Figure 20-3 shows the areas of cardiac auscultation that are examined in a patient with heart failure. The first (S_1) and second (S_2) heart sounds are expected. The sudden appearance of a third heart sound (S_3) is a warning of impending or worsening heart failure. In chronic heart failure, S_3 is a common and chronic finding. A fourth heart sound (S_4) is common in patients with long-standing hypertension and is not considered ominous. However, in severe heart failure, all four heart sounds may be heard; this is known as a summation gallop.

When valvular disease is the cause of heart failure, a heart murmur associated with the diseased valve is heard. In patients with dilated cardiomyopathy, a mitral regurgitation murmur is commonly heard. This holosystolic murmur is best heard at the left sternal border or, in patients with very large hearts, at the apex. The mitral valve is usually structurally intact. The dilation of the left ventricle in chronic heart failure dilates the mitral annulus and prevents the close approximation of the valve leaflets. Consequently, blood regurgitates back across the mitral valve into the left atrium with each systole.

When a mitral regurgitation murmur develops acutely, as when there is damage to the papillary muscles that open and close the mitral valve, severe, acute heart failure results. The sudden appearance of a mitral regurgitation murmur in a patient with MI is a warning of impending heart failure. The disappearance of this murmur in a patient with severe systolic dysfunction suggests a worsening of the heart failure; the ventricle cannot pump enough to generate the turbulence necessary to make the sound of the murmur.

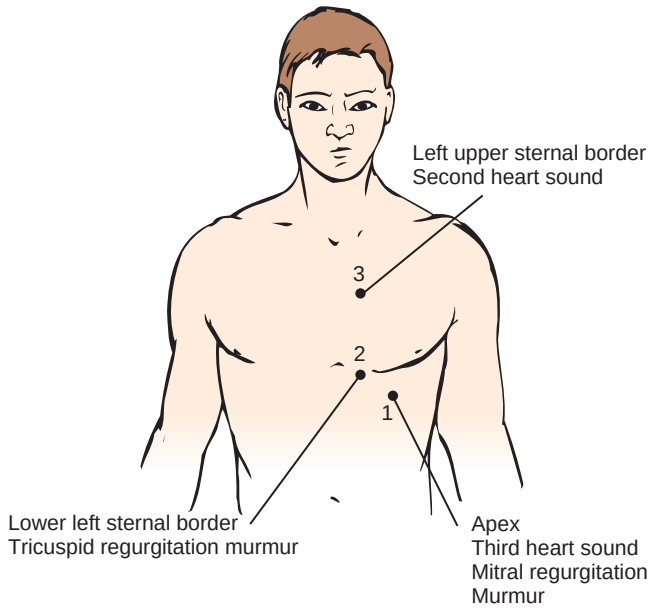

FIGURE 20-3 ▲ Cardiac auscultation in the patient with heart failure.

Tricuspid regurgitation develops in patients with right-sided heart failure alone or from left-sided heart failure for the same reasons as mitral regurgitation. This murmur is also a holosystolic murmur and is heard at the right sternal border. It may increase with inspiration. When both mitral regurgitation and tricuspid regurgitation murmurs are present, it may be impossible to distinguish between them.

Abdomen

It is necessary to palpate and percuss the abdomen to identify any ascites and the lower liver edge. High right atrial pressures that are translated into high venous pressures characterize right-sided heart failure, and the liver, which becomes a reservoir for the increased venous volume, increases in size (hepatomegaly) when congested. Once the liver becomes engorged, pressure increases in the portal vein and in the capillaries of the intestines. When the lymphatic system can no longer drain sufficient fluid to relieve the pressure, ascites develops. Ascites is the transudation or third spacing of fluid, and sometimes protein, into the abdominal cavity. In the absence of hepatomegaly and ascites, a congested liver may conceal significant fluid. Eliciting hepatojugular reflux may identify this concealed fluid. To assess hepatojugular reflux, it is necessary to observe the internal jugular vein while pressing on the liver. When the height of the pulse increases or the vein engorges, hepatojugular reflux is positive.

Extremities

The lower extremities are inspected for edema. The edema associated with heart failure is bilateral, dependent, and pitting. Unilateral or nonpitting edema is not related specifically to heart failure, and other causes, such as arterial insufficiency, myxedema, or lymphedema, should be suspected.

In the ambulatory patient, the edema can be assessed by pressing the skin over the tibia. Pitting here is referred to as pretibial edema. The edema is usually graduated and worse in the ankles than at the calf and is greater than at the thigh if the edema is present that high. In patients who are confined to bed, the edema is dependent posteriorly, and pretibial edema may be absent even in frank fluid overload. The patient must be assessed for pitting edema on the backs of the legs, the buttocks, and back. Occasionally, an ambulatory patient is so volume overloaded that presacral edema develops. To assess presacral edema and pitting, press the skin over the sacrum against the bone.

There are several schemes for describing the severity of pitting edema. None is superior to another; consistency is the most important factor. It is less important whether a series of pluses on a scale from 0 for no edema to 4+ for severe edema is based on the depth of the pit or the height of the edema on the lower extremity. When in doubt about the scale, a clear description of the depth of the pit and the level of the edema communicates the condition more effectively than a subjective number. A clear description allows for better continuity between clinicians and a better estimate of improvement. See Table 51-6 on page 1162 for the Pitting Edema Scale.

Long-standing venous stasis and the consequent edema produce skin color and texture changes. The skin becomes leathery and discolored and may be hard to assess. These changes always indicate that the edema is chronic and not acute. Acute increases in the chronic edema may also be hard to assess. Pressing the skin firmly to the side of the tibia instead of directly over it may be of some help. Figure 20-4 shows the physical assessment findings of a patient with ACC/AHA class D chronic heart failure.

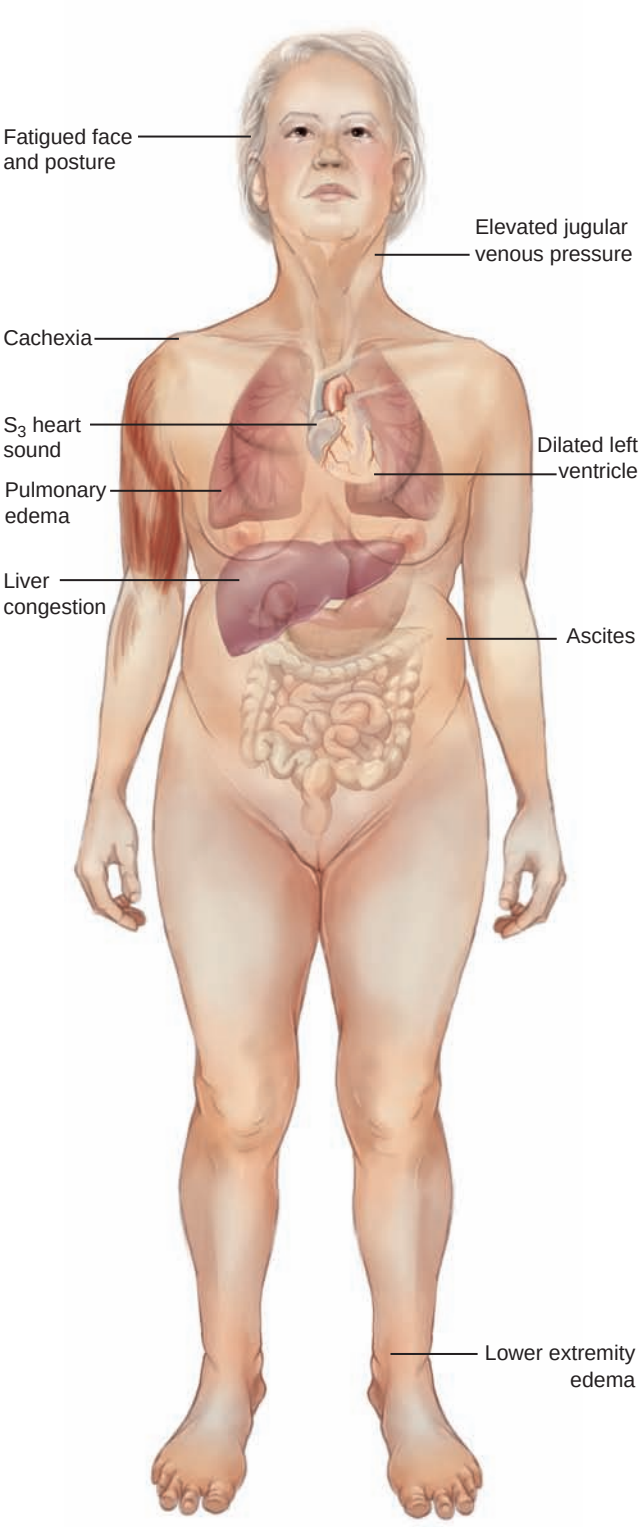

FIGURE 20-4 ▲ Physical examination findings for the person with ACC/AHA class D chronic heart failure.

Laboratory Studies

Laboratory studies are used to rule out some reversible causes of systolic dysfunction and to monitor the effects of management strategies. On initial evaluation of a patient presenting with new-onset heart failure, a battery of baseline laboratory studies is ordered (Table 20-3).

Patients receiving anticoagulation therapy with warfarin are also monitored regularly, using the international normalized ratio to adjust the dose. Before the initiation of amiodarone, patients have thyroid function and liver function tests performed to obtain baseline values, along with pulmonary function tests that include DLCO (diffusion capacity). These tests are repeated at least yearly and when any complications occur.

Brain natriuretic peptide (BNP) is a naturally occurring substance secreted by the ventricles when overfilled. It is elevated in proportion to increases in end-diastolic pressure, and levels may be greater than 1,000 pg/mL. Because the BNP level is also correlated with pulmonary artery occlusion pressure (PAOP), it is sometimes used as a marker of heart failure. Recent approval of laboratory assays for BNP and pro-BNP facilitate the use of BNP in the evaluation of patients with symptoms of heart failure. Patients with BNP levels greater than 80 pg/mL show evidence of elevated PAOP, confirming heart failure decompensation as the source of worsening symptoms.[15,16]

Although the relationship between BNP level and heart failure is clear, the appropriate use of BNP levels in heart failure management is less clear. One important use of BNP levels has been proposed: to distinguish between pulmonary-related and heart failure–related causes of dyspnea in the emergency department.[15] Many patients have both heart failure and lung disease, and the existence of a test that may distinguish between the two conditions as a cause of acute respiratory problems is a real advantage for individualizing and targeting treatment. In addition, BNP has been proposed as a marker for adequacy of treatment and for acute progression of heart failure, but the reliability of BNP for this use has not been established.[16]

Diagnostic Studies

Diagnostic studies are used to establish baseline values, identify potentially reversible etiologies, evaluate the effectiveness of treatment, and assess changes in condition. Several invasive and noninvasive tests are performed routinely when heart failure is suspected. Some tests are performed initially, when the symptoms of heart failure are first identified; some on a regular basis; and others only if indicated.

Electrocardiography

The electrocardiogram (ECG) is used to assess rate and rhythm, and it is also useful in diagnosing dysrhythmias, conduction defects, and MI. In addition, an ECG is often used to identify atrial enlargement and ventricular hypertrophy. However, in such cases, an echocardiogram is more helpful because it can quantify these structural changes.

ECGs are useful in identifying atrial fibrillation and ventricular dysrhythmias common in patients with heart failure. Sudden exacerbation of heart failure symptoms often results from new-onset atrial fibrillation, especially when it is associated with a rapid ventricular response. An ECG can also distinguish frequent premature ventricular beats, which are common in acute and chronic heart failure. Episodes of

Table 20-3 Laboratory Studies Used in the Baseline Evaluation of New-Onset Heart Failure

Laboratory Study	Significance	When Performed
Complete blood count	Used to identify any anemia or infection	Yearly if no specific indication With any exacerbation
Iron studies	Anemia workup Used to rule out hemochromatosis	As needed to evaluate any treatment for iron-deficiency anemia
Thyroid function tests (thyroid-stimulating hormone [TSH] and free thyroxine [T4])	Used to rule out hyperthyroidism or hypothyroidism as a cause of heart failure	No follow-up unless indicated before initiation of amiodarone
Electrolytes	Used to assess the effects of diuresis, in particular on potassium level Hyponatremia is common	With changes in diuretic dose, aggressive diuresis, and titration of drugs that affect potassium (angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers, spironolactone)
Blood urea nitrogen (BUN) and creatinine levels	Used to assess renal function; BUN:creatinine ratio distinguishes between prerenal azotemia and kidney disease	With increased edema or an exacerbation With titration of ACE inhibitors
Liver function tests, especially albumin, bilirubin, and alkaline phosphatase (AP)	Bilirubin and AP are often elevated in liver congestion caused by heart failure Low albumin makes peripheral edema more difficult to reduce	With any exacerbation Before initiation of lipid-lowering drugs or amiodarone
HIV	Used to rule out HIV/AIDS as etiologic factor	As indicated by history or change in status
Lipid panel	Used to assess risk for coronary artery disease and nutritional status	Yearly or more often as indicated to evaluate treatment

asymptomatic NSVT often occur in patients who are monitored in ICUs, in telemetry units, or with Holter monitors. These asymptomatic dysrhythmias are usually not treated, and their prognostic importance is unclear. In contrast, symptomatic ventricular tachycardia, even if it is nonsustained, requires evaluation and usually results in placement of an implantable cardioverter–defibrillator.

Conduction defects are also common in patients with heart failure. A left bundle branch block is the most common conduction defect in patients with systolic dysfunction and may make interpretation of the ECG very difficult. New anterior ischemia or infarct may be impossible to identify because of this block. Bundle branch blocks and AV blocks require a 12-lead ECG for diagnosis.

ECGs are also useful in diagnosing ischemia, MI, and prior MI that may explain new-onset heart failure. For patients who do not present with typical chest pain (such as those with diabetes mellitus and women), the ECG may show a prior MI that was never diagnosed. New-onset heart failure may be the first indication of MI. An ECG is completed as part of the workup for new-onset heart failure and then repeated as necessary for any new symptoms that may reflect new ischemia or a rhythm change. In addition, ECGs are performed on inpatients who experience chest pain to rule out ischemia as the source of the pain. For further discussion of the 12-lead ECG, see Chapter 21.

Echocardiography

Echocardiography uses the reflection of sound waves off cardiac structures to recreate a two-dimensional representation of the heart chambers, walls, valves, and large vessels, such as the aorta, pulmonary artery, and vena cava. This technique provides information about both the structure and function of the heart and is used to measure ejection fraction, evaluate valve structure and competence, and describe wall motion abnormalities. The addition of Doppler ultrasonography to the traditional echocardiogram allows for the evaluation of volume and direction of blood flow through the vessels and the heart. The reliability of echocardiography is greatly influenced by the competence of the echocardiographic technician and the cardiologist who interprets the echocardiograph. Echocardiography is of limited use in patients who are obese, have very large breasts, or have an increased anteroposterior chest diameter and air trapping (eg, patients with COPD).

Transesophageal echocardiography may be performed in addition to the transthoracic echocardiography previously described. The limitations of the transthoracic procedure can be remedied by the use of the transesophageal procedure; however, the risks are increased because the transponder must be passed down the esophagus, and conscious sedation is often required. The ability to assess the mitral valve and to identify transmural blood clots is greatly improved when transesophageal echocardiography is used.

Radionuclide Ventriculography

A radionuclide ventriculogram or multigated acquisition (MUGA) scan is a precise means of calculating ejection fraction using a radioactive isotope. A MUGA scan is currently the gold standard for calculating ejection fraction because it is not based on the subjective analysis of the person who "reads" it. A MUGA scan can describe abnormal wall motion, dilation, and wall thickness in addition to ejection fraction. Valve function and flow direction cannot be evaluated by MUGA scan.

Chest Radiography

Chest radiography is useful in screening the patient with shortness of breath or DOE. It allows the clinician to rule out infection or pneumonia, COPD, or a mass as the cause of the patient's symptoms. Chest radiography may also help identify pulmonary edema and chronic congestion. However, because changes in the patient's condition and fluid status may not be apparent on a chest radiograph for several days, this procedure is not helpful in evaluating therapy.

Exercise Testing

The details of exercise testing for ischemia are described in Chapter 17 and will not be discussed here. Patients with chronic heart failure, particularly NYHA class III and IV, may not be able to walk long enough or fast enough to document ischemia even when it exists and is the cause of worsening symptoms, dysrhythmia, or acute decompensation. Consequently, pharmacologic stress testing may be more helpful in identifying ischemia.

Cardiopulmonary exercise testing is also used to determine whether DOE is more related to cardiovascular causes (ventricular dysfunction), pulmonary causes (COPD, restrictive lung disease), or deconditioning. Such testing is performed when a precise measure of activity limitation is needed or when a patient is being evaluated for heart transplantation. The patient exercises on a treadmill or exercise bicycle while a 12-lead ECG is obtained and blood pressure is measured in response to graded exercise. In addition, all the patient's expired gases are collected and carbon dioxide is measured. This measures oxygen consumption, cardiac index, and anaerobic threshold.

Hemodynamics

The basics of hemodynamic monitoring are also discussed in Chapter 17. The application of hemodynamic monitoring in the assessment and management of acute heart failure and acute decompensation of chronic heart failure is discussed here. It may be necessary to obtain more sensitive information about fluid status, cardiac function, and symptom causation to guide evaluation and therapy. For most patients with acute heart failure or acute decompensation of chronic heart failure, the problem is obvious based on history and physical examination. The problem is a combination of decreased cardiac output and increased left ventricular end-diastolic pressure related to volume overload added to poor contractility. Precise quantification of the low cardiac output or the estimation of left ventricular end-diastolic pressure by PAOP does not change the basic assessments made on physical examination and does not affect management.

Indications for Hemodynamic Monitoring

The decision to use aggressive diuresis or inotropes is not based on any specific numerical values for PAOP or cardiac output. Pulmonary artery catheters are common in critical

care units today, but they are expensive and not without risk. The potential benefit of more specific, guided management must be weighed against the risk associated with pulmonary artery catheter placement. Results of the Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE) trial demonstrated no difference in change in symptoms, days alive and days out of the hospital during the first 6 months, length of stay in the hospital, deaths in hospital, or 30-day mortality. Adverse events were more common with pulmonary artery catheters.[17]

Three types of patients with heart failure may have indications for hemodynamic monitoring in the management of their condition. The first type is the patient who is empirically treated with inotropes and intravenous (IV) diuretics but has not responded appropriately by diuresis and improved symptoms. The second type of patient has both COPD and heart failure. At times, only pulmonary artery pressure measurements can differentiate the source of the current decompensation. BNP testing in this scenario may rule out heart failure when the result is less than 80 pg/mL, but elevations can be caused by either left-sided heart failure or right-sided heart failure associated with pulmonary embolus or exacerbation of COPD. The third type of patient continues to have congestion associated with peripheral edema or ascites and has renal function values indicating worsening azotemia. This patient may benefit from a clearer definition of fluid balance; without the aid of a pulmonary artery catheter, it may be impossible to determine fluid status.

In summary, a pulmonary artery catheter is indicated in the following situations:

- The patient does not respond to empirical therapy for heart failure.
- Differentiation between pulmonary and cardiac causes of respiratory distress is necessary.
- Complex fluid status needs to be evaluated.

These categories are not mutually exclusive, and there is much overlap. They are discussed separately here, for clarity.

INADEQUATE RESPONSE TO EMPIRICAL THERAPY FOR HEART FAILURE. Respiratory distress, volume overload, and renal insufficiency are common indicators of acute heart failure or acute decompensation of chronic heart failure. Typically, the patient needs inotropic support and IV diuresis to resolve the problem. These therapies are usually started empirically, and the patient's improvement is monitored as a basis for titration of dose. In most patients, improvement follows rapidly, and after 2 to 3 days of therapy, the inotrope is gradually discontinued, and the patient is restarted on oral therapy in preparation for discharge.

CARDIAC VERSUS PULMONARY CAUSE OF RESPIRATORY DISTRESS. In the minority of patients who do not respond to empiric therapy, a pulmonary artery catheter may be helpful in identifying any additional factors that have contributed to the persistence of symptoms, especially cardiac and pulmonary causes. It may be particularly difficult to differentiate the cause of worsening DOE, orthopnea, and PND in patients with both pulmonary disease and known heart failure. In COPD and in exacerbations of heart failure, results of history and physical examination are often identical. Pulmonary artery pressures, PAOP, and cardiac output or cardiac index can be very useful in distinguishing COPD from acute heart failure and therefore targeting therapy decisions based on the correct diagnosis. In patients with a predominantly pulmonary cause of their respiratory symptoms, pulmonary artery systolic and diastolic pressures are elevated, but PAOP, cardiac output, and cardiac index are normal. In patients with a primarily cardiac cause, pulmonary artery systolic and diastolic pressures are also elevated, but the PAOP is elevated and the cardiac output or cardiac index is decreased.

COMPLEX FLUID STATUS. Patients may respond initially to IV diuresis with or without inotropes. After this initial diuresis, they begin to have decreased urine output associated with increasing BUN and creatinine levels in the presence of persistent peripheral edema. They are typically referred to as intravascularly dry.

The strategy for dealing with this problem is unclear. Insertion of a pulmonary artery catheter may determine whether high pulmonary artery pressures are the cause and whether those pulmonary artery pressures are elevated because of an elevated left ventricular end-diastolic pressure. The readings can then be evaluated in light of the patient's serum albumin level and any comorbid diseases, such as primary liver failure, sepsis, or vascular insufficiency. Newer hypotheses about the relationship between cardiorenal syndrome and renal venous congestion may better explain this phenomenon.[18]

Pulse Oximetry

Pulse oximetry is a frequently used monitoring device in patients with heart failure. Unfortunately, routine intermittent monitoring is of little value. At best, it gives irrelevant information, and at worst, it enables a false sense of security over the patient's oxygen delivery status (Box 20-3). The results of pulse oximetry should be normal. Decreased estimates of oxygen saturation are usually not the result of heart failure unless the patient has severe pulmonary edema.

A low pulse oximetry reading in patients with heart failure and no pulmonary edema suggests that pulmonary disease is complicating the heart failure. Hypoxemia rarely occurs in the absence of comorbid pulmonary disease. Even patients with Cheyne-Stokes respirations associated with an acute decompensation may have blood oxygen saturations greater than 95%. The pulse oximetry reading is only half of the information needed to assess oxygenation accurately. The oxygen saturation is meaningless unless the hemoglobin level is known as well. Even normal arterial oxygen content in a patient with decreased cardiac output and no reserve may lead to tissue hypoxia. If the arterial oxygen content is decreased, as it is in patients with low hemoglobin (patients are rarely transfused unless the hemoglobin is <10 g/dL), cardiac output may not be able to increase enough to compensate in the patient with heart failure. Pulse oximetry may be of some value when used continuously in an ICU for patients with acute pulmonary edema. Particularly in patients with ischemic cardiomyopathy and MI, continuous monitoring may alert the nursing staff to impending ischemia or adverse effects of analgesia or conscious sedation.

BOX 20-3 Pulse Oximetry

Pulse oximetry (SpO_2) estimates arterial oxygen saturation (SaO_2) or the percentage of hemoglobin (Hgb) saturated with oxygen. Oxygen saturation and hemoglobin are the two major components of arterial oxygen content (CaO_2). The dissolved oxygen in the arterial blood (PaO_2) contributes only a tiny portion of the arterial oxygen content. Arterial oxygen content multiplied by cardiac output (CO) equals tissue oxygen delivery (DO_2). If arterial oxygen content is decreased for any reason, cardiac output (mostly heart rate) increases to compensate. This is why patients with anemia or hypoxemia are tachycardic. As long as cardiac output can increase to compensate for a decreased CaO_2, tissues have sufficient oxygen to carry out their functions and the patient is asymptomatic. When a patient cannot increase cardiac output, as in heart failure, then even modest decreases in CaO_2 produce symptoms and increase the likelihood of an exacerbation or death.

$$(SaO_2 \times Hgb \times 1.34) + (PaO_2 \times 0.0031) = CaO_2$$

$$CaO_2 \times CO \times 10 = DO_2$$

Most nurses would be concerned about a patient with a pulse oximetry reading of 85%, but not one with 98%. The following examples demonstrate that the patient with normal hemoglobin and a pulse oximetry reading of 85% has more oxygen in the blood and a better oxygen delivery than a person with a 98% saturation and a hemoglobin of 10. The patients in all these examples have a normal cardiac output at rest but cannot increase cardiac output in response to decreasing arterial oxygen content.

A patient with normal blood gases and a 5-L cardiac output would have a calculated oxygen delivery of 1,000 mL O_2/min:

$$(SaO_2 \times Hgb \times 1.34) + (PaO_2 \times 0.0031) = CaO_2$$

$$(0.98 \times 15 \times 1.34) + (90 \times 0.0031) =$$

$$19.7 + 0.3 = 20 \text{ mL } O_2/\text{min}$$

$$CaO_2 \times CO \times 10 = DO_2$$

$$20 \text{ mL } O_2/\text{min} \times 5{,}000 \text{ mL} \times 10 = 1{,}000 \text{ mL } O_2/\text{min}$$

Suppose a patient has a low SaO_2 and normal hemoglobin:

$$(SaO_2 \times Hgb \times 1.34) + (PaO_2 \times 0.0031) = CaO_2$$

$$(0.85 \times 15 \times 1.34) + (60 \times 0.0031) =$$

$$17.085 + 0.186 = 17.271 \text{ mL } O_2/\text{min}$$

$$CaO_2 \times CO \times 10 = DO_2$$

$$17.271 \text{mL } O_2/\text{min} \times 5{,}000 \text{ mL} \times 10 = 863.55 \text{ mL } O_2/\text{min}$$

Suppose a patient has a normal SaO_2 and low hemoglobin:

$$(SaO_2 \times Hgb \times 1.34) + (PaO_2 \times 0.0031) = CaO_2$$

$$(0.98 \times 10 \times 1.34) + (98 \times 0.0031) =$$

$$13.132 + 0.3 = 13.44 \text{ mL } O_2/\text{min}$$

$$CaO_2 \times CO \times 10 = DO_2$$

$$13.44 \text{ mL } O_2/\text{min} \times 5{,}000 \text{ mL} \times 10 = 672 \text{ mL } O_2/\text{min}$$

Suppose a patient has low SaO_2 and low hemoglobin:

$$(SaO_2 \times Hgb \times 1.34) + (PaO_2 \times 0.0031) = CaO_2$$

$$(0.85 \times 10 \times 1.34) + (60 \times 0.0031) =$$

$$11.39 + 0.186 = 11.58 \text{ mL } O_2/\text{min}$$

$$CaO_2 \times CO \times 10 = DO_2$$

$$11.58 \text{ mL } O_2/\text{min} \times 5{,}000 \text{ mL} \times 10 = 579 \text{ mL } O_2/\text{min}$$

▲ Management of Acute Decompensation of Heart Failure

Acute decompensation of heart failure is an acute worsening of chronic heart failure and may occur for many reasons. Left ventricular function may deteriorate; heart failure is a progressive disease. If function deteriorates beyond the patient's ability to compensate, then symptoms worsen. Although heart function may be stable, the development of other problems, such as pneumonia, anemia, dysrhythmia, hypertension, or trauma, may tax the ability of the compromised heart to increase cardiac output to meet the increased metabolic demand. Dietary lapses, medication disruption, or lack of vigilance on the part of the patient regarding progressive water weight gain may all contribute to decompensation. If possible, it is important to identify the cause of a decompensation so that a long-term strategy to control the underlying problem can be implemented. However, in the intervening period, an acute decompensation must be treated aggressively, often to save the life of a patient.

The main concerns for the care of patients with acute decompensation of chronic heart failure are the same as in any patient with any life-threatening condition. They start with the basic priorities: airway, breathing, and circulation. Once these issues are addressed, etiologic factors and long-term strategies can become the focus of care.

Airway and Breathing

For most patients with acute symptoms of heart failure, airway patency is not a problem. Likewise, oxygenation is not usually compromised unless pulmonary edema is severe or a comorbid pulmonary disease is present. However, when the acute onset of heart failure or the acute exacerbation is accompanied by profound pulmonary edema, such as in MI or flash pulmonary edema, the airway may become compromised. With severe pulmonary edema, surfactant may be washed out of the alveoli, decreasing lung compliance and making ventilation difficult. In patients who also have COPD or restrictive lung disease, the compromise in compliance may make normal minute ventilation difficult if not impossible. An indication

that normal minute ventilation is not being maintained is increased partial pressure of arterial carbon dioxide ($PaCO_2$) associated with increased work of breathing and respiratory acidosis. For example, a patient may initially do well but tire as the increased work of ventilating wet lungs is prolonged.

Intubation

The usual indications for endotracheal intubation in patients with heart failure are the same as for patients in respiratory distress. Intubation and assisted ventilation are indicated if patients are unable to maintain oxygenation or ventilation. Patients who have pulmonary edema and a persistent oxygen saturation level of less than 90% on 100% oxygen should be intubated and supported until they can obtain oxygen on their own. If the increased work of breathing is leading to fatigue of the respiratory muscles and the $PaCO_2$ is rising in association with a falling pH, intubation is indicated even if the patient is able to breathe unaided. The intubation may not be required for more than 12 to 24 hours, but it may be better to protect the airway than to try to intubate a patient after respiratory arrest. See Chapter 25 for more information about the care of the patient receiving mechanical ventilation.

Diuresis

Once the airway is protected, attention is directed toward reducing pulmonary edema. In most cases, aggressive IV diuresis is indicated. The presence of bilateral crackles on physical examination is not always an indication of total-body volume excess. Evaluation of crackles, along with peripheral edema, liver congestion or ascites, and renal function, allows for a better assessment of fluid status than crackles alone. If volume overload in the patient is determined, then IV diuretics facilitate the rapid excretion of excess fluid and the patient quickly feels better.

Aggressive diuresis usually starts with the patient's oral dose of loop diuretic in IV form. An adequate diuretic response is about 1 liter of urine within 2 hours of the IV dose. If urine output is less than 1 liter, the dose is doubled until a maximum dose is reached (for furosemide, a 400-mg single dose) or until the 1 liter urine output goal is met. If the IV loop diuretic is not sufficient to produce this level of diuresis, a thiazide, such as metolazone, may be given orally along with the loop diuretic.[19] The desired weight loss is 1 to 2 kg/d until the patient's dry weight is reached. Initial weight loss may be greater. Careful monitoring of potassium and magnesium is indicated. If the creatinine level begins to rise in response to the diuresis, then the ACE inhibitor should be held until after the diuresis is complete.[20]

Circulation

Once the airway is protected and breathing is adequate to maintain oxygen and carbon dioxide levels, the circulation of blood to perfuse cells and supply oxygen for cellular function becomes the priority. Two indicators are used to determine the adequacy of perfusion. The first indicator is function of organ systems. Inadequate perfusion affects the brain, leading to confusion and change in level of consciousness; the kidneys, leading to increased BUN and creatinine levels; and the gastrointestinal system, leading to ileus and liver failure. The second indicator is metabolic acidosis. If perfusion is severely inadequate or prolonged past the capacity of the body to buffer the lactic acid produced, the level of sodium bicarbonate decreases, as does the pH, producing metabolic acidosis. Metabolic acidosis is a system-wide measure of inadequate oxygen to meet the metabolic demands of tissues.

Hypotension alone is not sufficient to diagnose hypoperfusion in patients with heart failure because many such patients are chronically hypotensive. Hypotension associated with hypoperfusion should be treated in a way that increases flow without increasing afterload. The problem is decreased cardiac output caused by decreased contractility. Whether the patient has acute heart failure associated with cardiogenic shock or acute decompensation of chronic heart failure, the goal of treatment should be to increase cardiac output. Several interventions increase cardiac output.

The normal physiological response to decreased cardiac output is vasoconstriction and increased afterload. In patients with heart failure, afterload may be increased without a dramatic increase in blood pressure, and it is not safe to assume that a low blood pressure means a decreased afterload. Decreasing afterload increases stroke volume, and even in patients with low blood pressures, the increase in stroke volume and perfusion more than compensates for the low blood pressure.

One system for classifying patient symptoms and severity of congestion was developed by Nohria et al.[21] This 2 × 2 table can be used as a foundation for guiding therapy. Figure 20-5 is a representation of this original work.

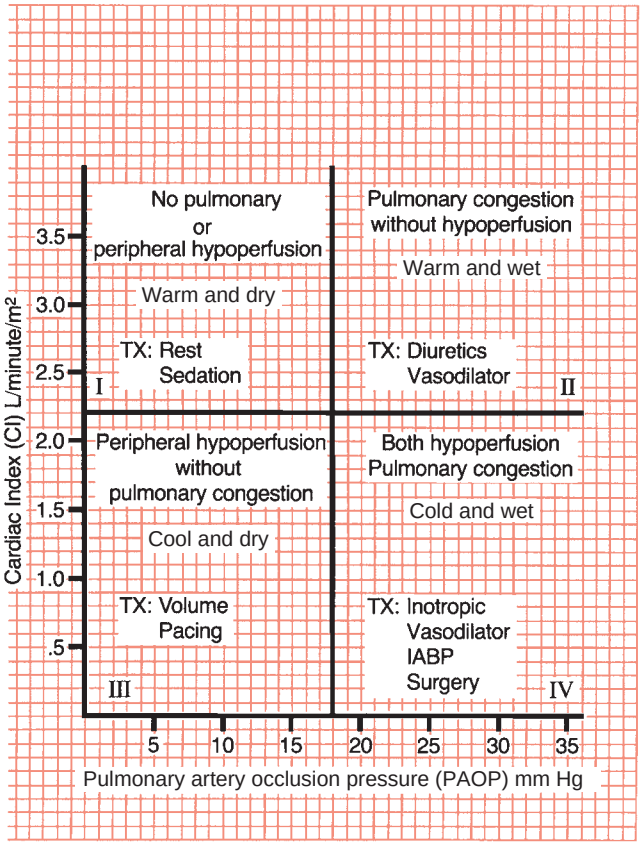

FIGURE 20-5 ▲ Forrester subsets: clinical states and therapy. IAPV, intra-aortic balloon pumping. (Woods SL, Froelicher S, Motzer, SA, et al: Cardiac Nursing, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 584.)

Optimize Hemodynamics

One way to increase cardiac output is to optimize preload.[21,22] If a patient is dehydrated or has fluid overload, contractility is compromised. Both the "warm and wet" and "cold and wet" categories benefit from diuresis. The "cold and wet" category may be impossible to diurese without inodilator or mechanical support. The "cold and dry" category usually requires careful rehydration.[23]

Decreased preload is usually related to iatrogenic overdiuresis. However, patients who are on stable doses of diuretics may become dehydrated if they become hyperglycemic or experience vomiting and diarrhea while continuing to take the prescribed diuretic dose. Careful fluid repletion usually corrects this problem and improves cardiac output. The symptomatic hypotension and increased BUN and creatinine that are the hallmarks of decreased preload should quickly return to baseline levels.

More commonly, increased preload or congestion is a problem; patients are total-body volume overloaded. The combination of fluid overload and decreased contractility leads to cardiopulmonary congestion with increased pulmonary artery pressures and overfilling of the heart. When the heart is overfilled, it becomes stiff and does not empty or fill well. The result is compromised stroke volume and sometimes localized ischemia. The ischemia further worsens contractility. Patients may present with classic angina even if they have no documented CAD. Diuresis with IV loop diuretics often restores the pressure–volume dynamics that optimize stroke volume. For patients who do not respond to diuresis, increasing contractility may decrease preload.

Persistent pulmonary artery pressure elevations lead to jugular venous congestion, liver congestion, ascites, and lower extremity edema. Newer theories of cardiorenal syndromes suggest that this congestion extends to the renal venous system raising efferent pressures sufficiently to impair afferent flow and decreasing glomerular filtration rate (GFR). The decreased GFR leads to the increase in BUN, creatinine, and BUN/creatinine ratio, resulting in poor response to diuresis and persistent symptoms despite an adequate cardiac output at rest.

Increase Contractility

To increase cardiac output, it may be necessary to increase contractility and decrease afterload. Drugs that directly increase contractility are called inotropes. All inotropes increase myocardial oxygen consumption. To be useful in patients with heart failure, there must be greater improvement in oxygen delivery than in oxygen consumption. For this reason, inotropes, such as epinephrine and isoproterenol, are not used.

The following are indications for using inotropes:

- Low cardiac output and high PAOP, especially with symptomatic hypotension
- High PAOP with poor response to diuretics in volume-overloaded patients
- Severe right-sided heart failure that is the direct result of left ventricular failure
- Symptoms of heart failure at rest despite excellent maintenance therapy.

Dopamine is also an excellent inotrope at mid-level doses. However, because dopamine is also a vasoconstrictor, especially at higher doses, it increases afterload in patients with heart failure and decreases stroke volume or, at the very least, does not increase it. Although there are no data to support its use, so-called renal-dose dopamine has been used frequently in patients with heart failure.[27] The use of renal-dose dopamine has been based on the knowledge that the effects of dopamine are dose related. At low doses of 1 to 3 mcg/kg/min, the hypothesized main effect of dopamine is stimulation of dopaminergic receptors that dilate renal and splanchnic circulations. Higher doses have inotropic and vasoconstrictor activity. There is no evidence supporting the routine administration of dopamine to improve diuresis or prevent acute renal failure

Drugs called inodilators are used to stimulate β-adrenergic receptors located in the heart and blood vessels to increase contractility and cause vasodilation.[27] The two inodilators most commonly used in ICUs are dobutamine and milrinone. Although these drugs have different pharmacological mechanisms, they both increase stimulation of β-adrenergic receptors. Because they stimulate β-adrenergic receptors, they are also chronotropic (ie, they increase heart rate), and they must be used carefully and titrated slowly in patients with tachycardia or ventricular dysrhythmia.

The effect of inotropes and inodilators can be measured when a pulmonary artery catheter is in place. As the drugs are titrated to optimum doses, cardiac output increases, and the PAOP decreases. Urine output should increase, and BUN and creatinine levels should return to baseline levels. Any organ function that was compromised because of inadequate perfusion should improve.

Vasodilation

Sometimes an inodilator alone is not sufficient to decrease afterload adequately. In patients with cardiogenic shock or patients who have an exacerbation related to hypertensive emergency, the afterload is the primary limiting factor. Decreasing and controlling the blood pressure or decreasing the workload of the damaged myocardium requires immediate treatment, and vasodilation with parenteral medications is necessary to maintain life or limit end-organ damage. Nitroprusside has the most rapid onset with the shortest half-life of any of these medications. It provides for rapid, efficient decrease in blood pressure, and the effect is limited to minutes if the medication is stopped because of an exaggerated response. Nitroprusside must be given as a continuous drip and requires reliable monitoring of blood pressure in a setting where emergency resuscitation is available.

Nesiritide, a BNP, has been approved as a vasodilator for treatment of acute decompensation of chronic heart failure.[22,24,25] It is unclear whether this vasodilator has any advantages over nitroprusside or nitroglycerin. Although nesiritide was originally marketed as superior to other vasodilators, questions were raised about increased risk of renal dysfunction and mortality. Much controversy still exists as to the appropriate use of nesiritide.[25]

For intermittent blood pressure control, IV or oral hydralazine provides vasodilation with a decrease in afterload, without any negative inotropic effects. Sublingual nifedipine should never be used to control blood pressure.[2] IV nitroglycerin is valuable in decreasing preload and in treating angina associated with hypertensive emergency, but it is not a good afterload reducer or antihypertensive.

Intra-aortic balloon counterpulsation has proved very successful in reducing afterload in cardiogenic shock by augmenting perfusion pressure and decreasing the workload of the left ventricle. Intra-aortic balloon counterpulsation is often critical

to survival in patients with acute MI who suffer acute left ventricular failure. Intra-aortic balloon counterpulsation is used for a limited time for support of the patient until a revascularization procedure can restore oxygenation and function or until the stunned myocardium has recovered somewhat (in a patient who cannot be revascularized). For a more detailed discussion of intra-aortic balloon counterpulsation, see Chapter 18.

Improvements in design and increased experience with left ventricular assist devices (LVADs) as well as FDA approval and Medicare reimbursement have led to increased use of these devices in treating intractable heart failure.[26] Where once LVADs were only approved as a bridge to transplant for those patients who were already on a waiting list for transplant, they are now used as destination therapy. That is, for patients who are not eligible for or do not desire transplant, LVADs are now used to treat heart failure. Devices include battery-operated functions that allow the patient to go home, socialize within the community, and to be an active participant in daily life.

Heart Rate

Heart rate and rhythm must be optimized for adequate cardiac output. If the heart rate is too slow, such as in sick sinus syndrome, second- or third-degree AV block, or sinus bradycardia, stroke volume cannot be increased adequately to compensate, resulting in an exacerbation. A heart rate that is too slow or too fast can compromise filling and, in patients with ischemia, can contribute directly to decreased contractility. A fast rate may be a compensation for a decreased stroke volume and usually responds to increasing stroke volume.

The administration of β-adrenergic inotropes may improve heart rate along with the inotropic effect and greatly improve cardiac output. However, the reason for the bradycardia must be identified and treated if the improvement is to be sustained. In many cases, problems with bradycardia result from ischemic damage to the conduction system. In this situation, a permanent pacemaker resolves the problem. If the bradycardia is the result of active ongoing ischemia, a temporary pacemaker along with treatment of the ischemia is indicated. (For a more detailed discussion of cardiac pacemakers, see Chapter 18.) If the bradycardia is the result of medication, the medication should be withheld or discontinued until the indication for the medication can be reevaluated. In this situation, β-blockers may be withheld for 24 to 36 hours but should not be discontinued suddenly. If the bradycardia is the result of β-blockers, temporary pacing may be required while the drug dosage is titrated down.

Sinus tachycardia is usually the result of decreased stroke volume and therefore cardiac output. Treatment of the tachycardia without increasing stroke volume leads to worsening end-organ perfusion. Sinus tachycardia usually resolves if the underlying decrease in stroke volume is corrected.

When the tachycardia is caused by atrial flutter or atrial fibrillation with rapid ventricular response, the heart rate is the cause of the problem, and it is necessary to control this directly. If the patient is unconscious secondary to the heart rhythm, direct-current countershock cardioversion is indicated. Otherwise, mechanical methods such as the Valsalva maneuver or carotid massage may be helpful. If medication is required to slow the rhythm, amiodarone is the least dangerous medication to use in systolic dysfunction. Calcium channel blockers, such as verapamil and diltiazem, are powerful negative inotropes and may aggravate the low–cardiac-output state. In many cases, the tachycardia is associated with ischemia or hypertensive crisis, and treatment of the underlying problem also treats the tachycardia.

BOX 20–4 EXAMPLES OF NURSING DIAGNOSES

- Decreased Cardiac Output related to altered preload
- Decreased Cardiac Output related to altered contractility
- Decreased Cardiac Output related to altered heart rate
- Activity Intolerance related to decreased cardiac output and deconditioning

After the patient is stabilized and cardiac output has been supported by inodilators or vasodilators, any uncontrolled comorbid diseases that may have triggered or worsened the exacerbation must be treated. Anemia with a hemoglobin level of less than 10 g/dL should usually be treated with transfusion, although this recommendation has recently been questioned. Transfusion is more clearly indicated in an anemic individual who is ischemic with diffuse CAD who is not a candidate for PCI and who is symptomatic or unstable, although this remains a decision based more on art than on science.[2] Pneumonia or other infection should be diagnosed and treated with the appropriate antibiotics. Blood glucose levels should be controlled using insulin if necessary. Examples of nursing diagnoses for heart failure are shown in Box 20-4.

Effective management of chronic heart failure is a key to the prevention of ADHF. Not all ADHF can be prevented because, even when medical regimens are optimal, patients are excellent at self-care, and providers have frequent and regular contact with patients and their care givers; events outside of their control can lead to decompensation. There should be a concerted effort to adequately reduce congestion, prescribe guideline-based medication regimens and educate patients and their care givers prior to discharge. It is critical then to understand guideline-based management of chronic heart failure.

▲ Management of Chronic Heart Failure

Heart failure is not a true disease but rather a manifestation of disease. Management is based on the same therapeutic principles that apply to any disease. The cause of disease should be identified and then treated. If an etiologic factor cannot be identified or cannot be treated, then its manifestations should be treated. Often, the cause of heart failure is not identified, and even when it is, it may not be reversible. Reversible causes of heart failure have been discussed previously and are not addressed here. Isolated right-sided heart failure (cor pulmonale) also is not addressed here.

Heart failure due to diastolic dysfunction is a complex and poorly defined entity. Few studies of investigational medications or therapies have included patients with diastolic dysfunction, and consequently, there is little in the way of evidence-based therapy. In general, treatment strategies are directed toward controlling blood pressure, fluid volume, and heart rate and rhythm. There is no consensus as to how this control should be established and maintained.

Chronic heart failure secondary to dilated cardiomyopathy and systolic dysfunction is better defined. This section discusses the current evidence-based guidelines for managing chronic heart failure and acute decompensation. When appropriate, management of acute heart failure is distinguished from management of acute decompensation; the use of IV inotropes, diuresis, and afterload reduction is similar in both conditions.

Pharmacological Treatment

The ACC and the AHA have published a consensus of evidence-based guidelines for the pharmacological management of heart failure[2] (Table 20-4). These guidelines present the most current recommendations based on available clinical trials for the medical management of heart failure. For example, heart failure in older patients has particular management implications (Box 20-5).

Table 20-4 Medications Used in the Treatment of Heart Failure

Drug	Action	Starting Dose	Target Dose	Indications, Contraindications, Adverse Effects
Chronic Heart Failure				
ACE inhibitors Lisinopril Enalapril Captopril	Block renin–angiotensin–aldosterone system, decrease symptoms and mortality Block conversion of angiotensin I to angiotensin II for afterload reduction	Lisinopril: 2.5–5 mg daily Enalapril: 2.5–5 mg twice daily Captopril: 6.25–12.5 mg twice daily	Lisinopril: 20–40 mg daily Enalapril: 10–20 mg twice daily Captopril: 50 mg twice daily	May cause angioedema, hyperkalemia, increased creatinine, symptomatic hypotension
Hydralazine	Pure vasodilator Used to decrease afterload	10–25 mg PO every 6–8 h	75 mg PO every 6 h or 100 mg PO every 8 h	May cause tachycardia Used for intolerance of ACE inhibitors, for additional blood pressure control, or for afterload reduction in severe mitral regurgitation or atrial insufficiency
Nitrates Isosorbide dinitrate Isosorbide mononitrate	Decrease preload, relieve angina, decrease orthopnea	Isosorbide dinitrate: 10 mg every 6 h (hold midnight dose) Isosorbide mononitrate: 30 mg daily	Isosorbide dinitrate: up to 40 mg every 6 h (hold midnight dose) Isosorbide mononitrate: up to 120 mg daily	Dose limited by symptoms such as headache or hypotension Use least dose that relieves symptoms
Digoxin	Oral inotrope Blocks neurohormonal bombardment of heart	0.125–0.25 mg PO daily	Same	Limited by renal excretion; smaller doses used when creatinine is >1.3 mg/dL Dose should be decreased in patients receiving amiodarone
Diuretics Furosemide Metolazone	Control fluid volume	Furosemide: 20–40 mg (in patient who has never been on diuretics) Metolazone: 2.5–5 mg daily	Up to 320 mg twice daily if necessary to control fluid Metolazone 10 mg daily if necessary in addition to furosemide	Diuretic dosage requirements are higher during aggressive diuresis than during maintenance Combination of furosemide and metolazone is very powerful, and loss of potassium, magnesium, and calcium can be dramatic, increasing risk for dysrhythmia
Spironolactone	Blocks effects of aldosterone and protects potassium	25 mg daily	25 mg daily	May cause hyperkalemia, so potassium should be monitored regularly May cause gynecomastia in men
β-Blockers Metoprolol SR Carvedilol Bisoprolol	Improve symptoms, increase exercise tolerance, decrease hospitalizations and mortality	Metoprolol SR: 12.5 mg daily Carvedilol: 3.125 mg twice daily Bisoprolol: 1.25 mg daily	Metoprolol SR: 100–200 mg daily Carvedilol: 25–50 mg twice daily Bisoprolol: 10 mg daily	May precipitate exacerbation during initiation and titration Monitor weight and heart rate carefully; do not stop drugs suddenly Benefit is long term and may not be evident for up to 3 mo

(continued on page 409)

Table 20-4 Medications Used in the Treatment of Heart Failure (continued)

Drug	Action	Starting Dose	Target Dose	Indications, Contraindications, Adverse Effects
Acute Heart Failure and Acute Exacerbation of Chronic Heart Failure				
Inodilators Dobutamine Milrinone	Increase contractility, decrease afterload and therefore increase cardiac output Increased forward flow decreases left ventricular end-diastolic pressure	Dobutamine: 2–5 mcg/kg/min Milrinone: 0.2–0.3 mcg/kg/min (with or without loading dose)	Dobutamine: 5–15 mcg/kg/min Milrinone: 0.375–0.7 mcg/kg/min	Use smallest dose that produces desired hemodynamic effect May cause tachycardia and ventricular dysrhythmias Can be given effectively to patients who are receiving β-blockers
Dopamine	May increase renal perfusion and improve diuresis	1–3 mcg/kg/min	1–3 mcg/kg/min	The higher the dose, the more likely dopamine is to increase afterload Do *not* give through a peripheral line
Nitroprusside	Used for afterload reduction and blood pressure control	0.5 mcg/kg/min	Up to 1.5 mcg/kg/min	High doses or prolonged administration is associated with increased cyanide levels and should be avoided
Nesiritide	Used for afterload reduction	2 mcg/kg/min bolus with 0.01 mcg/kg/min infusion	Increase by 0.005 mcg/kg/min to maximum of 0.3 mcg/kg/min	Use caution if systolic blood pressure <90 mm Hg
Hydralazine	Used for afterload reduction and blood pressure control	5–10 mg IV every 4 h PRN	5–10 mg IV every 4 h PRN	May cause tachycardia

BOX 20-5 CONSIDERATIONS FOR THE OLDER PATIENT

Heart Failure

Most patients with heart failure are elderly, and many fit the category of "old old." They have a variety of limitations and comorbid diseases that may or may not relate to heart failure, as well as a remarkable resiliency and adaptability not found in younger patients. Therefore, it is critical to evaluate their limitations and strengths on an individual basis. It is important to treat the comorbid diseases aggressively according to patients' wishes and to include them in the planning and treatment decisions at all levels.

It is also critical to assess fall risk, activity level, visual acuity, manual dexterity, cognitive ability, and memory when administering, evaluating, or teaching about any medication. For some older patients, the assistance of a family member or friend is critical to successful medication adherence. Financial considerations are also important because many older patients are on Medicare and have a limited drug plan to pay for expensive medications. Having to choose between medication and food is no choice.

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors are the mainstay of standard therapy for heart failure today; they represent one third of the classic three-drug combination used. The Studies of Left Ventricular Dysfunction (SOLVD) and Cooperative North Scandinavian Enalapril Survival Study (CONSENSUS) trials demonstrated improvement in mortality as well as symptom management and exercise tolerance in even the sickest of patients with heart failure.[2,27] ACE inhibitors are typically started at low doses and titrated to target doses established in clinical trials. Studies have shown that ACE inhibitors were being underprescribed for appropriate patients, and the Assessment of Treatment With Lisinopril and Survival (ATLAS) trial found that being on the medication alone was not sufficient and that target doses used in the clinical trials were necessary to achieve the optimum results.[28]

ACE inhibitors work by blocking the renin–angiotensin–aldosterone system, resulting in vasodilation and antagonism of aldosterone and decreasing afterload and sodium

reabsorption. Blockage of the long-term effects of myocardial cell exposure to the renin–angiotensin–aldosterone system is hypothesized to be the mechanism by which ACE inhibitors decrease mortality and limit the progression of remodeling.[29]

ACE inhibitors do have some side effects. Because some patients are allergic to ACE inhibitors, they experience angioedema, a potentially fatal reaction that involves edema of the mouth, pharynx, and larynx. There is no way to predict which patients will have this reaction, but when it presents, it is critical that the medication be stopped and a notation be made in the patient record so that it is not prescribed again. Patients should also be educated about the names of potential ACE inhibitors and why they should not be taken.

A troubling but not dangerous cough develops in some patients who take ACE inhibitors. Typically, after starting ACE inhibitors, patients may complain of a persistent, dry, nonproductive cough. The cough is not related to patient position or time of day, and it subsides when the ACE inhibitor is discontinued.

Hyperkalemia develops in some patients who take ACE inhibitors. Like the cough, the hyperkalemia resolves when the drug is discontinued. Serum potassium levels greater than 6.0 mEq/L are potentially dysrhythmogenic and should be treated with exchange resin. Patients with serum creatinine levels greater than 1.5 mcg/dL are often denied ACE inhibitors in the mistaken belief that they will develop renal failure if they are given ACE inhibitors. In fact, patients with elevated creatinine levels are no more likely to develop an increased creatinine level than patients with a normal creatinine level when the ACE inhibitors were started.[29,30] The two types of patients most likely to show increased creatinine levels when started on ACE inhibitors are patients with renal artery stenosis and those with hypovolemia.

Patients receiving ACE inhibitors also have decreased blood pressure. It is not uncommon to see asymptomatic systolic pressures of 80 to 99 mm Hg, and diastolic pressures may be 40 to 59 mm Hg. These low pressures are not symptomatic because perfusion of the brain and kidneys is not compromised as it might be in a patient with normal systolic function. The increased flow or stroke volume more than compensates for the decrease in resistance, and the tissues actually receive more blood and therefore oxygen than they would at a higher resistance and pressure. It is unnecessary to withhold or decrease ACE inhibitors for asymptomatic hypotension.

For patients who truly cannot tolerate ACE inhibitors, other options are available. The use of hydralazine and nitrates preceded the studies on ACE inhibitors, and these drugs offer similar reductions in mortality. Hydralazine must be taken three or four times daily, and many patients have trouble complying with a multidose medication regimen. Long-acting nitrates are used in conjunction with the hydralazine. Once-a-day preparations, such as isosorbide mononitrate or a nitroglycerin patch may be used if compliance is a problem. Isosorbide dinitrate can be used if a rest period of at least 6 to 8 hours is taken.

Another option for patients who cannot take ACE inhibitors because of cough is an angiotensin II receptor blocker. Losartan, valsartan, and candesartan were studied in the treatment of heart failure. Early results suggest that these agents are effective in patients who are not taking ACE inhibitors. Valsartan and candesartan have FDA indications for heart failure.

Digoxin

Cardiac glycosides have been used for centuries in the empirical management of heart failure. However, until recently, no objective evidence indicated that digitalis preparations made any actual difference in managing heart failure. Beginning in 1993, the Prospective Randomized Study of Ventricular Failure and the Efficacy of Digoxin (PROVED) trial and, more recently, the Randomized Assessment of Digoxin on Inhibitors of Angiotensin-Converting Enzyme (RADIANCE) and Digitalis Investigation Group (DIG) trials provided evidence that digoxin is of value in heart failure treatment.[31] Although none of the studies has shown that digoxin affects mortality, they all have consistently shown that digoxin leads to improvement in symptom management and exercise tolerance as well as decreased hospitalizations for heart failure.

Digoxin should be given in daily doses of 0.125 mg. Lower doses are used in patients who have renal insufficiency or also take amiodarone. Digoxin is safe and has few, if any, adverse effects as long as the blood levels remain less than 2.0 ng/mL. No studies have identified a therapeutic level for digoxin in heart failure or guidelines for interpreting drug levels.[2] The traditional therapeutic levels given in studies of atrial fibrillation may be excessively high; lower levels (ie, 1.0 ng/mL) may be equally beneficial and safer.

Diuretics

Since furosemide became available in the 1960s, diuretics have become a mainstay of heart failure management. Edema, a common finding in patients with heart failure, is the result of volume expansion in response to neurohormonally mediated salt and water retention. In certain conditions (eg, ascites, pleural effusions), "third spacing" of fluids is a common result of excess volume and increased hydrostatic pressure. Edema worsens when patients are unwilling or unable to reduce sodium in their diets. Patients who have advanced heart failure are frequently malnourished and may have low serum albumin levels with a consequent decrease in osmotic gradients to pull fluids back into the circulation. Patients who are symptomatic from volume overload feel dramatically better when diuresis reestablishes their dry weight. Drugs such as ACE inhibitors and β-blockers work best in euvolemic patients.

Loop diuretics, such as furosemide, are standard therapy for diuresis in patients with heart failure.[2] More expensive loop diuretics are available but have not been shown to be superior to furosemide. Loop diuretics are threshold drugs, and the threshold varies from patient to patient. This

means that the appropriate dosage must be determined by the patient's response. In a patient who requires furosemide in oral doses of 200 mg to maintain dry weight, 100 mg twice daily is not sufficient. Doses in excess of 200 mg daily may be necessary. When patients are receiving oral doses of 240 mg or more, yet continue to have edema or have increased edema, diuretic resistance must be considered. Loop diuretics should not be abandoned; however, a brief course of IV diuretic or the addition of a thiazide, such as metolazone, until the edema is controlled may be required.

The combination of loop and thiazide diuretics works more efficiently than either type of diuretic alone. However, this drug combination should be reserved for refractory edema, and when the edema resolves, an appropriate dose of loop diuretic should be determined and continued.

As heart failure progresses or when decompensations occur, dose adjustments are necessary. Patients should be taught to weigh themselves daily and record their weights. Increases of 2 pounds or more overnight or of 5 pounds or more in a week are water weight, which can be controlled with additional doses of diuretic (1 liter [1.06 quarts] of water weighs 1 kg [2.2 pounds]). Some patients can manage their fluid balance with a sliding-scale diuretic, much like patients with diabetes mellitus manage their blood glucose level with sliding-scale insulin.

Spironolactone

Spironolactone is a weak diuretic with potassium-sparing properties. It is not used specifically for its diuretic activity. The Randomized Aldactone Evaluation Study (RALES) trial[32] studied mortality in patients with NYHA class III or IV heart failure who took spironolactone as well as ACE inhibitors, digoxin, and diuretics. The results were a 30% reduction in mortality in patients who received only 25 mg/day of spironolactone. The reasons for the decreased mortality are unclear, but the hypothetical mechanism is that spironolactone blocks aldosterone and its damaging effects on heart muscle. Of theoretical concern is the addition of another potassium-sparing drug to the regimen of patients who are already taking an ACE inhibitor, which also spares potassium. However, few patients had serum potassium levels high enough to discontinue the spironolactone. Many of those patients tolerated every-other-day administration of spironolactone well, with excellent results.

β-Blockers

Intuitively, β-blockers, with their negative inotropic properties, ought to be the least likely intervention to benefit patients with systolic dysfunction. For many years, the prevailing standard of care specifically excluded β-blockers for patients with ineffective heart pumps. During the past 30 years, both small studies and large, multicenter, international, randomized, placebo-controlled studies challenged this idea. Meta-analysis of the smaller studies and primary analysis of the recent studies documented a 34% improvement in mortality in NYHA class II and III heart failure. Other long-term benefits of β-blockers include improved exercise tolerance, better symptom control, fewer hospitalizations, and improved ejection fraction.

Short-term use of β-blockers makes heart failure worse. Consequently, β-blockers should be used as a long-term strategy that is begun only when patients are stable using optimum background therapy with ACE inhibitors, digoxin, and diuretics. β-Blockers should not be started when a patient is in the midst of an decompensation. The specific drug used should be started at a very small dose and gradually increased to the target range. The initiation and titration of β-blockers are beyond the scope of this text but are outlined in detail elsewhere.[33]

Under no circumstances should β-blockers be stopped suddenly. The rebound tachycardia can be fatal, especially in patients with coronary insufficiency. Patients who come into the hospital because of a decompensation of heart failure who are on β-blockers should continue taking the β-blocker. If a temporal relationship exists between titration of the β-blocker dose and the onset of the exacerbation, the dose should be reduced to the last well-tolerated dose. Patients who are taking β-blockers may receive inotropes without discontinuing the β-blocker and may respond well because of the upregulation of β-adrenergic receptors.

Calcium Channel Blockers

First-generation calcium channel blockers, such as diltiazem, verapamil, and nifedipine, should be avoided in patients with systolic dysfunction. These drugs exert a strong negative inotropic effect without the long-term benefits of β-blockers. Second-generation calcium channel blockers, such as amlodipine or felodipine, have been used in patients with heart failure because they are vasodilators with minimal negative inotropic effects. They are most commonly used to control blood pressure in patients who are on target doses of ACE inhibitors but who continue to have blood pressure levels that exceed the recommendations of the Seventh Report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure (JNC7).[34] (The JNC7 recommends that blood pressure in patients with heart failure be <130/80 mm Hg.)

Nitrates

Nitrates are venodilators, and their primary effect is to decrease preload. As coronary vasodilators, they are used to treat angina. In very high doses, they may lower blood pressure, but they are not first-line drugs for the treatment of hypertension. When given to patients who are volume depleted or have right ventricular infarctions, nitrates may lead to abrupt hypotension, which is the result of inadequate preload to maintain stroke volume and cardiac output.

Nitrates are used in heart failure to help alleviate the symptoms of orthopnea and DOE.[35] Often, when patients

lie down, the increased venous return (preload) leads to increased pulmonary artery pressure because the volume is too great for the weakened left ventricle. This sudden increase in preload and pulmonary artery pressure causes the sensation of dyspnea. Sitting up reduces the preload and relieves the symptoms. Nitrates decrease preload and mediate the volume of blood presented to the left ventricle, thus helping to control dyspnea. For this reason, nitrates may be used for patients who do not have angina specifically for the management of orthopnea and DOE.

Nonpharmacological Treatment

Role of the Patient

Several strategies can be used to manage symptoms and prevent hospitalization of patients with heart failure.[36–38] The participation and commitment of the patient is necessary for success.

Sodium restriction is critical. Patients often believe that if they no longer use a salt shaker, they have eliminated all excess salt from their diet, and they may be surprised to learn that canned soup and canned vegetables are extremely rich in salt. Education about the natural salt content of foods and the salt that is added as part of food processing is essential. Patients must be taught to read labels and shop for foods that provide optimum nutrition with minimal salt.

Alcohol use should be stopped. As noted previously, alcohol is a powerful cardiac depressant. Many patients have read that a glass of wine or a drink each day decreases the risk for CAD. Although this may be true, the studies were performed in patients who did not have systolic dysfunction. It is important to clarify this fact and explain to the patient the adverse effects of alcohol.

Exercise should be encouraged. Patients with heart failure have limited stamina, and the goal is to increase stamina with low-level exercise over a longer period of time instead of intense exercise for short periods of time. Obviously, some patients with heart failure start at a higher level of functioning and have a better exercise tolerance than patients with advanced heart failure. Exercise for patients with heart failure is not the same as that for development of cardiovascular fitness, and heart rate is not a good indicator of exercise efficacy.

Patients with heart failure should be encouraged to maintain their level of activity. Walking is by far the best recommended exercise. Neither speed nor distance is important. Patients should aim for 15 to 20 minutes each day without stopping to rest or "catch their breath" at whatever pace they are able to manage. Some patients need to take many rests before they begin to exercise, and it may be quite a while before they can exercise for this length of time even at low levels. Weight-lifting is not recommended because this activity increases afterload and may worsen symptoms.

The most important thing patients can do to stay out of the hospital and control symptoms is to take their medication. The second most important activity is to measure their weight every day. An overnight weight change of more than 3 pounds is due to water weight. If patients take and record their weight every day, modest fluid accumulations of 1 quart or less can be identified. Diuresis can be initiated before patients experience so much fluid overload that hospitalization for IV diuresis is necessary.

Fluid restrictions are punishing, and there is no evidence that water restriction has any value in the absence of significant hyponatremia. Likewise, there is no physiological basis for decreasing or controlling edema by fluid restriction, or any evidence that restricting fluids is effective.[38] The problem for patients with heart failure is the retention of sodium, which "holds on" to water. Restricting sodium does decrease or control edema, as discussed in the section on diuretics.

Implantable Cardioverter–Defibrillator

In dilated cardiomyopathy, the incidence of sudden death from ventricular tachycardia or ventricular fibrillation is very high. Asymptomatic ventricular tachycardia is common, but its prognostic impact is unknown. For patients who have syncopal episodes or survive sudden death, an implantable cardioverter–defibrillator is usually indicated. An implantable cardioverter–defibrillator interrupts life-threatening dysrhythmias. If this device fires frequently or symptomatic NSVT occurs, amiodarone may be added to the regimen for rhythm control. See Chapter 18 for more information about the implantable cardioverter–defibrillator.

Biventricular Pacing

In with heart failure and intraventricular conduction delays (QRS duration more than 130 milliseconds) that lead to dysynchronous activation of the left and right ventricles, biventricular pacing or cardiac resynchronization improves cardiac output and therefore symptoms and exercise tolerance.[39,40] Pacing both ventricles of the spherically dilated heart reproduces the bottom-to-top contraction of a normal ventricle that is lost with myocardial remodeling and bundle branch block.

Patient Education

Many times, severe exacerbations requiring hospitalization can be avoided. If a weight gain of 2 to 3 pounds can be treated with intermittent extra doses of diuretic, then 15- and 20-pound weight gains that require hospitalization will not occur. Helping patients control both their heart failure and their comorbid diseases empowers them instead of victimizes them and gives them a sense of control that also helps to limit hospitalization. There have been many reports of improved quality of life, decreased hospitalizations, and decreased cost of care for patients in disease management programs.[41–43]

Home care provides many opportunities for disease management. As the home care nurse enters the patient's environment, the opportunities for teaching become evident.

Even in situations in which the number of visits after a hospital stay is limited, such as with patients covered by Medicare, there are many opportunities for the home care nurse not only to assess but also to intervene.

Discharge planning begins with the first day of hospitalization. A program of education, referral, and follow-up is initiated with the goal of preventing further hospitalization. Patient teaching is necessary, but it is not sufficient alone to allow patients to be effective partners in their care. Close follow-up, coaching, and skill development allow patients to effectively use the information they have been taught. (Box 20-6). Clearly, patients must be on target levels of standard medications to reap the benefits of the clinical studies in heart failure. However, patients must collaborate with health care providers to maximize this benefit (Box 20-7).

BOX 20-6 TEACHING GUIDE *Living With Heart Failure*

Medications
- Take all medications as instructed. If you cannot afford them, please let your provider know so that you can be put in touch with someone to help.
- Do not stop taking medication because you feel better. These are lifetime medications in most instances. Some of the medications will need to be adjusted over time, but your health care provider will discuss the changes with you.
- You may be taking several drugs. These medications do not interfere with each other, and they are given together so that they can work together to do more than any one or two of them can do alone.
- Do not let your medication supply run out because stopping some medications suddenly can cause serious problems.
- Take your medications about the same time every day.
- If you are going out for a few hours and will not have easy access to a bathroom when you need it, hold off on your diuretic until you return home. Do not skip a day's dose of diuretic because this could lead to serious water accumulations and worsening of your heart failure.

Diet
- Restrict your salt intake by removing the salt shaker from the table and the food preparation area. Do not add salt to any food you are cooking or any food on your plate.
- Avoid foods that have a high salt content naturally or because of the way they are preserved. Foods such as canned soup, canned vegetables, canned meats, foods frozen in sauces, cold cuts, sauerkraut, dill pickles, cheese, and processed foods of any kind are loaded with salt. Seasonings such as garlic and onion salt, Old Bay, and monosodium glutamate are the same as salt. Avoid salt substitutes because they are made with potassium; in combination with the medications you are taking, they can lead to potassium excesses. Avoid fast food such as hamburgers, French fries, fried chicken, and tacos.
- Seasonings such as pepper, Mrs. Dash, onion and garlic powder, herbs, seeds, and spices are acceptable.
- Fresh or frozen vegetables (frozen without sauces), fresh lean meats and poultry, and fish (not fried) are all good choices.

Daily Weights
- Weigh yourself every day at about the same time and record the value.
- The best time to weigh yourself is in the morning when you first get up and after you go to the bathroom.
- Weigh yourself without clothes if possible.
- Record your weight and the date in a daily diary. Bring this diary with you to the office when you visit your health care provider.
- Call if your weight goes up more than 2 pounds overnight and does not go back to baseline the next day, or if you gain more than 3 pounds in a week.

Activity
- Stay as active as possible.
- The stronger your skeletal muscles are, the easier it is for your heart.
- Do not use heart rate as a measure of adequacy of exercise effort.
- If you get tired or short of breath, stop and rest, and then try again. The goal is 15 to 20 minutes of continuous activity each day.
- There are no speed or distance goals, and walking at whatever pace you can accomplish is a good choice. Homemaking and gardening are good choices as well. Choose an activity that you enjoy.
- Shortness of breath is uncomfortable but not dangerous. It is an indication that you are nearing the end of your exercise tolerance for this period, but once your breathing normalizes, you can go again. If you stop before you get short of breath out of fear, you will not be able to increase your activity tolerance.
- If you have any questions about how much exercise you can tolerate, discuss it with your health care provider. That person is the best advisor for you because you are well known to him.
- Do not lift weights unless your health care provider has specifically said it is an acceptable activity for you.

Call Your Health Care Provider If
- Your weight increases or decreases suddenly.
- You begin waking up at night short of breath and need to sit up to breathe.
- You start needing more pillows at night to breathe when you lie down or you are unable to lie down.
- You become short of breath at rest.
- You cannot walk up stairs that you used to climb regularly because now it makes you too short of breath or tired.
- Your feet and legs start to swell.
- You faint or feel as though you are going to faint.
- You become dizzy and weak when you stand.

BOX 20-7 COLLABORATIVE CARE GUIDE for the Patient With Acute Decompensation of Chronic Heart Failure

Outcomes	Interventions
Oxygenation/Ventilation	
There will be adequate oxygen to meet the metabolic demands of the tissue. Minimum arterial oxygen content evidenced by: 1. Hemoglobin (Hgb) = 10 g/dL or more 2. SpO_2 = 90% or more	• Consider the transfusion of red blood cells if Hgb is 9.0 g/dL or less. • Supplemental oxygen to maintain SpO_2 at >90% • Consider intubation and mechanical ventilation if patient develops respiratory acidosis or cannot maintain oxygen saturation on 100% oxygen by mask. • Consider primary pulmonary problem as cause of hypoxemia and check brain natriuretic peptide level.
The patient's symptom of dyspnea will be managed. 1. Patient denies dyspnea at rest 2. Patient reports increased activity before feeling sufficient dyspnea to limit activity 3. NYHA class equal to or better than baseline before decompensation	• Elevate head of bed or allow patient to select upright position that best relieves dyspnea. • Apply damp washcloth to patient's face. • Use a fan or other means to create air movement across the patient's face. • Encourage the patient to ambulate as soon and as much as possible once dyspnea at rest is relieved.
Circulation/Perfusion	
Cardiac output will be maximized. Optimum cardiac output evidenced by: 1. Cardiac index > 2.0 2. SvO_2 > 50% 3. Urine output > 30 mL/h 4. Baseline level of consciousness and orientation	• Optimize preload with diuresis, fluid administration, or vasodilation with agent such as nitroglycerin, nitroprusside, or nesiritide. • Increase contractility with inotrope such as milrinone or dobutamine. • Decrease afterload with diuresis and vasodilation.
Hypotension will be asymptomatic, and the patient's blood pressure is at baseline.	• Determine the patient's baseline blood pressure; systolic pressure may be <90 mm Hg. • If blood pressure is less than baseline, assess for orthostatic decreases in blood pressure and increases in heart rate that would suggest dehydration. • Continue to give angiotensin-converting enzyme inhibitors and other afterload reducers if hypotension is asymptomatic. • If patient is symptomatic on standing, keep on bed rest until orthostasis resolves. • If patient is orthostatic, symptomatic, and BUN and creatinine levels are elevated, hold diuretics and consider giving intravenous normal saline solution.
Fluids/Electrolytes	
Euvolemia will be achieved. Euvolemia evidenced by: 1. Absence of peripheral edema 2. Absence of ascites 3. Documented dry weight 4. Baseline BUN and creatinine 5. Moist mucous membranes	• Administer loop diuretic sufficient to produce 1 liter of urine output within 2 h of administration. • Obtain daily weights. • Strive for a weight loss of 1–2 kg/d until dry weight is achieved. • Monitor electrolytes at least daily. • Replenish potassium, magnesium, and calcium as needed. • Measure serum albumin. • If inadequate response to loop diuretics, add metolazone or inotropes as above. • Report new or worsened rales to physician.
Teaching/Discharge Planning	
Rehospitalization will be prevented.	• Assess the patient's understanding of medication regimen. • Assess the patient's reading ability before giving written instructions. • Include a family member in the discussions if the patient has trouble reading, seeing, or remembering. • Consider a means of preparing medications so that the patient has to open only one container each day. • Teach the patient the importance of daily weights to follow fluid balance. • Have the patient weigh himself each day and record. Call physician if weight is 3–5 pounds over baseline. • Have the patient or family member repeat early signs and symptoms of worsening heart failure and when to call physician for them. • Teach the patient about foods that have a high sodium content. • Encourage the patient to abstain from alcohol. • Encourage the patient to walk and stay as active as possible. • Consider case management referral or social work referral if the patient has multiple admissions or problems obtaining medications.

▲ Clinical Applicability Challenges

CASE STUDY

A.J. is a 64-year-old farmer who had a septal myocardial infarction (MI) 4 years ago and has had chronic heart failure since then. His ejection fraction is 36%, and on his current medical regimen, he is considered in a New York Heart Association class II. In his compensated state, he is able to continue farming, care for his cows and chickens, and meet his responsibilities without problem, although he has slowed his pace since the MI. In the interim, he has developed type 2 diabetes which is well controlled with glypizide 5 mg twice a day by mouth. His most recent HbgA1c was 5.8%. Over the last 3 weeks, he has begun to get fatigued more easily with the same amount of effort. He notes that his ankles are swollen and have not gone down over night as they usually do and that his abdomen has increased in size to the point he cannot fasten his trousers. Last night he was unable to lie down in bed because he could not breathe; he slept in his recliner. His wife insisted that he see his cardiologist today. A.J.'s ECG demonstrated a new inferior MI and a left bundle branch block with a QRS duration of 162 milliseconds. He is admitted to the Coronary Care Unit for a diagnostic evaluation including cardiac catheterization and treatment for his acute decompensated heart failure (ADHF). A.J. does not weigh himself regularly at home and he was surprised to find his weight had increased 43 pounds since his last physician visit 4 weeks ago. His physical examination was significant for a new mitral regurgitation murmur (II/VI), an S3, jugular venous distention to his earlobe, and ascites. He did not have crackles or decreased breath sounds.

Vital signs are blood pressure 88/46, pulse rate 76, respiratory rate 28, and temperature 98.8°F.

The cardiac catheterization demonstrated a mid-right coronary artery occlusion of 95%, which was treated with a drug-eluting stent. His cardiac index after the stent placement was 3.1 L/min/m^2. Furthermore, his cardiologist ordered a new echocardiogram that demonstrated a decrease in his ejection fraction to 26% with ventricular dysynchrony. He will also receive an implantable cardioverter–defibrillator with a biventricular pacemaker during this hospitalization.

His significant laboratory values on admission were:

Glucose 186 mg/dL
Na 128 mg/dL
K 5.8 mEq/L
BUN 68 mg/dL
Creatinine 2.1 mg/dL
t bilirubin 3.8 mg/dL
albumin 3.8 g/dL
alkaline phosphatase 160 units/L

1. Silent MIs are common in patients with diabetes. What effect did having a new MI have on the increase in symptoms and decompensation A.J. experienced?

2. A.J. has ventricular dysynchrony. How will having a biventricular pacemaker improve his symptoms?

3. What specific things can A.J. do to decrease the likelihood that he will be surprised by a large weight gain associated with ADHF?

21 Acute Myocardial Infarction

Patricia Gonce Morton

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Explain the pathophysiology and risk factors for atherosclerosis.
2. Describe the classification, assessment, and management of patients with angina pectoris.
3. Compare and contrast the pathophysiological principles and assessment findings of a patient with angina pectoris versus a patient with a myocardial infarction (MI).
4. Discuss the diagnostic tests used for a patient with an MI.
5. Summarize principles of managing the patient with an MI in the early phase, intensive care phase, and intermediate care phase of management.
6. Describe the complications for a patient with an MI.
7. Explain the principles of cardiac rehabilitation and patient education.

Cardiovascular disease is a significant global health problem. Worldwide, an estimated 17.3 million people died from cardiovascular disease in 2008.[1] About 80% of these deaths occur in low- and middle-income countries.[1] In the United States, cardiovascular disease continues to be the leading cause of death for men and women.[2] About 2,200 Americans die each day from cardiovascular disease; this represents an average of one death every 39 seconds.[3]

Among the white population, 11.9% have cardiovascular disease; among blacks or African Americans, the rate is 11.2%; and among Latinos or Hispanics, 8.5% have cardiovascular disease. The overall death rate from cardiovascular disease is 251.2 per 100,000.[3] For white males the death rate is 294 per 100,000, and for black males the death rate is 405.9 per 100,000. For white females the overall death rate from cardiovascular disease is 205.7 per 100,000, and for black females the overall death rate from cardiovascular disease is 286.1 per 100,000.[3]

Of those who die from cardiovascular disease, the majority die as a result of coronary heart disease (myocardial infarction [MI] and angina pectoris).[3] About every 25 seconds, an American has a coronary event, and about every minute, a person dies from one.[3] Coronary heart disease caused about one in every six deaths in the United States in 2007.[3] Every year, about 785,000 Americans will have a new coronary attack and about 470,000 will have a recurrent attack.[3] An additional 195,000 silent first MIs occur each year.[3]

Overwhelming as the mortality and morbidity statistics appear, much progress has been made in the prevention, diagnosis, and management of cardiovascular disease. Since the Framingham Study of risk factors in 1951 and the development of coronary care units in the 1960s, the critical care nurse has played a major role in helping to reduce the mortality associated with heart disease. The critical care nurse uses advanced assessment skills, rapid decision making, and therapeutic interventions to treat the patient in the acute phase of cardiovascular disease. Patient education and psychological support provided by the nurse have enabled patients and their families to return home and maximize their health status.

▲ Atherosclerosis

Atherosclerosis is a major cause of cardiovascular disease. The term atherosclerosis comes from the Greek words *athere*, meaning "gruel" or "paste," and *sclerosis*, meaning "hardness."

Pathophysiological Principles

Atherosclerosis is a complex, insidious process, beginning long before symptoms occur. Although the process is not completely understood, scientific evidence suggests that it begins when the inner, protective layer of the artery (endothelium) is damaged. Three known causes of the damage include elevated levels of cholesterol and triglycerides in the blood, hypertension, and cigarette smoking.

Gradually, as fatty substances, cholesterol, cellular waste products, calcium, and fibrin pass through the vessel, they are deposited in the inner lining of an artery. As a result of the deposition of these materials, a lipid plaque with a fibrous

covering, also known as an atheroma, builds up, and blood flow in the artery becomes partially or completely blocked.

The injury to the vessel and the resulting accumulation of these substances in the inner lining of the artery cause white blood cells, smooth muscle cells, and platelets to aggregate at the site. As a result, a matrix of collagen and elastic fibers form, and the endothelium becomes much thicker. The core of the fibrous plaque can become necrotic, and hemorrhage and calcification may result. A thrombosis may also form, thus contributing even more to the blockage of the vessel lumen (Fig. 21-1). These fibrous plaques are most often found in the coronary, popliteal, and internal carotid arteries and in the abdominal aorta.

