries or thoracic injuries caused by blunt trauma should raise suspicion. Other injuries that may raise suspicion include first or second rib fractures, high sternal fractures, clavicular fractures at the sternal margin, and massive left-sided hemothorax.

Loss of effective blood transport because of major vessel rupture is the main physiological problem associated with aortic rupture. The goal of assessment is to identify evidence of poor perfusion beyond the aortic lesion. Many patients are asymptomatic on presentation. Findings associated with aortic injuries are given in Box 55-3.

A supine chest radiograph is obtained to aid in diagnosis of an aortic injury. After spinal injury has been ruled out, an upright chest radiograph may be obtained as well. If a widened mediastinum is detected on radiograph, additional evaluation is necessary for definitive management. Although an aortic tear is sometimes seen on CT scan, aortography is the study used for definitive diagnosis.[20,24]

BOX 55-3 PATIENT SAFETY

Signs and Symptoms of Aortic Injuries

- Pulse deficit in any area, particularly lower extremities or left arm
- Hypotension unexplained by other injuries
- Upper extremity hypertension relative to lower extremities
- Interscapular pain or sternal pain
- Precordial or interscapular systolic murmur caused by turbulence across the disrupted area
- Hoarseness caused by hematoma pressure around the aortic arch
- Respiratory distress or dyspnea
- Lower extremity neuromuscular or sensory deficit

Adapted from Frawley PM: Thoracic trauma. In McQuillan KA, Flynn Makic MB, Whalen E, et al (eds): Trauma Nursing, 4th ed. Philadelphia, PA: WB Saunders, 2009, pp 614–677.

A positive aortogram indicates the need for surgical repair. The torn aorta may require end-to-end anastomosis or, more commonly, the placement of a synthetic graft. Cardiopulmonary bypass may be necessary for repair of the ascending aorta or the aortic arch. However, repair of the descending thoracic aorta is usually accomplished during aortic cross-clamping. Because this maneuver occludes distal blood flow, it is imperative that the cross-clamp time be as brief as possible (preferably <30 minutes). To prevent leakage from the repair site, vasodilators may be administered after surgery to reduce afterload. After replacement of intravascular volume, a vasopressor may be added to support adequate blood pressure. Nursing care focuses on hemodynamic monitoring with a pulmonary artery catheter and titrating medications to maintain optimal blood pressure. Autotransfusion may also be necessary.

Complications are related to the level of the tear and the extent of altered perfusion. Hypoperfusion and resulting damage to organs below the level of the laceration can result from the injury itself or from prolonged cross-clamping during repair. Serious complications resulting from prolonged cross-clamp time include renal failure, bowel ischemia, lower extremity weakness, or permanent paralysis of the lower extremities. Other sequelae, such as ARDS or DIC, can be a consequence of hemorrhagic shock and multiple blood transfusions.

Abdominal Trauma

Abdominal trauma can be caused by both blunt and penetrating injuries. Abdominal injuries can rapidly lead to death secondary to hemorrhage, shock, and sepsis. Missed abdominal injuries are a frequent cause of trauma deaths. Compared with penetrating trauma, blunt abdominal trauma is associated with more fatalities because many of the injuries are "hidden," and often, more obvious but less severe injuries lead to a delay in diagnosis. Deaths that occur more than 48 hours after abdominal injury are due to sepsis and

its complications. In intra-abdominal trauma, rarely does single-organ or single-system injury occur.

The abdomen contains both solid and hollow organs. The solid organs include the liver, spleen, pancreas, and kidneys. The hollow organs include the intestines, stomach, gallbladder, and urinary bladder. Clinicians divide the abdomen into three main regions to facilitate description of the location of the injury. The three areas are the following:

- The peritoneal area, which includes the diaphragm, liver, spleen, stomach, transverse colon, and the portion covered by the bony thorax
- The retroperitoneal area, which includes the aorta, vena cava, pancreas, kidney, ureters, and parts of the duodenum and colon
- The pelvis, which includes the rectum, bladder, uterus, and the iliac vessels

MVCs are the most common cause of blunt abdominal trauma, although assaults, falls, pedestrian–motor vehicle collisions, and industrial accidents also contribute to blunt abdominal injuries. These injuries occur as the result of compressive, crushing, shearing, and deceleration forces. Diagnosis of blunt abdominal trauma can be difficult, especially if there are multisystem injuries. If the patient has abdominal tenderness or guarding, hemodynamic instability, lumbar spine injury, pelvic fracture, retroperitoneal or intraperitoneal air, or unilateral loss of the psoas shadow on radiograph, visceral damage should be suspected.

Blunt trauma is likely to cause serious damage to solid organs, and penetrating trauma most often damages the hollow organs. The compression and deceleration of blunt trauma leads to fractures of solid organ capsules and parenchyma, whereas hollow organs can collapse and absorb the force. However, the bowel, which occupies most of the abdominal cavity, is prone to injury by penetrating trauma. In general, solid organs respond to trauma with bleeding. Hollow organs rupture and release their contents into the peritoneal cavity, causing inflammation and infection.

Stab wounds, impalements, and gunshot wounds can cause penetrating trauma. Injury patterns differ depending on the mechanism. If the mechanism of penetrating trauma is a stab wound, knowledge of the size, shape, and length of the instrument used is helpful in determining the extent of intra-abdominal damage. However, it is estimated that only half of stab wounds enter the abdomen, which means that compared with gunshot wounds, stab wounds are less destructive and have a decreased morbidity and mortality.[25] Impalement is considered a "dirty" wound. "Dirty" wounds can result in high mortality secondary to the infection that is caused by bacterial contamination and subsequent multisystem organ failure. Gunshot wounds (missile injuries) are difficult to evaluate. The amount of major vessel disruption and multiple organ involvement are predictors of mortality. The velocity and amount of energy dispersed by the bullet often determine the extent of injury. A bullet can rebound off organs or bones, changing its trajectory and causing massive internal damage to organs and vessels. The blast effect from bullets can also cause significant intra-abdominal injury.

Abdominal trauma requires continual assessment. Frequently, unrecognized abdominal trauma is a cause of preventable death. The nurse must be organized and methodical in the approach to patient assessment. The nurse needs to understand the mechanism of injury as well as the patient's complaints to perform an adequate assessment and identify potentially life-threatening abdominal injuries. It is important to remember that in blunt trauma, the validity of the physical examination alone is questionable. It is often unreliable if alcohol, illicit drugs, analgesics, or narcotics were involved or if the patient has a reduced level of consciousness. In penetrating trauma, the physical examination tends to be more reliable.

Usually, a primary survey is completed, and the patient is resuscitated before the abdomen is assessed. During the secondary survey, the abdomen is assessed and reassessed, and laboratory and diagnostic tests are performed. An orogastric or nasogastric tube and a Foley catheter are placed during the secondary survey phase.

Often, diagnosis of penetrating trauma requires local wound exploration. However, it is important to note the site of the injury because wound exploration depends on mechanism and location. If the injury is in the anterior abdominal region (anterior costal margins to the inguinal creases between the anterior axillary lines), the likelihood that the peritoneum has been penetrated is low. If the injury is in the thoracoabdominal region (fourth intercostal space anteriorly and seventh intercostal space posteriorly to inferior costal margins), exploration is not recommended because there is an increased risk for tension pneumothorax. The patient requires a laparoscopy, thoracoscopy, or exploratory laparotomy. Exploration tends to be difficult in flank or back wounds. The patient usually requires a triple-contrast CT.

Diagnostic testing may include focused abdominal sonography for trauma (FAST), diagnostic peritoneal lavage (DPL), a chest radiograph (to determine gross abnormalities as well as any organ displacement), and an abdominal CT scan. Many trauma centers are performing FAST on all trauma patients. This is an ideal diagnostic study because it is portable, fast, and reproducible.[26] It is performed by placing an ultrasound probe over various areas on the abdomen to determine whether free fluid is located in those areas. The areas evaluated are Morison's pouch in the right upper quadrant, the pericardial sac, the splenorenal region in the left upper quadrant, and the pelvis (suprapubic region).[27] If the results of FAST are positive and the patient is hemodynamically unstable, an exploratory laparotomy is performed. The FAST allows the practitioner to forego other diagnostic tests and proceed to immediate operation.[27]

A DPL is a quick diagnostic procedure that is used during the resuscitation phase of care in hemodynamically unstable trauma patients to diagnose intra-abdominal bleeding (Box 55-4). DPL is not performed as regularly now because the FAST has proved to be very effective and efficient in diagnosing the immediate need for surgical intervention. Other indications for use may include the following:

1. Unexplained hypotension, decreased hematocrit, or shock
2. Equivocal results of abdominal examination
3. Altered mental status caused by brain injury or alcohol or drug intoxication
4. Spinal cord injury
5. Distracting injuries, such as major orthopedic fractures or chest trauma.

BOX 55-4 Diagnostic Peritoneal Lavage

Indications
- Blunt abdominal injury with:
  - Altered mental status
  - Unexplained hypotension, decreased hematocrit, shock
  - Equivocal results of abdominal examination
  - Spinal cord injury
  - Distracting injuries (eg, orthopedic fractures, chest trauma)
- Penetrating abdominal trauma (if exploration is not indicated)

Possible Contraindications
- History of multiple abdominal operations
- Third-trimester pregnancy
- Advanced cirrhosis of the liver
- Morbid obesity
- Known history of coagulopathy

Technique
1. Insert lavage catheter into peritoneal cavity through 1- to 2-cm incision.
2. Attempt to aspirate peritoneal fluid.
3. Infuse normal saline or Ringer's lactate by gravity.
4. Turn patient from side to side (unless contraindicated).
5. Allow fluid to run back into bag by gravity.
6. Send specimens to laboratory.

Positive Results
- 10 to 20 mL gross blood on initial aspirate
- Greater than 100,000 red blood cells/mm^3
- Greater than 500 white blood cells/mm^3
- Elevated amylase level
- Presence of bile, bacteria, or fecal matter

If the results of DPL are positive and the patient is hemodynamically unstable, an exploratory laparotomy is performed.

There are several contraindications to performing a DPL. These include morbid obesity, third-trimester pregnancy, advanced cirrhosis, a history of coagulopathy, and a history of multiple abdominal surgeries.[26] There is an increased risk for omental laceration and visceral or vascular perforation if DPL is performed in patients with these findings.

When performing DPL, it is important to first ensure that the patient has a Foley catheter and an orogastric or nasogastric tube in place to decompress the stomach and the bladder. Decompression of the stomach and bladder guards against accidental perforation when the lavage catheter is placed. Once the Foley catheter and an orogastric or nasogastric tube are placed, the lavage catheter is inserted into the peritoneal space. If fewer than 10 mL of frank blood are returned, a 1-liter bag of warm crystalloid (lactated Ringer's solution or 0.9% normal saline solution) is infused into the peritoneum. After the infusion is complete, the IV bag is placed in a dependent position to allow the fluid to exit the abdomen by gravity. A sample of the fluid is then sent to the laboratory for evaluation.

CT scans are now being used more often in trauma patients. In blunt trauma, the CT scan has become the mainstay of diagnosis for abdominal injury, with a 92% to 97% sensitivity and 98% specificity. Often, the CT scan is performed with both IV and oral contrast agents to visualize the organs and note any disruption. The CT scan allows visualization of the peritoneal, retroperitoneal, and pelvic areas and permits estimation of the amount of fluid in these areas. CT scans are also used to grade solid organ injuries. Limitations to the use of CT include penetrating trauma, the amount of time required to perform the study, the need to transport the patient out of the resuscitation area, and the requirement that the patient must be hemodynamically stable and have limited movement during the study.

Trauma to the Esophagus and Diaphragm

Esophageal injury is rare and very difficult to diagnose because of the lack of clinical signs initially and the severity of other injuries. Esophageal injuries often go unrecognized until sepsis develops. Esophageal injuries have a high death rate.[5] Penetrating trauma is the most likely cause of esophageal injury, and usually the cervical esophagus is where the injury occurs. The clinical symptoms are subtle. Presenting symptoms that should lead to a suspicion of esophageal injury include a hemothorax or pneumothorax without rib fractures.

Diagnosis includes CT scan of the chest, abdomen, and pelvis with and without contrast. Esophagoscopy, flexible endoscopy, and swallow studies are also performed. Treatment for esophageal injury is surgical repair. The patient is kept without anything by mouth (NPO) with a nasogastric tube to continuous suction, and antibiotic therapy is initiated. Nursing considerations include paying close attention to the airway of the patient, ventilation, oxygenation, and hemodynamic support.

Diaphragm rupture is more common in blunt injury than in penetrating injury. Such rupture occurs more frequently on the left side because there the diaphragm is not protected by the liver. Injury is often secondary to the rising and falling associated with respiration. If a diaphragm rupture is suspected, it is necessary to look for both thoracic and abdominal injury. It is not uncommon to see abdominal contents in the thorax, which subsequently causes bowel strangulation in approximately 30% of patients. Respiratory compromise may also be seen because of impairment of lung capacity and displacement of normal lung tissue.

The clinical picture of diaphragm rupture depends on the size and site of injury. This injury is often difficult to diagnose because there is minimal bleeding and the patient is often asymptomatic. Clinical findings may include marked respiratory distress, dyspnea, decreased breath sounds on the affected side, positive bowel sounds in the thorax, palpation of abdominal contents when inserting a chest tube, and paradoxical movement of the abdomen when breathing.

Chest radiography is the initial modality used to diagnose diaphragm rupture. However, findings are often normal or nonspecific. The presence of abdominal contents in the chest denotes an injury. If an injury is suspected, ultrasound and a CT scan should be performed. DPL may be falsely negative. The only definitive treatment for diaphragm rupture is surgical repair.

Trauma to the Stomach and Small Bowel

Significant gastric injury is rare. Small bowel injuries are much more common. Although frequently damaged by penetrating trauma, the small bowel can also burst when subjected to blunt trauma. The multiple convolutions occasionally form a closed loop, which can rupture when subjected to increased pressure caused by impact with a steering wheel or

BOX 55-5 PATIENT SAFETY

Complications Related to Stomach and Small Bowel Trauma

- Intolerance to tube feedings
- Peritonitis
- Postoperative bleeding
- Hypovolemia caused by third spacing
- Development of a fistula or obstruction

seat belt. The bowel's mobility around fixed points (such as the ligament of Treitz) predisposes it to shearing injuries with deceleration.

Blunt small bowel or gastric injury can present with blood in the nasogastric aspirate or hematemesis. Physical signs often are absent, and CT findings may be subtle and nonspecific. Close observation is required; often, the diagnosis is not made until peritonitis develops. Penetrating injuries usually cause positive results on DPL. Although a mild bowel contusion can be managed conservatively (gastric decompression and withholding oral intake), surgery usually is necessary to repair penetrating wounds or bowel rupture.

Postoperative decompression with a gastric tube is maintained until bowel function returns. In most cases, a feeding jejunostomy tube is placed distal to the repair site, and tube feedings can be initiated early in the postoperative course. As the concentration and rate of feedings are advanced slowly, frequent assessment for signs of intolerance (distention, vomiting) is essential.

Because the stomach and small bowel contain an insignificant amount of bacteria, the risk for sepsis is small after rupture of these organs. If the injury goes unrecognized, there is a risk for sepsis. On the other hand, the acidic gastric juice is irritating to the peritoneum and may cause peritonitis. Potential complications related to stomach and small bowel trauma are listed in Box 55-5. Some of these conditions may necessitate additional surgical procedures.

Trauma to the Duodenum and Pancreas

The pancreas and duodenum are discussed together because these retroperitoneal organs are closely related anatomically and physiologically. A great deal of force is necessary to injure these organs because they are well protected deep in the abdomen. Most injuries are related to penetrating trauma. Injuries to adjacent organs almost always are present. The retroperitoneal location makes these injuries difficult to diagnose with DPL. An abdominal CT scan is very useful in this instance. Signs and symptoms may include an acute abdomen, increased serum amylase levels, epigastric pain radiating to the back, nausea, and vomiting.

Small lacerations or contusions may require only the placement of drains, whereas larger wounds need surgical repair. Most pancreatic injuries require postoperative closed-suction drainage to prevent fistula formation. Distal pancreatectomy and Roux-en-Y anastomosis are two procedures commonly performed for injuries to the body and tail of the pancreas. Occasionally, the spleen also must be removed because of its multiple vascular attachments to the pancreas. Damage to the head of the pancreas is associated with duodenal injury and severe hemorrhage because of the close proximity of vascular structures. Surgical procedures used in these cases include pancreaticoduodenectomy, Roux-en-Y anastomosis, and, on rare occasions, total pancreatectomy.

Postoperative nursing assessment and care are similar for the various procedures. Patency of drains must be maintained, and the patient must be monitored for the development of fistulas, the most common complication. Skin protection is important if a cutaneous fistula does develop because of the high enzyme content of pancreatic fluid. Assessment of fluid and electrolyte balance is also important because a pancreatic fistula results in fluid loss, along with loss of potassium and bicarbonate. Pancreatic stimulation can be decreased by administering parenteral hyperalimentation or jejunal feedings instead of an oral diet. The onset of diabetes mellitus is rare unless a total pancreatectomy is performed.

Primary repair or resection with reanastomosis is sufficient to manage most penetrating duodenal injuries. A duodenostomy tube may be placed for decompression and a jejunostomy tube for feeding. Blunt trauma to the duodenum can cause an intramural hematoma, which may lead to duodenal obstruction. The diagnosis is made with a diatrizoate (Gastrografin) upper gastrointestinal study. A complete obstruction usually requires surgical drainage of the hematoma.

Trauma to the Colon

Usually, injury to the colon results from penetrating trauma. The nature of the injury most often dictates surgical exploration (exploratory laparotomy). Primary repair may be considered if the patient is hemodynamically stable and the injury is small and without fecal contamination. In some situations, such as injury to the left colon or when there is massive blood loss, an exteriorized repair or colostomy is required. A cecostomy tube may be placed for colon decompression. Subcutaneous tissue and skin of the incision site are often left open to decrease the chance of wound infection. The colon has a high bacteria count; spillage of the contents predisposes the patient to intra-abdominal sepsis and abscess formation.

Postoperative nursing care focuses on prevention of infection. Dressing changes are necessary for open incisions, and prophylactic antibiotics may be used. In the case of an exteriorized colon repair, resection and end-to-end anastomosis is performed, and the repair site is exteriorized to facilitate identification of a leak. The exteriorized colon must be kept moist and covered with a nonadherent dressing or bag to protect the integrity of the sutures. Because sepsis is a major complication of colon injuries, a series of radiographic and surgical procedures may be required to locate and drain abscesses.

A teaching guide for patients who have undergone a laparotomy can be found in Box 55-6.

Trauma to the Liver

Along with the spleen, the liver is the most commonly injured abdominal organ.[28] Both blunt and penetrating trauma can cause hepatic injuries. Fractures of the right lower ribs increase suspicion for a liver injury. Presenting signs and symptoms may include right upper quadrant pain, rebound tenderness, hypoactive or absent bowel sounds, or signs of hypovolemic shock. Box 55-7 presents the liver injury scale.

Hemodynamically stable patients with liver injuries are now managed nonoperatively. Observation is now considered

BOX 55-6 TEACHING GUIDE After a Laparotomy

Patient Activity

- No tub baths or showers while the staples/stitches are in place.
- If you are tired, rest.
- Only lift what you can easily lift with one hand.
- You may eat your normal diet.
- Take your temperature once a day at the same time and write it down.
- Maintain a normal schedule with your bowel movements.
- If you become constipated, drink more fruit juices.
- Do not drive until you have your doctor's permission.

Wound Care

- It is important to keep the staple/stitch line clean.
- Monitor your wound closely.
- Cleanse the area once a day. To do this, you will need 4" × 4" gauze pads and a solution of half peroxide/half saline solution.
- Wash your hands.
- Open the gauze pad and leave the pad on the paper.
- Pour a small amount of the peroxide/saline solution on the center of the pad while it is lying on the paper.
- Pick up the pad, pulling all four corners together without touching the center.
- Wipe over the stitches/staples from top to bottom, covering them well with the solution. It is normal to see bubbles when cleaning with this solution. Wipe the area only once with a single gauze pad.
- Repeat.
- Allow the area to air dry.
- Tape a gauze pad over the stitch or staple line to prevent rubbing or irritation caused by a belt or waistband.

Signs of Infection

- Swelling around the site
- Increased redness
- Increased tenderness
- Warmth around the site
- Wound edges separating
- Increased drainage
- Foul-smelling drainage
- Change in color of drainage
- Temperature of 101°F or higher
- Vomiting, diarrhea, or constipation

the standard treatment for liver injuries unless the patient is hemodynamically unstable or has frank peritonitis.[29] The liver is manifested to heal itself. It is thought that venous injuries occur in low-pressure systems and have little need for an operation. Also noted have been cases of worsening bleeding after manipulation in the operating room.[29] In this case, serial CT scans are performed to verify bleeding cessation. However, in some cases, the patient's unstable clinical condition dictates the need for surgery. Hepatic trauma can cause a large blood loss into the peritoneum, but bleeding may stop spontaneously. In some instances, bleeding vessels may be ligated or embolized. Small lacerations are repaired, whereas larger injuries may require segmental resection or débridement. In the case of uncontrollable hemorrhage, the liver is packed. After packing, the abdomen may be closed or simply covered and left open. An additional surgical procedure is required within the next few days to remove the packing and repair the laceration. Large liver injuries also need postoperative drainage of bile and blood with closed-suction drains.

After surgery, coagulopathies may be present. Incomplete hemostasis also is a possibility and must be differentiated from coagulopathy-induced bleeding. Severe bleeding resulting from incomplete hemostasis requires clot removal, packing, and additional repair. With a coagulopathy, bleeding arises from numerous sites, whereas with incomplete hemostasis, the bleeding is mainly from the surgical site.

Nursing care of patients with liver injuries includes the replacement of blood products while monitoring the hematocrit and coagulation studies. Assessment of the character and amount of tube drainage, along with fluid balance, also is essential. Potential complications of liver injury include hepatic or perihepatic abscess, biliary obstruction or leak, sepsis, ARDS, and DIC. In 6 to 8 weeks, physical examination findings should be improved. To prevent rebleeding, patients should not participate in contact sports until a repeated CT scan shows healing of the injury.

BOX 55-7 Liver Injury Scale

Hematomas

- **Grade I hematomas:** subcapsular and nonexpanding; involving less than 10% of surface area
- **Grade II hematomas:** subcapsular, less than 1-cm intraparenchymal hematoma; involving 10% to 50% of surface area
- **Grade III hematomas:** expanded and subcapsular, involving more than 50% of surface area, or ruptured and actively bleeding; intraparenchymal hematoma 2 cm or more or expanding
- **Grade IV hematomas:** ruptured parenchyma with active bleeding

Lacerations

- **Grade I lacerations:** capsular tear less than 1 cm deep and nonbleeding
- **Grade II lacerations:** actively bleeding capsular tear 1 to 3 cm deep without trabecular vessel involvement
- **Grade III lacerations:** more than 3 cm deep
- **Grade IV lacerations:** involving 25% to 50% hepatic lobe parenchymal disruption
- **Grade V lacerations:** involving more than 50% hepatic lobe parenchymal disruption; vascular injury includes retrohepatic vena cava and juxtahepatic venous injuries
- **Grade VI lacerations:** vascular hepatic avulsion

From Eckert KL: Penetrating and blunt abdominal trauma. Crit Care Nurse Q 28(1):41–59, 2005.

Trauma to the Spleen

Along with the liver, the spleen is the most commonly injured abdominal organ, usually as a result of blunt trauma.[28] In 60% of patients sustaining blunt trauma, the spleen is the only organ injured.[28] Because of its vascularity, the spleen has a tendency to lose blood rapidly.[30] Presence of left lower rib

fractures increases suspicion for a splenic injury. Presenting signs and symptoms include left upper quadrant pain radiating to the left shoulder (Kehr's sign), hypovolemic shock, and the nonspecific finding of an increased white blood cell count. FAST, DPL or abdominal CT is usually necessary for diagnosis. Box 55-8 provides the splenic injury scale.

Management for splenic injuries includes observation, embolization, or surgery, depending on the hemodynamic stability of the patient, their preexisting conditions, and the grade of splenic injury. Hemodynamically unstable patients with a positive FAST or DPL require immediate surgery to determine the source of bleeding. Hemodynamically stable patients with low-grade injury (grades I to III) without any evidence of bleeding on CT scan or FAST can be observed closely.[28] Patients with contrast extravasation on CT or with abdominal blush on CT may have a higher rate of failure and may require embolization. Also, patients with neurological compromise, who are unreliable to observe, may require surgery.[28]

Approximately 50% to 70% of hemodynamically stable patients are treated nonoperatively with observation and embolization. These patients tend to be adults with lower-grade injuries and most children. An observation period of 5 days is the standard. These patients are admitted to a monitored bed and watched carefully for hypotension and signs of bleeding. They have hemoglobin and hematocrit (H&H) analyses every 6 hours until stable. They are initially placed on bed rest, although there is no clinical significance to support this. Patients are kept NPO until their H&H is stable and then they begin a diet. Patients with a higher-grade injury require longer observation.[28]

Early complications include recurrent bleeding, subphrenic abscess, and pancreatitis resulting from surgical trauma. Rupture of an expanding subscapular hematoma or pseudoaneurysm may present days or weeks after an initial normal examination. Late complications consist of thrombocytosis and overwhelming postsplenectomy sepsis (OPSS). Because the spleen plays an important role in the body's response to infection, a splenectomy predisposes the patient to an increased risk for infection. This risk is especially high among children and highest in those younger than 2 years old. Pneumococcus, an encapsulated microorganism resistant to phagocytosis, is the organism that most often infects patients after splenectomy. OPSS frequently begins with the onset of pneumococcal pneumonia, which progresses to a fulminant sepsis. Postsplenectomy patients increase their immunity toward pneumococcal infections by receiving a polyvalent pneumococcal vaccine (Pneumovax). Complications of OPSS include adrenal insufficiency and DIC. OPSS has a high incidence and mortality rate, especially within 1 year of surgery. Patient and family teaching should focus on information about signs and symptoms of infection.

BOX 55-8 Splenic Injury Scale

Hematomas

- **Grade I hematomas:** involving less than 10% of surface area; subcapsular and nonexpanding
- **Grade II hematomas:** subcapsular; involving 10% to 50% of surface area or less than 1-cm intraparenchymal hematoma
- **Grade III hematomas:** expanding, subcapsular, and ruptured, with active bleeding, involving more than 50% of surface area; subcapsular hematoma 2 cm or more or expanding intraparenchymal hematoma
- **Grade IV hematomas:** involving ruptured parenchyma with active bleeding

Lacerations

- **Grade I lacerations:** nonbleeding capsular tear less than 1 cm deep
- **Grade II lacerations:** actively bleeding capsular tear 1 to 3 cm deep without trabecular vessel involvement
- **Grade III lacerations:** more than 3 cm deep or involving trabecular vessels
- **Grade IV lacerations:** including hilar vessel with more than 25% devascularization
- **Grade V lacerations:** involving completely shattered spleen; hilar vascular injury with total devascularization of the spleen

From Eckert KL: Penetrating and blunt abdominal trauma. Crit Care Nurse Q 28(1):41–59, 2005.

Trauma to the Kidneys

Injury to the kidney may lead to a "free" hemorrhage, contained hematoma, or the development of an intravascular thrombus. Sudden deceleration injury can cause the kidney to move, avulsing smaller renal vessels or tearing the renal artery intima, which also may lead to vessel thrombosis. Blunt and penetrating trauma can also cause a laceration or contusion of the renal parenchyma or rupture of the collecting system. Lower rib or lumbar vertebral fractures, along with liver and spleen injuries, should raise suspicion of an associated renal injury. Signs and symptoms, when present, consist of hematuria, pain, a flank hematoma, or ecchymosis over the flank. Because the bleeding is retroperitoneal, it can be difficult to detect. A helical CT scan, ultrasound, or an IV pyelogram (less commonly used) usually provides the diagnosis.

Renal injuries are graded based on their severity. Increased grade correlates with decreased function.[31] Many renal injuries can be managed conservatively with observation and bed rest until gross hematuria resolves. However, in some instances (mainly for vascular injury), surgical repair or nephrectomy is necessary.

Postoperative assessment and support of renal function are imperative. Optimal fluid balance must be maintained. Low-dose dopamine may be ordered to promote renal perfusion. Major complications consist of arterial or venous thrombosis and acute renal failure. Other complications include bleeding, perinephric abscess, the development of a urinary fistula, and late onset of hypertension.

Trauma to the Bladder

The bladder can be lacerated, ruptured, or contused, most often as the consequence of blunt trauma (usually because of a full bladder at the time of injury). Bladder injuries frequently are associated with pelvic fractures. Gross hematuria is typically noted with bladder rupture.[32] Presence of blood at the urethral meatus, a scrotal hematoma, or a displaced prostate gland requires examination for urethral injuries with a CT scan or conventional cystography before the insertion of a urinary catheter.[32]

A bladder injury can cause intraperitoneal or extraperitoneal urine extravasation. Extraperitoneal extravasation, usually associated with pelvic fractures, can often be managed with urinary catheter drainage. However, intraperitoneal extravasation (associated with a high-force injury) requires surgery. This injury has a high mortality rate because of associated injuries that occur secondary to the force involved. A suprapubic cystostomy tube may be placed. Complications are infrequent, but infection resulting from the urinary catheter or sepsis from extravasation of infected urine can occur. Patients may complain of an inability to void or of shoulder pain (caused by extravasation of urine into the peritoneal space).

Musculoskeletal Injuries

Although musculoskeletal injuries take a long time to heal and can often result in lifelong disability, they are usually not considered life threatening unless there is a traumatic amputation or pelvic fracture. Routinely, the musculoskeletal assessment is done in the secondary survey after hemodynamic stabilization. These injuries do require prompt recognition and stabilization to promote optimal recovery and function.

Although there are a variety of causes of trauma-related musculoskeletal injuries, the major ones include MVCs, falls, assaults, and industrial, farming, and home accidents. Musculoskeletal injuries are often associated with other injuries to the body.

It is important to understand the circumstances surrounding, and the mechanism involved in, musculoskeletal trauma. Force might be applied to one area, but the transferred energy and distribution of force may cause injury somewhere else. For example, in a person who falls off a two-story building and lands on his or her feet, one would expect to find calcaneus or ankle fractures, but the transference of energy may also cause a pelvic or lumbar spine fracture. Obviously, if the patient is conscious, he or she can verbalize his or her pain. However, many times, fractures and sprains go unrecognized because the patient is not able to verbalize and communicate the location of his or her pain.