Because of the fibrous plaque, the amount of blood flow through the artery is reduced, resulting in decreased supply of oxygen to tissues. However, symptoms often do not occur until 75% or more of the blood supply to the area is occluded. The occurrence of symptoms may depend to an extent on the development of collateral circulation. Collateral vessels are small arteries that connect two larger arteries or different segments of the same artery. Under normal conditions, these collateral arteries carry very little of the blood flow. As the larger artery gradually occludes, pressure builds on the proximal side of the occlusion. As a result, flow is redirected through the collateral vessels, which enlarge and dilate over time (Fig. 21-2). Blood is then allowed to flow around an area of blockage through these alternate routes.

Scientific advances have highlighted the role of inflammation in the pathophysiological process of atherosclerosis. The classic signs and symptoms of inflammation include redness, pain, heat, and swelling. They indicate that the injured tissue is in the process of restoring homeostasis, which includes three phases: vasodilation and increased permeability of the blood vessels, emigration of phagocytes from the blood into the tissue, and tissue repair. This process of restoring homeostasis is meant to be protective, but in the setting of atherosclerosis, the process has been found to be destructive. The atherosclerotic plaque continues to develop, aided by inflammatory molecules, and a fibrous cap forms over the lipid core. As the cap matures, inflammatory substances weaken the cap and cause it to rupture. Once the cap is ruptured, the coagulation cascade is initiated, and a clot is formed, resulting in obstruction of blood flow in the vessel.

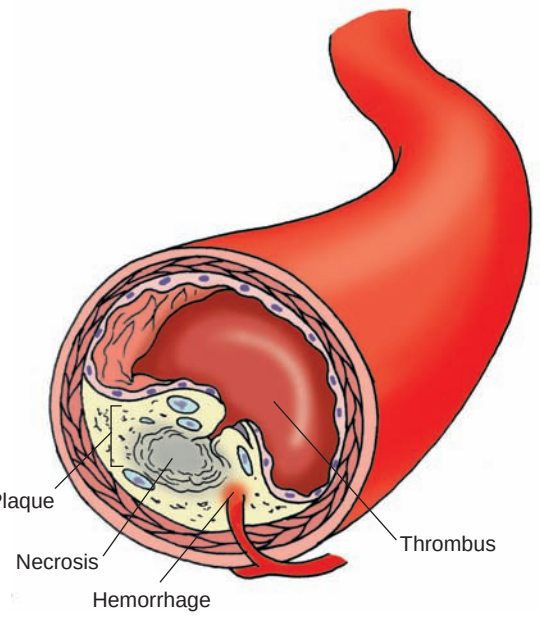

FIGURE 21-1 ▲ Thrombosis of an atherosclerotic plaque. It may partially or completely occlude the lumen of the vessel. (From Bullock BL: Pathophysiology: Adaptations and Alterations in Function, 4th ed. Philadelphia, PA: Lippincott-Raven, 1996.)

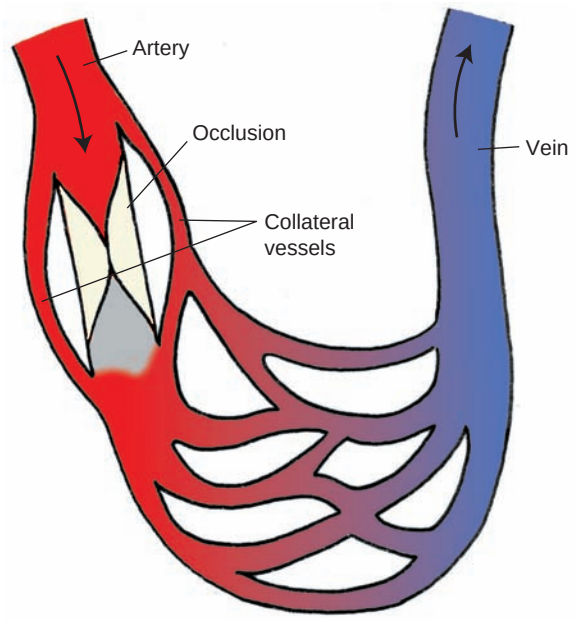

FIGURE 21-2 ▲ Collateral circulation can develop for slowly developing lesions to provide myocardial blood flow until the atherosclerosis progresses beyond the limits of collateral supply. (From Bullock BL: Pathophysiology: Adaptations and Alterations in Function, 4th ed. Philadelphia, PA: Lippincott-Raven, 1996.)

Markers of inflammation are now being used to assess the risk for atherosclerosis. C-reactive protein (CRP) is an acute-phase protein that increases during systemic inflammation. A newer, more sensitive CRP blood test called a highly sensitive C-reactive protein (hs-CRP) can be used to determine the risk for heart disease. High levels of hs-CRP have consistently predicted recurrent coronary events in patients with unstable angina and MI. An hs-CRP less than 1.0 mg/dL is associated with a low risk for developing cardiovascular disease, a value between 1.0 and 3.0 mg/dL with a moderate risk, and a value greater than 3.0 mg/dL with a high risk.[4]

Risk Factors

The cause of atherosclerosis is not clearly known. Through epidemiological studies, risk factors for the development of atherosclerosis have been identified. These risk factors are usually classified into two groups: major uncontrollable risk factors and major risk factors that can be modified, treated, or controlled. Major risk factors are those that have been shown through research to increase significantly the risk of cardiovascular disease. Other risk factors are known to be associated with an increased risk for cardiovascular disease, but their significance and prevalence are still under investigation. The more risk factors a patient has, the greater the chance of developing coronary heart disease.[5]

Major Uncontrollable Risk Factors

AGE. There is an increased incidence of all types of atherosclerotic disease with aging. More than 83% of people who die from coronary heart disease are 65 years of age and older. At older ages, women who have an MI are more likely than men to die from it within a few weeks.[5]

HEREDITY (INCLUDING RACE). The tendency to develop atherosclerosis seems to run in families, although the risk is presumed to be a combination of environmental and genetic influences. Even when other risk factors are controlled, the chance for developing coronary artery disease increases when there is a familial tendency. Most people with a strong family history of cardiovascular disease also have one or more additional risk factors. Rates of cardiovascular disease are higher in African Americans, Mexican Americans, Native Americans, Native Hawaiians, and some Asian Americans. High blood pressure, which is more severe in African Americans than Caucasians, contributes to a higher rate of heart disease. Higher rates of obesity and diabetes in Mexican Americans, American Indians, and Native Hawaiians help account for their higher rates of cardiovascular disease.[5]

GENDER. Men have a greater risk for coronary artery disease than woman, and men have MIs at a younger age. However, after menopause, the death rate from coronary disease rises in women, but it never reaches the risk level of men.[5]

Major Risk Factors That Can Be Modified, Treated, or Controlled

CIGARETTE SMOKING. A smoker's risk for an MI is two to four times that of a nonsmoker. Smoking is the biggest risk factor for sudden cardiac death. Cigarette smoking also acts with other risk factors to increase greatly the risk of coronary heart disease. Exposure to environmental smoke also increases the risk for heart disease in nonsmokers.[5]

HIGH BLOOD CHOLESTEROL. High cholesterol levels increase the risk for coronary artery disease. When other risk factors are present, the risk is even greater. Middle-aged adults with a total blood cholesterol level below 200 mg/dL have a relatively low risk for coronary artery disease. A total blood cholesterol level in the range of 200 to 239 mg/dL represents a moderate but increasing risk. When the level rises above 240 mg/dL, the risk for coronary artery disease is about double.[6]

Most cholesterol in the blood is carried in low-density lipoprotein (LDL), often called "bad" cholesterol. This type of cholesterol is deposited in the artery walls, and high blood levels of LDL increase the risk for coronary heart disease. An LDL level of less than 100 mg/dL is optimal. For patients classified as very high risk for MI, a therapeutic goal of less than 70 mg/dL may be recommended.[6]

High-density cholesterol (HDL) removes cholesterol from tissues and transports the excess cholesterol back to the liver, where it is metabolized. For this reason, HDL is often called "good" cholesterol. A low level of HDL (<40 mg/dL) is associated with a higher risk for coronary artery disease.

Triglyceride is the most common type of fat in the body, and the normal levels vary by age and sex. The rate of atherosclerotic development seems to be accelerated by a combination of high triglycerides with either high amounts of LDL or low amounts of HDL.

Patients at very high risk for MI are defined as those patients with cardiovascular disease with either multiple risk factors (especially diabetes) or severe or poorly controlled risk factors or metabolic syndrome (a group of risk factors associated with obesity including high triglycerides and low high-density lipids [HDL]). High-risk patients are those who have coronary heart disease or disease of the blood vessels of the brain or extremities, or diabetes, or multiple (two or more) risk factors resulting in a greater than 20% chance of having a heart attack within 10 years. Moderately high-risk patients are those with two or more risk factors for coronary heart disease with a 10% to 20% risk of heart attack within 10 years. Patients with lower/moderate risk of having an MI are those with two or more risk factors plus an under 10% risk of a heart attack in 10 years or those with zero to one risk factor.[6]

HYPERTENSION. Hypertension is a major risk factor that is termed the silent killer because it has no specific symptoms and no early warning signs. About 33.5% of U.S. adults over the age of 20 have hypertension.[3] The prevalence of hypertension is nearly equal in men and woman.[3]

In the United States, the prevalence of hypertension in blacks is among the highest in the world at 44%, and this value is increasing. Compared with whites, blacks develop hypertension earlier in life, with average blood pressures that are significantly higher.[2] When the risk factors of obesity, smoking, high cholesterol level, or diabetes occur with hypertension, the risk of heart disease or stroke increases several times.[5]

PHYSICAL INACTIVITY. A lack of physical activity plays a significant role in the development of heart disease. When lack of regular exercise is combined with overeating and obesity, high cholesterol can result and further increase the risk for heart disease. Regular moderate to vigorous physical activity helps prevent cardiovascular disease. Even moderate-intensity exercise helps prevent heart disease if done regularly and long-term.[5]

OBESITY AND OVERWEIGHT. Approximately 67% of the U.S. adult population is overweight, and about 33.7% is considered obese.[3] Obesity and excess weight are associated with an increased mortality rate from coronary artery disease and stroke. Excess weight is also linked with an increased incidence of hypertension, insulin resistance, diabetes, and dyslipidemia. Central obesity (intra-abdominal fat) appears to be a stronger predictor of cardiovascular disease than peripheral or subcutaneous obesity. The waist measurement and the body mass index (a measure of weight relative to height) are the recommended means to estimate a person's body fat. A higher risk for cardiovascular disease is found for women with a waist greater than 35 inch and for men with a waist greater than 40 inch.[3]

DIABETES MELLITUS. Diabetes mellitus is associated with a markedly increased risk for cardiovascular disease. This increased risk occurs even if the person maintains control of blood glucose levels. The risk of heart disease is even greater if blood glucose is poorly controlled. About 75% of people with diabetes die of some form of heart or blood vessel disease.[3,5]

Contributing Risk Factors

STRESS. A person's response to stress may be a contributing factor to cardiovascular disease. The behaviors that a person engages in when under stress (such as smoking and overeating) may contribute to the risk for cardiovascular disease.[3,5]

EXCESSIVE ALCOHOL INTAKE. The excessive intake of alcohol has been associated with hypertension, heart failure, and stroke. The risk for heart disease in moderate drinkers is lower than in nondrinkers. Moderate drinking means one drink for a woman per day and two drinks for a man per day. One drink is defined as 1.5 fluid ounces of 80-proof spirits, 1 fluid ounce of 100-proof spirits, 4 fluid ounces of wine, or 12 fluid ounces of beer.[5]

▲ Acute Coronary Syndrome

The term acute coronary syndrome (ACS) is used to describe patients with clinical symptoms compatible with acute myocardial ischemia. This term includes unstable angina and acute myocardial infarction (AMI). Unstable angina refers to unexpected chest pain or discomfort that usually occurs while at rest. Patients with MI are further classified into one of two groups: those with ST-segment elevation MI (STEMI) and those with non–ST-segment elevation MI (NSTEMI). The pathophysiologic origins and clinical presentations of unstable angina and NSTEMI are similar, but differ in severity. An NSTEMI is diagnosed when the ischemia is severe enough to cause myocardial damage and the release of a biomarker indicating myocardial necrosis into the circulation. However, on the electrocardiogram (ECG), ST segments do not elevate. For a patient with unstable angina, biomarkers are not detected in the circulation hours after the initial onset of ischemic pain. Unstable angina can present as rest angina usually lasting more than 20 minutes; new-onset (<2 months) severe angina; and a crescendo pattern of occurrence that increases in intensity, duration, frequency, or any combination of these factors. A patient with an STEMI shows the ST changes on the ECG and has detectable biomarkers in the circulation.[7] About two thirds of patients with an AMI have a non–ST-segment MI and about one third have an STEMI.[3]

▲ Angina Pectoris

The term angina comes from the Latin word meaning "to choke." Angina pectoris is the term used to describe chest pain or discomfort that result from coronary artery disease. The patient may describe the sensation as pressure, fullness, squeezing, heaviness, or pain.

Pathophysiological Principles

Angina pectoris is caused by transient, reversible myocardial ischemia precipitated by an imbalance between myocardial oxygen demand and myocardial oxygen supply. In most cases, angina pectoris is the result of a reduced oxygen supply. The most common cause of a reduced supply of oxygen is atherosclerotic narrowing of the coronary arteries. A nonocclusive thrombus develops on a disrupted atherosclerotic plaque, resulting in a reduction in myocardial perfusion. As blood flow to the myocardium decreases, autoregulation of coronary blood flow occurs as a compensatory mechanism. The smooth muscles of the arterioles relax, thus decreasing resistance to blood flow in the arteriolar bed. When this compensatory mechanism can no longer meet the metabolic demands, myocardial ischemia occurs, and the person feels pain.

A less common cause of unstable angina is dynamic obstruction resulting from intense focal spasm of a coronary artery. The spasm is caused by hypercontractility of vascular smooth muscle, endothelial dysfunction, or abnormal constriction of small resistance vessels. As a result of the spasm, perfusion to the myocardium is interrupted, thus reducing the supply of oxygen.

Arterial inflammation may be another cause of decreased oxygen supply that results in unstable angina. The inflammatory process may cause arterial narrowing, plaque destabilization, rupture, and thrombogenesis. More recent research has contributed to a better understanding of the role of inflammation in ACSs.

A marked increase in oxygen demand is another cause of unstable angina. Conditions such as fever, tachycardia, and thyrotoxicosis may result in an increased oxygen demand that is unable to be met, especially if the patient has underlying coronary artery disease.[8,9]

When the balance between oxygen supply and demand is not met, the myocardial tissue's need for oxygen and nutrients continues. The same work of pumping blood must be accomplished with less available energy and oxygen. The tissue that depends on the blood supply becomes ischemic as it functions with less oxygenated blood. Anaerobic metabolism can provide only 6% of the total energy needed. Glucose uptake by the cells is markedly increased as glycogen and adenosine triphosphate stores are depleted. Potassium rapidly moves out of the myocardial cells during ischemia. An acidotic cellular bath develops, further compromising cellular metabolism.

Classification of Angina

Many terms are used clinically to describe angina. Stable angina (also known as chronic stable angina, classic angina, or exertional angina) is a term used to describe paroxysmal substernal pain that is usually predictable. The pain occurs with physical exertion or emotional stress and is relieved by rest or nitroglycerin.[10]

Unstable angina, also called preinfarction angina or crescendo angina, refers to cardiac chest pain that usually occurs while at rest. The patient with unstable angina has more prolonged and severe chest discomfort than the person with stable angina. Unstable angina is a type of ACS and requires immediate treatment because the patient is at increased risk for AMI, cardiac dysrhythmias, or cardiac sudden death.[10]

Variant angina, also known as Prinzmetal's angina or vasospastic angina, is a form of unstable angina. Variant angina usually occurs at rest, most often between midnight and 8:00 AM. It does not usually occur after exertion or emotional stress. Variant angina is the result of coronary artery

BOX 21-1 Grading of Angina Pectoris by the Canadian Cardiovascular Society Classification System

Class I: Ordinary physical activity does not cause angina, such as walking and climbing stairs. Angina occurs with strenuous, rapid, or prolonged exertion at work or recreation.

Class II: Slight limitation of ordinary activity occurs. Angina occurs when walking or climbing stairs rapidly, walking uphill, walking or climbing stairs after meals, in cold, in wind, under emotional stress, or during the few hours after awakening. Angina occurs when walking more than two level blocks and climbing more than one flight of ordinary stairs at a normal pace and in normal conditions.

Class III: Ordinary physical activity is markedly limited. Angina occurs when walking one to two level blocks and climbing one flight of stairs in normal conditions and at a normal pace.

Class IV: Physical activity without discomfort is impossible; anginal symptoms may be present at rest.

From Campeau L: Grading of angina pectoris [letter]. Circulation 54:522–523, 1976; copyright 1976, American Heart Association, Inc, used with permission.

spasm. Most people who experience variant angina have severe coronary atherosclerosis of at least one major coronary artery, and the spasm occurs very near the area of blockage.[10]

The Canadian Cardiovascular Society also has proposed a classification system for grading for angina. Each stage of the four-class system is described in Box 21-1.

Assessment

History

The five most important factors that indicate a likelihood of ischemia from coronary artery disease are obtained rapidly during the health history. These factors include a description of the symptoms, information about a prior history of coronary artery disease, the patient's sex and age, and the number of risk factors present.[8,9]

The nurse uses the NOPQRST method of pain assessment when taking the patient's history. For a review of the assessment questions, see Box 17-1. After determining the patient's normal baseline, the nurse asks about the time of onset of the pain. The nurse determines causes (provocative) of the pain and any measures the patient has used to relieve the pain (palliative), such as rest or nitroglycerin. The pain of angina is often brought on by exertion or emotion. It may also occur after meals, exposure to cold, and at rest. Patients with angina often obtain relief from the pain with rest or by taking sublingual nitroglycerin. As the angina becomes more severe (unstable angina), the pain may occur at rest or be caused by less exertion and is no longer relieved with rest or sublingual nitroglycerin. The quality of anginal pain is frequently described as deep, poorly localized chest or arm discomfort. Patients often describe heaviness, squeezing, choking, or smothering sensations. When asked about region and radiation of the pain, patients report substernal, left-sided chest, or epigastric pain that may radiate to the left arm, neck, back, or jaw. The severity of the pain is evaluated by asking the patient to rate the pain on a scale of 0 to 10, with 10 being the worst pain they have experienced. Additional information is obtained related to time. The nurse asks how long the pain lasts, how frequently it occurs, and the time of day it occurs. Finally, the nurse asks about associated symptoms, such as dyspnea, nausea, vomiting, and diaphoresis. Box 21-2 summarizes the assessment findings for a patient with myocardial ischemia. Based on the information obtained, the angina may be classified as one of three principal presentations: rest angina, new-onset (<2 months) severe angina, and increasing angina (in intensity, duration, or frequency).[8,9]

The older patient, especially women, who experiences angina may have a different presentation because of changes in neuroreceptors. Considerations for the older patient are described in Box 21-3.

BOX 21-2 The NOPQRST Characteristics of Chest Pain Due to Myocardial Ischemia

N—Normal
- The patient's baseline before the onset of the pain

O—Onset
- The time when the pain/discomfort started

P—Precipitating and Palliative Factors

Precipitating
- Exercise
- Exercise after a large meal
- Exertion
- Walking on a cold or windy day
- Cold weather
- Stress or anxiety
- Anger
- Fear

Palliative
- Stop exercise.
- Sit down and rest.
- Use sublingual nitroglycerin; pain of myocardial infarction (MI) is often not relieved by sublingual nitroglycerin.

Q—Quality
- Heaviness
- Tightness
- Squeezing
- Choking
- Suffocating
- Vise-like

R—Region and Radiation
- Substernal with radiation to the back, left arm, neck, or jaw
- Upper chest
- Epigastric
- Left shoulder
- Intrascapular

S—Severity
- Pain rated on a scale of 0 to 10, with 10 being the worst pain ever experienced, often rated as 5 or above

T—Time
- Pain lasts from 30 seconds to 30 minutes.
- Pain can last longer than 30 minutes for unstable angina or MI.

BOX 21-3 CONSIDERATIONS FOR THE OLDER PATIENT

Acute Coronary Syndrome

Coronary artery disease is more common and more severe in the older patient. Older patients often present with special problems because of their numerous comorbidities, such as diminished β-sympathetic response, increased cardiac afterload due to decreased arterial compliance and arterial hypertension, cardiac hypertrophy, and ventricular diastolic dysfunction.[11]

The older patient is more likely to present with atypical symptoms such as dyspnea, confusion, weakness, or fainting rather than with typical substernal chest pain. Because of differences in amount and distribution of subcutaneous fat, the older person may develop anginal symptoms more quickly when exposed to cold. The older person should be taught to dress in warm clothing and to recognize feelings of weakness, shortness of breath, or fainting as possible indicators of angina.

Physical Examination

The physical examination helps determine the cause of the pain, detect comorbid conditions, and assess any hemodynamic consequences of the pain. When the vital signs are taken, the nurse should measure the blood pressure in both arms of the patient. If the physical examination is performed during an anginal episode, the patient may present with tachycardia and pulsus alternans. Pulsus alternans is a physical finding characterized by a regular alternation of the force of the arterial pulse. During the initial phase of an anginal episode, the patient may be hypertensive or hypotensive. The patient may exhibit pallor with cold, clammy skin. On further examination of the skin, the nurse may detect xanthomas, which are yellow nodules or plaques, especially on the skin. Xanthomas may be indications of hypercholesterolemia. Carotid or femoral bruits may be auscultated, indicating the possible presence of obstructive cardiovascular disease. The nurse may hear a paradoxical split of S_2 or auscultate an S_3 heart sound. Both sounds are indicators of left ventricular failure. An S_4 may be heard, which is suggestive of decreased left ventricular compliance. Deficits in peripheral pulses may indicate peripheral vascular disease.

Diagnostic Tests

A 12-lead ECG is a standard diagnostic test for patients with angina and should be obtained immediately in patients with chest discomfort. During the anginal episode, the ECG may show T-wave inversions and ST-segment depressions in the ECG leads associated with the anatomical region of myocardial ischemia (Fig. 21-3). Transient ST-segment changes (0.05 mV or more) that occur during a symptomatic episode while at rest and that resolve when the patient is asymptomatic are highly suggestive of severe coronary artery disease.[8,9] Ectopic beats may also be present during an anginal episode. The ECG should be compared with previous ECGs. Between anginal episodes, the ECG may appear normal. Ambulatory ECG monitoring may be used to assist in the diagnosis of angina, especially for patients with angina at rest. The standard 12-lead ECG is a limited diagnostic tool because it does not provide adequate information about the posterior, lateral, and apical walls of the heart.[7] A normal ECG does not exclude the possibility of ACS.[7]

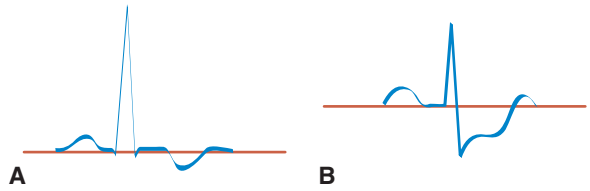

FIGURE 21-3 ▲ Inversion of T wave (**A**) and depression of ST segment (**B**). (From Bullock BL: Pathophysiology: Adaptations and Alterations in Function, 4th ed. Philadelphia, PA: Lippincott-Raven, 1996.)

Biochemical cardiac markers are useful in determining both the diagnosis and the prognosis of ACSs. For a more detailed discussion of cardiac markers, see Chapter 17. A cardiac-specific troponin (troponin T or troponin I) is the preferred marker to obtain in all patients who present with chest discomfort consistent with ACS. Troponin has replaced creatine kinase-MB (CK-MB) as the preferred biomarker for the diagnosis of myocardial necrosis.[7] However, troponin levels usually do not increase until at least 6 hours after the onset of symptoms.[7] For patients who present to the hospital within 6 hours of the onset of symptoms consistent with ACS, an early marker of cardiac injury, such as myoglobin, in conjunction with a late marker, such as troponin, may be obtained. If the patient has a negative cardiac marker within 6 hours of the onset of chest discomfort, another blood sample should be drawn in the 6- to 12-hour period after onset of chest discomfort.[8,9] Troponin levels remain elevated for between 5 and 14 days and therefore may be a useful biomarker for the patient who presents for evaluation several days after the onset of symptoms.[7] Additional blood tests include chemistry, complete blood count, and coagulation studies. A full lipid profile should be obtained within 24 hours of the onset of ACS.[6] Plasma markers of inflammation may also assist in the diagnosis of ACS. Elevated CRP levels detected by a high-sensitivity CRP test have been related to an increased risk of mortality.[7] A white blood cell count is another helpful marker of inflammation associated with higher mortality rates.[7]

Other diagnostic tests include exercise stress testing in which the ECG and blood pressure are monitored before, during, and after exercise. The exercise stress test is especially useful in risk stratification of patients. For patients who are unable to exercise, pharmacological stress testing may be done in which the medication increases myocardial oxygen demand while the patient remains inactive. Intravenous (IV) medications used for pharmacological stress testing include adenosine, dobutamine, and dipyridamole.

Cardiac imaging studies usually start with chest radiographs, although they have limited value in diagnosing coronary heart disease. Perfusion imaging can be used with exercise or pharmacological stress testing to detect perfusion defects. Positron emission tomography (PET) may be helpful in differentiating ischemic from infarcted myocardium. Echocardiography is performed to evaluate wall motion abnormalities and thickness, valvular function, and ejection fraction. Magnetic resonance imaging (MRI) and coronary computed tomographic angiography may be used to view structural cardiovascular abnormalities when other

diagnostic techniques (eg, the echocardiogram) are inconclusive or ambiguous.

Coronary angiography is an invasive diagnostic test that provides a definitive diagnosis of coronary artery disease. Results from coronary angiography are used to guide the decision whether to manage the patient medically or surgically. For further discussion of cardiovascular diagnostic tests, see Chapter 17.

Management

The goal of therapy for the patient with angina pectoris is to restore the balance between oxygen supply and oxygen demand. The nurse assesses the patient's vital signs and mental status frequently. The patient is placed on a cardiac monitor for ischemia and dysrhythmia detection. The patient is placed on bed rest until stabilized to minimize oxygen demands. Supplemental oxygen may be given to unstable patients to increase oxygen supply. A pulse oximeter and arterial blood gases are used to evaluate oxygenation status.

Pharmacological Therapy

Pharmacological therapy is an important component in managing patients with angina pectoris. The severity of symptoms, hemodynamic status of the patient, and medication history guide the drug regimen.

Nitroglycerin is a mainstay of therapy because it is a vasodilator that reduces myocardial oxygen demand by decreasing ventricular preload via vasodilation. Through vasodilation, nitroglycerin improves arterial and collateral flow to ischemic areas.[7] Nitroglycerin is used sublingually or as a spray for acute anginal attacks. If three sublingual tablets (0.4 mg) or spray taken 5 minutes apart (no more than three sprays in 15 minutes) does not relieve the pain of angina, IV nitroglycerin may be useful. IV nitroglycerin should be started at a rate of 10 mcg/min by continuous infusion and titrated up by 10 mcg/min every 3 to 5 minutes until some symptom or blood pressure response is noted. If signs and symptoms are relieved, there is no need to continue to increase the dose. However, if relief is not obtained, the dose can be increased until a blood pressure response is noted. A ceiling dose of 200 mcg/min is recommended. Once patients have been pain-free and have no other indications of ischemia for 12 to 24 hours, the IV nitroglycerin should be discontinued and replaced with oral or topical nitrates.[8,9]

Morphine sulfate is indicated for patients whose symptoms are not relieved after three serial sublingual nitroglycerin tablets or whose symptoms recur with adequate anti-ischemic therapy. Morphine is a potent analgesic and anxiolytic with hemodynamic benefits.[7] A dose of 1 to 5 mg IV is recommended to relieve symptoms and maintain comfort. The nurse carefully monitors the patient's respiratory rate and blood pressure, especially if the patient continues to receive IV nitroglycerin.[8,9]

β-Blockers may be used to decrease myocardial oxygen consumption by reducing myocardial contractility, sinus node rate, and atrioventricular (AV) node conduction velocity. The reduction in myocardial contractility reduces the work of the heart and decreases myocardial oxygen demand. The slowing of the heart rate helps increase the time for diastolic filling, thus improving blood flow to the coronary arteries. β-Blockers are started orally within the first 24 hours for patients with unstable angina and NSTEMI.[8,9]

Calcium channel blockers may be beneficial for the patient with unstable angina and NSTEMI. Calcium channel blockers decrease myocardial oxygen demand by decreasing afterload, contractility, and heart rate. Verapamil (Calan) and diltiazem (Cardizem) have been shown to have the greatest benefit. The nurse carefully monitors the patient for side effects, such as hypotension, worsening heart failure, bradycardia, and AV block. Calcium channel blockers can be administered to treat ischemia-related symptoms in patients unresponsive to or intolerant of nitrates and β-blockers.[8,9]

The combination of aspirin, an anticoagulant, and an additional antiplatelet drug is recommended for the patient with unstable angina or NSTEMI. Aspirin should be administered as soon as the diagnosis of unstable angina or NSTEMI is made or suspected, unless contraindicated. Clopidogrel (Plavix) is used if the patient is intolerant of asprin.[9] For additional antiplatelet therapy, thienopyridine (Ticlid) therapy is used and approved thienopyridine agents include clopidogrel and prasugrel (Effient).[9] Anticoagulant therapy also is recommended to modify the disease process and its consequences for the patient with unstable angina and NSTEMI. Anticoagulant drugs that are recommended include enoxaparin, unfractionated heparin, or fondaparinux (a factor XA inhibitor) and bivalirudin (direct thrombin inhibitor).[8,9]

For patients with pulmonary congestion or a left ventricular ejection fraction of 40% or less and in the absence of hypotension, an angiotensin-converting enzyme (ACE) inhibitor is administered orally within the first 24 hours. An angiotensin II receptor blocker is used for patients who cannot tolerate an ACE inhibitor.[8,9]

Invasive Therapy

Invasive therapy may be indicated for the management of patients with unstable angina. Intra-aortic balloon pump (IABP) support may be used in the critically ill patient to provide increased coronary artery perfusion and to decrease afterload. Percutaneous transluminal coronary angioplasty (PTCA) and stent placement may be used for treating patients with unstable angina. See Chapter 18 for a more detailed discussion of the IABP, PTCA, and stent placement. Coronary artery bypass grafting (CABG) is another invasive option for treatment. See Chapter 22 for a more detailed discussion of cardiac surgery.

Risk Factor Modification

Risk factor modification may help prevent an anginal episode or delay the worsening of existing angina. Patients should be encouraged to stop smoking, achieve or maintain optimal weight, and exercise daily. Diet and medications may be prescribed to control hypertension, diabetes, and hyperlipidemia. Patient education, including home care considerations, is essential for patients with angina pectoris. Patient education guidelines and home care considerations are described in Box 21-4.

BOX 21-4 TEACHING GUIDE Angina Pectoris

Activity and Exercise
- Participate in a daily program of exercise that does not precipitate pain.
- Alternate activity with periods of rest and moderate activity level as needed.

Diet
- Eat a well-balanced diet with an appropriate caloric intake.
- If obese, participate in a supervised weight-reduction program.
- Avoid activity immediately after meals.
- Restrict intake of caffeine because it can increase heart rate.
- Maintain a diet low in fat.

Smoking
- Participate in a smoking cessation program. Smoking can increase heart rate, blood pressure, and blood carbon monoxide levels.
- Avoid smoke-filled environments.

Cold Weather
- Avoid exposure to cold and windy weather. Exercise indoors when necessary.
- When outdoors, dress in warm clothing and cover mouth and nose with a scarf.
- Use a moderate pace when walking in cold weather.

Medications
- Carry sublingual nitroglycerin at all times.
- Keep the pills in a dark-colored glass bottle to protect them from sunlight.
- Do not place cotton in the bottle because the cotton will absorb the active ingredients of the medication.
- If pain occurs, place tablet under the tongue, stop activity, and wait for medication to dissolve. Take another tablet in 3 to 5 minutes if pain does not resolve.
- If pain continues, seek immediate care.
- Be aware of side effects of nitroglycerin, including headache, flushing, and dizziness.

▲ Myocardial Infarction

Prolonged ischemia caused by an imbalance between oxygen supply and oxygen demand causes MI. The prolonged ischemia causes irreversible cell damage and muscle death. Although multiple factors can contribute to the imbalance between oxygen supply and oxygen demand, the presence of a coronary artery thrombosis characterizes most MIs. In a classic investigation, DeWood et al[11] demonstrated that 87% of patients studied in the first 4 hours after onset of MI symptoms had a thrombotic occlusion. The incidence of thrombotic occlusion decreases to 65% at 12 to 24 hours.

MI can be determined from several different perspectives, including clinical, electrocardiographic, biochemical, imaging, and pathological. The European Society of Cardiology, the American College of Cardiology Foundation, the American Heart Association, and the World Heart Federation developed a joint consensus document for the redefinition of MI.[12] Their clinical classification of an AMI is shown in Box 21-5.

Pathophysiological Principles

Most patients who sustain an MI have coronary atherosclerosis. The thrombus formation occurs most often at the site of an atherosclerotic lesion, thus obstructing blood flow to the myocardial tissues. Plaque rupture is believed to be the triggering mechanism for the development of the thrombus in most patients with an MI. As mentioned previously, the role of inflammatory processes in the development of atherosclerotic plaque is an area of intense scientific investigation. Cardiovascular risk factors play a role in endothelial damage, resulting in endothelial dysfunction. The dysfunctioning endothelium contributes to the activation of the inflammatory response and the formation of atherosclerotic plaques. When the plaques rupture, a thrombus is formed at the site that can occlude blood flow, thus resulting in an MI. Figure 21-4 shows the atherosclerotic plaque in stable angina and in ACSs.

Irreversible damage to the myocardium can begin as early as 20 to 40 minutes after interruption of blood flow. However, the dynamic process of infarction may not be completed for several hours. Necrosis of tissue appears to occur in a sequential fashion. Reimer and associates demonstrated that cellular

BOX 21-5 Clinical Classification of Different Types of Myocardial Infarction

Type 1
Spontaneous MI related to ischemia due to a primary coronary event such as plaque erosion and/or rupture, fissuring, or dissection

Type 2
MI secondary to ischemia due to either increased oxygen demand or decreased supply (eg, coronary artery spasm, coronary embolism, anemia, dysrhythmias, hypertension, hypotension)

Type 3
Sudden unexpected cardiac death, including cardiac arrest, often with symptoms suggestive of myocardial ischemia, accompanied by presumably new ST-segment elevation, or new left bundle branch block, or evidence of fresh thrombus in a coronary artery by angiography and/or at autopsy, but death occurring before blood samples could be obtained, or at a time before the appearance of cardiac biomarkers in the blood

Type 4a
MI associated with percutaneous coronary intervention

Type 4b
MI associated with stent thrombosis as documented by angiography or at autopsy

Type 5
MI associated with coronary artery bypass grafting

From Thygesen K, Alpert JS, White HD; on behalf of the Joint ESC/ACCF/AHA/WHF Task Force for the Redefinition of Myocardial Infarction: Universal definition of myocardial infarction. Circulation 116:2637, 2007.

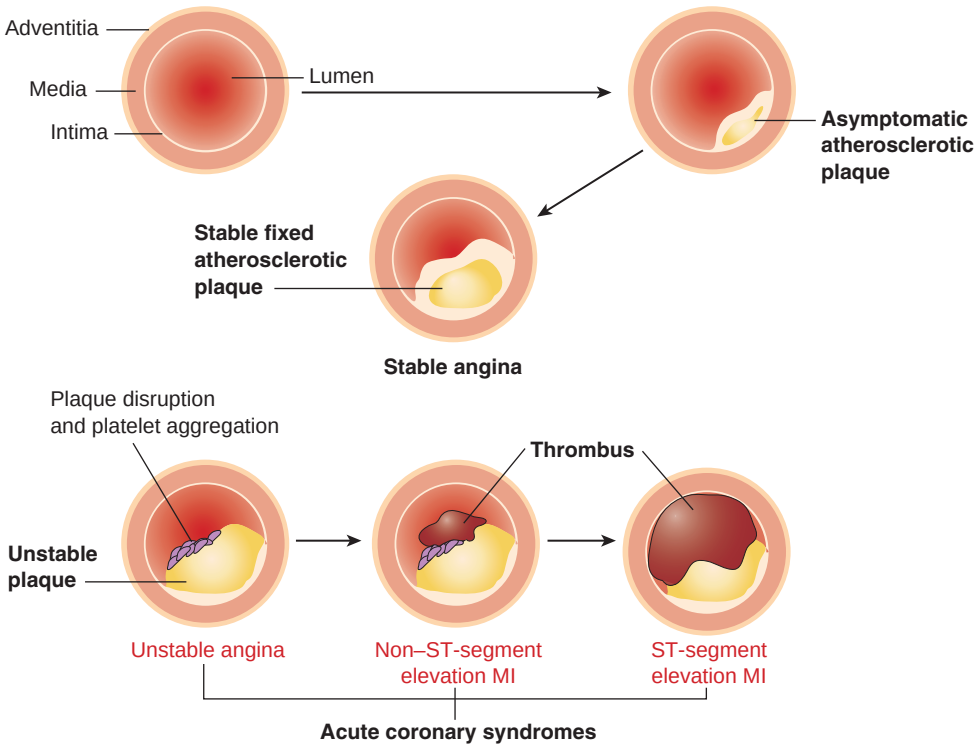

FIGURE 21-4 ▲ Atherosclerotic plaque. Stable fixed atherosclerotic plaque in stable angina and the unstable plaque with plaque disruption and platelet aggregation in the acute coronary syndromes (ACSs). (From Porth CM: Essentials of Pathophysiology, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2011, p 453.)

death occurs first in the subendocardial layer and spreads like a "wave front" throughout the thickness of the wall of the heart.[13] Using dogs, they showed that the shorter the time between coronary occlusion and coronary reperfusion, the greater the amount of myocardial tissue that could be salvaged. Their classic work indicates that a substantial amount of myocardial tissue can be salvaged if flow is restored within 6 hours after the onset of coronary occlusion. For the clinician, this means time is muscle.

The cellular changes associated with an MI can be followed by the development of infarction extension (new myocardial necrosis), infarction expansion (a disproportionate thinning and dilation of the infarct zone), or ventricular remodeling (a disproportionate thinning and dilation of the ventricle).

Size of the Infarction

Several factors determine the size of the resulting MI. These factors include the extent, severity, and duration of the ischemic episode; the size of the vessel; the amount of collateral circulation; the status of the intrinsic fibrinolytic system; vascular tone; and the metabolic demands of the myocardium at the time of the event. MIs most often result in damage to the left ventricle, leading to an alteration in left ventricular function. Infarctions can also occur in the right ventricle or in both ventricles.

The term transmural infarction is used to imply an infarction process that has resulted in necrosis of the tissue in all the layers of the myocardium. Because the heart functions as a squeezing pump, systolic and diastolic efforts can be significantly altered when a segment of the heart muscle is necrotic and nonfunctional. If the area of the transmural infarction is small, the necrotic wall may be dyskinetic, a term meaning "difficulty in moving." If the damage to the myocardial tissue is more extensive, the myocardial muscle may become akinetic, meaning "without motion."

The normal myocardial muscle contracts with systole and relaxes with diastole. When normal motion is not possible because of infarction, diastolic filling and systolic pumping are altered. As a result, cardiac output is compromised. The larger the area of infarction, the greater is the impact on ventricular function.

Location of the Infarction

In addition to size, location of the infarction is an important determinant of ventricular function. MIs can be located in the anterior, septal, lateral, posterior, or inferior walls of the left ventricle. In more recent years, clinicians have acknowledged the presence and clinical significance of MIs occurring in the right ventricle.

Anterior Left Ventricle

Infarctions of the anterior wall of the left ventricle and the interventricular septum result from occlusion of the left anterior descending (LAD) coronary artery. The LAD coronary artery supplies oxygenated blood to the anterior wall of the left ventricle, the interventricular septum, and the ventricular conducting tissue. (See Chapter 16 for a more detailed discussion of coronary artery anatomy and physiology.) Anteroseptal wall MIs are the most frequent type of infarction and have the potential for causing a significant amount of left ventricular dysfunction. Patients with an anteroseptal MI are at high risk for heart failure, pulmonary edema, cardiogenic shock, and death because of an inadequate pump. Anteroseptal wall MIs are also associated with increased risk for intraventricular conduction disturbances, such as bundle branch blocks and fascicular blocks, which are also known as hemiblocks.

Lateral and Posterior Left Ventricle

Infarctions of the lateral and posterior walls of the left ventricle result from occlusion of the left circumflex vessel. In addition to supplying oxygenated blood to the lateral and posterior walls, the left circumflex vessel is the source of blood supply to the sinoatrial (SA) node in about 50% of the population and to the AV node in about 10% of the population. Infarctions of the lateral and posterior walls are less common than infarctions of the anteroseptal wall. Although muscle necrosis occurs with lateral and posterior wall MIs, the impact on left ventricular function is usually less than for patients with anteroseptal MI. Patients with a lateral or posterior wall MI are also at risk for dysrhythmias associated with dysfunction of the SA or AV nodes. Examples include sinus arrest, wandering atrial pacemaker, sinus pause, or junction rhythm.

Inferior Left Ventricle

Infarctions of the inferior wall result from occlusion of the right coronary artery. The right coronary artery supplies oxygenated blood to the inferior wall and the right ventricle. In addition, it is the source of blood supply to the SA node in about 50% of the population and the AV node in about 90% of the population. Infarctions of the inferior wall are less common than anteroseptal MIs but occur more frequently than MIs of the lateral or posterior walls. The potential impact on left ventricular function usually is less for a patient with an inferior wall MI than for a patient with an anteroseptal wall infarction. Because the right coronary artery supplies oxygenated blood to much of the conducting tissue, patients are at frequent risk for dysrhythmias related to altered function of the SA and AV nodes.

Right Ventricle

The right coronary artery provides the blood supply to the inferior wall and the right ventricle. Consequently, right coronary artery disease causing an inferior wall MI is likely to be associated with concomitant right ventricular infarction. Patients may experience significant hemodynamic compromise due to biventricular dysfunction. As a result, patients with a right ventricular infarction and hemodynamic abnormalities with a concurrent inferior wall MI have a significantly higher mortality rate (25% to 30%).[14] Dysrhythmias associated with right ventricular infarction involve dysfunction of the SA and AV nodes.

Type of Infarction

Patients with chest pain may present with or without ST-segment elevations on their ECG. In most patients with ST-segment elevation, a Q wave ultimately develops on the ECG, and the term Q-wave MI is used to describe the type of MI they experience. In a much smaller number of patients who present with ST-segment elevation, a Q wave does not develop, and the term non–Q-wave MI is used to classify these patients. Patients who present without ST-segment elevations are diagnosed with either unstable angina or an NSTEMI[14] (Fig. 21-5).

The ST segment is the portion of the ECG tracing from the end of the QRS complex to the beginning of the T wave. Normally, the ST segment is isoelectric, meaning it joins the QRS complex at the baseline. When the ST segment is elevated, the amount of elevation is measured in millimeters on the ECG paper. See Evidence-Based Highlight 21-1 for information about ST-segment monitoring.

A Q wave is a portion of the QRS complex on the ECG. Specifically, the Q wave is the initial downward deflection of the QRS complex. A Q wave is not present on the normal ECG. The presence of significant Q waves indicates an MI. For a review of ECG waveforms, see Chapter 17.

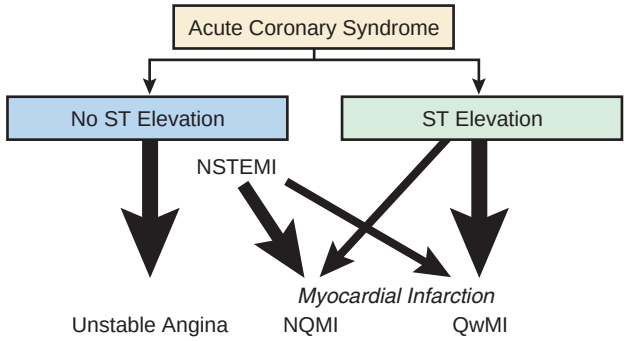

FIGURE 21-5 ▲ Acute coronary syndrome. Patients may present with or without ST-segment elevation on electrocardiography. Most patients with ST-segment elevation (*large arrows*) ultimately develop a Q-wave acute myocardial infarction (QwMI), whereas a minority (*small arrow*) develop a non–Q-wave AMI (NQMI). Patients who present without ST-segment elevation are experiencing either unstable angina or NSTEMI (non–ST-segment elevation MI). (Adapted from Committee to revise the 1999 guidelines for the management of patients with acute myocardial infarction. Circulation 110:e82–e293, 2004, p e88.)

Assessment

The nursing assessment of a patient with a probable MI must be organized and thorough. It is best to start with the history because this establishes rapport and provides valuable data. The history is followed by the physical examination and evaluation of diagnostic tests. Based on the data, a management plan is developed initially for the acute phase. Once the patient is stabilized, plans for cardiac rehabilitation are initiated.

History

The most common presenting complaint of a patient with an MI is the presence of chest discomfort or pain. Other assessment findings are similar to those described in Box 21-2 on page 421. Like patients with angina, patients with MI describe a heaviness, squeezing, choking, or smothering sensation. Patients often describe the sensation as "someone sitting on my chest." The substernal pain can radiate to the neck, left arm, back, or jaw. Unlike the pain of angina, the pain of an MI is often more prolonged and unrelieved by rest or sublingual nitroglycerin. For a review of the assessment questions, see Box 17-1 on page 207. Women and the elderly may present differently and often present with a primary complaint of shortness of breath.

Associated findings on history include nausea and vomiting, especially for the patient with an inferior wall MI. These gastrointestinal complaints are believed to be related to the severity of the pain and the resulting vagal stimulation. Patients may initially seek relief of the gastrointestinal

EVIDENCE-BASED PRACTICE HIGHLIGHT 21-1

ST-Segment Monitoring

△ Expected Practice

- If 12-lead ECG is available, continuous ST-segment monitoring should be performed using all 12 leads.
- If 12-lead ECG is unavailable, use the most appropriate leads for ST-segment monitoring based on the patient's needs and risk for ischemia and/or dysrhythmia.
  - For patients with acute coronary syndrome (ACS) and a known "ST fingerprint," obtained during ST-segment elevation myocardial infarction (STEMI) or percutaneous coronary intervention (PCI), use the lead(s) that best display(s) the patient's "ST fingerprint" when monitoring.
  - If the "ST fingerprint" is not known in ACS, use leads III and V_3.
  - For patients without definitive ACS, but are suspected of having or being ruled out for ACS, leads III and V_5 should be monitored.
  - In noncardiac patients undergoing surgical procedures or admitted to the ICU, lead V_5 is valuable for identifying demand-related ischemia, which appears to be more common in this group of patients.
- Properly prepare the patient's skin before attaching the ECG skin electrodes.
- Once proper lead placement has been determined, mark skin electrode placement with indelible ink. Do not alter the location of the skin electrodes during monitoring as this can created false-positive ST-segment changes.
- Evaluate ST segment with the patient in the supine position, set the ST alarm parameter 1 to 2 mm above and below the patient's baseline ST segment and measure ST-segment changes 60 ms beyond the J point of the ECG complex (See Fig. below).
- ST depression or elevation of 1 to 2 mm that lasts for at least 1 minute can be clinically significant and warrants further patient assessment.

△ Supporting Evidence

- ST-segment monitoring is useful for detecting silent ischemia.[2–4] ST-segment monitoring is more sensitive than patient's self-reporting of symptoms because 70% to 90% of episodes of myocardial ischemia detected with ECG are clinically silent.[2,4–8] It is important to point out that no randomized controlled trials have been conducted to determine whether the addition of ST-segment monitoring improves patient outcomes.[9] (Level V)
- Several studies have demonstrated that silent myocardial ischemia, as detected by continuous ST-segment monitoring, may occur during the process of weaning from mechanical ventilation.[10–15] The presence of ST-segment deviation prior to the initiation of the weaning process has been shown to increase the likelihood of weaning failure.[12–15] However, the effect of ST-segment monitoring on weaning outcomes is not known. The clinical utility of continuous ST-segment monitoring during weaning has not been studied. (Level IV)
- Research demonstrates that monitoring for ST-segment changes in multiple leads, preferably 12 leads, substantially improves the chance of identifying ischemic events.[4,16,17](Level V)
- If all 12 leads are not available in the bedside monitor, use the patient's "ST fingerprint" to select the best ECG lead(s), which show(s) maximal ST-segment deviation. An ST fingerprint is defined as the pattern of ST-segment elevation and/or depression unique to a particular patient based on the anatomic site of coronary occlusion. A fingerprint can be obtained during known ischemia (STEMI or during PCI).[4,9,18–22] (Level V)
- If only two leads are available for ST-segment monitoring, and an ST fingerprint is not available, leads III and V_3 are recommended for patients with acute coronary syndromes or suspected ACS.[4,9,19,23] (Level IV)
- In noncardiac patients undergoing surgical procedures[24] or admitted to the ICU,[26] lead V_5 is valuable for identifying demand-related ischemia, which appears to be more common in this group of patients. (Level IV)
- Failure to properly prep the skin before placing the electrodes may cause the monitoring alarms to sound erroneously. Preparation may include carefully clipping hair areas where electrodes are to be placed and/or cleaning the skin with alcohol to remove skin oils.[4,9,27, 28] (Level IV)
- Variability of electrode placement may occur during routine ECG. Expert consensus recommends marking the locations of the electrodes with indelible ink to assure that if electrodes are removed for any reason (leads V_2 and V_3 are typically removed during recording of echocardiograms), they can be replaced in their original locations. ECG information obtained from electrodes located close to the heart (precordial leads) is especially prone to waveform changes when the electrodes are relocated as little as 1 cm away from the original locations.[9,29] (Level II)
- Because a change in body position (right-, left-side lying) can alter the ST segment mimicking ischemia[30] when an ST alarm sounds and the patient is found in a side-lying position, the patient should be returned to the supine position. If the ST-segment deviation persists in the supine state, it should be considered indicative of myocardial ischemia.[3,14,9] If possible, obtain "positional 12-lead ECGs" with the patient assuming right and left side–lying positions at the initiation of ST monitoring. These positional ECGs can be used to identify false ST-segment changes. (Level IV)

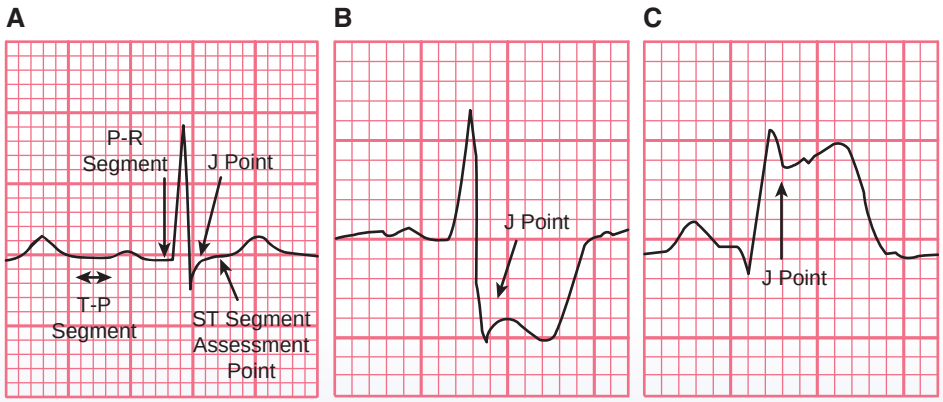

FIGURE ▲ A: A normal ECG complex shows T-P segment and P-R segment, which may be used as reference points to the isoelectric line. The ST-segment is measured at 0.06 seconds after the J point. This ST-segment is isoelectric. **B:** ECG complex show ST-segment depression of almost 5 mm. **C:** ST-segment elevation of approximately 4 mm is depicted. (Flanders SA. Continuous st-segment monitoring: Raising the bar. Crit Care Nurs Clin N Am. 2006;18(3):169–177.)

(continued on page 428)

EVIDENCE-BASED PRACTICE HIGHLIGHT 21-1 (continued)

ST-Segment Monitoring

- Set the ST-segment alarm parameter at 1 mm above and below the baseline ST segment in patients at high risk for ischemia and 2 mm in more stable patients.[9] (Level II)
- Measure ST-segment changes 60 ms beyond the J point of the ECG complex.[9] (Level II)
- ST depression or elevation of 1 to 2 mm that lasts for at least 1 minute can be clinically significant and warrants further patient assessment.[4,26,27] (Level II)
- Because most patients with coronary artery disease do not have perfectly isoelectric ST segments,[31] it is important to set alarm parameters to 1 to 2 mm around the patient's baseline ST level. (Level IV)
- The goal of monitoring must be considered for each patient. For instance, in patients presenting for STEMI, the goal of ST monitoring is to observe rapid ST-segment recovery (back to isoelectric) within the first hour of treatment. Whereas, in patients presenting with ACS, the goal is to defect transient or recurrent ST-segment changes.[9] (Level II)
- ST-segment elevations greater than 1 mm above the isoelectric line are uncommon in the newborn. In neonates and infants, it is better to consider as the isoelectric line the TP segment instead of the PR segment. T waves are normally quite variable in the first week of life. After 1 week, the T wave is negative in lead V_1 and positive in V_5 to V_6.[32] (Level II)

AACN Evidence Leveling System

Level A Meta-analysis of quantitative studies or metasynthesis of qualitative studies with results that consistently support a specific action, intervention, or treatment

Level B Well-designed, controlled studies with results that consistently support a specific action, intervention, or treatment

Level C Qualitative studies, descriptive or correlational studies, integrative review, systematic reviews, or randomized controlled trials with inconsistent results

Level D Peer-reviewed professional organizational standards with clinical studies to support recommendations

Level E Multiple case reports, theory-based evidence from expert opinions, or peer-reviewed professional organizational standards without clinical studies to support recommendations

Level M Manufacturer's recommendations only

symptoms through antacids and other home remedies, thus delaying their decision to go the hospital. Additional complaints described during the history include diaphoresis, dyspnea, weakness, fatigue, anxiety, restlessness, confusion, shortness of breath, or a sense of impending death.

After the patient is stabilized, a more comprehensive history is obtained. Information about risk factors, previous cardiac illnesses and surgeries, and family history is important to acquire. This information will be useful in guiding patient education, cardiac rehabilitation, and care at home.

Physical Examination

On physical examination, patients usually appear restless, agitated, and in distress. They often assume a position to promote breathing and alleviate pain. The skin is cool and moist. Vital signs may reveal a low-grade fever, hypertension, and tachycardia from increased sympathetic tone or hypotension and bradycardia from increased vagal tone. The pulse may be irregular and faint.

The cardiovascular examination may reveal additional abnormalities. When the patient is placed in the left lateral decubitus position, abnormalities of the precordial pulsations can be felt. These abnormalities include a lack of a point of maximal impulse or the presence of diffuse contraction. On auscultation, the first heart sound may be diminished as a result of decreased contractility. A fourth heart sound is heard in almost all patients with MI as a result of decreased left ventricular compliance. A third heart sound may be detected due to left ventricular systolic dysfunction. Transient systolic murmurs may be heard because of papillary muscle dysfunction. After about 48 to 72 hours, many patients acquire a pericardial friction rub. Additional findings on physical examination, such as jugular venous distention, may be related to the development of complications, such as heart failure or pulmonary edema. Breathing may be labored and rapid, and fine crackles, coarse crackles, or rhonchi may be heard when auscultating the lungs. These sounds may indicate the presence of heart failure or pulmonary edema.

Patients with right ventricular infarctions may present with jugular venous distention as well as peripheral edema and elevated central venous pressure. Their lungs may be clear because the failing right ventricle has not provided adequate forward flow.

Diagnostic Tests

THE ELECTROCARDIOGRAM. When a coronary artery becomes about 70% occluded and oxygen demand exceeds oxygen supply, myocardial ischemia may result. If the ischemic state is not corrected, injury to the myocardium may occur. Eventually, if adequate blood flow to the myocardium is not restored, an MI may result. Ischemia and injury are reversible processes; however, infarction is not.

An ECG can be used to detect patterns of ischemia, injury, and infarction. When the heart muscle becomes ischemic, injured, or infarcted, depolarization and repolarization of the cardiac cells are altered, causing changes in the QRS complex, ST segment, and T wave in the ECG leads overlying the affected area of the heart. Table 21-1 shows location of the MI, the artery affected, findings from the ECG, and clinical implications.

Ischemia. Myocardial ischemia may be a transient finding on ECG, or ischemic patterns may be more prolonged due to the presence of ischemic tissue surrounding a region of infarcted tissue. On the ECG, myocardial ischemia results in T-wave inversion or ST-segment depression in the leads facing the ischemic area. The inverted T wave representative

Table 21-1 Location of Myocardial Infarction, Electrocardiographic (ECG) Findings, and Clinical Implications

Anatomical Location	Coronary Artery	ECG Evidence	Clinical Implications
Anteroseptal wall	Left anterior descending: Supplies blood to the anterior wall of left ventricle, the interventricular septum, and the ventricular conducting tissue	V_1 through V_4, Q waves and ST-segment elevations	Potential for significant hemodynamic compromise; heart failure, pulmonary edema, cardiogenic shock; intraventricular conduction disturbances
Lateral wall	Left circumflex: Supplies blood to the left lateral and left posterior walls and to the sinoatrial (SA) node in 45% of people and atrioventricular (AV) node in 10% of people	I, aVL, V_5, and V_6, Q waves and ST-segment elevations	Evaluation for posterior wall involvement; some hemodynamic changes; dysrhythmias caused by SA and AV node dysfunction
Posterior wall	Left circumflex: Supplies blood to the left lateral and left posterior walls and to the SA node in 45% of people and AV node in 10% of people	V_1 and V_2, tall upright R waves with ST-segment depression; Q waves and ST-segment elevation in V_7 through V_9	Evaluation for lateral wall involvement; some hemodynamic changes; dysrhythmias caused by SA and AV node dysfunction
Inferior wall	Right coronary artery: Supplies blood to the inferior wall of the left ventricle, the right ventricle, and the SA node in 55% of people and the AV node in 90% of people	Q waves and ST-segment elevation in II, III, aVF	Evaluation for right ventricular wall involvement; some hemodynamic changes; potential for significant dysrhythmias caused by SA and AV node dysfunction
Right ventricular wall	Right coronary artery: Supplies blood to the inferior wall of the left ventricle, the right ventricle, and the SA node in 55% of people and the AV node in 90% of people	Q waves and ST-segment elevations in right precordial chest leads (RV_1 through RV_6)	Evaluation for inferior wall involvement; some hemodynamic changes; potential for significant dysrhythmias caused by SA and AV node dysfunction

of ischemia is symmetrical, relatively narrow, and somewhat pointed. In contrast, asymmetrical inversion of the T wave usually does not indicate ischemia. Instead, it may signify ventricular hypertrophy or bundle branch block (Fig. 21-6). ST-segment depressions of 1 to 2 mm or more for a duration of 0.08 second may indicate myocardial ischemia. Ischemia also should be suspected when a flat or depressed ST segment makes a sharp angle when joining an upright T wave rather than merging smoothly and imperceptibly with the T wave (Fig. 21-7).

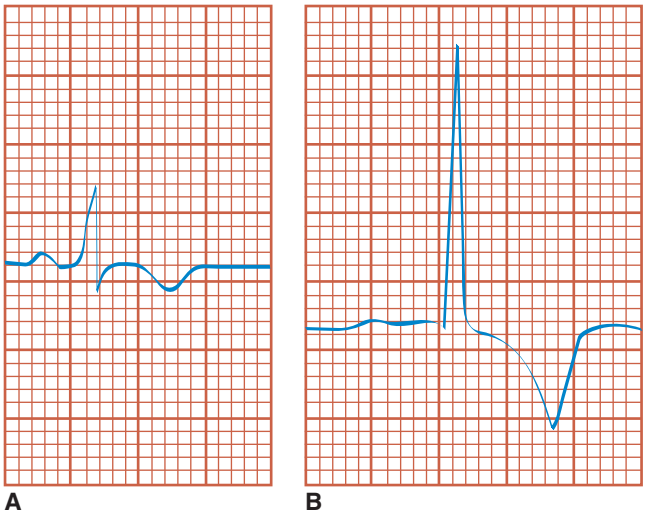

FIGURE 21-6 ▲ T-wave inversion seen with ischemia (**A**) versus T-wave inversion seen with left ventricular hypertrophy (**B**).

Injury. ECG patterns of myocardial injury indicate a state of cellular damage beyond ischemia. Like ischemia, myocardial injury is a reversible process if interventions are instituted rapidly. As described previously, the injury process begins in the subendocardial layer and moves throughout the thickness of the wall of the heart like a wave. If the injury process is not interrupted, it eventually results in a transmural MI.

On ECG, the hallmark of acute myocardial injury is the presence of ST-segment elevations. In the normal ECG, the ST segment should not be elevated more than 1 mm in the standard leads or more than 2 mm in the precordial leads. With an acute injury, the ST segments in the leads facing the injured area are elevated. The elevated ST segments also have a downward concave or coved shape and merge unnoticed with the T wave (Fig. 21-8).

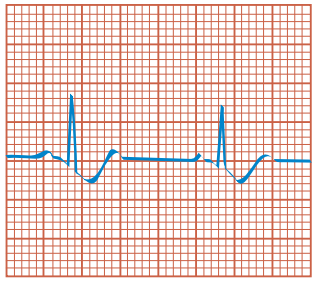

FIGURE 21-7 ▲ An ST-segment pattern consistent with myocardial ischemia. Notice how the ST segment forms a sharp angle when joining an upright T wave rather than merging smoothly and imperceptibly with the T wave.

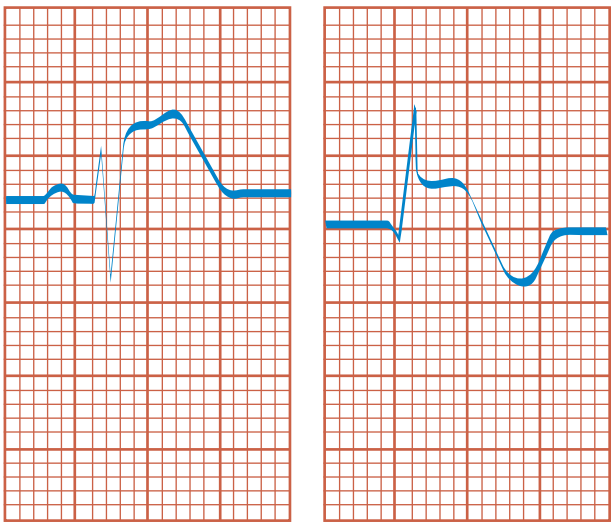

FIGURE 21-8 ▲ ST-segment pattern consistent with acute myocardial injury. **A:** ST-segment elevation without T-wave inversion. **B:** ST-segment elevation with T-wave inversion. The elevated ST segments have a downward concave or coved shape and merge unnoticed with the T wave.

Infarction. When myocardial injury persists, MI is the result. The pattern of the ECG indicative of an MI is seen on the ECG in stages and involves changes in the T wave, the ST segment, and the Q wave in the leads overlying the infarcted area. Figure 21-9 shows the evolution of the ECG in an MI. During the earliest stage of MI, known as the hyperacute phase, the T waves become tall and narrow. This configuration is referred to as hyperacute or peaked T waves. Within a few hours, these hyperacute T waves invert.

Next, the ST segments elevate, a pattern that usually lasts from several hours to several days. In addition to the ST-segment elevations in the leads of the ECG facing the injured heart, the leads facing away from the injured area may show ST-segment depression. This finding is known as reciprocal ST-segment changes. Reciprocal changes are most likely to be seen at the onset of infarction, but their presence on the ECG does not last long. Reciprocal ST-segment depressions may simply be a mirror image of the ST-segment elevations. However, others have suggested that reciprocal changes may reflect ischemia due to narrowing of another coronary artery in other areas of the heart.[15,16]

The last stage in the ECG evolution of an MI is the development of Q waves, the initial downward deflection of the QRS complex. Q waves represent the flow of electrical forces toward the septum. Small, narrow Q waves may be seen in the normal ECG in leads I, II, III, aVR, aVL, V_5, and V_6. Q waves compatible with an MI are usually 0.04 second or more in width or one fourth to one third the height of the R wave. Q waves indicative of infarction usually develop within several hours of the onset of the infarction, but in some patients, they may not appear until 24 to 48 hours after the infarction.

Within a few days after the MI, the elevated ST segments return to baseline. Persistent elevation of the ST segment may indicate the presence of a ventricular aneurysm. The T waves may remain inverted for several weeks, indicating areas of ischemia near the infarcted region. Eventually, the T waves should return to their upright configuration. The Q waves do not disappear and therefore always provide ECG evidence of a previous MI.

The ECG pattern can be used to distinguish acute MIs from "old" MIs. Abnormal Q waves accompanied by ST-segment elevations indicate an acute MI. Abnormal Q waves accompanied by a normal ST segment indicate a previous MI. How long ago the infarction occurred cannot be determined by the ECG. The pattern could signify an infarction that occurred 2 weeks or 20 years before.

The ECG is helpful not only in determining patterns of ischemia, injury, and infarction but also in revealing the anatomical region of the heart where the abnormality has occurred. ECG leads V_1 through V_4 show the anteroseptal wall of the left ventricle. The inferior wall is seen in leads II, III, and aVF. Leads I, aVL, V_5, and V_6 reveal the lateral wall of the left ventricle (see Fig. 21-10). The routine 12-lead ECG does not provide an adequate view of the right ventricle or of the posterior wall of the left ventricle. As a result, additional leads are needed to view these anatomical areas. To attain an accurate view of the right ventricle, right-sided chest leads are recorded by placing the six chest electrodes on the right side of the chest using landmarks analogous to those used on the left side (see Fig. 17-9, p. 224). These six right-sided views are examined for patterns of ischemia, injury, and infarction in the same way left-sided chest leads are evaluated.

Detection of posterior wall abnormalities is also difficult on the standard 12-lead ECG because none of the six chest leads provides an adequate view of the posterior wall. To detect posterior wall abnormalities, three of the precordial electrodes are placed posteriorly over the heart, a view

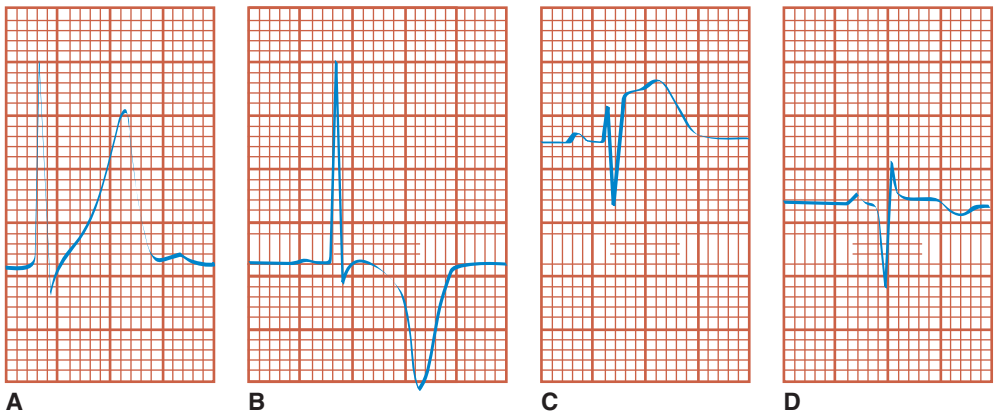

FIGURE 21-9 ▲ Evolution of the electrocardiogram (ECG) in a patient with MI. **A:** Tall peak T waves known as hyperacute T waves. **B:** Symmetrical T-wave inversions. **C:** ST-segment elevation. **D:** Development of the Q wave.

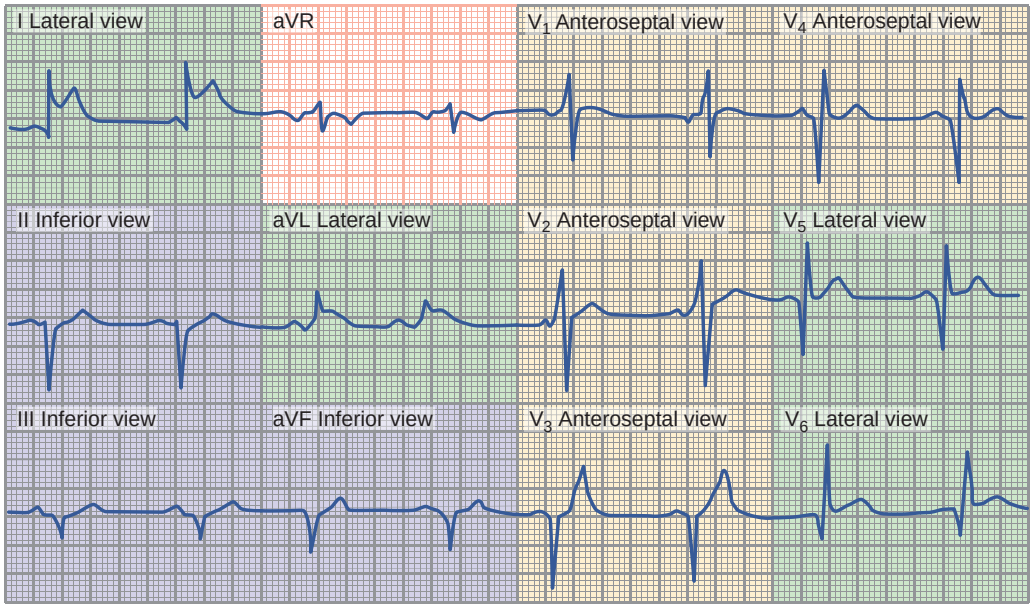

FIGURE 21-10 ▲ The 12-lead ECG: Correlation of lead with the view of the heart.

known as V_7, V_8, and V_9. V_7 is positioned at the posterior axillary line; V_8, at the posterior scapular line; and V_9, at the left border of the spine. All three posterior leads are positioned along the same horizontal line established by V_6. The recording is examined for evidence of ischemia, injury, or infarction using the same criteria as described previously. If posterior leads were not recorded, it may still be possible to detect posterior wall abnormalities. To do so, the principle of reciprocal change is used. When an infarction in the posterior wall is suspected, the leads anatomically opposite the posterior wall are examined. These include V_1 and V_2 because the anterior wall is anatomically opposite the posterior wall. If tall R waves with ST-segment depressions are noted in V_1 and V_2, the pattern is consistent with a posterior wall MI. Figures 21-11 through 21-14 show the 12-lead ECGs of patients with MIs.

LABORATORY TESTS. When myocardial cells are damaged by an infarction, biochemical markers are released into the bloodstream and can be detected by laboratory tests. The presence of abnormally high levels of biochemical markers, their distribution, and the time pattern for their appearance and disappearance make them very useful in the diagnosis of acute MI. For a more detailed discussion of laboratory tests, see Chapter 17.

Creatine Kinase. Creatine kinase (CK) is an enzyme found mainly in heart and skeletal muscles. When heart muscle is damaged, CK is released into the blood. The level of CK becomes abnormal within 6 to 8 hours after the onset of infarction, peaks within 12 to 28 hours, and returns to normal in 24 to 36 hours. The isoenzymes of CK are measured to determine whether the CK came from the heart (MB) or the skeletal muscle. Elevation of CK-MB offers a more definitive indication of myocardial cell damage than total CK alone. For the patient with an MI, CK-MB appears in the serum in 3 to 12 hours, peaks in 24 hours, and returns to normal levels in about 48 to 72 hours.[14]

New assay techniques to measure CK-MB based on monoclonal antibodies offer greater sensitivity and specificity than conventional means. In addition, the results can be available in 30 minutes, which provides a distinct advantage in the diagnosis of an MI, especially in the emergency department (ED).

Creatine Kinase Isoforms. When the myocardial cells release CK-MB, it is quickly transformed into two isoforms, also known as subforms. $CK\text{-}MB_1$ is the isoform found in the plasma, and $CK\text{-}MB_2$ is found in the tissues. In the normal person, these two isoforms are found in about equal amounts, resulting in a ratio of approximately 1. In the patient with an MI, the $CK\text{-}MB_2$ level rises, resulting in a $CK\text{-}MB_2/CK\text{-}MB_1$ ratio greater than 1. This ratio can be rapidly measured in the laboratory and provides an excellent diagnostic marker for acute MI. The $CK\text{-}MB_2$ to $CK\text{-}MB_1$ ratio has improved sensitivity and specificity for diagnosis of MI within the first 6 hours compared with conventional assays for CK-MB. Isoform $CK\text{-}MB_2$ is also a sensitive test for detecting an early extension of an MI during the first 24 hours.[14]

Myoglobin. Myoglobin is an oxygen-binding protein found in skeletal and cardiac muscle. Myoglobin's release from ischemic muscle occurs earlier than the release of CK. As a result, elevation of serum levels of myoglobin can be detected soon after the onset of symptoms. The myoglobin level can elevate within 1 to 4 hours of acute MI and peaks within 6 to 7 hours. Because myoglobin is also present in skeletal muscle, an elevated myoglobin level is not specific for the diagnosis of MI. Consequently, its diagnostic value in detecting an MI is limited. However, the early release of myoglobin makes it valuable in helping to detect MI.[14]

Troponin. Troponin is a contractile protein with two subforms (troponin T and troponin I) that are highly specific for cardiac muscle. Troponin levels are not detected in the healthy person, and skeletal muscle injury does not affect the level. Troponin has been found to be a sensitive marker

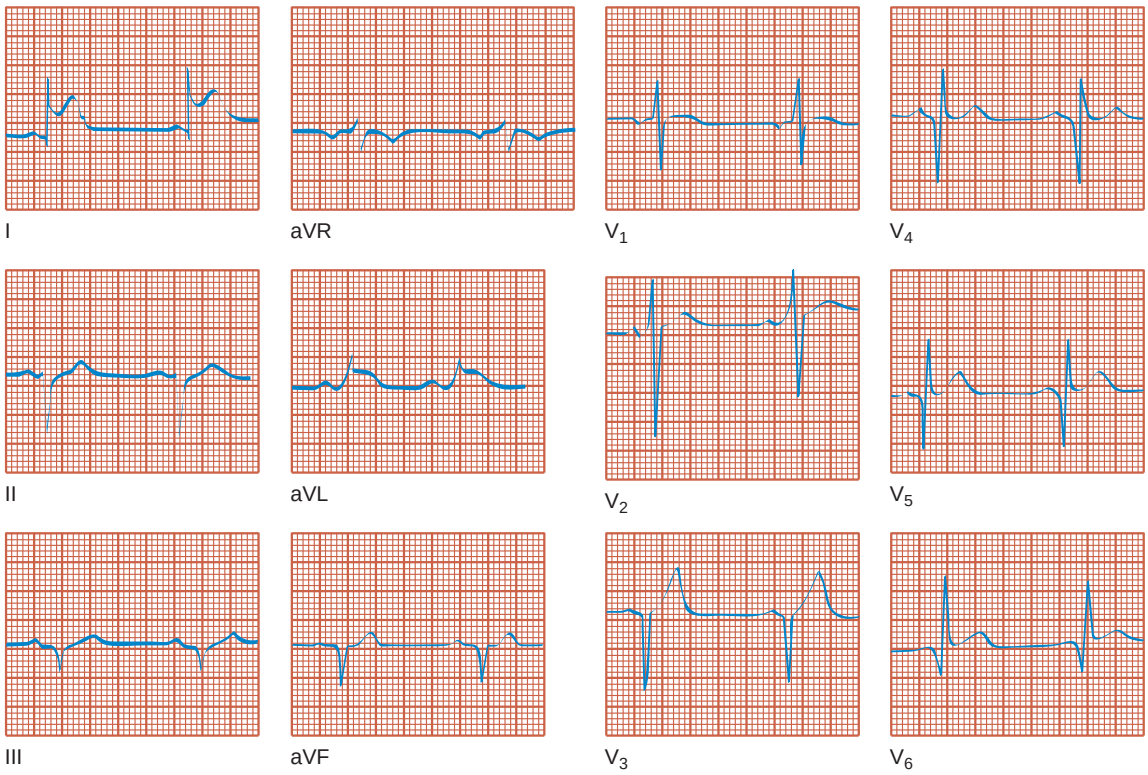

FIGURE 21-11 ▲ Twelve-lead ECG showing an acute lateral wall MI. ST-segment elevations can be seen in leads I, aVL, V5, and V6. Note also the deep Q waves in II, III, and aVF and normal ST segments, indicating a previous inferior wall MI.

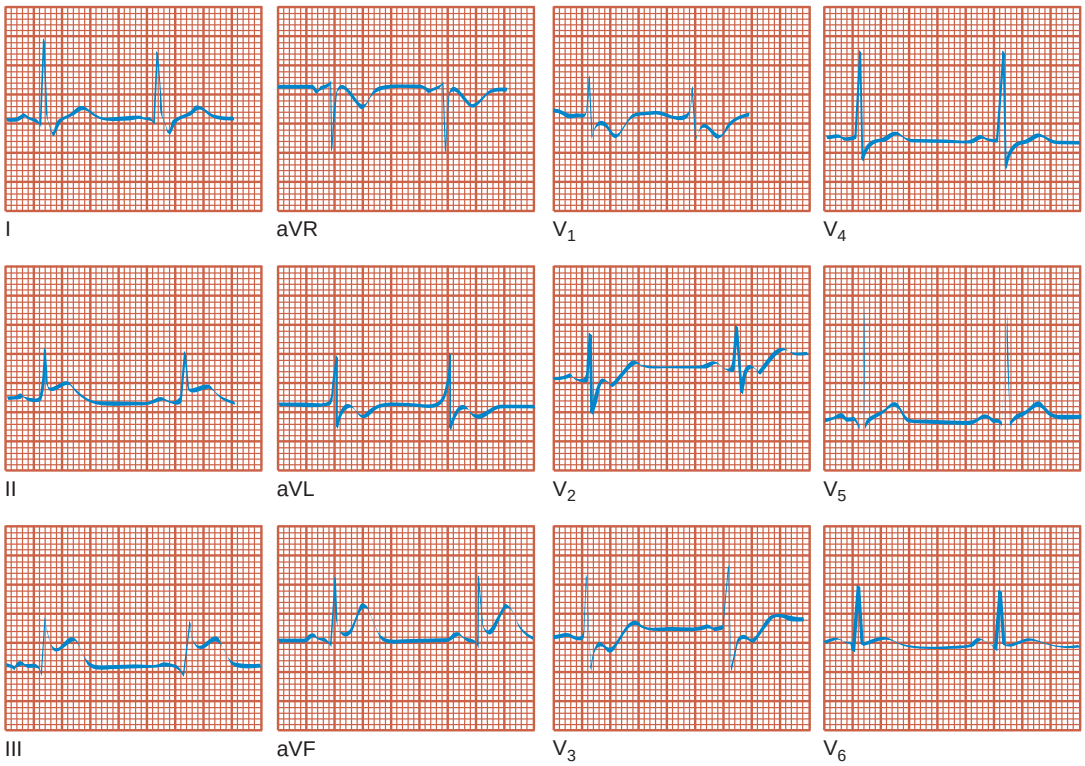

FIGURE 21-12 ▲ Twelve-lead ECG showing an acute inferior wall MI. Note the ST-segment elevations in II, III, and aVF. The posterior wall infarction is evidenced by a tall R wave, ST-segment depression, and inverted T wave in V1 and V2.