As in all trauma patients, initial assessment begins with the primary survey. Once this is complete and the patient is hemodynamically stable, the secondary assessment is conducted. When trauma patients are admitted to the resuscitation unit, cervical spine, chest, and pelvis films are obtained first. Sometimes, thoracic and lumbar spine films are obtained, depending on the mechanism of injury. The initial pelvic film tells the nurse whether the patient has a life-threatening pelvic fracture. If this is the case, immobilization of the pelvis should be maintained to prevent exsanguination. Immobilization of the pelvis is achieved with a C-clamp, external fixator, pelvic binder, or sheets wrapped tightly around the patient to attempt to stop the bleeding.

During the secondary survey, if limb swelling, ecchymosis, or deformity is noted, that extremity should be immobilized. Proper imaging is ordered to determine the extent of the injury. The nurse tests the extremities for capillary refill (<2 seconds is normal), pulses, crepitus, muscle spasm, movement, sensation, and pain.

The most common studies used to diagnose musculoskeletal injuries are plain radiographs, CT, and magnetic resonance imaging (MRI). When obtaining radiographs, it is important to get two views of the affected area. It is also important to assess the joint above and below the injured area. If the affected area is in a place that is difficult to visualize on plain films, a CT scan usually gives a better picture. An MRI also gives more specific detail about the area surrounding the injury and about the injury itself.

There are many types of musculoskeletal injuries, including fractures, fracture dislocations, amputations, and trauma to the soft tissue (ie, skin, muscle, tendons, ligaments, and cartilage). Fracture classification is based on type, cause, and anatomical location. Several fracture types are shown in Figure 55-6. If the skin is broken at the fracture site, the injury is considered to be an "open" fracture. If the skin is intact, the injury is said to be a "closed" fracture. An open fracture is further classified as grade I, II, or III, depending on the tissue damage involved.

Dislocation occurs when the articulating surfaces of a joint are no longer in contact because of joint disruption. Joint mobility may be restricted. There may also be associated vascular or nerve injury with dislocations. Ligamentous injury usually accompanies dislocations because ligaments stretch or tear at the time of dislocation.

Amputations are classified according to the amount of tissue, nerve, and vascular damage. A cut or guillotine amputation has clean lines and well-defined edges, whereas a crush amputation has more soft tissue damage and the edges are not as well defined. An avulsion amputation occurs when a force stretches and tears away tissues, causing nerves and vessels to be torn in different areas than the bone.

As with any injury, musculoskeletal trauma requires continuous assessment. It is not uncommon for vascular or neurological compromise, or both, to develop in patients with musculoskeletal injury. Any musculoskeletal injury involving bone or soft tissue can cause neurological or vascular compromise because nerves and blood vessels are located in such close proximity to the bones and muscles. The nerves and muscles are very sensitive to impaired circulation and compression.

It is also important to continually assess the patient for hypovolemia. As stated earlier, traumatic amputation and major pelvic ring fractures are known for their extensive blood loss. Other orthopedic injuries can also cause substantial blood loss. Very rarely do patients sustain severe musculoskeletal injuries without other systemic injuries; therefore, other sources of blood loss should also be investigated.

Pelvic fractures may occur in patients with isolated simple fractures as well as in critically injured patients with multisystem injuries. The primary causes of pelvic fractures are MVCs, MCCs, and motor vehicle–pedestrian collisions.[33,34] Although pelvic fractures are thought to contribute to traumatic death, they usually are not the main cause.[33] Mortality rates have ranged from 18% to 40%, and death within the first 24 hours was most often a result of acute blood loss.[35] The risk for death is increased in patients who have open pelvic fractures or who have been hit by a motor vehicle. Pelvic ring fractures are associated with high-energy mechanisms, and patients often have soft tissue

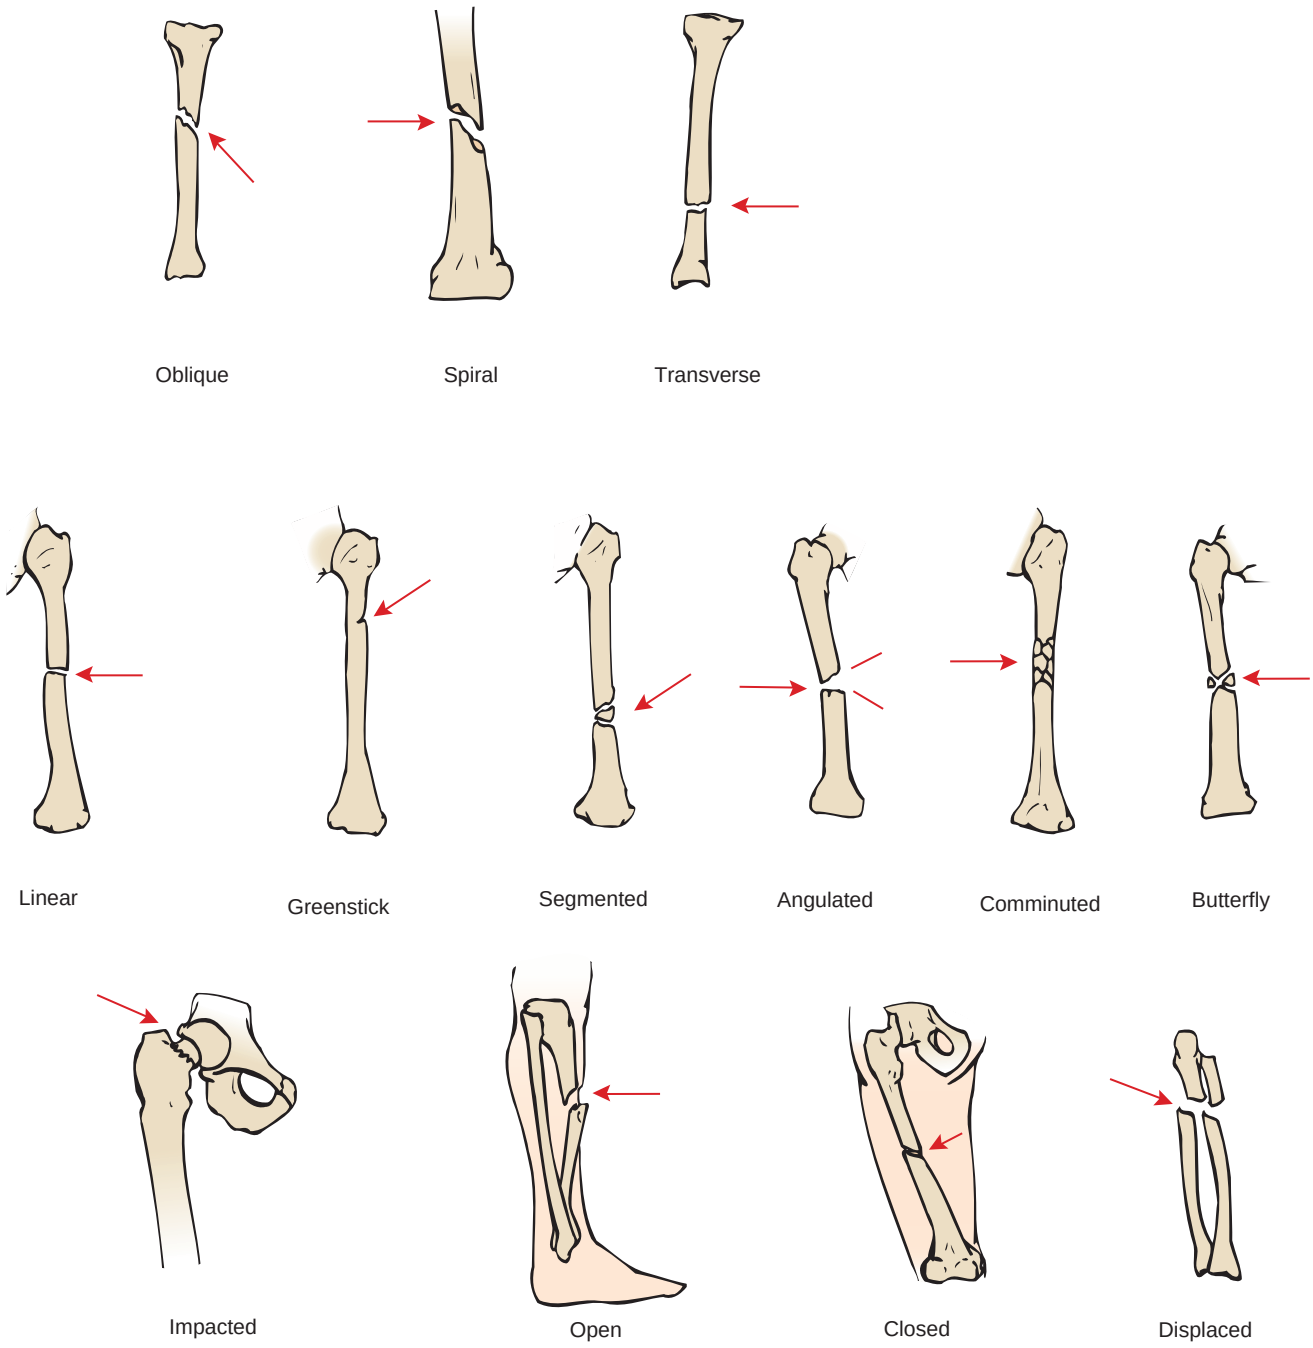

FIGURE 55-6 ▲ There are many different types of fractures.

injury.[36] In hemodynamically unstable patients, it is imperative to find the site of bleeding and control it. Bleeding can occur from three major sources: arterial, venous, and/or cancellous bone.[35]

Physical examination for pelvic fractures begins with inspection for abrasions, lacerations, contusions, and symmetry of the lower extremities. Palpation to assess for rotational and vertical instability is then necessary. Rectal and vaginal examinations should be performed to assess for a urethral tear in males and an open fracture in females.[34]

Radiographic evaluation of pelvic injuries includes an anteroposterior view. This film can detect up to 90% of pelvic fractures. Other radiographs include pelvic inlet and outlet views and lateral sacral views. CT scan is also used to evaluate the sacroiliac joints as well as the extent of the injury.[34] See Box 55-9 for classification of pelvic fractures.

Treatment goals of pelvic fractures are to control bleeding and to prevent loss of function and infection (sepsis) caused by open fractures.[34,36] Application of a pelvic binder or external fixator is used for temporary stabilization and to control bleeding. Embolization is also indicated for hemorrhage control.[34,36] Permanent orthopedic repair of pelvic fractures is usually performed within 24 to 72 hours after injury when the patient is adequately resuscitated and hemodynamically

BOX 55-9 Classification Schemes for Pelvic Fractures

Tile's Classification

Type A, Stable
A1, without involvement of pelvic ring
A2, with involvement of pelvic ring

Type B, Rotationally Unstable
B1, open book
B2, ipsilateral lateral compression
B3, contralateral lateral compression

Type C, Rotationally and Vertically Unstable
C1, rotationally and vertically unstable
C2, bilateral
C3, with associated acetabular fracture

Young and Burgess Classification

Lateral Compression (LC)
I, Sacral compression on side of impact
II, Iliac wing fracture on side of impact
III, LCI or LCII injury on side of impact with contralateral open-book injury

Anterior Posterior Compression
I, slight widening of pubis symphysis or anterior part of sacroiliac joint with intact anterior and posterior sacroiliac ligaments
II, widened anterior part of sacroiliac joint with disrupted anterior and intact posterior sacroiliac ligaments
III, complete disruption of the sacroiliac joint

Vertical Shear
Vertical displacement anteriorly and posteriorly
Combined mechanism
Combination of other injury patterns

From Frakes MA, Evans T: Major pelvic fractures. Crit Care Nurse 24(2):18–32, 2004.

stable. This can be accomplished with either internal or external fixation.

Infection is common in open injuries. Ideally, patients with musculoskeletal trauma are brought to the operating room within 6 hours of injury for a washout of the affected area. Sometimes, antibiotic prophylaxis is started; however, this practice is controversial. A tetanus booster is given if indicated to all patients with open injuries. Other serious complications of musculoskeletal injuries include compartment syndrome, deep venous thrombosis (DVT), pulmonary embolus, and fat embolus syndrome.

Compartment Syndrome

Compartment syndrome occurs when the pressure within the fascia-enclosed muscle compartment is increased, causing blood flow to the muscles and nerves in the compartment to become compromised. The final result is cellular anoxia.[37] It is suspected based on mechanism of injury. This ischemia then leads to tissue damage, which compromises nerve and muscle function. A prolonged elevation of compartmental pressure leads to death of the muscles and nerves involved.[37] Normal compartment pressure is between 0 and 8 mm Hg. Capillary blood flow is believed to become compromised at 20 mm Hg, pain develops at a pressure between 20 and 30 mm Hg, and ischemia occurs at pressures greater than 30 mm Hg.[37] Patients with higher diastolic pressures are able to tolerate higher tissue pressures without ischemic damage. Fasciotomy is recommended when the compartment pressure approaches 20 mm Hg below the diastolic pressure. Hypotensive trauma patients may experience significant muscle ischemia at lower compartment pressures.

Patients with compartment syndrome complain of increased pain in the affected area. Compartment syndrome occurs most often with long bone fractures in the lower leg or forearm.[37] The pain is described as being "out of proportion" to the injury. The most reliable early sign of compartment syndrome is decreased sensation. The compartment involved is firm, and the patient eventually has paresthesia. Pallor and pulselessness are late signs of compartment syndrome. When the compartment syndrome has progressed to the point that the patient is showing late signs, loss of the affected extremity is threatened. The nurse must constantly monitor the affected extremity and compare it with the nonaffected extremity. If any of the signs or symptoms of compartment syndrome are present, the orthopedic or general surgeon should be notified immediately so that compartment pressures can be measured. If it is deemed that the compartment pressures are high, a fasciotomy is performed to release the pressure and save the extremity. The extremity should never be elevated when compartment syndrome is suspected because this will decrease arterial inflow and exacerbate ischemia.[37]

Deep Venous Thrombosis

DVT is a significant risk for all trauma patients, especially those with musculoskeletal injuries. It is known as a common, life-threatening complication of major trauma. The danger of DVT is that it may progress to pulmonary embolus. The administration of low-dose heparin or low–molecular-weight heparin and the use of intermittent pneumatic compression devices are recommended to prevent DVT.[38]

The pathophysiology of DVT, and later pulmonary embolus, is related to Virchow's triad:

1. Venous stasis from decreased blood flow, decreased muscular activity, and external pressure on the deep veins
2. Vascular damage or concomitant pathological state
3. Hypercoagulability

The nurse assesses for signs and symptoms of DVT on a regular basis. These include the presence of Homans' sign (calf pain on dorsiflexion of the foot), swelling of the affected area, tachycardia, fever, and distal skin color and temperature changes.[39] If these signs or symptoms are found, they should be reported immediately. Sometimes, an acute pulmonary embolus is the first indication of DVT.