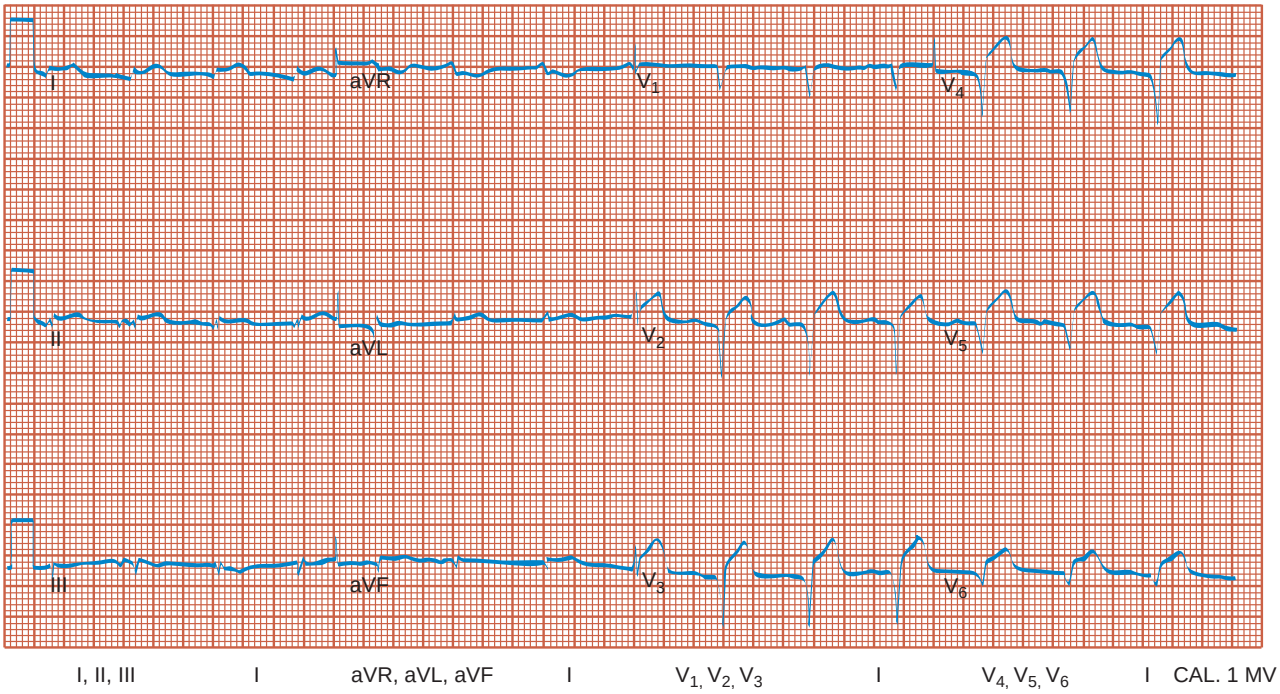

FIGURE 21-13 ▲ Twelve-lead ECG showing an acute anterior and lateral wall MI. Note the ST-segment elevations and Q waves in I, aVL, V5, and V6 (lateral), and V2, V3, and V4 (anterior).

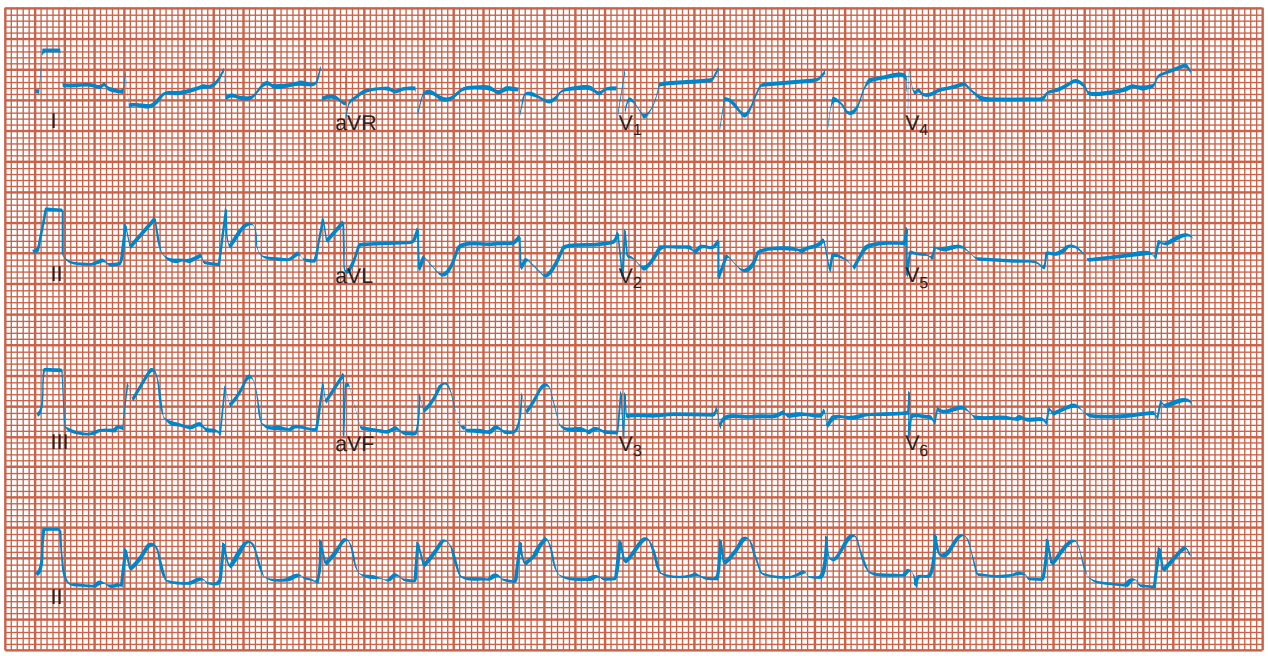

FIGURE 21-14 ▲ Twelve-lead ECG showing right ventricular infarction. The six chest leads have been positioned on the right side of the chest. Note the ST-segment elevation in RV4, RV5, and RV6. The ECG also shows elevated ST segments in the inferior leads (II, III, aVF). Patients with an inferior wall MI often also have an infarction in the right ventricle.

during the early hours after an MI. Troponin I levels rise in 3 to 12 hours, peak at 24 hours, and remain elevated for 5 to 10 days. Troponin T levels rise in 3 to 12 hours, peak in 12 hours to 2 days, and remain elevated for 5 to 14 days.[14] Because the cardiac troponins are highly sensitive and specific for MI, they are the preferred biomarker for diagnosing this coronary event.[14] Other laboratory tests are the same as described previously for the patient with suspected angina and include blood chemistry, complete blood count, coagulation tests, lipid panel, CRP, and white blood cell count.

Other Diagnostic Tests

Patients with an MI should have a chest radiograph. An echocardiogram may be done to detect structural abnormalities, such as valvular problems. Other tests may include radionuclide angiography, MRI, magnetic perfusion imaging, digital subtraction angiography, and single-photon emission computed tomography (SPECT) radionuclide imaging. For a more detailed discussion of these diagnostic tests, see Chapter 17.

Management

Early Management

When a patient with a possible MI arrives in the ED, the diagnosis and initial management of the patient must be rapid because the benefit of reperfusion therapy is greatest if therapy is initiated quickly. An initial evaluation of the patient should occur ideally within the first 10 minutes after arrival.[14] The patient's history and 12-lead ECG are the primary methods used to determine initially the diagnosis of MI. The ECG is examined for the presence of ST-segment elevations of 1 mm or greater in contiguous leads. This pattern provides evidence of thrombotic coronary arterial occlusion. The patient is placed on a continuous cardiac monitor with ST-segment monitoring capabilities.

If the initial screening suggests an MI, the interventions listed in Box 21-6 are initiated. The nurse checks the vital signs frequently, establishes IV access, and continuously assesses the patient's cardiac rhythm. Blood is drawn for serum cardiac markers, hematology, chemistry, and lipid profile. A chest radiograph and echocardiogram, obtained as soon as possible, are useful in ruling out an aortic dissection and acute pericarditis. During the initial evaluation, the patient and family may be anxious, necessitating brief and clear explanations of the interventions. Reassurance and support are essential components of the nurse's responsibilities.

FIBRINOLYTIC THERAPY. If the patient is diagnosed with an MI, fibrinolytic therapy may be used to establish reperfusion if there are no contraindications to its use. Fibrinolytic drugs lyse coronary thrombi by converting plasminogen to plasmin. This conversion causes the degradation of fibrin and fibrinogen, resulting in clot lysis. Box 21-7 lists contraindications to fibrinolytic therapy.[14] Fibrinolytic agents used for treating patients with STEMI include streptokinase, alteplase, reteplase, and tenecteplase.[17]

The goal is to complete the assessment of the patient and the administration of the fibrinolytic drug (if indicated) within 30 minutes of the patient's arrival to the ED. Fibrinolytic therapy provides maximal benefit if given within the first 3 hours after the onset of symptoms. There is a time-dependent decrease in efficacy of fibrinolytic therapy.[14]

For the patient receiving fibrinolytic therapy, two to three 18-gauge peripheral IV lines are usually started. One line is for the fibrinolytic agent, and one to two lines are for the administration of other drugs. Subclavian and jugular sites are avoided because they are noncompressible, and blood could be lost into the chest or neck. Some type of blood sampling device is also inserted so that peripheral venous punctures can be avoided.

The patient is closely monitored during and after the infusion of a fibrinolytic agent. The nurse assesses the patient for

BOX 21-6 Initial Management of the Patient With a Suspected Myocardial Infarction

Action: Administer aspirin, 160 to 325 mg chewed.
Rationale: Aspirin is used because it diminishes platelet aggregation. This effect is important because platelets are one of the main components in thrombus formation when a coronary plaque is disrupted. Aspirin has been shown to reduce mortality rates independently in patients with acute myocardial infarction (AMI). Patients diagnosed with an MI should be continued on aspirin indefinitely.
Action: After recording the initial 12-lead electrocardiogram (ECG), place the patient on a cardiac monitor and obtain serial ECGs.
Rationale: The 12-lead ECG is central in the decision pathway for the diagnosis and treatment of the patient. The patient is placed on a continuous cardiac monitor after the 12-lead ECG is recorded to detect dysrhythmias and to monitor ST-segment changes.
Action: Give oxygen by nasal cannula.
Rationale: Hypoxemia often occurs in patients with an MI because of pulmonary edema. If severe pulmonary edema is present and the patient is in respiratory distress, intubation may be necessary. A pulse oximeter is often applied, and, when time permits, an arterial blood gas may be drawn.
Action: Administer sublingual nitroglycerin (unless the systolic blood pressure is <90 mm Hg or the heart rate is <50 or >100 beats/min). Give 0.4 mg every 5 minutes for a total of three doses.
Rationale: Nitroglycerin helps to promote vasodilation but is relatively ineffective in relieving pain in the early stages of an MI. Intravenous nitroglycerin is recommended for patients with AMI with persistent pain, for control of hypertension, or for management of pulmonary congestion.
Action: Provide adequate analgesia with morphine sulfate.
Rationale: Morphine is the drug of choice to relieve the pain of an MI. The drug is given intravenously in small doses (2 to 4 mg) and can be repeated every 5 minutes until the pain is relieved. Close respiratory and blood pressure monitoring are indicated because morphine can depress respirations and cause hypotension.
Action: Administer β-blocker.
Rationale: During the first few hours after the onset of ST-segment elevation MI, β-blocking agents may diminish myocardial oxygen demand by reducing heart rate, systemic arterial pressure, and myocardial contractility.

From Antman, EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to revise the 1999 guidelines for the management of patients with acute myocardial infarction). Circulation 110:e82–e293, 2004.

BOX 21-7 Contraindications and Cautions for Fibrinolysis in ST-Segment Elevation Myocardial Infarction*

Absolute Contraindications
- Any prior intracranial hemorrhage
- Known structural cerebral vascular lesion (eg, arteriovenous malformation)
- Known malignant intracranial neoplasm (primary or metastatic)
- Ischemic stroke within 3 months *except* acute ischemic stroke within 3 hours
- Suspected aortic dissection
- Active bleeding or bleeding diathesis (excluding menses)
- Significant closed-head or facial trauma within 3 months

Relative Contraindications
- History of chronic, severe, poorly controlled hypertension
- Severe uncontrolled hypertension on presentation (systolic blood pressure >180 mm Hg or diastolic blood pressure >110 mm Hg)†
- History of prior ischemic stroke greater than 3 months, dementia, or known intracranial pathology not covered in contraindications
- Traumatic or prolonged (>10 minutes) CPR or major surgery (<3 weeks)
- Recent (within 2 to 4 weeks) internal bleeding
- Noncompressible vascular punctures
- For streptokinase/anistreplase: prior exposure (more than 5 days ago) or prior allergic reaction to these agents
- Pregnancy
- Active peptic ulcer
- Current use of anticoagulants: the higher the INR, the higher the risk of bleeding

*Viewed as advisory for clinical decision making and may not be all inclusive or definitive.

†Could be an absolute contraindication in low-risk patients with myocardial infarction.

CPR, cardiopulmonary resuscitation; INR, international normalized ratio.

From Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to revise the 1999 guidelines for the management of patients with acute myocardial infarction). Circulation 110:e127, 2004, with permission.

resolution of chest pain, normalization of elevated ST segments, development of reperfusion dysrhythmias, any allergic reactions, evidence of bleeding, and the onset of hypotension. Commonly seen reperfusion dysrhythmias include an accelerated idioventricular rhythm, ventricular tachycardia, and AV heart block.

Evaluation of complications remains a key nursing intervention. The patient is closely monitored for evidence of reocclusion of the coronary artery. Indicators of reocclusion include chest pain, ST-segment elevation, and hemodynamic instability. Close observation for evidence of bleeding also is essential. The patient is carefully assessed for indications of subcutaneous or mucous membrane bleeding. The nurse also monitors the patient for signs of internal bleeding, including positive results of urine and stool for blood or altered levels of consciousness due to intracranial bleeding.

PERCUTANEOUS CORONARY INTERVENTION. Early reperfusion of myocardial tissue is essential to preserve myocardial function. In addition to pharmacological therapy, percutaneous coronary intervention (PCI) is an effective alternative to reestablish blood flow to ischemic myocardium. PTCA, an invasive procedure in which the infarction-related coronary artery is dilated with a balloon catheter, is the type of PCI used. Once the artery is opened by the balloon, a stent may be placed in the artery. PTCA is used for patients who present within 12 hours of the onset of symptoms, and it also can be performed in patients whose ischemic symptoms persist. This therapeutic intervention necessitates the availability of a cardiac catheterization laboratory and skilled personnel at all times.[14] A glycoprotein IIb/IIIa antagonist is often used for the MI patient who is undergoing a PCI. These drugs are potent and specific inhibitors of platelet aggregation.[7] (See Chapter 18 for a more detailed discussion of the PTCA procedure.)

Evaluation of patients for PTCA is similar to that of fibrinolytic therapy. The accessibility of the lesion in the coronary artery is an additional factor that must be considered. PTCA may be an excellent reperfusion alternative for patients ineligible for fibrinolytic therapy. The nurse must carefully monitor the patient after a PTCA for evidence of complications. These complications can include retroperitoneal or vascular hemorrhage, other evidence of bleeding, early acute reocclusion, and late restenosis. If the PCI is not successful, the patient may be evaluated for an emergent CABG procedure.

Intensive and Intermediate Care Management

The management goal for the patient in the intensive care unit and intermediate care unit continues to be maximizing cardiac output while carefully minimizing cardiac workload. To achieve this goal, the patient frequently has vital signs taken and continues on a cardiac monitor with ST-segment monitoring. The lead selected for monitoring should be based on the infarct location and underlying rhythm. Serial ECGs and serial evaluations of serum cardiac markers of infarction are recorded. Serum hematology and chemistry are monitored.

For the first 12 hours of hospitalization, patients who are hemodynamically stable and free of ischemic-type chest discomfort remain on bed rest with bedside commode privileges. Activity level increases gradually in hemodynamically stable patients. Careful attention is paid to maximal pain relief. Nitroglycerin is not an appropriate substitute for analgesics. A pulse oximeter is used to monitor oxygen saturation continuously and is a good indicator of early hypoxemia. When the oxygen saturation level is stable for more than 6 hours, the need for continuous oxygen therapy is reassessed.[14]

The patient is often not given anything by mouth until pain free. When pain free, the patient is given clear liquids and progressed to a heart-healthy diet as tolerated. Daily weights are recorded, and intake and output are measured to detect fluid retention. Stool softeners are administered so that the patient avoids a Valsalva maneuver. During a Valsalva maneuver, forced expiration against a closed glottis causes sudden and significant changes in systolic blood pressure and heart rate. These changes may influence regional endocardial repolarization and place the patient at risk for ventricular dysrhythmias. Nursing diagnoses for patients with acute MI are listed in Box 21-8.

PHARMACOLOGICAL THERAPY. Prophylactic antidysrhythmics during the first 24 hours of hospitalization are not recommended. However, easy access to atropine, lidocaine, amiodarone, transcutaneous pacing patches,

BOX 21–8 EXAMPLES OF NURSING DIAGNOSES

For the Patient With Acute Myocardial Infarction

- Acute Pain related to MI, angina
- Decreased Cardiac Output: Electrical factors affecting rate, rhythm, or conduction
- Decreased Cardiac Output: Mechanical factors related to preload, afterload, or left ventricular failure
- Deficient Knowledge related to illness and impact on patient's future
- Anxiety, Stress Overload related to fear of illness, death, and critical care environment
- Activity Intolerance related to decreased cardiac output or alterations in myocardial tissue perfusion
- Risk for Ineffective Cerebral Tissue Perfusion related to thrombolytic therapy impact

transvenous pacing wires, a defibrillator, and epinephrine is essential for management of dysrhythmias. Daily aspirin is continued on an indefinite basis. Clopidogrel is added to the aspirin regimen for patients with an STEMI and is continued for 14 days.[17]

ACE inhibitors are administered orally within the first 24 hours to patients with anterior wall MI, pulmonary congestion, or left ventricular ejection fraction less than 40%, in the absence of hypotension. ACE inhibitors help prevent ventricular remodeling (dilation) and preserve ejection fraction.[14]

During the first several days after STEMI, it is important to normalize the patient's blood glucose levels. An insulin infusion may be required to achieve this goal.[14]

Patients with a documented magnesium deficit should receive magnesium. Patients with torsades de pointes ventricular tachycardia with prolonged QT intervals also should be treated with magnesium.[14]

IV β-blocker therapy should be administered within the initial hours of the evolving infarction, followed by oral therapy provided there are no contraindications. β-Blockers are one of the few pharmacological agents that have been shown to reduce morbidity and mortality in the patient with an MI. They reduce oxygen demand by decreasing the heart rate and contractility. They also increase coronary artery filling by prolonging diastole. Calcium channel blockers may be given to patients in whom β-blocker therapy is ineffective or contraindicated.[14] The continuation of nitrate therapy beyond the first 24 to 48 hours may be useful for patients with recurrent angina or persistent heart failure.[14]

IV unfractionated heparin or low–molecular-weight heparin is used after STEMI in patients who are at high risk for systemic emboli. The risk is highest in patients with an anterior MI, atrial fibrillation, cardiogenic shock, or a previous embolus.[14]

HEMODYNAMIC MONITORING. Use of a pulmonary artery catheter for hemodynamic monitoring is indicated in the patient with MI who has severe or progressive congestive heart failure or pulmonary edema, cardiogenic shock, progressive hypotension, or suspected mechanical complications, such as ventricular septal defect, papillary muscle rupture, or pericardial tamponade.[14] The pulmonary artery occlusion pressure (PAOP) is closely followed for assessment of left ventricular filling pressures. A PAOP below 18 mm Hg may indicate volume depletion, whereas a PAOP greater than 18 mm Hg indicates pulmonary congestion or cardiogenic shock. Using the thermodilution technique, frequent measurements of cardiac output and cardiac index can be made to evaluate hemodynamic status further. In some situations, monitoring venous oxygen saturation may also be useful. For a more detailed discussion of hemodynamic monitoring, see Chapter 17.

Invasive arterial monitoring is indicated for patients with MI who have severe hypotension or for those receiving vasopressor or vasodilator drugs. The collaborative care guide for the patient with an MI (Box 21-9) provides further information about the care of these patients.

ADDITIONAL DIAGNOSTIC TESTING. At times, additional testing may be needed.

Computer Imaging Tests. One category of computer imaging test is radionuclide imaging and radionuclide angiography. Radionuclide studies provide information about the presence of coronary artery disease as well as the location and quantity of ischemic and infracted myocardium. A radioactive tracer is injected into the patient, and computer-generated images are created. Radionuclide tests include thallium tests, multiple-gated acquisition scans, and infarction scintigraphy.

Another type of computer imaging test is MRI. This diagnostic test uses strong magnets and low-energy radiofrequency signals to reveal structural and functional abnormalities of the heart and aorta. Coronary magnetic resonance angiography uses the principles of MRI in combination with a contrast medium to create images of vessel walls and the presence of any plaques.

Computed tomography (CT) is a type of computer imaging study that provides cross-sectional images of the chest, including the heart and aorta. CT angiography involves a CT scan of the heart after injection of a contrast medium. In addition to providing information about the structure of the heart, CT angiography offers information about the circulation of blood in the heart and coronary arteries. Electron beam CT is a type of ultrafast CT and is considered the gold standard for detecting and quantifying the amount of calcium in coronary plaques. Electron beam CT can note the formation of an atherosclerotic plaque before the development of significant stenotic lesions.[18]

Cardiac PET is another type of computed imaging test. PET combines CT imaging with radionuclide agents to detect coronary artery disease and injured but viable myocardial muscle. PET is a helpful test to determine myocardial muscle viability.

SPECT is a computed imaging test that involves the injection of a radionuclide agent followed by a series of computed graphics of the chest. SPECT is used to determine the extent and severity of blood flow abnormalities and coronary artery disease.[18]

A more detailed discussion of computed imaging tests can be found in Chapter 17.

Echocardiogram. An echocardiogram is a noninvasive ultrasonographic test involving the transmission of high-frequency sound waves into the heart. This commonly used diagnostic test helps determine ejection fraction, segmental wall motion, systolic and diastolic ventricular volumes, valve function, mural thrombi, pericardial fluid, intracardiac

BOX 21–9 COLLABORATIVE CARE GUIDE for the Patient With Myocardial Infarction

Outcomes	Interventions
Oxygenation/Ventilation	
Patient has arterial blood gases within normal limits and pulse oximeter value >90%.	• Assess respiratory rate, effort, and breath sounds every 2–4 h. • Obtain arterial blood gases per order or signs of respiratory distress. • Monitor arterial saturation by pulse oximeter. • Provide supplemental oxygen by nasal cannula or face mask for the first 6 h, then as needed. • Provide intubation and mechanical ventilation as necessary. (Refer to Box 25-16, pp. 538–539).
There is no evidence of pulmonary edema on chest x-ray and by clear breath sounds.	• Obtain chest x-ray daily. • Administer diuretics per order. • Monitor signs of fluid overload as described below.
There is no evidence of atelectasis.	• Encourage nonintubated patients to use incentive spirometer, cough, and deep breath every 4 h and PRN. • While on bed rest, turn patient side to side every 2 h.
Circulation/Perfusion	
Vital signs are within normal limits, including MAP > 70 mm Hg and cardiac index > 2.2 L/min/m^2.	• Monitor HR and BP every 1–2 h and PRN during acute failure phase. • Assist with pulmonary artery catheter insertion. • Monitor PAP and pulmonary artery occlusion pressure (PAOP), CVP, or right atrial pressure (RAP) every 1 h and cardiac output, SVR, and PVR every 6–12 h if pulmonary artery catheter is in place. • Maintain patent IV access. • Administer positive inotropic agents, and reduce afterload with vasodilating agents guided by hemodynamic parameters and physician orders. • Evaluate effect of medications on BP, HR, and hemodynamic parameters. • Prepare patient for intra-aortic balloon pump assist if necessary.
Patient has no evidence of heart failure due to decreased cardiac output.	• Restrict volume administration as indicated by PAOP or CVP values. • Assess for neck vein distention, pulmonary crackles, S_3 or S_4, peripheral edema, increased preload parameters, elevated a wave of CVP, RAP, or PAOP waveform. • Monitor 12-lead ECG daily and PRN.
Patient has no evidence of further myocardial dysfunction, such as altered ECG or cardiac enzymes.	• Monitor cardiac markers, magnesium, phosphorus, calcium, and potassium as ordered. • Monitor ECG for changes consistent with evolving MI. • Consider obtaining right precordial chest leads, 12-lead ECG, if inferior wall/right ventricle is involved. • Report and treat abnormalities per protocols or orders.
Dysrhythmias are controlled.	• Provide continuous ECG and ST-segment monitoring in the appropriate leads. • Document rhythm strips every shift. • Anticipate need for/administer pharmacological agents to control dysrhythmias.
After fibrinolytic therapy, patient will have relief of pain; no evidence of bleeding; no evidence of allergic reaction.	• Assess, monitor, and treat pain as described below. • Monitor signs of reperfusion, such as dysrhythmias, ST-segment return to baseline. • Monitor for signs of bleeding, including neurological, GI, and GU assessment. • Monitor PT, aPTT, ACT per protocol. • Have anticoagulant antidotes available. • Assess for itching, hives, sudden onset of hypotension, or tachycardia. • Administer hydrocortisone or diphenhydramine (Benadryl) per protocol.
There is no evidence of cardiogenic shock, cardiac valve dysfunction, or ventricular septal defect.	• Monitor ECG, heart sounds, hemodynamic parameters, level of consciousness, and breath sounds for changes. • Report and treat deleterious changes as indicated.
Fluids/Electrolytes	
Renal function is maintained as evidenced by urine output >30 mL/h and normal laboratory values.	• Monitor intake and output every 1–2 h. • Monitor blood urea nitrogen, creatinine, and electrolytes daily and PRN. Take daily weights. • Administer fluid volume and diuretics as ordered.

(continued on page 438)

BOX 21–9 COLLABORATIVE CARE GUIDE for the Patient With Myocardial Infarction (continued)

Outcomes	Interventions
Mobility/Safety	
Patient will comply with activity of daily living limitations.	• Provide clear explanation of limitations. • Provide bed rest with bed side commode privileges first 6 h. • Progress to chair for meals, bathing self, and bathroom privileges. Continually assess patient response to all activities.
Patient will not fall or accidentally harm self.	• Provide environment to prevent falls, bruising, or injury. • Use self-protective devices as indicated and per hospital policy.
Skin Integrity	
Patient has no evidence of skin breakdown.	• Turn side to side every 2 h while patient is on bed rest. • Evaluate skin for signs of pressure areas when turning. • Consider pressure relief/reduction mattress for high-risk patients. • Use Braden scale (see Chapter 51) to monitor risk for skin breakdown.
Nutrition	
Caloric and nutrient intake meets metabolic requirements per calculation (eg, basal energy expenditure).	• Provide appropriate diet: oral, parenteral, or enteral feeding. • Provide clear or full liquids during the first 24 h. • Restrict sodium, fat, cholesterol, fluid, and calories if indicated. • Consult dietitian or nutritional support services.
Patient has normal laboratory values reflective of nutritional status.	• Monitor albumin, prealbumin, transferrin, cholesterol, triglycerides, total protein.
Comfort/Pain Control	
Patient has relief of chest pain.	• Use visual analog scale to assess pain quantity.
There is no evidence of pain, such as increased HR, BP, RR, or agitation during activity or procedures.	• Assess quality, duration, and location of pain. • Administer IV morphine sulfate, and monitor pain and hemodynamic response. • Administer analgesics appropriately for chest pain and assess response. • Monitor physiological response to pain during procedures or after administration of pain medication. • Provide a calm, quiet environment.
Psychosocial	
Patient demonstrates decreased anxiety by calm demeanor and vital signs during, for example, procedures and discussions.	• Assess vital signs during treatments and interactions. • Provide explanations and stable reassurance in calm and caring manner. • Cautiously administer sedatives and monitor response.
Patient/family demonstrates understanding of MI and treatment plan by asking questions and participating in care.	• Consult social services and clergy as appropriate. • Assess coping mechanism history. • Allow free expression of feelings. • Encourage patient/family participation in care as soon as feasible. • Provide blocks of time for adequate rest and sleep.
Teaching/Discharge Planning	
Patient reports occurrence of chest pain or discomfort.	• Explain importance of reporting all episodes of chest pain. • Provide frequent explanations and information to family.
Family demonstrates appropriate coping during the critical phase of an acute MI.	• Encourage family to ask questions regarding treatment plan, patient response to therapy, prognosis, and so forth.
In preparation for discharge to home, patient understands activity levels, dietary restrictions, medication regimen, and what to do if pain recurs.	• Make appropriate referrals and consults early during hospitalization. • Initiate family education regarding heart-healthy diet, cardiac rehabilitation program, stress-reduction strategies, and management of chest pain after crisis phase has passed.

tumors, and aortic dissection.[14] Two-dimensional, Doppler, and transesophageal echocardiograms are the most frequently used types of echocardiograms for patients with an MI. (See Chapter 17 for further discussion of echocardiograms.)

Stress Test. Stress testing, also known as exercise electrocardiography, may be performed before discharge or within the first 3 weeks after discharge. The test is intended to assess the patient's functional capacity and ability to perform activities of daily living, to evaluate the efficacy of the patient's medical therapy, and to risk-stratify the patient based on the likelihood of a subsequent cardiac event. Stress testing may be combined with perfusion imaging to determine better the size of the infarction. (See Chapter 17 for further discussion of stress testing.)

Coronary Angiography. During the course of hospitalization, patients may be further evaluated by coronary angiography. Results of the angiography help the physician determine whether a PTCA or placement of a stent is indicated, or if the patient is a candidate for CABG. (A more detailed discussion of PTCA can be found in Chapter 18, and a more detailed discussion of CABG can be found in Chapter 22.)

Complications

The nurse closely monitors the patient with MI for evidence of complications. Numerous complications can occur, and a list of possible complications is provided in Box 21-10. Prompt recognition and management of complications are essential in reducing mortality and morbidity.

Hemodynamic Complications

Recurrent myocardial ischemia can occur in patients and is often transient. A recurrent MI is another possible complication. If the reinfarction occurs within the first 24 hours, it may be hard to diagnose because the cardiac serum markers have not yet returned to baseline. Early recognition and management are essential for both of these vascular complications. Efforts are made to lower myocardial oxygen demand and to relieve pain. Emergent PTCA or surgical revascularization may be considered.

Cardiogenic shock is the most serious myocardial complication of MI. It occurs because of the loss of contractile forces in the heart, resulting in left ventricular dysfunction. Cardiogenic shock is the most common cause of in-hospital death for patients with MI. (For a more detailed discussion of cardiogenic shock, see Chapter 54.)

Clinical manifestations of cardiogenic shock include a rapid, thready pulse; a narrow pulse pressure; dyspnea; tachypnea; inspiratory crackles; distended neck veins; chest pain; cool, moist skin; oliguria; and decreased mentation. Arterial blood gas analysis reveals a decreased PaO_2 and respiratory alkalosis. Hemodynamic findings include a systolic blood pressure less than 85 mm Hg, a mean arterial blood pressure less than 65 mm Hg, a cardiac index less than 2.2 L/min/m^2, and a PAOP greater than 18 mm Hg. Cardiac enzymes may show an additional rise or a delay in reaching peak values.

The goal of treatment for cardiogenic shock is to minimize myocardial workload and maximize myocardial oxygen delivery. Immediate actions must be taken to improve tissue perfusion and preserve viable myocardium. To improve oxygenation, supplemental oxygen is given to the patient and, if necessary, the patient may be intubated and placed on a mechanical ventilator. Efforts are aimed toward restoring blood pressure. This may require discontinuation of vasodilator drugs and drugs with negative inotropic effects. An IV dopamine drip may be initiated to improve the patient's blood pressure and improve myocardial contractility. Dobutamine may be used to improve contractility, especially in low cardiac output states. Nitroprusside, a vasodilator, may be used with a vasopressor to improve cardiac output by decreasing peripheral vascular resistance and reducing left ventricular preload. Treatment may also require the use of an IABP. This invasive device helps improve coronary artery perfusion and decrease left ventricular afterload. (For a more detailed discussion of IABP therapy, see Chapter 18.)

BOX 21-10 Complications of Acute Myocardial Infarction

Hemodynamic Complications
- Hypotension
- Pulmonary congestion
- Cardiogenic shock
- Right ventricular infarction
- Recurrent ischemia
- Recurrent infarction

Myocardial Complications
- Diastolic dysfunction
- Systolic dysfunction
- Congestive heart failure

Mechanical Complications
- Mitral valve regurgitation
- Left ventricular free wall rupture
- Ventricular septal rupture
- Left ventricular aneurysm

Pericardial Complications
- Pericarditis
- Dressler's syndrome
- Pericardial effusion

Thromboembolic Complications
- Mural thrombosis
- Systemic thromboembolism
- Deep venous thrombosis
- Pulmonary embolism

Dysrhythmia Complications
- Ventricular tachycardia
- Ventricular fibrillation
- Supraventricular tachydysrhythmias
- Bradydysrhythmias
- Atrioventricular block (first, second, or third degree)

From Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to revise the 1999 guidelines for the management of patients with acute myocardial infarction). Circulation 110:e82–e293, 2004.

Mechanical Complications

The most catastrophic mechanical complications of MI are intraventricular septal rupture and left ventricular free wall rupture. These clinical situations develop rapidly and result in almost immediate physiological deterioration.

VENTRICULAR SEPTAL WALL RUPTURE. The frequency of acute rupture of the intraventricular septum has declined with the use of reperfusion therapy. Ventricular septal rupture occurs in about 1% of patients with an STEMI and in about 4% of those patients who also have cardiogenic shock.[14] The greatest risk for ventricular septal wall rupture is within the first 24 hours and continues for up to 5 days.[14] The patient presents with a new, loud, holosystolic murmur associated with a thrill felt in the parasternal area. In addition, the patient has progressive dyspnea, tachycardia, and pulmonary congestion. Oxygen samples taken from the right atrium, right ventricle, and pulmonary artery show a higher PaO_2 in the right ventricle than in the right atrium because the oxygenated left ventricular blood is shunted to the right ventricle. This testing can be accomplished during pulmonary artery catheterization. Urgent cardiac catheterization and surgical correction are needed. The patient can be supported with fluid administration, inotropic support (dopamine and dobutamine), afterload reduction (nitroprusside), and IABP counterpulsation until emergency surgery is possible. Some fibrosis of the tissue is needed for suturing. Often it is impossible to maintain the patient medically until this occurs.

LEFT VENTRICULAR FREE WALL RUPTURE. Left ventricular free wall rupture occurs in about 1% to 6% of patients with STEMI.[14] Left ventricular free wall rupture is more likely to occur either within the first 24 hours after MI or 3 to 5 days after MI.[14] Early rupture is a result of the initial evolution of the infarction before significant collagen deposition. Late rupture is related to expansion of the infarction in the ventricular wall.[14] Left ventricular free wall rupture is more likely to occur in patients older than 70 years of age, women, hypertensive patients, and patients with their first MI. The patient experiences prolonged chest pain, dyspnea, sudden hypotension, jugular venous distention, tamponade, and ECG evidence of electrical–mechanical dissociation. This event occurs so suddenly and with such severity that lifesaving efforts are often futile.

PERICARDIAL COMPLICATION. Pericarditis is common after MI and can occur as soon as the first 3 days after infarction or as late as several weeks after infarction. The patient reports chest pain that may be confused with ischemic pain. The precordial pain of pericarditis intensifies with deep breathing, coughing, swallowing, and lying flat. The pain is lessened when the patient sits up and leans forward. The patient may have a fever, with a temperature usually less than 38.6°C, that lasts for several days. Often on auscultation, a friction rub can be heard along the left sternal border. Some friction rubs are transient; therefore, the absence of such a rub is not conclusive. Often the ECG shows concave upward ST-segment elevation on five or more leads. Anti-inflammatory agents, such as aspirin, indomethacin, and corticosteroids, are given in usual doses for 7 to 14 days.[14]

THROMBOEMBOLIC COMPLICATIONS. Thromboembolisms occur in fewer MI patients than previously because of the routine use of anticoagulants. Those patients with a deep venous thrombosis (DVT) may be predisposed because of the systemic inflammatory response associated with infarction, immobility, venous stasis, and reduced cardiac output. Pulmonary embolism is a risk for patients with DVT. After MI, patients are also at risk for systemic emboli that usually originate in the wall of the left ventricle. These emboli can occlude the cerebral, renal, mesenteric, or iliofemoral artery. Patients are systemically anticoagulated with unfractionated or low–molecular-weight heparin followed by warfarin (Coumadin) for 6 to 12 months.[14]

DYSRHYTHMIA COMPLICATIONS. Cardiac dysrhythmias and conduction disturbances often accompany acute MIs and can be life threatening. The causes of electrical complications are many and include myocardial ischemia, myocardial necrosis, altered autonomic tone, electrolyte imbalances, acid–base disturbances, and adverse drug effects.

Ventricular dysrhythmias that occur in the prehospital phase cause the majority of sudden cardiac deaths. Ischemic myocardium has a lower fibrillatory threshold, and few ventricular dysrhythmias are considered benign after an infarction. Patients may experience tachydysrhythmias or bradydysrhythmias during the hospital phase of treatment. Supraventricular rhythms may be the result of high left atrial pressures caused by left ventricular failure.

Conduction disturbances after MI can include those caused by SA node, AV node, or ventricular conducting tissue abnormalities. The right coronary artery supplies the SA node in about half of all patients, and the left circumflex coronary artery supplies the SA node in the other half. Because the right coronary artery is also the source of oxygenated blood for the inferior, right posterior, and right ventricular walls, patients with inferior, right posterior, or right ventricular wall MIs are at risk for conduction disturbances resulting from poor SA node functioning. Patients with lateral wall MIs also are at risk for SA nodal conduction disturbances because the left circumflex vessel supplies the lateral wall of the heart.

The right coronary artery also is the source of oxygenated blood for the AV node in about 90% of people. Therefore, patients with inferior, right posterior, or right ventricular wall infarctions due to right coronary artery occlusion are at risk for AV nodal conduction disturbances. First-degree heart block and Mobitz type I (Wenckebach) block may appear, but often are transient. These rhythm disturbances may progress to complete heart block and require pacing therapy.

The LAD coronary artery is the primary source of blood supply to the bundle of His and bundle branches. Therefore, patients with an anterior wall MI caused by an LAD occlusion are at risk for ventricular conduction defects. Conduction defects, such as right bundle branch block, left bundle branch block, anterior fascicular block, posterior fascicular block, bifascicular block, or trifascicular block, may occur.

For patients with MI, the nurse continuously monitors the cardiac rate and rhythm, assesses the apical and peripheral pulses, auscultates the heart, and monitors blood pressure and other indicators of hemodynamics, such as urine output and level of consciousness. The goals of therapy for cardiac dysrhythmias and conduction disturbances are to restore normal rate, rhythm, and AV synchrony and to maintain

Table 21-2 Patient Teaching: Goals After Acute Myocardial Infarction

	When Mastery of Content Is To Be Expected:		
Content	***Acute Phase***	***Before ICU Discharge***	***At Hospital Discharge***
Pathophysiology of heart disease	Can identify angina, using 0–10 pain scale for reference	Can initiate treatment of angina (rest, nitroglycerin, O_2 use)	Knowledgeable about medications, when to seek medical assistance
Environment of hospital	Understands procedures	Asks appropriate questions	Knowledgeable about disease process and therapy
Lifestyle modifications	Complies with activity limitations Complies with dietary limitations	Can state relationship between activity and cardiac workload Begins light activity States risk factors Selects appropriate meals	Can progress activity as tolerated Placement in cardiac rehabilitation program Can state dietary restrictions
Treatment of disease	Accepts medications as ordered	Can identify medications Can identify risk factors	Knowledgeable about medications, dose, timing, action, and side effects Plans for risk factor reduction Begins cardiac rehabilitation program
Emotional adaptation	Able to define support system	Begins to communicate about lifestyle changes Becomes involved with resolving emotions related to surviving a critical illness	Involves self and loved ones in plans for lifestyle changes Expresses feelings Participates in group recovery program

adequate cardiac output. To achieve these goals, pharmacological therapy may be indicated. Cardioversion may be used to treat patients with supraventricular dysrhythmias, such as atrial fibrillation or atrial flutter. Transcutaneous pacing may be indicated in an emergent situation for heart block dysrhythmias until a transvenous temporary pacemaker can be initiated. The patient may require permanent pacemaker implantation to maintain an adequate rate and rhythm. Some patients may require an implantable cardioverter–defibrillator to manage ventricular dysrhythmias. (For a more detailed discussion of pacemakers and implanted cardioverter–defibrillators, see Chapter 18.)

Cardiac Rehabilitation

Preparation for discharge must begin early in the patient's course of hospitalization. Patient and family education is an essential component of the process. A severely compromised, critically ill patient may lack the ability to process and retain new information but usually is motivated to learn after the life-threatening event. Guidelines for patient and family education after an acute MI are described in Table 21-2.

Cardiac rehabilitation is recommended for most patients after MI. Cardiac rehabilitation involves a combination of prescribed exercise, education, and counseling. The goals of cardiac rehabilitation are to limit the adverse physiological and psychological effects of heart disease, modify risk factors, reduce the risk for sudden death or reinfarction, control cardiac symptoms, stabilize or reverse the atherosclerotic process, and enhance the patient's psychosocial and vocational status.[14] Components of cardiac rehabilitation programs include exercise, smoking cessation, lipid management, weight control, blood pressure control, psychological interventions, and guidance for return to work. Cardiac rehabilitation programs have been shown to improve the patient's functional capacity and quality of life and to decrease emotional distress, risk for subsequent coronary events, and cardiovascular mortality. Although the benefits of cardiac rehabilitation are well known, fewer than one third of patients receive information or counseling about cardiac rehabilitation before being discharged from the hospital.[14]

Family members of patients with MI should be included in the educational process so that they can learn about heart disease and help the patient achieve the goals of rehabilitation. Family members also should be given the opportunity to learn cardiopulmonary resuscitation because most episodes of cardiac arrest in patients with MI occur within the first 18 months after discharge from the hospital.[14]

▲ Clinical Applicability Challenges

CASE STUDY

Mr. M., a 71-year-old white male, was brought to the emergency department by an ambulance at 10:30 AM. He described substernal chest pain with radiation to his left arm that began 1 hour ago. The pain is not relieved by rest or sublingual nitroglycerin. He describes the pain as dull and rates it an 8 on a scale of 10. He feels nauseated but has not vomited. Mr. M. has a history of smoking, obesity, diabetes, and elevated cholesterol levels. He has no known drug allergies.

On physical examination, he was awake, alert, oriented, and agitated. His skin was cool and diaphoretic. Blood pressure was 98/50 mm Hg; heart rate, 110 beats/min and regular; respiratory rate, 22 breaths/min on 2 L O_2 per nasal cannula; and temperature, 98°F (36.7°C). Cardiac examination revealed S_1, S_2, and an S_3. Mr. M. had no jugular venous distention. Peripheral pulses were present but thready, and there was 1+ pedal edema bilaterally. Auscultation of the lungs revealed bilateral basilar crackles. He had no evidence of cyanosis or clubbing. His abdominal examination showed positive bowel sounds in all quadrants. His abdomen was soft and nontender with no palpable masses.

The nurse immediately recorded a 12-lead ECG that showed a 4-mm ST-segment elevation in leads V_1 through V_4. Blood samples were drawn that revealed an elevated CK level positive for MB. His troponin level was also abnormal. Mr. M. was given an aspirin, and an intravenous (IV) line was started. His pain was treated with IV morphine sulfate. Mr. M. was diagnosed with an acute anteroseptal wall MI and was admitted to the coronary care unit. On day 2 after admission, Mr. M.'s blood pressure was 82/58 mm Hg. His pulse was 128 beats/min and thready and respirations were 28 breaths/min. On physical examination, he displayed inspiratory crackles, distended neck veins, and cool moist skin. His urine output declined to 30 mL/h.

1. Mr. M. was diagnosed with an anteroseptal wall myocardial infarction (MI). What coronary artery is most likely occluded and what potential complications are priorities for you to monitor?

2. On day 2, Mr. M. sustained significant physiologic changes as noted by the physical examination findings. Mr. M. is most likely having what complication post-MI?

3. What are the goals for treating Mr. M. during day 2 after admission?

22 Cardiac Surgery

Nancy Munro

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Discuss the indications for coronary artery bypass grafting surgery and valvular surgery.
2. Describe the nursing care of the patient before and after coronary artery bypass grafting surgery.
3. Compare and contrast the pathophysiological implications of stenosis and insufficiency in the mitral and aortic valves.
4. Explain nursing interventions used to prevent complications post cardiac surgery.
5. Discuss the nursing care of the patient before and after carotid endarterectomy.

Despite emphasis on modifying and eliminating risk factors, cardiovascular disease remains a leading cause of disability and death in the United States. Development of new treatments, such as thrombolytic and anticoagulation therapy, balloon and laser angioplasty, and coronary artery stenting, has improved medical management of cardiac disease. These nonsurgical approaches are discussed in Chapter 18. However, surgical intervention remains the treatment of choice in some patient populations with coronary artery disease (CAD) and valvular disease.

▲ Indications for Cardiac Surgery

Coronary Artery Disease

A discussion of the pathophysiology of coronary artery disease (CAD) is found in Chapter 21.

Coronary Artery Bypass Graft Surgery

In coronary artery bypass graft (CABG) surgery, native vessels or conduits are "harvested" during the initial phase of surgery and used to reroute or bypass blood flow past diseased areas of the coronary arteries. CABG surgery has become an acceptable treatment for CAD. Compared with medical treatment, CABG surgery has proved effective in relieving angina and improving exercise tolerance, and it prolongs life in patients with left main CAD and three-vessel disease with poor left ventricular function.[1]

Increased use of percutaneous transluminal coronary angioplasty and stenting has decreased the need for CABG surgery in many cases. Patients selected for such surgery today are older, have more advanced coronary disease, have more impaired left ventricular function, and, in many cases, have had previous CABG surgery. To decrease the mortality associated with bypass surgery, it is necessary to consider several factors: urgency of operation, age, previous heart surgery, sex, left ventricular ejection fraction, percentage stenosis of the left main coronary artery, and number of major coronary arteries with greater than 70% stenosis.[1]

Desired characteristics for a graft or conduit are (1) diameter similar to the coronary arteries, (2) no disease or vessel wall abnormalities, and (3) adequate length. Commonly used grafts include saphenous vein grafts and internal mammary artery grafts.

SAPHENOUS VEIN GRAFTS. Saphenous vein grafts are used to bypass the obstruction in the coronary artery by anastomosing one end of the vein to the aorta (proximal anastomosis) and the other end to the coronary artery just past the obstruction (distal anastomosis). Saphenous vein grafts may be simple, with an end-to-side anastomosis to the aorta and the coronary artery, or sequential (also called skip), with an end-to-side anastomosis to the aorta, a side-to-side anastomosis to one coronary artery, and an end-to-side anastomosis to another coronary artery (Fig. 22-1).

Although the saphenous vein can be taken from above or below the knee, a vein from below the knee is generally preferred because it is close in diameter to the size of the coronary artery. To remove the vein, an incision is made along the inner aspect of the leg. Alternatively, small incisions can be made in the area of the vein, and a flexible fiberoptic scope is inserted to visualize the vessel and remove it. The fiberoptic method of vein removal is associated with improved wound healing and reduced complications involving the incision site.[2]

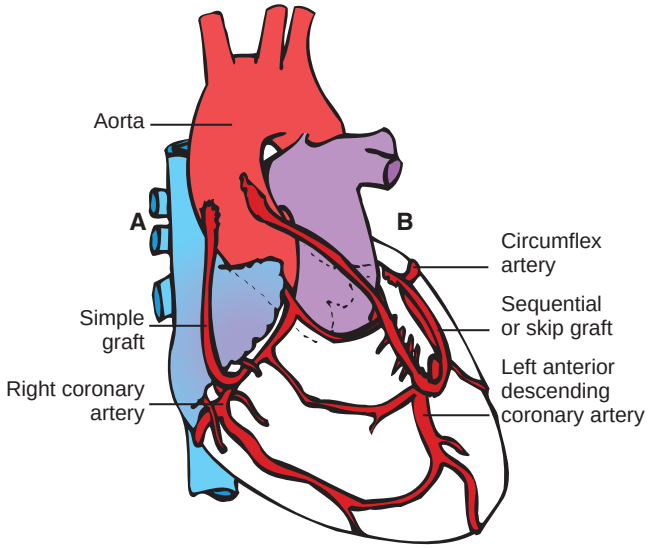

FIGURE 22-1 ▲ Aortocoronary bypass grafts using saphenous vein. **A:** Simple graft from aorta to right coronary artery. **B:** Sequential graft from aorta to left anterior descending coronary artery to diagonal or circumflex artery.

About 50% of saphenous vein grafts are occluded after 10 years. Three main processes account for saphenous vein failure: thrombosis, fibrointimal hyperplasia, and atherosclerosis. Thrombosis is most common in the first month but may occur as long as 1 year after surgery. Aspirin is the drug recommended for use postoperatively to prevent early saphenous vein graft closure and should be continued indefinitely.[1] To decrease the incidence of occlusion of the saphenous vein graft, grafts from other vessels are being used.[3]

INTERNAL MAMMARY ARTERY GRAFTS. The internal mammary artery is a preferred alternative to the saphenous vein for surgical revascularization. The internal mammary artery is used as a pedicle graft (ie, the proximal end remains attached to the subclavian artery) to bypass diseased coronary arteries. Both the left and the right internal mammary artery can be used. Because the left internal mammary artery is longer and larger than the right, it is usually used to bypass the left anterior descending coronary artery. The right internal mammary artery is anastomosed to the right coronary artery or the circumflex coronary artery. To isolate the internal mammary artery, the pleural space is entered, the internal mammary artery is dissected free from the chest wall, and the intercostal artery branches are cauterized. Compared with saphenous vein grafts, internal mammary artery grafts have superior graft patency rates; 90% were patent 10 years after surgery. In addition, internal mammary artery grafts exhibit less atherosclerosis over time, and they have been associated with lower long-term morbidity and improved long-term survival.[1]

OTHER GRAFTS. The search for other native vessels to serve as conduits continues as patients return for reoperation. The use of the radial artery has gained popularity; occlusion rates have lowered as harvesting techniques have improved. The radial artery, a thick, muscular artery, is prone to spasm with mechanical stimulation, and to prevent spasm, the artery is perfused with a calcium channel blocker solution during surgery and minimally stimulated. After the radial artery has been implanted, spasm has not been a major factor, and this conduit has good patency rates.[4] Initiation of nitroglycerin followed by oral nitrates (isosorbide mononitrate) postoperatively has helped decrease the occurrence of spasm; results have been better than with calcium channel blockers.[5]

Acceptable alternative conduits must have short- and long-term acceptable patency rates. The right gastroepiploic artery, which is harvested by extending the sternotomy incision toward the umbilicus and dissecting the artery off the greater curvature of the stomach, is used for coronary grafting. Patency rates have been acceptable, but long-term data are not available.[1] Homologous (nonnative) conduits using the saphenous vein, umbilical vein, or bovine internal mammary artery have resulted in poor patency rates and therefore are not recommended.[1] A comparison of common conduits used for revascularization is presented in Table 22-1.

Table 22-1 Common Conduits Used for Coronary Artery Bypass Grafting

Type of Graft	Advantages	Disadvantages
Internal mammary artery	• Vascular endothelium adapted to arterial pressure and high flow, resulting in decreased intimal hyperplasia and atherosclerosis • Improved long-term patency • Retains nerve innervation and therefore its ability to adapt diameter to blood flow • No leg incision • Diameter closer to coronary artery	• Dissection off the chest wall takes more time; long dissection time may increase risk for postoperative bleeding • Pleural chest tube needed because pleural space violated • Increased postoperative pain • Use of bilateral internal mammary arteries may increase risk for infection and sternal infection, especially in patients with diabetes
Saphenous vein	• Technically easier to harvest • Longer length (if able) may allow for several grafts	• Less long-term patency compared with internal mammary artery graft • Leg incision has tendency toward edema and infection; less common with fiberoptic approach
Radial artery	• Technically easier to harvest • Better patency rate compared with saphenous vein graft • Vascular endothelium adapted to arterial pressure and high flow, resulting in decreased intimal hyperplasia and atherosclerosis	• Tendency to spasm, although this can be treated medically • Preoperative assessment of ulnar artery's ability to supply alternative blood flow is important

Off-Pump Coronary Artery Bypass Graft Surgery

CABG surgery actually began as a surgical procedure performed on a beating heart because the cardiopulmonary bypass machine was not yet available. Once the cardiopulmonary bypass machine was perfected, "beating heart" surgery was used less often. This machine, also called a pump oxygenator, assumes the job of oxygenating the patient's blood and circulating it throughout the body. However, complications associated with cardiopulmonary bypass have led surgeons to reconsider performing CABG surgery "off pump" (OPCABG)—in other words, on beating hearts—in the hope of improving patient outcome.

Initially, surgeons wanted to avoid using the midline sternotomy incision and use the less invasive "mini" left and right thoracotomy approaches while performing CABG surgery, on or off bypass. This approach, which is known as minimally invasive direct coronary artery bypass grafting (MIDCABG), restricts the number of grafts that can be performed because the small incision does not allow access to the entire heart surface. Grafts to the left anterior descending artery are most frequent. Depending on where the "mini" incision is placed, grafts to the right coronary artery and the posterior descending artery can also be made.[6] Experience with MIDCABG has not been as successful as anticipated, but the technique is still used depending on the patient situation. The trend is toward using the median sternotomy incision but performing the grafting process off bypass.

In the 1990s, as neurological complications associated with the cardiopulmonary bypass machine, especially cognitive dysfunction, became more prominent, OPCABG surgery was reinstituted.[7] The initial results of OPCABG surgery have been promising but sometimes difficult to compare with the large data pool for on-pump CABG surgery. Length of stay in patients after OPCABG surgery has decreased compared with length of stay in patients who have had on-pump CABG surgery.[8] In addition, neurological dysfunction seems less after OPCABG surgery. However, Peel et al demonstrated that the stroke rate is similar in patients who undergo OPCABG compared with those who undergo on-pump CABG; after OPCABG, the symptoms of the stroke appear 48 to 72 hours after surgery, and after on-pump CABG, the symptoms of stroke occur immediately after surgery.[9] The explanation for this finding is that systemic inflammatory response syndrome (SIRS; discussed in detail in Chapter 54) causes diffuse microembolic events that take time to develop. The microembolization is the result of the inflammation of the endothelium, which activates the coagulation cascade.

The significance of these differences for patient care after OPCABG surgery is not well documented in the nursing literature because OPCABG surgery is a new procedure. Data from institutions with larger numbers of patients who have had this surgery seem to suggest that emphasis should be placed on anticoagulation interventions.[9] Traditional agents, such as heparin (weight-based protocols), aspirin, clopidogrel (Plavix), and low-molecular-weight heparin, are aggressively implemented to prevent platelet activation and suppress activation of the coagulation cascade. Nursing assessment focuses on the detection of embolic events in any body system and monitors for side effects of anticoagulation, such as gastrointestinal bleeding and heparin-induced thrombocytopenia. Because SIRS can develop in 48 to 72 hours, the critical care nurse must continually reassess the patient who has undergone OPCABG surgery and report any changes that may occur, especially with regard to neurological changes or electrocardiographic (ECG) ST-segment monitoring. If the thoracotomy approach is used, the increased need for pain medication may decrease patient compliance to cough and deep-breathe postoperatively. A high index of suspicion is the key nursing intervention after OPCABG surgery and may improve patient outcome.

Transmyocardial Laser Revascularization

Transmyocardial laser revascularization (TMR; TMLR) may be an option for patients who continue to have unstable angina that is refractory to interventions. Eligible patients usually have had prior CABG surgery, multiple cardiac interventions with maximal medication manipulation, or both. A laser probe is inserted into the wall of the left ventricle to create channels that encourage revascularization. The location and number of channels created depend on the patient's preoperative cardiac performance. Revascularization theoretically occurs through two mechanisms: (1) angiogenesis and (2) direct channel patency and endothelialization.[10] With angiogenesis, the formation of new blood vessels or the modeling of existing blood vessels increases collateral flow to the dysfunctional areas. Direct channel patency with endothelialization may result in direct perfusion to impaired walls of the left ventricle. Although the actual mechanisms are not clearly understood, the clinical outcomes are promising. In TMR, revascularization takes months to develop, which should be emphasized to the patient and family. In TMR, three types of lasers of different wavelengths are used: holmium:YAG, excimer, and carbon dioxide. All produce clean channels with minimal tissue trauma.[10]

Care of patients after TMR is similar to care after cardiovascular surgery, with some special concerns. The life of patients who have had TMR can become relatively normal, but careful observation is required. In TMR, patients have sustained direct myocardial insult that can result in a decrease in left ventricular function 48 to 72 hours after the surgery. Inotropic support using dobutamine or milrinone may be required for several days. Vigilant monitoring of fluid status is necessary because congestive heart failure tends to occur, although patients have higher filling pressures because the desired effects of TMR develop over time. Antiarrhythmic therapy may also be necessary because there may be irritable foci in the ventricle; amiodarone is frequently used. Angina may occur, but because the channel areas are denervated in TMR, the patient may be unable to perceive anginal pain. Continuous ST-segment monitoring is needed to detect any changes that occur. Nitrates are started as part of the medication regimen. Anticoagulation is initiated to prevent myocardial infarction (MI) and also to maintain the patency of the channels.[11]

Valvular Disease

Cardiac valves maintain the unidirectional flow of blood. If structural changes occur as a result of disease, this function is disrupted. Disease causes either valvular stenosis or insufficiency (regurgitation; Fig. 22-2). The stenotic valve

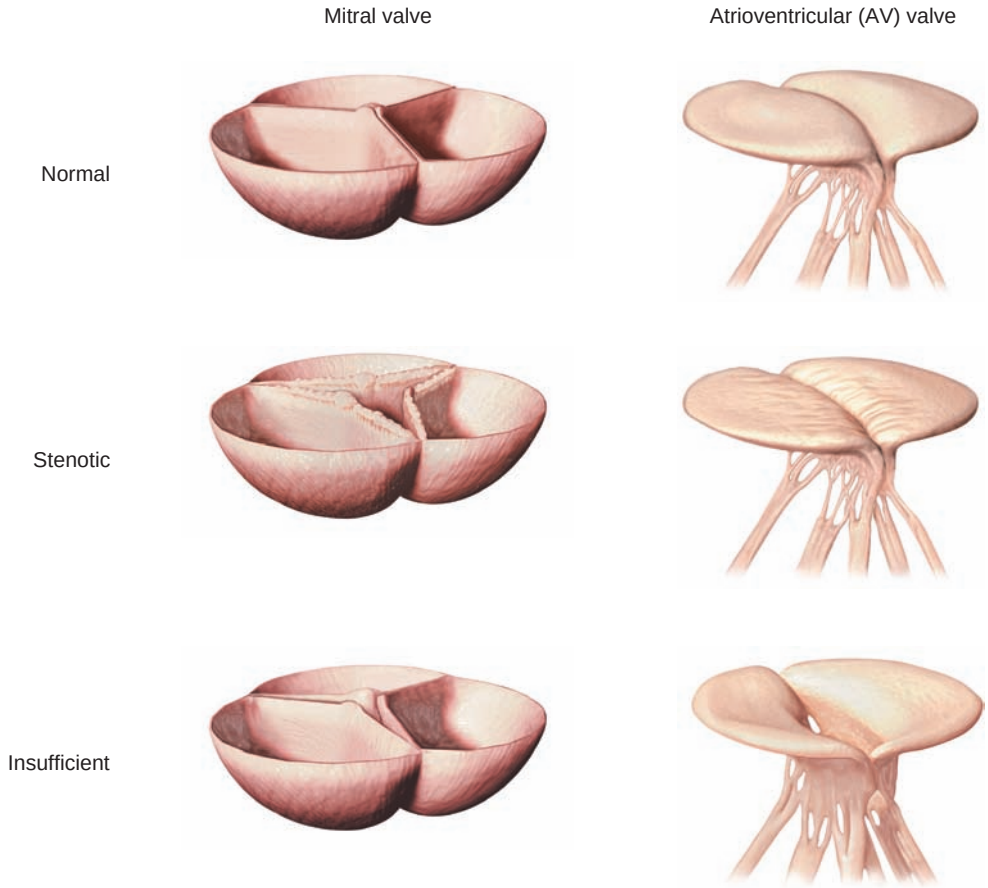

FIGURE 22-2 ▲ Normal and diseased heart valves. (From Anatomical Chart Company: Atlas of Pathophysiology. Springhouse, PA: Springhouse, 2010, pp 77.)

has a narrowed orifice that creates a partial obstruction to blood flow, resulting in increasing pressure behind the valve and decreasing forward blood flow. The insufficient valve is incompetent or leaky; blood flows backward, increasing the pressure and volume behind the valve. Stenosis and insufficiency can occur alone or in combination, in the same valve, or in more than one valve. Abnormalities can affect all four valves, but mitral and aortic abnormalities are more common and produce profound hemodynamic changes.

The diagnosis of valvular disease is suggested by the history, clinical signs and symptoms, physical examination, and auscultation of the characteristic murmur. Diagnosis is confirmed by echocardiography and catheterization of both sides of the heart, at which time valvular gradients are measured. To determine the gradient across the mitral valve, left atrial and left ventricular pressures are measured during diastole. A gradient of more than 15 to 20 mm Hg (ie, left atrial diastolic pressure is 15 to 20 mm Hg higher than left ventricular diastolic pressure) means that severe mitral stenosis exists. Valve area is also calculated during cardiac catheterization. The normal mitral valve area is 4 to 6 cm^2. An area less than 1.5 cm^2 signifies critical mitral stenosis, and surgery is indicated.

To determine the gradient across the aortic valve, the left ventricular and aortic root pressures are measured during systole. A gradient of more than 50 mm Hg is associated with clinically significant aortic stenosis. Normal aortic valve area is 2.6 to 3.5 cm^2. Hemodynamically, significant aortic stenosis occurs if the valve area is less than 1 cm^2. Valvular insufficiency is diagnosed by regurgitation of the contrast medium backward through the incompetent valve.

Pathophysiology

MITRAL STENOSIS. Mitral stenosis (Fig. 22-3A) occurs most frequently as a result of rheumatic heart disease. The disease process causes fusion of the commissures and fibrotic contraction of valve leaflets, commissures, and chordae tendineae. As forward flow from the left atrium to the left ventricle decreases, cardiac output falls, creating a decrease in systemic perfusion. Blood backed up behind the stenotic valve causes left atrial dilation and increased left atrial pressure. This pressure is reflected backward into the pulmonary circulation, and with prolonged high pressures, fluid moves from the pulmonary capillaries into the interstitial space and eventually the alveoli. Pulmonary hypertension develops, which can eventually lead to right-sided heart failure. As a result of this pathophysiology, patients with mitral stenosis present with fatigue, exertional dyspnea, orthopnea, and even pulmonary edema. Left atrial dilation causes atrial fibrillation in 40% to 50% of affected patients.

MITRAL INSUFFICIENCY. Mitral insufficiency (see Fig. 22-3B) can occur acutely or develop over a period of time. Chronic mitral insufficiency may result from rheumatic heart disease, degenerative changes associated with aging, or left ventricular dilation. The basic valve dysfunction is caused by

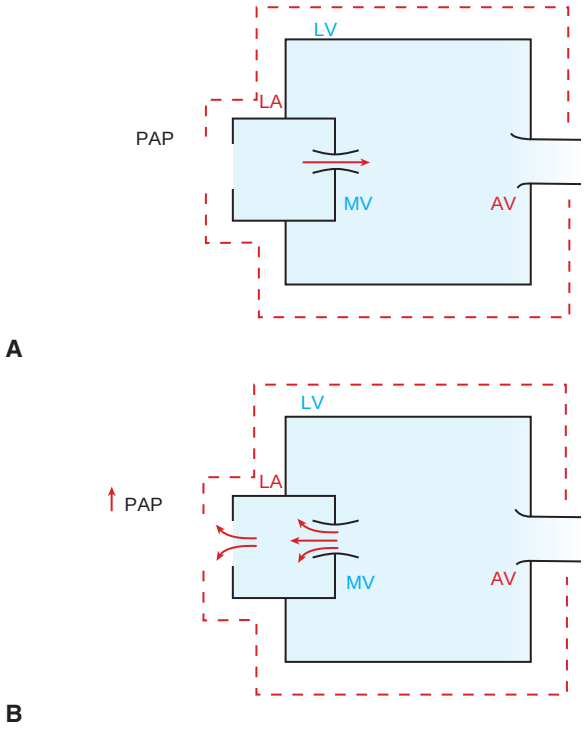

FIGURE 22-3 ▲ Mitral valve dysfunction. **A:** Mitral stenosis. **B:** Mitral insufficiency. AV, aortic valve; LA, left atrium; LV, left ventricle; MV, mitral valve; PAP, pulmonary artery pressure.

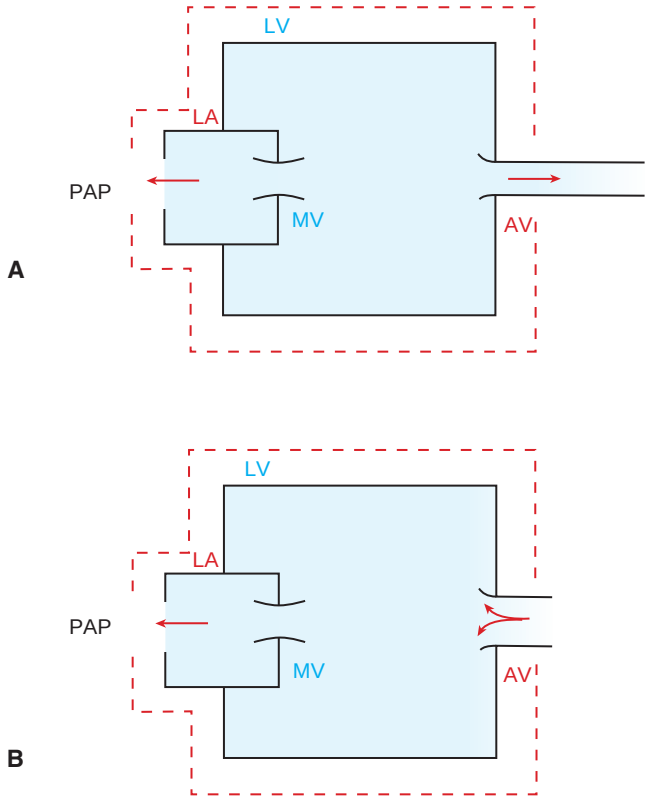

FIGURE 22-4 ▲ Aortic valve dysfunction. **A:** Aortic stenosis. **B:** Aortic insufficiency. AV, aortic valve; LA, left atrium; LV, left ventricle; MV, mitral valve; PAP, pulmonary artery pressure.

thickening or stretching of the leaflets, resulting in backward blood flow. During ventricular systole, some of the left ventricular blood regurgitates into the atrium rather than being ejected through the aortic valve. This regurgitation decreases the forward cardiac output. Left ventricular hypertrophy occurs in an attempt to improve the cardiac output, but the hypertrophy can actually worsen the regurgitation. Left ventricular volume overload causes left ventricular dilation. Regurgitant flow into the left atrium causes increased left atrial pressure and dilation. This volume overload can be reflected backward to the pulmonary circulation; however, pulmonary and right-sided heart symptoms usually do not develop until late in the disease process. As a result of this pathophysiology, patients with chronic mitral insufficiency commonly present with fatigue, palpitations, and sometimes shortness of breath.

Acute mitral insufficiency may result from endocarditis, chest trauma, or MI. Endocarditis erodes or perforates the valve leaflets or chordae. Trauma may rupture the chordae. MI may cause papillary muscle rupture, allowing blood to flow backward into the left atrium during ventricular systole. Because of the acute nature of the valve dysfunction, there is inadequate time for dilation or hypertrophy to compensate. In acute mitral insufficiency, cardiac output decreases dramatically, cascading into pulmonary edema and shock. The treatment of choice for acute mitral regurgitation with hemodynamic compromise is emergent mitral valve replacement.

AORTIC STENOSIS. Aortic stenosis may develop as a result of rheumatic fever, calcification of a congenital bicuspid valve, or calcific degeneration, especially in elderly patients. The resultant fusion of the commissures and fibrous contractures of the cusps leads to obstruction of left ventricular outflow. Forward cardiac output is diminished, and the left ventricle hypertrophies to maintain the cardiac output. As the stenosis worsens, compensation fails, and volume and pressure overload in the left ventricle causes left ventricular dilation. Increased left ventricular pressures are reflected backward through the left atrium and pulmonary vasculature (Fig. 22-4A).

Diminished cardiac output in the person with aortic stenosis may lead to two major problems—angina and syncope. Extreme left ventricular hypertrophy increases myocardial oxygen demand at the same time that cardiac output and coronary artery perfusion are decreased. Ischemic myocardium develops, which may lead to angina. Syncope occurs in the late stages of aortic stenosis, when the forward cardiac output cannot increase to meet the body's demands. As a person with severe aortic stenosis exercises, the blood vessels to the skeletal muscles dilate to increase the blood supply. The normal response to this increased demand is increased cardiac output. However, the person with aortic stenosis is unable to respond in such a way. The vasodilation without a concomitant increase in cardiac output results in insufficient cerebral perfusion and syncope. Patients with aortic stenosis also experience exertional dyspnea, orthopnea, and paroxysmal nocturnal dyspnea.

AORTIC INSUFFICIENCY. Aortic insufficiency, like mitral insufficiency, can occur acutely or develop over a period of time. Chronic aortic insufficiency is commonly caused by rheumatic fever and aneurysm of the ascending aorta. Rheumatic disease results in thickened and retracted valve cusps, whereas aortic aneurysm causes annular dilation. Both conditions prevent the edges of the valve leaflets

from approximating, allowing blood to regurgitate backward from the aorta into the left ventricle during ventricular diastole. Forward cardiac output decreases, and left ventricular volume and pressure increase. Left ventricular hypertrophy ensues. Eventually, the increase in left ventricular pressure is reflected backward into the left atrium and pulmonary circulation (see Fig. 22-4B). Patients with chronic aortic insufficiency present with fatigue, and they have a low diastolic blood pressure and a widened pulse pressure. The pulse may rise rapidly and collapse suddenly (water-hammer or Corrigan's pulse) because of the forceful ventricular contraction and subsequent diastolic regurgitation from the aortic root into the left ventricle. Angina may occur because aortic insufficiency creates an imbalance between left ventricular myocardial oxygen supply and demand. As left ventricular hypertrophy worsens, the oxygen demand increases, but regurgitant flow from the aortic root during diastole decreases coronary artery perfusion.

Acute aortic insufficiency may be caused by blunt chest trauma, ruptured ascending aortic aneurysm, or infective endocarditis. Left-sided heart failure and pulmonary edema develop rapidly in the patient with acute aortic insufficiency because compensatory left ventricular hypertrophy does not have time to develop. In response to the diminished cardiac output, systemic vascular resistance (SVR) increases to maintain the blood pressure. The elevated SVR increases the degree of regurgitation and worsens the situation.

Surgical Treatment

The goals of valvular surgery are to relieve symptoms and restore normal hemodynamics. Surgery is indicated before left ventricular function deteriorates significantly and the patient's activity becomes severely limited or before severe signs and symptoms, such as angina or syncope from aortic stenosis or pulmonary hypertension from mitral stenosis, develop. Percutaneous balloon valvuloplasty, a procedure that is indicated primarily for patients considered too high risk for surgery, is discussed in Chapter 18. Surgical intervention consists of either valve reconstruction or valve replacement. Because valve reconstruction is associated with decreased operative mortality and fewer thromboembolic and anticoagulation-related complications than valve replacement, valve reconstruction is gaining popularity.

VALVE RECONSTRUCTION. With the development of transesophageal echocardiography to assess the effectiveness of repair during surgery, the use of valve reconstruction is increasing. Most valve reconstruction procedures are performed on the mitral valve. Compared with mitral valve replacement, reconstruction eliminates the need for long-term anticoagulation, decreases the risks for thromboembolism and endocarditis, decreases the need for reoperation, and increases survival rates. However, for aortic valve disorders, most attempts at reconstruction have not been successful because of late insufficiency and restenosis.

A common reconstruction technique for mitral stenosis is commissurotomy. Although not indicated for patients with severe mitral stenosis, commissurotomy may be effective for patients with moderate stenosis with minimal calcification and regurgitation. During commissurotomy, the fused commissures are surgically divided. Calcified tissue is débrided and fused, and shortened chordae are incised. This procedure improves leaflet mobility and increases the mitral valve area, decreasing the degree of stenosis.

Another technique for treatment of mitral insufficiency is reconstruction. If annular dilation causes the regurgitation, annuloplasty can be performed using sutures or a prosthetic ring (eg, Carpentier-Edwards annuloplasty ring). The ring is sewn around the mitral annulus so that excess annular tissue is drawn up. Suturing and the ring reduce the circumference of the enlarged annulus so that the edges of the leaflets coapt, diminishing regurgitation. If the chordae tendineae are stretched or ruptured, surgical shortening or transposition of chordae to substitute for ruptured chordae can be effective. Redundant mitral leaflets are repaired by resecting a portion of the leaflet, and perforated valve leaflets can be reconstructed by patching. Such repairs are usually supported by an annuloplasty ring.

Reconstruction procedures are more likely to be successful if performed early in the course of the disease, before left ventricular function deteriorates and irreparable damage occurs. Anticoagulation is not usually needed after valve repair unless an annuloplasty ring is used. In such cases, anticoagulants are given for only 3 months until the ring is endothelialized. If reconstruction cannot be accomplished, valves are replaced.

VALVE REPLACEMENT. The first valve replacement was performed by Harken and Starr in 1960 with a caged ball prosthesis. Since then, many new valve designs have evolved. Valve replacement surgery is done through a median sternotomy incision, and cardiopulmonary bypass and myocardial preservation techniques (discussed in detail later in this chapter) are used. The mitral valve is approached through the left atrium. Rather than excising the native valve, the chordae and papillary muscles are preserved when the prosthetic valve is sutured in place. This technique helps maintain left ventricular function and ejection fraction. The aortic valve is approached through the ascending aorta. The native aortic valve is excised, the annulus is sized, and the prosthetic valve of correct size is sutured to the annulus. Once the surgery is completed, the patient is transferred to the intensive care unit (ICU).

Ideally, a prosthetic valve would be durable, last for a patient's life, and perform exactly like a normal human valve. The valve would have normal hemodynamics with unimpeded, nonturbulent blood flow through a central opening, no transvalvular gradient, and no regurgitation when closed. It would be nonthrombogenic and not damaging to blood components and acceptable to the patient in terms of noise and the need for anticoagulation. Unfortunately, no artificial valve currently meets these criteria, so research continues.

Choosing a Valve. Two major types of prosthetic valves are available—biological and mechanical. Mechanical valves are made entirely of synthetic materials, whereas biological valves combine synthetic materials with chemically treated biological tissues. When choosing an appropriate valve for a particular patient, it is necessary to compare the advantages and disadvantages of the various valve types. The advantages and disadvantages of prosthetic cardiac valves are listed in Box 22-1. Mechanical valves offer the benefits of good long-term durability but pose a significant risk for thromboembolism and require long-term anticoagulation. Biological valves decrease the risk for thromboembolism and can obviate the

BOX 22-1 Advantages and Disadvantages of Prosthetic Cardiac Valves

Mechanical Valves
- Good long-term durability
- Adequate hemodynamics
- High risk for thromboembolism; necessity for long-term anticoagulation
- Increased risk for bleeding complications

Biological Valves
- Poor long-term durability
- Better hemodynamics than mechanical valves (except in small sizes)
- No hemolysis
- Low incidence of thromboembolism; possibly no necessity for anticoagulation
- Fewer bleeding complications

need for long-term anticoagulation, but they are not as durable as mechanical valves. Biological valves studied at autopsy have shown structural deterioration beginning as early as 6 years after implantation, and their total useful lifetime is usually considered to be less than 10 years.

Patients with a long life expectancy may receive mechanical valves because they are particularly durable.

Biological Valves. Older patients may receive biological valves because less calcification and deterioration occur in older people, long-term durability is less important, and the risk for anticoagulation may increase with advancing age. Biological valves are indicated for patients who are unable to comply with an anticoagulation regimen, for those in whom a long-term anticoagulation regimen is contraindicated, and for women of childbearing age who plan to become pregnant (the anticoagulant warfarin crosses the placental barrier).

Mechanical Valves. Mechanical valves include the caged ball, tilting disk, and bileaflet designs (Fig. 22-5). The caged ball valve consists of a plastic or metal ball inside of a metal cage attached to a sewing ring. When pressure behind the valve increases, the ball is forced down into the cage, and blood flows around it. When pressure in front of the valve increases, the ball is forced upward against the sewing ring, preventing regurgitant flow. An example of the caged ball valve is the Starr-Edwards valve (see Fig. 22-5C, D).

Hemodynamically, the ball in the cage produces a central obstruction to blood flow, which can result in a small stenotic pressure gradient, and ventricular outflow may be partially obstructed because of the cage's size and high profile. Because of the thrombogenicity of the plastic and metal and the turbulent flow around the ball and through the cage, blood clots can form on or around the valve. Thromboembolism is a common problem, and chronic anticoagulant therapy is essential. Caged ball valves have good long-term durability.