Pulmonary Embolus

A pulmonary embolus occurs when a blood clot dislodges from the vein, travels through the heart, and lodges in the pulmonary artery, obstructing blood flow. Sudden onset of dyspnea is the classic sign of a pulmonary embolus, but signs and symptoms vary, depending on the size of the clot and the number of vessels occluded. Signs and symptoms may include a decline in oxygenation, substernal chest pain,

hypovolemic relative shock, tachypnea, shortness of breath, anxiety, a feeling of impending doom, a low-grade fever, an altered level of consciousness, and a pale, dusky, or cyanotic skin color. Often, a patient with a pulmonary embolus also has a DVT.[40]

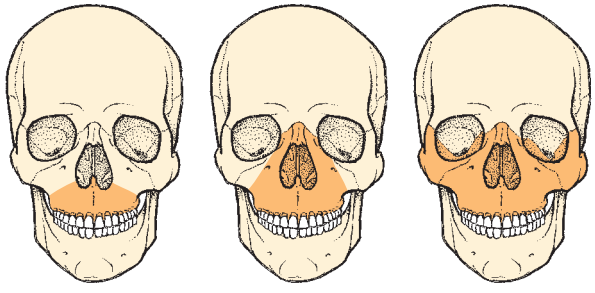
Fat Embolism Syndrome

Fat emboli are fat globules in the lung tissue and peripheral circulation after a long bone fracture or major trauma. Fat emboli may or may not cause systemic symptoms. Fat embolism syndrome is a serious (but rare) manifestation of fat emboli that involves a classic triad of symptoms: hypoxemia, neurological decline, and petechial rash.[41] It usually occurs within 24 to 72 hours of injury. Clinical indications of this syndrome include tachypnea, dyspnea, and hypoxemia.[41] Many patients develop neurological changes after respiratory distress. These changes are usually completely reversible. Petechial rash often occurs on the head, neck, anterior thorax, axilla, and subconjunctiva. It typically lasts 5 to 7 days.[41] Nurses should be aware of the potential for fat embolism syndrome and monitor the patient for hypoxemia with pulse oximetry.

Maxillofacial Trauma

Despite laws that mandate lower speed limits and the use of air bags and seat belts, the incidence of maxillofacial trauma remains high because the face is unprotected during rapid deceleration. The degree of maxillofacial injury is directly related to the force at impact when the face makes contact with a stationary object. As the force increases, the amount of energy that is dispersed increases, causing an increase in injury. Penetrating injury is less common than blunt injury in patients with maxillofacial trauma.

As with any trauma patient, initial management priorities remain ABC. The trauma team cannot be distracted from these priorities by obvious deformities that may be associated with maxillofacial injuries.[42] Maxillofacial trauma can cause airway obstruction and death if airway and breathing are not adequately and urgently established. When the primary survey is completed, an adequate assessment of the maxillofacial injuries is performed. Figure 55-7 shows diagnosis of maxillae fractures according to Le Fort's classification.



A. Le Fort I **B**. Le Fort II **C**. Le Fort III

FIGURE 55-7 ▲ Le Fort fractures. **A:** Le Fort I: Transverse disarticulation of the maxillary dentoalveolar process from the remaining basal bone of maxilla and midface. **B:** Le Fort II: Pyramidal fracture involving entire maxilla and nasal complex. **C:** Le Fort III: Complete craniofacial–midface disassociation. (Courtesy of Neil O. Hardy, Westpoint, CT.)

When assessing for maxillofacial injuries, the nurse assesses soft tissues as well as bony structures. The nurse inspects the face for symmetry and then palpates systematically to observe for any movement of bony structures. Cranial nerves are assessed. Often, maxillofacial injuries coincide with head injuries, reinforcing the importance of a thorough neurological examination (see Chapter 33). Any midface fractures that communicate through the orbit require a thorough ocular assessment and frequent reassessment.

Most maxillofacial injuries involve the soft tissue. In any soft tissue injury, there is potential for contamination. Therefore, each patient's immunization to tetanus is assessed. If needed, a tetanus booster is given. All wounds are assessed for dirt, grease, particles, and other contaminants. Many wounds require an operation for washout to débride the tissue and clean the area.[42] These injuries are usually not life threatening and are treated in the appropriate order. However, even a small abrasion to a person's face can lead to a lifetime of disfigurement; therefore, all injuries must be attended to appropriately.

As stated earlier, in any type of trauma, but especially in maxillofacial trauma when the patient's airway may be compromised, it is imperative to assess and maintain an adequate airway for the patient continuously. Loss of an artificial airway (eg, inadvertent removal of the endotracheal tube) can be life threatening because of soft tissue swelling. It is also essential to assess for and treat hypovolemia secondary to hemorrhage from facial arteries. Epistaxis may also occur with any fracture that communicates with the nose. The nurse continuously assesses the patient's neurological status and reports any abnormalities. The patient's pain and anxiety must be assessed and treated. Many patients with maxillofacial injuries are robbed of their senses. They may be unable to see, smell, taste, or speak secondary to their injury. This is an anxiety-provoking situation; patients require continuous reassurance and medication as necessary. Many maxillofacial injuries require multiple surgeries before the patient is definitively treated.

▲ Complications of Multiple Trauma

Complications associated with multiple trauma are numerous (Box 55-10). Because most trauma patients are in the ICU when these complications develop, the nurse plays an essential role in detecting, preventing, and treating them.

The unexpected nature of trauma tends to amplify fear and anxiety. Therefore, nursing care must also provide psychosocial support for the seriously injured patient and his or her family. A multidisciplinary approach that recognizes concerns and offers frequent explanations is recommended. Special considerations for older trauma patients can be found in Box 55-11.

Death after multiple traumatic injuries, when it occurs, may occur immediately, or it may occur as a result of early or late complications. Immediate deaths occur at the scene and within minutes of the injury. Most common causes of immediate deaths are brainstem or high spinal cord injury, cardiac rupture, transection of the great vessels, and airway obstruction.

BOX 55-10 PATIENT SAFETY

Delayed Complications of Multiple Trauma

Hematologic
- Hemorrhage, coagulopathy, disseminated intravascular coagulation

Cardiac
- Dysrhythmia, heart failure, ventricular aneurysm

Pulmonary
- Atelectasis, pneumonia, emboli (fat or thrombotic), ARDS

Gastrointestinal
- Peritonitis, adynamic ileus, mechanical bowel obstruction, acalculous cholecystitis, anastomotic leak, fistula, bleeding

Hepatic
- Liver abscess, liver failure

Renal
- Hypertension, myoglobinuria, renal failure

Orthopedic
- Compartment syndrome

Skin
- Wound infection, dehiscence, skin breakdown

Systemic
- Sepsis

BOX 55-11 CONSIDERATIONS FOR THE OLDER PATIENTS

Trauma
- Trauma is the seventh most frequent cause of death among the elderly.
- The older person is injured less frequently than the younger person; however, when an older person does sustain injuries, the injuries are more likely to be life threatening.
- The injuries occurring in the elderly population tend to be less severe but are associated with a greater risk for death.
- Falls are the most prominent cause of trauma in the older person.
- Constant monitoring is essential with the older trauma patient.
- Providers should have a decreased threshold for invasive monitoring with an elderly patient, secondary to predisposing conditions and past medical history.
- Management considerations are as follows:
  - Consider cervical osteoarthritis when intubation is necessary.
  - Pain management should be more local if possible (eg, epidural catheter, nerve block).
  - Fluid management should be done cautiously. Older adults require adequate rapid fluid replacement without excess. Consider a pulmonary artery or central venous pressure line for guidance in fluid replacement.
  - Older adults tend to become hypothermic more quickly than younger people. Use warm fluid and warming devices as indicated.

Adapted from Plummer E: Trauma in the elderly. In McQuillan KA, In McQuillan KA, Flynn Makic MB, Whalen E, et al (eds): Trauma Nursing, 4th ed. Philadelphia, PA: WB Saunders, 2009, pp 835–849.

Early Complications

Severe head injuries and hemorrhage are the early complications of multiple trauma most often responsible for causing death within hours of the injury, usually in the emergency department or operating room. Often, death at this stage can be prevented with quick assessment, resuscitation, and management of injuries.

Management of head injuries is discussed in Chapter 36. To prevent exsanguination, hemorrhage must be controlled and volume resuscitation begun with the infusion of crystalloids and blood. Patients may require emergent surgical ligation or packing, or embolization by angiography. Massive hemorrhage complicated by hypothermia, metabolic acidosis, and coagulopathy is highly lethal.

Late Complications

Late complications of multiple trauma include hypovolemic shock, infection and septic shock, ARDS, and multiple organ dysfunction syndrome (MODS).

Hypovolemic Shock

Massive hemorrhage or continued bleeding because of incomplete hemostasis or an undiagnosed injury can lead to hypovolemic shock and eventually decreased organ perfusion. The various organs respond differently to the decrease in perfusion caused by hypovolemia. Multiple blood transfusions are often necessary, further increasing the likelihood of ARDS and MODS.

Infection and Septic Shock

Another frequent and potentially serious complication of multiple trauma is infection. The risk for infection is increased after close-range shotgun blasts, high-velocity penetrating injuries, penetrating wounds to the colon, prolonged surgery, multiple blood transfusions, and injury to multiple organs. Other risk factors include advanced age, underlying immunosuppression, and a history of diabetes mellitus.

Infections can range from a minor wound infection to fulminant sepsis syndrome and septic shock. In septic shock, the release of toxins causes dilation of vessels, leading to venous pooling that results in a decreased venous return. Initially, cardiac output increases to compensate for decreased systemic vascular resistance. Eventually, the compensatory mechanisms fail, and cardiac output falls along with blood pressure and organ perfusion (ie, septic shock).

The source of infection must be found and eradicated to treat sepsis effectively. The nurse must watch for the sometimes subtle indicators of sepsis. Hyperthermia or hypothermia and altered mental status are often present early in the septic process, as well as tachycardia, tachypnea, and an increase in the white blood cell count. These findings should prompt further assessment to detect a possible infectious source.

When sepsis is suspected, cultures are obtained, antibiotics are prescribed, radiological studies are done, and exploratory surgery frequently is performed. Intra-abdominal abscess is a frequent cause of sepsis. Some abscesses can be drained percutaneously, whereas others require surgery. After the surgical drainage of an abdominal abscess, the incision is left open with drains in place to allow healing and prevent recurrence. Other sources of infection are invasive lines, the urinary tract, and the lungs. Pneumonia is a common cause of sepsis in trauma patients. Risk factors for pneumonia include advanced age, aspiration, underlying pulmonary disease, thoracic or abdominal surgery, and prolonged intubation.

Hemodynamics are altered and metabolic demands are increased during sepsis. The typical patient exhibits elevated cardiac output, decreased systemic vascular resistance, and increased oxygen consumption. Hemodynamics must be supported and a balance between oxygen delivery and oxygen consumption maintained. Research suggests that early nutritional support decreases the development of sepsis and MODS. Enteral feeding should be used whenever possible because it is associated with a lower incidence of sepsis than total parenteral nutrition.

Acute Respiratory Distress Syndrome

ARDS refers to a "syndrome of lung injury characterized by dyspnea, severe hypoxemia, decreased lung compliance and diffuse bilateral pulmonary infiltrates."[43] ARDS can be caused by direct (pneumonia, aspiration of gastric contents, inhalation injury, fat emboli, etc.) or indirect (insult anywhere in the body: sepsis, multiple blood transfusions, shock, burns, etc.) injuries.[43]

Sepsis may predispose the patient to ARDS (see Chapter 27). In addition to sepsis, specific injuries (eg, head trauma, pulmonary contusion, multiple major fractures), massive blood transfusions, aspiration, and pneumonia can also increase the likelihood of ARDS. With a mortality rate between 50% and 80%, ARDS is characterized by hypoxemia with shunting, decreased lung compliance, tachypnea, dyspnea, and the appearance of diffuse bilateral pulmonary infiltrates.

Treatment of ARDS is multifaceted. Initially, therapy is aimed at treatment of the primary cause. Fluid and hemodynamic management, management of infection, adequate nutrition, mechanical ventilation, and supportive oxygen delivery are incorporated in the therapeutic regimen. The main goal of ARDS treatment is to increase oxygen in the body.[43]

Systemic Inflammatory Response Syndrome

Systemic inflammatory response syndrome (SIRS) describes a pathophysiological response to a cascade of events precipitated by shock, which usually occurs after trauma. A controlled inflammatory response takes place, designed to heal wounds and ward off infection. Continuous stimulation or severe infection may result in sustained inflammation—SIRS. The result is an imbalance of cellular oxygen supply and demand, causing an oxygen extraction deficit.[8]

Multiple Organ Dysfunction Syndrome

Sixty percent of trauma patients have clinical signs of sepsis without an apparent bacterial source. Many factors have been associated with the development of MODS, including hemorrhage, massive blood transfusion, hypovolemic shock, and sepsis. Characterized by the failure of two or more organs, MODS accounts for many late deaths in trauma patients. Usually, the lungs are the first organs to fail (heralded by the onset of ARDS), followed by the liver, gastrointestinal tract, and kidneys.

Liver failure can result from initial damage, vascular compromise, shock, or sepsis. Jaundice is a common indicator of deteriorating liver function, although other causes, such as posttraumatic biliary obstruction, must be ruled out. Liver function tests are diagnostic. Liver failure can lead to a decreased level of consciousness, abnormal clotting study results, and hypoglycemia (see Chapter 41).

Gastrointestinal failure manifests with hemorrhage from stress ulcers requiring blood transfusion. Prophylactic neutralization of gastric acid can minimize the risk for bleeding (see Chapter 41).

Renal failure can be precipitated by a renal injury, ischemia, radiographic contrast material, rhabdomyolysis, hypovolemia (due to hemorrhage, third spacing), or sepsis. Initial signs include increasing blood urea nitrogen and serum creatinine levels. Renal failure may be polyuric or oliguric. Dialysis may be necessary (see Chapter 30).

Cardiovascular failure, DIC, metabolic changes (eg, hyperglycemia, metabolic acidosis), and central nervous system changes, ranging from confusion to obtundation, also may be evident in MODS (see Chapter 49 for a discussion of DIC).

Psychosocial Considerations

As medical advances extend life expectancy, the elderly population (65 and older) are expected to be greater than 20% of the population by the year 2020.[42] Elderly trauma patients are the fastest growing segment of patients admitted to trauma centers and have a six-time risk of dying when compared with similarly injured younger patients.[42,43] This age group is more active and mobile than ever; however, this leads to an increased risk of injury. This also leads to multiple discussions on end-of-life care, of losing independence, and health care cost.

Another important issue in trauma care is patients' families. It is very difficult to care for a trauma patient because you are caring not only for the patient but also for the family. Trauma is an unexpected event that occurs and disrupts the life of many. Both patients and families go through grief and denial. Many family members are unable to accept that their loved one was injured because they just saw them minutes ago and they were "fine." Many ICUs and resuscitation areas are offering 24-hour visiting and presence during resuscitation to support the patient and the family.

▲ Clinical Applicability Challenges

CASE STUDY

Mr. S. is a 42-year-old male patient who was struck and run over by a trailer. At the time of admission he was awake, very tachypneic, and complaining of difficulty breathing and abdominal pain. His vital signs were as follows: blood pressure was 80/50 mm Hg, heart rate 127 beats/min, and respiratory rate 33 per minute. He is pale and diaphoretic and now complaining of being thirsty.

During Mr. S.'s primary survey, he is intubated and placed on the ventilator. Although his respiratory rate is improved with intubation, he continues to be tachycardic and hypotensive. There is no evidence of outward bleeding.

Once radiographs are obtained, Mr. S. is found to have multiple right-sided rib fractures as well as a pulmonary contusion. He is also noted to have a crushed pelvis on x-ray. His FAST examination is positive for blood in his abdomen. Because he continues to be unstable, he is given multiple units of blood products. Although he is becoming increasingly more difficult to ventilate, he is taken to the operating room emergently for a damage-control laparotomy and then transferred to the ICU with a pelvic binder in place.

1. After reviewing this case study, is there any other information that you would like to know in order to adequately care for Mr. S.?

2. Mr. S. has a pelvic binder in place; what nursing considerations do you need to be aware of when caring for this patient? If Mr. S. continues to show signs of instability despite blood products and an operation, what would you expect the next procedure to be?

3. What expectations do you have for Mr. S.'s lungs after the operation, especially knowing that he was becoming more difficult to ventilate and has rib fractures and a pulmonary contusion?