The tilting disk valve is constructed of a disk held in place by struts attached to a sewing ring. When the pressure behind the valve increases, the disk tilts open approximately 60 to 80 degrees, allowing blood to flow around it. When the pressure in front of the valve increases, the disk tilts back flush with the sewing ring to close. Because of its semicentralized flow and lower profile, the tilting disk valve

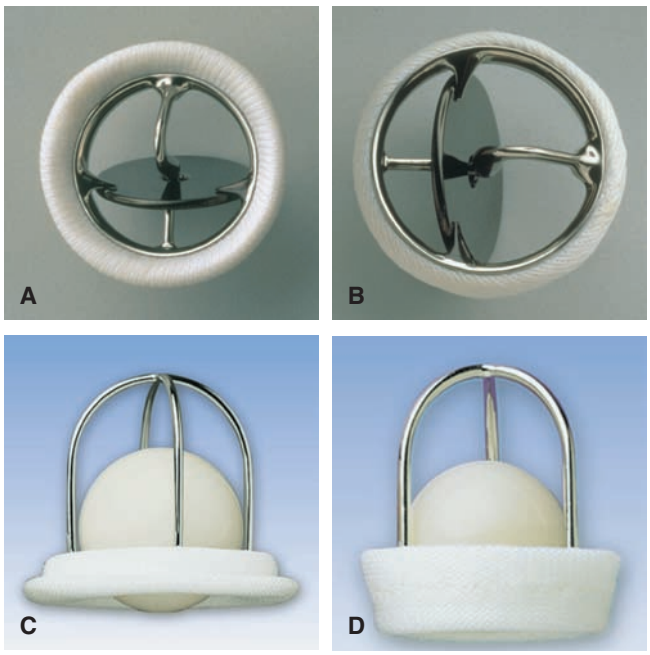

FIGURE 22-5 ▲ **A:** Medtronic Hall Easy-Fit, aortic model. **B:** Medtronic Hall Easy-Fit, mitral model. **C:** Starr-Edwards Silastic ball valve, aortic model. **D:** Starr-Edwards Silastic ball valve, mitral model. (A and B courtesy of Medtronic Heart Valves, Minneapolis, MN; C and D courtesy of Edwards Life Sciences, Irvine, CA.)

produces less obstruction to blood flow and has better hemodynamic characteristics than the caged ball valve. The tilting disk valve has good long-term durability, but the risk for thromboembolism requires long-term anticoagulant therapy. Examples of the tilting disk valve are the Medtronic-Hall and the omniscience valves.

The bileaflet tilting disk valve, which consists of two pyrolytic carbon semicircular disks or leaflets hinged to a sewing ring, is the newest type of mechanical valve (see Fig. 22-5A, B). When the pressure behind the valve increases, the leaflets open perpendicular to the sewing ring, and blood flows through the central opening with minimal obstruction. When pressure in front of the valve increases, the leaflets return to their flat position against the sewing ring, preventing insufficiency. The bileaflet tilting disk valve has good hemodynamic characteristics and durability, but it is thrombogenic and requires long-term anticoagulation. An example of the bileaflet tilting disk valve is the St. Jude Medical valve.

Biological Valves. Biological prostheses, or tissue valves, offer another alternative for valve replacement. The porcine heterograft is constructed of an excised pig aortic valve preserved in glutaraldehyde and mounted on a frame attached to a sewing ring. Examples of porcine valves are the Hancock and the Carpentier-Edwards valves. Biological prostheses provide good hemodynamics, except in smaller sizes, where obstruction to flow can occur and a gradient can develop. Their main advantage is a lower risk for thromboembolism compared with mechanical valves. Because most thromboembolic events occur during the first 3 months after implantation before the sewing ring is endothelialized, most patients with biological valves receive anticoagulants during that time only. However, the decision regarding anticoagulation must be based on the patient's condition. Patients in chronic

atrial fibrillation undergoing mitral valve replacement frequently receive long-term anticoagulation therapy even with a biological prosthesis because of stagnant blood flow in the atria, a condition that may lead to clot formation.

▲ Cardiac Surgery

With managed care, rising costs, and the demand for high-quality care, cardiac surgery has come under increased scrutiny. The unique challenge for the critical care nurse is to integrate theoretical knowledge, assessment skills, and problem-solving ability to provide optimal nursing care and maintain high-quality outcomes while decreasing resource consumption, yet always keeping the patient as the focus.

Preoperative Phase

Preoperative preparation for cardiac surgery includes physiological and psychological components. The physiological preparation is similar to that for any preoperative patient and includes history, physical examination, chest radiography, and an ECG. The history and physical examination are extremely important; they can provide information about previous neurological status, current medications, and any other coexisting conditions (eg, diabetes mellitus, pulmonary disease, renal disease). The chest radiograph can give the surgeon general information about aortic calcification, and the ECG provides baseline information about the patient's heart rhythm. Laboratory tests include complete blood count (CBC), electrolytes, prothrombin time (PT), partial thromboplastin time (PTT), blood urea nitrogen (BUN), and creatinine. Pulmonary function tests and arterial blood gas (ABG) analyses may be performed if a patient has underlying pulmonary problems. Cost is always a consideration; only necessary tests should be ordered.

Effective preoperative teaching, which reduces anxiety and physiological responses to stress before and after surgery, is an important aspect of psychological preparation. The surgical procedure and the intraoperative and postoperative experiences are explained. The patient usually is not in the ICU before surgery, and a tour of the ICU helps familiarize the patient and family with the specialized equipment and environment. The sight of a patient who is successfully recovering from cardiac surgery helps instill confidence and allay anxiety. Incorporating family members or significant others in the education process is pivotal in patient care. Specific teaching topics related to the patient's stay in the ICU are listed in Box 22-2.

Intraoperative Phase

Surgical Approach

The surgical approach most commonly used for myocardial revascularization and valve surgery is median sternotomy. The sternum is split with a sternal saw from the manubrium to below the xiphoid process, and the ribs are spread to expose the anterior mediastinum and pericardium. After the pericardium is opened and the heart and aorta are exposed, the patient is connected to the cardiopulmonary bypass machine.

BOX 22-2 TEACHING GUIDE *Preoperative Teaching About the ICU Experience for the Patient Undergoing Cardiac Surgery*

Equipment to Point Out
- Cardiac monitor
- Arterial line
- Thermodilution catheter
- IV lines and IV infusion pumps
- Endotracheal tube and ventilator
  - Suctioning
  - Explain how to communicate when intubated; unable to talk
  - Explain when extubation can be anticipated
- Foley catheter (increased sensation to urinate)
- Chest tubes (anticipated removal)
- Pacing wires
- Nasogastric tube
- Soft hand restraints

Incisions and Dressings to Expect
- Median sternotomy or other incision
- Leg incision (if saphenous vein is used)

Patient's Immediate Postoperative Appearance
- Skin yellow from use of Betadine solution in operating room
- Skin pale and cool to touch because of hypothermia during surgery
- Generalized "puffiness," especially noticeable in neck, face, and hands because of third spacing of fluid given during cardiopulmonary bypass

Awakening From Anesthesia
- Patient recovers in the intensive care unit (ICU); does not go to the postanesthesia care unit (PACU)
- Each patient recovers from anesthesia differently
- Patient may feel certain sensations
- Patient may hear certain noises
- Patient may be aware or able to hear but unable to respond

Discomfort
- Amount of discomfort to be expected
- When pain might be expected
- Relief mechanisms
  - Positioning/splinting
  - Medications
  - Patient-controlled analgesia (PCA) and the importance of early administration of pain medication

Postoperative Respiratory Care
- Turning
- Use of pillow to splint median sternotomy incision
- Effective coughing and deep breathing after extubation; have patient practice exercises before surgery
- Incentive spirometry
- Early mobilization

Miscellaneous
- Postoperative activity progression
- Hospital visiting policy in intensive care area
- Avoiding use of arms to protect stability of sternotomy

As myocardial revascularization has become increasingly sophisticated, new interventions to minimize the invasive nature of the surgery have been developed. The number of patients undergoing reoperations using CABG surgery has increased, and if the mediastinal approach is used in a reoperation, injury to old bypass grafts or embolization of debris resulting from manipulation of diseased grafts may cause problems.[12] A smaller lateral thoracotomy incision is often used to decrease the risks associated with reentry into the mediastinum. The choice of incision is based on the specific needs of each patient and the experience of the surgeon.

CARDIOPULMONARY BYPASS. Cardiac surgery as it is known today was made possible by the development and practical application of cardiopulmonary bypass procedure by Gibbon in 1953.[1] Because the heart must be still (not beating) and empty during the surgery, a cardiopulmonary bypass machine is used, unless OPCABG surgery is to be performed. Before the bypass is implemented, the tubing of the machine is primed with a balanced electrolyte solution. Blood can be used if indicated. The patient's deoxygenated venous blood is brought to the pump either through one cannula placed in the right atrial appendage or by two cannulas, one of which is placed directly in the inferior vena cava and the other directly in the superior vena cava. Another cannula is placed in the ascending aorta to return oxygenated blood to the patient's systemic circulation (Fig. 22-6). Heparin is administered throughout cardiopulmonary bypass to prevent massive extravascular coagulation as the blood circulates through the mechanical parts of the bypass system. During bypass, the patient's core body temperature is lowered to 28° to 32°C (82.4°F to 89.6°F) to decrease metabolism. This reduction in metabolic demands helps protect the major organ systems from possible ischemic injury and the adverse effects of nonpulsatile perfusion during cardiopulmonary bypass.

Oxygenated blood is filtered and returned to the patient's ascending aorta through the arterial cannula (see Fig. 22-6). Once extracorporeal circulation is established and systemic hypothermia is achieved, the aorta is cross-clamped just above the coronary arteries, and either crystalloid or blood cardioplegia solution is infused into the aortic root. After the aorta is cross-clamped, no blood circulates through the coronary arteries, so the myocardium becomes ischemic. Cold cardioplegia solution at 4°C (39.2°F) is infused into the aortic root under pressure. As it circulates through the coronary arteries, the high potassium concentration causes immediate asystole and relaxation, and the cold produces myocardial hypothermia. Asystole and hypothermia protect against myocardial ischemia by decreasing the metabolic needs of myocardial tissue. The cardioplegia solution provides a substrate for ongoing cellular metabolism and ensures appropriate pH and calcium ion levels for myocardial preservation.[13] The inclusion of blood or oxygenated crystalloid in the cardioplegia solution lessens myocardial ischemia by supplying oxygen. Cardioplegia solution may be infused into the aortic root continuously or intermittently every 15 to 30 minutes and whenever cardiac electrical activity recurs. This process varies, depending on the surgeon's preference.

Because perfusion of cardioplegia solution through occluded or diseased coronary arteries may not produce an even myocardial cooling, inadequately cooled areas risk ischemic damage. Therefore, hypothermia is also created topically by pouring iced normal saline slush solution over the heart into the pericardial well. Cardioplegia with concomitant topical hypothermia cools the heart evenly. Several disadvantages to cold cardioplegia have been identified, including postoperative myocardial depression, ventricular dysrhythmias, decreased cerebral blood flow, irreversible platelet dysfunction, and shifts of the oxygen–hemoglobin dissociation curve to the left so that blood delivers oxygen to the tissues less readily. A heart receiving cold crystalloid cardioplegia must have blood reintroduced into the coronary circulation (reperfusion). This reintroduction of oxygen may cause release of toxic substances that injure myocardial cells (reperfusion injury). To avoid these disadvantages, some cardiac surgeons use normothermic blood cardioplegia delivered at 37°C (98.6°F), which keeps the heart at a normal temperature. Patients who have undergone warm cardioplegia require less time on the ventilator and almost no rewarming technology in the ICU.

After surgery is completed, the heat exchanger rewarms the blood to return the patient's core temperature to 37°C (98.6°F) if hypothermic techniques were used. After air is vented from the heart chambers and the aortic root, the aortic cross-clamp is removed so that blood again perfuses the coronary arteries, warming the myocardium. As perfusion

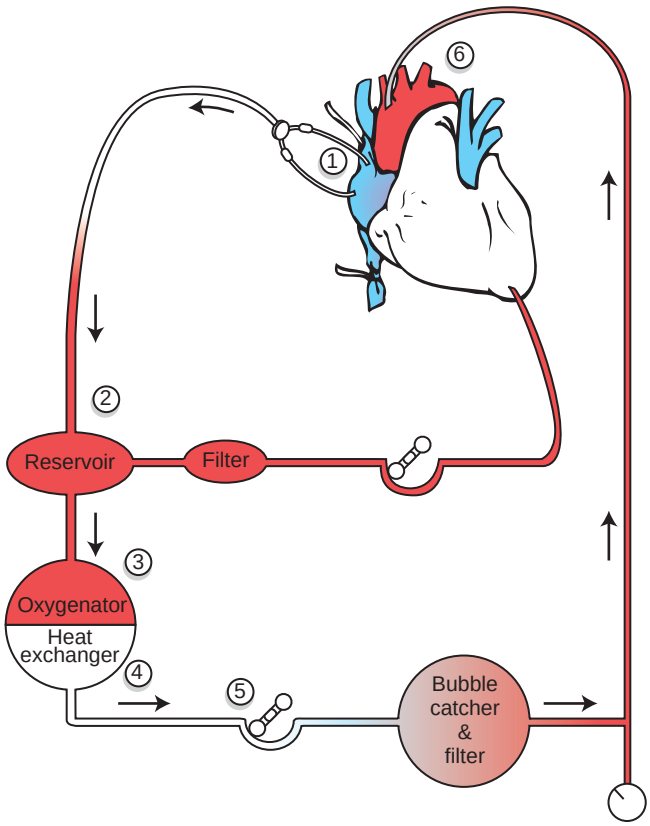

FIGURE 22-6 ▲ Blood flow through the circuit of the cardiopulmonary bypass machine: (**1**) Patient's deoxygenated blood enters the bypass circuit from the venous cannulas in the superior and inferior vena cavae. (**2**) The reservoir holds the blood temporarily. (**3**) The oxygenator removes carbon dioxide from and adds oxygen to the patient's blood. (**4**) The heat exchanger initially cools the blood and then rewarms the blood. (**5**) Roller pumps pump the blood through the circuit and back to the patient. (**6**) Oxygenated blood is returned to the ascending aorta by way of the aortic cannula.

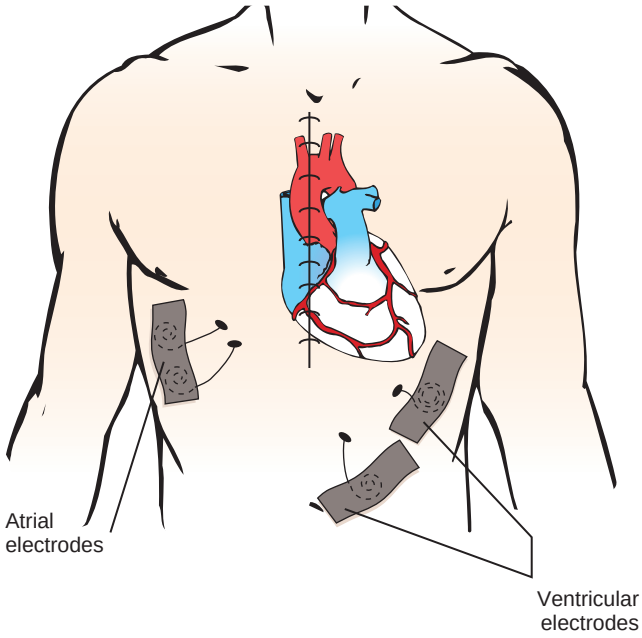

FIGURE 22-7 ▲ Temporary epicardial pacing wires: position of atrial and ventricular wires on chest wall.

and rewarming continue, a spontaneous cardiac rhythm may resume, ventricular fibrillation may develop (necessitating internal defibrillation), or pacing may be used to initiate a rhythm. After a reliable rhythm with a rate adequate to maintain the cardiac output and blood pressure is established, the patient is weaned from total cardiopulmonary bypass, and the cannulas are removed from the right atrium and aorta. Heparinization is reversed by the administration of protamine sulfate. If adequate cardiac output cannot be maintained during the weaning process, positive inotropic agents or intra-aortic balloon counterpulsation can be instituted (see Chapter 18 for more information about care of the patient on the intra-aortic balloon pump [IABP]).

COMPLETION OF SURGERY. If the need for postoperative cardiac pacing is anticipated, temporary pacing electrodes are placed on the epicardial surface of the heart and brought out through the chest wall on either side of the median sternotomy incision. Ventricular pacing electrodes are typically located to the left and atrial wires to the right of the sternum (Fig. 22-7). For more information about care of the patient with a pacemaker, see Chapter 18.

Chest tubes placed in the mediastinum and pericardial space for drainage are brought out through stab wounds just below the median sternotomy. If the pleural space has been entered, pleural tubes are also placed. Smaller, more flexible chest drains are being used instead of the stiff, larger-bore tubes to enhance drainage of the pleural and mediastinal space.[14] After adequate hemostasis is obtained, the edges of the sternum are approximated with stainless steel wires, the incision is closed, and dressings are applied.

Postoperative Phase

Patients are transported directly to the ICU, where they recover from anesthesia and usually remain for 24 hours after surgery. Patients arrive in the ICU with numerous lines and tubes (eg, endotracheal tube, hemodynamic monitoring lines). Immediate postoperative care involves cardiac monitoring and maintenance of oxygenation and hemodynamic stability, as described in Box 22-3. Because cardiopulmonary bypass produces abnormal blood interface and altered blood flow patterns, it has profound physiological effects (Table 22-2).

The postoperative course depends on the patient's preoperative condition. Factors that may increase mortality include age, sex, previous similar surgery (resurgery), preoperative occurrence of acute MI, and concomitant conditions such as diabetes mellitus, peripheral vascular disease, renal insufficiency, and chronic obstructive pulmonary disease (COPD).[1] Whether the surgery is elective or emergent may also influence outcome. Awareness of these conditions helps the critical care nurse anticipate problems. Accurate assessments, vigilant monitoring, and proper interventions are critical in stabilizing patients who have just undergone cardiac surgery. Box 22-4 lists some nursing diagnoses in cardiac surgery. Box 22-5 presents a collaborative care guide for the patient after such surgery. Certain patient populations present special problems. Box 22-6 on page 457 lists factors to consider in managing older cardiac patients.

BOX 22-3 Nursing Responsibilities in Caring for the Cardiac Surgery Patient in the Immediate Postoperative Period

Priority Interventions Performed by the Critical Care Team on Arrival

- Attach patient to bedside cardiac monitor and note rhythm.
- Attach pressure lines to bedside monitor (arterial and pulmonary artery); level and zero transducers and note pressure values and waveforms.
- Obtain cardiac output/index and note existing inotropic or vasoactive drips.
- After ventilator is connected to endotracheal tube, auscultate breath sounds bilaterally.
- Apply end-tidal carbon dioxide ($ETCO_2$) device to ventilator circuit and note waveform and value (best indicator of endotracheal tube placement).
- Apply pulse oximetry device to patient and note SpO_2 value and waveform.
- Check peripheral pulses and perfusion signs.
- Monitor chest tubes and character of drainage: amount, color, flow. Check for air leaks.
- Measure body temperature and initiate rewarming if temperature is less than 96.8°F (36°C).

Once the Patient Is Determined to Be Hemodynamically Stable

- Measure urine output and note characteristics.
- Obtain clinical data (within 30 minutes of arrival).
- Obtain chest radiograph.
- Obtain 12-lead ECG.
- Obtain routine blood work within 15 minutes of arrival; tests may include ABGs, potassium, glucose, PTT, and hemoglobin (varies with institution).
- Assess neurological status.
- Test pacemaker function by assessing capture and sensing.

Table 22-2 Effects of Cardiopulmonary Bypass

Effects	Clinical Implications
Increased Capillary Permeability	
Interface between blood and nonphysiological surfaces or bypass circuit leads to • Complement activation that increases capillary permeability • Platelet activation—platelets secrete vasoactive substances that increase capillary permeability • Release of other vasoactive substances that increase capillary permeability	Large amounts of fluid move from the intravascular to the interstitial space during and up to 6 h after cardiopulmonary bypass. Patient becomes edematous.
Hemodilution	
Solution used to prime extracorporeal circuit dilutes patient's blood. Secretion of vasopressin (antidiuretic hormone) is increased. Levels of renin–angiotensin–aldosterone are increased because of nonpulsatile renal perfusion. Total body water is increased.	Decreased blood viscosity improves capillary perfusion during nonpulsatile flow and hypothermia. Hgb and Hct decrease. Levels of coagulation factors are decreased because of dilution. Intravascular colloid osmotic pressure is decreased, contributing to movement of fluid from intravascular to interstitial spaces. Water is retained at collecting tubule of kidney. Aldosterone causes retention of sodium and water at renal tubule. Weight gain occurs.
Altered Coagulation	
Procoagulant effects: • Interface between blood and nonendothelial surfaces of bypass circuit activates intrinsic coagulation cascade. • Platelet damage activates intrinsic pathway. • Anticoagulant effects: • Interface between blood and nonendothelial surfaces of bypass circuit causes platelets to adhere to tubing and to clump; abnormal platelet function; activation of coagulation cascade, which depletes clotting factors; denaturation of plasma proteins, including coagulation factors. • Coagulation factors are decreased as a result of hemodilution.	Risk for microemboli is increased. Platelet count decreases by 50%–70% of baseline. Abnormal postoperative bleeding occurs. Possibility of bleeding diathesis exists.
Damage to Blood Cells	
Exposure of blood to nonendothelial surfaces causes mechanical trauma and shear stress. • Platelet damage occurs. • Red blood cell hemolysis occurs. • Leukocytes are damaged.	 Platelet count is decreased. Free hemoglobin and hemoglobinuria are increased. Hct is decreased. Immune response is diminished.
Microembolization	
Emboli form from tissue debris, air bubbles, platelet aggregation.	Microemboli to body organs (brain, lungs, kidney) are possible.
Increased Systemic Vascular Resistance (SVR)	
Catecholamine secretion is increased when cardiopulmonary bypass is initiated. Renin secretion is due to nonpulsatile flow to kidney. Hypothermia develops.	Hypertension is possible. Increased SVR may decrease cardiac output.

Prevention of Hypothermia

Whether the cardiac procedure is performed on or off the cardiopulmonary bypass system, hypothermia is a common side effect. During rewarming on cardiopulmonary bypass, the patient's core temperature is returned to 98.6°F (37°C). However, as this warmed blood begins to circulate to the periphery, heat transfer to the surrounding tissues again causes the core temperature to decline. Patients frequently enter the ICU with a temperature in the 95° to 96.8°F (35° to 36°C) range. OPCABG surgery causes hypothermia because of heat loss secondary to prolonged exposure to cool operating room temperatures. Hypothermia causes peripheral vasoconstriction

BOX 22-4 EXAMPLES OF NURSING DIAGNOSES

For Cardiac Surgery Patients

- Decreased Cardiac Output related to changes in ventricular preload, afterload, and contractility
- Decreased Cardiac Output related to cardiac dysrhythmias
- Ineffective Peripheral Tissue Perfusion related to cardiopulmonary bypass, decreased cardiac output, hypotension
- Ineffective Peripheral Tissue Perfusion related to microembolization secondary to the SIRS process
- Impaired Gas Exchange related to cardiopulmonary bypass, anesthesia, poor chest expansion, atelectasis, retained secretions
- Impaired Comfort related to endotracheal tube, surgical incision, chest tubes, rib spreading
- Anxiety related to fear of death, ICU environment
- Risk for Deficient Fluid Volume related to abnormal bleeding
- Risk for Infection related to surgical procedure, invasive lines, drainage tubes, hypoventilation, retained secretions

and a shift of the oxygen–hemoglobin dissociation curve to the left, which means that less oxygen is released from the hemoglobin to the tissues. Hypothermia can also impair coagulation because all enzyme systems in the body depend on a tight temperature range for optimal performance.[15]

The nurse assesses the patient's temperature on ICU admission using pulmonary artery or tympanic membrane temperature; if performed properly, both are considered accurate indicators of core temperature. Rectal temperature does not correlate with core temperature measurements until 8 hours after surgery, and bladder temperature differs significantly from core temperature with rapid cooling and rewarming. Increasing the room temperature and using radiant heat, blankets, or a warming blanket are effective techniques for increasing core temperature. Rewarming should occur slowly to prevent hemodynamic instability caused by rapid vasodilation.

It is important to prevent shivering, which occurs most often from 90 to 180 minutes after ICU admission, because shivering increases metabolic rate, oxygen consumption, carbon dioxide production, and myocardial workload. If left ventricular function is compromised, shivering should be managed with a neuromuscular blocker in combination with simultaneous sedation to avoid further cardiac compromise. In unusual situations, the patient may experience discomfort with shivering, which can be treated with meperidine (Demerol).

After rewarming, many patients experience an overshoot in body temperature. One etiological theory is that narcotics

BOX 22-5 COLLABORATIVE CARE GUIDE for the Patient After Cardiac Surgery

Outcomes	Interventions
Oxygenation/Ventilation	
Patient will have ABG values within normal limits and pulse oximeter value >92%.	• Obtain ABG levels per protocol. • Correlate pulse oximeter and end-tidal CO_2 with ABG results.
Pulmonary edema will be minimized on chest x-ray and demonstrated by improved breath sounds.	• Adjust ventilator settings after consulting with the respiratory therapist and physician. • Wean from mechanical ventilation per protocol using the expertise of respiratory therapy. • Extubate when patient is hemodynamically stable; able to protect airway. • Provide supplemental oxygen after extubation.
Atelectasis will improve.	• Encourage use of incentive spirometer, cough, and deep breath every 2–4 h after extubation.
Chest tubes will remain patent.	• Milk chest tubes if necessary to facilitate forward drainage movement.
Circulation/Perfusion	
Patient will maintain adequate clinical perfusion. Vital signs will be within normal limits, including MAP more than 70 mm Hg; cardiac index will be in a suitable range for the patient's left ventricular function.	• Monitor pulmonary artery pressure (PAP) and PAOP, CVP, cardiac output, SVR, and pulmonary vascular resistance (PVR) per protocol if pulmonary artery catheter is in place. • Monitor ECG, ST segments, and arterial blood pressure continuously. • Administer positive inotropic agents and reduce afterload with vasodilating agents guided by hemodynamic parameters and physician orders. • Regulate volume administration as indicated by PAOP or CVP values. • Evaluate effect of medications on BP, HR, and hemodynamic parameters. • Monitor and treat dysrhythmias per protocol and physician orders. • Anticipate need for temporary cardiac pacing; wires will be properly isolated for electrical safety. • Prepare patient for IABP assist if necessary. • Congestive heart failure from decreased cardiac output or perioperative MI will be minimized by collaborating with a physician. • Assess for neck vein distention, pulmonary crackles, S_3 or S_4, peripheral edema, increased preload parameters, elevated "a" wave of CVP, or PAOP waveform.
Patient will be euthermic.	• Monitor 12-lead ECG if ECG changes are observed. • Assess temperature every hour. • Warm patient 1°C/h by using warming blankets, lights, and fluid warmer.

(continued on page 456)

BOX 22-5 *COLLABORATIVE CARE GUIDE for the Patient After Cardiac Surgery (continued)*

Outcomes	Interventions
Hematological Issues	
Patient will have minimal bleeding and avoid cardiac tamponade.	• Chest tube drainage will be <200 mL/h. • Monitor for signs of cardiac tamponade (hypotension, pulsus paradoxus, tachycardia, PA pressure equalization). • Evaluate chest x-ray for widened mediastinum, consulting with a physician as needed. • Monitor PT, PTT, CBC per protocol. • Administer protamine, blood products, and other procoagulants per order or protocol. • Monitor vasoactive drug need and report marked increase of drugs to physician immediately because this change may indicate possible tamponade.
Fluids/Electrolytes	
Patient will maintain or improve preoperative renal function.	• Renal function will be maintained as evidenced by urine output of approximately 0.5 mL/kg/h. • Potassium will be replaced to maintain K^+ at more than 4.0 mEq/L. • Monitor intake and output every 1 to 2 h. • Monitor BUN, creatinine, electrolytes, magnesium, PO_4. • Record daily weights. • Administer fluid volume or diuretics as ordered.
Mobility/Skin Integrity	
Patient will maintain range of motion and muscle strength and will have intact skin integrity	• Turn patient side to side every 2 h while on bed rest and evaluate skin closely. • Mobilize out of bed after extubation. • Progress activity to chair for meals, bathroom privileges, increased distance walking, delegating to assistive personnel as indicated. • Monitor vital signs, respiratory effort during activity.
Incisions will heal without evidence of infection.	• Check stability of sternotomy incision daily, especially with diabetic patients. • Assess sternotomy and leg incision for redness, swelling, drainage. • Apply compression hose and elevate legs to reduce edema. • Caloric and nutrient intake meets metabolic requirements per calculation for long-term patients. • Monitor prealbumin for trends on long-term patients.
Comfort and Pain Control	
Patient will have relief of surgical pain. Patient will demonstrate no evidence of pain or anxiety such as increased heart rate, blood pressure, respiratory rate, or agitation during activity or procedures. Timely administration of pain medication will be a priority.	• Assess quality, duration, location of pain. Use visual analog scale to assess pain quantity. • Provide a calm environment. Provide for adequate periods of rest and sleep.
Teaching/Discharge Planning	
Patient and family will understand need for: Tests, procedures, treatments. Self-protective devices as indicated and per hospital policy. In preparation for discharge to home, patient will understand activity levels, dietary restrictions, medication regimen, incision care.	• Consult nutritional support services. • Make appropriate social work referrals early during hospitalization. • Initiate family education regarding heart-healthy diet, physical activity limitations (eg, lifting over 10–15 pounds and driving restrictions), stress reduction strategies, management of pain, incision care.

and anesthetics administered during surgery reset the hypothalamic regulatory center, altering peripheral blood flow and feedback.[16] A cold, constricted peripheral vascular bed may also be a factor in preventing heat dissipation. If the patient is bleeding after surgery, correction of temperature is imperative to aid in the return of normal coagulation enzyme function and clotting ability.

Monitoring for Systemic Inflammatory Response Syndrome

Any process, including surgery, initiates the SIRS. In recent years, research in critical care medicine has focused on SIRS because it may be the cause of many patient problems. An entire "body" inflammatory response may occur after CABG

BOX 22-6 CONSIDERATIONS FOR THE OLDER PATIENT: AFTER CARDIAC SURGERY

Physiological Changes

Cardiovascular System
- Increased stiffness of myocardial muscle
- Increased stiffness of peripheral vasculature and decreased ability to adjust to changes in blood volume
- Replacement of cells in conduction system with collagen and elastin
- Decreasing number of pacemaker cells in the sinoatrial (SA) and atrioventricular (AV) nodes
- Decreased cardiac responsiveness to β-adrenergic stimulation

Pulmonary System
- Breakdown of elastin and collagen that impairs elastic recoil of lung
- Thoracic cage less compliant
- Decreased expiratory muscle strength and mucociliary clearance

Renal System
- Progressive loss of cortical nephrons and decrease in corticomedullary concentration gradient
- Impaired renal concentrating ability
- Decreased clearance of medications excreted by the kidneys (may be reduced by up to 40% by 80 years of age)

Gastrointestinal System
- Decreased and more variable gastrointestinal absorption of medications
- Decline in liver function, resulting in decreased hepatic breakdown of medications

Musculoskeletal System
- Skeletal osteoporosis

Immune System
- Immune response may be decreased, especially if concomitant malnutrition and decrease in serum proteins

Neurological System
- Decline in neurotransmitters
- Increased risk for acute confusion

Response to Medications
- Decreased percentage of lean body tissue
- Increased percentage of body fat
- Decrease in body water

Clinical Effect
- Higher filling pressures (pulmonary artery diastolic [PAD] pressure and pulmonary artery occlusion pressure [PAOP])
- Decreased ability for vasoconstriction with position change, leading to orthostatic hypotension
- SA and AV node impairment
- Cardiac output maintained by increase in stroke volume
- Slowing of renal response to dehydration
- Decreased effectiveness of fluid conservation
- Toxic medication levels or abnormally prolonged duration of action
- Sensitive to drugs with narrow therapeutic range, such as digoxin
- More intense medication effect and longer duration of action for medications broken down in liver (eg, benzodiazepines)
- As a result of decreased body water, water-soluble medications concentrated in the bloodstream, resulting in higher serum drug levels
- Fat-soluble medications stored in fat; increase in fat tissue may result in slower therapeutic response and longer duration of action as drug is released slowly from fat

Patient Teaching
- Accommodate sensory deficits.
  - Ensure hearing aids are in and functional.
  - Speak loudly and face patient.
  - Use large print, easy-to-read materials.
- Teach one thing at a time and ensure that patient understands before moving on.
- Start with simple and progress to more complex information.
- Teach both patient and care giver.

Adapted from Dixon V: Effects of vascular surgery on the elderly vascular patient. J Vasc Nurs 17:86–88, 1999.

surgery that appears to be an infection. Symptoms and signs include fever, tachycardia, tachypnea, and an increased white blood cell count. To attempt to differentiate between SIRS and infection or sepsis, the American College of Chest Physicians convened a consensus conference in 1997.[17] The conference developed definitions differentiating the two conditions (Box 22-7), which are now used frequently by critical care experts.

SIRS is a natural defense mechanism that is initiated when tissue or vessels are injured. A vascular injury, the inflammatory response, and the coagulation cascade are interrelated. An event that disrupts the integrity of the endothelium, such as trauma from cutting the vessel or hypoxia in a few endothelial cells, triggers the process. Once the injury occurs, a local inflammatory reaction begins with the release of mediators called cytokines from "protector" cells (eg, lymphocytes, macrophages). These mediators signal other cells (eg, neutrophils, monocytes) to the injured area, which release other mediators. The endothelium then releases vasodilating mediators (eg, nitric oxide), which increase blood flow to the area, thereby increasing oxygen delivery. Counter-regulatory mediators cause vasoconstriction to balance vasodilatory actions. Platelets are attracted to the area to start coagulation. As a result of the endothelial damage, increased capillary permeability inevitably occurs.[18] This highly complex process is discussed in more detail in Chapter 54.

It was once believed that the cardiopulmonary bypass machine was the major trigger of SIRS; this prompted experts to reconsider the use of this machine. However, Vallely et al[7]

BOX 22-7 Definition of Systemic Inflammatory Response Syndrome (SIRS)

SIRS is defined by the presence of two or more of the following conditions:

Temperature	More than 100.4°F (38°C) or <96.8°F (36°C)
Heart rate	More than 90 beats/min
Respiratory rate	More than 20 breaths/min or $PaCO_2$ <32 mm Hg
White blood cell count	More than 12,000 cells/m^3, <4,000 cells/m^3, or more than 10% immature (bands) cells

Sepsis is a systemic response to documented infection and is determined by the same criteria as SIRS.

From Muckart D, Bhagwanjee S: American College of Chest Physicians/Society of Critical Care Medicine Consensus Conference: Definitions of the systemic inflammatory response syndrome and allied disorders in relation to critically injured patients. Crit Care Med 25:1789–1795, 1997.

demonstrated that OPCABG surgery also initiates a SIRS response involving the release of different mediators from the on-pump procedure. Few interventions limit SIRS; the inflammatory process is so complex that it has been difficult to develop medications to counter all the numerous reactions. Steroids have been shown to decrease SIRS somewhat if given before surgery, but they should be used with caution, especially in patients with diabetes mellitus.[1] Nursing responsibilities focus on refining assessment skills to increase early detection of embolic events in any system, especially the nervous, cardiovascular, pulmonary, and renal systems. It is important to have a high degree of suspicion when assessing patients and providing postoperative care.

Controlling Pain

After cardiac surgery, the patient may experience pain resulting from the chest or leg incision, the chest tubes, rib spreading during surgery, and care activities. The ICU environment may accentuate the pain physiologically because of light and noise as well as psychologically because of separation and fear. Pain often stimulates the sympathetic nervous system, increasing heart rate and blood pressure, which can be detrimental to the patient's hemodynamic status. Discomfort can also result in diminished chest expansion, increased atelectasis, and retention of secretions.

Although pain perception varies from person to person, a median sternotomy incision is usually less painful than a thoracotomy incision, and most people report that the pain is most severe the first 3 to 4 days after surgery. Discomfort from the leg incision often worsens after the patient is ambulatory, especially if leg swelling occurs. Stretching of back and neck muscles as the ribs are spread and immobilization for several hours during surgery can cause back and neck discomfort. Patients who have internal mammary artery grafts may have increased pain because of increased stretching of the intercostal muscles and the incision into the parietal pleura, which is richly innervated.

Angina after CABG surgery may indicate graft failure; therefore, the nurse must be able to differentiate angina from incisional pain. Typical median sternotomy pain is localized, does not radiate, and can be sharp, dull, aching, or burning. It is often worse with deep breathing, coughing, or movement. Angina is usually precordial or substernal; not well localized; and frequently radiates to arms, neck, or jaw. It is often described as a pressure sensation and is not affected by respiration or movement.

One of the goals of nursing management is a thorough assessment of the patient's pain using a pain scale; administration of analgesics based on the reported pain intensity; provision of adequate pain relief as reported by the patient; and alleviation of factors that enhance pain perception, such as anxiety and fear. The common analgesic drugs used are morphine sulfate, fentanyl, and hydromorphone (Dilaudid), as needed. These drugs can be supplemented with nonsteroidal anti-inflammatory drugs (NSAIDs), such as ketorolac (Toradol), which decrease pain through a different mechanism. Caution should be used in administering NSAIDs to patients with compromised renal function. Patient-controlled analgesia (PCA) pumps are frequently used to allow the patient to control administration of pain medication. Interventions, such as intercostal nerve blocks and spinal analgesia, are less common. Regardless of the mechanism used, pain control is aggressively pursued to ensure comfort and rapid mobilization, which in turn can lessen complications. Alternative therapies, such as music therapy and guided imagery, may also be useful in controlling pain.

Preventing Cardiovascular Complications

Many cardiovascular complications can be anticipated and prevented, which can lead to decreased length of stay and better patient outcomes. Astute nursing observations and appropriate interventions can contribute to better outcomes.

VOLUME RESUSCITATION. Adequate intravascular volume to provide preload is a primary concern. Increased capillary permeability resulting from SIRS causes intravascular volume to shift into the interstitial spaces. To maintain optimal cardiac performance and blood pressure, proper volume resuscitation is imperative. A variety of fluids may be used, including normal saline, hetastarch, and hyperosmolar fluids (eg, 3% saline).[19] No fluid is definitively recommended. If the patient is bleeding, blood products should be the fluid of choice. If the patient's blood pressure is unresponsive to moderate infusion rates, usually 500 mL is infused using a pressure bag and a large-bore catheter. Hemodynamic parameters, including a low central venous pressure (CVP; <8 to 10 mm Hg), low pulmonary artery diastolic pressure, and low pulmonary artery occlusion pressure (PAOP; <14 to 18 mm Hg), in combination with a low cardiac index (<2.5 L/min/m^2), help guide interventions.[15] Caution should be exercised in using these numerical values as absolute goals.

The preoperative condition of the heart is important to consider. If the patient has had a recent MI or poor left ventricular performance, higher pressures may be required to maintain optimal cardiac work. The patient with a hypertrophied left ventricle, especially with valvular disease, is heavily dependent on volume resuscitation.

The effectiveness of all interventions must be assessed against the patient's response. Mottling of the extremities, especially the knees, and the character of the peripheral pulses (especially dorsalis pedis) are clinical indications of perfusion.[20] The combination of weak pulses and mottled knees may indicate hypoperfusion. Resolution of these clinical findings, as well as improved pressure values, signals the return of adequate perfusion. The astute critical care nurse continually monitors the appearance of the extremities and the pulses.

MONITORING FOR DYSRHYTHMIAS. Dysrhythmias are a major issue after CABG surgery. The hemodynamic response to a change in cardiac rhythm dictates the speed of the intervention in patients who have undergone CABG surgery, as in all critical care patients. In emergent situations, advanced cardiac life support (ACLS) algorithms are used. Knowledge of the patient's baseline rhythm is important. The types of dysrhythmias that may occur range from premature atrial contractions to ventricular fibrillation and asystole.

Sinus tachycardia is common and may result from many factors. Some of the more common causes are sympathomimetic drugs, SIRS, hypovolemia, fever, and pain. Prolonged periods of tachycardia may be harmful because of decreased coronary artery filling time. Sinus bradycardia may occur, but it is not anticipated because patients are in a sympathetically responsive state. In many cases, preoperative beta blockade may be the cause.

Causes of premature atrial contractions are usually electrolyte disturbances, ischemia or infarction, or hypoperfusion. Frequent premature atrial contractions may be a precursor to atrial fibrillation and occur very commonly, especially in patients with a previous history of pulmonary or valve disease in which the atria can be distended. The simple treatment for premature atrial contractions is repletion of potassium and magnesium. Maintenance of adequate potassium (range, 4 to 4.5 mEq/L) and IV infusion of 2 g magnesium may minimize premature atrial contractions.

Atrial fibrillation may occur after CABG surgery, and prevention is a high priority. Cardiac decompensation or cerebrovascular accidents are the major risks associated with atrial fibrillation. For new-onset atrial fibrillation, the goal is conversion to sinus rhythm using antiarrhythmics, especially amiodarone (Cordarone). The loading dose is 150 mg IV over 10 minutes followed by a 1 mg/min drip for 6 hours, then a 0.5 mg/min drip for 18 hours. Additional loading may be necessary. Control of the ventricular response is a goal and can be achieved using diltiazem (Cardizem), starting with a loading dose up to 0.75 mg/kg IV followed by a drip, which is usually started at 5 mg/h. Intravenous beta blockers including metoprolol are also used and administered in small boluses of 2.5 to 5 mg. Combination of antiarrhythmics may be used but should be monitored carefully. If atrial fibrillation persists or reoccurs for more than 24 hours, warfarin (Coumadin) anticoagulation for 4 weeks may be needed.[1] For chronic atrial fibrillation, conversion is not a goal (unless the patient has received anticoagulants) because of the risk for atrial thrombus and possible embolization. If emergent cardioversion is required in the immediate postoperative period and anticoagulation is not an option, echocardiography, either Doppler or transesophageal, may be performed to check for thrombus formation in the left atrium.

Heart block dysrhythmias occur in patients with valve surgery secondary to the edema at the surgical site, near the conduction system. Resolution of this rhythm is usually attained 48 to 72 hours after surgery once the edema decreases. Myocardial ischemia and infarction also cause the heart block. Patients who have had cardiac surgery have an advantage with the placement of epicardial pacing wires. Use of these wires allows better control of ventricular response compared with the use of drugs, such as atropine and isoproterenol (Isuprel). Atrial pacing is preferred if the atrioventricular (AV) node is intact because it allows optimal hemodynamics with an atrial contraction. If the AV node is not functioning properly, AV sequential pacing may be required. Ventricular pacing is the last choice. If pacing is required for more than 72 hours, permanent pacemaker placement should be considered, especially in patients who have had valve surgery. An in-depth discussion of pacing can be found in Chapter 18.

The occurrence of tachyarrhythmias may lead to emergent situations. If the patient is hemodynamically unstable in a fast rhythm, the first intervention is cardioversion, following ACLS guidelines. If ventricular dysrhythmias develop, electrical or pharmacological interventions are necessary. If premature ventricular contractions appear after surgery, 2 to 4 g IV of magnesium may help resolve this problem. The new ACLS guidelines de-emphasize the use of lidocaine and recommend amiodarone as the drug of choice, especially in patients with poor left ventricular function. If ventricular tachycardia deteriorates into ventricular fibrillation or other rhythms with no pulse, cardiopulmonary resuscitation should be started immediately; medical personnel should be prepared to open the chest at the bedside to determine and correct the cause of arrest.

IMPROVING CARDIAC CONTRACTILITY. Contractility may be depressed because of the exposure of the heart muscle to manipulation, temperature change, and possible hypoperfusion. The first step taken to improve performance is to ensure optimal volume resuscitation; it will quickly become clear if volume does not increase the cardiac output and index. The addition and titration of sympathomimetic drugs is a common part of the care of patients with decreased contractility. Various drugs, including epinephrine, dobutamine, and milrinone, may be used. Dopamine is another drug that can increase contractility but may cause unwanted tachycardia. The choice of drug varies with institution and health care provider.

As the drug of choice is added, the cause of the ventricular dysfunction should be pursued. Myocardial ischemia and infarction typically cause decreased cardiac function, but other factors may be sources of the problem. Stunned myocardium, the transient depression of left ventricular function from a temporary reduction of myocardial blood flow, may cause transient dysfunction; it is usually associated with normally functioning myocardium.[21] Hibernating myocardium is chronically impaired yet viable myocardial tissue, which results in left ventricular dysfunction at rest because of persistently hypoperfused myocardium or repeated stunning.[21] This state can lead to more chronic dysfunction. The state of the right ventricle should also be considered. If a patient had a right ventricular infarct preoperatively, surgery should be delayed up to 4 weeks to allow recovery of function.[1] If right ventricular dysfunction develops after CABG surgery, use of nitric oxide is one of the more effective interventions. Evaluation of cardiac work is not limited to cardiac output and cardiac index. Cardiac biomarkers can be used in the first 24 hours after CABG surgery. Troponin and creatine kinase muscle band are parameters that can be monitored to determine if the patient may have sustained myocardial damage.[1] In more complicated cases, sampling of mixed venous blood gases/mixed venous saturation (SvO_2) and the arterial–venous difference in oxygen may be useful. These values are indicators of oxygen transport and consumption and can help direct therapy. Although continuous SvO_2 monitoring may be used in patients with severe myocardial dysfunction, it is not a standard intervention; it is costly and has not been shown to make a difference in outcomes.

The IABP is a mechanical method used to improve coronary perfusion in any of the previously mentioned situations.[1] For a complete discussion of IABP, see Chapter 18. Mechanical factors may lead to depressed cardiac function. Cardiac tamponade, the most common such factor, may require surgical correction. This topic is discussed later in the chapter. Whatever the cause, time and support of function are usually the major factors that improve cardiac performance. However, protracted periods of time with mechanical or pharmacological support may be the signal to start to consider the placement of a ventricular assist device, usually as a bridge to heart transplantation.

CONTROLLING BLOOD PRESSURE. A reduction in SVR is another clinical maneuver that can increase cardiac performance. If the patient has an adequate blood pressure (mean arterial pressure [MAP] exceeding 70 mm Hg or

systolic blood pressure over 120 mm Hg) without pharmacological support (ie, alpha-agonist agents to increase blood pressure), afterload reduction should be started even if the patient is on inotropic support. Various agents, including nitroprusside, nitroglycerin, hydralazine, labetalol, and angiotensin-converting enzyme (ACE) inhibitors, such as captopril (preferred agent), can be used. The necessary speed of response dictates the choice of drug. For example, IV drugs, especially nitroprusside, rapidly cause a reduction in afterload. Other agents, such as hydralazine and ACE inhibitors, can then be used to augment this effect. ACE inhibitors should be used with caution in patients with impaired renal function because this drug category can exacerbate renal dysfunction. The previously named drugs also reduce blood pressure; in the immediate postoperative period, this is very important in maintaining the integrity of the grafts.

Preventing Pulmonary Complications

Postoperative pulmonary function depends on preoperative function. The degree of preoperative evaluation in preparation for surgery has changed in the current era of cost containment. If the patient has a significant pulmonary history (eg, COPD, pulmonary hypertension), baseline pulmonary function tests and ABG values can be very helpful in setting goals in the postoperative period. These tests may help predict how the patient will respond to mechanical ventilation.

The causes of pulmonary dysfunction after cardiac surgery can be attributed to changes that occur with the inflammatory response. Various triggers, such as surgical trauma and regional myocardial ischemia, activate the complement system and release cytokines, leading to an egress of neutrophils and fluid across endothelium. These triggers can also cause end-organ dysfunction, including organs such as the lungs.[7] Such changes in the lungs can lead to alterations in microcirculation and gas exchange that ultimately result in ventilation–perfusion mismatching, shunting, and atelectasis.[15]

Mechanical ventilation is required to achieve adequate oxygenation and ventilation. Adequate oxygenation is achieved by adjusting the level of oxygen delivered by the ventilator; the usual starting point is 40% to 50% oxygen. Effective oxygenation is monitored using pulse oximetry with intermittent ABG sampling. Positive end-expiratory pressure (PEEP) is a standard intervention used to help keep the alveoli open and improve oxygenation. PEEP usually starts at 5 cm H_2O but can be increased to 10 cm H_2O or more if hypoxemia is present. Care must be taken when increasing PEEP because it can decrease preload, thereby decreasing cardiac output and blood pressure. The initial mode for the ventilator is usually assist-control ventilation and is changed to continuous positive airway pressure (CPAP) when the patient is awake, stable, and ready to be weaned for extubation.

Adequate ventilation is maintained by selecting tidal volumes that are appropriate for body size as well as setting a sufficient rate for the ventilator tidal volumes. Monitoring of ventilation should include end-tidal carbon dioxide ($ETCO_2$) monitoring, which should be correlated with the partial pressure of carbon dioxide ($PaCO_2$) on an ABG analysis. $ETCO_2$ monitoring is also used to confirm proper endotracheal tube placement.

The recent implementation of newer techniques in cardiac anesthesia, which allows for faster recovery times, has led to shorter times on mechanical ventilation. Weaning from mechanical ventilation is a quick process in patients who have undergone CABG surgery. Once the patient has displayed the ability to follow commands and the strength to protect the airway, a short CPAP trial is instituted. The patient can be extubated if (1) cardiac performance is good (cardiac index more than 2.2 L/min/m^2), (2) adequate oxygenation and ventilation are achieved without acidosis, and (3) chest tube bleeding is minimal. Aggressive use of incentive spirometry and physical mobility ensures proper pulmonary function. Continual assessment by the critical care nurse is very important. Auscultation of breath sounds should be performed at frequent intervals and as the patient's condition dictates. Diminished breath sounds, especially in the left lower lobe, are common because left lower lobe atelectasis is an expected postoperative outcome. Observation of the work of breathing is also important, and signs, such as tachypnea, use of accessory muscles, and prolonged expiratory time can indicate compromised pulmonary function. Bronchodilator therapy may be indicated and should be continued if the patient was using bronchodilators at home.

Prolonged mechanical ventilation may be a complication of cardiac surgery. Protracted poor cardiac function requires continued mechanical ventilation. Phrenic nerve damage due to cold preservation techniques for myocardial protection or physical transection is another cause of ventilatory failure due to diaphragm dysfunction. Acute respiratory distress syndrome associated with SIRS, a hypoperfusion state, or both can also be a reason for prolonged ventilator days. A tracheostomy should be considered in patients with compromised pulmonary function because it can enhance the ventilator weaning process and promote patient comfort. Expert nursing and multidisciplinary care of the patient in ventilatory failure using weaning protocols may make a difference in patient outcome.[22,23]

Preventing Neurological Complications

Neurological recovery of the cardiac surgery patient depends on several factors, such as preoperative neurological state; age (more than 70 years); presence of conditions such as aortic atherosclerosis, hypertension, and diabetes mellitus; and use of the IABP.[1] The usual course of neurological recovery is much faster since anesthetic agents have changed. Narcotics and benzodiazepines, with neuromuscular blockade, are used now, and gases are used less.[15] There is little need for sedation when the patient is transported from the operating room unless hemodynamic instability is present. The patient is allowed to wake up and recover from the anesthesia as soon as possible. There may be some barriers to this process, including age and renal failure. The elderly patient is not able to metabolize narcotics and paralytics as quickly as a younger patient and may require a longer recovery time. If the patient is difficult to arouse and has pinpoint pupils, reversal of narcotics with naloxone (Narcan) may be indicated. Naloxone diluted 0.4 mg in 10 mL normal saline solution and given 1 to 2 mL IV every 5 minutes is a delicate method of regaining level of consciousness that does not reverse pain control. If the patient does not have good muscle strength, reversal of neuromuscular blockade is indicated. Glycopyrrolate, 0.6 mg IV, and neostigmine, 3 mg IV (or more), are used. The patient in renal failure is not able to clear these drugs and probably needs reversal of both narcotic and neuromuscular blockade agents to expedite extubation.

Once the patient is awake, continual evaluation using the standard neurological examination that assesses the level of consciousness and motor and sensory ability is mandatory. Postoperative neurological deficits are divided into two categories: (1) major focal deficits (stroke), stupor, or coma and (2) deterioration in intellectual function.[1] The best predictor of stroke is proximal aortic atherosclerosis, which is the source of emboli that are released with the manipulation of the aorta, especially during cannulation or cross-clamping. Hypoxia, hypoperfusion, hemorrhage, or metabolic abnormalities may also cause strokes.[1] Cognitive changes are more difficult to detect because there may be deficits in memory, language, and psychomotor function. The family of the patient may be helpful in detecting any subtle changes. These changes are most noticeable immediately after surgery but may still be present 12 to 36 months after the procedure.[24] Confirmation of a stroke can be performed with computed tomography or magnetic resonance imaging of the head, but these studies may need to be repeated; embolic events do not immediately appear on scans. Prevention of such a catastrophic event is difficult, but the risk can be reduced by patient selection and procedure selection.[24] If a patient has known carotid disease, maintaining higher blood pressure may help increase perfusion of the cerebral tissues. Thrombolytic therapy, which is used successfully in other patients with emboli, cannot be used after surgery in the patient who has just had CABG surgery because of bleeding concerns.

Monitoring Postoperative Bleeding

Postoperative bleeding is expected; the challenge is to know when and how to intervene. Anticoagulation interventions that have improved outcomes for the cardiac patient in general confound bleeding problems in the patient who has had CABG surgery. Timely correction of bleeding problems can decrease both the occurrence of complications and the cost of patient care. Preoperative anticoagulation such as therapy with thrombolytics and antiplatelet drugs (eg, aspirin and clopidogrel [Plavix]) hamper coagulation, and their effects are difficult to reverse; reversal may not even be an option, and postoperative bleeding may increase. It is recommended that if the patient is receiving clopidogrel, it should be stopped 5 days before surgery.[1]

Drainage and decompression of the pericardial and pleural spaces are required after cardiac surgery. Traditionally, chest tubes were large, rigid tubes, which were very uncomfortable for patients. Recently, smaller, more flexible chest tubes with bulb suction have been introduced to decrease discomfort, increase early ambulation, and decrease the accumulation of pleural effusions. Large postoperative pleural effusions may require increased hospital days or rehospitalization. These tubes are longer and more flexible to enhance pleural drainage; they have been found to decrease clinically significant pleural effusions at 6-week follow-up.[14]

Vigilant monitoring of chest tube drainage is imperative to anticipate impending problems. Chest tube drainage is monitored hourly. The usual chest tube output can range from 100 to 200 mL/h, with periods of increased drainage due to a change in position or temperature. Measurement of drainage may be required at more frequent intervals (every 15 or 30 minutes) if drainage is high.

If the chest tube output continues to be greater than 200 mL/h, then intervention is necessary. Protamine, the first level of intervention, is given at 1 mg for every 100 units of heparin to reverse the effects of heparin, which is used in the surgical process (both on and off bypass).[25] PTT is commonly used to monitor the intrinsic pathway of the coagulation cascade, which heparin affects. Additional protamine may be necessary, especially if the patient is hypothermic, because a "rebound" phenomenon may occur. Aggressive rewarming is very important in a patient who has increased bleeding because the coagulation cascade, with its enzymatic reactions, cannot function properly at hypothermic temperatures. However, as the patient's temperature rises, heparin is reactivated, causing increased bleeding. Platelet infusion (usually 6 units per infusion) is used next to help decrease bleeding. It is important to remember that a platelet infusion can cause a blood product reaction because each infusion may be from multiple donors. Before surgery, patients require therapy to make platelets dysfunctional, thus preventing thrombus formation in the coronary arteries. Causes of platelet dysfunction and postoperative bleeding include medications, such as aspirin; the bypass machine itself; the IABP, which mechanically destroys platelets; and heparin-induced thrombocytopenia, a recent phenomenon in which heparin exposure disables platelet function.

Follow-up coagulation studies act as a guide to the need for further infusions as well as monitoring blood loss, but they are not absolute parameters. If bleeding is increasing, a PT can be ordered to monitor the extrinsic pathway of the coagulation cascade and determine whether other factors need to be replaced. An elevated PT (more than 15 seconds) may indicate that bleeding is due to a lack of factors, such as fibrinogen, that can be replaced using fresh frozen plasma, usually 4 to 6 units/infusion. The overall goal is to determine whether bleeding is due to a coagulopathy or surgical bleeding. Chest tube bleeding that exceeds 500 mL/h is considered surgical bleeding and mandates surgical reexploration.

Other therapeutic interventions may also be used to decrease bleeding. Coagulation factors, such as cryoprecipitate (factors I and VIII) and factor VII, are indicated in severe bleeding. Various drugs, such as aminocaproic acid (Amicar), a potent inhibitor of fibrinolysis; aprotinin (Trasylol), a serine-protease inhibitor that blocks kallikrein at the beginning of the coagulation cascade; and desmopressin acetate (DDAVP), which influences factor VIII and enhances platelet adhesion, can be administered to promote coagulation.[25] Autotransfusion of mediastinal chest tube drainage using special drainage systems has been used to decrease blood transfusion requirements. However, the possibility that reinfusion can stimulate fibrinolysis and exacerbate bleeding is a concern; therefore, this treatment method is not recommended for routine use (especially in low-risk patients).[1]

Intraoperative measures to prevent bleeding include minimizing hemodilution, minimizing autologous losses, and optimizing coagulation status with full rewarming and antifibrinolytics.[26] Blood loss requires replacement, which should be considered carefully. Transfusion of red blood cells not only can increase exposure to infectious diseases, especially hepatitis and human immunodeficiency virus, but also is associated with increased immunosuppressive and microcirculatory complications.[27] The hemoglobin level indicated for transfusion is a controversial issue. Recent research indicates that a restrictive transfusion strategy (hemoglobin < 7 g/dL) has demonstrated a lower mortality rate in patients who are less critically ill. Autotransfusion of chest drainage also has

been used, but there are no clear data that support improved outcomes with this intervention.

Cardiac tamponade is a serious complication of increased postoperative bleeding that occurs when excessive fluid or blood accumulates in the pericardial space, resulting in increasing pressure on the right atrium and ventricle that can lead to collapse of those structures. Tamponade may develop rapidly or slowly, depending on how fast blood accumulates in the pericardial sac. When a patient is treated for excessive bleeding, it is important to monitor the chest tube drainage closely and maintain patency. Decreasing cardiac output and blood pressure and significant increases in pharmacological support (especially norepinephrine [Levophed]) are important warning signs. The mechanism of cardiac tamponade is the collapse of the lower pressure chambers of the right heart as a result of the increasing and equalizing of the CVP, pulmonary artery diastolic pressure, and the PAOP. This increase and equalization of the three values is classic evidence of cardiac tamponade. However, the clinical situation can be a late finding, and decreasing cardiac performance and blood pressure, despite volume resuscitation, is an earlier indicator. An arterial line waveform with significant respiratory variation (best illustration of an increased pulsus paradoxus) is another warning sign that cardiac tamponade is pending.[28] Definitive diagnosis is made with an echocardiogram (two-dimensional or transesophageal).

Interventions to prevent tamponade include stripping and milking chest tubes when the blood begins to clot, although stripping the tubes can generate increased negative pressure. Because the chambers (atria and ventricles) are being compressed, cardiac pressures, especially CVP, may be elevated. Another useful intervention involves the infusion of volume even with increased pressure to keep the structures from collapsing. Performing a pericardial window is the best surgical intervention.

Preventing Renal Complications

The postoperative course of renal function is influenced by preoperative function. Preoperative risk factors are age, history of moderate to severe congestive heart failure, prior CABG surgery, and preexisting conditions including type 1 diabetes mellitus and renal disease (serum creatinine 1.4 to 2.0 mg/dL).[1] The usual postoperative course also depends on whether the surgery was performed on or off bypass. After on-bypass CABG surgery, brisk initial urine output is expected because of the priming of the bypass circuit with mannitol and the possible use of diuretics. The output diminishes as these effects decrease with time. After OPCABG surgery, there is a smaller urine volume because patients are not exposed to these interventions. Some patients are able to autodiurese excess volume, but as the inflammatory response diminishes within 24 to 48 hours, the leaky capillary membranes seal and extra interstitial fluid shifts into the intravascular space, increasing the need for pharmacological diuresis with drugs, such as furosemide (Lasix). Electrolyte repletion with potassium and magnesium after diuresis is also important to maintaining a regular cardiac rhythm. A slight metabolic acidosis may be present in the patient with existing renal failure and may persist after surgery. If acidosis is present, the source (respiratory, metabolic, or combined) should be determined to intervene appropriately. The focus of interventions is to remove excess fluid while protecting metabolic and cardiac function.

OLIGURIA. Decreasing urine output (<0.5 mL/kg/h) is usually caused by decreased renal perfusion. Obvious causes, such as Foley catheter obstruction or malposition, may often be overlooked and should be considered initially, so that mechanical problems may be ruled out. Decreased cardiac function may also cause a decrease in urine output. Hypovolemia is a very common problem that can be addressed with fluid boluses, and monitoring pulmonary artery pressures and the cardiac output/cardiac index shortly after fluid infusions indicates whether the intervention was therapeutic. Caution must be exercised when adding volume because excess fluid can cause decreased function in compromised myocardial muscle. In that situation, inotropic agents or vasoactive drugs may be required. Determining the patient's baseline blood pressure is important so that control of vasoactive drugs can be titrated according to a perfusion pressure (MAP or systolic blood pressure) that the patient's kidneys require.

If none of these interventions is successful, diuresis may be necessary. Loop diuretics (eg, furosemide) are the usual first-line drugs. If urine output does not increase, larger doses may be indicated, or other diuretics that act on other areas of the renal tubular system, such as thiazides, may be added. Creatinine and BUN values are closely monitored.

RENAL FAILURE. If acute renal failure develops, dialysis is necessary. The method used depends on patient condition and practitioner preference. Continuous venovenous hemofiltration (CVVH) and hemodialysis are among the several methods that may be used. CVVH is preferred in the patient who is severely hemodynamically compromised because it is more gradual and minimizes preload compromise, which could decrease cardiac performance. Patients who undergo dialysis require fluid restriction, nutrition modification for prolonged renal dysfunction, and other standard interventions, such as dietary modifications to decrease protein and potassium intake. Chapter 31 provides a further discussion of renal failure and Chapter 30 discusses dialysis. Unfortunately, the mortality rate from acute renal failure in postoperative cardiac surgery patients is greater than 60%.[1]

Preventing Endocrine Complications

Diabetes mellitus is one of the major risk factors for the development of cardiovascular disease. This disease affects almost all systems in the body and requires that the vigilant clinician continually monitor blood glucose and maintain strict glucose control. In the initial postoperative period, a blood glucose level less than 200 mg/dL is particularly important in managing wound healing. Intervention using an insulin drip initially may reduce the incidence of deep sternal wound infections by 50%.[1] Once good glucose control has been achieved, insulin is given subcutaneously, and glucose levels are followed closely. Such insulin therapy also decreases the incidence of diabetic ketoacidosis or hyperosmolar coma. It is important to remember that whereas hyperglycemia is detrimental, severe hypoglycemia can be fatal. The need for vigilant blood glucose monitoring cannot be overemphasized.

Adrenal insufficiency may occur, especially in patients who were receiving steroids at regular intervals before surgery. The administration of steroids can suppress adrenal function. To prevent suppression, postoperative stress doses of hydrocortisone (100 mg every 8 hours) should be given, and the patient's regular dose should be restarted. If the

patient is taking vasoactive drugs and is not weaning off the drips, adrenal insufficiency is considered; this condition may be the result of hypoperfusion of the adrenal gland. Cortisol levels are low and confirm adrenal insufficiency.

Thyroid dysfunction, especially hypothyroidism, is common in elderly persons and women. Although perioperative effects do not result in dysfunction, preoperative function is an important consideration, and undiagnosed dysfunction may become apparent in the postoperative period because the thyroid hormones, especially triiodothyronine (T_3), can have cardiovascular effects.

Preventing Gastrointestinal Complications

Fortunately, the gastrointestinal aspects of the postoperative course are uneventful and similar to those of general surgery. After extubation, the patient takes nothing by mouth (NPO) for up to the first 8 hours, with a nasogastric tube in place to decompress the stomach. Then the patient is allowed to have small amounts of ice or water. This relatively simple aspect of nursing care is very important for the postoperative patient, who may experience significant thirst because of the anticholinergic drugs that were given before surgery. The use of ice pops and ginger ale can help with compliance and decrease the possibility of nausea, vomiting, and aspiration.

Complications such as cholecystitis, pancreatitis, and bowel infarction rarely occur. Their pathogenesis is not always clear but is attributed to splanchnic hypoperfusion and general gastrointestinal ischemia. Thorough assessment of the abdomen looking for pain, distention, or tympany may help discover subtle abnormalities. Lactate levels greater than 2.5 mmol/L may indicate splanchnic hypoperfusion. However, they may also be the result of nonpulsatile flow of the bypass machine, which may cause a release of angiotensin II, exacerbating splanchnic ischemia.[15] The need for further evaluation is dictated by the clinical presentation.

Monitoring for Infection

In the early postoperative period, hypothalamic resetting is the cause of temperature derangement. Febrile reactions are usually attributed to SIRS and to overshoot from rewarming. If the fever (temperature more than 100.4°F [38°C]) persists for more than 48 to 72 hours, infection should be considered. Infection prevention is the major goal of all programs. This goal is achieved through the prudent use of antibiotics, vancomycin, and a cephalosporin (eg, cefazolin, ceftazidime). Timing of antibiotic administration is pivotal. For optimal results, preoperative doses should be completely infused before the skin is cut. Antibiotic dosing depends on preoperative renal function. A short postoperative course should also be anticipated.

Mediastinitis is the major infection in patients who have undergone CABG surgery and may be a devastating complication that increases the length of hospital stay and mortality. Risk factors associated with mediastinitis are obesity; prior cardiac surgery; preexisting type 1 diabetes mellitus; and perioperative factors, such as excessive electrocautery and use of both internal mammary arteries resulting in compromised blood flow to the chest wall. Therapy is an extended antibiotic course and plastic surgery. The aggressive regulation of the blood glucose level using insulin drips initially instead of subcutaneous administration has been shown to decrease the occurrence of mediastinitis.[1] This intervention is also used in cases that do not involve CABG; a decrease in mortality has been demonstrated.[29] It is very important to instruct the patient not to use the arms excessively when moving and to use a "cough pillow" with coughing (a small pillow that is placed on the sternal incision and squeezed when coughing). Other interventions, such as having the patient sleep on his or her back, are also important. Following these instructions may help maintain the stability of the sternum.

Patient Teaching and Discharge Planning

With managed care, capitation, rising costs, and limited resources, the usual length of hospitalization after cardiac surgery is 4 to 7 days. Discharge planning that begins at admission is imperative because of the short length of hospital stays. The patient should be discharged with the following medications, unless contraindicated: aspirin, a beta blocker, an ACE inhibitor (if the ejection fraction is <40%), and a statin. If a medication is contraindicated, the rationale should be documented. Smoking cessation interventions, if applicable, should be included in discharge teaching. Box 22-8 summarizes patient teaching about cardiac postoperative care.

BOX 22-8 TEACHING GUIDE *Recovering From Cardiac Surgery*

General Instructions

- Avoid lifting heavy objects (10 to 15 pounds or more) for first 3 months.
- Avoid strenuous arm movement, such as golf or tennis. When getting in and out of chair or bed, use legs. Arms should not bear weight and should be used only for balance.
- Do not drive for 6 weeks after surgery. (May ride in automobile.)
- Follow physician's instructions for activity progression.
- Resume sexual activity when you can climb two flights of stairs without stopping (with physician's recommendations).
- Use alternative positions for 3 to 4 months to decrease stress on sternum; avoid side-lying and prone positions.
- Inspect and cleanse surgical incisions daily with soap and water.
- Understand medications, including reason for taking, dosage, frequency, and side effects.
- Follow dietary restrictions.
- Understand how much pain to expect and how to manage it.

Risk Factors

- Follow instructions on individual risk factors, understand their impact on health after cardiac surgery, and learn how to modify them.
- Seek referrals as appropriate (eg, for a weight loss program or a smoking cessation program).

Follow-Up With Physician

- Know how and when to schedule follow-up appointments.
- Be alert for signs and symptoms of infection, such as fever, increased redness, tenderness, drainage, or swelling of incisions.
- Report palpitations, tachycardia, or an irregular pulse (if normally regular) to the physician immediately.
- Seek follow-up care if you experience dizziness or increased fatigue, sudden weight gain or peripheral edema, shortness of breath, or chest pain.

▲ Carotid Endarterectomy

Stenosis or occlusion of the carotid arteries is usually due to atherosclerotic disease and may cause stroke, a leading cause of morbidity and mortality in the United States. Carotid endarterectomy is the most common noncardiac vascular procedure performed to restore flow to the carotid arteries and is designed to decrease the risk for stroke and stroke-related death.[30]

The right carotid artery is a branch of the innominate artery that arises from the right side of the aortic arch. The left common carotid artery arises directly from the aortic arch. At the level of the thyroid, the common carotids bifurcate into the external and internal carotids. Located near this bifurcation, in the carotid sinus, are the carotid chemoreceptors, which are sensitive to blood carbon dioxide and oxygen levels, and the baroreceptors, which help regulate blood pressure. The external carotid arteries supply blood to the structures in the head and neck, excluding the eyes and brain. The internal carotid arteries give rise to the ophthalmic arteries and the posterior communicating, anterior cerebral, and middle cerebral arteries, which help supply blood to the brain (Fig. 22-8).

Patients with carotid artery occlusive disease may have sudden dysphagia, unilateral motor weakness, expressive aphasia, dizziness, memory deficits, or monocular blindness.[31] They often exhibit signs of vascular disease in other parts of the body, such as the heart (CAD) or the legs (peripheral arterial disease). Risk factors for carotid artery occlusive disease are associated with stroke and should guide patient care. Hypertension is the most important risk factor for stroke, and blood pressure regulation is essential in the postoperative period. Cigarette smoking, hyperlipidemia, alcohol consumption, and postmenopausal use of estrogen may also affect patient care.[30]

Patients with risk factors for carotid artery occlusive disease must be examined carefully. A carotid bruit can usually be auscultated over the artery because of turbulent flow through the narrowed artery. Carotid Doppler ultrasonography is usually performed to estimate the presence and amount of stenosis, but angiography is the most reliable method to determine the exact amount of stenosis. Magnetic resonance angiography, which is less invasive, may also be used.

Indications for Carotid Endarterectomy

Carotid artery occlusive disease is part of the systemic atherosclerotic process, which is reviewed in Chapter 21. Carotid endarterectomy is indicated for recently symptomatic patients with 70% to 99% carotid artery stenosis.[31] This surgery should not be considered for symptomatic patients with less than 50% stenosis; these patients have better outcomes if treated medically.[31] To be considered for carotid endarterectomy, patients should be between 40 and 75 years of age, with a 5-year life expectancy.[31]

Surgical Procedure

A skin incision is made along the lower anterior border of the sternocleidomastoid muscle just below the angle of the jaw, and the common, internal, and external carotid arteries are isolated. The carotid arteries on the operative side must be clamped. Clamping puts the ipsilateral cerebral hemisphere and eye at risk for ischemia and infarct because the only perfusion to these areas occurs through the circle of Willis and collaterals, which may be inadequate. To prevent thromboembolus formation while the arteries are clamped, a heparin bolus may be given before clamping. Adequacy of circulation is

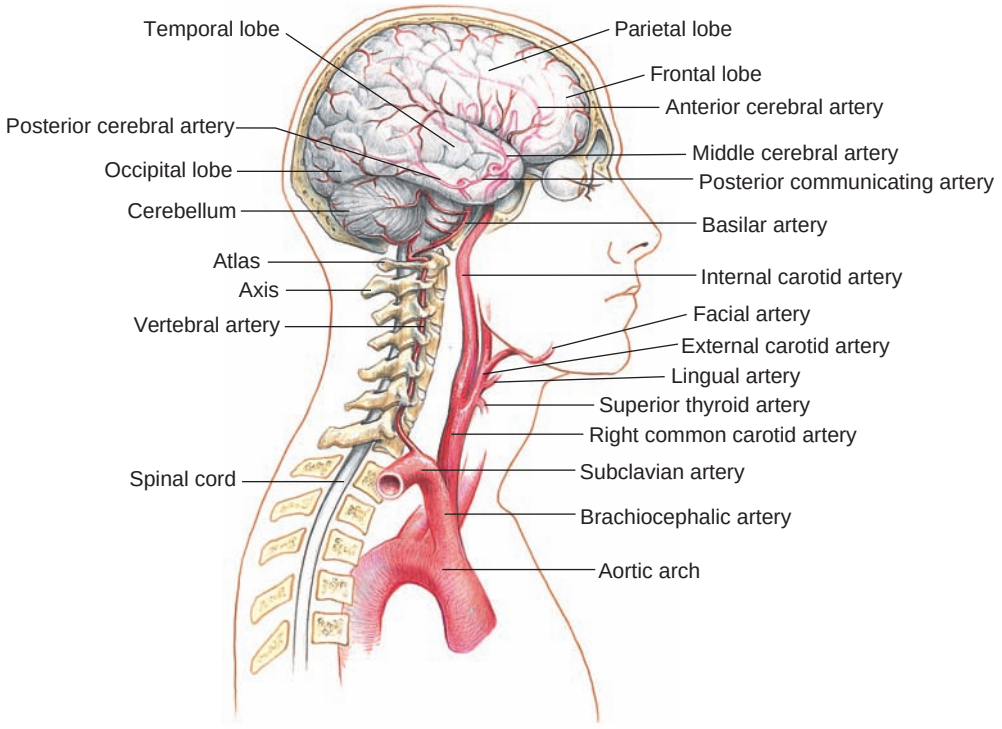

FIGURE 22-8 ▲ Branches of the right external carotid artery. (Courtesy of Anatomical Chart Company.)

determined by continuous electroencephalographic monitoring in the operating room. If circulation is determined to be inadequate, a temporary bypass or shunt may be placed from the common carotid artery to the distal portion of the internal carotid to provide continued intraoperative perfusion. Patients treated with shunts often include those with contralateral carotid stenosis, neurological deficits, history of cerebrovascular accidents, and stroke in evolution.

Endarterectomy or removal of the ulcerated or stenotic atheromatous plaque is then performed, and the artery is closed. If primary closure will cause a narrowing in the vessel, a patch may be used.

Postoperative Care

After extubation in the recovery room, patients are transferred to the ICU with ECG monitoring, an arterial line, CVP monitoring, and oxygen. Traditionally, patients stay in the ICU for 24 hours. However, cost concerns have led to monitoring patients in an intermediate care unit and reducing the hospital stay to 1 day.[32]

Controlling Blood Pressure

Blood pressure is commonly labile up to 24 hours after surgery because of surgically induced abnormalities of the carotid baroreceptor sensitivity. This is characterized as baroreflex failure syndrome and is usually associated with bilateral surgical procedures.[30] Preoperative hypertension is thought to be the most important determinant of postoperative hypertension, which means that the critical care nurse must be aware of the patient's preoperative blood pressure range. Increased blood pressure may also increase the risk for wound bleeding and possible hematoma formation. The goal of blood pressure regulation is a systolic blood pressure between 120 and 170 mm Hg. A systolic blood pressure greater than 170 mm Hg should be treated with nitroprusside or other IV agents, whereas one less than 120 mm Hg should be treated with IV fluid or a norepinephrine or phenylephrine drip if the patient is unresponsive to volume.

Wound Care

To minimize stress on the operative site, the patient's head and neck are kept in alignment. The dressing and the area behind the patient's neck and shoulders are assessed for the presence of blood. Persistent oozing from deep tissue, coughing, straining during extubation, and disruption of suture lines may all lead to bleeding into the operative site. The risk for bleeding can be further aggravated by anticoagulation with heparin, aspirin, or antiplatelet therapy. The nurse assesses the neck size, comparing the operative side with the nonoperative side. Swelling could indicate hematoma formation. Any patient complaints of difficulty talking, swallowing, or breathing should be reported to the physician immediately. If a hematoma is suspected because of tracheal compression by a hematoma, surgical evacuation may be indicated. Wound hematomas occur in about 5.5% of patients.[30]

Preventing Neurological Complications

Brain injury, local nerve injury, or both may occur. Perioperative stroke occurs in approximately 3% of patients and may be due to embolization of atheromatous debris, air from the operative site, or low flow during carotid artery clamping.[31] Neurological assessment includes monitoring level of consciousness, pupil reactivity, eye movement, orientation, appropriateness of response, and motor function (flexion, extension, and hand grips) for the first 24 hours. Abnormalities should be reported to the physician immediately.

Hyperperfusion syndrome occurs in patients with high-grade stenosis. Theoretically, the hemisphere distal to the stenotic area has suffered hypoperfusion that causes the small blood vessels to remain maximally dilated with a loss of autoregulation. Once the stenosis is repaired, autoregulation is still paralyzed, but a marked increase in blood flow occurs that cannot be controlled with vasoconstriction to protect the capillaries. Edema or hemorrhage to the area results.[31] Strict blood pressure control is imperative.

Several cranial nerves (CN) traverse the surgical area and can be exposed to trauma. The most commonly affected are CN VII (the facial nerve), CN X (the vagus nerve), CN XII (the hypoglossal nerve), and CN XI (the spinal accessory nerve). Specific functional assessment for each nerve should be performed after surgery, including those listed in Table 22-3. If a deficit is present, the nurse should notify the physician and explain to the patient how it occurred and that the deficit is usually temporary.

Table 22-3 Postoperative Functional Assessment of Cranial Nerves Following Carotid Endarterectomy

Nerve	Nerve Intervention	Functional Assessment	Functional Damage
Facial nerve (VII)	Motor function of facial muscles	Ability to smile and frown	Asymmetrical contraction of the mouth
Vagus nerve (X)	Motor and sensory function of larynx and throat	Quality and tone of voice and ability to swallow	Difficult swallowing, hoarseness, speech problems, loss of gag reflex
Hypoglossal nerve (XII)	Muscles to tongue	Movement of tongue	Difficult swallowing, speech problems, deviation of tongue, sometimes airway damage
Spinal accessory nerve (XI)	Trapezius and sternocleidomastoid muscles	Ability to shrug shoulders and raise arm to horizontal position	Shoulder may sag, difficulty raising shoulder against resistance, difficulty raising arm to horizontal position

BOX 22-9 TEACHING GUIDE Recovering From Carotid Endarterectomy

Risk Factor Reduction
- Stop smoking.
- Eat a low-fat diet.
- Control hypertension if present.

Activity
- There are usually no restrictions on activity. It is all right to move your neck in a normal manner.

Incision Care
- Bruising and discoloration are common.
- Wash the incision site with soap and water.

General
- Be familiar with signs and symptoms of incisional infection.
- Notify your physician of visual defects, changes in memory or sensation, or an inability to swallow or speak.
- Be knowledgeable about medication indications, including reason for taking, dosage, frequency, and side effects.
- Keep physician appointments.

Home Care Considerations

Patients are usually discharged on the first or second postoperative day. Aspirin (81 or 325 mg/d) should be prescribed postoperatively for at least 3 months to reduce the possibility of stroke, MI, or death.[31] The critical care nurse plays an essential role in the care of the patient who has had a carotid endarterectomy. Although considered a vascular surgical procedure, postoperative complications usually manifest as neurological symptoms, and the nurse must assess the patient for subtle neurological changes. Patient education is also a key component of care. Patients and their families should understand that the patient has an underlying cardiovascular disease and that risk factor modification is necessary. Education should include the items listed in Box 22-9.

▲ Clinical Applicability Challenges

CASE STUDY

Ms. W., a 54-year-old woman who has had CABG surgery with three grafts and good left ventricular function preoperatively (ejection fraction about 50%), has arrived in the intensive care unit (ICU) from the operating room after 5 hours in surgery. An internal mammary artery graft to the left anterior descending coronary artery and saphenous vein grafts to the right coronary artery and diagonal artery were performed using the standard bypass technique. Ms. W. has a history of arthritis and takes large doses of ibuprofen for pain relief. Her chest tube output upon arrival in the ICU was 200 mL and increased to 250 mL in the next 30 minutes × 2. Her blood pressure is 100/50 mm Hg, and her normal blood pressure averages 130/70 mm Hg.

1. What do you think caused the increased amount of bleeding in this patient situation?
2. What would be your immediate intervention for Ms. W.?
3. What interventions would be the most important to make the provider aware of?

PART 6

RESPIRATORY SYSTEM

23

Anatomy and Physiology of the Respiratory System

Megan Cecere Lynn and Karen L. Johnson

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Identify the major structures of the respiratory system that are located in the thorax.
2. Describe the movement of air through the airways from the nose to the alveoli.
3. Discuss the function of surfactant in maintaining alveolar inflation.
4. Differentiate the function of bronchial and pulmonary circulations.
5. Describe the mechanics of ventilation in terms of air movement into and out of the lungs, lung compliance, and airway resistance.
6. Explain four factors that affect the diffusion of gases across the alveolar–capillary membrane.
7. Identify physiological and pathophysiological conditions that produce a ventilation–perfusion mismatch.
8. Discuss conditions that affect the relationship described in the oxyhemoglobin dissociation curve and how these conditions affect oxygen exchange.
9. Describe the function of the chemoreceptors and lung receptors.

The structures of the respiratory system allow gases to move between the external environment and the internal environment. The cardinal function of the respiratory system is gas exchange, a process by which oxygen moves from the air into the blood and carbon dioxide moves out of the blood and is exhaled to the external environment. The respiratory system also has several other functions, including regulation of acid–base balance, metabolism of some compounds, and filtration of inhaled unwanted materials. Intact respiratory structures and proper functioning of the respiratory system are necessary for transport of gases in and out of the body. Knowledge of respiratory anatomy and physiology helps the nurse understand respiratory assessment techniques, principles of respiratory system management, and common disorders of the respiratory system.

▲ Anatomy of the Respiratory System

The Thorax

The thorax contains the major structures of the respiratory system. These structures include the bony thoracic cage, the muscles of ventilation, the lungs, the pleural space, and the mediastinum (Fig. 23-1). The thoracic cage is a rigid, yet flexible, structure. Its bony structure protects the major organs in the thoracic cavity. Flexibility allows for inhalation/inflation and exhalation/deflation of the lungs. The thoracic cage consists of 12 vertebrae, each with a pair of ribs. Posteriorly, each rib is attached to a vertebra (Fig. 23-2). Anteriorly, the first seven ribs are attached to the sternum (Fig. 23-3). The

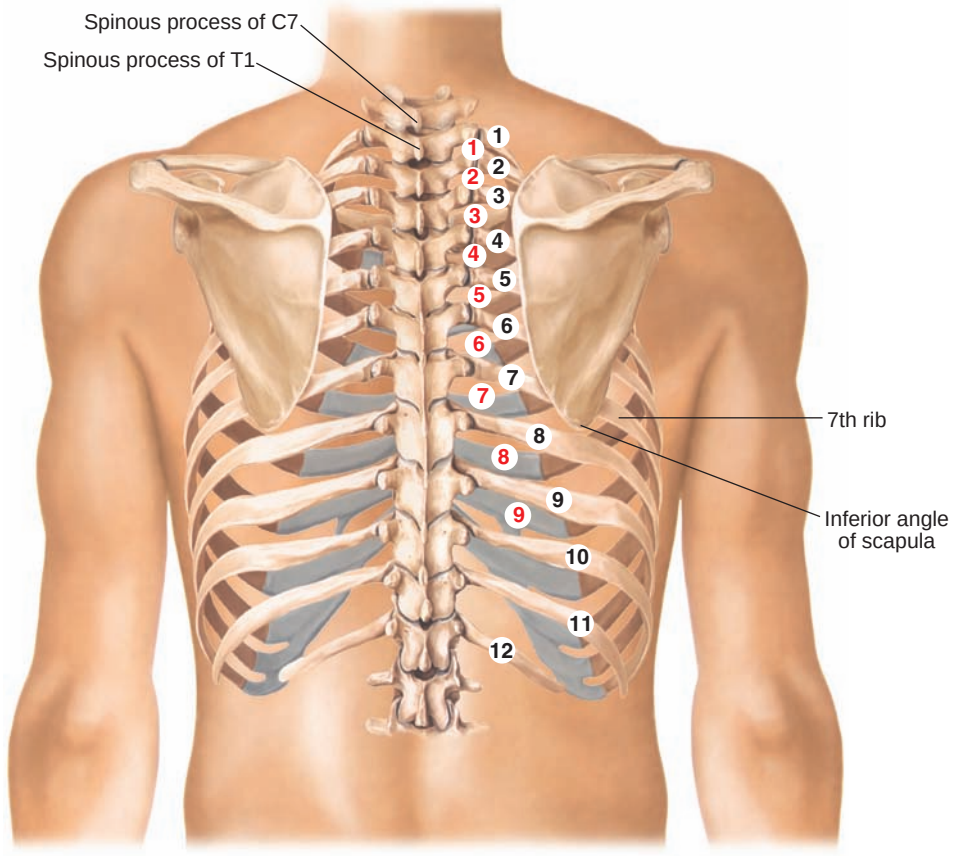

FIGURE 23-2 ▲ Posterior thoracic cage. (From Bickley LS: Bates' Guide to Physical Examination and History Taking, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 285.)

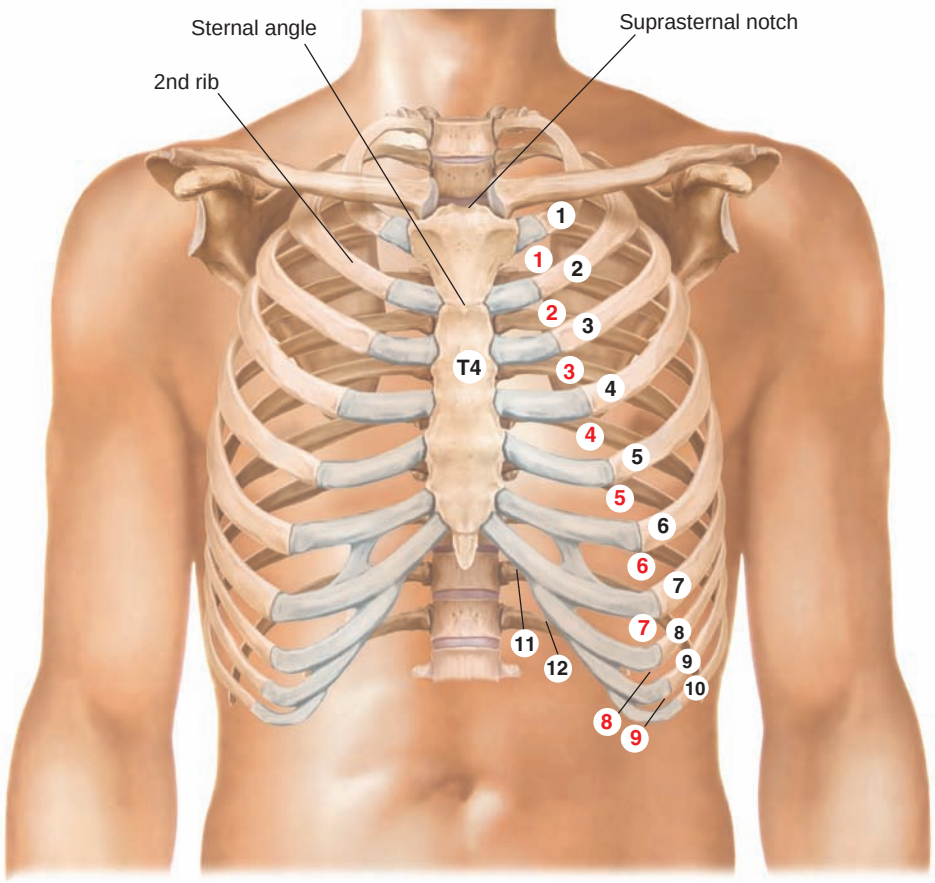

FIGURE 23-3 ▲ Anterior thoracic cage. (From Bickley LS: Bates' Guide to Physical Examination and History Taking, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 284.)

8th, 9th, and 10th ribs are attached by cartilage to the ribs above them. The 11th and 12th ribs are called "floating ribs," because they are not attached anteriorly to another structure.

The Lungs, Mediastinum, and Pleural Space

Positioned within, and protected by, the thoracic cage, the lungs are located on either side of the chest. These air-filled, spongy structures are attached to the body only at the pulmonary ligament at the mediastinum. The right lung contains three lobes, and the left lung contains only two lobes because of the space limitation imposed by the heart. The base of each lung rests anteriorly at the level of the 6th rib at the mid-clavicular line and at the 8th rib at the mid-axillary line. The apices extend 2 to 4 cm above the inner aspects of the clavicles.

The space between the two lungs is the mediastinum. The mediastinum contains the heart, blood vessels, lymph nodes, thymus gland, nerve fibers, and esophagus.

Pleural membranes surround the lungs and line the thoracic wall. The parietal pleura is the membrane lining the chest wall, and the visceral pleura overlays the lung parenchyma (Fig. 23-4). A thin layer of serous fluid in the small space between these two pleurae allows the parietal and visceral pleurae to slide over each other during inspiration and expiration. The pressure within the pleural space is called the intrapleural pressure. The intrapleural pressure is normally less than the pressures within the lung. It is this negative pressure that keeps the lungs inflated. If the intrapleural space loses its negative pressure (by exposure to atmospheric pressure; eg, as a result of chest trauma), the lung collapses, a condition known as a pneumothorax. The pleural space is also a potential space for the accumulation of fluid. An abnormal collection of fluid in the pleural space is a pleural effusion.

The Respiratory Muscles

The muscles that elevate the thoracic cage are classified as *muscles of inspiration*.[1] The major muscle involved with inspiration is the diaphragm. The diaphragm is a thin, dome-shaped muscle that is innervated by the phrenic nerves. When it contracts, the abdominal contents are forced downward, and the chest expands vertically (Fig. 23-5). In normal breathing, the level of the diaphragm moves about 1 cm, but on forced inspiration, a total excursion of up to 10 cm may occur.[2] The external intercostal muscles also assist with inspiration (Fig. 23-6). These muscles attach to adjacent ribs and slope downward and forward. When the external muscles contract, the ribs are pulled forward and upward, and this increases the lateral and anterior–posterior diameters of the thoracic cage. The accessory muscles of inspiration include the scalene and sternocleidomastoid muscles. The scalene muscles elevate the first two ribs, and the sternocleidomastoid muscles raise the sternum.[2] During normal breathing, these muscles are not used, but during exercise, these muscles contract to aid in inspiration.

Muscles that depress the thoracic cage are classified as *muscles of expiration*.[1] Expiration is a largely passive process during normal breathing. During expiration, the diaphragm relaxes, and the elastic recoil of the lungs, chest wall, and abdominal structures compresses the lungs. Expiration can become an

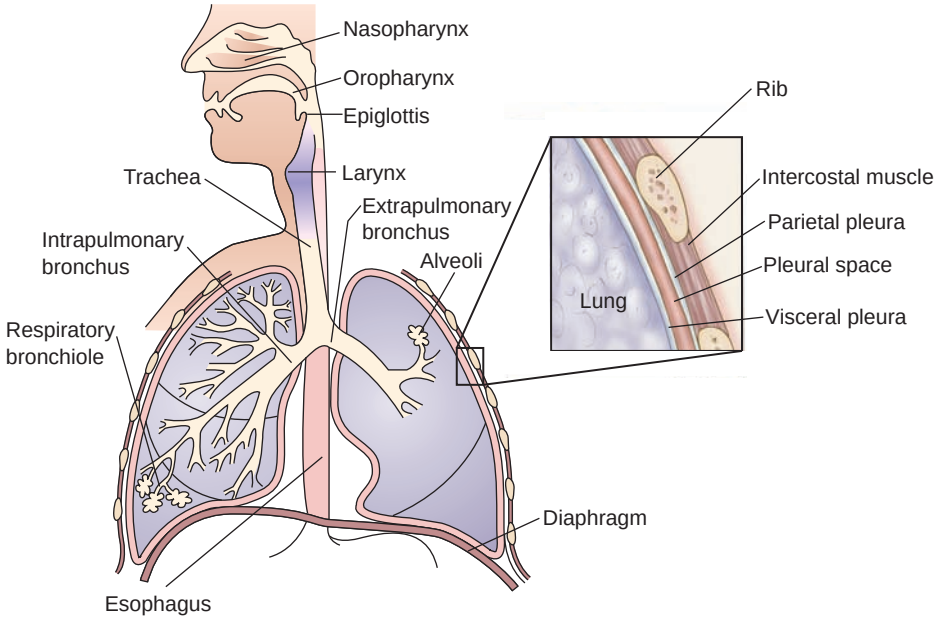

FIGURE 23-4 ▲ Structures of the respiratory system. (From Porth CM: Pathophysiology: Concepts of Altered Health States, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 641.)

active process during exercise. The abdominal and intercostal muscles can increase expiratory effort (see Fig. 23-5). When the abdominal muscles contract, the intra-abdominal pressure increases and pushes the diaphragm upward. These muscles are also used during defecation, vomiting, and coughing. When the internal intercostal muscles contract, the ribs are pulled downward and inward, decreasing the thoracic volume.

The Conducting Airways

The conducting airways include the nasopharynx, oropharynx, trachea, bronchi, bronchioles, and the terminal bronchioles (see Fig. 23-4). These airways—a series of tubes that become more numerous and narrow as they penetrate deeper into the lungs (Fig. 23-7)—warm, humidify, and filter air that is inhaled as it is channeled to the gas exchange region. Because the conducting airways contain no alveoli and do not participate in gas exchange, they constitute the *anatomic dead space*. The volume in the anatomic dead space is approximately 150 mL.[3]

The Nasopharynx and Oropharynx

The nasopharynx is the preferred route for entrance of air into the respiratory tract during normal breathing because it filters and warms inspired air.[4] The outer passages are lined with coarse hairs that filter large particles. The upper portion of the nasal cavity supplies warmth and moisture to the air inhaled. If nasal passages are plugged or when larger volumes of gases need to be exchanged (eg, during exercise), the oropharynx provides an alternate route. Obstruction of the oropharynx leads to immediate cessation of ventilation ("choking"). Foreign bodies and swelling of the pharyngeal airways from infection, injury, or allergic reaction can also cause airway obstruction.

The Epiglottis

The epiglottis is located posterior to the root of the tongue (see Fig. 23-4). It is a leaf-shaped piece of cartilage that moves up and down. During inhalation, the epiglottis moves upward to allow air to move through the trachea. During swallowing, it moves downward to cover the larynx and allow food and

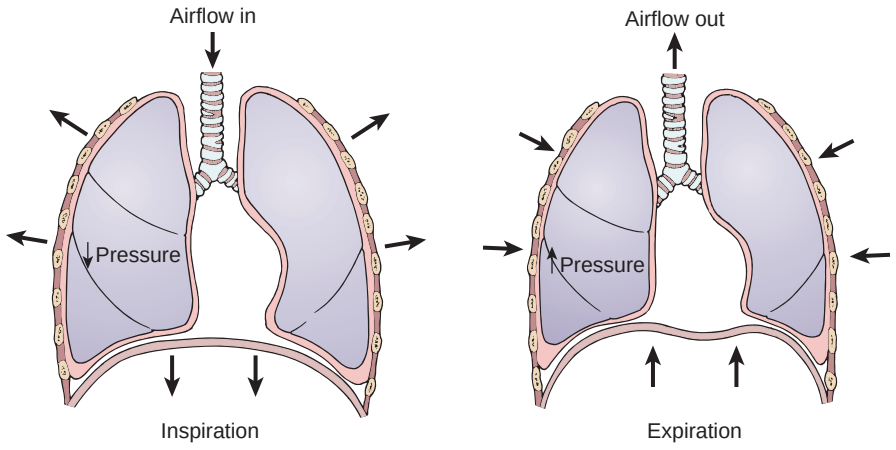

FIGURE 23-5 ▲ Frontal section of the chest showing the movement of the rib cage and diaphragm during inspiration and expiration. (From Porth CM: Pathophysiology: Concepts of Altered Health States, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 650.)

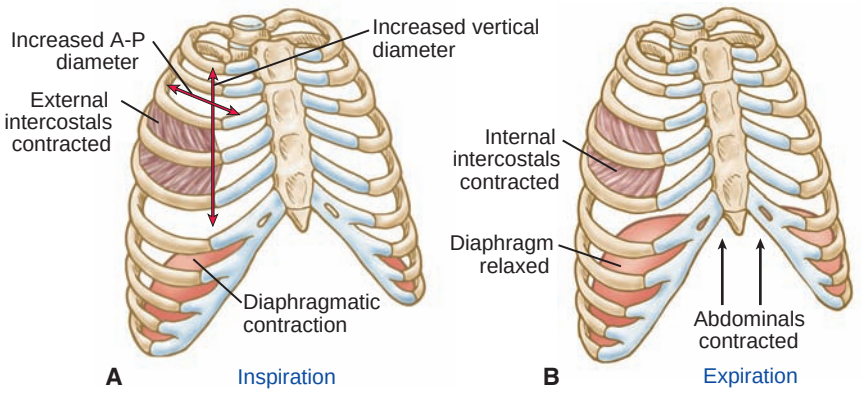

FIGURE 23-6 ▲ **A, B:** Contraction and expansion of the thoracic cage during expiration and inspiration, demonstrating diaphragmatic contraction, function of the intercostals, and elevation and depression of the rib cage. (From Porth CM: Pathophysiology: Concepts of Altered Health States, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 651.)

liquid to pass into the esophagus. During defecation, especially during defecation associated with straining and constipation, inhaled air is temporarily held in the lungs by closure of the glottis. Contraction of the intra-abdominal muscles causes an increase in the intra-abdominal and intrathoracic pressures. These collective processes are called the *Valsalva maneuver*. The Valsalva maneuver can be dangerous because the abrupt increase in intrathoracic pressure can significantly reduce venous return and therefore cardiac output.

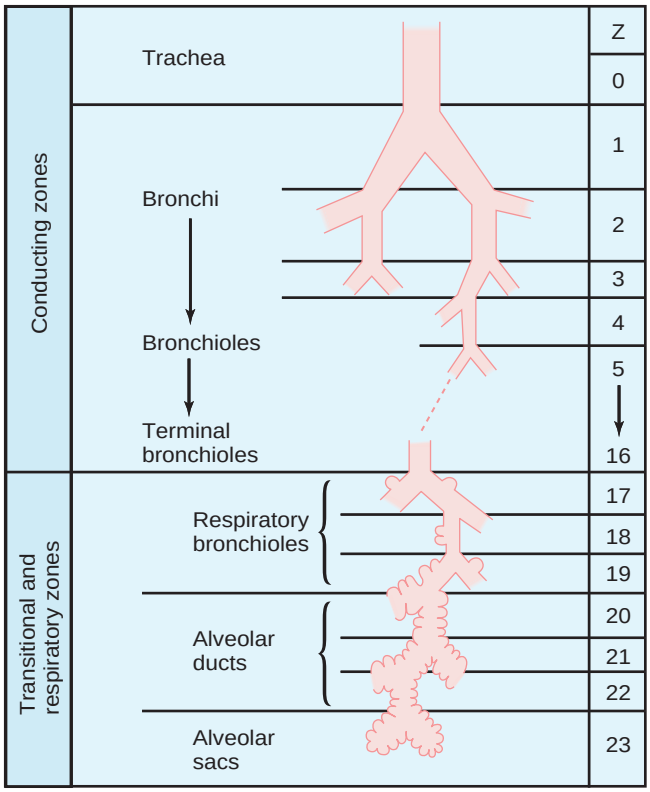

FIGURE 23-7 ▲ Idealization of the human airways. Note that the first 16 generations (Z) make up the conducting zone, and generations 17 to 23 make up the transitions and respiratory zones. Throughout childhood, the airways increase in diameter and length, and the number and size of the alveoli increase until adolescence, when respiratory development matures to that of an adult. (Adapted from West JB: Respiratory Physiology: The Essentials, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2008, p 6.)

The Tracheobronchial Tree

The tracheobronchial tree consists of the trachea, bronchi, and bronchioles. The trachea is a hollow tube, or "windpipe," that connects the larynx and the major bronchi of the lungs (see Fig. 23-4). The trachea is primarily smooth muscle and is supported by horseshoe-shaped rings of cartilage that prevent the trachea from collapsing during coughing or bronchoconstriction of the smooth muscle.

The end of the trachea divides, forming the two large mainstem bronchi. The point at which the trachea divides is called the *carina*. The carina is innervated with sensory neurons. When the carina is stimulated (eg, during tracheal suctioning), the cough reflex and bronchoconstriction are elicited. The right mainstem bronchus is wider and shorter than the left bronchus. Thus, the right mainstem bronchus is the most common site of aspiration of foreign bodies. The right and left mainstem bronchi divide into branches that become smaller and more numerous as they divide (Fig. 23-8). The right and left mainstem bronchi divide into lobar and segmental bronchi, which divide into bronchioles, which become terminal bronchioles. The terminal bronchioles are the smallest airways without alveoli. The mainstem bronchi are similar in structure to the trachea, in that they are airways supported by cartilage rings. However, as the bronchi extend into the lungs, the cartilage rings become irregular and smaller until they disappear at about the level of the respiratory bronchioles. Here, smooth muscle wraps around the bronchioles. Contraction of these muscles (bronchospasm) causes narrowing of the bronchioles and impairs gas flow.[4]

The Respiratory Airways

The terminal bronchioles branch into the respiratory airways. These airways include the respiratory bronchioles, the alveolar ducts, and the alveolar sacs (see Fig. 23-7). The respiratory zone makes up most of the lung, its volume being about 2.5 to 3 L.[5]

The Respiratory Bronchioles

Each respiratory bronchiole forms a lobule. The lobule is the smallest functional unit of the lung and is where gas exchange

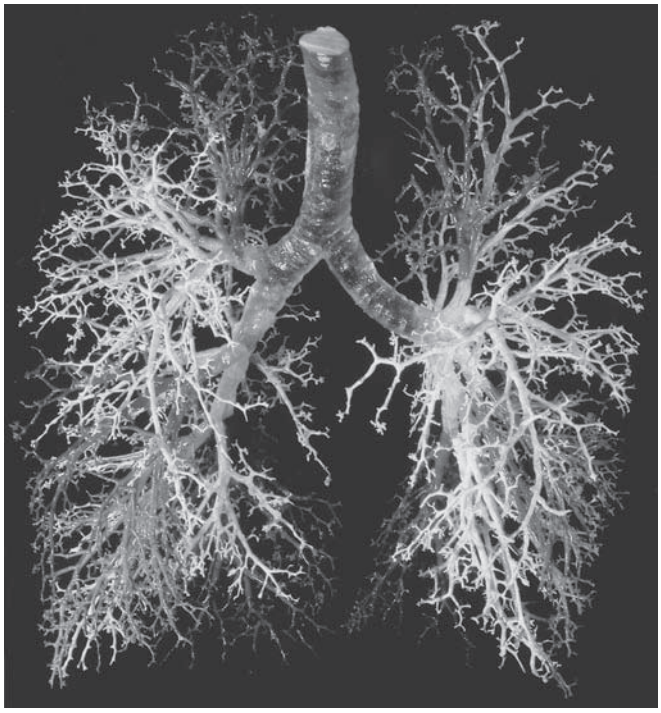

FIGURE 23-8 ▲ Cast of the airways of a human lung. The alveoli have been pruned away, allowing the conducting airways from the trachea to the terminal bronchioles to be seen. (From West JB: Respiratory Physiology: The Essentials, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2008, p 5.)

takes place. A lobule consists of an arteriole, the pulmonary capillaries, and a venule (Fig. 23-9). Blood enters through a pulmonary artery and exits through a pulmonary vein. This is the only place in the body where highly oxygenated blood flows through a vein.

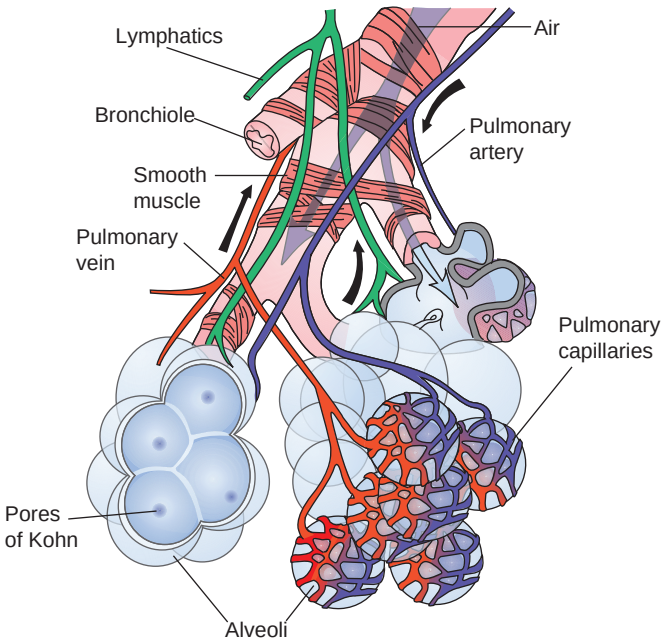

FIGURE 23-9 ▲ Lobule of the lung, showing the bronchial smooth muscle fibers, pulmonary blood vessels, and lymphatics. (From Porth CM: Pathophysiology: Concepts of Altered Health States, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 645.)

The Alveoli

Each respiratory bronchiole gives rise to several alveolar ducts that terminate in a cluster of alveoli, as shown in Figure 23-9. The alveolus is the end point of the respiratory tract, and it is here where gas exchange takes place. The alveoli are thin-walled, cup-shaped structures. There are approximately 300 million alveoli in the adult lung, with a total surface area of 85 m^2.[5] The alveoli also contain macrophages that perform a phagocytic role. These cells move from alveolus to alveolus, removing foreign substances and keeping the alveoli sterile.

Alveolar structures are composed of two types of cells: type I alveolar cells and type II alveolar cells. *Type I alveolar cells* are flat squamous epithelial cells and comprise approximately 90% of the total alveolar surface area. Gas exchange takes place along these cells. *Type II alveolar cells* secrete pulmonary surfactant. Surfactant is a lipoprotein that decreases surface tension in the alveoli. This prevents collapse of the smaller airways during expiration and makes it easier to inflate the alveoli during inspiration. Therefore, injury to type II alveolar cells leads to alveolar collapse and impaired pulmonary gas exchange.

The Lung Circulation

The lungs have a dual blood supply: the bronchial circulation and the pulmonary circulation. The bronchial circulation distributes blood to the airways, and the pulmonary circulation contributes to gas exchange.

The Bronchial Circulation

The bronchial arteries that perfuse the left side of the thorax arise from the aorta, and the arteries that perfuse the right side of the thorax branch from the internal mammary, subclavian, and intercostal arteries. The capillaries of the bronchial circulation drain into the bronchial veins and eventually empty into the vena cava or the pulmonary vein. The bronchial circulation does not participate in gas exchange. Blood that is emptied into the pulmonary vein is unoxygenated blood and mixes with oxygenated blood flowing to the left side of the heart. This contributes to the "anatomic shunt" and is why arterial oxygen saturation is always less than 100%. The flow through the bronchial circulation is minimal, and the lung can function fairly well without it, such as after lung transplantation.[5]

The Pulmonary Circulation

The pulmonary circulation arises from the pulmonary artery and provides for the gas exchange function of the lung (Fig. 23-10). As shown in Figure 23-10, deoxygenated blood leaves the right ventricle and enters the pulmonary artery. The blood passes from the pulmonary artery through a series of branching arteries to the capillaries, and then back through a series of venules to the pulmonary vein.

In the walls of the alveoli, the capillaries form a dense network (see Fig. 23-9). The diameter of a capillary segment is about 10 micrometers, just large enough for one red blood cell.[5] The extreme thinness of the blood–gas barrier is extremely efficient for gas exchange but also means these capillaries are easily damaged. Increasing pressure in the alveoli (such as occurs with high levels of positive

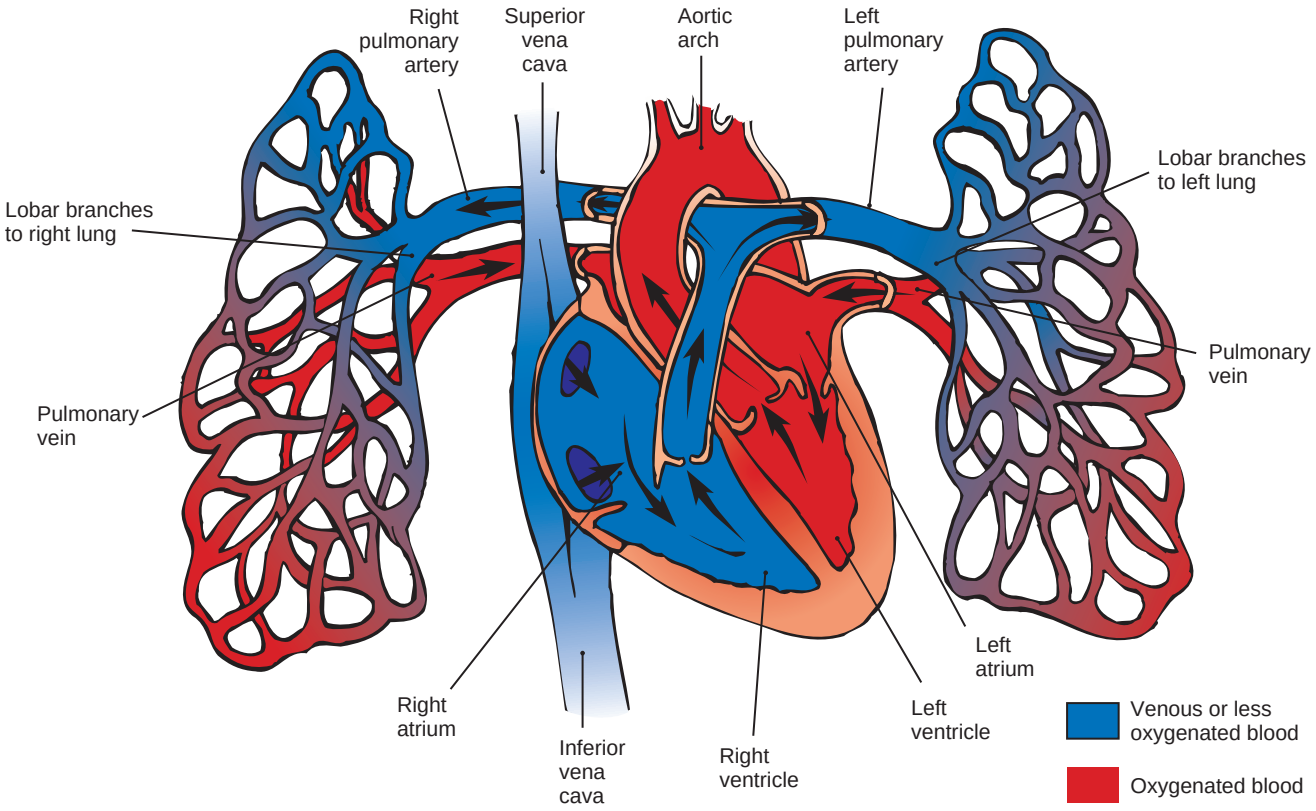

FIGURE 23-10 ▲ Circulation from the right heart to the lungs and left heart.

end-expiratory pressure) or increasing volume in the alveoli (such as occurs with mechanical ventilation with large tidal volumes) can damage capillaries, causing them to leak plasma into the alveolar spaces. Each red blood cell spends about 0.75 second in the capillary network and during this time probably transverses two or three alveoli.[5] Almost complete equilibrium of oxygen and carbon dioxide between alveolar gas and capillary blood can occur during this very brief time.

The pulmonary artery receives the whole output from the right ventricle. However, the resistance of the pulmonary circuit is extremely low, compared with the systemic vascular resistance, because the pulmonary vascular structures do not have vascular smooth muscle like the systemic vascular structures do. Thus, systolic and diastolic pressures in the pulmonary circulatory system are much lower. Normal pulmonary artery pressures are 20 to 30/8 to 15 mm Hg. Just as hypertension can develop in the systemic circulatory system, hypertension can occur within the pulmonary circulatory system and is called pulmonary hypertension.

The Pulmonary Lymphatics

The lungs represent the largest surface area of the body that is exposed to an increasingly hostile environment.[5] Fortunately, the lungs have multiple mechanisms to handle inhaled particles. The nose filters large particles. Particles that deposit in the conducting airways are removed by cilia that line the airways. The cilia brush the particles up toward the epiglottis, where they are then swallowed. By the process of phagocytosis, macrophages or leukocytes destroy foreign particles in the alveoli. Foreign materials that reach the alveoli are then removed by lymphatic tissue. The lungs have a vast supply of lymphatic tissue. The lymphatic vessels parallel the pulmonary vasculature (see Fig. 23-9). They surround the lobule and aid in the removal of particles and protein from the interstitial spaces. These vessels eventually drain into lymph nodes located at the hila of the lungs.

▲ Physiology of the Respiratory System

The goals of respiration are to provide oxygen to tissues and to remove carbon dioxide. The physiology of respiration involves the following three processes: (1) *ventilation*, or the movement of air between the atmosphere and the alveoli; (2) *diffusion* of oxygen and carbon dioxide between the pulmonary capillaries and the alveoli; and (3) *transport* of oxygen and carbon dioxide in the blood to and from the cells.[6]

Ventilation

During ventilation, the movement of air into the lungs is known as *inhalation*, and the movement of air out of the lungs is known as *exhalation*. Air flows from a region of higher pressure to a region of lower pressure. To initiate a breath, a drop in pressure in the alveoli must precipitate airflow into the lungs.

The Mechanics of Ventilation

Ventilation is a complex process with multiple variables, including the change in pressures and the integrity of the muscles responsible for moving air in and out of the lungs, the compliance of the lungs, and the resistance afforded by the airways. Collectively, these variables are referred to as the *mechanics of ventilation*.

MOVEMENT OF AIR INTO AND OUT OF THE LUNGS. The movement of air in and out of the lungs requires muscles to expand and contract the chest cavity and a change in gas pressures to facilitate movement of air from one compartment to another. The lungs can be expanded and contracted in two ways: (1) by downward and upward movement of the diaphragm to lengthen and shorten the chest cavity and (2) by elevation and depression of the ribs to increase and decrease the anterior–posterior diameter of the chest cavity.[1]

According to the laws of physics, the movement of gases is always from an area of higher pressure to lower pressure. Several pressures are involved in the process of respiration: airway pressure, intrapleural pressure, intra-alveolar pressure, and intrathoracic pressure (Fig. 23-11). The *airway pressure* is the pressure in the conducting airways. The *intrapleural pressure* is the pressure in the narrow space between the visceral and parietal pleurae. The *intra-alveolar pressure* is the pressure inside the alveoli. The pressure difference between the intra-alveolar pressure and the intrapleural pressure is called the *transpulmonary pressure*. The *intrathoracic pressure* is the pressure within the entire thoracic cavity.

Figure 23-12 illustrates the mechanics involved in ventilation. Figure 23-12A shows the pressures in the resting state. Pleural pressure, a slightly negative pressure, creates a suction that holds the lungs open to their resting level. Without this negative pressure to hold the lungs against the chest wall, the elastic recoil properties of the lungs would cause them to collapse. When the glottis is open and no air is flowing, the pressure in the conducting airways and alveoli equals atmospheric pressure. Figure 23-12B shows the pressures during inspiration. During inspiration, as the diaphragm and intercostal muscles contract, the volume of the chest cavity increases. Expansion of the chest wall pulls outward on the lungs, and the intrapleural pressure becomes more negative. As the alveolar pressure becomes more negative, air flows in from the atmosphere through the conducting airways to the alveoli. After inspiration, the muscles relax, and the chest cavity returns to its resting position. With this decrease in chest size and resultant compression of the lungs, the intra-alveolar pressure builds and forces air out of the lungs during expiration. One respiratory cycle consists of one inhalation and one exhalation. At rest, inhalation requires 1 second and exhalation lasts 2 seconds.

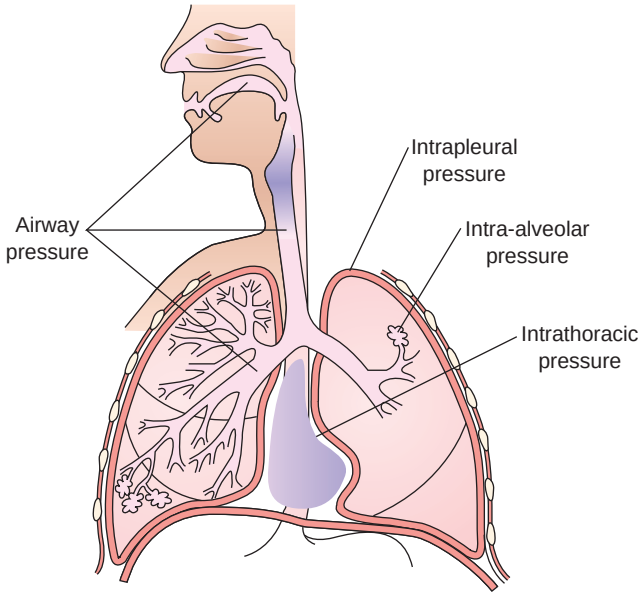

FIGURE 23-11 ▲ Partitioning of respiratory pressures. (From Porth CM: Pathophysiology: Concepts of Altered Health States, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 650.)

LUNG COMPLIANCE. The extent to which the lungs expand is called *compliance*. Compliance is a measurement of distensibility, or how easily a tissue is stretched. If compliance is reduced, it is more difficult to expand the lungs for inspiration. And conversely, if compliance is increased, it is easier to expand lung tissue. Compliance is expressed as the ratio of the change in lung volume to the change in lung pressure.

$$\text{Compliance} \quad \frac{\text{Change in lung volume (L)}}{\text{Change in lung pressure (cm } H_2O\text{)}}$$

Compliance can be appreciated by comparing the ease of blowing up a new balloon that is stiff and resistant with one that has been previously blown up and is more compliant. Lung compliance is determined by the elastin and collagen fibers of the lung and the surface tension in the alveoli.

Lung tissue is made up of elastin and collagen fibers. Collagen fibers resist stretching and make lung inflation difficult, whereas elastin fibers are easily stretched and increase the ease of lung inflation. When elastin fibers are replaced with scar tissue, such as that which occurs with pulmonary fibrosis or interstitial lung disease, the lungs become stiff and noncompliant.

The fluid lining the alveoli has a high surface tension. When the surface tension is high, the moist interior surfaces of an alveolus are difficult to separate from one another, and more energy is required to open and fill the alveolus with air during inspiration. When the surface tension is low, the alveoli walls separate more easily, requiring less effort for alveolar filling during inspiration. Recall that a lipoprotein substance called *surfactant*, which is secreted by type II alveolar cells, decreases the surface tension of these fluids in the alveoli.

Surfactant has four important effects on lung inflation: it lowers the surface tension, increases lung compliance and ease of inflation, provides for stability and more even inflation of the alveoli, and assists in preventing pulmonary edema by keeping the alveoli dry.[4] Without surfactant, lung inflation is extremely difficult. The type II alveolar cells that produce surfactant do not mature until the 26th to 28th weeks of gestation.[4] Premature infants do not have sufficient amounts of surfactant, which leads to alveolar collapse and severe respiratory distress, a condition known as *infant respiratory distress syndrome*. Lack of surfactant or inefficient surfactant production may also play a role in the development of *acute respiratory distress syndrome* (ARDS) in adults.

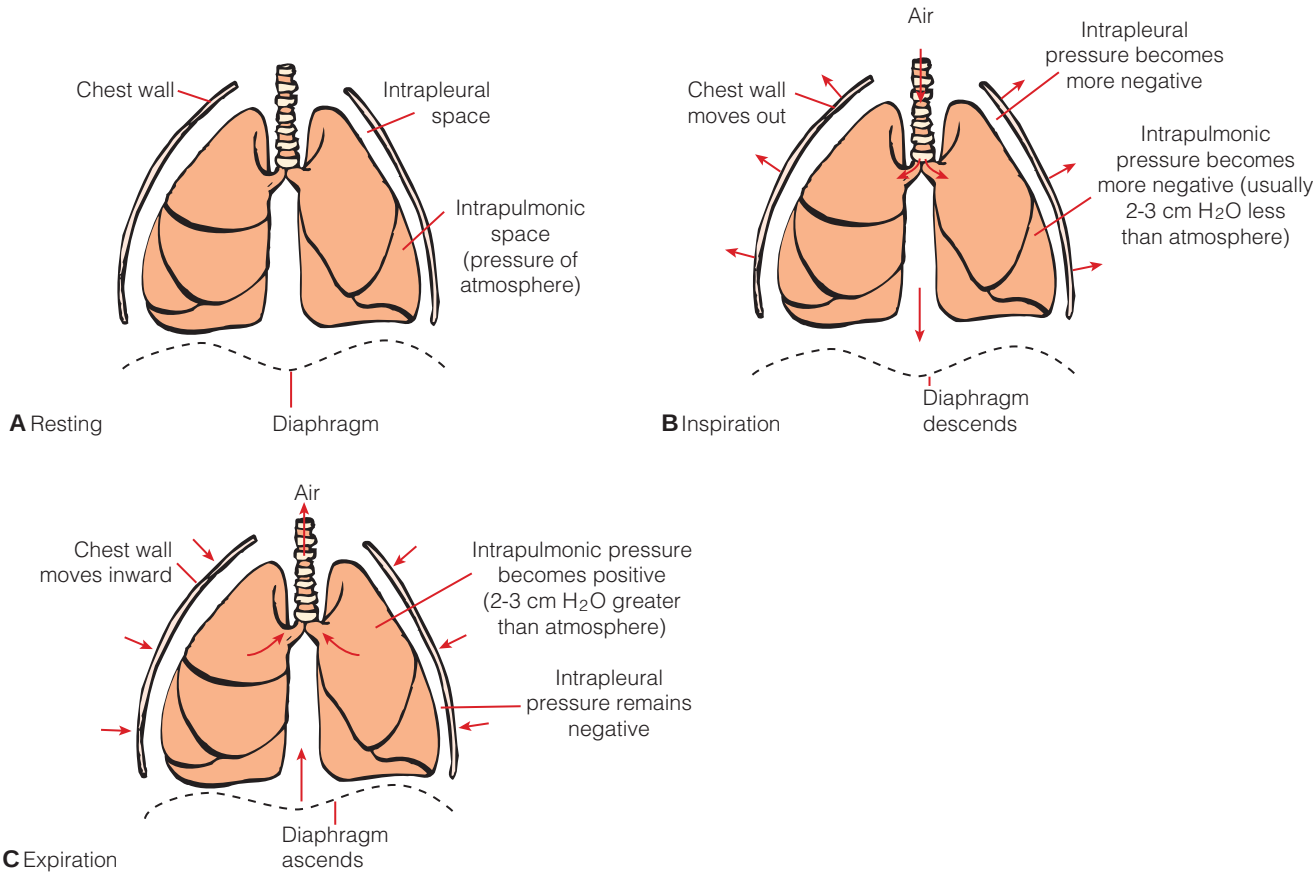

FIGURE 23-12 ▲ Phases of ventilation. **A:** No air movement (resting). **B:** Air moves from the environment to the intrapulmonic space (inspiration). **C:** Air moves from the intrapulmonic space to the environment (expiration).

AIRWAY RESISTANCE. Airflow in the conducting airways is affected not only by pressure differences between the atmosphere and alveoli but also by the resistance that air encounters as it moves through the airways. According to Poiseuille's law, the resistance to flow is inversely proportional to the fourth power of the radius ($R = 1/r^4$). If the radius of the tube that gas is flowing through is cut in half, the resistance is increased 16-fold ($2 \times 2 \times 2 \times 2 = 16$). In the respiratory airways, this means that small changes in airway diameter can have enormous effects on airflow resistance. Normally, airway resistance is so small that only small changes in pressure are needed to move large volumes of air into the lungs. But in conditions that decrease airway diameter, such as those caused by pulmonary secretions or bronchospasm, marked increases in airway resistance occur. To maintain the same rate of airflow as before the onset of increased airway resistance, people with these conditions must increase the driving pressure (or respiratory effort) to move air.

Assessment of Ventilation

Minute ventilation is the volume of air inhaled and exhaled per minute. It is calculated by multiplying tidal volume (VT) and respiratory rate. At rest, minute ventilation is approximately 7,500 mL/min.

Not all the air that enters the airways reaches the alveoli where gas exchange takes place. The part of VT that does not participate in alveolar gas exchange is called *dead space ventilation*. Dead space ventilation includes anatomical dead space volume and physiological dead space volume. Anatomical dead space is the amount of air in the conducting airways and is normally about 2 mL/kg, or about 150 mL.[7] Anatomical dead space depends on body posture and disease states. In certain disease states, such as chronic obstructive pulmonary disease (COPD), anatomical dead space is larger than normal. Physiological dead space occurs when ventilation is normal but perfusion to the alveoli is reduced or absent. This can occur with certain disease states, such as reduced cardiac output or pulmonary embolism. Dead space increases the partial pressure of arterial carbon dioxide ($PaCO_2$) because blood that is carrying carbon dioxide back from the tissues cannot reach the alveoli.

The *alveolar ventilation* is the volume of fresh gas entering the respiratory zone each minute. Alveolar ventilation is of key importance because it represents the amount of fresh inspired air available for gas exchange.[3] Alveolar ventilation is the minute ventilation minus dead space. It is inversely proportional to $PaCO_2$ levels. If one breathes excessively, alveolar ventilation is increased, and $PaCO_2$ decreases. If alveolar ventilation is decreased, $PaCO_2$ levels increase.

Pulmonary Volumes and Capacities

The flow of air in and out of the lungs provides tangible measures of lung volumes. Although referred to as "pulmonary function" measures, in reality, these volumes represent

BOX 23-1 CONSIDERATIONS FOR THE OLDER PATIENT

Anatomical and Physiological Changes in the Respiratory System That Occur With Aging

- The anterior–posterior diameter increases.
- Compliance is increased.
- Anatomical dead space is increased.
- The residual volume (RV) increases.
- Respiratory muscle strength decreases.
- The number of alveoli is reduced, resulting in decreased surface area for diffusion.
- Alveolar elasticity is decreased.
- Chest wall motility is decreased.
- The vital capacity (VC) decreases.
- Blood oxygen levels are decreased—subtract 1 mm Hg from a baseline arterial oxygen tension (PaO_2) of 80 mm Hg for every year over age 60.
- Anemia is common due to decreased hemoglobin and oxygen carrying capacity.

"pulmonary anatomy" measures. In the evaluation of ventilation, structure or anatomy often determines function.

Ventilatory or pulmonary function tests measure the ability of the chest and lungs to move air into and out of the alveoli. Pulmonary function tests include volume measurements, capacity measurements, and dynamic measurements. These measurements are influenced by exercise and disease. Age, sex, body size, and posture are other variables that are taken into consideration when the test results are interpreted. (For a summary of age-related changes affecting the anatomy and physiology of the respiratory system, see Box 23-1.) Figure 23-13 illustrates pulmonary function tests showing normal lung volumes and capacity. Volume measurements show the amount of air contained in the lungs during various parts of the respiratory cycle. Measures of lung volume include V_T, inspiratory reserve volume (IRV), expiratory reserve volume (ERV), and residual volume (RV), as shown in Table 23-1. Capacity measurements quantify a part of the pulmonary cycle. They are measured as a combination of the previous volumes and include inspiratory capacity (IC), functional residual capacity (FRC), vital capacity (VC), and total lung capacity (TLC; see Table 23-1).

The "Work" of Breathing

In normal quiet breathing, muscle contraction occurs during inspiration, and expiration is a passive process caused by elastic recoil of the lung. Thus, under normal resting conditions, muscle contraction (or work) is required only during inspiration. The work of inspiration can be divided into three categories: (1) work required to expand the lungs against lung and chest wall elastic forces, called *compliance work* or *elastic work*; (2) work required to overcome the viscosity of the lung and chest wall structures, called *tissue resistance work*; and (3) work required to overcome airway resistance during the movement of air into the lungs, called *airway resistance work*.[1] Normally during quiet respiration, only a small percentage of the total work is used to overcome tissue resistance, and a little more is used to overcome airway resistance; only 3% to 5% of the total energy expended by the body is required for ventilation. However, during heavy breathing when air must flow through the airways at a higher velocity, more work is used to overcome airway resistance.

All three types of work are frequently increased in pulmonary disease. Fibrosis of the lungs increases compliance work and tissue resistance work. Diseases that obstruct the airways increase airway resistance work. During heavy exercise, the amount of energy required can increase as much as 50-fold, especially if the person has any degree of increased airway resistance or decreased pulmonary compliance.[1]

Diffusion

After the alveoli are ventilated with fresh air, the next step in the respiratory process is diffusion of oxygen from the alveoli to the pulmonary capillaries and diffusion of carbon dioxide from the pulmonary capillaries to the alveoli. Diffusion, or movement of molecules, occurs from an area of high to low concentration. Fick's law describes the diffusion of gases through the alveolar–capillary membrane (Fig. 23-14). Fick's law states that the rate of transfer of gas through a semipermeable membrane is proportional to the tissue surface area and the difference in gas pressures between the two sides, and inversely proportional to the tissue thickness. Recall that the surface area of the alveoli is very large (50 to 100 m^2) and that the thickness of the alveolar membrane is 0.3 micrometers, so the dimensions of the blood–gas barrier are ideal for diffusion of gases.[8] Different gases also cross the barrier at different rates

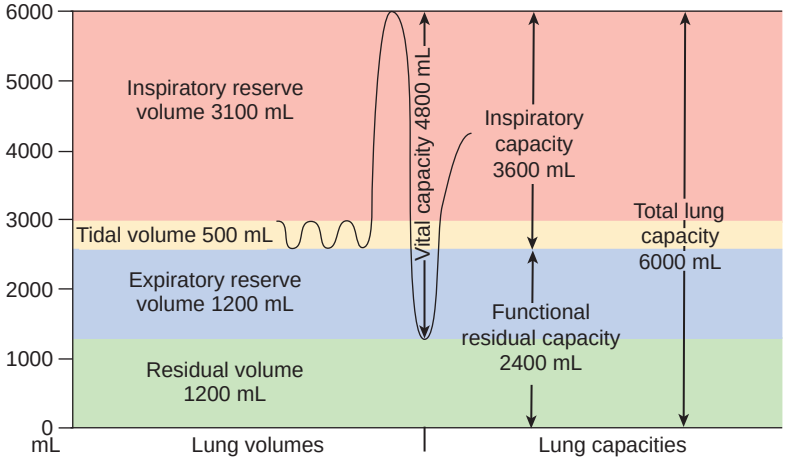

FIGURE 23-13 ▲ Tracings of the respiratory volumes (**left**) and lung capacities (**right**) as they would appear if made using a spirometer. The tidal volume (*yellow*) represents the amount of air inhaled and exhaled during normal breathing; the inspiratory reserve volume (*pink*), the maximal amount of air in excess of the tidal volume that be forcefully inhaled; the maximal expiratory reserved (*blue*), the maximal amount of air that can be exhaled in excess of the tidal volume; and the residual volume (*green*), the air that continues to remain in the lung after maximal expiratory effort. The inspiratory capacity represents the sum of the inspiratory reserve volume and the tidal volume; the functional residual capacity, the sum of the maximal expiratory reserve and residual volumes; and the total lung capacity, the sum of all the volumes. (From Porth CM: Pathophysiology: Concepts of Altered Health States, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 654.)

Table 23-1 Lung Volumes and Lung Capacities

Term Used	Symbol	Description	Remarks	Normal Values
Lung Volumes				
Tidal volume	V_T	Volume of air inhaled and exhaled with each breath	Tidal volume may not vary, even with severe disease.	500 mL
Inspiratory reserve volume	IRV	Maximum volume of air that can be inhaled after a normal inhalation		3,000 mL
Expiratory reserve volume	ERV	Maximum volume of air that can be exhaled forcibly after a normal exhalation	ERV is decreased with restrictive disorders, such as obesity, ascites, and pregnancy	1,100 mL
Residual volume	RV	Volume of air remaining in the lungs after a maximum exhalation	RV may be increased with obstructive diseases.	1,200 mL
Lung Capacities				
Vital capacity	VC	Maximum volume of air exhaled from the point of maximum inspiration	Decrease in VC may be found in neuromuscular disease, generalized fatigue, atelectasis, pulmonary edema, and COPD	4,600 mL
Inspiratory capacity	IC	Maximum volume of air inhaled after normal expiration	Decrease in IC may indicate restrictive disease.	3,500 mL
Functional residual capacity	FRC	Volume of air remaining in lungs after a normal expiration	FRC may be increased with COPD and decreased in ARDS.	2,300 mL
Total lung capacity	TLC	Volume of air in lungs after a maximum inspiration and equal to the sum of all four volumes (V_T, IRV, ERV, RV)	TLC may be decreased with restrictive disease (atelectasis, pneumonia) and increased in COPD.	5,800 mL

depending on their molecular characteristics. Carbon dioxide diffuses about 20 times more rapidly than oxygen. Thus, four factors affect alveolar–capillary gas exchange: (1) the surface area available for diffusion, (2) the thickness of the alveolar–capillary membrane, (3) the partial pressure of gas across the membrane, and (4) solubility and molecular characteristics of the gas (Table 23-2). Any condition or disease that affects one or more of these factors may impair diffusion of oxygen and carbon dioxide across the alveolar–capillary membrane.

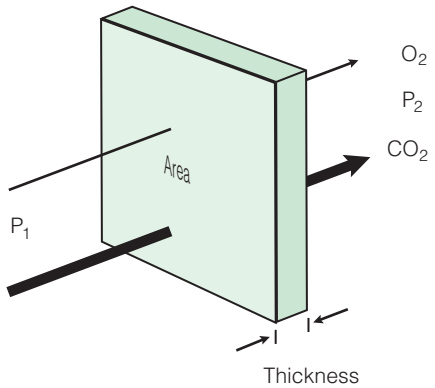

FIGURE 23-14 ▲ Fick's law describes diffusion through a tissue sheet. The amount of gas diffused is directly proportional to the surface area and the difference in partial pressures between the tissue sheets (P1 to P2). The amount of gas diffused is inversely proportional to the thickness of the tissue sheet. The molecular characteristics of carbon dioxide (CO_2) allow it to diffuse about 20 times more rapidly than oxygen (O_2). (From West JB: Respiratory Physiology: The Essentials, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2008, p 26.)

Perfusion

Once oxygen has diffused from the alveolus to the pulmonary capillary, it is carried away from the lung by the bloodstream. This gas exchange function of the lungs requires a constant flow of blood through the respiratory airways. The term *perfusion* is used to describe the flow of blood through the pulmonary capillary bed. As previously described in this chapter, pulmonary capillaries form a dense network around the alveolar wall, making an extremely efficient structure for gas exchange to take place (see Fig. 23-9, p. 474). The meshwork of the capillaries in the respiratory portion of the lungs is so dense that the flow in these vessels often is described as being similar to a "sheet" of blood.[4] When these blood vessels sense a low oxygen content in the alveoli, they vasoconstrict. The precise mechanism of this response, called *hypoxic vasoconstriction*, is not known.[9] Hypoxic vasoconstriction has the effect of directing blood flow away from hypoxic areas of the lung. By diverting blood flow from these areas, the deleterious effects on gas exchange are reduced.

Relationship of Ventilation to Perfusion

Distribution of Ventilation

Not all areas of the lung have the same ventilation. Body position affects distribution of ventilation. In a seated or standing position, lower regions of the lung ventilate better than upper zones. In a supine position, the apex and base of the lung ventilate about the same; however, ventilation in the lowermost (posterior) lung is greater than that of the uppermost (anterior) lung. In a lateral position, the dependent lung is best ventilated.[3]

Table 23-2 Factors Affecting Alveolar–Capillary Gas Exchange

Factors Affecting Gas Exchange	Examples
Surface area available for diffusion	Removal of a lung or diseases, such as emphysema and chronic bronchitis, which destroy lung tissue or cause mismatching of ventilation and perfusion
Thickness of the alveolar–capillary membrane	Conditions, such as pneumonia, interstitial lung disease, and pulmonary edema, which increase membrane thickness
Partial pressure of alveolar gas	Ascent to high altitudes where the partial pressure of oxygen is reduced. In the opposite direction, increasing the partial pressure of a gas in the inspired air (eg, oxygen therapy) increases the gradient for diffusion.
Solubility and molecular weight of the gas	Carbon dioxide, which is more soluble in the cell membranes, diffuses across the alveolar–capillary membrane more rapidly than oxygen

From Porth CM: Pathophysiology: Concepts of Altered Health States, 7th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2005, p 650.

Distribution of Perfusion

As with ventilation, the distribution of pulmonary blood flow is affected by body position and gravity. For a person in the upright position, blood flow is better at the base of the lungs than the apex of the lungs. For a person in a supine position, the blood flow from apex to base is almost uniform, but blood flow in the posterior (dependent) regions of the lung exceeds that of the anterior regions. For a person in the prone position, the same holds true: blood flow in the dependent region (now the anterior chest) exceeds that of the posterior chest.

Considerable inequality of blood flow exists within the human lung (Fig. 23-15). The uneven distribution of blood flow can be explained by the hydrostatic pressure differences in the blood vessels. In zone 1, alveolar pressures exceed pulmonary arterial and pulmonary venous pressures. The capillaries are basically squashed flat by the pressure in the alveoli, and there is no blood flow. In zone 2, pulmonary arterial pressures are greater than alveolar pressures, so some blood flow occurs. Blood flow here is determined by the differences in arterial and alveolar pressures. In zone 3, there is minimal alveolar pressure influence on the pulmonary vasculature, and blood flow is determined in the usual way by the arteriovenous pressure difference.

Matching of Ventilation to Perfusion

Effective pulmonary gas exchange depends on a balance or matching of ventilation to perfusion (Fig. 23-16A). Two factors may interfere with the matching of ventilation to perfusion: dead space and shunt. As previously described in this chapter, dead space refers to areas in the respiratory system that do not participate in gas exchange. The air in the conducting airways (about 150 mL) does not participate in gas exchange and is referred to as *anatomical dead space*. Anatomical dead space increases with intubation. In zone 1 of the lung, the region is ventilated but not perfused, and this is referred to as *alveolar dead space*. Other areas of the lung may also contain alveolar dead space, such as that which occurs with collapsed alveoli from atelectasis or pneumonia. Shunt refers to blood that bypasses, or shunts by, alveoli without picking up oxygen. There are two types of shunts: anatomical and physiological. With an anatomical shunt, blood moves from the right side to the left side of the heart without passing through the lungs. Anatomical shunts occur with congenital heart diseases. With a physiological shunt, blood is shunted past alveoli without picking up sufficient amounts of oxygen.

A ventilation–perfusion imbalance, known as a ventilation–perfusion mismatch, occurs when there is

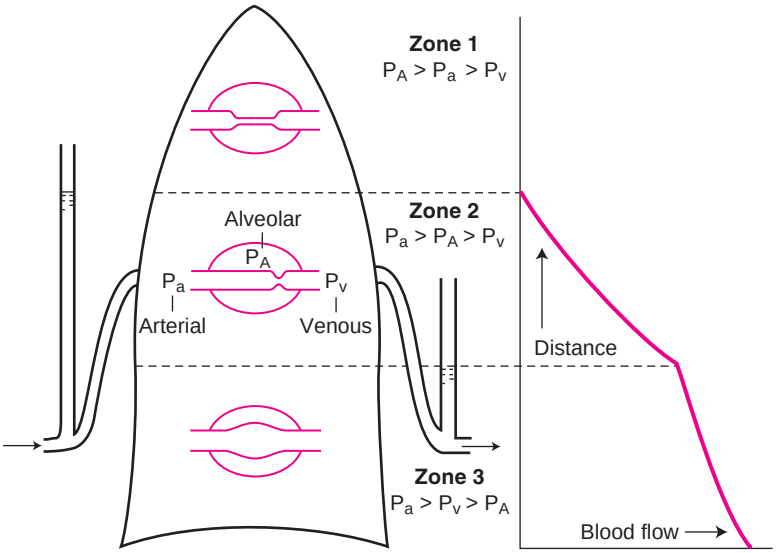

FIGURE 23-15 ▲ Explanation of the uneven distribution of blood flow in the lung, based on the pressures affecting the capillaries. P_A, alveolar pressure; Pa, arterial pressure; Pv, venous pressure. (From West JB: Respiratory Physiology: The Essentials, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2008, p 44.)

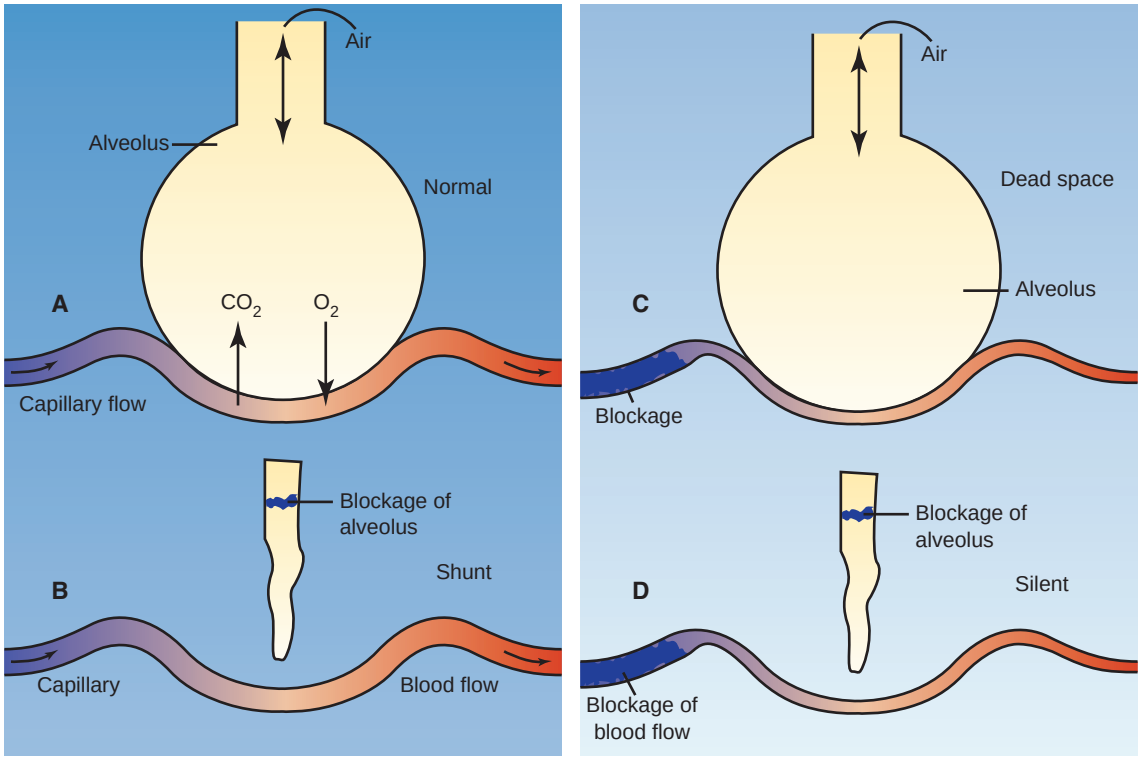

FIGURE 23-16 ▲ A schematic representation of various ventilation–perfusion situations. **A:** Normal unit with normal ventilation and normal perfusion. **B:** Low-ventilation/perfusion ratio—alveoli with no ventilation but normal perfusion. **C:** High-ventilation/perfusion ratio—alveoli with normal ventilation but no perfusion. **D:** Silent unit—alveoli with no ventilation and no perfusion. CO_2, carbon dioxide; O_2, oxygen. (From Smeltzer SC, Bare BG: Brunner and Suddarth's Textbook of Medical Surgical Nursing, 12th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 492.)

inadequate ventilation, inadequate perfusion, or both. Three types of ventilation–perfusion imbalances may occur:

- *Physiological shunt* (low ventilation/perfusion ratio). When perfusion exceeds ventilation, the ratio is low, and a shunt is present. A shunt means that blood passes by alveoli without gas exchange occurring. A low ventilation–perfusion ratio is seen with pneumonia, atelectasis, tumor, or a mucous plug (see Fig. 23-16B).
- *Alveolar dead space* (high ventilation/perfusion ratio). When ventilation exceeds perfusion, the ratio is high and an alveolar dead space develops. The alveolus has inadequate perfusion available, and gas exchange cannot occur. A high ventilation/perfusion ratio is seen with a pulmonary embolus, pulmonary infarction, cardiogenic shock, and mechanical ventilation associated with high tidal volumes (see Fig. 23-16C).
- *Silent unit*. When both ventilation and perfusion are decreased, a silent unit occurs. A silent unit is seen with pneumothorax and severe ARDS (see Fig. 23-16D).

Gas Transport

Oxygen

Oxygen is carried in the blood in two forms: dissolved and attached to hemoglobin. The partial pressure of oxygen in arterial blood (PaO_2) represents the level of dissolved oxygen in plasma. Less than 3% of all oxygen is carried in this form, whereas 97% of oxygen carried in the blood is bound to hemoglobin and is called *oxyhemoglobin*. Each gram of hemoglobin carries approximately 1.34 mL of oxygen when it is completely saturated. As oxygen diffuses across the alveolar–capillary membrane, it combines with hemoglobin in the red blood cell where it forms a reversible bond. Oxyhemoglobin is transported in arterial blood and made available to the tissues for use in cell metabolism. The saturation of oxygen in arterial blood (SaO_2) represents the percentage of hemoglobin molecules that are bound with oxygen.

The hemoglobin molecule is said to be fully saturated when oxygen is bound to all four of its oxygen-binding sites and only partially saturated when less than four molecules are bound to it. The term *affinity* is used to refer to the capacity of hemoglobin to combine with oxygen. When the affinity is high, hemoglobin binds readily with oxygen at the alveolar–capillary membrane. But, at the tissue level, hemoglobin does not readily release oxygen. When the affinity is low, hemoglobin does not bind readily with oxygen at the alveolar–capillary membrane. Instead, when affinity is low, hemoglobin releases oxygen more readily at the tissue level. The affinity of hemoglobin and oxygen is described by the oxyhemoglobin dissociation curve (Fig. 23-17).

The oxyhemoglobin dissociation curve is a graphic depiction of the relationship between oxyhemoglobin saturation (the percentage of hemoglobin combined with oxygen or the SaO_2) and the arterial oxygen tension (PaO_2) to which it is exposed. The initial part of the curve is very steep and then flattens at the top. The flat portion represents the binding of

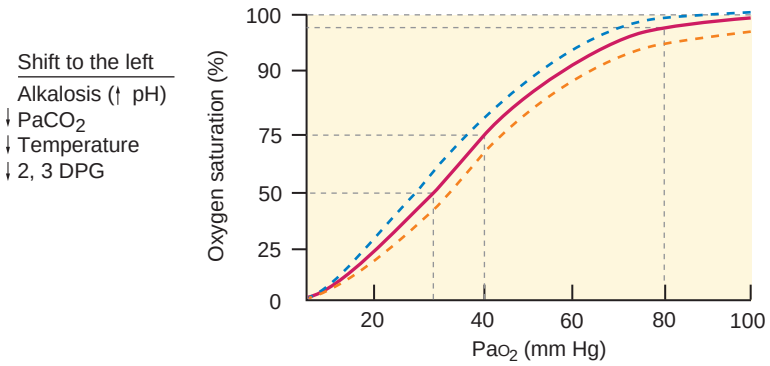

FIGURE 23-17 ▲ Oxyhemoglobin dissociation curve. The shift to the left indicates a higher oxygen saturation at any given arterial oxygen tension (PaO_2), an increased affinity of hemoglobin for oxygen, and a decreased release of oxygen to the tissues. A shift to the right indicates a lower oxygen saturation at any given PaO_2, a decreased affinity of hemoglobin for oxygen, and an increased release of oxygen to the tissues.

oxygen to hemoglobin in the lungs. The steep portion of the curve (between 40 and 60 mm Hg) represents the release of oxygen from the hemoglobin that occurs in the capillaries. At an arterial oxygen tension (PaO_2) of 40 mm Hg, hemoglobin molecules are still about 70% to 75% saturated with oxygen. This provides a reserve supply of oxygen that can be given to the tissues in cases of emergency or strenuous exercise.

Hemoglobin's affinity for oxygen is influenced by pH, carbon dioxide concentration, temperature, and 2,3-diphosphoglycerate (2,3-DPG). 2,3-DPG is a metabolically important phosphate compound found in the blood in different combinations under different metabolic conditions.[10] Hemoglobin binds more readily with oxygen under conditions of increased pH, decreased carbon dioxide, decreased body temperature, and decreased 2,3-DPG. This is represented on the oxyhemoglobin dissociation curve as a shift to the left (see Fig. 23-17). With a shift to the left, there is higher oxygen saturation for any given PaO_2, increased affinity of hemoglobin for oxygen, and decreased release of oxygen to tissues. Hemoglobin more readily releases oxygen under conditions of decreased pH, increased carbon dioxide, increased body temperature, and increased 2,3-DPG. This relationship is represented on the curve by a shift to the right (see Fig. 23-17). With a shift to the right, there is lower oxygen saturation for any given PaO_2, decreased affinity of hemoglobin for oxygen, and increased release of oxygen to the tissues.

Carbon Dioxide

Carbon dioxide is carried in the blood in three forms: as dissolved carbon dioxide (10%), attached to hemoglobin (30%), and as bicarbonate (60%).[4] Carbon dioxide is formed as a metabolic byproduct. It diffuses out of the cell and into the capillaries. Most of it diffuses into red blood cells, where it attaches to hemoglobin, and most of that is released from the red blood cell as bicarbonate. In the pulmonary capillaries, the concentration of carbon dioxide is greater in the capillaries than in the alveoli, so the carbon dioxide moves down this concentration gradient and diffuses into the alveoli and is exhaled. An increased rate of exhalation leads to greater elimination of carbon dioxide. The transport of carbon dioxide has a profound effect on the acid–base status of the blood and the body as a whole. The lung excretes more than 10,000 mEq of carbonic acid per day, compared with the kidney, which excretes less than 100 mEq of fixed acids per day.[11] Therefore, by altering alveolar ventilation (and subsequently, the elimination of carbon dioxide), the body is able to exert precise control over its acid–base balance.

Regulation of Respiration

Breathing is controlled by both the nervous system and chemical regulation. Nervous system regulation is achieved by the respiratory centers, which are located in the medulla and pons (ie, the brainstem). Chemical regulation of breathing occurs through chemoreceptors, which respond to blood pH and the levels of oxygen and carbon dioxide in the blood. Chemoreceptors are located near the respiratory center in the medulla, in the carotid arteries, and in the aortic arch.

Brainstem Centers and the Respiratory Cycle

Unlike the heart, the lungs have no spontaneous rhythm. Ventilation depends on rhythmic operation of brainstem centers and intact pathways to the respiratory muscles. There are two centers in the medulla: a center that stimulates inspiration by diaphragmatic contraction (by way of phrenic nerves) and another center that innervates both inspiratory and expiratory intercostal and accessory muscles (Fig. 23-18). The pons also contains two centers involved in controlling respiration: the pneumotaxic center and the apneustic center. The apneustic center produces sustained inspiration if stimulated. Voluntary control and involuntary control are further established by descending fibers from other brain centers. Neural control of ventilation is illustrated in Figure 23-18. In breathing at rest, the following sequence is thought to occur. The neurons innervating the inspiratory muscles fire bursts of impulses to these muscles, leading to inspiration. These neurons also stimulate the pneumotaxic center. This center, in turn, fires inhibitory impulses back to the inspiratory neurons, causing a halt in inspiration. Expiration follows passively. After expiration, the inspiratory neurons are again stimulated to fire automatically. During exercise or other occasions when more vigorous ventilation occurs, the expiratory neurons of the medulla are postulated to participate in this sequence, causing active exhalation.

Chemoreceptors

Chemoreceptors are like radar screens planted in the body to monitor blood levels of carbon dioxide and oxygen. Signals from these receptors are transmitted to the respiratory center, and ventilation is adjusted to maintain these gases in a normal range. There are two types of chemoreceptors: central chemoreceptors and peripheral chemoreceptors.

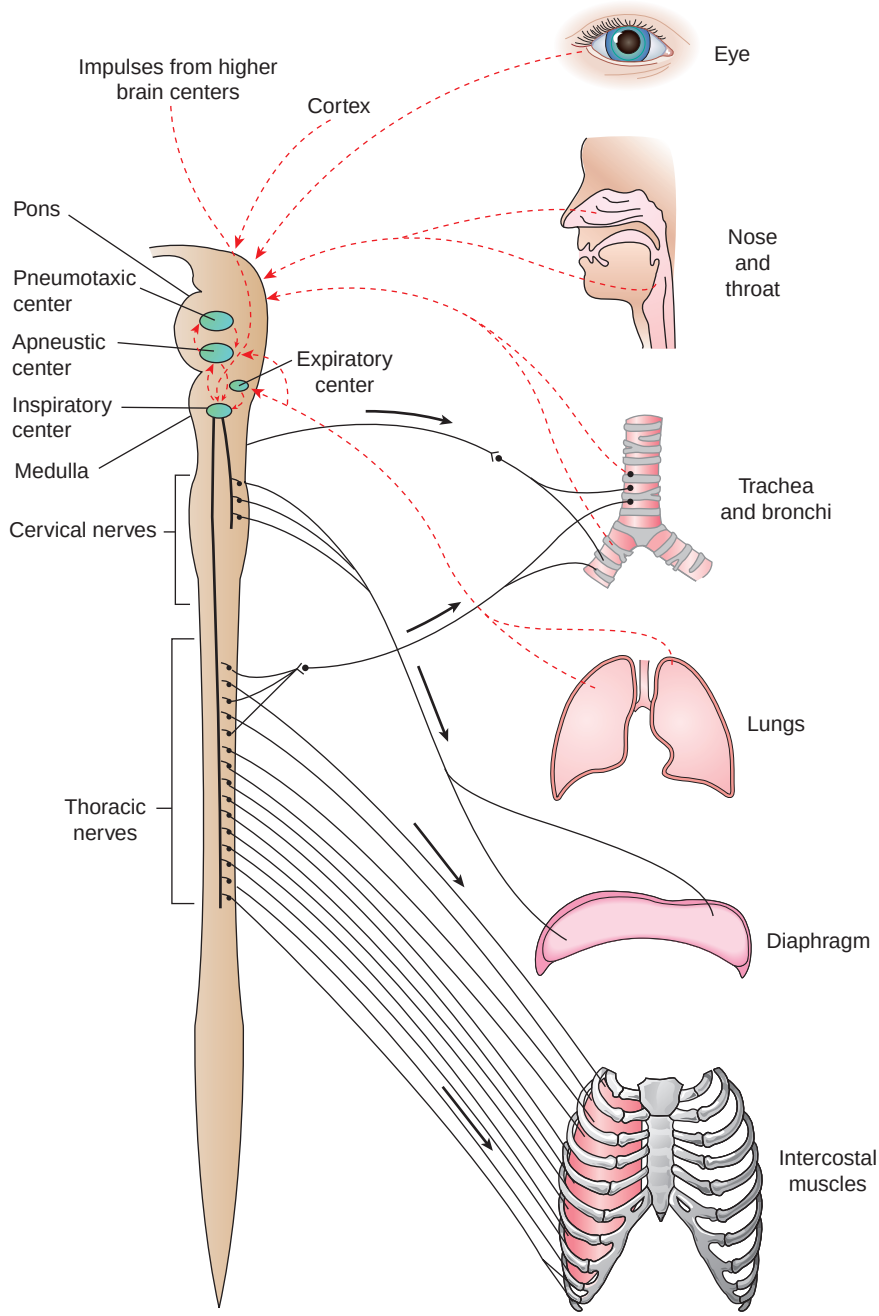

FIGURE 23-18 ▲ Schematic representation of activity in the respiratory center. Impulses traveling over afferent neurons activate central neurons, which activate efferent neurons that supply the muscles of respiration. Respiratory movements can be altered by a variety of stimuli.

Central chemoreceptors sense changes in carbon dioxide content. They are located near the respiratory center in the medulla and are in close contact with cerebrospinal fluid (CSF). Carbon dioxide freely diffuses across the blood–brain barrier into the CSF. As the level of carbon dioxide in the CSF increases and the pH decreases, the nearby respiratory center is stimulated to increase respirations to "blow off" more carbon dioxide.

Peripheral chemoreceptors are located in the arch of the aorta and in the carotid arteries. These chemoreceptors are sensitive to changes in oxygen content in arterial blood. These receptors exert little control over respirations until the PaO_2 is below 60 mm Hg.[4] When this occurs, the respiratory center is stimulated to increase the rate and depth of respirations to inhale more oxygen.

Lung Receptors

Recall the importance of airway resistance and lung expansion in the respiratory process. Lung and chest wall receptors provide information to the respiratory center on the status of these processes. There are three types of lung receptors: stretch, irritant, and juxtacapillary receptors. Stretch receptors, located in the smooth muscle layers of the conducting airways, respond to pressure changes in the airways. When the lungs are fully inflated, they inhibit further inspiration and trigger exhalation. These receptors are important because they establish respiratory patterns by adjusting respiratory rate and tidal volume in an attempt to respond to changes in airway resistance and lung compliance.

Irritant receptors, located in the airways, are stimulated by inhaled dust, smoke, chemicals, and cold air. Stimulation of these receptors triggers airway constriction and more rapid, shallow breathing. It is possible that these receptors play a key role in the bronchoconstriction that occurs with asthma.[4]

Juxtacapillary receptors are located in the alveolar wall close to the pulmonary capillaries. These receptors sense lung congestion. It may be stimulation of these receptors that produces the rapid, shallow breathing that is characteristic in patients with pneumonia and pulmonary edema.

▲ Clinical Applicability Challenges

SHORT ANSWER QUESTIONS

1. Discuss the process of inspiration and exhalation.
2. What are the four factors that affect the alveolar-capillary gas exchange?
3. Discuss the oxyhemoglobin saturation curve. What does a shift to the left indicate? What does a shift to the right indicate? Identify the four factors that are responsible for the shift in the oxyhemoglobin saturation curve.

24 Patient Assessment: Respiratory System

Patricia Gonce Morton and Kenneth J. Rempher

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Describe the components of the history for respiratory assessment.
2. Explain the use of inspection, palpation, percussion, and auscultation for respiratory assessment.
3. Discuss the purpose of pulse oximetry and end-tidal carbon dioxide monitoring.
4. Explain the components of an arterial blood gas and the normal values for each component.
5. Compare and contrast the causes, signs, and symptoms of respiratory acidosis, respiratory alkalosis, metabolic acidosis, and metabolic alkalosis.
6. Analyze examples of an arterial blood gas result.
7. Describe the purpose of mixed venous oxygen saturation monitoring.
8. Discuss the purpose of respiratory diagnostic studies and associated nursing implications.