56 Drug Overdose and Poisoning

Eric Schuetz and Julie Schuetz

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Explain the initial assessment and management of acutely poisoned or overdosed patients.
2. Describe the groups of symptoms that may help identify the drugs or toxins to which a patient may have been exposed.
3. Compare and contrast methods used to prevent absorption and enhance elimination of a drug or toxin.
4. Formulate a plan of care for the poisoned patient.

In 2008, more than 2.49 million exposures to various drugs and toxins were reported to the American Association of Poison Control Centers. Of these exposures, 1,756 resulted in death.[1] The types of toxic exposure reported to poison control centers are diverse: herbal remedies purchased at health food stores, snake and arthropod envenomations, alcohol or drugs, fumes emitted by faulty furnaces, poisonous plants, and industrial hazardous material spills or releases.

Because of clinical experience and new research information, therapy for toxic exposure changes rapidly. Health care professionals may find it challenging to keep abreast of the most advanced therapy. Fortunately, phone consultation with poison control centers offers rapid access to this information. A local poison control center can be reached nationwide by calling 1-800-222-1222. The services of a local poison control center are a useful resource for both health care professionals and the public. Nurses, pharmacists, and physicians with specialized training in clinical toxicology staff such centers.

This chapter presents general guidelines for the assessment and management of the acutely poisoned or overdosed patient. It lists commonly observed poisonings and contains a collaborative care guide for the patient with cocaine toxicity. The chapter ends with a section discussing prevention through patient teaching.

▲ The Poisoned or Overdosed Patient

Poisonings and drug overdoses can cause quick physical and mental changes in a person. Bystanders usually are the ones who must initiate care and call a poison control center or emergency number.

Poisoning

The most common routes of exposure in poisoning are inhalation, ingestion, and injection. Toxic chemical reactions can compromise cardiovascular, respiratory, central nervous, hepatic, gastrointestinal (GI), and renal systems.

Most exposures to toxic fumes occur in the home. Poisoning may result from the improper mixing of household cleaning products or malfunctioning household appliances that release carbon monoxide. Burning wood, gas, oil, coal, or kerosene also produces carbon monoxide. Carbon monoxide gas is colorless, odorless, tasteless, and nonirritating, which makes it especially dangerous.

The ingestion of poisons and toxins occurs in various settings and in different age groups. Poisoning in the home usually occurs when children ingest household cleaners or medicines. Improper storage of these items contributes to such accidents. Plants, pesticides, and paint products are also potential household poisons. Because of mental or visual impairment, illiteracy, or a language barrier, older adults may ingest incorrect amounts of medications. In addition, poisoning may occur in the health care environment when medications are administered improperly.

Similarly, poisoning can also occur in the health care environment when a medication normally given only by the subcutaneous or intramuscular route is given intravenously (IV) or when the incorrect medication is injected. Poisoning by injection can also occur in the setting of substance abuse, as when an addict inadvertently injects bleach or too much heroin.

Substance Abuse and Overdose

Admission of most poisoned patients to a critical care unit is for an intentional or suspected suicidal overdose. As part of their histories, these patients frequently have mental illness, substance abuse problems, or both. Often, withdrawal symptoms complicate the assessment of potential toxidromes. A toxidrome is a group of signs and symptoms (syndrome) associated with overdose or exposure to a particular category of drugs and toxins.

Commonly abused substances are nicotine, alcohol, heroin, marijuana, narcotic analgesics, amphetamines, benzodiazepines, and cocaine. Some children and adolescents turn to common household substances because they are readily available. People who attempt to manage stress through substance abuse require a comprehensive treatment program to address their coping and adaptation problems.

▲ Assessment

A health care facility's systematic approach to the assessment of the poisoned or overdosed patient includes performing triage, obtaining the patient's history, performing a physical examination, and conducting laboratory studies.

Triage

Although some type of triage usually is performed at the scene or by an emergency response team, triage is always the first step performed in the emergency department. Two essential questions to be considered in the triage evaluation are the following: (1) Is the patient's life in immediate danger? (2) Is the patient's life in potential danger? If the patient's life is in immediate danger, the goals of immediate treatment are patient stabilization and evaluation and management of airway, breathing, and circulation (ABC).

History

A history of the patient's exposure provides a framework for managing the poisoning or overdose. Key points include identifying the drugs or toxins, the time and duration of the exposure, first aid treatment given before arrival at the hospital, allergies, and any underlying disease processes or related injuries. This information may be obtained from the patient, family members, friends, rescuers, or bystanders.

Physical Examination

A quick but thorough physical examination is essential. Preliminary examination results lead to the in-depth evaluation and serial assessment of affected systems (actual or anticipated). As noted previously, a toxidrome is a group of signs and symptoms associated with overdose or exposure to a particular category of drugs and toxins. Recognizing the presence of a toxidrome may help identify the toxins or drugs to which the patent was exposed, and the crucial body systems that may be involved. Table 56-1 lists four common toxidromes with their signs and symptoms and common causes.

Laboratory Studies

Relevant clinical laboratory data are vital to the assessment of the poisoned or overdosed patient. Tests that provide clues to the agents taken by the patient include electrolytes, hepatic function, urinalysis, electrocardiography, and serum osmolality tests. A serum level measurement of acetaminophen is obtained in all patients who have overdosed because acetaminophen is a component of many prescription and over-the-counter preparations. In the event of an acetaminophen overdose, the result of the level is plotted against the time since ingestion on the Rumack-Matthew nomogram (Fig. 56-1). Serum level measurements are also available for carbamazepine, iron, ethanol, lithium, aspirin, and valproic acid and may be obtained if these agents are suspected in an overdose.

▲ Management

Management of the poisoned or overdosed patient seeks to prevent absorption of and further exposure to the agent. After triage to determine the status of the patient's ABC, the patient must be stabilized. Treatment begins with first aid at the scene and continues in the emergency department and often in the critical care unit. Advanced general management involves further steps to prevent absorption and enhance elimination of the agent. Antidotes, antivenins, or antitoxins, when available, may be administered. The

Table 56-1 Toxidromes

Toxidrome	Signs/Symptoms	Common Causes
Anticholinergic agents	Delirium; dry, flushed skin; dilated pupils; elevated temperature; decreased bowel sounds; urinary retention; tachycardia	Antihistamines, atropine, jimson weed
Cholinergic agents	Excessive salivation, lacrimation, urination, diarrhea, and emesis; diaphoresis, bronchorrhea, bradycardia, fasciculations, central nervous system (CNS) depression, constricted pupils	Organophosphate insecticides (eg, malathion, diazinon); carbamate insecticide (eg, carbaryl, propoxur)
Opioid agents	CNS depression, respiratory depression, constricted pupils, hypotension, hypothermia	Opiates (eg, codeine, morphine, propoxyphene, heroin), diphenoxylate (eg, diphenoxylate/atropine sulfate [Lomotil])
Sympathomimetic agents	Agitation, tachycardia, hypertension, seizures, metabolic acidosis	Amphetamines, cocaine, theophylline, caffeine

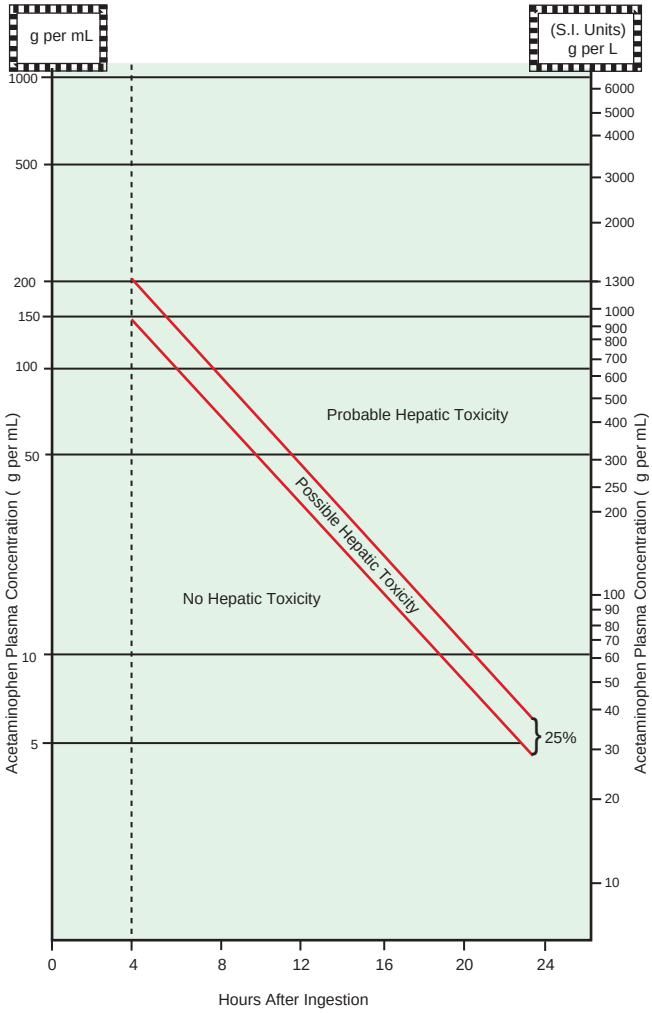

FIGURE 56-1 ▲ Semilogarithmic plot of plasma acetaminophen levels versus time. (From Rumack BH, Matthew HJ: Acetaminophen poisoning and toxicity. Pediatrics 55:871–876, 1975.)

health care team must further support vital functions and monitor and treat multisystem effects. Patient and family teaching to prevent future exposures is another part of the nurse's management strategy. Examples of nursing diagnoses for the poisoned or overdosed patient are listed in Box 56-1.

Stabilization

Stabilization of patients includes performing the steps summarized in Box 56-2, which are also discussed in the following list:

- *Airway patency*. Nasotracheal or endotracheal intubation may be necessary to adequately maintain and protect the patient's airway.

BOX 56-1 EXAMPLES OF NURSING DIAGNOSES

For the Poisoned or Overdosed Patient

- Ineffective Breathing Pattern related to overdose of medication
- Decreased Cardiac Output related to ingestion of poisonous substance
- Impaired Verbal Communication related to overdose of medication
- Acute Confusion related to overdose of medication.
- Impaired Gas Exchange related to carbon monoxide poisoning
- Impaired Swallowing related to poisoning

- *Breathing*. Mechanical ventilation may be necessary to support the patient. Many drugs and toxins depress the respiratory drive. Patients therefore may require ventilator assistance until the drugs or toxins are eliminated from the body.
- *Circulation*. Complications range from shock caused by fluid loss to fluid overload. These are often related to the patient's hydration status and the ability of the cardiovascular system to adjust to drug- or toxin-induced changes. For example, rattlesnake envenomations often cause third spacing of fluid into the area of the bite, leading to intravascular hypovolemia. As a consequence, the patient develops hypotension, which usually responds to aggressive IV fluid therapy. Some toxic drug ingestions impair myocardial contractility, and fluid overload may result because of the heart's inability to pump effectively. In these cases, fluid balance needs to be carefully controlled. Invasive monitoring (eg, central venous pressure, pulmonary artery catheter, Foley catheter with urometer) and drug therapy may be necessary to prevent or minimize complications such as pulmonary edema.
- *Cardiac function*. Many drugs and toxins cause cardiac conduction delays and dysrhythmias. The history of the drugs or toxins involved may not be reliable or even known, especially when patients are found unconscious or have attempted suicide. In these cases, continuous cardiac monitoring and 12-lead electrocardiograms (ECGs) help detect cardiotoxic effects.
- *Acid–base balance and electrolyte homeostasis*. Electrolyte abnormalities and metabolic acidosis frequently occur, which may require serial measurements of electrolytes and arterial blood gases (ABGs), as well as other specific

BOX 56-2 NURSING INTERVENTIONS

For the Stabilization of the Poisoned or Overdosed Patient

- Assess, establish, and maintain the airway.
- Evaluate respiratory effort.
- Maintain adequate circulation.
- Monitor cardiac function.
- Maintain or correct acid–base balance and electrolyte homeostasis.
- Assess mentation.
- Identify injuries and disease processes that increase risk.
- Measure vital signs and temperature frequently to track changes.

laboratory tests. For example, serial measurements of electrolytes, ABGs, and salicylate levels are the means of evaluating aspirin toxicity.

- *Mentation*. Many factors can affect the patient's mental status. Hypoglycemia and hypoxemia are two that can be life threatening but easily addressed by administering oxygen and IV dextrose until laboratory results are available. Naloxone (Narcan) is a narcotic antagonist that reverses narcotic-induced central nervous system and respiratory depression. It is often initially given to comatose patients. However, it must be given cautiously because it can precipitate withdrawal in narcotic-dependent individuals, which may present as violent, agitated behavior, thus placing nurses and other health care providers in danger. In the critical care unit, it may be necessary to continue to administer boluses of naloxone to a patient because of its short duration of action compared with the duration of action of most opioids. In such circumstances, it may be necessary to give naloxone by continuous infusion.[2]
- *Injuries associated with toxic exposure and underlying disease processes*. Any injuries associated with toxic exposure and other underlying disease processes identified during the initial physical examination are treated or monitored, or both. For example, the street drug phencyclidine (PCP) may provoke violent, agitated, bizarre behavior, leading to trauma during the acute toxic phase. Also, for instance, the patient with preexisting ischemic heart disease may not be able to tolerate the hypoxemia associated with carbon monoxide poisoning as well as a young, healthy patient.
- *Vital signs and temperature*. The critical or potentially critical patient's vital signs and temperature are measured frequently to track changes indicating additional problems.

Initial Decontamination

First aid may be given by a bystander, health care provider, or emergency response team or in the emergency department. The physicochemical properties of the agent and the amount, route, and exposure time help determine the type and extent of management required. Decontamination methods for ocular, dermal, inhalation, and ingestion exposures follow.

Ocular Exposure

Many substances can accidentally splash into the eyes. When this happens, the eyes must be flushed to remove the agent. Immediate irrigation with lukewarm water or normal saline solution is recommended. Continuous flooding of the eyes with a large glass of water or low-pressure shower should be done for 15 minutes. The patient should blink the eyes open and closed during the irrigation. An ophthalmological examination is needed if ocular irritation or visual disturbance persists after irrigation.

Dermal Exposure

When dermal exposure occurs, the patient should flood the skin with lukewarm water for 15 to 30 minutes. Most companies that produce or use chemical agents have showers for this purpose. The patient should remove any clothing that may have been contaminated. After standing under running water for the allotted time, the patient should then wash the area gently with soap and water and rinse thoroughly.

Some toxins may require further decontamination. For example, three separate soap-and-water washings or showers are recommended to decontaminate organophosphate pesticides (eg, malathion or diazinon). Protective clothing should be worn to reduce the risk for toxicity while handling contaminated clothing or assisting with skin decontamination.

Although it may seem logical to apply an acid to neutralize a base exposure and a base to neutralize an acid exposure, this can be quite dangerous. Neutralization is the reaction between an acid and a base in which the H^+ of the acid and the OH^- of the base react to produce H_2O (water) and heat. The heat produced by this reaction is significant enough to cause burns. Therefore, neutralizing the skin after a dermal exposure is not recommended.

Inhalation Exposure

A person who has experienced an inhalation exposure should be moved to fresh air as quickly as possible. The responder must also protect himself or herself from the airborne toxin. Further evaluation is needed if the patient experiences respiratory irritation or shortness of breath. Large-scale exposures or those that occur at the workplace may require consultation with a Hazmat team, a group of individuals specially trained to manage exposures to hazardous materials.