Nurses contribute significantly to the care of patients with respiratory problems by taking a comprehensive history and performing a thorough physical examination. This information allows the nurse to establish a baseline level of assessment of the patient's status and provides a framework for detecting rapid changes in the patient's condition. Assessments are valuable if made before, during, and after interventions that are likely to alter or improve respiratory status. Because the nurse is with the patient more consistently than most other health care professionals, it is often the nurse who detects the patient's changing condition. High-quality assessments often uncover complications or changes that precede the information provided by other diagnostic tests.

▲ History

A thorough review of the patient's clinical history is an essential component of the overall physical assessment process. A properly conducted review of the patient's clinical history should serve as a guide for the remainder of the physical examination. In many cases, obtaining a clinical history is the first step in developing a relationship with the patient. Patients often suppress information or underreport personal experiences that may be essential in identifying the underlying cause of illness. As a result, constant subjective evaluation of the patient's report should also serve to guide the clinical history. The interviewer must conduct the examination in such a way that the patient feels as comfortable as possible.

The clinical history of the respiratory system is divided into six components: (1) chief complaint, (2) history of present illness, (3) past health history, (4) family history, (5) personal and social history, and (6) review of systems (Box 24-1). The patient's history starts with the chief complaint and information about the present illness. Often, if the patient is very ill, a relative or friend provides more information. Data about the present illness and any symptoms are thoroughly investigated using the mnemonic NOPQRST: normal (N), onset (O), precipitating and palliative factors (P), quality and quantity (Q), region and radiation (R), severity (S), and time (T), as described in Box 17-1. Principal symptoms that should be investigated in more detail commonly include dyspnea, chest pain, sputum production, and cough. An overview of the patient's past medical history and family's respiratory history, as well as personal and social history, may uncover elements that are contributing to the patient's current health problem. Because smoking has a significant impact on the patient's respiratory health, the patient's use of tobacco should be quantified by amount and how long the patient has smoked. Box 24-2 demonstrates the process for calculating this quantity, which is known as pack years.

Dyspnea

Dyspnea is commonly seen in patients with pulmonary or cardiac compromise. Information about the onset of symptoms

BOX 24–1 HEALTH HISTORY for Respiratory Assessment

Chief Complaint
- Patient's description of the problem

History of the Present Illness
- Complete analysis of the following signs and symptoms (using the NOPQRST format; see Box 17-1, p. 207).
- Dyspnea, dyspnea on exertion
- Shortness of breath
- Chest pain
- Cough
- Sputum production
- Hemoptysis
- Wheezing
- Orthopnea
- Clubbing
- Fatigue
- Cyanosis

Past Health History
- Relevant childhood illnesses and immunizations: whooping cough (pertussis), mumps, cystic fibrosis
- Past acute and chronic medical problems, including treatments and hospitalizations: streptococcal infection of the throat, upper respiratory infections, tonsillitis, bronchitis, sinus infection, emphysema, asthma, bronchiectasis, tuberculosis, cancer, pulmonary hypertension, heart failure, musculoskeletal and neurological diseases affecting the respiratory system
- Risk factors: age, obesity, smoking, environmental exposure such as asbestos, coal dust, chemicals, poison gas/vapors, dust, allergens
- Past surgeries: tonsillectomy, thoracic surgery, coronary artery bypass surgery, cardiac valve surgery, aortic aneurysm surgery, trauma surgery, tracheostomy
- Past diagnostic tests and interventions: tuberculin skin test, allergy tests, pulmonary function tests, chest radiograph, computed tomography scan, magnetic resonance imaging, bronchoscopy, cardiac stress test, ventilation–perfusion scanning, pulmonary angiography, thoracentesis, sputum culture
- Medications: use of oxygen, bronchodilators, antitussives, expectorants, mucolytics, antiinfectives, antihistamines, methylxanthine drugs, antiinflammatory drugs
- Allergies and reactions
- Transfusions

Family History
- Health status or cause of death of parents and siblings: tuberculosis, cystic fibrosis, emphysema, asthma, malignancy

Personal and Social History
- Tobacco, alcohol, and substance use
- Family composition
- Occupation and work environment: asbestos, chemical, and coal dust exposure
- Living environment: exposure to allergens and toxic substances, type of heating and ventilation system
- Diet
- Sleep patterns: use of pillows
- Exercise
- Cultural beliefs
- Spiritual, religious beliefs
- Coping patterns and social support systems
- Leisure activities
- Sexual activity
- Recent travel

Review of Systems
- HEENT: strep throat, sinus infections, ear infection, deviated nasal septum, tonsillitis
- Cardiac: heart failure, dysrhythmias, coronary artery disease, valvular disease, hypertension
- Gastrointestinal: weight loss, nausea, vomiting
- Neuromuscular: Guillain-Barré syndrome, myasthenia gravis, amyotrophic lateral sclerosis, weakness
- Musculoskeletal: scoliosis, kyphosis

gives clues as to the source and duration of the problem. The nurse asks questions such as the following:

- Does the dyspnea occur when the patient is lying flat (therefore requiring the patient to sit up, as is seen more commonly in heart failure)?
- Does the dyspnea awaken the patient at night (paroxysmal nocturnal dyspnea)?
- Does the dyspnea occur only with exertion?

Paroxysmal nocturnal dyspnea and orthopnea often signify heart failure but may occur in a variety of pulmonary disorders. Description of the entire course of dyspnea, including exacerbating factors, length of episodes, and any relief measures attempted, is warranted.

BOX 24-2 Steps for Calculating Pack Years

Pack years = (Number of packs smoked per day) × (Number of years smoking)
Example: The patient reports during the physical assessment that he has smoked two packs per day for 15 years.
(2 packs per day) × (15 years) = 30 pack years

Chest Pain

Dyspnea that occurs with primary lung disease is associated with an anterior chest discomfort that must be distinguished from angina. First, the nurse determines whether the patient experiences more than one type of pain. For each type of chest pain, the nurse asks the patient to describe the pain using the mnemonic NOPQRST. The detailed information obtained from using the mnemonic is key to determining the cause of the pain.

Sputum Production

A pulmonary illness often results in the production (or a change in the production) of sputum. The nurse questions the patient about the amount (eg, tablespoonful, one-half cup) and color of the sputum produced in 24 hours. The color of the sputum provides important information about infection. An increase in either the color or the amount of sputum often means infection. Yellow, green, or brown sputum typically signifies bacterial infection; clear or white sputum may signify absence of bacterial infection. The color comes from

white blood cells in the sputum. However, a yellow color may occur if there are many eosinophils in the sputum, thereby signifying allergy rather than infection. Rust-colored sputum (yellow sputum mixed with blood) may signify tuberculosis. Mucoid, viscid, or blood-streaked sputum is often a sign of a viral infection. Persistent slightly blood-streaked sputum is present in patients with carcinoma. Large amounts of clotted blood are present in the sputum of patients who have suffered a pulmonary infarction.

Occasionally, coughing does not yield sputum. Sometimes, the patient with an infection is unable to cough up sputum. For example, a decrease in sputum production associated with worsening hypoxemia may signify bronchiolitis. A cough without sputum production usually means that the problem is not bacterial in origin.

It is important to know whether the sputum comes from the nose, the chest, or sinus postnasal drainage. Chronic sputum production may indicate chronic obstructive pulmonary disease (COPD).

Sometimes, the patient is afraid to mention that there has been blood in the sputum; it is essential to ask the patient, family members, and care givers about the presence of blood. The amount of blood should be evaluated. Was it just streaks or specks, blood-colored mucus, or pure blood (bright red or dark)? Through careful questioning, the nurse determines whether the blood is associated with retching and vomiting or sputum production, as it often is in bronchitis and pneumonia, or whether it occurs alone, as is often true with a pulmonary embolus.

Cough

A cough is a frequent respiratory symptom with varying significance. External agents, inflammation of the respiratory mucosa, or pressure on an airway caused by a tumor may stimulate a cough. Specifically, smoking, allergies, heartburn, asthma, and certain medications, including angiotensin-converting enzyme inhibitors and β-blockers, may cause a cough.

▲ Physical Examination

Physical assessment of the respiratory system is a reliable means of gathering essential data and is guided by the information obtained through the history. A thorough physical assessment includes inspection, palpation, percussion, and auscultation.

Inspection

Inspection of the patient involves checking for the presence or absence of several factors (Box 24-3).

Cyanosis refers to a bluish discoloration of the skin or mucous membranes. Cyanosis is notoriously difficult to detect in a patient with anemia. The patient with polycythemia may have cyanosis in the extremities even if oxygen tension is normal. Peripheral cyanosis occurs in the extremities or on the tip of the nose or ears. Even with normal oxygen tensions, peripheral cyanosis may appear if there is diminished blood flow to these areas, particularly if they are cold or in a dependent position. Central cyanosis is apparent on the tongue or lips and usually means the patient has low oxygen tension. Unfortunately, the presence of cyanosis is a late and often ominous sign.

Labored breathing is an important marker of respiratory distress. As part of the inspection, the nurse determines whether the patient is using the accessory muscles of respiration (the scalene and sternocleidomastoid muscles). *Intercostal retractions* (ie, sucking in of the muscles and skin between the ribs during inspiration) usually mean that the patient is making a larger effort at inspiration than normal. The nurse also observes the patient for use of the abdominal muscles during the usually passive expiratory phase.

BOX 24-3 Components of the Inspection Process in the Physical Assessment of the Respiratory System

General
- Mentation
- Anxiety level
- Speech
  - Staccato
  - Coherence
  - Aphasia
  - Articulation
  - Hoarseness
- Skin turgor
- Skin integrity
  - Scars
  - Rash
  - Wounds
- Skin color
  - Pallor
  - Cyanosis
- Weight
  - Obese
  - Malnourished
- Body position
  - Leaning forward
  - Arms elevated

Thorax
- Symmetry of thorax
- Position of sternum
- Anteroposterior diameter less than transverse by at least half
- Rate, pattern, rhythm, and duration of breathing
- Use of accessory muscles
- Synchrony of chest and abdomen movement
- Alignment of spine
- Supernumerary nipples
- Superficial venous patterns

Head and Neck
- Nasal flaring
- Pursed-lip breathing
- Mouth breathing versus nose
- Use of neck and shoulders
- Tracheal position

Extremities
- Clubbing
- Edema
- Peripheral cyanosis

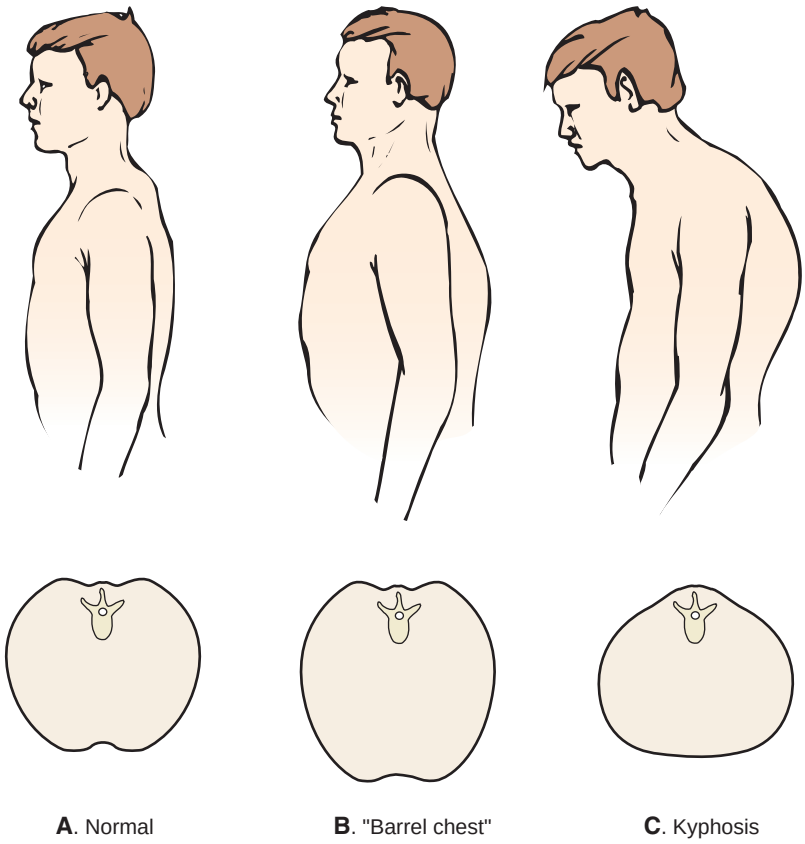

FIGURE 24-1 ▲ Deformities and configurations of the human thorax. **A:** Normal chest. **B:** "Barrel chest," a chest deformity that typically results from emphysema. **C:** Kyphosis, a chest deformity that is most common in older adults.

Staccato speech, in which the patient's speech pattern is frequently interrupted as he or she gulps for air, may accompany labored breathing. Sometimes, the number of words a patient can say before having to gasp for another breath is a good measure of the degree of labored breathing.

The *anterior–posterior diameter of the chest* (ie, the size of the chest from front to back) is also checked (Fig. 24-1). Often, the cause of an increased anterior–posterior diameter is overexpansion of the lungs from obstructive pulmonary disease. Patients with kyphosis (curvature of the spine) may also have an increase in anterior–posterior diameter.

Chest deformities and scars are important in helping to determine the reason for respiratory distress. A chest deformity, such as kyphoscoliosis or flail chest from trauma, may indicate why the patient has respiratory distress. A scar may signify recent or old injuries to the chest and provides clues to possible sources of distress. For example, evidence of recent trauma to the chest, such as a stabbing or compression injuries from an automobile collision, could be responsible for the present distress.

Observation of the *patient's posture* is necessary. Patients with obstructive pulmonary disease often sit and prop themselves up on outstretched arms or lean forward with their elbows on a table in an effort to elevate their clavicles. This posture gives the patient a slightly greater ability to expand the chest.

It is important to observe the *position of the trachea*. The nurse determines whether the trachea is in the midline as it should be or if it is deviated off to one side. Pleural effusion, hemothorax, pneumothorax, or a tension pneumothorax can deviate the trachea away from the affected side (toward the opposite side). However, atelectasis, fibrosis, and phrenic nerve paralysis often pull the trachea toward the affected side.

The *respiratory rate* is an important parameter to follow. It should be counted over at least a 15-second period for stable patients and over a full minute for critically ill patients. The patient's rate must be compared with his or her usual rate. Breathing 24 to 26 times a minute may be normal in one patient but abnormal in another. The patient's family or friends may provide additional important information about the patient's usual rate of breathing.

The *respiratory effort* is often as meaningful as the respiratory rate. For instance, if a patient is breathing 40 times per minute, the nurse might think a severe respiratory problem is the source of patient distress. However, the rate may be the result of Kussmaul respirations caused by diabetic acidosis. If a patient's respiration is shallow at a rate of 40 breaths/min (tachypnea), the indication may be severe respiratory distress from a primary pulmonary problem. Deep, rapid respirations, known as hyperventilation, may indicate compensation for acidosis. The pattern of respirations also should be noted because it may correlate with various disease processes. Table 24-1 provides a description of respiratory patterns and their clinical implications.

The *duration of inspiration versus the duration of expiration* helps determine the presence of obstructive lung disease. In patients with any of the obstructive lung diseases, expiration is more than one and a half times as long as inspiration.

Observation of *thoracic expansion* is an integral part of examining a patient. Normally, chest expansion of about 3 inches occurs from maximal expiration to maximal inspiration. Motion of the abdomen in breathing efforts (more likely to be normal in men than women) may be

Table 24-1 Respiration Patterns

Type	Description	Pattern	Clinical Indication
Normal	12–20 breaths/min and regular		Normal breathing pattern
Tachypnea	More than 24 breaths/min and shallow		May be a normal response to fever, anxiety, or exercise Can occur with respiratory insufficiency, alkalosis, pneumonia, or pleurisy
Bradypnea	Less than 10 breaths/min and regular		May be normal in well-conditioned athletes Can occur with medication-induced depression of the respiratory center, diabetic coma, neurologic damage
Hyperventilation	Increased rate and increased depth		Usually occurs with extreme exercise, fear, or anxiety. Causes of hyperventilation include disorders of the central nervous system, an overdose of the drug salicylate, or severe anxiety.
Kussmaul	Rapid, deep, labored		A type of hyperventilation associated with diabetic ketoacidosis
Hypoventilation	Decreased rate, decreased depth, irregular pattern		Usually associated with overdose of narcotics or anesthetics
Cheyne-Stokes respiration	Regular pattern characterized by alternating periods of deep, rapid breathing followed by periods of apnea		May result from severe congestive heart failure, drug overdose, increased intracranial pressure, or renal failure May be noted in elderly persons during sleep, not related to any disease process
Biot's respiration	Irregular pattern characterized by varying depth and rate of respirations followed by periods of apnea		May be seen with meningitis or severe brain damage
Ataxic	Significant disorganization with irregular and varying depths of respiration		A more extreme expression of Biot's respirations indicating respiratory compromise
Air trapping	Increasing difficulty in getting breath out		In chronic obstructive pulmonary disease, air is trapped in the lungs during forced expiration

observed. Ankylosing spondylitis, a chronic condition resulting in painful, progressive inflammatory arthritis that typically affects the spine and sacroiliac joints, may be present. General chest expansion is limited in this condition. During the inspection, the nurse compares the expansion of the upper chest with that of the lower chest. The nurse also observes the movement of the diaphragm to determine whether the patient with obstructive pulmonary disease is concentrating on expanding the lower chest and using the diaphragm properly. Expansion of one side of the chest versus the other side is important to note because atelectasis, especially that caused by a plug of mucus, may cause unilaterally diminished chest expansion because the air cannot move equally through the pulmonary bed. Abnormal chest expansion may also occur with flail chest, in which the chest collapses instead of expanding during inspiration. Flail chest may result from broken or fractured ribs that cannot maintain the integrity of the chest wall during respiration. The nurse also notes whether the abdomen and chest rise and fall together as they should, or if the effort is not coordinated, is there symmetry of respiratory effort? Asynchronous respiratory effort decreases the quality of respiration at the cost of increased work of breathing and often precedes the need for ventilatory support.

A pulmonary embolus, pneumonia, pleural effusion, pneumothorax, or any problem associated with chest pain, such as fractured ribs, may lead to diminished chest expansion. An endotracheal or nasotracheal tube positioned beyond the trachea into one of the mainstem bronchi (usually the right) is a serious cause of diminished expansion of one side of the chest. If the tube slips into the right mainstem bronchus, the left lung is not expanded, and the patient may experience atelectasis on the left side and hypoxemia.

FIGURE 24-2 ▲ In clubbing, the angle between the nail plate and the proximal nail fold increases to 180 degrees or more. Clubbing of the fingers is seen in patients with respiratory and cardiovascular disease. (Photo from Bickley LS: Bates' Guide to Physical Examination and History Taking, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 193. Line art from Weber J, Kelley J: Health Assessment in Nursing, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 203.)

Examination of the *patient's extremities* may provide additional information about the patient's respiratory status. Clubbing of the fingers is an enlargement of the distal portion of the finger and is seen in many patients with respiratory and cardiovascular diseases (Fig. 24-2). Although the exact cause is not known, chronic hypoxia is a contributing factor. It is also important to assess the extremities for edema and peripheral cyanosis.

Palpation

Chest palpation may indicate lung or chest abnormalities. To palpate the chest, the nurse places his or her hand flat against the patient's chest. When the patient speaks, sounds are generated by the larynx, and these sounds travel along the bronchial tree, resulting in a resonant motion of the chest wall. *Tactile fremitus* is the ability to feel the sound on the chest wall. Tactile fremitus is more easily palpated over the large bronchi and is more difficult to palpate over the distant lung fields.

To assess tactile fremitus, the nurse asks the patient to say "ninety-nine" while moving his or her hands over the posterior surfaces of the chest wall (Fig. 24-3). Tactile fremitus should be symmetrical. Tactile fremitus may be diminished or absent if there is an increase in air per unit volume of lung because air impedes the transmission of sound. For example, patients with emphysema have little or no tactile fremitus on physical examination. Tactile fremitus is slightly increased by the presence of solid substances, such as the consolidation of a lung from pneumonia. Other respiratory conditions causing an alteration in tactile fremitus are listed in Table 24-2.

Palpation is also used to assess for subcutaneous emphysema, a condition in which air "leaks" out of the alveolus and moves through the subcutaneous tissue. By moving the fingers in a gentle rolling motion across the chest and neck, it is possible to feel the pockets of air underneath the skin. Feeling subcutaneous emphysema is often likened to the "crunch" of Rice Krispies under the skin. Subcutaneous

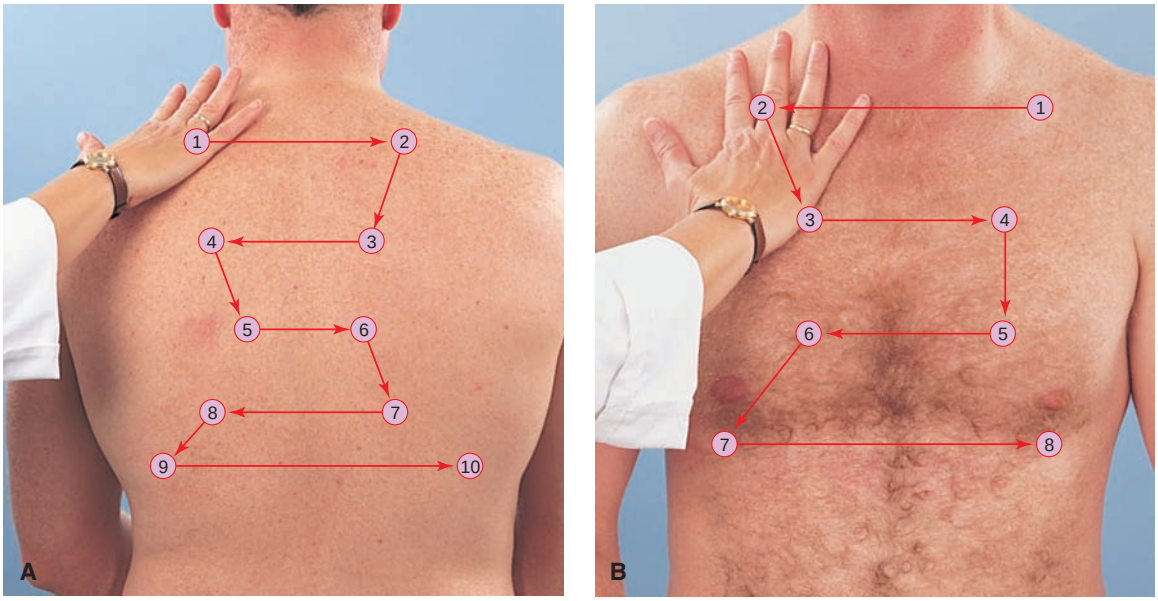

FIGURE 24-3 ▲ Palpating the thorax is performed in a sequential fashion, starting near the neck and moving systematically downward. **A:** Posterior thorax. **B:** Anterior thorax. (Adapted from Weber J, Kelley J: Health Assessment in Nursing, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2007, p 321.)

Table 24-2 Physical Findings in Selected Chest Disorders

Condition	Percussion Note	Trachea	Breath Sounds	Adventitious Sounds	Tactile Fremitus and Transmitted Voice Sounds
Normal The tracheobronchial tree and alveoli are clear; pleurae are thin and close together; mobility of the chest wall is unimpaired.	**Resonant**	Midline	Vesicular, except perhaps bronchovesicular and bronchial sounds over the large bronchi and trachea, respectively	None, except perhaps a few transient inspiratory crackles at the bases of the lungs	Normal
Chronic Bronchitis The bronchi are chronically inflamed and a productive cough is present. Airway obstruction may develop.	**Resonant**	Midline	Vesicular (normal)	None; or scattered coarse *crackles* in early inspiration and perhaps expiration; or *wheezes* or *rhonchi*	Normal
Left-Sided Heart Failure *(Early)* Increased pressure in the pulmonary veins causes congestion and interstitial edema (around the alveoli); bronchial mucosa may become edematous.	**Resonant**	Midline	Vesicular	*Late inspiratory crackles* in the dependent portions of the lungs; possibly *wheezes*	Normal
Consolidation Alveoli fill with fluid or blood cells, as in pneumonia, pulmonary edema, or pulmonary hemorrhage.	**Dull** over the airless area	Midline	*Bronchial* over the involved area	*Late inspiratory crackles* over the involved area	*Increased* over the involved area, with *bronchophony, egophony,* and *whispered pectoriloquy*
Atelectasis *(Lobar Obstruction)* When a plug in a mainstem bronchus (as from mucus or a foreign object) obstructs air flow, affected lung tissue collapses into an airless state.	**Dull** over the airless area	May be *shifted toward involved side*	*Usually absent* when bronchial plug persists. Exceptions include right upper lobe atelectasis, where adjacent tracheal sounds may be transmitted.	None	*Usually absent* when the bronchial plug persists. In exceptions (eg, right upper lobe atelectasis) may be increased
Pleural Effusion Fluid accumulates in the pleural space, separates air-filled lung from the chest wall, blocking the transmission of sound.	**Dull** to flat over the fluid	*Shifted toward opposite side* in a large effusion	*Decreased to absent,* but bronchial breath sounds may be heard near top of large effusion.	None, except a *possible pleural* rub	*Decreased to absent, but may be increased* toward the top of a large effusion

(continued on page 492)

Table 24-2 Physical Findings in Selected Chest Disorders (continued)

Condition	Percussion Note	Trachea	Breath Sounds	Adventitious Sounds	Tactile Fremitus and Transmitted Voice Sounds
Pneumothorax When air leaks into the pleural space, usually unilaterally, the lung recoils from the chest wall. Pleural air blocks transmission of sound.	**Hyperresonant** or tympanitic over the pleural air	*Shifted toward opposite side* if much air	*Decreased to absent* over the pleural air	None, except a *possible pleural rub*	*Decreased to absent* over the pleural air
Chronic Obstructive Pulmonary Disease Slowly progressive disorder in which the distal air spaces enlarge and lungs become hyperinflated. Chronic bronchitis is often associated.	Diffusely **hyperresonant**	Midline	Decreased to absent	None, or the crackles, wheezes, and rhonchi of associated chronic bronchitis	Decreased
Asthma Widespread narrowing of the tracheobronchial tree diminishes air flow to a fluctuating degree. During attacks, air flow decreases further, and lungs hyperinflate.	**Resonant** to diffusely **hyperresonant**	Midline	Often obscured by wheezes	Wheezes, possibly crackles	Decreased

The black boxes in this table suggest a framework for clinical assessment. Start with the three boxes under Percussion Note: resonant, dull, and hyperresonant. Then move from each of these to other boxes that emphasize some of the key differences among various conditions. The changes described vary with the extent and severity of the disorder. Abnormalities deep in the chest usually produce fewer signs than superficial ones, and may cause no signs at all. Use the table for the direction of typical changes, not for absolute distinctions.

From Bickley LS: Bates' Guide to Physical Examination and History Taking, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, pp 320–321.

emphysema may result from a pneumothorax, small pockets of alveoli that have burst with increased pulmonary pressure, or the use of positive end-expiratory pressure. In severe cases, the subcutaneous emphysema may spread into the lower thorax, arms, and face.

Evaluation of thoracic expansion during respiration also requires palpation (Fig. 24-4). To perform this procedure, the nurse stands behind the patient, identifies the level of the 10th rib, and places his or her thumbs along the spine using the bony processes as a guide, letting the palms come in light contact with the posterolateral surface. The nurse asks the patient to breathe normally and then deeply, both times watching as the thumbs diverge. Expansion of the chest wall should be symmetrical. Asymmetrical expansion may be indicative of a collapsed lung or unilateral disease. Retractions may be a sign of obstruction to inspiration and require immediate attention.

Palpation of the patient's trachea is an important element in the physical assessment of the respiratory system. To palpate the trachea to evaluate the midline position, the nurse positions his or her index finger in the suprasternal notch, feeling each side of the notch and palpating the tracheal rings (Fig. 24-5). The trachea should be in the midline position directly above the suprasternal notch.

Percussion

Percussion of the chest results in slight motion of the chest wall and underlying structures, causing audible and tactile vibrations. To percuss a patient's chest, the nurse presses one finger from the nondominant hand flat against the chest and uses a fingertip from the dominant hand to strike the knuckle pressed against the chest (Fig. 24-6). Normally, the chest has a resonant or hollow percussion note. In diseases in which there is increased air in the chest or lungs, such as pneumothorax and emphysema, there can be hyperresonant percussion notes. However, these loud, low-pitched sounds are sometimes difficult to detect.

More important is a flat percussion note (eg, the sound that is heard when percussing over a part of the body that contains no air). A flat percussion note is a soft, high-pitched sound that is more easily distinguished by noting the change in sound when one moves from percussing an area with air to an area with no

FIGURE 24-4 ▲ Palpating chest expansion. The thumbs are positioned at the level of the 10th rib. (From Weber J, Kelley J: Health Assessment in Nursing, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 315.)

air. It is more likely to be heard if a large pleural effusion is present in the lung beneath the examining hand. A dull percussion note is medium in intensity and pitch. It is heard if atelectasis or consolidation resulting from pneumonia, pulmonary edema, or pulmonary hemorrhage is present. A tympanic drum-like sound is a high-pitched noise heard if asthma or a large pneumothorax

FIGURE 24-5 ▲ Palpating the trachea. The trachea should be midline, above the suprasternal notch. (Photograph B. Proud. From Weber J, Kelley J: Health Assessment in Nursing, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 220.)

is present. See Table 24-2 for a description of percussion sounds associated with various respiratory pathologies.

Auscultation

In chest auscultation, the diaphragm of the stethoscope is pressed firmly against the chest wall. The sequence for auscultating the posterior and anterior thorax is given in Figure 24-7. The nurse listens to the intensity or loudness of breath sounds. Normally, there is a fourfold increase in loudness of breath sounds when a patient takes a maximal deep breath as opposed to quiet breathing. Sounds are louder in the upper and central chest when listening to the larger bronchus and become quieter as the smaller airways are auscultated. The intensity of the breath sounds may be diminished because of decreased flow through the airways or the presence of substances between the lungs and the stethoscope. In pleural thickening, pleural effusion, pneumothorax, and obesity, an abnormal substance (fibrous tissue, fluid, air, or fat) lies between the stethoscope and the underlying lung; this substance insulates the breath sounds from the stethoscope, making the breath sounds seem less loud. In airway obstruction, such as COPD or atelectasis, the intensity of breath sounds is diminished. With shallow breathing, there is diminished air movement through the airways, and the breath sounds are not as loud. With restricted movement of the thorax or diaphragm, there are diminished breath sounds in the restricted areas.

In general, four types of sounds are heard in the normal chest (Table 24-3). *Vesicular breath sounds* are quiet, low-pitched sounds, and the inspiratory phase is longer than the expiratory phase. *Bronchovesicular breath sounds* are medium in pitch, and the inspiratory and expiratory phases are of equal length. *Bronchial breath sounds* are higher pitched and louder compared with vesicular sounds, and the expiratory phase is longer than the inspiratory phase. *Tracheal breath sounds* are loud, high-pitched sounds, and the inspiratory and expiratory phases are about equal in length.[1]

Bronchial breath sounds are heard over the manubrium not only in the normal state but when consolidation is present, as in pneumonia. Bronchial breath sounds are also heard above a pleural effusion in which the normal lung is compressed and sounds are transmitted through the tissue, which is not participating in airflow. Wherever there is bronchial breathing, there also may be two associated changes: E to A changes and whispered pectoriloquy.

An *E to A change* occurs when the patient says "E" and the nurse listening with a stethoscope actually hears an "A" sound rather than an "E" sound. This occurs if consolidation is present. *Egophony* is the term used to describe voice sounds that are distorted.

Whispered pectoriloquy is the presence of loud, clear sounds heard through the stethoscope when the patient whispers. Normally, the whispered voice is heard faintly and indistinctly through the stethoscope. The increased transmission of voice sounds indicates that air in the lungs has been replaced by fluid as a result of pneumonia, pulmonary edema, or hemorrhage.

Adventitious sounds are additional breath sounds heard with auscultation and include discontinuous sounds, continuous

Table 24-3 Characteristics of Breath Sounds

	Duration of Sounds	Intensity of Expiratory Sound	Pitch of Expiratory Sound	Location Where Heard Normally
Vesicular* 	Inspiratory sounds last longer than expiratory ones.	Soft	Relatively low	Over most of both lungs
Bronchovesicular 	Inspiratory and expiratory sounds are about equal.	Intermediate	Intermediate	Often in the first and second interspaces anteriorly and between the scapulae
Bronchial 	Expiratory sounds last longer than inspiratory ones.	Loud	Relatively high	Over manubrium, if heard at all
Tracheal 	Inspiratory and expiratory sounds are about equal.	Very loud	Relatively high	Over the trachea in the neck

*The thickness of the bars indicates intensity; the steeper their incline, the higher the pitch.From Bickley LS: Bates' Guide to Physical Examination and History Taking, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 303.

sounds, and rubs. Discontinuous sounds are brief, nonmusical, intermittent sounds and include fine and coarse *crackles*. (Crackles were formerly known as *rales*.) Fine crackles are soft, high-pitched, very brief popping sounds that occur most commonly during inspiration. Crackles result from fluid in the airways or alveoli, or from the opening of collapsed alveoli. Restrictive pulmonary disease results in crackles during late inspiration, whereas obstructive pulmonary disease results in crackles during early inspiration. Crackles become coarser as the air moves through larger fluid accumulations, as in bronchitis or pneumonia. Crackles that clear with coughing are not associated with significant pulmonary disease. When assessing crackles, the nurse also notes their loudness, pitch, duration, amount, location, and timing in the respiratory cycle.[2]

Continuous adventitious breath sounds are longer in duration than crackles and include wheezes and rhonchi. *Wheezes* are continuous musical sounds that are longer than crackles in duration and persist throughout the respiratory cycle. Wheezes (also known as sibilant wheezes) are continuous, high-pitched adventitious sounds that have a shrill quality. They are caused by the movement of air through a narrowed or partially obstructed airway, such as in asthma, COPD, or bronchitis.

Rhonchi, another type of continuous adventitious breath sound, are deep, low-pitched rumbling noises that are sometimes referred to as sonorous wheezes or gurgles. The presence of rhonchi indicates the presence of secretions in the large airways.[1] Conditions such as bronchitis cause sonorous wheezing. These sounds may clear somewhat with coughing.

A *friction rub* is a crackling, grating sound heard more often with inspiration than expiration. The sound of friction results from the visceral and parietal pleurae rubbing against each other. A friction rub can be heard with pleural effusion, pneumothorax, or pleurisy. It is important to distinguish a pleural friction rub from a pericardial friction rub. To determine the origin of the rub, the nurse asks the patient to hold his or her breath while the lungs are auscultated. If the sounds continue while the patient is holding his or her breath, it is most likely a pericardial friction rub; a pleural friction rub stops when breathing stops.

In elderly people, unique anatomical and physiological characteristics manifest in different assessment findings. Box 24-4 shows specific respiratory assessment findings in older patients.

BOX 24-4 CONSIDERATIONS FOR THE OLDER PATIENT

Respiratory Assessment

- Decreased ability to hold breath during examination
- Increased hyperresonance (caused by increased distensibility of the lungs)
- Decreased chest wall expansion
- Decreased use of respiratory muscles
- Increased use of accessory muscles secondary to calcification of rib articulations
- Less subcutaneous tissue
- Possible pronounced dorsal curvature
  - Kyphosis (abnormal convexity of the spine—see Fig. 24-1C, p. 488)
  - Gibbus (severe kyphosis)
- Presence of basilar crackles in the absence of disease (should clear after a few coughs)

▲ Respiratory Monitoring

Pulse Oximetry

Approximately 3% of oxygen is dissolved in the plasma (Box 24-5). The partial pressure of oxygen dissolved in the arterial blood is measured by the PaO_2. The normal PaO_2 is 80 to 100 mm Hg at sea level. The remaining 97% of oxygen is attached to hemoglobin molecules in red blood cells. Each gram of hemoglobin can carry a maximum of 1.34 mL of oxygen. The percentage of saturation of hemoglobin is defined as

BOX 24-5 How Oxygen Is Carried in the Blood

Oxygen dissolved in the plasma measured as PaO_2	0.3 mL/100 mL of blood
Oxygen combined with hemoglobin measured as SaO_2	19.4 mL/100 mL of blood
Total oxygen in blood	19.7 mL/100 mL of blood

the amount of oxygen that hemoglobin is carrying compared with the amount of oxygen that hemoglobin (Hgb) can carry, expressed as a percentage:

$$\text{Percent } O_2 \text{ saturation of Hgb} = \frac{\text{Amount of } O_2 \text{ hemoglobin is carrying}}{\text{Amount of } O_2 \text{ hemoglobin can carry}} \times 100$$

Because the amount of oxygen that hemoglobin can carry is a constant 1.34 mL/g,

$$1.34 \text{ mL/g} \times \text{g Hgb} \times \% \text{ saturation Hgb} = \text{mL of } O_2 \text{ that Hgb is carrying}$$

The arterial oxygen saturation of hemoglobin is known as the SaO_2. The normal SaO_2 ranges from 93% to 99%.

The relationship between PaO_2 and SaO_2 is depicted by the oxyhemoglobin dissociation curve (Fig. 24-8). The initial part of the curve is very steep and flattens at the top. The flattened part means that large changes in the PaO_2 result in only small changes in SaO_2. A critical point of the curve occurs when the PaO_2 drops below 60 mm Hg. At this point, the curve drops sharply, signifying that a small decrease in PaO_2 is associated with a large decrease in SaO_2.

When the curve shifts to the right, there is a reduced capacity for hemoglobin to combine with oxygen, resulting in more oxygen released to the tissues. When the curve shifts to the left, there is an increased capacity for hemoglobin to combine with oxygen, resulting in less oxygen released to the tissues. See Chapter 23 for a more detailed discussion of the oxyhemoglobin dissociation curve.

A pulse oximeter, illustrated in Figure 24-9, is a device used to measure a value known as SpO_2 (oxygen saturation as measured by pulse oximetry). The SpO_2 reflects the arterial oxygen saturation of hemoglobin. Through oximetry, light-emitting and light-receiving sensors quantify the amount of light absorbed by oxygenated/deoxygenated hemoglobin in arterial blood. The value displayed on the pulse oximeter is an average of numerous readings taken in a 3- to 10-second period. This reduces the effects of pressure waveform variation caused by patient activity. Usually, the sensors are in a clip placed on a finger or ear lobe and allow for evaluation of the quality of the pulsatile waveform. The oximeter sensor in some devices is placed on the forehead. For assessment of pulse oximetry in infants, flexible probes can measure saturation when placed on the palm, arm, penis, or foot.

Oximetry should not be used in place of arterial blood gas (ABG) monitoring. Instead, pulse oximetry may be used to assess trends in oxygen saturation when the correlation between arterial blood and pulse oximetry readings has been established. Values obtained by pulse oximetry are unreliable when vasoconstricting medications or intravenous dyes are used and when shock, cardiac arrest, or severe anemia is present. Pulse oximetry has limited usefulness in patients with known dyshemoglobins, such as carboxyhemoglobin, which is elevated in smokers, and methemoglobin, which is seen in patients undergoing nitrate and lidocaine therapy. These limitations should be considered when interpreting pulse oximetry readings in certain patients.

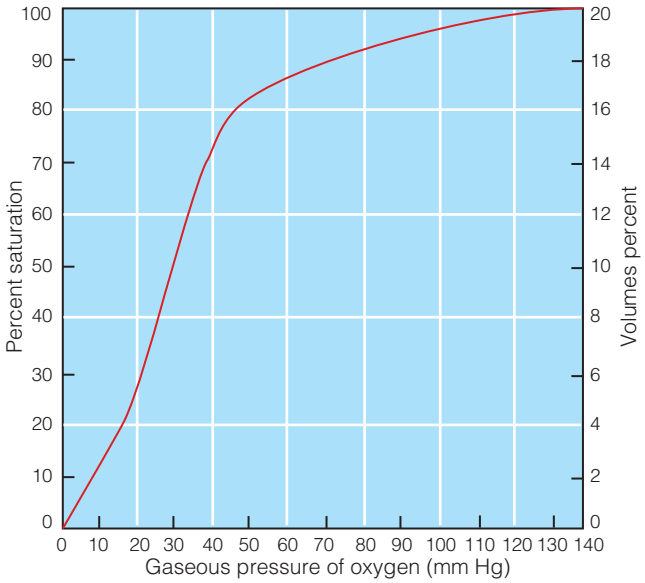

FIGURE 24-8 ▲ Oxyhemoglobin dissociation curve.

End-Tidal Carbon Dioxide Monitoring

End-tidal carbon dioxide ($ETCO_2$) monitoring measures the level of carbon dioxide at the end of exhalation, when the percentage of carbon dioxide dissolved in the arterial blood

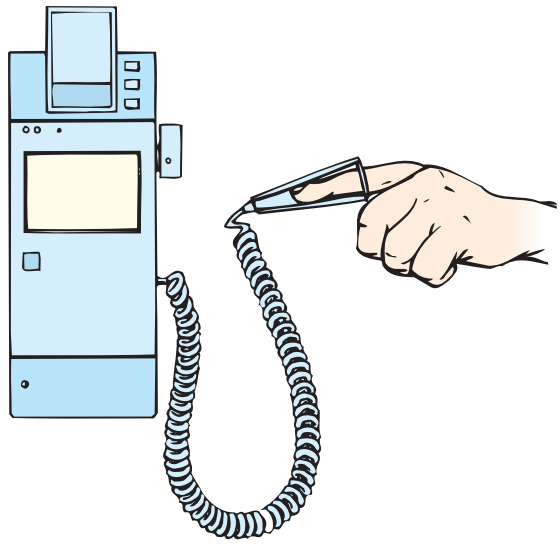

FIGURE 24-9 ▲ Pulse oximetry monitor.

($PaCO_2$) approximates the percentage of alveolar carbon dioxide ($PACO_2$). Therefore, samples of exhaled carbon dioxide measured at the end of exhalation ($ETCO_2$) can be used to approximate levels of $PACO_2$. Levels of alveolar carbon dioxide and arterial carbon dioxide are similar; therefore, $ETCO_2$ can be used to estimate $PaCO_2$. Although $PaCO_2$ and $ETCO_2$ values are similar, $ETCO_2$ is usually lower than $PaCO_2$ by 2 to 5 mm Hg. The difference between $PaCO_2$ and $ETCO_2$ ($PaCO_2$–$ETCO_2$ gradient) may be attributed to several factors; pulmonary blood flow is the primary determinant.

$ETCO_2$ values are obtained by monitoring samples of expired gas from an endotracheal tube, an oral airway, or a nasopharyngeal airway. Because $ETCO_2$ provides continuous estimates of alveolar ventilation, its measurement is useful for monitoring the patient during weaning from a ventilator, in cardiopulmonary resuscitation, and in endotracheal intubation.

The accuracy of the $ETCO_2$ readings may be affected by high concentrations of oxygen and water vapor. The nurse using $ETCO_2$ technology must be aware of these conditions and their effect on the monitor being used. Impaired infrared absorption from the interaction of carbon dioxide and oxygen in high concentrations may cause falsely low $ETCO_2$ measurements, and the interference of water vapor with the absorption of infrared light may cause falsely elevated measurements. The nurse must combine $ETCO_2$ readings with a variety of other clinical data.

The exhaled carbon dioxide waveform is displayed on the monitor as a plot of $ETCO_2$ versus time called a capnogram, which provides the nurse with a continuous graphic reading of the patient's $ETCO_2$ level with each exhaled breath. Changes in the waveform indicate clinical abnormalities, mechanical abnormalities, or both and require immediate assessment by the nurse or other trained professional.

On a capnogram, the waveform is composed of four phases, each one representing a specific part of the respiratory cycle (Fig. 24-10):

1. The first phase is the baseline phase, which represents both the inspiratory phase and the very beginning of the expiratory phase, when carbon dioxide–free air in the anatomical dead space is exhaled. This value should be zero in a healthy adult.
2. The second phase is the expiratory upstroke, which represents the exhalation of carbon dioxide from the lungs. Any process that delays the delivery of carbon dioxide from the patient's lungs to the detector prolongs the expiratory upstroke. Conditions such as COPD and bronchospasm are known physiological causes of prolonged expiratory upstroke. Mechanical obstructions, such as kinked ventilator tubing, may also cause prolonged expiratory upstroke.
3. The third phase begins as carbon dioxide elimination rapidly continues; a plateau on the capnogram indicates the exhalation of alveolar gases. The $ETCO_2$ is the value generated at the very end of exhalation, indicating the amount of carbon dioxide exhaled from the least ventilated alveoli.
4. The fourth phase is known as the inspiratory downstroke. The downward deflection of the waveform is caused by the washout of carbon dioxide that occurs in the presence of the oxygen influx during inspiration.

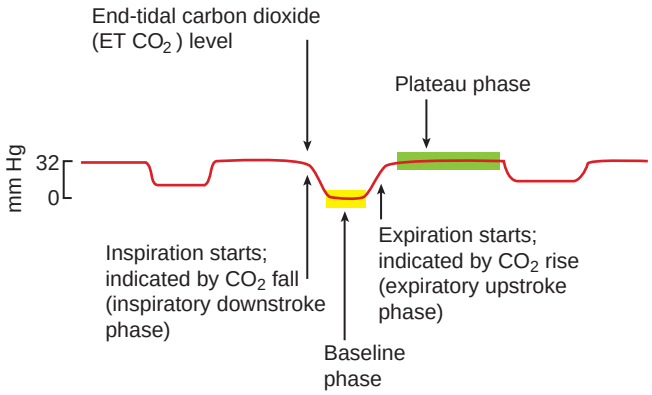

FIGURE 24-10 ▲ Capnogram tracing, with four phases labeled. CO_2, carbon dioxide.

Arterial Blood Gases

In an ABG test, a sample of arterial blood is drawn and analyzed to help determine the quality and extent of pulmonary gas exchange and acid–base status. The ABG test measures PaO_2, SaO_2, $PaCO_2$, pH, and the bicarbonate (HCO_3) level. The procedure involves obtaining arterial blood from a direct arterial puncture or from an arterial line often placed in the radial artery. More recent technology allows the continuous monitoring of ABGs using a fiberoptic sensor placed in the artery. Normal ABG values are given in Box 24-6.

Measuring Oxygen in the Blood

Oxygenation may be measured using an ABG by evaluating the PaO_2 and the SaO_2. As mentioned previously, only 3% of oxygen is dissolved in the arterial blood, and the remaining 97% is attached to hemoglobin in the red blood cells.

The normal PaO_2 is 80 to 100 mm Hg at sea level (barometric pressure of 760 mm Hg). For people living at higher altitudes, the normal PaO_2 is lower because of the lower barometric pressure. PaO_2 tends to decrease with age. For patients who are 60 to 80 years of age, a PaO_2 of 60 to 80 mm Hg is normal. An abnormally low PaO_2 is referred to as hypoxemia. Hypoxemia may result from many conditions, which are most commonly grouped according to their origin: intrapulmonary (disturbances in the lung), intracardiac (disturbance of flow to or from the heart, which impedes pulmonary flow or function), or perfusion deficits (inadequate perfusion of the lung tissues, which causes decreased oxygen uptake from the alveoli).

BOX 24-6 Normal Values for an Arterial Blood Gas

PaO_2: 80 to 100 mm Hg
SaO_2: 93% to 99%
pH: 7.35 to 7.45
$PaCO_2$: 35 to 45 mm Hg
HCO_3: 22 to 26 mEq/L

The normal SaO_2 ranges between 93% and 97%. SaO_2 is an important oxygenation value to assess because most oxygen supplied to tissues is carried by hemoglobin.

Measuring pH in the Blood

The pH is a measure of the hydrogen ion concentration in the blood and provides information about the acidity or alkalinity of the blood. A normal pH is 7.35 to 7.45. As hydrogen ions accumulate, the pH drops, resulting in acidemia. Acidemia refers to a condition in which the blood is too acidic. Acidosis refers to the process that caused the acidemia.

A decrease in hydrogen ions results in an elevation of the pH and alkalemia. Alkalemia refers to a condition in which the blood is too alkaline. Alkalosis refers to the process that causes the alkalemia. Box 24-7 reviews the terms used in acid–base balance.

ACIDS. An acid is a substance that can donate a hydrogen ion (H^+) to a solution. There are two different types of acids: volatile acids and nonvolatile acids.

Volatile acids are those that can move between the liquid and gaseous states. Once in the gaseous state, these acids can be removed by the lungs. The major acid in the blood serum is carbonic acid (H_2CO_3). This acid is broken down into carbon dioxide and water by an enzyme produced in the kidneys.

Nonvolatile ("fixed") acids are those that cannot change into a gaseous form and therefore cannot be excreted by the lungs. They can only be excreted by the kidneys (a metabolic process). Examples of nonvolatile acids are lactic acid and ketoacids.

An acid–base disorder may be either respiratory or metabolic in origin. Table 24-4 lists the possible causes and signs and symptoms of acid–base disorders. An excess of either kind of acid results in acidemia. Also see Table 29-6 in Chapter 29. If carbon dioxide from volatile acids accumulates, then respiratory acidosis exists. If nonvolatile acids accumulate, then metabolic acidosis exists.

Alkalemia may be the result of losing too many acids from the serum. If too much carbon dioxide is lost, the result is respiratory alkalosis. If there are less than normal amounts of nonvolatile acids, the result is metabolic alkalosis.

BASES. A base is a substance that can accept a hydrogen ion (H^+), thereby removing it from the circulating serum. The main base found in the serum is bicarbonate (HCO_3). The amount of bicarbonate that is available in the serum is regulated by the kidney (a metabolic process). If there is too little bicarbonate in the serum, the result is metabolic acidosis. If there is too much bicarbonate in the serum, the result is metabolic alkalosis.

Conditions leading to acidemia or alkalemia are influenced by a multitude of physiological processes (see Table 24-4). Some of these processes include respiratory and renal function or dysfunction, tissue oxygenation, circulation, lactic acid production, substance ingestion, and electrolyte loss from the gastrointestinal tract. The identification of a pH abnormality should lead to the investigation of possible contributing factors.

BOX 24-7 Clinical Terminology

Acid: A substance that can donate hydrogen ions (H^+). Example: H_2CO_3 (an acid) $\rightarrow H^+ + HCO_3$
Base: A substance that can accept hydrogen ions, H^+; all bases are alkaline substances. Example: HCO_3 (base) + $H^+ \rightarrow H_2CO_3$
Acidemia: Acid condition of the blood in which the pH is <7.35
Alkalemia: Alkaline condition of the blood in which the pH is >7.45
Acidosis: The process causing acidemia
Alkalosis: The process causing alkalemia

Measuring Carbon Dioxide in the Blood

The $PaCO_2$ refers to the pressure or tension exerted by dissolved carbon dioxide gas in arterial blood. Carbon dioxide is the natural byproduct of cellular metabolism. Carbon dioxide levels are regulated primarily by the ventilatory function of the lung. The normal $PaCO_2$ is 35 to 45 mm Hg. In interpretation of ABGs, $PaCO_2$ is thought of as an "acid." Elimination of carbon dioxide from the body is one of the main functions of the lungs, and an important relationship exists between the amount of ventilation and the amount of carbon dioxide in blood.

If a patient hypoventilates, carbon dioxide accumulates, and the $PaCO_2$ value increases above the upper limit of 45 mm Hg. The retention of carbon dioxide results in respiratory acidosis. Respiratory acidosis may occur even with normal lungs if the respiratory center is depressed and the respiratory rate or quality is insufficient to maintain normal carbon dioxide concentrations.

If a patient hyperventilates, carbon dioxide is eliminated from the body, and the $PaCO_2$ value decreases below the lower limit of 35 mm Hg. The loss of carbon dioxide results in respiratory alkalosis.

Measuring Bicarbonate in the Blood

Bicarbonate (HCO_3), the main base found in the serum, helps the body regulate pH because of its ability to accept a hydrogen ion (H^+). The concentration of bicarbonate is regulated by the kidneys and is referred to as a metabolic process of regulation. The normal bicarbonate level is 22 to 26 mEq/L. Bicarbonate may be thought of as a "base" (alkaline). When the bicarbonate level increases above 26 mEq/L, a metabolic alkalosis exists. Metabolic alkalosis results from a gain of base (alkaline) substances or a loss of metabolic acids. When the bicarbonate level decreases below 22 mEq/L, a metabolic acidosis exists. Metabolic acidosis results from a loss of base (alkaline) substances or a gain of metabolic acids.

Alterations in Acid–Base Balance

Disturbances in acid–base balance result from an abnormality of the metabolic or respiratory system. If the respiratory system is responsible, it is detected by the carbon dioxide in the serum. If the metabolic system is responsible, it is detected by the bicarbonate in the serum.

RESPIRATORY ACIDOSIS. Respiratory acidosis is defined as a $PaCO_2$ greater than 45 mm Hg and a pH of less

Table 24-4 Possible Causes and Signs and Symptoms of Acid–Base Disorders

Condition	Possible Causes	Signs and Symptoms
Respiratory Acidosis		
$PaCO_2$ > 45 mm Hg pH < 7.35	Central nervous system depression Head trauma Oversedation Anesthesia High cord injury Pneumothorax Hypoventilation Bronchial obstruction and atelectasis Severe pulmonary infections Heart failure and pulmonary edema Massive pulmonary embolus Myasthenia gravis Multiple sclerosis	Dyspnea Restlessness Headache Tachycardia Confusion Lethargy Dysrhythmias Respiratory distress Drowsiness Decreased responsiveness
Respiratory Alkalosis		
$PaCO_2$ < 35 mm Hg pH > 7.45	Anxiety and nervousness Fear Pain Hyperventilation Fever Thyrotoxicosis Central nervous system lesions Salicylates Gram-negative septicemia Pregnancy	Light-headedness Confusion Decreased concentration Paresthesias Tetanic spasms in the arms and legs Cardiac dysrhythmias Palpitations Sweating Dry mouth Blurred vision
Metabolic Acidosis		
HCO_3 < 22 mEq/L pH < 7.35	*Increased acids* Renal failure Ketoacidosis Anaerobic metabolism Starvation Salicylate intoxication *Loss of base* Diarrhea Intestinal fistulas	Headache Confusion Restlessness Lethargy Weakness Stupor/coma Kussmaul respiration Nausea and vomiting Dysrhythmias Warm, flushed skin
Metabolic Alkalosis		
HCO_3 > 26 mEq/L pH > 7.45	*Gain of base* Excess use of bicarbonate Lactate administration in dialysis Excess ingestion of antacids *Loss of acids* Vomiting Nasogastric suctioning Hypokalemia Hypochloremia Administration of diuretics Increased levels of aldosterone	Muscle twitching and cramps Tetany Dizziness Lethargy Weakness Disorientation Convulsions Coma Nausea and vomiting Depressed respiration

than 7.35. Respiratory acidosis is characterized by inadequate elimination of carbon dioxide by the lungs and may be the result of inefficient pulmonary function or excessive production of carbon dioxide.

RESPIRATORY ALKALOSIS. Respiratory alkalosis is defined as a $PaCO_2$ less than 35 mm Hg and a pH of greater than 7.45. Respiratory alkalosis is characterized by excessive elimination of carbon dioxide from the serum.

METABOLIC ACIDOSIS. Metabolic acidosis is a bicarbonate level of less than 22 mEq/L and a pH of less than 7.35. Metabolic acidosis is characterized by an excessive production of nonvolatile acids or an inadequate concentration of bicarbonate for the concentration of acid within the serum.

METABOLIC ALKALOSIS. Metabolic alkalosis is a bicarbonate level of greater than 26 mEq/L and a pH of greater than 7.45. Metabolic alkalosis is characterized by excessive loss of nonvolatile acids or excessive production of bicarbonate.

Interpreting Arterial Blood Gas Results

When interpreting ABG results, three factors must be considered: (1) oxygenation status, (2) acid–base status, and (3) degree of compensation. A suggested approach for interpreting ABG results is presented in Box 24-8, along with sample values for interpretation.

EVALUATING OXYGENATION. It is necessary to examine the patient's oxygenation status by evaluating the PaO_2 and the SaO_2. If the PaO_2 value is less than the patient's norm, hypoxemia exists. If the SaO_2 is less than 93%, inadequate amounts of oxygen are bound to hemoglobin.

EVALUATING ACID–BASE STATUS. The first step in evaluating acid–base status is the examination of the arterial pH. If the pH is less than 7.35, acidemia exists. If the pH is greater than 7.45, alkalemia exists.

The second step in evaluating acid–base status is examination of the $PaCO_2$. A $PaCO_2$ of less than 35 mm Hg indicates a respiratory alkalosis, whereas a $PaCO_2$ of greater than 45 mm Hg signifies a respiratory acidosis.

The third step in evaluating acid–base status is examination of the bicarbonate level. If the bicarbonate value is less than 22 mEq/L, metabolic acidosis is present. If the bicarbonate value is greater than 26 mEq/L, metabolic alkalosis exists.

Occasionally, patients present with both respiratory and metabolic disorders that together cause an acidemia or alkalemia. For example, alkalosis could result from an increase in bicarbonate and a decrease in carbon dioxide, or an acidosis could result from a decrease in bicarbonate and an increase in carbon dioxide. A patient with metabolic acidosis from acute renal failure could also have a very slow respiratory rate that causes the patient to retain carbon dioxide, creating a respiratory acidosis. Therefore, the ABG reflects a mixed respiratory and metabolic acidosis. Box 24-9 lists examples of mixed gases.

DETERMINING COMPENSATION. If the patient presents with an alkalemia or acidemia, it is important to determine whether the body has tried to compensate for the abnormality. If the buffer systems in the body are unable to maintain normal pH, then the renal or respiratory systems attempt to compensate. If the problem is respiratory in origin, the kidneys work to correct it. If the problem is renal in origin, the lungs try to correct it. It may take as little as 5 to 15 minutes for the lungs to recognize a metabolic presentation and start to correct it. It may take up to 1 day for the kidneys to correct the respiratory-induced problem. One system will not overcompensate; that is, a compensatory mechanism will never make an acidotic patient alkalotic or an alkalotic patient acidotic.

The respiratory system responds to metabolic-based pH imbalances in the following manner:

- Metabolic acidosis: increase in respiratory rate and depth
- Metabolic alkalosis: decrease in respiratory rate and depth

The renal system responds to respiratory-based pH imbalances in the following manner:

- Respiratory acidosis: increase in hydrogen secretion and bicarbonate reabsorption
- Respiratory alkalosis: decrease in hydrogen secretion and bicarbonate reabsorption

ABGs are defined by their degree of compensation: uncompensated, partially compensated, or completely compensated. To determine the level of compensation, the pH, carbon dioxide, and bicarbonate are examined. First, it is determined whether the pH is acidotic or alkalotic. In some cases, the pH is not within the normal range, indicating an acidosis or alkalosis. If it is within the normal range, it

BOX 24-8 Interpretation of Arterial Blood Gas Results

Approach

1. Evaluate oxygenation by examining the PaO_2 and the SaO_2
2. Evaluate the pH. Is it acidotic, alkalotic, or normal?
3. Evaluate the $PaCO_2$. Is it high, low, or normal?
4. Evaluate the HCO_3. Is it high, low, or normal?
5. Determine whether compensation is occurring. Is it complete, partial, or uncompensated?

Examples

Sample Blood Gas: Case 1

PaO_2	80 mm Hg	Normal
SaO_2	95%	Normal
pH	7.30	Acidemia
$PaCO_2$	55 mm Hg	Increased (respiratory cause)
HCO_3	25 mEq/L	Normal

Conclusion: Respiratory acidosis (uncompensated)

Sample Blood Gas: Case 2

PaO_2	85 mm Hg	Normal
SaO_2	90%	Low saturation
pH	7.49	Alkalemia
$PaCO_2$	40	Normal
HCO_3	29 mEq/L	Increased (metabolic cause)

Conclusion: Metabolic alkalosis with a low saturation (uncompensated)

BOX 24-9 Arterial Blood Gases in Mixed Respiratory and Metabolic Disorders

Mixed Acidosis
pH: 7.25
$PaCO_2$: 56 mm Hg
PaO_2: 80 mm Hg
HCO_3: 15 mEq/L

Mixed Alkalosis
pH: 7.55
$PaCO_2$: 26 mm Hg
PaO_2: 80 mm Hg
HCO_3: 28 mEq/L

is important to determine on which side of 7.40 (midpoint of the normal pH range) the pH lies. For example, a pH of 7.38 is tending toward acidosis, whereas a pH of 7.41 is tending toward alkalosis. Next, an evaluation is made to see whether carbon dioxide or bicarbonate has changed to account for the acidosis or alkalosis. Finally, it is determined whether the opposite system (metabolic or respiratory) has worked to try to shift back toward a normal pH. The primary abnormality (metabolic or respiratory) is correlated with the abnormal pH (acidotic or alkalotic). The secondary abnormality is an attempt to correct the primary disorder. By using the rules for defining compensation in Box 24-10, it is possible to determine the compensatory status of the patient's ABGs.

BOX 24-10 Compensatory Status of Arterial Blood Gases

Uncompensated: pH is *abnormal* and *either* the CO_2 or HCO_3 is also abnormal. There is no indication that the opposite system has tried to correct for the other.

In the example below, the patient's pH is alkalotic as a result of the low (below the normal range of 35 to 45 mm Hg) CO_2 concentration. The renal system value (HCO_3) has not moved out its normal range (22 to 26 mEq/L) to compensate for the primary respiratory disorder.

PaO_2:	94 mm Hg	Normal
pH:	7.52	Alkalotic
$PaCO_2$:	25 mm Hg	Decreased
HCO_3:	24 mEq/L	Normal

Partially compensated: pH is *abnormal*, and *both* the CO_2 and HCO_3 are also abnormal; this indicates that one system has attempted to correct for the other but has not been completely successful.

In the example below, the patient's pH remains alkalotic as a result of the low-CO_2 concentration. The renal system value (HCO_3) has moved out its normal range (22 to 26 mEq/L) to compensate for the primary respiratory disorder but has not been able to bring the pH back within the normal range.

PaO_2:	94 mm Hg	Normal
pH:	7.48	Alkalotic
$PaCO_2$:	25 mm Hg	Decreased
HCO_3:	20 mEq/L	Decreased

Completely compensated: pH is *normal* and *both* the CO_2 and HCO_3 are abnormal; the normal pH indicates that one system has been able to compensate for the other.

In the example below, the patient's pH is normal but is tending toward alkalosis (>7.40). The primary abnormality is respiratory because the $PaCO_2$ is low (decreased acid concentration). The bicarbonate value of 18 mEq/L reflects decreased concentration of base and is associated with acidosis, not alkalosis. In this case, the decreased bicarbonate has completely compensated for the respiratory alkalosis.

PaO_2:	94 mm Hg	Normal
pH:	7.44	Normal, tending toward alkalosis
$PaCO_2$:	25 mm Hg	Decreased, primary problem
HcO_3:	18 mEq/L	Decreased, compensatory response

Mixed Venous Oxygen Saturation

Mixed venous oxygen saturation (SvO_2) is a parameter that can be measured to evaluate the balance between oxygen supply and oxygen demand. Blood obtained from a vein in an extremity gives information mostly about that extremity; it can be quite misleading if the metabolism in the extremity differs from the metabolism of the body as a whole. This difference is accentuated if the extremity is cold or underperfused (eg, in shock), if the patient has performed local exercises with the extremity (eg, opening and closing the fist), or if there is local infection in the extremity.

Sometimes blood is sampled through a central venous pressure (CVP) catheter in the hope of obtaining mixed venous blood, but even in the superior vena cava or right atrium where a CVP catheter ends, there is usually incomplete mixing of venous return from various parts of the body. For complete mixing of the blood, it is necessary to obtain a blood sample from a pulmonary artery catheter. Use of the pulmonary artery catheter provides a sample of blood that has returned from the extremities and has been mixed in the right ventricle.

Oxygen measurements of mixed venous blood indicate whether the tissues are being oxygenated, but SvO_2 does not distinguish the independent contributions of the heart and the lungs. SvO_2 indicates the adequacy of the supply of oxygen relative to the demand for oxygen at the tissue levels. Normal SvO_2 is 60% to 80%; this means that supply of oxygen to the tissues is adequate to meet the tissue's demand. However, a normal value does not indicate whether compensatory mechanisms were needed to maintain the perfusion. For example, in some patients, an increase in cardiac output is needed to compensate for a low supply of oxygen.

A low SvO_2 may be caused by a decrease in oxygen supply to the tissues or an increase in oxygen use caused by a high demand. A decrease in oxygen supply results from low hemoglobin, hemorrhage, or low cardiac output. An increase in oxygen demand results from hyperthermia, pain, stress, shivering, or seizures. An SvO_2 of 40% to 60% may occur in heart failure, and values less than 40% may indicate profound shock. A decrease in SvO_2 often occurs before other hemodynamic changes and, therefore, is an excellent clinical tool in assessing and managing critically ill patients. The goals of interventions for a low SvO_2 include increasing the oxygen supply by blood transfusions or by increasing cardiac output. Treatment may also be aimed at eliminating the cause of the high demand.

A high SvO_2 value indicates that oxygen supply exceeds demand or a decrease in the demand. Elevated SvO_2 values are associated with increased delivery of oxygen (high fraction of inspired oxygen [FiO_2]) or with decreased demand from hypothermia, hypothyroidism, or anesthesia. An elevated SvO_2 also is seen in the early stages of septic shock when the tissues are unable to use the oxygen. Table 24-5 summarizes possible causes of abnormalities in SvO_2.

A pulmonary artery catheter with an oximeter built into its tip that allows continuous monitoring of SvO_2 provides ongoing assessment of oxygen supply and demand imbalances. If a catheter with a built-in oximeter is not available, the nurse can draw blood from the pulmonary artery through

Table 24-5 Possible Causes of Abnormalities in Mixed Venous Oxygen Saturation (SvO_2)

Abnormality	Possible Cause
Low SvO_2 < 60%	***Decreased oxygen supply***
	Low hematocrit from anemia or hemorrhage
	Low arterial saturation and hypoxemia from lung disease, ventilation–perfusion mismatches
	Low cardiac output from hypovolemia, heart failure, cardiogenic shock, myocardial infarction
	Increased oxygen demand
	Increased metabolic demand, such as hyperthermia, seizures, shivering, pain, anxiety, stress, strenuous exercise
High SvO_2 > 80%	***Increased oxygen supply***
	Supplemental oxygen
	Decreased oxygen demand
	Anesthesia, hypothermia, early stages of sepsis
	Technical problems
	False high reading because of wedged pulmonary artery catheter
	Fibrin clot at end of catheter

a regular pulmonary artery catheter, send the sample to the laboratory for blood gas and SvO_2 analysis, and use the information in the same manner.

▲ Respiratory Diagnostic Studies

Chest Radiography

Chest radiography is a valuable diagnostic tool that clinicians frequently use to assess anatomical and physiological features of the chest and to detect pathological processes. X-rays pass through the chest wall and make it is possible to visualize various structures. Dense tissues, such as bones, absorb the x-ray beam and appear as opaque or white on the radiograph. Blood vessels and blood-filled organs, such as the heart, are moderately dense structures and appear as gray areas on the radiograph. During inspiration, normal lungs fill with air and appear black on the radiograph. When parts of the lungs fill with fluid, which is a more dense material, the lungs appear white.

The nurse uses the radiograph as an assessment parameter to validate clinical findings and suspected abnormalities. Using a systematic approach, the nurse examines the radiograph by comparing the film with previous films. The approach can be to examine the film starting in the periphery and then to move toward the center of the chest or to start centrally and move outward toward the soft tissue. Whatever the method, the objects of scrutiny are the soft tissue areas, the bony structures, the inner layers just under the bone, and the internal structures. See Figure 17-15 in Chapter 17. The nurse examines the soft tissues on the radiograph by looking for homogeneity, beginning with lateral areas and moving medially. Air visualized in the lateral soft tissue may indicate a pneumothorax.

Bony structures inspected on the chest film include the ribs, clavicles, sternum, manubrium, spine, and vertebrae. Approximately eight to nine ribs should overlie lung tissue on the normal chest film. The nurse examines the ribs for fractures by following the curve of each rib, beginning anteriorly and moving around posteriorly. Like the ribs, the other bony structures are examined for correct position and intactness.

The contour of the diaphragm is also visible on the radiograph. Normally, the diaphragm is rounded with sharp, pointed costophrenic angles. Pleural effusions may cause the angles to become blunted. The top of the diaphragm is apparent at about the sixth rib. A lowered diaphragm may indicate hyperinflation caused by emphysema.

The nurse assesses lung parenchyma by comparing right and left sides, moving top to bottom. Normal air-filled lungs should appear black or very dark compared with the bones and heart. It is important in the evaluation to look for symmetry. Abnormally high density on one side of the chest may indicate edema, a mass, pleural effusion, or pneumonia.

Interlobar fissures separate the lobes of the lungs. The minor fissure in the right lung is usually visible in the frontal film. Displacement of the normal fissures seen on the film may indicate atelectasis or lobar collapse.

The trachea should appear midline over the thoracic vertebrae. The trachea can shift toward areas of atelectasis and away from areas of pneumothorax or pleural effusion.

Ventilation–Perfusion Scanning

Ventilation–perfusion scanning is a nuclear imaging test used to evaluate a suspected alteration in the ventilation–perfusion relationship. (See Chapter 23 for a discussion of ventilation–perfusion relationships.) A ventilation–perfusion scan is helpful in detecting the percentage of each lung that is functioning normally, diagnosing and locating pulmonary emboli, and assessing the pulmonary vascular supply.

The ventilation–perfusion scan consists of two parts: a ventilation scan and a perfusion scan. In the ventilation scan, the patient inhales radioactive gas, which follows the same pathway as air in normal breathing. In pathological conditions, the diminished areas of ventilation are visible on the scan. In the perfusion scan, a radioisotope is injected intravenously, enabling visualization of the blood supply to the lungs. When a pulmonary embolus is present, the blood supply beyond the embolus is restricted, revealing poor or no visualization of the affected area.

Ventilation–perfusion scans are often not useful in patients who depend on mechanical ventilation because the ventilation component of the scan is difficult to perform. Ventilation–perfusion mismatches may make interpretation of ventilation–perfusion scans difficult in patients with lung diseases, such as pneumonia. Because of these limitations, pulmonary angiography may be appropriate in the critically ill patient, especially if a pulmonary embolus is suspected.

Pulmonary Angiography

Pulmonary angiography involves the rapid injection of a radiopaque substance for radiographic studies of the pulmonary vasculature. Suspected pulmonary embolus is the most common indication for pulmonary angiography. A radiopaque substance is injected into one or both arms, the femoral vein, or a catheter that has been placed in the pulmonary artery. A positive test result is indicated by the impaired flow of the radiopaque substance through a narrowed vessel or by the abrupt cessation of flow of the substance in a vessel.

Bronchoscopy

Bronchoscopy involves the direct visualization of the larynx, trachea, and bronchi through a flexible fiberoptic bronchoscope. Bronchoscopy is used diagnostically to examine tissues, collect secretions, determine the extent and location of a pathologic process, and obtain a biopsy. In addition, bronchoscopy is used therapeutically as a means to remove foreign bodies or secretions from the tracheobronchial tree, treat postoperative atelectasis, and excise lesions.

In preparation for a bronchoscopy, a history and physical examination should be performed. A chest radiograph, clotting studies, and ABGs are also obtained. The patient often receives intravenous sedation or analgesia before the procedure. If the purpose of the bronchoscopy is therapeutic, medications that suppress a cough or diminish secretions are avoided (eg, intratracheal topical anesthetics, atropine, and codeine).

Careful monitoring of the patient is indicated after a bronchoscopy. The nurse assesses for any evidence of complications, which may include laryngospasm, fever, hemodynamic changes, cardiac dysrhythmias, pneumothorax, hemorrhage, or cardiopulmonary arrest.

Thoracentesis

In thoracentesis, a needle is inserted into the pleural space to remove air, fluid, or both; obtain specimens for diagnostic evaluation; or instill medications. A chest radiograph, coagulation studies, and patient education are essential before a thoracentesis. Some patients may require medication to reduce anxiety. Unlike bronchoscopy, thoracentesis requires the cooperation of the patient; therefore, a local anesthetic, rather than moderate sedation, is used to minimize the pain and discomfort that accompanies the procedure. During the procedure, the patient is placed either in a chair or on the edge of the bed in an upright position with arms and shoulders raised so that the ribs lift and separate, allowing easier needle insertion. If a patient is unable to lift his or her arms, sitting on the bed with the arms placed above the head on a table is an alternative position.

During thoracentesis, the nurse's primary function is to provide comfort for the patient, perform ongoing assessment of the patient's respiratory system, dress the wound with sterile dressings on completion of the procedure, and send labeled specimens to the laboratory as ordered. Postthoracentesis nursing care includes assessment for complications, including pneumothorax, pain, hypotension, and pulmonary edema.

Sputum Culture

Sputum specimens are often part of the respiratory assessment. Because healthy patients do not produce sputum, obtaining a specimen requires the patient to cough to bring up sputum from the lungs. It is essential that the nurse distinguishes sputum from saliva before sending the specimen to the laboratory.

In most cases, sputum specimens are obtained for culture and sensitivity study. The specimen is examined for specific microorganisms and their corresponding drug sensitivities. In addition, sputum specimens are also required for studies of cytology and acid-fast bacilli. Culture of acid-fast bacilli requires serial collection (usually over 3 days) and is used to identify tuberculosis and mycobacteria.

Pulmonary Function Tests

The flow of air in and out of the lungs provides tangible measures of lung volumes. Although these volumes are referred to as measures of "pulmonary function," in reality, they are measures of pulmonary anatomy. In the evaluation of ventilation, structure or anatomy often determines function. Ventilatory or pulmonary function tests measure the ability of the chest and lungs to move air into and out of the alveoli.

Pulmonary function tests include volume measurements, capacity measurements, and dynamic measurements. These measurements are influenced by exercise and disease. Age, sex, body size, and posture are other variables that are taken into consideration when the test results are interpreted. Figure 23-13 in Chapter 23 illustrates normal lung volumes and capacity.

Volume Measurements

Volume measurements show the amount of air contained in the lungs during various parts of the respiratory cycle. Measures of lung volume include tidal volume (V_T), inspiratory reserve volume (IRV), expiratory reserve volume (ERV), and residual volume (RV; see Chapter 23, Table 23-1).

Capacity Measurements

Capacity measurements quantify part of the pulmonary cycle. They are a combination of the previous volumes and include inspiratory capacity (IC), functional residual capacity (FRC), vital capacity (VC), and total lung capacity (TLC; see Chapter 23, Table 23-1).

Dynamic Measurements

The following measurements, called dynamic measurements, provide data about airway resistance and the energy expended in breathing (work of breathing).

- Respiratory rate or frequency is the number of breaths per minute. At rest, the respiratory rate is about 15 breaths/min.
- Minute volume, sometimes called minute ventilation, is the volume of air inhaled and exhaled per minute. It is calculated by multiplying tidal volume by respiratory

rate. At rest, the minute volume is approximately 7,500 mL/min.

- Dead space is the part of the tidal volume that does not participate in alveolar gas exchange. The dead space (measured in milliliters) is the air contained in the airways (anatomical dead space) plus the volume of alveolar air that is not involved in gas exchange (physiological dead space; eg, air in an unperfused alveolus from pulmonary embolism or, more commonly, air in underperfused alveoli). Adult anatomical dead space is usually equal to the body weight in pounds (eg, 140 mL in a 140-pound person). In a healthy person, dead space is composed only of anatomical dead space. Physiological dead space occurs in certain disease states. Dead space is calculated by subtracting the partial pressure of arterial carbon dioxide ($PaCO_2$) from the partial pressure of alveolar carbon dioxide (P_ACO_2). The normal value of dead space in healthy adults is typically less than 40% of the tidal volume. The dead space/tidal volume ratio is used to follow the effectiveness of mechanical ventilation.
- Alveolar ventilation, the complement of dead space, is expressed as the volume of tidal air that is involved in alveolar gas exchange. This volume is represented as volume per minute by the symbol $\dot{V}_A$. $\dot{V}_A$ is a measure of ventilatory effectiveness. It is more relevant to the blood gas values than either the dead space or tidal volume because these last two measures include physiological dead space. $\dot{V}_A$ is calculated by subtracting the dead space (V_D) from the tidal volume (V_T) and multiplying the result by the respiratory rate (f):

$$\dot{V}_A = (V_T - V_D) \times f$$

About 2,300 mL of air (FRC) remains in the lung at the end of expiration. Each new breath introduces about 350 mL of air into the alveoli. The ratio of new alveoli air to total volume of air remaining in the lungs is

$$\frac{350\,mL}{2,300\,mL}$$

Therefore, new air is only about one seventh of the total volume contained in the lungs. The normal is 5,250 mL/min (350 mL/breath × 15 breaths/min = 5,250 mL/min). A normal breath (V_T) can replace 7,500 mL of air/min (500 mL/breath × 15 breaths/min = 7,500 mL/min), requiring 0.008 s/mL:

$$\frac{1\,minute}{7,500\,mL} \times \frac{60\,seconds}{1\,minute} = 0.008\ seconds/mL$$

Therefore, the FRC of the lungs can be completely replaced in 18.4 seconds (2,300 mL × 0.008 s/mL = 18.4 seconds) if air diffusion is uniform. This slow turnover rate prevents rapid fluctuations of gas concentrations in the alveoli with each breath.

▲ Clinical Applicability Challenges

CASE STUDY

Mrs. S. is a 56-year-old white female admitted to the intermediate care unit from the postanesthesia care unit (PACU), status: post laproscopic cholecystectomy. Her procedure was uneventful and she has been placed on patient-controlled analgesia (PCA) to help control her pain. She has a medical history significant for hypertension, morbid obesity, and hypercholesterolemia. Her PCA pump is set to deliver a PCA dose of hydromorphone at 0.2 mg with a 10-minute lockout, basal rate at zero, and a maximum of 1.2 mg/h.

At change of shift assessment, Mrs. S. has stable vital signs with heart rate at 68 beats/min, respiratory rate at 18 breaths/min, blood pressure at 149/175 mm Hg, and temperature at 36.7°C. She is in sinus rhythm with occasional premature atrial contractions (PACs). Her breath sounds are clear to auscultation and her pulse oximetry reading shows that she is saturating at 96% on 2 liters of oxygen. Because Mrs. S. is receiving PCA pain control, her end-tidal CO_2 is being monitored and is at 36 mm Hg. Mrs. S. is rating her pain at 9/10 and asks for additional pain medication. After consultation with the physician, an order is received to increase the hydromorphone by adding a basal rate of 0.3 mg/h with a maximum of 1.5 mg/h maximum. One hour after the change in pain medication, you assess Mrs. S. and notice that there is a change in her level of sedation and her respiratory rate has dropped to 8 breaths/min. In addition, her SpO_2 has decreased to 86% and the $ETCO_2$ has increased to 48 mm Hg.

1. What is the primary factor contributing to the change in the patient's respiratory status?
2. What is the explanation for the increase in the $ETCO_2$?
3. In addition to the increased infusion of narcotic medication, what other factor may have contributed to respiratory depression in Mrs. S.?

25 Patient Management: Respiratory System

John C. Hagen, Tracey Wilson, Charles Fisher, Donna Charlebois, Sidenia S. Tribble, and Paul K. Merrel

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Summarize the desired outcomes of the various bronchial hygiene therapies.
2. Compare and contrast situations in which chest physiotherapy (including postural drainage) is useful versus contraindicated situations.
3. Describe the nursing assessment and management of patients on oxygen therapy.
4. Compare and contrast indications for, and complications of, orotracheal intubation versus nasotracheal intubation.
5. Compare and contrast the principles governing chest tube drainage systems.
6. Discuss nursing management of the patient with a chest tube drainage system.
7. Discuss the pharmacology for the treatment of bronchospasm in asthma and chronic obstructive pulmonary disease.
8. Differentiate between the principles of negative-pressure ventilation and positive-pressure ventilation.
9. Differentiate between pressure-cycled and volume-cycled ventilators in positive-pressure ventilation.
10. Compare and contrast the following ventilator modes: assist-control, synchronized intermittent mandatory, pressure-support, and pressure-controlled ventilation.
11. Summarize strategies to maximize oxygen delivery with the goal of achieving a nontoxic FiO_2 setting.
12. Summarize adverse effects of positive end-expiratory pressure, how they are identified, and the appropriate treatment.
13. Compare and contrast the advantages and disadvantages of tracheostomy versus endotracheal intubation.
14. Describe the nursing management of the ventilated patient, and explain how to prevent complications.
15. Discuss the differences between short-term and long-term ventilation weaning.

Respiration is necessary to sustaining life, and the nurse plays an important role in helping the critically ill patient breathe. The nurse must be knowledgeable and skilled in assessing patient needs, providing quick and efficient care, evaluating results of intervention, and supporting and teaching the patient and family. Techniques, equipment, and procedures vary according to the patient's respiratory status.

▲ Bronchial Hygiene Therapy

Bronchial hygiene therapy (BHT), also known as pulmonary toilet, is helpful in preventing and treating pulmonary complications. The primary phases of lung function that BHT aims to improve are ventilation and diffusion (Fig. 25-1).

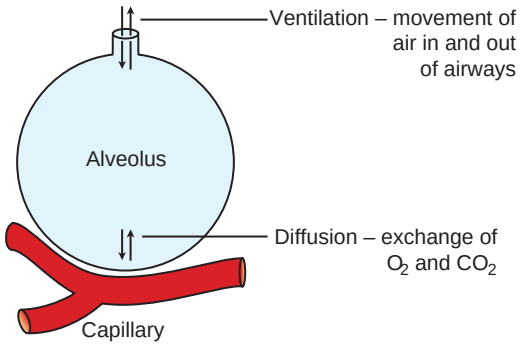

FIGURE 25-1 ▲ Primary lung functions: ventilation and diffusion.

These are accomplished through the therapeutic goals of (1) secretion mobilization and removal and (2) improved gas exchange.

Specific BHT depends on existing pulmonary dysfunction. The normal airway has a functioning mucociliary "escalator" with a cough reflex and normal mucous production. In contrast, the hospitalized patient may have pneumonia, atelectasis, or inability to perform deep breathing, cough, or clear mucus effectively because of weakness, sedation, or pain. The patient may also have chronic conditions such as chronic obstructive pulmonary disease (COPD), cystic fibrosis, pulmonary fibrosis, or quadriplegia.

The need for and the effectiveness of various methods of BHT are based on physical assessment, chest radiography, measurement of arterial blood gases (ABGs), and additional sources of information as indicated. Any one or a combination of the following measures is used: coughing and deep-breathing maneuvers, airway clearance adjunct devices, chest physiotherapy (CPT), and bronchodilator aerosol therapy (pharmacology is discussed later in the chapter).

Coughing and Deep Breathing

Effective coughing is necessary for the patient to clear secretions. The objectives of deep breathing and coughing are to promote lung expansion, mobilize secretions, and prevent the side effects of retained secretions (eg, atelectasis and pneumonia). These techniques are effective only if the patient is able to cooperate and has the strength to cough productively.

The patient is positioned seated and upright on the edge of the bed or chair with the feet supported. The nurse instructs the patient to take a slow, deep breath; hold it for 2 to 3 seconds; and exhale slowly for auscultation. If adventitious sounds are auscultated, indicating the presence of secretions, the patient must be made to maximally inhale and cough. Even if secretions are not auscultated, the patient should be encouraged to cough and deep breathe as a prophylactic measure every hour. The patient must be taught the effective use of the incentive spirometer (IS) to have immediate visual feedback on the breath depth, and coached to increase the volume. Ideally, the patient uses the IS hourly while awake, completing 10 breaths each session followed by coughing, and then the patient progressively increases breath volumes. The nurse coaches the patient to maximize the deep breaths, followed by coughing, and documents the IS volume results. IS, along with coughing and deep-breathing exercises, improves inhaled volumes and prevents atelectasis.

Airway Clearance Adjunct Therapies

Various adjunct therapies may be useful, in general, for patients who require mucous removal and, in particular, when coughing efforts are limited by a disease process, injury, or surgery. The Acapella and Flutter valves, two such methods of airway clearance, provide intermittent positive expiratory pressure (PEP) therapy, which improves mucous removal by causing airway vibration to loosen secretions that can be cleared with a cough.[1] The Acapella valve is just as effective as the Flutter valve and may be easier to use, especially in elderly patients. Both produce PEP and oscillatory vibrations in the airways to loosen mucus, but the Acapella valve is adjustable for the patient, with two types for patients who can sustain flow of greater than or equal to 15 L/min and less than or equal to 15 L/min; this provides flexibility, especially in those with very low expiratory flows. The nurse assists the patient's cough with positive pressure on the abdominal costal margin during exhalation to increase the cough force, thus producing a manually assisted cough. Various specialized BHTs are used for patients with cystic fibrosis and other chronic pulmonary diseases, including autogenic drainage (AD), which may be used with the huff cough.[1] The nurse teaches AD to patients who have reactive airway disease with likelihood of wheezing with normal cough. AD is a series of controlled breaths and uses low-pressure cough with minicoughs instead of one to two big coughs.

The Vest system (Hill-Rom, Batesville, IN), another method of airway clearance, is a chest wall oscillation device that creates chest wall motion through a machine that rapidly alternates air into sections of a vest that is placed circumferentially around the chest. The method is called high-frequency chest wall oscillation, which results in improved secretion removal. This is an alternative to traditional CPT. The Vest system has been used in trials involving patients with bronchiectasis, cystic fibrosis, COPD, lung transplantation, and even spinal cord injury or quadriplegia, as well as in postoperative intensive care units (ICUs). The Vest system has been shown to improve the removal of mucus and improve pulmonary function. It is well tolerated by surgical patients and can be self-administered at home.

Other therapies include EzPAP, bilevel positive airway pressure (BiPAP), and IS, which may be given before any of the BHTs to improve mucous removal. EzPAP and BiPAP are positive airway pressure devices that enable airway recruitment and prevent atelectasis using between 5 and 20 cm H_2O with variable flow of oxygen during therapy. Both work to reduce atelectasis using positive-pressure therapy, often in combination with aerosol pharmacology agents. EzPAP has only one setting of continuous positive airway pressure (CPAP), and BiPAP has both inspiratory high-pressure and expiratory lower pressure levels. Both are used in patients when IS or other therapies are not sufficient to reduce or prevent atelectasis.

Chest Physiotherapy

Postural drainage, positioning, and chest percussion and vibration are methods of CPT used to augment the patient's efforts and to improve pulmonary function. These may be used in sequence in different lung drainage positions and should be preceded by bronchodilator therapy and followed by deep breathing and coughing or other BHT. Changing the patient's position from supine to upright affects gas exchange, and positioning the patient in the lateral position may improve gas exchange, especially in unilateral lung disease. Positioning the patient with the "good" lung down improves oxygenation.[2] This improvement occurs because shunting is decreased when the "good" lung is in the dependent position.

Postural Drainage

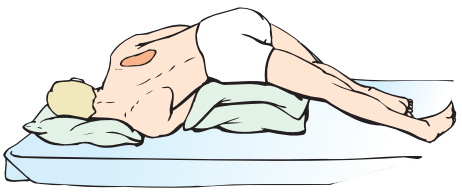
Postural drainage positions facilitate gravitational drainage of pulmonary secretions into the main bronchi and trachea based on anatomy of the lung segments (Fig. 25-2). The focus of postural drainage should be on the lobes affected by atelectasis and on increasing mucous removal with suctioning or by cough effort. Postural drainage is not indicated in all positions for all critically ill patients. Contraindications are listed in Box 25-1. The nurse must closely monitor the patient who is in a head-down position for aspiration, respiratory distress, and dysrhythmias. Alternate techniques may include gentle percussion and using a mechanical percussor to stimulate mucous movement while avoiding surgical areas.

Chest Percussion and Vibration

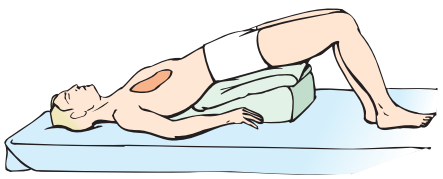
Chest percussion (tapotement) and vibration, performed by a trained health care professional, are used to dislodge secretions. Percussion involves striking the chest wall with the hands formed into a cupped shape by flexing the fingers and placing the thumb tightly against the index finger. The patient's position depends on the segment of lung to be percussed. A towel or pillowcase is draped over the area to be percussed, and percussion is performed for 3 to 5 minutes per position. Percussion is never performed over the spine, over the sternum, or below the thoracic cage. Percussion and vibration are performed only on the rib cage. If performed correctly, percussion does not hurt the patient or redden the skin. A clapping sound (as opposed to slapping) indicates correct hand position. Mechanical percussors are also available.

Vibration takes place during a prolonged pursed-lip exhalation. It increases the velocity and turbulence of exhaled air to

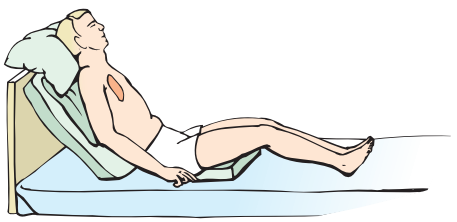
A. Face-lying—hips elevated 16–18 inches on pillows, making a 30°–45° angle.
Purpose: to drain the posterior lower lobes.



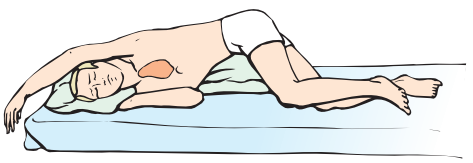
B. Lying on the left side—hips elevated 16–18 inches on pillows.
Purpose: to drain the right lateral lower lung segments.



C. Back lying—hips elevated 16–18 inches on pillows.
Purpose: to drain the anterior lower lung segments.



D. Sitting upright or semireclining.
Purpose: to drain the upper lung field and allow more forceful coughing.



E. Lying on the right side—hips elevated on pillows forming a 30°–45° angle.
Purpose: to drain the left lower lobes.

FIGURE 25-2 ▲ Positions used in lung drainage.

BOX 25-1 *PATIENT SAFETY*

Contraindications to Chest Physiotherapy

Contraindications to Postural Drainage

- Increased intracranial pressure (ICP)
- After meals/during tube feeding
- Inability to cough
- Hypoxia/respiratory instability
- Hemodynamic instability
- Decreased mental status
- Recent eye surgery
- Hiatal hernia
- Obesity

Contraindications to Percussion/Vibration

- Fractured ribs/osteoporosis
- Chest/abdominal trauma or surgery
- Bronchopleural fistula
- Pulmonary hemorrhage or embolus
- Coagulopathy
- Chest malignancy/mastectomy
- Pneumothorax/subcutaneous emphysema
- Cervical cord trauma
- Tuberculosis
- Pleural effusions/empyema
- Pulmonary edema
- Asthma

loosen secretions. This technique is accomplished by placing the hands side by side with fingers extended and applying the flat of the palm over the affected chest area. The patient inhales deeply and then slowly exhales. While the patient exhales, the nurse vibrates the patient's chest by quickly contracting and relaxing the arm and shoulder muscles. Vibration is used instead of percussion if the chest wall is extremely painful.

Modern ICU beds have options to percuss, vibrate, or provide continuous lateral rotation therapy (CLRT), using either an added module or a system integrated into the bed. These bed features can be used to provide BHT to critically ill patients who may not tolerate manual therapy. The nurse assesses patients for tolerance to both position changes and the level of therapy because most bed systems allow variable settings of high to low frequency of percussion or vibration. Continuous lateral rotation is effective for certain patients, especially ventilated patients.[3]

Contraindications and Adaptations

No single method of CPT has been shown to be superior, and there are many contraindications to using these techniques (see Box 25-1). Studies have questioned the efficacy of CPT, except in segmental atelectasis caused by mucous obstruction and diseases that result in increased sputum production (at least 30 mL/d), such as cystic fibrosis and bronchiectasis.[4] Bronchoscopy is an alternative treatment to remove mucous plugs that result in atelectasis. CPT may produce bronchospasm in asthmatics and spread infected material to uninfected lung tissue in patients with unilateral pneumonia.

The inclusion of CPT in the plan of care should be individualized and evaluated in terms of derived benefit versus potential risks. In addition, CPT should be discontinued when it fails to promote treatment goals. In patients who cannot tolerate CPT, turning the patient laterally every 2 hours aids in mobilizing secretions for removal with cough or suctioning. Progressive mobility from sitting up in a chair to weight bearing and to ambulation is used in all ventilated patients as part of pulmonary hygiene as well as increasing patient strength and endurance. Patients with an artificial airway or an ineffective cough may require suctioning after CPT.

To be effective, CPT must be accompanied by the postural drainage position specific to the affected area of the lung. Patients with unilateral disease are positioned with the healthy lung down for better ventilation and perfusion. Positioning the patient with the diseased lung down is likely to cause hypoxemia with ventilation–perfusion mismatching and shunting. Positioning is altered if the patient has a lung abscess. In such cases, the preferred position is with the diseased lung down because the abscessed lung in a gravity-dependent position can drain its purulent contents into the opposite lung. The abscessed lung would then contaminate the healthy lung.

Patient Positioning

Studies demonstrate improved oxygenation in patients with acute respiratory failure who were placed in the prone position, although this maneuver may not ultimately improve survival.[5] Prone positioning is an advanced technique used with critically ill ventilated patients who have acute lung injury (ALI) or acute respiratory distress syndrome (ARDS). ALI is defined by a PaO_2/FiO_2 ratio less than 300. ARDS is defined by a PaO_2/FiO_2 ratio less than 200. The enhanced oxygenation is attributed to recruitment of collapsed lung areas related to body position change, allowing dependent lung regions to have improved perfusion and ventilation. Prone positioning involves multiple personnel and specialized beds or equipment, and it should be performed only by specially trained staff to prevent the many complications related to prone positioning.

Patients who are ventilated benefit from having the head of the bed (HOB) elevated 30 degrees at all times. The rationale is to promote lung expansion, prevent the aspiration that can occur in the recumbent position in intubated patients, and prevent ventilator-associated pneumonia (VAP). Keeping the HOB elevated 30 degrees, with the associated reduction in VAP, is included in the ventilator bundle to prevent VAP and is part of the Institute for Healthcare Improvement's 5 Million Lives Campaign.[6] Mobilization of the patient contributes to improved oxygenation, secretion removal, and airway patency. Using lateral rotational therapy beds is more effective than the inconsistent nursing care of turning every 2 hours at minimum. (See the *American Association of Critical-Care Nurses* [AACN] *Protocols for Practice, Care of Mechanically Ventilated Patients*, 2nd edition, for a complete explanation of prone therapy.)

Mobilization of the patient using CLRT improves oxygenation and blood flow to the lung tissue in affected regions. CLRT is defined as continuous lateral positioning of less than 40 degrees for 18 of 24 hours daily. The lateral positioning improves blood flow and ventilation in the superior lung regions. CLRT may help reduce incidences of pneumonia, although it may not reduce days on the ventilator or the length of hospital stay. The results do not show improved survival for ventilated patients using either prone positioning or rotational therapy. However, with CLRT, the improved

oxygenation and recruitment lead to a reduction in VAP and in the cost associated with VAP, and with prone positioning, there is improved oxygenation. The rotation should be at the maximum to each side, and rotation should be continuous for 18 of 24 hours to obtain best outcomes. Rotation therapy with kinetic therapy refers to beds that rotate greater than or equal to 40 degrees and to CLRT beds that rotate to less than 40 degrees.[7] Both types of beds may include percussion and vibration modules that allow frequent use of those functions to further improve secretion mobilization.

Positioning of critically ill patients remains a nursing intervention for ventilated patients not only to improve oxygenation but also to prevent pressure ulcers. The additional benefit of using CLRT over conventional patient position changes by nursing staff is prevention of skin ulceration. Turning by nurses has become more significant, with the Joint Commission-mandated safety goal of requiring the risk assessment and reassessment for pressure ulcers followed by implementing actions to prevent them.[8] Turning every 2 hours allows the nurse to assess pressure points on the torso and extremities, including the back of the head, and this is even more important in patients with low perfusion. Guidelines should be in place for the use of a scale such as the Braden scale (see Chapter 51) to assess for pressure ulcer risk.[9] The Braden scale is a tool used to reassess increased risk factors daily; its use should be followed by consulting the wound care team and providing additional actions to treat pressure ulcers. Repositioning manually, using CLRT or prone positioning, requires care to avoid causing tissue injury when positioning for extended periods. Prolonged positioning in any one position leaves a patient at risk for developing a pressure ulcer, and turning can result in the dislodging of various tubes or lines. The critical care staff should be well trained in prone positioning, monitoring tubes and lines during rotation therapy, and preventing prolonged pressure in lateral positions. Low-pressure airflow mattresses may help reduce skin ulcer occurrence but should not be relied on as a primary prevention method. Mobilization of ventilated patients using rotation therapy specialty beds is one method for nurses to improve patient outcomes of improved oxygenation; this technique also helps prevent VAP and skin ulcers. Ultimately, the critically ill patient should progress to weight-bearing positions, sitting up in a chair, and, with physical therapy, to ambulation that improves overall physical reconditioning toward a return to independent functioning.

▲ Oxygen Therapy

The administration of oxygen therapy to a patient is designed to correct hypoxemia (low oxygen blood levels). When tissue oxygen availability is decreased, it is referred to as hypoxemia. Hypoxia is reduced oxygen supply, which can be generalized or region limited, for example, tissue hypoxia. If external or internal respiration is impaired, supplemental oxygen is vital to maintain the patient's cellular function. Oxygen therapy corrects hypoxemia, decreases the work of breathing, and decreases myocardial work. Any disease process that alters the gas exchange can cause hypoxemia.

Asthma, bronchitis, pneumonia, ALI and ARDS, COPD, and emphysema are disease processes that alter oxygen supply. Traumatic events that lead to pneumothorax or hemothorax, as well as surgical events, such as pneumonectomy and lobectomy, or events causing large pleural effusions can significantly alter gas exchange. Oxygen delivery by nasal cannula may provide sufficient additional oxygen to reduce air hunger and shortness of breath. A patient with COPD may also need continuous oxygen because of permanent alterations in the lungs, which result in lowered oxygen delivery, especially with stress, illness, infection, and exercise. Patients with COPD and emphysema require close monitoring for carbon dioxide retention and narcosis/stupor associated with the delivery of too high a concentration of oxygen. These patients normally tolerate higher levels of carbon dioxide because their chemoreceptors no longer respond to the normally accepted partial pressure of carbon dioxide (PCO_2) levels and serum pH. These patients' primary drive to breathe comes from their oxygen, rather than carbon dioxide, levels. The desired goals for all patients on oxygen therapy are stable arterial oxygen saturation (SaO_2) level, nonlabored respirations, and a decrease in anxiety and shortness of breath. These goals should be accomplished through delivery of the least amount of supplemental oxygen needed, so the nurse continuously monitors the patient on oxygen for the desired result and complications (Box 25-2). Appropriate physician or advanced practice nurse orders are necessary to initiate this therapy.

Patient Assessment

Assessment of the patient's oxygen need is based on the disease process and the severity of the hypoxemia. The nursing assessment considers the patient's level of consciousness, vital signs (including the rate and depth of breathing), nail bed color, airway patency or presence of an artificial airway, SaO_2, and ABGs. The use of accessory muscles or abdominal breathing may indicate severe distress, and the inability to speak (or the tendency to respond using only one-syllable words) is ominous. A patient with asthma who comes in with bilateral wheezes but who can communicate in complete sentences is less likely to have increased dyspnea and require intubation than the patient with asthma who sits bolt upright, only nods the head to questions, and is using the shoulder and neck accessory muscles to breathe. Accessory muscle use in any patient is usually a sign of respiratory fatigue. Laboratory data, including hemoglobin, hematocrit, electrolyte panel, ABGs, and chest radiographs, may be obtained to assist in correcting electrolyte and pH

BOX 25-2 PATIENT SAFETY

Complications of Oxygen Therapy

- Respiratory depression/arrest
- Discomfort with skin breakdown from straps and masks
- Dry mucous membranes, epistaxis, or infection in the nares
- Oxygen toxicity (prolonged high levels seen in acute lung injury or acute respiratory distress syndrome [ARDS])
- Absorptive atelectasis
- Carbon dioxide narcosis (manifested by altered mental status, confusion, headache, somnolence)

imbalances. A low phosphorus level, or hypophosphatemia, is associated with muscle weakness including the diaphragm impacting ventilation. A low hemoglobin level affects oxygen transport and delivery to tissues. A full assessment, which may include collection of blood for blood gas analysis, takes time, whereas assessment of the person's vital signs, SaO_2, respiratory effort, and symptoms is possible to do quickly and repeatedly. To establish baseline activity tolerance and respiratory function, it may be necessary to involve the family if the patient cannot communicate in complete sentences. Clinicians need to compare the usual symptoms exhibited by a patient with asthma or COPD with the presenting symptoms to establish the severity of the patient's illness. They should initiate oxygen therapy for distress and hypoxemia. After a thorough assessment including laboratory data, it is necessary to adjust the oxygen delivery method to meet the therapeutic goal.

The patient's acuity and underlying disease process dictate the level of oxygen delivery required. The choice of oxygen delivery method is based on the assessment and presentation of the patient, the SaO_2 on room air, and the desired outcome. The desired oxygen level for a patient with COPD may be much lower than that for a patient with pneumonia but without COPD. The patient with pneumonia tolerates higher levels of oxygenation for longer periods than the patient with COPD, who is susceptible to carbon dioxide narcosis.

After giving oxygen, it is necessary to reassess the patient. Signs of improvement include reduced respiratory rate, a more comfortable breathing pattern, increased SaO_2, and the patient's own subjective statement of improved breathing with decreased anxiety or distress. Altered mental status may indicate hypoxemia but may also be due to pH, electrolyte, or carbon dioxide abnormalities. The nurse assesses the patient's respiratory status as often as needed until the desired results are achieved. ABG values guide therapy, especially in patients known to have carbon dioxide retention or continued lethargy or sedation and in those unable to clear secretions. Ultimately, the ABG values indicate success or failure of efforts to correct the underlying hypoxemia.

Oxygen Delivery Systems

Several methods of oxygen delivery are available. The choice of a delivery method depends on the patient's condition. Oxygen delivery systems are traditionally divided into high-flow and low-flow systems (Box 25-3).

BOX 25-3 Oxygen Delivery Methods With Delivered Fraction of Inspired Oxygen (FiO_2)

Nasal Cannula—Low-Flow Device

Flow (L/min)	FiO_2
1	21%–25%
2	25%–28%
3	28%–32%
4	32%–36%
5	36%–40%
6	40%–44%

High-Flow Nasal Cannula

Flow (L/min)	FiO_2
1–40	21%–100%

The high-flow nasal cannula (eg, AquinOx system or Vapotherm) is adjusted for the desired clinical effect depending on the arterial blood gas (ABG), SaO_2, and breaths per minute. These high-flow systems allow for humidification at 100%, with high levels of oxygen delivery maintaining nasal mucosa moisture not possible with a low-flow nasal cannula. The nurse should monitor the SaO_2 closely for at least 30 to 60 minutes when switching from another oxygen delivery device, evaluate ABG as needed, and assess patient tolerance. Be aware of clinical contraindications with increased oxygen delivery.

Face Mask—Low-Flow Device

Flow (L/min)	FiO_2
5–6	40%
6–7	50%
7–10	60%

Face Tent—Low-Flow Device

Variable oxygen delivery of 21% to 50% depends on patient breathing (21% delivered with compressed air and up to 50% delivered with 10 L/min oxygen flow attached). Air is mixed with the oxygen flow in the mask, resulting in variable delivery with humidification. This is often used for humidification as well as oxygen delivery in patients who do not like the claustrophobic feeling associated with more traditional masks.

Venturi Mask—Low-Flow Device

Oxygen Flow (Minimal Rate) (L/min)	FiO_2 Setting*
4	25%
4	28%
6	31%
8	35%
8	40%
10	50%
15	60%

*FiO_2 setting is based on Venturi setting/adapter used and oxygen flow.

Nonrebreather Mask–Low-Flow Device

The nonrebreather mask is used in severe hypoxemia to deliver the highest oxygen concentration. The one-way valve on one side allows for the exhalation of carbon dioxide. The mask delivers 80% to 95% FiO_2 at a flow rate of 10 L/min depending on the patient's rate and depth of breathing, with some room air entrained through the open port on the mask. However, the mask should fit snugly to prevent additional entrainment of room air.

Tracheostomy Collar and T-Piece—Low-Flow Device

The T-piece is a T-shaped adapter used to provide oxygen to either an endotracheal or tracheostomy tube. The flow rate should be at least 10 L/min with humidification. Flow can also be provided by a ventilator. The tracheostomy collar may also be used and is generally the preferred method because it is more comfortable than the T-piece. The strap on the tracheostomy collar is adjusted to keep the collar on top of the tracheostomy. With both the T-piece and tracheostomy collar, the goal is to provide a high-enough flow rate to ensure that there is a minimal amount of entrained room air.

Low-flow oxygen devices work by supplying oxygen at flow rates less than the patient's inspiratory volume, usually 1 to 10 L/min. The rest of the volume is pulled from room air (entrained). Because of this oxygen and room air mixing (entrainment), the actual fraction of inspired oxygen (FiO_2) delivered to the patient is difficult to specify. Low-flow oxygen devices are suitable for patients with normal respiratory patterns, rates, and ventilation volumes. High-flow oxygen devices supply flow rates high enough to accommodate two to three times the patient's inspiratory volume, at 1 to 40 L/min. These devices are suitable for patients with high oxygen requirements because high-flow devices deliver 100% O_2 and maintain 100% humidification essential to prevent drying of the nasal mucosa.

Oxygen delivery devices all deliver different levels of oxygen. Device selection is based on the desired FiO_2. For example, a patient admitted with pneumonia who has an SaO_2 of 88% might improve to the desired level with a nasal cannula at 2 L/min. In contrast, a patient who has an SaO_2 of 88% but who also has a PaO_2 of 52 mm Hg and is using accessory muscles may require a higher liter flow or a nonrebreather oxygen mask. Both patients are monitored for improved SaO_2, respiratory rate and pattern, and ABG improvement. If increased distress, desaturation, or both are noted, more extreme interventions (such as intubation) may be necessary.

If lower concentrations of oxygen are needed, the system selected is usually nasal cannula. The cannula can be used even with mouth breathers because oxygen fills the nasopharynx and, with inspiration, oxygen is entrained. A patient who is primarily a mouth breather with sinusitis needs to be monitored closely for nasal cannula effectiveness or placed on mask oxygen delivery. The exact concentration of oxygen depends on the patient's inspired tidal volume (VT). If the patient hypoventilates, the oxygen concentration increases in the upper airway. In contrast, if hyperventilation occurs, the concentration of oxygen decreases because of large amounts of room air diluting the oxygen delivered. A simple calculation for nasal cannula delivery is to add another 4% for each liter of FiO_2 delivered to the room air value of 21% (see Box 25-3). Each of the other oxygen delivery devices delivers a variable FiO_2, based on breathing pattern and what device is used, as well as the oxygen flow in liters per minute.

If the oxygen concentration must be constant, as is the case for patients with COPD, Venturi systems (eg, the Venturi mask) are used. The Venturi mask delivers an exact percentage of oxygen regardless of the patient's tidal volume. Patients with COPD may require oxygen delivery by the Venturi system. These patients are "sensitive" to oxygen, and a small increase in the percentage of FiO_2 delivered may result in an elevated $PaCO_2$ and respiratory depression. The patient with COPD may have a respiratory drive based on his or her PaO_2, and with this disease process, ventilation decreases with an increased FiO_2, resulting in hypercapnia. The carbon dioxide level can be detected through serial ABG monitoring, which may reveal large increases in $PaCO_2$ with small increases in oxygen flow.

As higher concentrations of oxygen are required, the nasal cannula is replaced by a mask system. A simple mask delivers the lowest concentrations of oxygen, and a nonrebreather mask delivers the highest concentration. The alternative to a nonrebreather for high FiO_2 delivery is the high-flow nasal cannula system. The high-flow nasal cannula is used on a variety of patients with higher oxygen requirements. For example, patients may be those just off the ventilator with low oxygen saturation for prevention of dry secretions with increased humidity (100%), those in pulmonary rehabilitation with decreased exercise tolerance, and those with COPD and asthma, for whom high-flow nasal cannula systems improve breathing rate and dyspnea. It must be stated that patients who have high oxygen requirements on mechanical ventilation should not be extubated until their clinical condition improves. The AquinOx system is an example of a high-flow oxygen device. It allows high-liter oxygen flow through a nasal cannula with humidification at flows of 35 L/min. The high-flow nasal cannula can be more comfortable and allow improved tolerance by providing a constant temperature and high humidity without condensation and moisture buildup in the tubing, which would enter the nose in a low-flow nasal cannula. The other advantage of the high-flow nasal cannula is the ability to deliver a range of FiO_2, up to 100%, to meet patient oxygen demand. If a patient's PaO_2 and SaO_2 cannot be maintained using the nonrebreather mask or high-flow nasal cannula, respiratory failure, with the need for intubation and mechanical ventilation, is imminent.

Complications of Oxygen Delivery

The delivery of oxygen can cause discomfort, skin breakdown, and other complications. Long-term oxygen by nasal cannula, even with humidification, can cause dry mucous membranes, epistaxis, or infection in the sinuses. Nasal cannula tubing, face masks (including the straps), and tracheostomy collars can cause skin breakdown along the face, bridge of the nose, back of the neck, or behind the ears. Oxygen delivery can fail if the tubing is disconnected from the wall, leading to hypoxemia with dysrhythmias or increased dyspnea. The edematous or malnourished patient is at higher risk for alteration in skin integrity, and contaminated oxygen delivery devices should be replaced. Contamination can occur with copious secretions coughed onto a tracheostomy collar or with mucus on any other device used. To prevent a fire-related injury, a "no smoking" rule must be enforced for all patients receiving oxygen therapy.

The nurse routinely inspects the skin and mucous membranes of the mouth and nares for signs of breakdown. Should skin injury occur, further breakdown can be prevented by providing skin barriers or cushions and possibly changing to another type of device. For example, if the bridge of the nose is irritated by a face mask, then switching to a nasal cannula may relieve the discomfort to the nose, as long as the patient receives the same level of oxygen. The mask may cause some patients anxiety, with feelings of suffocation, and, as with all devices, the nurse should ensure the patients' comfort. The nasal cannula can cause breakdown behind the ears or on the upper lip, and even in the nares. Because oxygen delivered by nasal cannula is not highly humidified, except from high-flow devices, it may dry the mucous membranes in the nose. Finally, it is necessary to change disposable humidification systems according to manufacturer specifications to prevent system-related infections. Oxygen humidification sets for any device need routine changing at least every 72 hours. The key to preventing any complication, including

hypoxemia, is accurate and timely assessment of oxygenation parameters and monitoring for complications of the therapies by the nurse.

Oxygen toxicity starts to occur in patients breathing a concentration of more than 50% for longer than 24 hours. Patients who are ventilated with high oxygen concentration for prolonged periods are at risk for oxygen toxicity. To prevent the pathological cellular changes of oxygen toxicity, the patient's FiO_2 should be decreased as tolerated to the lowest possible setting as long as the PaO_2 remains greater than 60 mm Hg. The pathophysiological changes that occur with oxygen toxicity occur at the alveolar level and may progress from capillary leaking to pulmonary edema and possibly to ALI if the high FiO_2 continues for several days. Once the oxygen concentration is decreased to safer levels, the pathophysiological cellular changes may reverse, but if high FiO_2 levels continue, there may be permanent cellular changes and impairment of pulmonary function.

Carbon dioxide narcosis is a risk in patients with COPD who are "sensitive" to oxygen, and an increased FiO_2 may result in an elevated $PaCO_2$, hypoventilation, and respiratory depression or respiratory arrest. Oxygen must therefore be administered with caution to patients with COPD and often at low levels to prevent respiratory depression. Patients on high FiO_2 may develop absorptive atelectasis resulting from less nitrogen in the delivered gas mixture. Because nitrogen is not absorbed, it normally exerts a pressure within the alveoli, keeping the alveoli open. When nitrogen is "washed out," the oxygen replacing it is absorbed, resulting in alveolar collapse (atelectasis).

Respiratory arrest is a complication that can occur even in patients on oxygen therapy. Nurses prevent this complication by monitoring the patient's overall respiratory status, neurological status, vital signs with SaO_2, and ABG values to evaluate for signs of impending respiratory failure. Respiratory arrest can also occur for reasons such as mucous plugging within the tracheobronchial airways or plugging of a tracheostomy or endotracheal tube (ETT). Respiratory failure from fatigue caused by the increased work of breathing can occur quickly in a patient with pulmonary compromise, such as a patient with COPD and new-onset pneumonia. Risk of aspiration of food or gastric contents can occur in hospitalized patients with dysphagia (eg, from a stroke, sedation, or secondary to prolonged intubation with vocal cord paralysis). The nurse must monitor the vulnerable patient more frequently when there is a clear comorbidity that may result in respiratory failure or arrest.

▲ Artificial Airways

Rigorous BHT and carefully monitored oxygen therapy may eliminate the need for an artificial airway or ventilatory support. An artificial airway and ventilatory support become mandatory if these measures fail to provide adequate oxygenation and removal of carbon dioxide. Artificial airways have a fourfold purpose:

- Establishment of an airway
- Protection of the airway, with the cuff inflated
- Provision of continuous ventilatory assistance with ETT and tracheostomy
- Facilitation of airway clearance

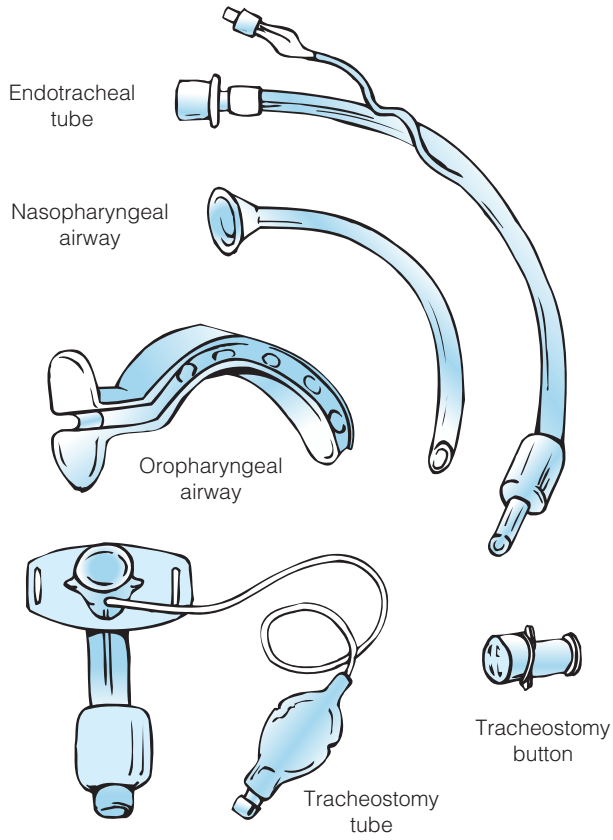


FIGURE 25-3 ▲ Five frequently used artificial airways.

Knowledgeable, aggressive nursing care is required to maintain airway patency, maximize therapeutic effects, and minimize damage to the patient's natural airway.

The selection of the appropriate artificial airway is important. Because all artificial airways increase airway resistance, it is essential that the largest tube possible be used for intubation. The cuff on the endotracheal or tracheostomy tube must be very compliant (soft) so that trauma to the trachea, vocal cords, and subglottic area is minimized. The competency of the cuff must be established before intubation. Approximately 10 mL of air is injected into the cuff before use, and the clinician checks for leaks.

If a patient is sedated and lying supine or becomes unconscious, tongue and airway muscle tone is decreased, causing the tongue to occlude the airway. Although an oropharyngeal or nasopharyngeal airway will maintain the air passage, it will not eliminate the potential for aspiration. Figure 25-3 illustrates some frequently used artificial airways. The nasopharyngeal airway (nasal trumpet) is a flexible tube that is inserted nasally past the base of the tongue to maintain airway patency. This airway may be better tolerated than the oropharyngeal airway in patients with an intact gag reflex.

Oropharyngeal Airway

An oropharyngeal airway is never placed in a conscious patient because it stimulates the gag reflex and can cause vomiting and aspiration. Before placing an artificial airway,

the nurse makes sure any possible obstruction is cleared. Insertion of an oropharyngeal airway follows three steps:

1. Gently open the patient's mouth using a crossed-finger technique or a modified jaw thrust.
2. Hold down the tongue with a depressor and guide the airway over the back of the tongue. (An optional method is to position the tip of the airway toward the roof of the mouth, with the curved end toward the roof, and gently advance the airway by rotating it 180 degrees.)
3. Monitor the patient frequently for airway patency by listening to breath sounds. Provide oropharyngeal suction as needed for emesis or oral secretions.

Oral suctioning is important to maintain oral hygiene when the patient is intubated because the patient's ability to swallow can be limited. The nurse performs oral suctioning as needed for copious oral secretions and after suctioning the endotracheal or tracheostomy tubes to maintain oral hygiene and comfort.

To perform oral suctioning, use a Yankauer device (tonsil-tip suction apparatus). The larger openings on the Yankauer tip allow for suctioning of thick or copious secretions better than other suction catheters designed for suctioning through endotracheal or nasotracheal tubes, which are smaller in diameter. In addition, the smaller suction catheters are flexible, which may cause them to kink. The Yankauer device is angled to allow it to follow the contour of the oral cavity along the palate. This facilitates suctioning in the posterior oropharynx and the buccal pouches, where secretions may collect. After suctioning, the nurse rinses the tubing with tap water to clear it of thick secretions and ensure that the suction will continue to function in the future. To remove an oropharyngeal airway, the oropharynx is suctioned, and the airway is gently removed.

Nasopharyngeal Airway

The insertion of a nasopharyngeal airway involves the following steps:

1. Determine and select the correct tube length by measuring from the tip of the nose to the earlobe. Use a tube with the largest outer diameter that fits the patient's nostril.
2. Lubricate the tube with water, water-soluble jelly, or lidocaine jelly, which alleviates discomfort.
3. Reassure the patient and familiarize him or her with the procedure.
4. Insert the airway into the nostril up to the end of the nasal trumpet.
5. Have the patient exhale with the mouth closed. (If the tube is in the correct position, air can be felt exiting from the tube opening.)
6. Open the patient's mouth, depress the tongue, and look for the tube's tip just behind the uvula.

In patients who require frequent nasotracheal suctioning, nasopharyngeal airways are frequently used to prevent patient discomfort and airway trauma from repeated suction catheter introduction through the nares. Nasotracheal suctioning is best done using a red rubber suction catheter, which is more flexible and better tolerated than standard plastic catheters. Nasotracheal suctioning is done as a sterile procedure. The catheter is lubricated with water-soluble jelly and passed to the back of the nasopharynx initially. Supplemental oxygen is given before suctioning and in between each suction attempt. The oxygen can be given using a bag–valve–mask (BVM) apparatus or manual resuscitation bag (MRB) and gently bagging with each inspiration to provide a high FiO_2. Other high-flow devices, such as a Venturi mask, may also be used to provide more accurate concentrations of oxygen. The nurse or respiratory therapist then asks the patient to cough, which opens the epiglottis and allows the catheter to be advanced. A change in the sound of the cough and the return of sputum with suctioning indicates passage into the tracheal tree. The technique of nasotracheal suctioning is difficult and should only be attempted by experienced practitioners. The novice ICU nurse should seek the help of experienced clinicians to learn this skill.

The nasopharyngeal airway may have to be gently rotated to withdraw it from the nares. It is important to be prepared for the potential of epistaxis with nasopharyngeal airway removal. Prior history of epistaxis or known coagulopathy should be carefully reviewed before placing a nasopharyngeal airway or performing nasotracheal suctioning that may lead to bleeding.

Endotracheal Tubes

An ETT is inserted if the patient needs ventilation or protection of the airway from aspiration. Equipment listed in Box 25-4 is assembled before intubation. The ETT can be inserted nasally or orally.

To reduce the incidence of complications, personnel with specialized training must perform tracheal intubation. The nurse explains rationale for the procedure to the patient and family. The patient is positioned on his or her back with a small blanket under the shoulder blades to hyperextend the neck and open the airway. Air is injected (10 mL) into the endotracheal cuff before insertion to ensure an intact cuff, and then the cuff is deflated.

The nurse's role in intubation includes patient assessment; monitoring vital signs, pulse oximetry, and intubation and suction equipment; and collaborating with additional support staff as needed.

Before the procedure, the nurse confirms that the suction is working properly. Using an MRB and mask, the nurse preoxygenates the patient. The physician may use topical anesthetics, sedatives, or a short-acting neuromuscular blocking (NMB) agent to facilitate rapid and nontraumatic

BOX 25-4 Equipment for Endotracheal Intubation

- Laryngoscope with curved and straight blades and intact bulb
- Suction setup with Yankauer suction
- Correct size endotracheal tube (ETT) with stylet*
- 10-mL syringe for cuff inflation
- Adhesive tape, twill tape, or commercial ETT holder
- Magill forceps (may be used with nasal intubation)
- Pulse oximetry
- Oxygen source
- Manual resuscitation bag (MRB) with mask
- End-tidal CO_2 ($ETCO_2$) monitor or disposable detector
- Sedation and paralytic medication

*In adults, tube size is usually 8.0 initially unless the procedure is difficult, the patient is small, or a difficult intubation is anticipated, in which case smaller sizes are used. An ETT larger than 7.0 mm facilitates bronchoscopy.

intubation. Newer short-acting intravenous (IV) anesthetics facilitate rapid intubation. Sedation with neuromuscular blockade must always be provided.

The nurse assists during intubation by providing suction as necessary and monitoring the patient's SaO_2 by pulse oximetry as well as the patient's heart rate and blood pressure. Intubation attempts should be withheld and the patient oxygenated with the MRB if the SaO_2 falls below 90%. Hypoxemia during intubation may cause bradycardia, hypotension, dysrhythmias, cardiac arrest, and other complications.

After placement of the ETT, the cuff is inflated. It is necessary to auscultate the chest bilaterally for equal breath sounds, which may indicate a right mainstem intubation, and the abdomen for evidence of esophageal intubation. Waterproof tape is used to secure the ETT, and the centimeter mark is noted at the lips, teeth, or nostril for the nasotracheal tube. The level of the ETT must be noted to prevent changing of position, which could result in either right mainstem bronchus placement with left lung collapse or self-extubation. A portable chest radiograph is obtained immediately after the insertion to confirm proper tube placement, which is about 2 to 3 cm above the carina.

Complications of ETT placement are noted in Box 25-5. Initially during intubation, complications of hypoxemia, gastric intubation, mainstem intubation, and oral or tracheal tissue damage can occur. Vomiting during the procedure can lead to aspiration, which may result in lung injury. If the patient has prolonged hypoxemia and hypercapnia (as might result with a difficult intubation), dysrhythmias such as bradycardia or tachycardia can occur, possibly leading to hemodynamic instability.

Once the patient is intubated, potential complications include disconnection, failure of the ventilator, tube obstruction, sinusitis, and tracheoesophageal fistula. Vocal cord paralysis or laryngeal or tracheal stenosis may present after extubation. Accidental extubation in a critically ill patient is a preventable complication. The most challenging cases involve confused patients who attempt to self-extubate. Orienting the patient to the need for the ETT and reassuring the patient that you will help make him or her more comfortable are the first interventions. Occasionally, physical or pharmacological restraints are necessary.

Many complications can be avoided by ensuring adequate fixation of the ETT, securing ventilator tubing properly, suctioning only as needed, and following other care maintenance protocols. These include providing oral care to remove secretions and maintaining the HOB elevated at 30 degrees to help prevent aspiration. Following aseptic policies decreases nosocomial infections, and maintaining proper cuff pressure helps prevent tracheal erosion. Ultimately, the long-term ventilated patient, intubated longer than 72 hours, may require a tracheostomy to continue ventilatory support and weaning.

BOX 25-5 PATIENT SAFETY

Complications of Intubation

- Laryngospasm/bronchospasm
- Hypoxemia/hypercapnia during intubation
- Laryngeal edema resulting in stridor with extubation
- Trauma/bleeding to nasal, oral, esophageal, tracheal, or laryngeal sites
- Fractured teeth
- Nosocomial infection (pneumonia, sinusitis, abscess)
- Displacement of tube (right mainstem intubation, gastric intubation)
- Aspiration of oral or gastric contents
- Tracheal stenosis/tracheomalacia
- Laryngeal damage, paralysis, and necrosis
- Dysrhythmias, hypertension, hypotension

Suctioning

The presence of an artificial tube prevents glottic closure. As a result, the patient is unable to use the normal clearing mechanism (ie, effective coughing). Additionally, the foreign object increases production of secretions. Suctioning, therefore, becomes paramount to removing secretions and maintaining airway patency. Suctioning is not without risks and should be done only when needed. Possible complications of suctioning are listed in Box 25-6. Indications for suctioning include observing secretions in the airway, identifying secretions or mucous plugs by chest auscultation, coughing, increasing peak airway pressure, decreasing tidal volume during pressure ventilation, or deteriorating oxygenation as noted by decreased SaO_2.

The procedure for suctioning is presented in Box 25-7. The nurse performs suctioning as a sterile procedure, using practices recommended by the Centers for Disease Control and Prevention (CDC). In-line suction catheters are available for use in patients on high levels of positive end-expiratory pressure (PEEP) who do not tolerate disconnection of the ventilator tubing for suctioning. Additionally, in-line suction catheters are used for patients with copious secretions requiring frequent suctioning and for those with grossly bloody secretions. Patients who are identified as having the potential for long-term mechanical ventilation and patients who have been reintubated following a failed extubation are candidates for the use of the continuous aspiration of subglottic secretions (CASS) ETT. This device is used to prevent the subglottic accumulation of secretions above the ETT cuff that may lead to aspiration and is discussed as part of the VAP section.

Hyperoxygenation and Saline Instillation

The patient must be hyperoxygenated using the ventilator set to 100% if an in-line system is used. Patients not on ventilators also need to be hyperoxygenated before suctioning. The patient should be instructed to take deep breaths while

BOX 25-6 PATIENT SAFETY

Complications of Suctioning

- Hypoxemia
- Dysrhythmias
- Vagal stimulation (bradycardia, hypotension)
- Bronchospasm
- Elevated ICP
- Atelectasis
- Tracheal mucosal trauma
- Bleeding
- Nosocomial infection

BOX 25-7 Procedure for Suctioning

Equipment

Sterile suction catheter*
Sterile gloves
Sterile normal saline for irrigation, only when indicated
Sterile disposable container

Technique

1. Perform routine procedures before suctioning: Administer medication, assemble equipment, explain the procedure to the patient, adjust bed to comfortable working position, prepare suction pressure, wash hands, prepare and open equipment and supplies, and don gloves.
2. Hyperoxygenate the patient with 100% oxygen using an MRB or the ventilator. If the ventilator method is used, preoxygenation must last at least 2 minutes. Return to the previous oxygen setting after suctioning is completed. In patients who do not tolerate suctioning with hyperoxygenation, a positive end-expiratory pressure (PEEP) attachment should be on the MRB at the appropriate setting, or in-line suctioning should be used to avoid loss of PEEP and desaturation.
3. Quickly but gently, insert the catheter as far as possible into the artificial airway without application of suction. For tracheostomy patients, limit the distance to just beyond the end of the tracheostomy device.
4. Withdraw the catheter 1 to 2 cm, and apply intermittent suction while rotating and removing the catheter. Limit suction pressure to 80 to 120 mm Hg. Aspiration should not exceed 10 to 15 seconds. (Prolonged aspiration can lead to severe hypoxemia, hemodynamic instability, and ultimately cardiac arrest.) Tracheostomy patients are usually suctioned for a briefer period of 3 to 5 seconds because of the very short device.
5. Do not instill sterile normal saline solution unless the patient has thick secretions and trial use has shown that it improves secretion removal. Routine instillation has been shown to decrease oxygenation and have other negative effects.[28–31]
6. Hyperoxygenate the patient before and after each subsequent pass of the catheter for at least 30 seconds, and before reconnection to the ventilator.
7. Monitor heart rate and rhythm and pulse oximetry during and after suctioning.
8. Discontinue the procedure if the patient does not tolerate it, as evidenced by dysrhythmias, bradycardia, or a drop in SaO_2.
9. Remove equipment.
10. Perform oral hygiene. Cleanse suction tubing with a water rinse to remove secretions into the suction container.
11. Wash your hands.
12. Document procedure.

*Suction catheter sized for either ETT or tracheostomy; with tracheostomy, the red rubber or more flexible suction catheter brand is used to prevent tracheal bleeding.

connected to a 100% oxygen source. Patients incapable of taking a deep breath should be assisted using an MRB with mask, timing a squeeze on the MRB with the patient's own breath. The presence of epiglottitis or croup is an absolute contraindication to any kind of suctioning of patients without an artificial airway as this may worsen the patient's condition.

The routine instillation of normal saline solution has become increasingly questionable. In a test tube, saline and sputum act as oil and water, and they do not form a mixture. Therefore, it is unlikely that saline instillation liquefies or increases the amount of sputum obtained during suction. In addition, instilling saline solution causes oxygenation to decrease and may predispose patients to nosocomial infection by transporting bacteria to lower airways.[10]

ETT care and cuff pressure monitoring are discussed in more detail later in this chapter, under Ventilatory Support, Assessment and Management beginning on page 537. After the patient is intubated, the patient loses the ability to communicate easily. This inability to communicate can become a major stressor during the ventilated period.

▲ Chest Tubes

The chest tube is a drain. Its purposes are to remove air, fluid, or blood from the pleural space; restore negative pressure to the pleural space; reexpand a collapsed or partially collapsed lung (pneumothorax); and prevent reflux of drainage back into the chest. Chapter 23 provides a review of the anatomical and physiological principles of the lungs and chest that helps explain how chest tube systems work.

Equipment

Equipment needed for chest tube insertion is listed in Box 25-8.

Most chest tubes are multifenestrated transparent tubes with distance and radiopaque markers. This enables the physician or other qualified health care professional to visualize the tube on chest radiograph and position it correctly in the pleural space. All openings in the tube must be placed within the rib cage to ensure that air leaks do not develop either in subcutaneous tissue or outside the chest wall. Chest tubes may be pleural or mediastinal, depending on distal tip location. Patients can have more than one tube in different locations, depending on the purpose of each tube.

Larger tubes (20 to 36 French) are used to drain blood or thick pleural drainage. Smaller tubes (16 to 20 French) are used to remove air.

Drainage Systems

To reestablish intrapleural negative pressure, a seal for the chest tube that prevents outside air from entering the system

BOX 25-8 Equipment for Chest Tube Insertion

- Chest tube tray or thoracotomy tray (with scalpel)
- Chest tube
- 1% lidocaine
- Syringe for lidocaine infiltration
- Topical antiseptic
- Sterile gloves
- Large curved hemostats
- Suture material (0-0 or 2-0 silk) on a cutting needle
- Bacteriostatic ointment or petrolatum gauze
- Sterile gauze with a slit
- Tape—both wide and narrow, or an occlusive dressing
- Chest tube drainage system and suction
- Sterile water for water seal systems
- Medication for pain and sedation

is required. The simplest way to accomplish this is to use an underwater system of drainage. A review of multichamber systems can provide a basis for understanding all the commonly used disposable drainage units. Knowledge of these systems enables the nurse to safely manage the most complex chest tube drainage setup. Modern chest drainage systems are composed of disposable materials and may be configured in either two- or three-chamber systems. The two-chamber system has a water seal and a collection chamber, whereas the three-chamber system adds a suction control chamber.

Two-Chamber System

In a two-chamber system, the first chamber is the collection receptacle and the second chamber is the water seal. In a disposable system that requires water, sterile water is added to the second chamber to the 2-cm level to achieve the seal. This level represents the negative pressure that is exerted on the pleural space as the water closes the chest drain to outside air, acting as a one-way valve. The water seal allows air to escape while preventing outside air from entering the pleural space. A fluid level higher than 2 cm H_2O exerts a greater negative pressure on the pleural space and may prevent resolution of the air leak. In addition, a higher column of water in the water seal chamber can make breathing more difficult because the patient has a longer column of fluid to move during respiration. Figure 25-4 depicts disposable chest drainage systems.

The patient's chest tube is connected to a 6-ft length of latex tubing that is attached to an outlet on the top of the drainage collection chamber. The second chamber (the water seal) has a vent that remains open, allowing air from the pleural space to escape as it bubbles through the water seal to the atmosphere. Except for the vented cap, the drainage system from the chest tube insertion site to the bottle is airtight.

The fluid level in the water seal fluctuates ("tidals") during respiration. During inspiration, pleural pressures become more negative, causing the fluid level in the water seal chamber to rise. During expiration, pleural pressures become more positive, causing the fluid level to descend. If the patient is receiving mechanical ventilation, this process is reversed. Bubbling should be seen only in the underwater seal chamber during expiration (or during inspiration with positive-pressure ventilation) as air and fluid drain from the pleural cavity. Constant bubbling indicates an air leak in either the system or a bronchopleural fistula; this is discussed further under Assessment and Management.

Three-Chamber System

In the three-chamber system, a suction control chamber is added to the two-chamber system. This is the safest way to regulate the amount of suction. In a disposable system that requires water, suction is achieved by adding water to the prescribed level in the suction chamber, usually −20 cm H_2O, and newer waterless suction systems adjust with a dial to the desired suction in centimeters of water.

In this system, it is the height of the water column in the third chamber, not the amount of wall suction, that determines the suction amount applied to the chest tube, most commonly −20 cm H_2O. Once the wall suction exceeds the force necessary to "lift" this column of fluid, any additional suction simply pulls air from a vented cap atop the chamber up through the water. The amount of wall suction applied to the third chamber should be sufficient to create a "gently rolling" bubble in the suction control chamber. Vigorous bubbling results in water loss through evaporation, changing suction pressure and increasing the noise level in the patient's room. It is important to assess for water loss and to add sterile water as necessary to maintain the prescribed level of suction. The bubbling should be assessed for gentle action, and the water level (−20 cm H_2O) is assessed every 8 hours and when the patient's clinical status changes.

Suction

Dry suction (waterless) systems use a spring mechanism to control the suction level and can provide higher levels of suction with easier setup. The dry suction systems can be easily adjusted for any setting between −10 and −40 cm H_2O and allow for safer use if the device is accidentally tipped over. If this happens, the drainage can be returned to the correct collection chamber without replacing the unit, resulting in cost savings. This system affords the patient a quieter environment. Dry suction systems that can deliver higher levels of suction may be necessary in patients with large bronchopleural fistulas, hemorrhage, or obesity.

The Emerson pleural suction pump may be used instead of wall suction. It can be set up using a two- or three-bottle system as well as a disposable chest drainage system. In contrast to the wall unit, the pressure-control knob on the front of the pump controls the suction generated. The amount of pressure is registered on the suction dial.

Heimlich valves are reserved for treating pneumothoraces on an outpatient basis or by emergency medical providers to treat blunt or penetrating chest trauma. The valve is composed of a small-bore chest tube attached to a one-way valve, which is enclosed in a plastic case. The one-way valve allows air to escape but not reenter the pleural space. The Heimlich valve is not appropriate for fluid removal.

Chest Tube Placement

If injury, surgery, or any disruption in the integrity of the lungs and chest cavity occur, placement of a chest tube is warranted. In addition, iatrogenic pneumothorax can occur in the ICU during thoracic central line placement, thoracentesis, high mechanical ventilation pressures, or cardiopulmonary resuscitation (CPR), or after transbronchial lung biopsy. Indications for chest tube placement are listed in Table 25-1.

Chest tube insertion can be accomplished in the operating room, in the emergency department, or at the bedside. Placement is based on the principle that, because of their different densities and weights, air rises and liquid sinks. The insertion site for air removal is near the second intercostal space along the midclavicular line. The insertion site for liquid drainage is near the fifth or sixth intercostal space on the midaxillary line. Fluid may occasionally become loculated (walled off), requiring ultrasound or computed tomography guidance for drainage tube placement. After heart surgery, placement can be in the mediastinum to drain blood from around the heart.

The nurse prepares the patient and family for the procedure, answering any questions they may have. The nurse also prepares the patient physically. Because parietal pleurae are

FIGURE 25-4 ▲ Chest tube drainage systems. **A:** The Atrium Ocean is an example of a water seal chest drain system composed of a drainage chamber and water seal chamber. The suction control is determined by the height of the water column in that chamber (usually 20 cm). (*A*, suction control chamber; *B*, water seal chamber; *C*, air leak zone; *D*, collection chamber). **B:** The Atrium Oasis is an example of a dry suction water seal system that uses a mechanical regulator for vacuum control, a water seal chamber, and a drainage chamber. (*A*, dry suction regulator; *B*, water seal chamber; *C*, air leak monitor; *D*, collection chamber; *E*, suction monitor bellows.) (Courtesy of Atrium Medical Corporation, Hudson, New Hampshire.)

Chest drainage units (CDUs) work with the same three chambers shown in the examples above. The collection chamber collects fluid with air passing through, the water seal prevents air going back into the patient, and a suction control chamber allows suction level settings depending on the medical condition. A collection chamber allows fluid volume up to 2,000 mL. This allows for assessment of type of drainage, amount of drainage, and rate changes, with some models having a sampling port. The water seal chamber is the one-way valve action that prevents air from returning to the chest while allowing air removal as in pneumothorax. The water seal chamber is filled to the –2 cm H_2O level that maintains a slight negative pleural pressure and prevents air entering the pleural space when the CDU is off suction and on water seal. The suction control chamber is either the dry suction or a water-filled chamber. Water-filled suction is set by adjusting the water level. With continuous high suction, evaporation occurs, changing the volume of water that will change the suction level. Nursing care includes assessing the water level daily with suction off to refill the chamber to the desired level. Dry suction uses a mechanical system that allows the set suction level to be maintained regardless of the external suction level applied. The bellow window on dry suction systems allows a visual check that correct suction is applied; the colored indicator rises when sufficient suction is applied to maintain the set suction level from –10 to –40 cm H_2O. The wall suction regulator should be adjusted to –80 mm Hg, with a continuous gentle bubbling in the water seal chamber. All CDUs follow these same functions of collection, water seal, and suction regulation chambers, and the nurse adheres to manufacturer instructions concerning proper setup and monitoring of the system.

Table 25-1 Indications for Chest Tube Placement

Indication	Cause
Hemothorax	Chest trauma Neoplasms Pleural tears Excessive anticoagulation Postthoracic surgery/open lung biopsy
Pneumothorax	
Spontaneous: >20%	Bleb rupture Symptomatic patient Presence of lung disease
Tension	Mechanical ventilation Penetrating puncture wound Prolonged clamping of chest tubes Lack of seal in chest tube drainage system
Bronchopleural fistula	Tissue damage Tumor (esophageal cancer) Aspiration of toxic chemicals Boerhaave's syndrome (spontaneous rupture)
Pleural effusion	Neoplasms Cardiopulmonary disease, congestive heart failure Inflammatory conditions Recurrent infections/pneumonia
Chylothorax	Trauma or thoracic surgery Malignancy Congenital abnormalities

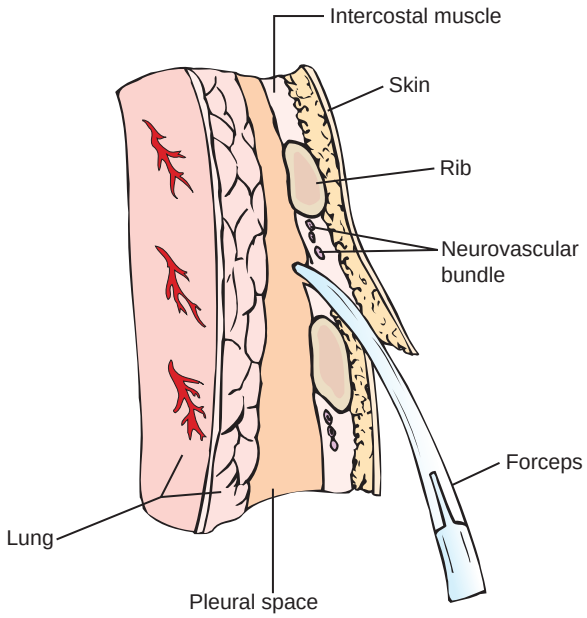

FIGURE 25-5 ▲ Forceps penetrate the pleural space and are spread to create a track within the pleural space for the chest tube to be positioned. A gloved finger may also be used to create this track.

innervated from the intercostal and phrenic nerves, this is a painful procedure, and administration of analgesics is indicated. The patient is placed in Fowler's or semi-Fowler's position. After the skin has been cleaned and anesthetized, the physician or other qualified health care professional makes a small skin incision. A hemostat is used to penetrate the pleural space (Fig. 25-5). The tract made by the hemostat is then dilated with a sterile, gloved finger. The proximal end of the tube is clamped with the hemostat and then inserted into the pleural space. If the placement is difficult, a metal trocar can be used to penetrate the chest wall, leaving the tube in place and removing the trocar.

After insertion, the external end of the tube is connected to a chest drainage unit (CDU). It is important to remember that the ends of both the chest tube and the drainage system tubing must remain sterile as they are connected. To prevent the tube from dislodging, the tube is sutured to the skin around the insertion site. The ends of the suture are wrapped around the tube and tied off. Bacteriostatic ointment or petrolatum gauze can be applied to the incision site. Petrolatum gauze has been preferred because it is thought to prevent air leaks; however, it also has the potential to macerate the skin and predispose the site to infection. A 4″ × 4″ drain sponge is positioned over the tube and taped occlusively to the chest. All connections from the insertion site to the drainage collection system are securely taped to prevent air leaks as well as inadvertent disconnection. The proximal tube is taped to the chest to prevent traction on the tube and sutures if the patient moves.

A postinsertion chest radiograph is always ordered to confirm proper positioning. The lungs are auscultated, and the condition of the tissue around the insertion site is evaluated for the presence of subcutaneous air. This assessment provides a baseline for determining improvement or worsening of the patient's condition. Daily chest radiographs may be necessary to assess the clinical picture. Pain management continues to be an issue throughout the duration of chest tube use. Narcotics, nonsteroidal anti-inflammatory drugs, or a lidocaine transcutaneous patch may help reduce pain. The application of a lidocaine-infused patch proximal to the incision or at the chest tube incision site, which slowly releases medication over 12 to 24 hours, is an additional pain relief tool. Dressings are changed per institutional protocol, or as needed if soiled or loose. It is necessary to assess chest tube output every 2 hours, looking for sudden cessation or increase to greater than 200 mL/h or a sudden change in the character of the drainage.

Chest tubes are removed after drainage is minimal and 12 to 24 hours after the chest tube is on water seal as ordered by the health care practitioner. Placement to water seal only (without suction) identifies persistent air leaks or reaccumulation of fluid with a repeat chest radiograph. Other indications for removal of the chest tube are listed in Box 25-9. When the tube is connected to water seal, disconnect the suction tube to facilitate atmospheric venting. Premature clamping or removal of the tube may cause reaccumulation of the pneumothorax.

Before removing the chest tube, the patient is placed in a Fowler's or semi-Fowler's position (head of bed elevated 45 to 90 degrees). Premedication is recommended to alleviate pain and discomfort. The dressing over the insertion site is removed, and the area is cleaned. The suture is clipped. The tube is removed in one quick movement at peak inspiration or during expiration to prevent entraining air back into the

BOX 25-9 Indications for Chest Tube Removal

- One day after cessation of air leak
- Drainage of less than 50 to 100 mL of fluid/d
- One to three days after cardiac surgery
- Two to six days after thoracic surgery
- Obliteration of empyema cavity
- Serosanguineous drainage from around the chest tube insertion site
- Chest tube partially migrated out with holes visible (may require a new chest tube insertion)

pleural cavity through the chest tube eyelets. Immediately after tube removal, the lung fields are auscultated for any change in breath sounds, and an occlusive sterile dressing is applied over the site. A chest radiograph is usually obtained several hours later to look for the presence of residual air or fluid.

Assessment and Management

Nursing care is directed at maintaining patency and proper functioning of the chest tube drainage system. Vigilant and expert nursing care can prevent serious complications in the patient with a chest tube and drainage system. The latex tubing is frequently drained into the collection container. Coiling the latex tubing loosely on the bed prevents kinks and pooling of blood or drainage in a dependent loop hanging on the floor. Ensure that the patient does not inadvertently lie on the tubing. The chest tube drainage system is never raised above the chest or the drainage will back up into the chest. At frequent intervals, check the chest tube drainage system for drainage, suction level, and water seal integrity. The system should be secured to the foot of the patient's bed or taped to the floor to avoid accidental overturning and possible reaccumulation of the pneumothorax. Inspect all tubing connections for leaks, and secure them with tape to prevent accidental disconnection.

To check for chest tube patency and respiratory cycle fluctuations, it is necessary to momentarily disconnect the suction (system placed only to water seal—not clamped). A step-by-step system can be used to evaluate and troubleshoot the system:

1. Assess cardiopulmonary status and vital signs every 2 hours and as needed.
2. Check and maintain tube patency every 2 hours and as needed.
3. Monitor type and amount of drainage.
4. Mark amount of drainage on collection chamber in hourly or shift increments and document in output record.
5. Prevent dependent loops from forming in tubing; ensure that the patient does not inadvertently lie on the tubing.
6. Refill water systems with sterile water to the water seal level and prescribed suction level (secondary to evaporation).
7. Assess for "tidaling" in the water seal chamber with respiration or mechanical ventilation breaths.
8. Assess for the location of air leaks (constant bubbling in the water seal chamber). Turn off the suction. Begin at the insertion site; occlude the chest tube or drainage tube (briefly) below each connection point until the drainage unit is reached.
9. Check that all tubing connections are securely sealed and taped. Another technique for sealing the connections is to use a banding gun that secures a plastic loop around the connections to prevent air leakage.[11]
10. Assess the patient for pain and medicate as needed.
11. Assess the actual chest tube insertion site for signs of infection and subcutaneous emphysema with dressing changes.
12. Change the dressing twice daily or per unit guideline, when soiled, and when ordered.

Drainage Monitoring

The nurse assesses and documents the color, consistency, and amount of drainage while remaining alert to significant changes. A sudden increase indicates hemorrhage or sudden patency of a previously obstructed tube. A sudden decrease indicates chest tube obstruction or failure of the chest tube or drainage system. The following nursing actions are recommended to reestablish chest tube patency:

- Attempt to alleviate the obstruction by repositioning the patient.
- If the clot is visible, straighten the tubing between the chest and drainage unit and raise the tube to enhance the effect of gravity.

Studies suggest that milking and stripping techniques may not be beneficial for maintaining chest tube patency.[11]

These techniques may excessively increase intrapleural and intrapulmonary pressures, affecting ventricular function or causing trauma from aspiration of lung tissue into chest tube eyelets. However, under health care practitioner direction, this procedure may be necessary in cases of active bleeding to prevent blood clotting in the tubing that could lead to cardiac or pleural tamponade.

Water Seal Monitoring

Monitoring the water seal of the chest tube drainage system is as important as observing the drainage. Visual checks are made to ensure water seal chambers are filled to the 2-cm water line. If suction is applied, the nurse ensures that the water line in a water-controlled suction chamber is at the ordered level (usually −20 cm H_2O) because water evaporates over time, decreasing the amount of suction being applied. It is important to add only sterile water to the system. If an Emerson pleural suction pump is used, the nurse checks the suction gauge for the desired suction level. It is essential that the air vent opening is never occluded. The suction tubing is disconnected briefly to accurately assess the water level in the chamber (water suction control) only after clamping the tubing. Then, the tubing is reattached and the clamp opened. The tubing should never be left clamped because this can result in pneumothorax or buildup of fluid in the chest, leading to respiratory distress.

Respiratory fluctuations are observed in the water seal chamber. The absence of fluctuations can indicate that the lung is reexpanded or that there is an obstruction in the system. Continuous vigorous bubbling in the water seal chamber, without suction, indicates continued pneumothorax, or it can indicate the tube has been displaced or disconnected, or the drainage system is damaged. It is necessary to check

the entire system for disconnections and to inspect the chest tube to see if it is displaced outside the chest. In the setting of mechanical ventilation at high volumes and pressures, bubbling in a chest tube system that persists may indicate a bronchopleural fistula when there is no pneumothorax or other known cause.

Positioning

The ideal position for a patient with a chest tube is semi-Fowler's. Turning the patient every 2 hours enhances air and fluid evacuation. The nurse teaches patients how to support or "splint" the chest wall near the tube insertion site using a pillow, bath blanket, or their arms placed firmly against the chest. The nurse also encourages coughing, deep breathing, and ambulation. Administration of pain medication before these exercises decreases pain and enhances lung expansion.

Complications

The most serious complication resulting from chest tube placement is tension pneumothorax, which can develop if there is any obstruction in the chest tube drainage system. Clamping chest tubes as a routine practice predisposes patients to this complication. Clamping of chest tubes is recommended in only two situations:

- To locate the source of an air leak if bubbling occurs in the water seal chamber (*clamping is only momentary*)
- To replace the chest tube drainage unit (*clamping is only momentary*)

If the tube must be clamped, padded hemostats are used to avoid lacerating the vinyl chest tube.

Occasionally, the chest tube may become dislodged or be accidentally removed. In such a circumstance, the insertion site is quickly sealed off using petrolatum gauze covered with dry gauze and occlusive tape dressing to prevent air from entering the pleural cavity.

Transporting the Patient With Chest Tubes

As in any transport situation for critically ill patients, constant assessment is necessary to prevent inadvertent chest tube removal, resulting in recurrent pneumothorax. Maintain chest drainage system integrity by positioning the drainage system below the level of the chest. Secure the system to the foot of the bed, and ensure that the tubing does not become crushed or kinked. If the system requires suction to evacuate the pleural space, then portable suction must be implemented. The nurse performs frequent assessment of the patient and the drainage system per unit guidelines as needed to check for air leaks, dressing integrity, water seal integrity, water level, and drainage.

▲ Pharmacological Agents

Bronchodilator Therapy

Asthma is characterized by recurrent airway inflammation and increased hypersensitivity to a wide range of stimuli (noxious fumes and gases, air pollutants, animal dander, extreme cold, and exercise). The hypersensitivity leads to hyperreactivity of the airways with obstruction, with widely variable symptoms even in the same person. Asthma is an episodic disease with recurrent exacerbations and periods without symptoms. Management goals include symptom control to maintain normal activities, prevention of exacerbations, and minimization of pharmacological side effects and toxicity. Pharmacological therapy is designed around multiple classes of drugs and is aimed at reducing inflammation, treating acute symptoms, and maintaining a plan for the short- and long-term therapy. Bronchospasm may also be present in COPD and can be treated with the same pharmacological agents.

Delivery of agents typically has been by propellant inhalers, with dosage dependent on the number of puffs per treatment using a metered-dose inhaler (MDI). The breath, depth, inspiratory flow rate, and use of a spacer (vs. administering just into the mouth) create variable medication delivery. Cleaning and proper fitting together of the actuator to the valve stem, and onto a spacer (if used), are necessary. The preferred MDI method involves using a spacer—a tube attached to the inhaler to hold the medication until it is breathed in by the patient. In many patients, this makes MDIs easier to use and deposits medications into the lungs better. Dry powder inhalers (DPIs) allow some asthma medications to be taken in a dry powder form. The difference between DPIs and MDIs is that DPIs do not use a propellant, only a medication. Patient inhalation ensures delivery into the lungs. Patients must practice the proper use of these devices, maintain consistent inspiratory flow, and consistently use a spacer or aim the device directly into the mouth to achieve consistent medication dosage. Patients may range in age from 5 years to elderly, although they must be able to inhale forcefully enough to breathe in the medication. As with MDIs, patients need training to follow the directions and process for each form of DPI inhaler.

The Diskus inhaler is a version of the DPI. Usually, it contains a set number of metered doses, such as a long-acting β_2-agonist (eg, Serevent) or the newer combination of Flovent and Serevent called Advair. The Diskus type of medication is used for asthma control and not for an acute asthma attack because the medication is long acting for daily use. A spacer is not used with the Diskus inhaler. The patient has to breathe in deeply and steadily, hold the breath for up to 10 seconds, and then slowly exhale. With the Diskus inhaler, it is important to point out that the mouthpiece should never be washed in water and that the inhaler should not be placed in water. In addition, the patient does not breathe into the Diskus before inhaling.

Bronchodilators

Bronchodilators act principally to dilate the airways by relaxing bronchial smooth muscles. The goals of bronchodilator therapy are to relax the airways, mobilize secretions, and reduce mucosal edema. Bronchodilator therapy can be delivered through MDIs, preferably with a spacer attachment, or nebulization. Regardless of the mode of delivery, assessment before, during, and after the therapy is essential.

Assessment before and after treatment includes breath sounds, pulse, and respiratory rate. The last two commonly increase during bronchodilator therapy and can remain

elevated for as long as 1 to 1.5 hours after treatment. (In people with asthma, measurement of peak expiratory flow rate with a peak flow meter before and after a treatment measures the improvement in severity of airway obstruction.) Objective evaluation is crucial, but subjective information is also valuable. Evaluation of patient response should be ascertained by asking about improvement in breathing, presence of wheezing, and side effects, such as tremor or palpitations.

Bronchodilators may be divided into three categories based on their mechanism and site of action. These are β_2-adrenergic agonists, anticholinergic agents, and methylxanthines.

β_2-Adrenergic Agonists

The bronchodilator effects of β-adrenergic agonists result from the stimulation of β_2-adrenergic receptors in the lung bronchial smooth muscle. In addition, these agents may decrease the release of mediators from mast cells and basophils. β_1-Adrenergic receptors in the heart may also be stimulated and lead to undesired cardiac effects. Newer β-agonists are more specific for the β_2-receptor, although they retain some β_1 activity.

β-Agonists may be administered orally or inhaled. Aerosolized or inhaled therapy is preferred and has been shown to produce comparable bronchodilation and fewer systemic adverse effects.

β-Agonists are the bronchodilators of choice for treating acute exacerbation of asthma because of their rapid onset of action. They produce less bronchodilation in patients with COPD than in those with asthma. Albuterol (2.5 to 5 mg diluted in 3 mL normal saline solution) is the bronchodilator of choice in the acute setting and may be administered by continuous or intermittent frequent nebulization (every 15 to 20 minutes) then scheduled on an "as-needed" basis depending on patient response. Until recently, all available inhaled β-agonists, such as albuterol, had short durations of action (4 to 6 hours). Salmeterol is the first long-acting β-agonist, with duration of action of 12 hours. Salmeterol cannot be used for acute exacerbations of asthma because of its slow onset of action. The medication DuoNeb combines albuterol and ipratropium, allowing for a synergistic effect of both a bronchodilator and an anticholinergic agent, as discussed later. In addition, Advair Diskus combines a long-acting β_2-adrenergic agonist, salmeterol, with fluticasone propionate, an inhaled corticosteroid, to provide twice-daily dosing for patients who do not achieve adequate control using other asthma medications.

Anticholinergic Agents

Anticholinergic agents produce bronchodilation by reducing intrinsic vagal tone to the airways. They also block reflex bronchoconstriction caused by inhaled irritants.

Atropine is the prototype anticholinergic agent but is used infrequently. It is readily absorbed from the respiratory tract but produces unwanted systemic effects (eg, blurred vision, drying of respiratory secretions, tachycardia, and anxiety). Ipratropium, a quaternary amine that is not well absorbed from the respiratory tract, produces fewer systemic adverse effects and has taken the place of atropine. It is most effective in patients with COPD when used on a regular basis. It decreases submucosal gland secretion and relaxes bronchial smooth muscle. Ipratropium should not be used alone in acute exacerbations because of its slower onset of effect compared with β-agonists. It has been shown to be effective during status asthmaticus when administered through a nebulizer in combination with β-agonists as in DuoNeb.

Methylxanthines

Using methylxanthines for treating bronchospastic airway disease is controversial. The agents' mechanism of action is poorly understood. They inhibit phosphodiesterase, an enzyme that catalyzes the breakdown of cyclic adenosine monophosphate. They may also possess some degree of anti-inflammatory activity and may augment respiratory muscle contractility.

Theophylline, the prototype methylxanthine, may be used chronically in treating bronchospastic disease but is usually considered third- or fourth-line therapy. Some patients with severe disease that is not controlled with β-agonists, anticholinergics, or anti-inflammatory agents may benefit from theophylline. Aminophylline, the IV form of theophylline, is rarely used in acute exacerbations because of the lack of evidence that it is beneficial in this situation.

Theophylline has a narrow therapeutic index. Depending on the clinical situation, serum drug concentration should be monitored to ensure efficacy and prevent toxicity. The accepted therapeutic range is 10 to 20 mcg/mL, although some references use 5 to 15 mcg/mL.[12] Theophylline interacts with a variety of other medications that may alter its serum concentration. These include erythromycin, ciprofloxacin, and cimetidine. Patients with liver disease or congestive heart failure eliminate theophylline more slowly and may be at an increased risk for toxicity. The level should be monitored 12 to 24 hours after the loading dose is administered and frequently as clinical condition and liver and renal function dictate.

Anti-Inflammatory Agents

Anti-inflammatory agents interrupt the development of bronchial inflammation and have a prophylactic or preventive action. They may also reduce or terminate ongoing inflammation in the airway. Anti-inflammatory agents include corticosteroids, mast cell stabilizers, and leukotriene receptor antagonists.

Corticosteroids

Corticosteroids are the most effective anti-inflammatory agents for treating reversible airflow obstruction. Corticosteroid therapy should be initiated simultaneously with bronchodilator therapy because the onset of action may be 6 to 12 hours. They may be administered parenterally, orally, or as aerosols. In acute exacerbations, high-dose parenteral steroids (eg, IV methylprednisolone) are used and then tapered as the patient tolerates. Short courses of oral therapy may be used to prevent the progression of acute attacks. Long-term oral therapy is associated with systemic adverse effects and should be avoided if possible. If necessary, the chronic use of inhaled corticosteroids, such as fluticasone (Flovent) or budesonide (Pulmicort), is preferred because of the decreased risk for systemic adverse effects.