Ingestion Exposure

Milk or water dilutes ingested irritants, such as bleach, or caustics, such as drain cleaner. After such an ingestion, adults should drink 8 oz of milk or water, and children should drink 2 to 8 oz (based on their size). Further evaluation is necessary after dilution if there is mucosal irritation or burns. Because of the risk for aspiration, ingestions should not be diluted when they are accompanied by seizures, depressed mental status, or loss of the gag reflex. Again, neutralization is not used because of the risk for thermal burn.

Gastrointestinal Decontamination

Gastric lavage, adsorbents, cathartics, and whole-bowel irrigation are used to prevent absorption of, and forestall toxicity from, almost all drugs and a variety of toxins. The American Academy of Pediatrics no longer recommends the use of emetics (such as of ipecac syrup) for GI decontamination.

Gastric Lavage

Gastric lavage is a method of GI decontamination. Fluid (usually normal saline solution) is introduced into the stomach through a large-bore orogastric tube and then drained in an attempt to reclaim part of the ingested agent before it is absorbed. A small-bore nasogastric tube is ineffective for lavage because particulate matter, such as tablets or capsules, is too large to pass through the tube. If airway protection is necessary, the patient should be intubated before lavage begins.

As noted, a large-bore orogastric tube (36- to 40-French in adults and 16- to 28-French in children) is used to evacuate particulate matter, including whole tablets and capsules. For the lavage, the patient is positioned in the left lateral decubitus position, with the head lower than the feet. Before beginning, the tube should be coated with a jelly lubricant

such as hydroxyethylcellulose. The position of the tube must be confirmed after passing, either by aspirating and checking the pH of the aspirate or by insufflation of air, while listening over the stomach. The lavage is accomplished by attaching a funnel or syringe to the end of the tube and instilling aliquots of 150 to 200 mL (50 to 100 mL in children) of 100°F (38°C) saline solution into the stomach. Placing the funnel and tube below the patient allows the fluid to return by gravity. This procedure is repeated until clear fluid returns or 2 L of fluid has been used. The contents of the stomach can then be collected for drug or toxin identification.

Complications of gastric lavage include esophageal perforation, pulmonary aspiration, electrolyte imbalance, tension pneumothorax, and hypothermia (when cold lavage solutions are used). Lavage is contraindicated in cases of ingestion of caustics or hydrocarbons with a high aspiration potential. Because of the associated risks and the lack of clear evidence supporting its use, gastric lavage should be used only if the patient has ingested a life-threatening amount of a substance and the procedure is undertaken within an hour of the ingestion.[3]

Adsorbents

An adsorbent is a solid substance that has the ability to attract and hold another substance to its surface ("to adsorb"). Activated charcoal is an effective nonspecific adsorbent of many drugs and toxins. Activated charcoal adsorbs, or traps, the drug or toxin to its large surface area and prevents absorption from the GI tract. Box 56-3 identifies both drugs and toxins that are adsorbed effectively by activated charcoal and those not adsorbed effectively.

Activated charcoal is a fine, black powder that is given as a slurry with water, either orally or by nasogastric or orogastric tube, as soon as possible after the ingestion. Commercially available activated charcoal products may be mixed with 70% sorbitol to decrease grittiness, increase palatability, and serve as a cathartic. The usual dose that is given is one 50-g bottle. Administration of more than one dose is controversial and usually is limited to overdoses of large quantities of aspirin, valproic acid, and theophylline. Activated charcoal is used cautiously in patients with diminished bowel sounds and is contraindicated in patients with bowel obstruction.[3]

BOX 56-3 Adsorption of Drugs and Toxins by Activated Charcoal

Drugs and Toxins Well Adsorbed by Activated Charcoal
- Acetaminophen
- Amphetamines
- Antihistamines
- Aspirin
- Barbiturates
- Benzodiazepines
- β-Blockers
- Calcium channel blockers
- Cocaine
- Opioids
- Phenytoin
- Theophylline
- Valproic acid

Drugs and Toxins Not Well Adsorbed by Activated Charcoal
- Acids
- Alkalis
- Alcohols
- Iron
- Lithium
- Metals

Cathartics

A cathartic is a substance that causes or promotes bowel movements. The use of cathartics alone in the management of poisoning is not an acceptable means of GI decontamination. In theory, cathartics decrease the absorption of drugs and toxins by speeding their passage through the GI tract, thereby limiting their contact with mucosal surfaces. Magnesium citrate or 70% sorbitol often is used. Currently, however, there is no clinical evidence that shows that a cathartic can reduce the bioavailability of drugs or improve the outcome of poisoned patients. Data regarding the effectiveness of mixing cathartics with activated charcoal are not yet available. Clearly, more research needs to be done in this area of clinical practice.[3]

Whole-Bowel Irrigation

The goal of whole-bowel irrigation is to give large volumes of a polyethylene glycol with electrolytes solution rapidly (1 to 2 L/h) to flush the patient's bowel mechanically without creating electrolyte disturbances. Used as a bowel preparation for colonoscopy, it is also used as a GI decontamination procedure for patients who have ingested bags or vials of narcotics to avoid arrest, for drug smugglers who pack their GI tracts with narcotics (either orally or rectally), and for patients who have overdosed on modified-release pharmaceuticals.

Commercial products used in whole-bowel irrigation include GoLYTELY and Colyte. Both products are dispensed as powders and are given after adding water. Whole-bowel irrigation is contraindicated in the patient with bowel obstruction or perforation.[3]

Enhanced Elimination of the Drug or Toxin

The pharmacological and kinetic characteristics of a drug or toxin greatly influence the severity and length of the clinical course in the acutely poisoned or overdosed patient. The absorption rate, body distribution, metabolism, and elimination must be considered when choosing methods to eliminate the drug or toxin from the body

Multiple-Dose Activated Charcoal

Administering multiple doses of activated charcoal can result in greater adsorption of certain drugs such as aspirin, valproic acid, and theophylline. Multiple-dose activated charcoal is given orally, by nasogastric tube, or by orogastric tube every 2 to 6 hours. Complications of multiple-dose activated charcoal include aspiration and bowel obstruction.[3]

Alteration of Urine pH

Alkalinizing the patient's urine enhances excretion of drugs that are weak acids by increasing the amount of ionized

drug in the urine. This form of enhanced elimination is also termed ion trapping. The urine is alkalinized by administering a continuous IV infusion of 1 to 3 ampules of sodium bicarbonate per 1 liter of fluid. Urine alkalinization is frequently used in patients experiencing a salicylate overdose. Complications of alkalinization include cerebral or pulmonary edema and electrolyte imbalances. Urine acidification is no longer recommended because of low drug clearance and the risk for complications such as rhabdomyolysis.

Hemodialysis

Hemodialysis is the process of altering the solute composition of blood by removing it from an artery, diffusing it across a semipermeable membrane (between the blood and a salt solution), then returning it into a vein. It is used in moderate to severe intoxications to remove a drug or toxin rapidly when more conservative methods (eg, gastric lavage, activated charcoal, antidotes) have failed or in patients with decreased renal function. Hemodialysis requires consultation with a nephrologist and specially trained nurses to perform the procedure and monitor the patient. Low molecular weight, low protein binding, and water solubility are factors that make a drug or toxin suitable for hemodialysis. Drugs and toxins that may be removed by hemodialysis include ethylene glycol (commonly found in antifreeze), methanol, lithium, salicylates, and theophylline.[4]

Hemoperfusion

Hemoperfusion removes drugs and toxins from the patient's blood by pumping the blood through a cartridge of adsorbent material, such as activated charcoal. An advantage of hemoperfusion over hemodialysis is that the total surface area of the dialyzing membrane is much greater with the hemoperfusion cartridges. As in hemodialysis, drugs that have high tissue-binding characteristics and a large volume distributed outside the circulation are not good candidates for hemoperfusion because little drug is found in the blood. Although rarely used in the poisoned and overdosed population, hemoperfusion has been used successfully in patients experiencing a theophylline overdose.[4]

Chelation

Chelation involves the use of binding agents to remove toxic levels of metals from the body, such as mercury, lead, iron, and arsenic. Examples of chelating agents are dimercaprol (BAL in oil), calcium disodium edetate (EDTA), succimer (DMSA), and deferoxamine. Concerns about the toxicity of the chelators; their tissue distribution characteristics; and the stability, distribution, and elimination of the chelator–metal complex make chelation a complicated procedure.

Hyperbaric Oxygenation Therapy

In hyperbaric oxygenation therapy (HBO) therapy, oxygen is administered to a patient in an enclosed chamber at a pressure greater than the pressure at sea level (eg, 1 atm). This therapy is sometimes used in carbon monoxide poisoning. Elimination of carbon monoxide is as follows: in room air, the half-life of carbon monoxide is 5 to 6 hours; in 100% oxygen, it is 90 minutes; and in an HBO chamber, it is 20 minutes. Complications of HBO therapy include pressure-related otalgia, sinus pain, tooth pain, and tympanic membrane rupture. Confinement anxiety, convulsions, and tension pneumothorax also have been observed in patients receiving HBO therapy.[5]

Antagonists, Antitoxins, and Antivenins

In pharmacology, an antagonist is a substance that counteracts the action of another drug. Although the general public often believes there is an antidote for every drug or toxin, the opposite is closer to the truth. There are, in fact, very few antidotes. Antidotes for specific intoxications are listed in Table 56-2.

Antitoxins neutralize a toxin. For instance, botulism antitoxin trivalent (equine) is available through the Centers for Disease Control and Prevention (CDC) to counteract the effects of botulism.

Antivenins are antitoxins that neutralize the venom of the offending snake or spider. There are several antitoxins; each is active against a specific venom. Recently approved

Table 56-2 Antidotes for Specific Drugs and Toxins

Drug/Toxin	Antidote
Acetaminophen	*N*-acetylcysteine (NAC) (Mucomyst [PO], Acetadote [IV])
Anticholinergics	Physostigmine (Antilirium)
Benzodiazepines	Flumazenil (Romazicon)
β-Blocking agents	Glucagon
Calcium channel blockers	Glucagon, calcium chloride, hyperinsulinemia-euglycemia
Carbon monoxide	Oxygen
Cyanide	Lilly Cyanide Antidote Kit: amyl nitrite, sodium nitrite, and sodium thiosulfate, Cyanokit (hydroxocobalamin)
Digoxin	Digoxin-specific fab fragments (Digibind or DigiFAB)
Ethylene glycol	Fomepizole (Antizol)[6], ethanol
Methanol	Fomepizole (Antizol)[7], ethanol
Nitrites	Methylene blue
Opioids	Naloxone (Narcan)
Organophosphate insecticides	Atropine, pralidoxime

by the U.S. Food and Drug Administration (FDA) is crotalidae polyvalent immune Fab (CroFab), a product that is produced using a purification process that removes the Fc fragment and leaves only the Fab fragments of the immunoglobulins. Typically, this process results in a product that causes fewer reactions in humans. Antivenin (*Latrodectus mactans;* equine) is available for black widow spider bites as well as for envenomations by the eastern and Texas coral snake (*Micrurus fulvius;* equine). However, there are many venomous snakes and spiders for which no antivenin exists. Envenomation from one of these species is treated with symptomatic and supportive care.[6,7]

Continuous Patient Monitoring

Seriously poisoned or overdosed patients may require continued monitoring for hours or days after exposure. Physical examination, the use of diagnostic tools, and careful assessment of clinical signs and symptoms provide information about the patient's progress and direct medical and nursing management. Diagnostic tools include the following:

- *Electrocardiography*. Electrocardiography can provide evidence of drugs causing dysrhythmias or conduction delays (eg, tricyclic antidepressants).
- *Radiology*. Many substances are radiopaque or can be visualized using a contrast-enhanced computed tomography scan (eg, heavy metals, button batteries, some modified-release tablets or capsules, aspirin concretions, cocaine or heroin containers). Chest radiographs provide evidence of aspiration and pulmonary edema.
- *Electrolytes, ABGs, and other laboratory tests*. Acute poisoning can cause an imbalance in a patient's electrolyte levels, including sodium, potassium, chloride, carbon dioxide content, magnesium, and calcium. Signs of inadequate ventilation or oxygenation include cyanosis, tachycardia, hypoventilation, intercostal muscle retractions, and altered mental status. Such signs should be evaluated by pulse oximetry and ABG measurements. Seriously poisoned patients require routine screening of electrolytes, ABGs, creatinine, and glucose; complete blood count; and urinalysis.
- *Anion gap*. The anion gap is a simple, cost-effective tool that uses common serum measurements, such as sodium, chloride, and bicarbonate, to help evaluate the poisoned patient for certain drugs or toxins. The anion gap represents the difference between unmeasured anions and cations in the blood. Using measured anions and a cation, the anion gap is calculated using the following formula:

$$[Na] - ([Cl] + [HCO_3]) = \text{anion gap}$$

The normal value for the anion gap is approximately 8 to 16 mEq/L. An anion gap that exceeds the upper normal value can indicate metabolic acidosis caused by an accumulation of acids in the blood. Drugs, toxins, or medical conditions that can produce an elevated anion gap include iron, isoniazid (INH), lithium, lactate, carbon monoxide, cyanide, toluene, methanol, metformin, ethanol, ethylene glycol, salicylates, hydrogen sulfide, strychnine, diabetic ketoacidosis, uremia, seizures, and starvation. Although these substances and processes can cause an elevated anion gap, a normal anion gap alone does not preclude a toxic exposure.

- *Osmolal gap*. The osmolal gap is the difference between the measured osmolality (using the freezing point depression method) and the calculated osmolality. The calculated osmolality is derived using laboratory values for the major osmotically active substances in the serum, such as sodium, glucose, and blood urea nitrogen (BUN). Like the anion gap, it is a simple, cost-effective tool for evaluating the poisoned patient for certain drugs or toxins. The calculated osmolality (using serum electrolyte values) is defined as follows:

$$2(Na^+) + \frac{\text{glucose}}{18} + \frac{\text{BUN}}{2.8} = \text{calculated osmolality}$$

The osmolal gap is then calculated as follows:

Measured osmolality − calculated osmolality = osmolal gap

An osmolal gap that exceeds 10 mOsm is abnormal. Toxins that can cause an elevated osmolal gap include ethanol, ethylene glycol, and methanol. If an ethanol level is known, it can be factored into the following equation:

$$2(Na^+) + \frac{\text{glucose}}{18} + \frac{\text{BUN}}{2.8} + \frac{\text{BAL}}{4.6} = \text{calculated osmolality}$$

where BAL is the blood alcohol level measured in milligrams per deciliter.

- *Toxicology screens*. A toxicology screen is a laboratory analysis of a body fluid or tissue to identify drugs or toxins. Although saliva, spinal fluid, and hair may be analyzed, blood or urine samples are used more frequently. The number and type of drugs assessed by toxicology screens vary. Each screen tests for specific drugs or agents. For example, drug abuse screens usually identify several common street or prescription drugs, whereas a coma panel detects common drugs that cause CNS depression. Comprehensive screens include many drugs (ranging from antidepressants to cardiac drugs to alcohols) and are more expensive. A number of factors limit the role of toxicology screens in managing poisonings or overdoses. The test sample must be collected while the drug or toxin is in the body fluid or tissue used for testing. For example, cocaine is a rapidly metabolized drug; however, its metabolite, benzoylecgonine, can be detected in the urine for several hours after cocaine use. Also, a toxicology screen with a negative result does not necessarily mean that no drug or toxin is present, but rather that none of the drugs or toxins for which a patient has been screened is present. For example, γ-hydroxybutyrate is not included in toxicology screens because it is rapidly metabolized to small, unmeasurable molecules.

Patient care in some of the more common poisonings and overdoses is summarized in Table 56-3. Clinical manifestations are included in the table. Management of the patient who is toxic with cocaine is summarized in Box 56-4 on page 1272–1273.[8,9]

Patient Teaching

One of the interventions the nurse can perform in the emergency department or intensive care unit is preventive

Text continued on page 1273

Table 56-3 Common Patient Care in Poisonings and Overdoses

Drug/Substance	Clinical Presentation and Assessment	Intervention
Acetaminophen (APAP)		
Common OTC antipyretic and analgesic Often sold as a component of combination drugs for pain, cough, cold, and sleep Examples: OTC remedies such as Tylenol, Tylenol Extended Relief, Tempra, Liquiprin, Panadol, Excedrin PM (diphenhydramine-APAP) and in controlled-substance combination drugs such as oxycodone-APAP (Percocet), codeine-APAP (Tylenol #3), hydrocodone-APAP (Vicodin) Acetaminophen toxicity: hepatotoxicity and occasionally renal dysfunction, 1–3 d postingestion	• Phase 1 (up to 24 h postingestion): anorexia, nausea, malaise • Phase 2 (24–48 h postingestion): clinical picture improves, increase in AST, ALT, and total bilirubin, prolongation of prothrombin time • Phase 3 (72–96 h postingestion): peak hepatotoxicity usually observed • Coagulopathies • Jaundice • AST and ALT may rise into the 10,000–20,000 IU/L range and return to normal without the patient experiencing long-term sequelae. • Chronic toxicity well described in the medical literature	*Prevention of absorption:* • Activated charcoal *Laboratory:* • Draw acetaminophen level at 4 h (or later if patient presents late to the health care facility), plot level on the Rumack-Matthew nomogram (see Fig. 56-1, p. 1263) to determine whether antidote is indicated. • Monitor daily AST, ALT, total bilirubin, blood urea nitrogen, creatinine, and prothrombin time in patients with a toxic acetaminophen level. *Treatment:* • Antidote: NAC • Oral: NAC, Mucomyst • Loading dose: 140 mg/kg orally • Maintenance doses: 70 mg/kg orally every 4 h for a total of 17 maintenance doses • Dilute NAC (20% solution) 3:1 with a soft drink or juice • Repeat any dose not retained 1 h, may need large doses of antiemetics to control vomiting[10] • IV: Acetadote • Loading dose: 150 mg/kg in 200 mL of D_5W IV over 60 min • First maintenance dose: 50 mg/kg in 500 mL of D_5W IV over 4 h • Second maintenance dose: 100 mg/kg in 1,000 mL of D_5W IV over 16 h • Supportive care
Amphetamines		
Group of drugs used therapeutically for narcolepsy, short-term treatment of obesity, and attention-deficit disorder As drugs of abuse, used for ability to stimulate CNS to combat fatigue or produce a “high” Prescription amphetamines and related agents: methylphenidate (Ritalin), dextroamphetamine (Dexedrine), mixed salts of amphetamine (Adderall) Street names: speed, uppers, crank, E, X, ecstasy, ice, crystal	• Flushing • Diaphoresis • Restlessness • Talkativeness • Irritability • Confusion • Panic • Seizures • Intracranial hemorrhage • Hypertension • Tachycardia • Chest pain • Myocardial infarction • Cardiac dysrhythmias • Palpitations • Peripheral vasoconstriction • Nausea • Vomiting • Chronic amphetamine toxicity may lead to the development of paranoia or hallucinations. • IV abusers may also have complications such as hepatitis, sepsis, abscesses, and HIV infection.	*Prevention of absorption:* • Activated charcoal *Laboratory:* • Monitor electrolytes and acid–base status • Urine drug screen may detect amphetamines *Treatment:* • External cooling measures for hyperthermia • Benzodiazepines to control agitation • Severe hypertension controlled with IV nitroprusside (Nipride), other drugs suggested • Supportive care

(*continued on page 1269*)

Table 56-3 Common Patient Care in Poisonings and Overdoses (continued)

Drug/Substance	Clinical Presentation and Assessment	Intervention
Benzodiazepines		
Antianxiety agents, anticonvulsants, muscle relaxants, and sedatives Examples: alprazolam (Xanax), clonazepam (Klonopin), diazepam (Valium), lorazepam (Ativan), midazolam (Versed) Primarily cause CNS and respiratory depression. Due to their low order of toxicity, fatalities unlikely unless ingested with other CNS depressants	• Respiratory depression • Airway protection/gag reflex • Lethargy • Coma • Confusion • Slurred speech • Ataxia	*Prevention of absorption:* • Activated charcoal *Laboratory:* • Urine drug screen may detect benzodiazepines. *Treatment:* • Flumazenil reverses CNS and respiratory depression; due to risk in unmasking controlled seizures, flumazenil is contraindicated in the face of simultaneous potential seizure causing overdose. • Supportive care
Carbon Monoxide		
Colorless, odorless gas that is a component of automobile exhaust, natural gas or propane furnace emissions, cigarette smoke, wood stove emissions, and pollution Methylene chloride, a component found in some paint strippers, is metabolized in the body to carbon monoxide after inhaled or ingested It displaces oxygen from the hemoglobin, leading to hypoxia It is absorbed rapidly by inhalation and combines readily with hemoglobin due to a greater affinity than oxygen Fetal carboxyhemoglobin levels are possibly 10%–15% greater than the maternal carboxyhemoglobin level	• Flu-like symptoms • Headache • Nausea • Vomiting • Syncope • Fatigue • Weakness • Lack of concentration • Irritability • Chest pain, especially in people with underlying cardiovascular disease • Occasionally, irreversible changes in memory and personality • Fetotoxicity • People usually report feeling better when not in the area of the carbon monoxide; for example, if the exposure is occurring in the home because of a faulty furnace, the person will often report a decrease or resolution of symptoms when away from the home.	*Prevention of absorption:* • Fresh air *Laboratory:* • Carboxyhemoglobin levels *Treatment:* • 100% oxygen until all signs and symptoms resolve • Thorough neurological examination • Hyperbaric oxygenation therapy (HBO) to decrease half-life; however, due to lack of available HBO chambers, use is limited and efficacy not well documented by research • Supportive care
Cocaine		
Common street drug that produces a temporary feeling of well-being for the user Routes of exposure: IV, snorting, smoking Street names: crack, rock, coke, snow, blow Toxic effects related to the rapid onset of CNS and cardiac stimulation	• Tachycardia • Hypertension • Cardiac dysrhythmias • Chest pain • Myocardial infarction • Aortic dissection • Bowel infarction • Hyperthermia • Anxiety • Seizures • Tactile hallucinations (“cocaine bugs”) • Cerebral hemorrhage • Cerebral infarction • Rhabdomyolysis • Rapid onset of toxic effects • In pregnant women, abruptio placentae or abortion possible • Chronic snorting, nasal septal perforation If clinical presentation is inconsistent with cocaine alone, possibly adulterants, substitutes, coingestants, or withdrawal	*Prevention of absorption (for ingested packets):* • Activated charcoal • Whole-bowel irrigation *Laboratory:* • Urine drug screen to detect metabolite of cocaine: benzoylecgonine • Cardiac enzymes as indicated to rule out myocardial infarction *Treatment:* • Benzodiazepines such as diazepam (Valium) usually control hyperactivity, hypertension, tachycardia, anxiety, hyperthermia, and seizures. • Phenobarbital may be necessary if seizures not controlled with benzodiazepines. • Life-threatening hyperthermia may be reduced by external cooling measures. • Cardiac monitoring and serial 12-lead ECG are used to evaluate dysrhythmias and myocardial ischemia.[8] • Monitor for other organ ischemia or infarction. • Provide supportive care.

(Continued on page 1270)

Table 56-3 Common Patient Care in Poisonings and Overdoses (continued)

Drug/Substance	Clinical Presentation and Assessment	Intervention
Halogenated Hydrocarbons		
Agents used as propellants and refrigerants Freon, dichlorodifluoromethane (Freon 12) and trichloromonofluoromethane (Freon 11) included in this category Exposures to leaking household air conditioners are usually minor, causing transient eye, nose, and throat irritation; dizziness; and palpitations More concentrated exposures such as in industrial spills or deliberate abuse ("huffing") associated with possible fatal ventricular dysrhythmias (due to myocardial sensitization to catecholamines) and pulmonary edema	• Eye, nose, and throat irritation • Cough • Dizziness • Disorientation • Palpitations • Bronchial constriction • Pulmonary edema • Ventricular dysrhythmias • Frostbite possible with dermal exposures	*Prevention of absorption:* • Fresh air *Laboratory:* • No specific laboratory tests *Treatment:* • Quiet environment • Cardiac monitoring • Frostbite: complete rewarming • Supportive care
Heroin		
Common street drug that produces a temporary euphoria in the user Routes of exposure: IV, snorting Street names: dope, smack, junk	• Miosis • Decreased respiratory drive • Decreased level of consciousness • "Nodding"	*Prevention of absorption:* • Not applicable *Laboratory:* • As clinically indicated • Serum toxicology screen *Treatment:* • Careful administration of naloxone • Referral to substance abuse counselor
Lysergic Acid Diethylamide (LSD)		
Common name for psychedelic drug LSD Common drug of abuse since its rise in popularity in the 1960s Street drug: available in tablet, capsule, sugar cubes, or as a substance on blotting paper known as "blotter acid" One source of LSD is ingestion of morning glory seeds In addition to the psychedelic experience, may result in physical effects and behavior-related trauma during the acute toxic phase	• Anxiety • Impaired color perception • Impaired judgment • Paranoia or ideas of persecution • Time distortions • Blood pressure normal • Tachycardia • Tachypnea • Slight temperature elevation • Flashbacks (transient recurrences of a psychedelic experience) possible after a period of abstinence, may recur for years • Trauma due to behavioral changes associated with LSD use	*Prevention of absorption:* • Activated charcoal • Cathartic *Laboratory:* • Urine drug screen *Treatment:* • Acute anxiety may be managed with IV or oral diazepam (Valium). • A quiet, nonstimulating environment may be useful while trying to help the patient who is experiencing a bad reaction. • Evaluate for evidence of trauma. • Provide supportive care.
Methanol		
Highly toxic antifreeze and solvent Available forms: most windshield washer fluids, Sterno canned heat, and components of some paints, gasoline additives, and shellacs Toxic effects: life-threatening acidosis and irreversible blindness, caused by the toxic metabolite, not the methanol itself	• Blurred vision • Decreased visual acuity • Subjective description of vision as if walking in a snowstorm • Retinal edema • Hyperemia of the optic disk • Headache • Vertigo • Lethargy • Confusion • Coma • Nausea • Vomiting • Abdominal pain • Metabolic acidosis	*Prevention of absorption:* • Syrup of ipecac • Gastric lavage • Activated charcoal and cathartic are of little value *Laboratory:* • Methanol level drawn 1 h postingestion • Serial electrolytes • If using ethanol therapy, serial glucose and blood ethanol level monitored every hour initially *Treatment:* • Treatment is aimed at preventing the formation of toxic metabolites with either Antizol (4-methylpyrazole: 4-MP) or ethanol.

(*continued on page 1271*)

Table 56-3 Common Patient Care in Poisonings and Overdoses (continued)

Drug/Substance	Clinical Presentation and Assessment	Intervention
Methanol		
		• Hemodialysis usually indicated for methanol levels more than 50 mg/dL, visual changes, renal failure, or refractory acidosis. • Folic acid administration to assist with oxidation of the toxic metabolite formic acid to carbon dioxide • Supportive care
Salicylates		
Group of drugs used primarily for anti-inflammatory, antipyretic, and analgesic properties Common sources: aspirin, some formulations of Alka-Seltzer, Aspergum, PeptoBismol, sunscreens, liniments such as Icy Hot, and oil of wintergreen (methylsalicylate) Life-threatening metabolic acidosis, cerebral edema, and pulmonary edema from salicylism Aspirin ingestions difficult to manage due to the formation of a mass of aspirin in the gastrointestinal (GI) tract called a concretion Concretion formation leads to delayed absorption and therefore delayed toxicity Chronic salicylism more common in older adults and easily missed due to lack of careful history taking Higher salicylate levels tolerated with acute overdose as opposed to chronic toxicity	• Tinnitus • Tachypnea • Pulmonary edema • Confusion • Lethargy • Seizures • Cerebral edema • Respiratory alkalosis coupled with metabolic acidosis (initially) • Hypokalemia • Platelet dysfunction • Hypothrombinemia • GI hemorrhage • Nausea • Vomiting • Hyperthermia • Dehydration	*Prevention of absorption:* • Syrup of ipecac • Gastric lavage • Multiple-dose activated charcoal • Single-dose cathartic *Laboratory:* • Serial salicylate levels • Serial electrolytes • Arterial blood gas (ABG) as indicated • Hematological and coagulation studies *Treatment:* • IV hydration • Urinary excretion is enhanced by urine alkalinization (urine pH = 7.5–8.0); IV fluid is usually D_5W with 20–40 mEq KCl and 2–3 ampules of sodium bicarbonate/L to infuse at a rate of 2–3 mL/kg/h to achieve equal urine output Note: It is difficult to alkalinize the urine without a normal serum potassium level. • Potassium is replaced IV as needed. • Monitor onset of cerebral or pulmonary edema; chest radiograph is taken as needed. • Hemodialysis is indicated for renal failure, cerebral edema, pulmonary edema, refractory acidosis, chronic salicylate level more than 50 mg/dL, or acute salicylate level more than 100 mg/dL postingestion. • Provide supportive care Note: Treatment is based on serial salicylate levels and clinical presentation; each case is individually assessed and managed.
Tricyclic Antidepressants (TCA)		
Class of drugs prescribed for depression and chronic pain Examples: amitriptyline (Elavil), clomipramine (Anafranil), desipramine (Norpramin), doxepin (Adapin, Sinequan), imipramine (Tofranil), nortriptyline (Pamelor, Aventyl), protriptyline (Vivactil), and trimipramine (Surmontil)	• Tachycardia • Ventricular dysrhythmias (including ventricular tachycardia and ventricular fibrillation) • Cardiac conduction delays (eg, QRS >100 ms) • Hypotension • Agitation • Sedation • Seizures • Coma • Dry, flushed skin • Decreased GI motility • Urinary retention • Metabolic acidosis	*Prevention of absorption:* • Syrup of ipecac contraindicated because of the rapid onset of sedation or seizures • Gastric lavage • Activated charcoal • Cathartic *Laboratory:* • Serum TCA levels not clinically useful in managing overdoses • Urine drug screen for TCAs • Serial electrolytes and ABGs as indicated *Treatment:* • Prepare for rapid onset of cardiovascular collapse • Seizures may be treated initially with IV benzodiazepines (diazepam, lorazepam) and, if necessary, phenobarbital.

(Continued on page 1272)

Table 56-3 Common Patient Care in Poisonings and Overdoses (continued)

Drug/Substance	Clinical Presentation and Assessment	Intervention
Tricyclic Antidepressants (TCA)		
		• Ventricular dysrhythmias may initially be controlled with systemic alkalinization (keeping blood pH +7.45–7.55 using IV boluses of sodium bicarbonate or intubation and hyperventilation); ventricular dysrhythmias not controlled with systemic alkalinization may be controlled with lidocaine or bretylium (Bretylol); do not use procainamide (Pronestyl) or quinidine due to effects on cardiac conduction similar to those of TCAs. • Cardiac conduction delays (eg, QRS > 100 ms) also are treated with systemic alkalinization as outlined in previous point; conduction delays not responsive to systemic alkalinization may be treated with phenytoin • Hypotension may be addressed initially with Trendelenburg position and IV fluids; if necessary, follow with dopamine infusion; norepinephrine (Levophed) may be necessary. • Provide supportive care.

ALT, alanine aminotransferase; AST, aspartate aminotransferase; OTC, over the counter.

BOX 56-4 *COLLABORATIVE CARE GUIDE for the Patient With Cocaine Toxicity*

Outcomes	Interventions
Oxygenation/Ventilation	
Arterial blood gases (ABGs) are within normal limits.	• Monitor pulse oximetry and ABGs. • Validate significant changes in pulse oximetry with co-oximetry arterial saturation measurement.
Respiratory rate and depth are within normal limits.	• Monitor every 15 min, then every 1 h. • Prepare for intubation and mechanical ventilation (see Collaborative Care Guide for the Patient on Mechanical Ventilation, p. 538).
Circulation/Perfusion	
Blood pressure and heart rate are within normal limits. Patient is free of dysrhythmias. There is no evidence of myocardial dysfunction, such as altered electrocardiogram (ECG) or cardiac enzymes.	• Monitor vital signs every 15 min then hourly. • Provide continuous ECG monitoring. • Monitor 12-lead ECG daily and PRN. • Monitor cardiac enzymes, magnesium, phosphorus, calcium, and potassium as ordered. • Assess for chest pain. • Monitor ECG for dysrhythmias and changes consistent with evolving myocardial infarction.
Patient is euthermic.	• Assess temperature every 15–30 min, then hourly. • Provide a cool environment, and institute cooling strategies (eg, hypothermia blanket, tepid sponge bath), as indicated.
Fluids/Electrolytes	
Patient's urine output >30 mL/h (or >0.5 mL/kg/h)	• Take intake and output hourly. • Administer fluids and diuretics to maintain intravascular volume and renal function per order.
There is no evidence of electrolyte imbalance or renal dysfunction.	• Monitor electrolytes daily and PRN. • Replace electrolytes as ordered. • Monitor blood urea nitrogen, creatinine, serum osmolality, and urine electrolytes daily.

(Continued on page 1273)

BOX 56-4 COLLABORATIVE CARE GUIDE for the Patient With Cocaine Toxicity (continued)

Outcomes	Interventions
Mobility/Safety	
There is no evidence of seizure activity.	• Monitor for seizure activity. • Administer anticonvulsants. • Assess anticonvulsant levels daily if indicated. • Maintain calm, quiet environment.
Patient does not harm self.	• Institute seizure precautions. • Institute fall precautions. • Assess need for physical or chemical restraint to protect from self-injury. • Monitor agitation and administer sedation when appropriate. • Evaluate risk for suicide and take measures to protect patient.
Skin Integrity	
There is no evidence of skin breakdown.	• Document skin integrity every 8 h. • Turn and reposition every 2 h. • Use Braden Scale to assess risk for skin breakdown.
Nutrition	
Caloric and nutrient intake meets metabolic requirements per calculation (eg, basal energy expenditure).	• Provide parenteral or enteral nutrition if patient is NPO. • Consult dietitian or nutritional support service. • Monitor protein and calorie intake. • Monitor albumin, prealbumin, transferrin, cholesterol, triglycerides, and glucose.
Comfort/Pain Control	
Patient will have minimal discomfort related to withdrawal from cocaine and other substances.	• Obtain toxicology screen to identify other substances used by the patient. • Treat drug withdrawal and overdose symptoms promptly and with appropriate intervention (eg, remove from circulation, administer antidote, administer methadone).
Psychosocial	
Patient and family acknowledge substance abuse.	• Assess patient and family response to overdose. • Support healthy coping behaviors. • Consult substance abuse counselor and social worker. • Encourage patient discussion regarding use of illegal drugs, support system, financial concerns, and readiness for substance abuse treatment.
Teaching/Discharge Planning	
Patient and family have information about treatment and self-help resources. Patient and family each have a plan for follow-up care.	• Assess patient and family knowledge and understanding of substance abuse. • Provide literature and explanations to patient and family regarding substance abuse, treatment, relapse, legal issues, and self-help groups. • Refer family to self-help resources. • If patient agrees, initiate referral for substance abuse rehabilitation. • Coordinate referral with patient, family, and social worker to address other possible issues (eg, housing, financial issues, long-term care planning).

teaching. All patients (and parents of pediatric patients) who have survived a toxic encounter should be taught how to prevent such an incident from recurring. Parents of young children need information on child-proofing their home. Family teaching guidelines for lead poisoning are included in Box 56-5. Finally, a summary of poison prevention for the older patient can be found in Box 56-6.

In addition, carbon monoxide detectors alert families to problems in their homes. Utility companies and local health and fire authorities can help identify and remove sources of fumes.

BOX 56-5 TEACHING GUIDE Lead Poisoning

- Lead is commonly found in old homes, in paint, plumbing, and dinnerware.
- Lead is excreted more slowly than it is absorbed, leading to a buildup of lead in the body.
- Accumulation of lead in high levels is frequently missed through lack of blood lead level screening, and not detected until effects such as learning disabilities are diagnosed.
- Children can be tested for lead by their health care providers.
- The local health department can provide lead poisoning treatment and information about lead abatement programs.

BOX 56-6 CONSIDERATIONS FOR THE OLDER PATIENT

Accidental Poisoning

- Poison control centers receive many calls from or related to older adults regarding accidental poisonings.
- Telephone numbers for the health care provider and the poison control center should be in a readily accessible place.
- The older population uses more medicine than any other age group.
- Older people may be more susceptible to the effects of drugs.
- When questions arise concerning drugs, a responsible adult should not hesitate to call a health care provider.
- The patient should not change the dose or discontinue taking prescription drugs without first consulting the physician or nurse.
- Avoid doubling medication when a pill is forgotten. The patient should seek the advice of his or her physician, nurse, or pharmacist.
- Medications and alcohol should not be mixed without first checking with the pharmacist for possible interactions.
- The pharmacist can provide large-print labels.
- A medication calendar or diary will help the older person keep track of the dosing schedule.
- Pill dispensers are helpful for the patient who has to take a variety of pills or who has trouble remembering the prescribed schedule.
- When a medication is discontinued, the remaining medication should be discarded with regard for the environment; for example, it may be returned to a pharmacy for responsible disposal.

▲ Clinical Applicability Challenges

CASE STUDY

D.L. is a 40-year-old, 143-pound (65-kg) woman who is brought to the emergency department by her husband. He states that D.L. took 100 acetaminophen 500 mg tablets 1 hour ago as a suicide gesture. She appears alert, with the following vital signs: blood pressure, 132/76 mm Hg; pulse, 94 beats/min; respirations, 18 breaths/min; and oxygen saturation, 99% on room air. Her pupils were equal and reactive to light. Her skin was warm and dry. She had no complaints of pain. The nurse called the poison control center who recommended that the patient be given 50 g of activated charcoal, and a stat acetaminophen blood level be measured with a repeat level measured at 4 hours postingestion along with liver function tests. The patient drank the charcoal with no complaints of nausea or vomiting, and the initial acetaminophen level came back at 259 mcg/mL. The 4-hour postingestion acetaminophen level was 269 mcg/mL. Initial aspartate aminotransferase (AST) and alanine aminotransferase (ALT) were 28 and 26, respectively, and D.L.'s international normalized ratio (INR) was 1.0. The poison control center recommended that she be given the oral loading dose of *N*-acetylcysteine (NAC) of 140 mg/kg, as she has not had any vomiting or nausea and would likely tolerate the therapy. The patient successfully received her dose of 9,100 mg of the NAC and was admitted to a regular medical bed for further dosing and observation. The poison center recommended that measures of the acetaminophen level, liver function tests, and INR should be repeated 2 hours prior to the end of the second maintenance infusion of the NAC and that the poison center routinely followed up daily to ensure the continuity of care.

Overnight, the patient continued to receive 70 mg/kg (4,550 mg) doses every 4 hours. Morning laboratory values revealed an acetaminophen concentration of 22 mcg/mL at approximately 16 hours postingestion. The AST/ALT values were 44 and 36, respectively, and the INR was 1.2. The following morning, the patient's acetaminophen level was less than 2 mcg/mL, her AST/ALT values were 40 and 47, her INR was 1.3, and her NAC dosing was discontinued, and she was transferred to the psychiatric floor.

1. What are the primary body systems affected by an acetaminophen overdose? Discuss the effects and the implications for nursing care.
2. Why is the time of ingestion so important in an acetaminophen overdose? Discuss the relationship between the time of ingestion and the measured acetaminophen levels.
3. How would the management change if the patient came in several hours after the overdose?
4. What would the options be if the patient were to have intractable vomiting of the oral doses of NAC? Discuss the differences in risk, benefit, and cost of oral vs. IV NAC.
5. What would be the recommendation if, at the end of her prescribed course of oral NAC, D.L still had a measurable acetaminophen level? Elevated AST/ALT? INR more than 2.0?

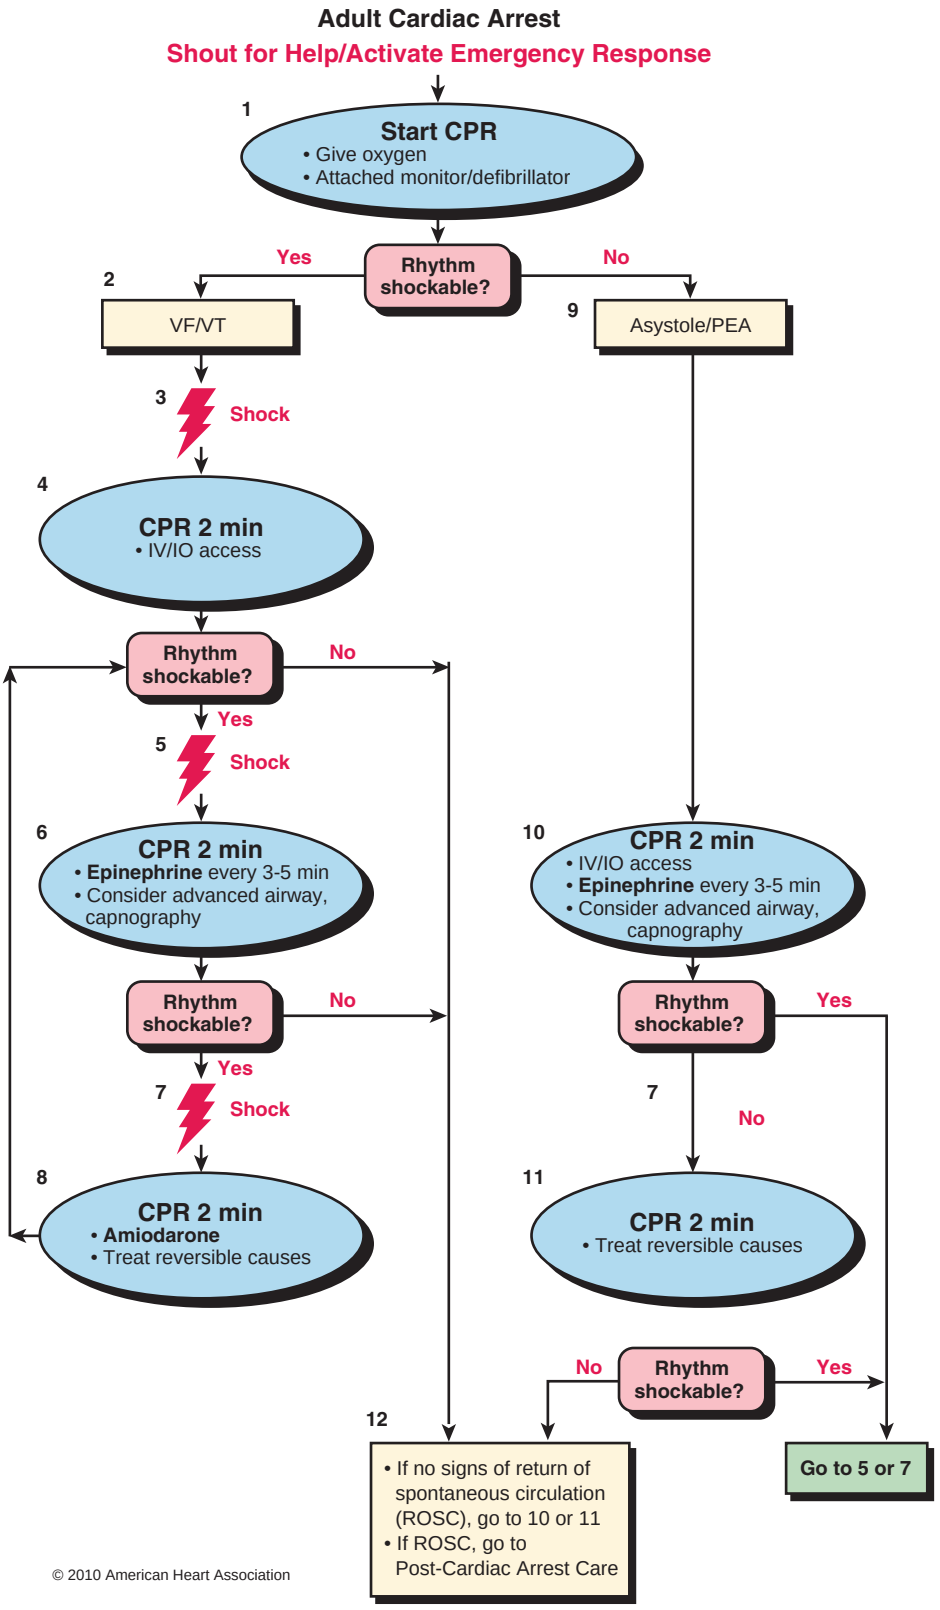
ACLS GUIDELINES



CPR Quality
- Push hard (≥2 inches [5 cm]) and fast (≥100/min) and allow complete chest recoil
- Minimize interruptions in compressions
- Avoid excessive ventilation
- Rotate compressor every 2 minutes
- If no advanced airway, 30:2 compression-ventilation ratio
- Quantitative waveform capnography
  – If P_{ETCO_2} <10 mm Hg, attempt to improve CPR quality
- Intra-arterial pressure
  – If relaxation phase (diastolic) pressure <20 mm Hg, attempt to improve CPR quality

Return of Spontaneous Circulation (ROSC)
- Pulse and blood pressure
- Abrupt sustained increase in P_{ETCO_2} (typically ≥40 mm Hg)
- Spontaneous arterial pressure waves with intra-arterial monitoring

Shock Energy
- **Biphasic:** Manufacturer recommendation (eg, initial dose of 120-200 J); if unknown, use maximum available. Second and subsequent doses should be equivalent, and higher doses may be considered.
- **Monophasic:** 360 J

Drug Therapy
- **Epinephrine IV/IO Dose:** 1 mg every 3-5 minutes
- **Vasopressin IV/IO Dose:** 40 units can replace first or second dose of epinephrine
- **Amiodarone IV/IO Dose:** First dose: 300 mg bolus. Second dose: 150 mg.

Advanced Airway
- Supraglottic advanced airway or endotracheal intubation
- Wave form capnography to confirm and monitor ET tube placement
- 8-10 breaths per minute with continuous chest compressions

Reversible Causes
– **H**ypovolemia
– **H**ypoxia
– **H**ydrogen ion (acidosis)
– **H**ypo-/hyperkalemia
– **H**ypothermia
– **T**ension pneumothorax
– **T**amponade, cardiac
– **T**oxins
– **T**hrombosis, pulmonary
– **T**hrombosis, coronary