Mast Cell Stabilizers

The two available mast cell stabilizers are cromolyn and nedocromil. They are thought to stabilize the membrane and prevent the release of mediators from mast cells. These agents are not indicated for acute exacerbations of asthma because they are used *prophylactically* to prevent acute airway narrowing after exposure to allergens (eg, exercise, cold air). A 4- to 6-week trial may be required to determine the efficacy in individual patients. The desired endpoint is to reduce the frequency and severity of asthma attacks and enhance the effects of concomitantly administered bronchodilator and steroid therapy. As a result, it may be possible to decrease the dose of bronchodilators or corticosteroids in patients who respond to mast cell stabilizers.

Leukotriene Receptor Antagonists

Leukotriene receptor antagonists, such as montelukast, may be used in managing exercise-induced bronchospasm, asthma, allergic rhinitis, and urticaria. These agents block the activity of endogenous inflammatory mediators, particularly leukotrienes. These mediators cause increased vascular permeability, mucous secretion, airway edema, bronchoconstriction, and other inflammatory cell process activities. Leukotriene receptor antagonists are administered once daily and are usually well tolerated. They are not to be administered for acute conditions but as a part of an ongoing program of therapy.

Cystic Fibrosis Agent (DNase)

DNase is used in cystic fibrosis patients to break down molecules in tenacious secretions to facilitate expectoration as well as decrease the amount of medium for bacterial growth. This also improves gas flow through airways. It is administered in an inhaled form either daily or twice daily.

Antibiotics

Pneumonia is often treated empirically until the results of cultures and sensitivities are available. Then, the antibiotic regimen is tailored to eradicate the specific pathogenic organism (Table 25-2). Commonly, broad-spectrum antibiotics or combination therapy is used. The critically ill patient is at increased risk for developing pneumonia due to mechanical ventilation, decreased immune responses, use of corticosteroids, debilitated general health, and cross-infection by health care workers. Antibiotic therapy should be driven by institutional protocols to prevent antibiotic overuse and following guidelines for antimicrobial selection to limit resistance.

Empiric therapy for community-acquired pneumonia includes therapy directed toward the most common organisms associated with this type of pneumonia. These organisms include *Streptococcus pneumoniae* and *Haemophilus influenzae*. Methicillin-resistant *Staphylococcus aureus* should be suspected in patients admitted to the hospital from a nursing home. *Legionella* species should be suspected in patients with severe multilobar pneumonia. Patients infected with the human immunodeficiency virus require empiric treatment if there is suspected *Pneumocystis jiroveci* pneumonia, previously referred to as *Pneumocystis carinii* pneumonia.

Hospital-acquired pneumonia (HAP) or health care–associated pneumonia is often associated with Gram-negative bacilli, such as *Pseudomonas aeruginosa*, or it may be polymicrobial. HAP is the term for pneumonia that develops at least 48 hours after hospitalization; formerly, it was known as nosocomial pneumonia, and it includes VAP. Aspiration is a concern in mechanically ventilated patients or patients unable to protect their airway. Aspiration pneumonia is associated with anaerobic organisms (eg, *Actinomyces* species). Atypical organisms (*Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *Legionella* species) should also be considered, as should viral infection. Patients should have a quantitative sputum culture to identify species on admission, and they may require bronchoscopy for specimen collection.

Consensus guidelines for pneumonia management are constantly under revision. The causes of pneumonia may stem from multiple factors and these must be taken under consideration when treating the critically ill patient. Because of the prevalence of multi-drug resistance and evolving antibiotic regimens, priority must be placed on obtaining a sputum culture and defining the susceptibility of the organism to several antibiotics. This will further ensure appropriate antibiotic use.

Table 25-2 Antibiotic Therapy in Pulmonary Disease

Pulmonary Infection	Empiric Therapy
Community-Acquired Pneumonia (CAP)	
Outpatient	Macrolide or doxycycline. If cardiac disease gives beta-lactamase inhibitor and either a macrolide or doxycycline
Hospitalized with CAP	Beta-lactamase inhibitor and either a macrolide or doxycycline
Methicillin-resistant *Staphylococcus aureus* pneumonia	Vancomycin, linezolid, or anti-staphylococcal penicillin. Adjust dose for weight and renal function
Legionella pneumonia	Fluoroquinolone, azithromycin or doxycycline
Pneumocystis jiroveci pneumonia	Sulfa drug; adjust dose for renal function Prednisone if acutely ill
Hospital-acquired (nosocomial) pneumonia	Antipseudomonal quinolone in addition to a beta-lactamase inhibitor or carbapenem
Anaerobe (aspiration)	Beta-lactam or carbapenem
Mycoplasma pneumoniae	Macrolide, a tetracycline or fluoroquinolone

Sedative Agents

Critically ill patients frequently require pharmacological intervention for analgesia, sedation, control of anxiety, and facilitation of mechanical ventilation. The selection of appropriate pharmacological agents is based on the cause of the agitation (Box 25-10), underlying illness, possible adverse effects, history of previous drug use, and cost. Agents most commonly used in the ICU include opiates, benzodiazepines,

haloperidol (Haldol), and propofol (Diprivan). Specifically, haloperidol is recommended for patients with delirium, and opiates are used synergistically to treat pain.

Several agents can be given as bolus doses, by continuous infusion, or by using a combination of the two approaches, although some drugs, such as haloperidol, are limited to bolus dosing. When administering these agents by continuous infusion, it is important to monitor the patient's response closely and adjust the dose to meet his or her individual needs. This is best accomplished by using an objective sedation rating scale for consistent assessment and documentation of the medication's efficacy. Such a protocol can help prevent the prolonged use of these agents and can lower the cumulative amount required for the control of pain or agitation. This can contribute to a decreased length of hospital stay and decreased length of mechanical ventilation.

When using a continuous infusion, if an increase in dosage is necessary, an additional small bolus dose should be given to facilitate rapid increase to the new desired blood level. To prevent withdrawal symptoms, dosages given to patients who have received large amounts of opiates or benzodiazepines for 2 or more weeks must be tapered gradually. For example, the dose may be decreased by 25% a day. Some protocols promote the conversion of benzodiazepine infusions to the enteral route before stopping the infusion. Enteral administration is performed to maintain an appropriate level of sedation and to wean patients who have required prolonged sedation, usually over 7 days. Protocols that include daily tapering or weaning of infusions along with daily sedation interruption are recommended. Another method of nurse-controlled monitoring, bispectral index monitoring, has been studied and found to be useful for controlling sedation in critically ill patients who are receiving sedation.[13]

Neuromuscular Blocking Agents

If metabolic demands and work of breathing continue to compromise ventilatory or hemodynamic stability after maximization of sedation, NMB agents may be required. The goal of therapy with NMB agents is to maximize oxygenation and prevent complications such as barotrauma (alveolar rupture that can result in death), which can be caused by high ventilatory pressures.

The use of NMB agents is usually required if the pressure-controlled inverse ratio mode of ventilation is used. NMB drugs do *not* possess analgesic or sedative properties. When NMB agents are used, sedation and analgesia are required, along with patient and family education. Do not leave a chemically paralyzed patient unattended.

Recent reports of prolonged paralysis following use of NMB agents have prompted many institutions to initiate protocols for instituting, monitoring, and withdrawing these drugs. These range from the use of peripheral nerve stimulators to assess the level of neuromuscular blockade to the routine daily discontinuation of NMB agents to assess neurological status and the need for continued administration.

Commonly used NMB agents are vecuronium (Norcuron), atracurium (Tracrium), and cisatracurium (Nimbex). Each has advantages and disadvantages related to concomitant drug effects, underlying illness, and cost. Both atracurium and cisatracurium have fewer side effects than other NMB agents. Both atracurium and cisatracurium are useful for patients with renal failure because metabolic breakdown of the drugs is in the plasma independent of renal or hepatic function. These two NMB agents are eliminated by ester hydrolysis and Hoffman elimination in the plasma, which is a spontaneous nonenzymatic degradation that is optimal with physiological pH and temperature. Atracurium and cisatracurium may have prolonged duration in the setting of acute acidosis or hypothermia. Atracurium and cisatracurium are good for patients with multisystem organ failure because the other NMB drugs may have more prolonged effects with both renal and hepatic failure than these two. Cisatracurium is less prone than atracurium to trigger histamine release.

▲ Ventilatory Support

When a patient is unable to maintain a patent airway, adequate gas exchange, or both, despite aggressive management with the interventions discussed previously, more invasive support with intubation and mechanical ventilation must be considered. This step carries its own risks and imposes significant physical and psychological burdens on the patient and family. Every effort should be made to avoid mechanical ventilation, but it is usually necessary at the point when respiratory distress becomes respiratory failure.

Respiratory failure is defined as the inability to maintain adequate respiration as measured by arterial blood pH, $PaCO_2$, and PaO_2. Respiratory failure may be categorized as hypoxemic or hypoxemic hypercapnic. Hypoxemic respiratory failure is when PaO_2 is less than 60 mm Hg. Hypoxemic hypercapnic respiratory failure is when PaO_2 is less than 60 mm Hg and $PaCO_2$ exceeds 55 mm Hg. If the ABG values deteriorate beyond these parameters, mechanical ventilatory support is often indicated. Patients are predisposed to developing acute respiratory failure if any of the systems involved in respiration are compromised or overwhelmed (Table 25-3). The degree of risk for developing respiratory failure depends on the patient's ability to move air, secretions, and oxygenated blood. The nurse plays a key role in recognizing the onset of acute respiratory failure.

Table 25-3 Possible Events Leading to Respiratory Failure

Body System	Event
Nervous system	Head trauma
Brainstem	Poliomyelitis
Spinal cord and nerves	Cervical (C1–C6) fractures
	Overdose
Muscular system	
Primary—diaphragm	Myasthenia gravis
Secondary—respiratory	Guillain-Barré
Skeletal system	Flail chest
Thorax	Kyphoscoliosis
Respiratory system	Obstruction
Airways	Laryngeal edema
	Bronchitis
	Asthma
Alveoli	Emphysema
	Pneumonia
	Fibrosis
Pulmonary circulation	Pulmonary embolus
Cardiovascular system	Congestive heart failure
	Fluid overload
	Cardiac surgery
	Myocardial infarction
Gastrointestinal system	Aspiration
Hematological system	Disseminated intravascular coagulation
Genitourinary system	Renal failure

Identification of high-risk patients, serial monitoring and evaluation of respiratory status, and institution of appropriate measures may forestall or negate the need for ventilatory assistance. Before intubation and ventilation, the patient may have required increased FiO_2 to meet his or her oxygen demand.

When ventilatory assistance is required, the objective of mechanical ventilation is to support the patient through an episode of illness. Clinical goals of mechanical ventilation may include reversal of hypoxemia; reversal of acute respiratory acidosis; relief of respiratory distress; prevention or reversal of atelectasis; resting of ventilatory muscles; reduction in systemic oxygen consumption, myocardial oxygen consumption, or both; reduction in intracranial pressure (ICP); and stabilization of the chest wall. Mechanical ventilation is not curative and can actually cause complications (as discussed later in this chapter).

Physiological Principles

To understand the effects of modern mechanical ventilation, the reader is encouraged to review the physiology of normal respirations and lung compliance, as discussed in Chapter 23. The relationship between intrapulmonary pressures during inspiration and expiration is reversed during mechanical ventilation. The ventilator delivers air by pumping it into the patient; therefore, pressures during inspiration are positive. The positive pressure pumped into the lungs results in increased intrathoracic pressures and decreased venous return during inspiration. With the institution of PEEP, even greater pressures are generated during inspiration. During expiration, the pressure in the lungs decreases to the "baseline" PEEP level and continues to be positive throughout expiration. Most patients compensate for this hindrance to venous return by increasing peripheral venous tone. If conditions of decreased sympathetic response (eg, hypovolemia, sepsis, heart disease, drugs, or older age) are present, hypotension may develop. In addition, a large tidal volume (>10 to 12 mL/kg) that generates pressures greater than or equal to 35 cm H_2O not only reduces cardiac output but also increases the risk for pneumothorax.

Positive pressure can result in barotrauma. Barotrauma occurs when air leaks from the alveoli into the pleural space; this is called a pneumothorax. Another form of lung injury is called volutrauma and is caused by delivery of large tidal volumes in patients with stiff, noncompliant lungs. With volutrauma, the alveoli develop fractures that allow fluid and protein to seep into the lungs. This phenomenon is a form of noncardiogenic pulmonary edema. Lung damage from either barotrauma or volutrauma can increase mortality, especially in susceptible patients (such as those with asthma or ARDS). To prevent lung injury, it is important to determine lung compliance so that the ventilator can be appropriately adjusted to minimize airway pressures.

Ventilator-associated lung injury (VALI) and *ventilator-induced lung injury* (VILI) are terms used to describe the damage to lungs from prolonged ventilation. Other causes of VALI and VILI are volutrauma resulting from the overexpansion of alveoli with high ventilation pressures and atelectrauma, which is shear-induced injury from the repeated opening and closing of alveoli. In addition, prolonged high levels of FiO_2, high volumes and pressures leading to the loss of surfactant as well as inflammation of the lung tissue and alveoli, and the primary injury of pneumonia or aspiration result in lung injury while the patient's ventilator is on settings that lead to damage of the lung tissue. Vulnerable patients with ALI or ARDS may be more prone to VALI and VILI. The medical community in the United States has developed a research system to study the diagnosis and treatment of ARDS known as ARDSNet.[14] The ARDSNet protocols for protecting the lungs (from VALI and VILI) when the patient is on mechanical ventilation have recommended the following:

- Keep the plateau pressures at 30 cm H_2O or less.
- Reduce the FiO_2 to 50%.
- Maintain V_T at 5 to 6 mL/kg ideal body weight or less.
- Maintain PEEP to avoid collapse of alveoli at the end of expiration.[15]

Compliance

Compliance refers to the ability of the lung to distend. In terms of its compliance, the lung is frequently compared to a balloon. Initially, it is difficult to inflate (noncompliant) until it is stretched. After repeated inflations, this elastic resistance is lost (overly compliant), and the balloon becomes very easy to blow up. In conditions that reduce the lung's elasticity, such as inflammation, fibrotic changes, or edema, the lung requires more force to inflate. A patient who has

BOX 25-11 Factors Decreasing Compliance

Airway Factors
Peak flow
Size of airways
Airway obstructions
External obstructions (kinked ventilator tubing or water in the tubing)

Lung Factors
Elasticity (stiffness) of the lung
Presence of auto-PEEP
Shunt (ARDS)

Chest Wall Factors
Chest wall deformities
Position of patient
External compression of chest wall or diaphragm (distended abdomen, obesity)

normal lungs and who is on a ventilator should have compliance near 100 mL/cm H_2O (normal). In contrast, a patient who has pulmonary disease and who is on a ventilator that causes "stiff" lungs (eg, ARDS, sarcoidosis) has a compliance as low as 20 to 30 mL/cm H_2O, indicating a severely compromised lung.

As the volume of gas is delivered to a patient on a mechanical ventilator, the ventilator's pressure gauge slowly rises from zero to peak inspiratory pressure (PIP). The rise in pressure is caused by airway resistance (to flow) as well as by lung and chest wall compliance (Box 25-11). A graph of pressure over time, depicting inspiration, would look like the example shown in Figure 25-6. Dynamic pressures and PIP can give an indication of both airway resistance and lung compliance.

Static Pressure

One of the measurements used to obtain compliance is static pressure (SP) or plateau pressure. Plateau pressure is obtained by pushing the end-inspiratory hold button on a ventilator at the end of a maximal inspiration while on a volume mode of ventilation. This holds the volume of delivered air in the patient's chest by preventing exhalation. The PIP drops to a plateau pressure with this maneuver, which reflects the pressure necessary to hold the lungs open. A graph depicting SP and PIP can be seen in Figure 25-7. Static compliance is determined by dividing the tidal volume by the plateau pressure minus the total PEEP:

$$\text{Exhaled } V_T / [\text{plateau pressure} - \text{PEEP}] = \text{static compliance}$$

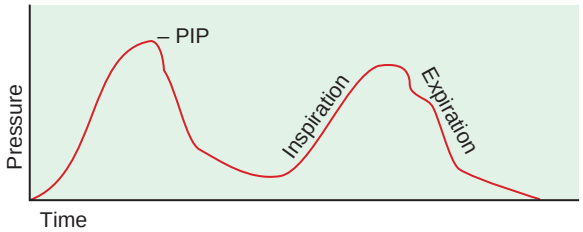

FIGURE 25-6 ▲ Graph displaying peak inspiratory pressure (PIP).

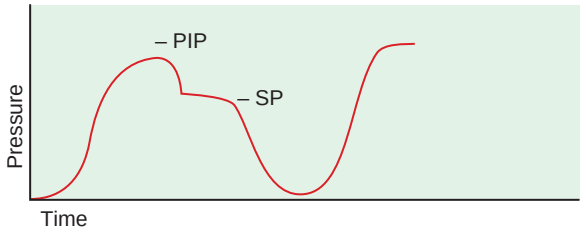

FIGURE 25-7 ▲ Graph depicting static pressure (SP) and peak inspiratory pressure (PIP).

A higher compliance means that the lung is more easily distended, whereas a lower compliance means that the lung is stiffer and difficult to distend. In other words, a higher compliance is better. Low compliance may be due to stiff lungs as with ARDS, a restrictive chest wall (ie, kyphoscoliosis), or ventilation of only a small portion of lung, such as occurs with partial lung collapse from consolidation. Serial measurements of compliance performed by the respiratory care professional can alert the nurse to sudden decreases, which may be due to pneumothorax, mucous plugging, or pulmonary edema.

Equipment

Many different ventilatory support systems are available. Manual resuscitators are typically used in emergencies, such as acute respiratory failure. Several types of mechanical ventilators are in use, and they offer a variety of modes.

Manual Resuscitators

The nurse's first line of defense for acute respiratory failure is the MRB, sometimes referred to as an Ambu bag or BVM apparatus. During CPR or hyperinflation with bagging and suctioning of any mechanically ventilated patient, MRBs with reservoirs must be used and connected to an oxygen source to deliver 74% to 100% concentrations of oxygen. MRBs without reservoirs may deliver a lower FiO_2 but must also be connected to an oxygen source.

Knowledge of the bag and skill in using it are vital. The function of this simple ventilator can be compared with that of the more sophisticated models. The following guidelines pertain to the manual resuscitator:

- The force of squeezing the bag determines the tidal volume delivered to the patient.
- The number of hand squeezes per minute determines the assisted respiratory rate.
- The force and rate that the bag is squeezed determine the peak flow.

While the bag is being used, the nurse must carefully observe the patient's chest rise to determine whether the bag is ventilating properly and whether any gastric (abdominal) distention is developing. In addition, the amount of resistance encountered can roughly indicate lung compliance. If a patient becomes progressively more difficult to ventilate, an increase in secretions, pneumothorax, worsening bronchospasms, or other condition that might decrease the patient's compliance must be considered. Breaths delivered to a conscious patient must be timed to coincide with spontane-

ous inspiratory effort, or the discomfort of dyssynchronous breathing will create anxiety. Then the patient will not tolerate the additional ventilation.

When delivering breaths with an MRB, the nurse allows time for complete exhalation between breaths to prevent air trapping (referred to as auto-PEEP), which can cause hypotension and barotrauma, especially in patients with obstructive airway disease.

Mechanical Ventilators

The goal of mechanical ventilation is to maintain alveolar ventilation appropriate for the patient's metabolic needs and to correct hypoxemia and maximize oxygen transport. Ventilators are classified into two categories: negative-pressure ventilators and positive-pressure ventilators. Regardless of which type or model is used, the nurse must be familiar with the ventilator's function and limitations. The following discussion of ventilators is in order of evolution of ventilator technology and subsequent use in clinical practice.

Negative-Pressure Ventilators

Early negative-pressure ventilators were known as "iron lungs." The patient's body was encased in an iron cylinder, and negative pressure was generated by a large piston to enlarge the thoracic cage. This caused alveolar pressures to fall, and a pressure gradient was formed so that air flowed into the lungs. The iron lung was used most frequently during the poliomyelitis epidemics of the 1930s and 1940s, but iron lungs are rarely used today. Intermittent short-term negative-pressure ventilation is sometimes used in patients with chronic diseases. Rarely, this method of support is chosen for patients who are not candidates for aggressive mechanical ventilation as provided through an artificial airway. These patients suffer from a wide variety of conditions such as COPD, diseases of the chest wall (kyphoscoliosis), and neuromuscular diseases (Duchenne's muscular dystrophy, amyotrophic lateral sclerosis [ALS]).

The iron lung is cumbersome to use and very large. Most negative-pressure ventilators in use today are more portable. To improve mobility and comfort, there is a device that fits like a tortoise shell, forming a seal over the chest. A hose connects the shell to a negative-pressure generator. The thoracic cage is literally pulled outward to initiate inspiration. However, the use of negative-pressure ventilators is restricted in clinical practice; they limit positioning and movement and lack adaptability to large or small body torsos.

Positive-Pressure Ventilators

VOLUME VENTILATORS. The volume ventilator is commonly used in critical care settings. The basic principle of this ventilator is that a designated volume of air is delivered with each breath. The amount of pressure required to deliver the set volume depends on the patient's lung compliance and patient–ventilator resistance factors. Therefore, PIP must be monitored in volume modes because it varies from breath to breath. With this mode of ventilation, a respiratory rate, inspiratory time, and tidal volume are selected for the mechanical breaths.

PRESSURE VENTILATOR. The use of pressure ventilators is increasing in critical care units. A typical pressure mode delivers a selected gas pressure to the patient early in inspiration and sustains the pressure throughout the inspiratory phase. By meeting the patient's inspiratory flow demand throughout inspiration, patient effort is reduced and comfort increased. Although pressure is consistent with these modes, volume is not. Volume will vary based on changes in resistance or compliance. Therefore, exhaled tidal volume is the variable to monitor closely. With pressure modes, the pressure level to be delivered is selected, and with some mode options (described later), rate and inspiratory time are preset as well. Figure 25-8 shows a typical ventilator with computer-controlled system and multiple screens showing monitoring data and mode of ventilation.

HIGH-FREQUENCY VENTILATOR. The high-frequency ventilator accomplishes oxygenation by the diffusion of oxygen and carbon dioxide from high to low gradients of concentration. This diffusion movement is increased if the kinetic energy of the gas molecules is increased. High-frequency ventilators use small tidal volumes (1 to 3 mL/kg) at frequencies greater than 100 breaths/min. The breathing pattern of a person on a high-frequency ventilator is somewhat analogous to the breathing pattern of a panting dog; panting entails moving small volumes of air at a very fast rate.

Theoretically, a high-frequency ventilator would be used to achieve lower peak ventilatory pressures, thereby reducing the risk for barotrauma and improving ventilation–perfusion matching because of its different flow delivery characteristics. Clinical data showing that use of high-frequency oscillatory ventilation improves outcomes in adults are limited so far; however, studies have revealed improvement in oxygenation with the ability to transfer back to conventional ventilation.[16] Potential adverse effects associated with high-frequency ventilators include gas trapping and necrotizing tracheobronchitis, when used in the absence of adequate humidification.

Ventilator Modes

Several different modes of ventilatory control are available on ventilators. Figure 25-9 and Table 25-4 compare these modes. Volume modes include assist-control (A/C) mode and synchronized intermittent mandatory ventilation (SIMV) mode. Pressure modes include pressure-support ventilation (PSV) mode, pressure-controlled ventilation (PCV) mode, airway pressure release ventilation (APRV) mode, volume-guaranteed pressure options (VGPO) mode, CPAP/PEEP mode, and noninvasive BiPAP mode. There is no one best mode for managing patients in respiratory failure, although each mode has its advantages and disadvantages.

Volume Modes

ASSIST-CONTROL MODE. In assist control, or volume-control mode as it is often termed, a mandatory (or "control") rate is selected. If the patient wishes to breathe faster, he or she can trigger the ventilator and receive a full-volume breath. This mode of ventilation is often used to fully support a patient, such as when the patient is first intubated or when the patient is too weak to perform the work of breathing (eg, when emerging from anesthesia).

FIGURE 25-8 ▲ The Puritan-Bennett 840 (PB 840) Ventilator System. The close-up photos of the screens and controls are an example of the type of controls used with computer-controlled ventilators.

The controls on the PB 840 are simple to use. This ventilator has a battery system allowing for transport with bottled oxygen. Dual screens display monitoring and alarm data in the upper screen and ventilator settings in the lower screen. On the top of the upper screen are the patient's ventilator parameters, indicating respiratory rate, tidal volume, minute volume, PEEP, IPL, and other values. Primary ventilator controls are accessed by screen touch boxes, and then a value or mode is selected by turning the select knob on the right followed by touching the "Accept" button for changes made. There is also a cancel button to remove changes before entering them. The nurse should be familiar with each ventilator system; each uses similar controls, but configurations of screens and touch buttons differ. The PB 840 also has additional quick action buttons along the bottom of the controls for 100% FiO_2 setting that lasts 2 minutes. This function allows preoxygenation before suctioning, or if the SaO_2 drops, it can improve oxygenation until troubleshooting of the patient and ventilator identifies the problem. An alarm pause button along the bottom controls only stops alarms for 2 minutes during therapy such as suctioning. Current alarms are viewed on the upper display screen, with the two most urgent alarms visible for review. There is a three-tiered system of warning lights on the right upper corner, with red (three lights blink rapidly) for high-urgency situations that require immediate attention, yellow (two lights blink slowly) for medium-urgency situations that require prompt attention, and yellow (one light is steadily lit) for low-urgency situations that indicate a change in the ventilator system. Alarm sounds also increase to the highest level continuous with reduced intensity or duration sounds for the other alarm levels. There is an alarm reset button that resets the alarms, but if the condition persists, the alarm reactivates until the problem is corrected with the patient or the ventilator. Only registered respiratory therapists should enter the ventilator setting controls for adjustments. The nurse should be familiar with the alarm pause and 100% FiO_2 setting. He or she should know the alarm levels to respond immediately for high-urgency situations and be able to know the meaning of the alarm problem displayed in the upper screen for this ventilator. Familiarity with this and other ventilator manufacturers' alarm systems and controls is essential for every nurse who cares for ventilated patients.

SYNCHRONIZED INTERMITTENT MANDATORY VENTILATION MODE. In SIMV mode, the rate and tidal volume are preset. If the patient wants to breathe above this rate, he or she may. However, unlike the A/C mode, any breaths taken above the set rate are spontaneous breaths taken through the ventilator circuit. The tidal volume of these breaths can vary drastically from the tidal volume set on the ventilator because the tidal volume is determined solely by the patient's spontaneous effort. Adding pressure support (discussed in the next section) during spontaneous breaths can minimize the risk for increased work of breathing. In the past, SIMV was used as a popular weaning mode. To wean the patient, the mandatory breaths were gradually decreased, thereby allowing the patient to assume more and more of the work of breathing.

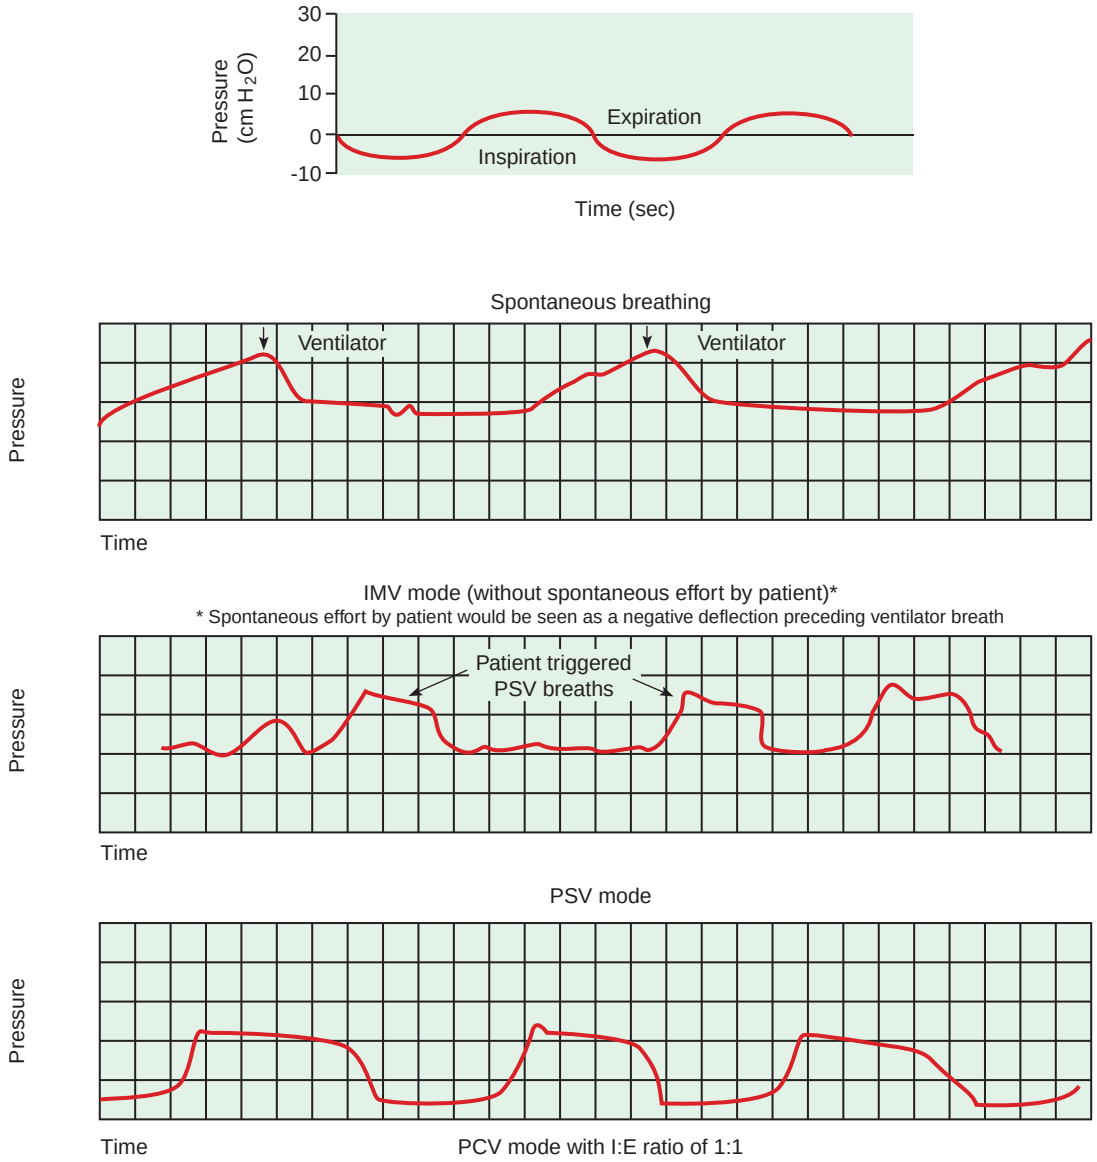

FIGURE 25-9 ▲ Comparison of ventilatory modes using continuous airway pressure monitoring.

Pressure Modes

PRESSURE-SUPPORT VENTILATION (PSV) MODE. PSV mode augments or assists spontaneous breathing efforts by delivering a high flow of gas to a selected pressure level early in inspiration and maintaining that level throughout the inspiratory phase. The patient's effort determines the rate, inspiratory flow, and tidal volume. When PSV mode is used as a stand-alone mode of ventilation, the pressure-support level is adjusted to achieve the approximate targeted tidal volume and respiratory rate. At high-pressure levels, PSV mode provides nearly total ventilatory support.

Specific uses of PSV are to promote patient comfort and synchrony with the ventilator, to decrease the work of breathing necessary to overcome the resistance of the ETT, and for weaning. As a weaning tool, PSV is thought to increase the endurance of the respiratory muscles by decreasing the physical work and oxygen demands during spontaneous breathing. Because the level of pressure support can be gradually decreased, endurance conditioning is enhanced.

In PSV mode, the inspired tidal volume and respiratory rate must be monitored closely in order to detect changes in lung compliance. Generally, if compliance decreases or resistance increases, tidal volume decreases and respiratory rate increases. PSV mode should be used with caution in patients with bronchospasm or other reactive airway conditions.

PRESSURE-CONTROLLED VENTILATION (PCV) MODE. The PCV mode is used to control plateau pressures in conditions, such as ARDS, in which compliance is decreased and the risk for barotrauma is high. It is used when the patient has persistent oxygenation problems despite a high FiO_2 and high levels of PEEP. The inspiratory pressure level, respiratory rate, and inspiratory/expiratory (I:E) ratio must be selected. Tidal volume varies with compliance, and airway resistance must be closely monitored. Sedation and

Table 25-4 Comparison of Modes of Ventilation

Ventilatory Mode	Indications	Advantages/Disadvantages	Special Monitoring
Assist-control (A/C)	Often used as initial mode of ventilation	Advantages: Ensures vent support during every breath Each breath same tidal volume Disadvantages: Hyperventilation, air trapping; may require sedation and paralysis	Work of breathing may be increased if sensitivity or flow rate is too low.
Synchronized intermittent mandatory ventilation (SIMV)	Often used as initial mode of ventilation and for weaning	Advantages: Allows spontaneous breaths (tidal volume determined by patient) between vent breaths; weaning is accomplished by gradually lowering the set rate and allowing the patient to assume more work Disadvantages: Patient–ventilator asynchrony possible	
Pressure-support ventilation (PSV)	Intact respiratory drive in patient necessary Used as a weaning mode, and in some cases of dyssynchrony	Advantages: Decreases work of breathing; increases patient comfort; can be combined with SIMV to allow a more comfortable mode Disadvantages: Should not be used in patients with acute bronchospasm or with altered mental status with reduced spontaneous breathing	Adjust PSV level to maintain desired respiratory rate and tidal volume. Monitor for changes in compliance, which can cause tidal volume to change. Monitor respiratory rate and tidal volume at least hourly.
Pressure-controlled ventilation (PCV)	Used to limit plateau pressures that can cause barotrauma Severe ARDS	Disadvantages: Patient–ventilator asynchrony possible, necessitating sedation/paralysis	Monitor tidal volume at least hourly. Monitor for barotrauma, hemodynamic instability.
Inverse ratio ventilation (IRV)	Usually used in conjunction with PCV	Advantages: Increases I:E ratio to allow for recruitment of alveoli and improve oxygenation Disadvantages: Almost always requires paralysis	
Volume-guaranteed pressure options (VGPO)	Combines advantages of pressure ventilation with guaranteed tidal volume	Advantages: Ensures a delivered tidal volume Disadvantages: Requires sophisticated knowledge of the mode and waveform analysis	Monitor for auto-positive end-expiratory pressure, barotrauma, and hemodynamic instability.
Continuous positive airway pressure (CPAP)	Constant positive airway pressure for patients who breathe spontaneously	Advantages: Used in intubated or nonintubated patients Disadvantages: On some systems, no alarm if respiratory rate falls	Monitor for increased work of breathing.
Noninvasive bilateral positive-pressure ventilation (BiPAP)	Nocturnal hypoventilation in patients with neuromuscular disease, chest wall deformity, obstructive sleep apnea, and chronic obstructive pulmonary disease; to prevent intubation; to prevent reintubation initially after extubation	Advantages: Decreased cost when patients can be cared for at home; no need for artificial airway Disadvantages: Patient discomfort or claustrophobia	Monitor for gastric distention, air leaks from mouth, aspiration risk.

the use of NMB agents are frequently indicated because any patient–ventilator asynchrony usually results in profound drops in the SaO_2. This is especially true when inverse ratios are used. The "unnatural" feeling of this mode often requires muscle relaxants to ensure patient–ventilator synchrony.

Most ventilators operate with a short inspiratory time and a long expiratory time (1:2 or 1:3 ratio). This promotes venous return and allows time for air to passively exit the lungs. Inverse ratio ventilation mode reverses this ratio so that inspiratory time is equal to, or longer than, expiratory time (1:1 to 4:1). Inverse I:E ratios are used in conjunction with pressure control to improve oxygenation in patients with ARDS by expanding stiff alveoli using longer distending times, thereby providing more opportunity for gas exchange and preventing alveolar collapse.

As expiratory time is decreased, the nurse must monitor for the development of hyperinflation or auto-PEEP. Regional alveolar overdistention and barotrauma may result from excessive total PEEP. When the PCV mode is used, the mean airway and intrathoracic pressures rise, potentially resulting in a decrease in cardiac output and oxygen delivery. Therefore, it is necessary to monitor the patient's hemodynamic status closely.

Airway Pressure Release Ventilation (APRV) Mode

APRV has been used in trauma and ARDS patients to reduce airway pressure and lower minute volume while allowing spontaneous breathing throughout the ventilator cycle, all with decreased sedation and NMB agent use. APRV mode allows lung protective strategies to be followed with limitation of plateau and peak pressures. The mode functions by having a time-triggered, pressure-limited, time-cycled mode of ventilation. It consists of a high-pressure setting and a low-pressure setting, with recruitment and oxygenation occurring during the high-pressure setting at a long set time interval (eg, 5 seconds) followed by a brief controlled release (eg, 0.6 second) to the low-pressure setting. What this means is that the patient spontaneously breathes both at a set high pressure with preset brief times and at low pressure, which is synchronized during exhalation. Because the patient is breathing spontaneously throughout both high- and low-pressure phases, sedation may be limited. Weaning from APRV is done by decreasing the high-pressure limit while increasing the time at high pressure. At the same time, the low-pressure limit may be dropped, allowing for reduced mean airway pressure. Usually, the low-pressure limit is reduced to 5 cm H_2O, and as the high pressure is lowered, this allows release to a PEEP level that prevents derecruitment. When the patient tolerates an FiO_2 of 50% or less, the patient can be switched to PSV and further weaning. This mode may improve oxygenation and prevent VALI and VILI in patients with ARDS or ALI.[17]

Volume-Guaranteed Pressure Options (VGPO) Mode

VGPO mode ensures delivery of a prescribed tidal volume while using a decelerating flow pattern by means of a "pressure" breath. The options include both spontaneous and control rate parameters, and the volume guarantee is provided differently, depending on the ventilator. VGPO can be used in acutely ill patients as well as more stable, weaning patients. Some examples include the volume support and pressure-regulated volume-control options (Siemens Medical) as well as pressure augmentation (Bear Medical Systems).

In the acutely ill, unstable patient, this option may provide pressure ventilation while guaranteeing tidal volume and minute ventilation (MV) at a set rate. In the spontaneously breathing patient, the option is used as a "safety" when pressure ventilation is desired. The use of a volume guarantee in the spontaneously breathing patient may be especially important at night (when respiratory rates and volumes normally decrease) and in patients for whom secretions are a problem (because secretions increase resistance and result in decreased spontaneous volumes).

Continuous Positive Airway Pressure (CPAP)/ Positive End-Expiratory Pressure (PEEP) Mode

CPAP is the term used when PEEP is supplied during spontaneous breathing. PEEP is the term used to describe positive end-expiratory pressure with positive-pressure breaths. CPAP assists spontaneously breathing patients to improve their oxygenation by elevating the end-expiratory pressure in the lungs throughout the respiratory cycle. CPAP can be used for intubated and nonintubated patients. It may be used as a weaning mode and for nocturnal ventilation (nasal or mask CPAP) to splint open the upper airway, preventing upper airway obstruction in patients with obstructive sleep apnea.

PEEP is positive pressure exerted at the end of exhalation. It is common practice to use low levels of PEEP (2 to 5 cm H_2O) in the intubated patient. PEEP is increased in 2- to 5-cm H_2O increments when FiO_2 levels are greater than 50% to attain an acceptable SaO_2 (>90%) or PaO_2 (>60 to 70 mm Hg). PEEP is most often necessary in patients with refractory hypoxemia (such as those with ARDS) in whom the PaO_2 deteriorates rapidly, despite greater concentrations of oxygen administration.

PEEP is used to keep alveoli stent open, and it may recruit alveolar units that are totally or partially collapsed during any mode of ventilation. This end-expiratory pressure increases the functional residual capacity (FRC) by reinflating collapsed alveoli, maintains the alveoli in an open position, and improves lung compliance. This decreases shunt and improves oxygenation. In addition, there is some evidence that keeping the alveoli open enhances surfactant regeneration. High levels of PEEP should rarely be interrupted because it may take several hours to recruit alveoli again and restore the FRC; until this occurs, oxygenation may suffer. In the patient who does not have adequate circulating blood volume, institution of PEEP decreases venous return to the heart, decreases cardiac output, and decreases oxygen delivery to the tissues. If hypotension or decreased cardiac output results from PEEP application, restoring circulating intravascular volume with administration of IV fluids may correct the hypotension. Another serious complication of PEEP is barotrauma. It can occur in any mechanically ventilated patient but is most common when high levels of PEEP are used (10 to 20 cm H_2O or more) in lungs with high ventilating pressures and low compliance and in patients with obstructive airway disease. The development of barotrauma is an emergency and usually requires placement of a chest tube in the event of pneumothorax.

Noninvasive Bilateral Positive-Pressure Ventilation Mode

BiPAP is a noninvasive form of mechanical ventilation provided by means of a nasal mask, nasal prongs, or a full face mask. It is used in the treatment of patients with chronic respiratory insufficiency to manage acute or chronic

respiratory failure without intubation and conventional mechanical ventilation. It is also used as a bridge to weaning patients from mechanical ventilation and as an alternative to conventional mechanical ventilation in patients who are ventilated in their homes. The system allows the clinician to select two levels of positive-pressure support: an inspiratory pressure-support level (referred to as IPAP) and an expiratory pressure called EPAP (PEEP/CPAP level). Because BiPAP allows for the provision of assisted inspiration with ventilator rate set, application of this mode to those patients who hypoventilate as well as obstruct during sleep is possible.

BiPAP is beneficial in patients with worsening hypoventilation, obstructive apneic episodes, or both. It is also useful to prevent intubation in patients with respiratory failure and hypercarbia as well as to prevent reintubation following extubation in borderline cases. Use of a full face mask may increase the risk for aspiration and risk for rebreathing carbon dioxide; therefore, ventilation with a full face mask should be used cautiously. Thick or copious secretions and poor cough may be relative contraindications for BiPAP.

Use of Mechanical Ventilators

Setting Ventilator Controls

The nurse must know how to monitor the various ventilators, modes, and controls before giving mechanical ventilatory support to a patient. The following section discusses these various controls and settings and their implications for nursing care. In some institutions, the respiratory therapists share or have complete responsibility for managing the ventilator, but the nurse still needs to be fully aware of the implications for the patient of the mode and level of mechanical support.

Ventilator settings must be frequently evaluated against patient response. Iatrogenically induced complications include overventilation (which causes respiratory alkalosis) and underventilation (which causes respiratory acidosis or hypoxemia). ABG studies determine the effectiveness of mechanical ventilation. Patients with chronic pulmonary disease, however, should be ventilated to stay relatively close to their normal ABG values. This usually means accepting relatively high carbon dioxide levels, lower-than-average oxygenation, or both.

Fraction of Inspired Oxygen

Ventilators allow for adjustment of oxygen percentage (FiO_2) with in-circuit or external oxygen analyzers, thus allowing the nurse to ascertain the FiO_2 being delivered. Changes in FiO_2 are based on ABG values and the SaO_2. Usually, the FiO_2 is adjusted to maintain an SaO_2 of greater than 90% (roughly equivalent to a PaO_2 > 60 mm Hg). Oxygen toxicity is a concern when an FiO_2 of greater than 60% is required for more than 24 hours; therefore, most clinicians attempt to use strategies to allow for maintaining an FiO_2 of 60% or less.

Respiratory Rate

The number of breaths per minute delivered to the patient can be directly set on most ventilator models. Ventilator monitoring should be performed frequently as to appropriate settings, patient response, and airway patency. In the pressure ventilator, the inspiratory time determines the duration of inspiration by regulating the gas flow rate. The higher the flow rate, the faster peak airway pressure is reached and the shorter the inspiration; conversely, the lower the flow rate, the longer the inspiration. A very high flow rate may produce turbulence, shallow inspirations, and uneven distribution of volume.

Respiratory rate times tidal volume equals minute ventilation (RR × VT = MV). In turn, minute volume determines alveolar ventilation. These two parameters are adjusted according to the $PaCO_2$. Increasing the minute volume decreases the $PaCO_2$; conversely, decreasing the minute volume increases the $PaCO_2$. In special cases, hypoventilation or hyperventilation is desired. For example, in a patient with a head injury, respiratory alkalosis may be required to promote cerebral vasoconstriction, with a resultant decrease in ICP. In this case, the tidal volume and respiratory rate are increased to achieve the desired alkalotic pH by manipulating the $PaCO_2$. In contrast, a patient with COPD whose baseline ABG values reflect an elevated $PaCO_2$ should not be hyperventilated. Instead, the goal should be restoration of the baseline $PaCO_2$. These patients usually have a large carbonic acid load, and lowering their carbon dioxide levels rapidly may result in seizures. Rate adjustments may also be necessary to enhance patient comfort or when rapid rates cause air trapping that results in auto-PEEP.

Tidal Volume

In the volume ventilator, the number of milliliters of air to be delivered with each breath is set by the clinician. Traditionally, tidal volumes of 10 to 15 mL/kg of body weight were used. Research has identified a phenomenon of iatrogenic lung injury (VILI or VALI), in which forces produced in the lungs by the large tidal volumes may aggravate the damage inflicted on the lungs by the pathological process that necessitated mechanical ventilation.[18] For this reason, lower tidal volume targets (5 to 8 mL/kg) are now recommended.

Peak Flow

Peak flow is the velocity of gas flow per unit of time and is expressed as liters per minute. On many volume ventilators, this is a separate setting. If auto-PEEP (due to inadequate expiratory time) is present, peak flow is increased to shorten inspiratory time so that the patient may exhale completely. However, increasing peak flow increases turbulence, which is reflected in increasing airway pressures.

Inspiratory Pressure Limit

On volume-cycled ventilators, the inspiratory pressure limit (IPL) control limits the highest pressure allowed in the ventilator circuit. Once the high-pressure limit is reached, inspiration is terminated. Therefore, if the IPL is being constantly reached, the designated tidal volume is not being delivered to the patient. The cause of this can be coughing, accumulation of secretions, kinked ventilator tubing, pneumothorax, decreasing compliance, or a pressure limit alarm set too low. IPL is used with PSV to adjust the pressure during spontaneous breathing, providing reduced work of breathing. Weaning can be accomplished in the PSV mode, reducing IPL to low levels as the patient increases the work of breathing.

Positive End-Expiratory Pressure

The PEEP control adjusts the pressure that is maintained in the lungs at the end of expiration. PEEP and CPAP can be visualized on the respiratory pressure gauge or display. Instead of returning to zero (atmospheric pressure) at the end of expiration, the pressure value drops to the PEEP/CPAP level. PEEP reduction is considered if the patient has a PaO_2 of 80 to 100 mm Hg or an FiO_2 of 50% or less, is hemodynamically stable, and has stabilization or improvement of the underlying illness. To evaluate whether the effects of PEEP are beneficial, monitoring ABG values, SaO_2, compliance, and hemodynamic pressures (including cardiac output and blood pressure) is necessary. Baseline values are obtained before changes in PEEP are made. PEEP is usually increased in increments of 2 to 5 cm H_2O. The patient is monitored for adverse effects, such as hypotension and dysrhythmias. If these occur, the PEEP is reduced. If higher PEEP is tolerated, the patient is stabilized on the new PEEP settings for approximately 15 minutes. The monitored parameters are then repeated.

Hemodynamic measurements (cardiac output, pulmonary artery pressure [PAP], central venous pressure, and pulmonary artery occlusion pressure) are taken at end expiration with the patient on PEEP. Accuracy in selecting the point of end expiration on the waveform tracing is facilitated by using continuous airway monitoring (Fig. 25-10). PEEP does not need to be discontinued before obtaining hemodynamic measurements. Hemodynamic measurements can be inaccurate (as an indicator of volume status) if a patient is on high PEEP or the position of the transducer is not leveled at the phlebostatic axis. The position of the catheter within the pulmonary circulation should also be verified on a chest radiograph.

Attempts are made to minimize removing the patient from the ventilator when using high levels of PEEP. Oxygenation can deteriorate and be slow to rebound because it takes a significant amount of time for the effects of PEEP to be reestablished. Therefore, if the patient is being oxygenated using an MRB, it must be equipped with a valve that allows levels of PEEP to be dialed in. An in-line suction apparatus may be helpful to prevent breaking the PEEP circuit to suction the patient.

Sensitivity

The sensitivity function controls the amount of patient effort needed to initiate an inspiration, as measured by negative inspiratory effort. Increasing the sensitivity (requiring less negative force) decreases the amount of work the patient must do to initiate a ventilator breath. Likewise, decreasing the sensitivity increases the amount of negative pressure that the patient needs to initiate inspiration and increases the work of breathing.

Responding to Alarms

Mechanical ventilators are used to support life. Alarm systems are necessary to warn the nurse of developing problems. Alarm systems can be categorized according to volume and pressure, high and low. Low-pressure alarms warn of disconnection of the patient from the ventilator or circuit leaks. High-pressure alarms warn of rising pressures. Electrical failure alarms are necessary for all ventilators. A nurse or respiratory therapist must respond to every ventilator alarm. Alarms must never be ignored or disarmed. Some clinical troubleshooting guidelines are presented in Table 25-5.

Ventilator malfunction is a potentially serious problem. Nursing or respiratory therapists perform ventilator checks every 2 to 4 hours, and recurrent alarms may alert the clinician to the possibility of an equipment-related issue. When device malfunction is suspected, a second person manually ventilates the patient while the nurse or therapist looks for the cause. If a problem cannot be promptly corrected by ventilator adjustment, a different machine is procured so that the ventilator in question can be taken out of service for analysis and repaired by technical staff.

Ensuring Humidification and Thermoregulation

Mechanical ventilation bypasses the upper airway, thereby negating the body's protective mechanism for humidifying and warming inspired air. These two processes must be added to the ventilator circuit in the form of a humidifier with a temperature control. All air delivered by the ventilator passes through the water in the humidifier, where it is warmed and saturated, and this decreases insensible water loss. In most instances, the temperature of the air is about the same as body temperature. In some rare instances (severe hypothermia), the air temperatures can be increased. Caution is advised because prolonged inhalation of gas at high temperatures can cause tracheal burns. An empty humidifier contributes to drying the airway, often with resultant mucous plugging and less ability to suction out secretions. A heat and moisture

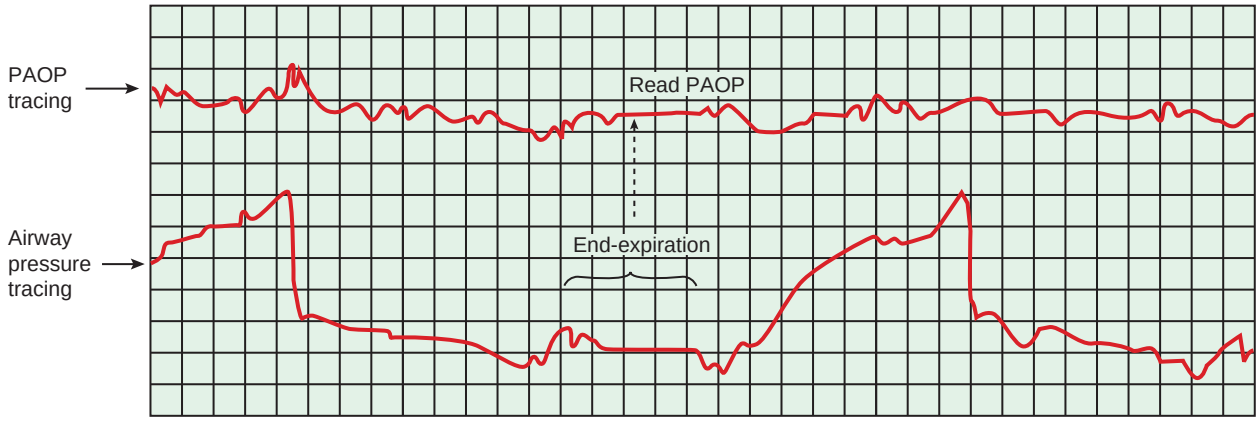

FIGURE 25-10 ▲ Use of continuous airway pressure monitoring to assist in identifying point of end expiration.

Table 25-5 Troubleshooting the Ventilator

Problem	Possible Causes	Action
Volume or pressure alarm	*Patient related*	
	Patient disconnected from ventilator	Reconnect STAT. Auscultate neck for possible leak around endotracheal tube (ETT) cuff.
	Loss of delivered V_T	Review chest radiograph for ETT placement—may be too high. Check for loss of V_T through chest tube.
	Decrease in patient-initiated breaths	Evaluate patient for cause: check respiratory rate, arterial blood gases (ABGs), last sedation.
	Increased compliance	May be due to clearing of secretions or relief of bronchospasms.
	Ventilator related	
	Leaks	Check all tubing for loss of connection, starting at patient and moving toward humidifier. Check for change in ventilator settings. (*Note*: If problem is not corrected STAT, use mandatory resuscitation bag until ventilator problem is corrected.)
High-pressure or peak-pressure alarm	*Patient related*	
	Decreased compliance Increased dynamic pressures	Suction patient. Administer inhaled β-agonists. If sudden, evaluate for pneumothorax. Evaluate chest radiograph for ETT placement in right mainstem bronchus. Sedate if patient is bucking the ventilator or biting the ETT.
	Increased static pressure	Evaluate ABG values for hypoxia, fluids for overload, chest radiograph for atelectasis. Auscultate breath sounds.
	Ventilator related	
	Tubing kinked	Check tubing.
	Tubing filled with water	Empty water into a receptacle: Do not drain back into the humidifier.
	Patient–ventilator asynchrony	Recheck sensitivity and peak flow settings. Provide sedation/paralysis if indicated.
Abnormal (ABGs)	*Patient related*	
Hypoxemia	Secretions	Suction. Increase FiO_2.
	Increase in disease pathology	Evaluate patient and chest radiograph.
	Positive fluid balance	Evaluate intake and output.
Hypocapnia	Hypoxia	Evaluate ABG values and patient.
	Increased lung compliance	Evaluate potential for weaning.
Hypercapnia	Sedation Fatigue	Increase respiratory rate or V_T settings.
	Ventilator related	
Hypoxemia	FiO_2 drift	Check ventilator with oxygen analyzer.
Hypocapnia	Settings not correct	Decrease respiratory rate, V_T, or minute ventilation (MV).
Hypercapnia	Settings not correct	Increase respiratory rate, V_T, or MV.
Heater alarm	Adding cold water to humidifier	Wait.
	Altered setting	Reset.
	Cold air blowing on humidifier	Redirect air flow.

exchanger unit may be attached to the airway to act as an artificial nose in lieu of a humidifier.

As air passes through the ventilator to the patient, water condenses in the corrugated tubing. This moisture is considered contaminated and must be drained into a receptacle and not back into the sterile humidifier. If the water is allowed to build up, resistance is developed in the circuit, and PEEP is generated. In addition, if moisture accumulates near the ETT, the patient can aspirate the water. The nurse and respiratory therapist jointly are responsible for preventing this condensation buildup. The humidifier is an ideal medium for bacterial growth. Institutional policies should describe the frequency of ventilator circuit changes.

Complications of Mechanical Ventilation

Complications that can occur with mechanical ventilation are listed in Box 25-12. Although all these adverse consequences occur over time in some ventilated patients, the incidence of these complications can be minimized by good preventive care practices.

Aspiration

Aspiration can occur before, during, or after intubation. The potential for developing nosocomial pneumonia or ARDS increases if aspiration occurs. The risk for aspiration after

BOX 25-12 Complications of Mechanical Ventilation

Airway
- Aspiration
- Decreased clearance of secretions
- Ventilator-acquired pneumonia

Endotracheal Tube
- Tube kinked or plugged
- Rupture of piriform sinus
- Tracheal stenosis or tracheomalacia
- Mainstem intubation with contralateral lung atelectasis
- Cuff failure
- Sinusitis
- Otitis media
- Laryngeal edema

Mechanical
- Hypoventilation with atelectasis
- Hyperventilation with hypocapnia and respiratory alkalosis
- Barotrauma (pneumothorax or tension pneumothorax, pneumomediastinum, subcutaneous emphysema)
- Alarm "turned off"
- Failure of alarms or ventilator
- Inadequate nebulization or humidification
- Overheated inspired air resulting in hyperthermia

Physiological
- Fluid overload with humidified air and sodium chloride retention
- Depressed cardiac function and hypotension
- Stress ulcers
- Paralytic ileus
- Gastric distention
- Starvation
- Dyssynchronous breathing pattern

intubation can be minimized by maintaining appropriate cuff inflation, evacuating gastric contents and relieving distention with suction, suctioning the oropharynx (especially before cuff deflations), and elevating the head of the patient's bed 30 degrees or more at all times. Elevation of the HOB may be limited when the patient has femoral central venous catheters; however, the bed can be raised up to 15 to 20 degrees and then placed in slight reverse Trendelenburg to approximately 30 degrees of elevation.

Barotrauma and Pneumothorax

Mechanical ventilation involves "pumping" air into the airway filling the chest, creating positive pressures during inspiration that may lead to barotrauma. If PEEP is added, the pressures are increased and continued throughout expiration. These positive pressures, especially with PEEP greater than 10 to 15 cm H_2O, can spontaneously rupture an alveolus or emphysematous bleb in the patient with COPD. Air then escapes into, and is trapped in, the pleural space, accumulating until it begins to collapse the lung. Eventually, the collapsing lung impinges on the mediastinal structures, compressing the trachea and eventually the heart; this is called tension pneumothorax. Signs and symptoms of tension pneumothorax are listed in Box 25-13. Signs of pneumothorax include extreme dyspnea, hypoxemia, and an abrupt increase

BOX 25-13 PATIENT SAFETY

Signs and Symptoms of Tension Pneumothorax
- Tachycardia
- Tachypnea
- Agitation
- Diaphoresis
- Tracheal shift from midline
- Muffled heart tones
- Absent breath sounds over affected lung
- Hyperresonance to percussion over affected lung
- Elevation in peak airway pressures in ventilated patients
- Decrease in saturation of oxygen in arterial blood (SaO_2) or arterial oxygen tension (PaO_2)
- Hypotension
- Cardiac arrest

in PIP. Breath sounds may be decreased or absent on the affected side; however, this sign may not be reliable in the patient on positive-pressure ventilation. Observation of the patient may reveal a tracheal deviation (to the opposite side) or the sudden development of subcutaneous emphysema. The PIP may become elevated and a ventilator alarm will be activated due to increased intrathoracic pressure. The most ominous signs of tension pneumothorax are hypotension and bradycardia that can deteriorate into a cardiac arrest without timely medical intervention. The physician or other qualified health care professional may decompress the chest by inserting a needle to evacuate the trapped air until a chest tube can be inserted.

Ventilator-Associated Pneumonia

VAP is the second most common hospital-acquired infection.[19] The incidence of nosocomial pneumonia is increased 10-fold in intubated patients, and the risk for developing VAP is especially great in critically ill patients who are mechanically ventilated. Factors that lead to nosocomial pneumonia are oropharyngeal colonization, gastric colonization, aspiration, and compromised lung defenses. Mechanical ventilation, reintubation, self-extubation, presence of a nasogastric tube, and supine position are a few of the associated risk factors for VAP. Maintenance of the natural gastric acid barrier in the stomach plays a major role in decreasing incidence and mortality from nosocomial pneumonia. The widespread use of antacids or histamine (H_2) blockers can predispose the patient to nosocomial infections because they decrease gastric acidity (increase alkalinity). These medications are used to guard against stress bleeding and may increase colonization of the upper gastrointestinal tract by bacteria that thrive in a more alkaline environment.

VAP is defined as nosocomial pneumonia in a patient who has been mechanically ventilated (by ETT or tracheostomy) for at least 48 hours at the time of diagnosis. A patient should be suspected of having a diagnosis of VAP if the chest radiograph shows new or progressive and persistent infiltrates. Other signs and symptoms can include a temperature higher than 100.4°F (38°C), leukocytosis, new-onset purulent sputum or cough, and worsening gas exchange.

There are numerous strategies for preventing VAP. The first step is to prevent colonization by pathogens of the oropharynx and gastrointestinal tract. Basic nursing care principles, such

as meticulous handwashing and wearing gloves when suctioning patients orally or through the ETT, are essential. Gloves should also be worn when suctioning through closed-suction devices. In addition, critically ill patients have an increased risk for colonization by the microorganisms associated with poor oral hygiene. Oral care for a mechanically ventilated patient involves brushing the patient's teeth (at least every 8 hours), using antimicrobial solutions and alcohol-free mouthwash to cleanse the mouth, applying a water-based mouth moisturizer to maintain the integrity of the oral mucosa, and thoroughly suctioning oral and subglottic secretions. Chlorhexidine oral rinse is one agent that provides antimicrobial action and is used in many institutions. An oral care protocol should be in place for every adult critical care unit using the current evidence-based research and practice. See Evidence-Based Practice Highlight 25-1.

In patients receiving enteral feedings, the HOB should be elevated 30 to 45 degrees (unless contraindicated) to decrease the risk for aspiration.[20] Long-term nasally placed endotracheal and gastric tubes (ie, longer than 3 days) should be placed orally unless contraindicated or not tolerated by the patient. This intervention reduces the risk for the patient developing sinusitis, which is associated with the development of VAP. Sinusitis is relatively common in nasally intubated patients and can cause bacteremia and sepsis. Signs of sinusitis (fever, purulent nasal drainage) must be reported immediately. Lastly, the use of an ETT that provides a port for the CASS appears to prevent the development of VAP in the first week of intubation, and it may decrease the overall incidence of VAP but does not affect mortality or length of stay.[21] The use of the CASS ETT is typically reserved for those patients who can be identified as potentially requiring long-term ventilation.

The advent of the ventilator bundle of standard orders, which incorporates gastrointestinal and deep venous thrombosis prophylaxis, along with getting the patient out of bed, oral care, and keeping the HOB elevated 30 to 45 degrees, has reduced the incidence of VAP in many institutions.[22] These procedures should be included as an integral part of the care of ventilated patients.

Decreased Cardiac Output

Decreased cardiac output, as reflected by hypotension, may be observed at the initiation of mechanical ventilation. Although this is often attributed to the drugs used for intubation (narcotics, sedatives, and NMB agents all reduce blood pressure), the most important contribution to this phenomenon is lack of sympathetic tone and decreased venous return due to the effects of positive pressure within the chest. In addition to hypotension, other signs and symptoms can include unexplained restlessness, decreased levels of consciousness,

EVIDENCE-BASED PRACTICE HIGHLIGHT 25-1
Ventilator-Associated Pneumonia

△ Expected Practice

- All patients receiving mechanical ventilation, as well as those at high risk for aspiration (eg, decreased level of consciousness, with enteral tube in place), should have the HOB elevated at an angle of 30 to 45 degrees unless medically contraindicated.[1–7] (Level VI)
- Use an ETT with a dorsal lumen above the endotracheal cuff to allow drainage by continuous suctioning of tracheal secretions that accumulate in the subglottic area.[1,2,8–13] (Level VI)
- Do not routinely change, on the basis of duration of use, the patient's ventilator circuit.[1,14–17] (Level VI)

△ Supporting Evidence

- Critically ill patients who are intubated for more than 24 hours are at 6 to 21 times the risk of developing ventilator-associated pneumonia (VAP),[1,2,18–20] and those intubated for less than 24 hours are at three times the risk of VAP.[20] Other risk factors for VAP include decreased level of consciousness, supine positioning with HOB flat, use of H_2 antagonists and antacids, gastric distention, presence of gastric or small intestine tubes, enteral feedings, and a trauma or chronic obstructive pulmonary disease diagnosis.[1,18–22] VAP is reported to occur at rates of 10 to 35 cases per 1,000 ventilator days, depending on the clinical situation.[1,19]
- Morbidity and mortality associated with the development of VAP is high, with mortality rates ranging from 20% to 41%.[20,23–25] Development of VAP increases ventilator days, critical care, and hospital lengths of stay by 4, 4, and 9 days, respectively,[18,23,26] and results in more than $11,000 of additional costs per VAP case.[18,25,27]
- Micro- or macroaspiration of oropharyngeal and/or gastric fluids is presumed to be an essential step in the development of VAP.[1,2,12,28] Pulmonary aspiration is increased by supine positioning and poking of secretions above the ETT cuff.[1,3,19]
- Compared to supine positioning, studies have shown that simple positioning with HOB elevation to 30 degrees or higher significantly reduces gastric reflux and VAP,[3–7] yet national surveys and reports in the literature describe poor compliance rates with HOB elevation in critical care units.[20,29–34]
- Studies on the use of special ETTs, which remove secretions pooled above the cuff with continuous suction, found that it decreases VAP by 45% to 50%.[8–11]
- Studies on the frequency of ventilator circuit changes have found no increase in VAP with prolonged use.[14–17]
- National regulatory and expert consensus groups include the AACN VAP Practice Alert interventions as critical to decreasing VAP rates.[1,2,35–37]

AACN Grading Level of Evidence

Level A Manufacturer's recommendations only
Level B Theory based—no research data to support recommendations; recommendations from expert consensus group may exist
Level C Laboratory or bench data only—no clinical data to support recommendations
Level D Limited clinical studies to support recommendations
Level E Clinical studies in more than one or two different populations or situations to support recommendations
Level F Clinical studies in a variety of patient populations and situations to support recommendations

decreased urine output, weak peripheral pulses, slow capillary refill, pallor, fatigue, and chest pain. Increasing fluids to correct the relative hypovolemia usually treats hypotension. However, in this setting, vasopressors may be needed.

Water Imbalance

The decreased venous return to the heart is sensed by the vagal stretch receptors located in the right atrium. This sensed hypovolemia stimulates the release of antidiuretic hormone from the posterior pituitary. The decreased cardiac output, leading to decreased urine output, compounds the problem by stimulating the renin–angiotensin–aldosterone response. A mechanically ventilated patient may be hemodynamically unstable and may require large amounts of fluid resuscitation. This patient can experience extensive edema, including limb, scleral, and facial edema.

Complications Associated With Immobility

Many complications that contribute to the morbidity and mortality of mechanically ventilated patients are the result of immobility. These complications include muscle wasting and weakness, contractures, loss of skin integrity, pneumonia, and deep venous thrombosis that can result in pulmonary embolus, constipation, and ileus.

Gastrointestinal Problems

Gastrointestinal complications associated with mechanical ventilation include distention (from air swallowing), hypomotility and ileus (from immobility and the use of narcotic analgesics), vomiting, and breakdown of the intestinal mucosa from the lack of normal nutritional intake. This breakdown allows translocation of bacteria from the gut into the bloodstream, leading to increased risk for bacteremia in patients who cannot be fed enterally. Maintenance of an adequate bowel elimination pattern is necessary to prevent abdominal distention with resulting impingement on diaphragmatic excursion.

Many mechanically ventilated patients are already malnourished because of underlying chronic disease. Research verifies that the many side effects of clinical starvation can lead to pulmonary complications and death, as listed in Box 25-14. Early enteral nutrition is advocated for trauma and critically ill patients with either small-bore or Salem-sump tubes that end in the stomach or small intestine.[23] The advantage of small-bore feeding tubes is comfort, and with postpyloric placement, enteral feeding goal rates can be achieved sooner.

Muscle Weakness

The muscles used in respiration, like other muscles, become deconditioned and may even atrophy with prolonged disuse. The ventilated patient's respiratory muscles may not be used (other than passive movement) while on the ventilator, especially if muscle relaxants, heavy sedation, or both have been part of the care plan. A retraining period to exercise and strengthen the respiratory muscles may be necessary before ventilatory support can be discontinued. Especially at risk for "critical illness myopathies" are patients who have been on corticosteroids in combination with NMB agents as well as those with multiorgan failure, sepsis, and ARDS.[24]

BOX 25-14 Side Effects of Clinical Starvation

- Atrophy of respiratory muscles
- Decreased protein
- Decreased albumin
- Decreased cell-mediated immunity
- Decreased surfactant production
- Decreased replication of respiratory epithelium
- Intracellular depletion of adenosine triphosphate
- Impaired cellular oxygenation
- Central respiratory depression

Muscle weakness also occurs as a result of muscle fatigue. Those patients requiring mechanical ventilation typically have one or more reasons for an increase in the work of breathing. These include an increase in carbon dioxide production, physiological dead space (non-gas-exchanging air passages), or both; decreased lung compliance; and increased airway resistance, as with bronchospasm or thick secretions. When the work of breathing exceeds the capacity of weakened muscles, the patient begins to display abnormal respiratory mechanics with inefficient use of these muscles. This often occurs during a weaning trial after prolonged ventilation. The accepted intervention for fatigue in this setting is returning to muscle rest on the ventilator. However, this carries the risk for contributing further to muscle atrophy. The diaphragm muscle also requires sufficient electrolytes of calcium, magnesium, and phosphorus to optimize function during weaning. The nurse should review electrolyte values daily to ensure these diaphragm-essential electrolytes are kept normalized.

Assessment and Management

The patient who needs ventilatory support also needs primary nursing care. One of the greatest contributions the nurse can make to decreasing costs, length of stay, and mortality in patients with respiratory problems is to implement interventions that will prevent or minimize complications. Because mechanical ventilation is supportive rather than curative, the focus of care for the mechanically ventilated patient is holistic. The nurse must interact effectively with each member of the health care team to achieve desired patient outcomes. Box 25-15 gives examples of nursing diagnoses for the patient who needs ventilatory support. Box 25-16 summarizes care of the patient on a ventilator. The mechanical ventilator, the artificial airway, and the care necessary to maintain mechanical ventilation require specialized nursing knowledge and skills, which are discussed in the following sections.

Endotracheal Tube Care

To prevent tube movement, tube migration, or inadvertent extubation, ETTs must be anchored securely. Anchoring can be accomplished with adhesive tape or with commercially manufactured tube immobilization appliances. Usual practice is to retape the ETT every 1 to 2 days or when it is soiled or insecure. In orally intubated patients, the position of the ETT should be changed from side to side to facilitate oral

BOX 25–15 EXAMPLES OF NURSING DIAGNOSES

- Ineffective Coping
- Excess Fluid Volume
- Impaired Gas Exchange
- Ineffective Breathing Pattern
- Ineffective Airway Clearance
- Ineffective Peripheral Tissue Perfusion
- Risk for Increased Cardiac Tissue Perfusion
- Disturbed Body Image related to intubation or tracheostomy
- Risk for Infection
- Risk for Activity Intolerance
- Ineffective Airway Clearance
- Anxiety
- Risk for Aspiration
- Ineffective Breathing Pattern
- Impaired Bed Mobility
- Sleep Deprivation
- Dysfunctional Ventilatory Weaning Response

care and to prevent areas of pressure necrosis on the lips, mouth, and tongue. The disadvantage of frequent retaping is that patients with fragile skin or prolonged intubation may incur skin breakdown. Twill tape can be substituted for adhesive tape in these situations and for patients with heavy beards. Retaping by two people is desirable to prevent accidental tube displacement. The final step in retaping is to check tube placement in comparison to placement before retaping. ETT placement is verified by radiography following initial intubation. The position in centimeters at the lips/teeth or nostril is recorded; this placement is verified every shift to detect inadvertent position changes. Tube placement is checked, following retaping, by comparing the centimeter markings at the lips/teeth or nostril with the last radiological documentation of position. Placement of an oral bite block can prevent biting on the tube, which can cause airway narrowing or tube displacement. The use of a swivel connector (connecting the tube to the ventilator circuit), along with anchoring a large loop of tubing to the bed, facilitates patient movement without ETT movement. Oral inspection and hygiene are of paramount importance when a bite block is used.

Persistent coughing may suggest that the ETT has migrated to touch the carina, requiring the tube to be withdrawn to an appropriate level. The pilot cuff balloon is protected from inadvertent disruption; cuff rupture or ETT occlusion with a mucous plug usually requires reintubation. If a patient is prematurely extubated for any reason, the airway must be kept patent. Oxygenation and ventilation may be provided with an MRB and mask until reintubation can be accomplished.

BOX 25–16 COLLABORATIVE CARE GUIDE for the Patient on Mechanical Ventilation

Outcomes	Interventions
Oxygenation/Ventilation	
A patent airway is maintained. Lungs are clear to auscultation. Patient is without evidence of atelectasis. Peak, mean, and plateau pressures are within normal limits. ABG values are within normal limits.	• Auscultate breath sounds every 2–4 h and as needed. • Suction as needed for rhonchi, coughing, or oxygen desaturation. • Hyperoxygenate and hyperventilate before and after each suction pass. • Monitor airway pressures every 1–2 h • Monitor airway pressures after suctioning. • Administer bronchodilators and mucolytics as ordered. • Perform chest physiotherapy (CPT) if indicated by clinical examination or chest radiograph. • Turn patient side to side every 2 h • Consider kinetic therapy or prone positioning as indicated by clinical scenario. • Get patient out of bed to chair or standing position when stable. • Monitor pulse oximetry and $ETCO_2$. • Monitor ABG values as indicated by changes in noninvasive parameters, patient status, or weaning protocol.
Circulation/Perfusion	
Blood pressure, heart rate, cardiac output, central venous pressure, and pulmonary artery pressure remain stable on mechanical ventilation.	• Assess hemodynamic effects of initiating positive-pressure ventilation (eg, potential for decreased venous return and cardiac output). • Monitor electrocardiogram for dysrhythmias related to hypoxemia. • Assess effects of ventilator setting changes (inspiratory pressures, V_T, PEEP, and fraction of inspired oxygen [FiO_2]) on hemodynamic and oxygenation parameters. • Administer intravascular volume as ordered to maintain preload.
Fluids/Electrolytes	
Intake and output (I & O) measurements are balanced. Electrolyte values are within normal limits.	• Monitor hydration status in relation to clinical examination, auscultation, amount, and viscosity of lung secretions. • Assess patient weight, I & O totals, urine specific gravity, or serum osmolality to evaluate fluid balance. • Administer electrolyte replacements (intravenous or enteral) per physician's order.

(*continued on page 539*)

BOX 25–16 *COLLABORATIVE CARE GUIDE for the Patient on Mechanical Ventilation (continued)*

Outcomes	Interventions
Mobility	
Patients will maintain/regain baseline functional status related to mobility and self-care. Joint range of motion is maintained.	• Collaborate with physical/occupational therapy staff to encourage patient effort/participation to increase mobility. • Progress activity to sitting up in chair, standing at bedside, ambulating with assistance as soon as possible. • Assist patient with active or passive range-of-motion exercises of all extremities at least every shift. • Keep extremities in physiologically neutral position using pillows or appropriate splint/support devices as indicated.
Safety	
ETT will remain in proper position. Proper inflation of ETT cuff is maintained. Ventilator alarm system remains activated.	• Securely stabilize ETT in position; use respiratory therapy expertise for best method. • Note and record the "cm" line on ETT position at lip or teeth. • Use patient self-protective devices or sedation per hospital protocol. • Evaluate ETT position on chest radiograph daily (by viewing film or by report). • Keep emergency airway equipment and MRB readily available, and check each shift. • Inflate cuff using minimal leak technique or pressure <25 mm Hg by manometer. • Monitor cuff inflation/leak every shift and as needed. • Protect pilot balloon from damage. • Perform ventilator setting and alarm checks every 4 h (minimum) or per hospital protocol.
Skin Integrity	
Patient is without evidence of skin breakdown.	• Assess and document skin integrity at least every shift. • Turn patient side to side every 2 h; reassess bony prominences for evidence of pressure injury. • When patient is out of bed to chair, provide pressure relief to sitting surfaces at least hourly. • Remove self-protective devices from wrists, and monitor skin per hospital policy.
Nutrition	
Nutritional intake meets calculated metabolic need (eg, basal energy expenditure equation). Patient will establish regular bowel elimination pattern.	• Consult dietitian for metabolic needs assessment and recommendations. • Provide early nutritional support by enteral or parenteral feeding. • Monitor actual delivery of nutrition daily with I & O calculations. • Weigh patient daily. • Administer bowel regimen medications as ordered, along with adequate hydration.
Comfort/Pain Control	
Patients will indicate/exhibit adequate relief of discomfort/pain while on mechanical ventilation.	• Document pain assessment, using numerical pain rating or similar scale when possible. • Provide analgesia as appropriate, document efficacy after each dose. • Prevent pulling and jarring of the ventilator tubing and endotracheal or tracheostomy tube. • Provide meticulous oral care every 1–2 h with oropharynx suctioning and mouth moisturizer as needed; teeth brushing scheduled at least three times daily, antimicrobial irrigation twice daily, oral assessment at least daily. • Administer sedation as indicated.
Psychosocial	
Patient participates in self-care and decision making related to own activities of daily living (ADLs) (eg, turning, bathing). Patient communicates with health care providers and visitors.	• Encourage patient to move in bed and attempt to meet own basic comfort/hygiene needs independently. • Establish a daily schedule for bathing, time out of bed, treatments, and so forth, with patient input. • Provide a means for patient to write notes and use visual tools to facilitate communication. • Encourage visitor conversations with patient in normal tone of voice and subject matter. • Teach visitors to assist with range of motion and other simple care delivery tasks to facilitate normal patterns of interaction.
Teaching/Discharge Planning	
Patient cooperates with and indicates understanding of need for mechanical ventilation. Potential discharge needs are assessed.	• Provide explanations to patient/significant others regarding: Rationale for use of mechanical ventilation Procedures such as suctioning, airway care, CPT Plan for and progress toward weaning and extubation • Initiate early social worker involvement to screen for needs, resources, and support systems.

Tracheostomy Care

In patients requiring long-term mechanical ventilation, the airway is converted to a tracheostomy at some point to prevent the complications of endotracheal intubation, such as tracheal stenosis and vocal cord paralysis. The preferred method of airway management is the tracheostomy tube for long-term ventilation. Past practice involved tracheostomy after 11 and up to 21 days on the ventilator. Current practice promotes earlier tracheostomy at 72 hours after intubation. Earlier tracheostomy (eg, after 3 to 7 days on the ventilator) is performed to facilitate earlier weaning, particularly if the patient has multiple comorbidities and demonstrates difficulty weaning or has trauma or neurological diagnoses associated with prolonged need for an artificial airway. Tracheostomy is also performed for patient comfort and safety when mobilizing the patient and may lead to decreased ventilator weaning time. In addition to long-term ventilation, indications for tracheostomy include upper airway obstruction, airway edema from anaphylaxis, failed intubation, multiple intubations (high risk for complications), complications of ETT intubation, absence of protective reflexes, home care, conditions in which ETT intubation is not possible (eg, facial trauma, cervical fractures), and the desire for improved patient comfort.

The advantages of tracheostomy over endotracheal intubation include faster weaning (at least in part because of decreased dead space), enhanced patient comfort, enhanced communication, and the possibility of oral feeding. The tracheostomy is inserted into the trachea, thereby avoiding the mouth, upper airway, and glottis, and this decreases problems of airway resistance and occlusion.

Tracheostomy is not without disadvantages. These include hemorrhage, infection, pneumothorax, and the need for an operative procedure that is itself a risk. Box 25-17 presents complications of tracheostomy. The most serious complication is erosion into the innominate artery, which can result in exsanguination. If bleeding occurs, the cuff can be hyperinflated in an attempt to control bleeding until emergency surgery can be performed. The practice of bedside percutaneous tracheostomy using a progressive dilation technique has been touted to decrease the morbidity and cost incurred with an operative procedure because it is often earlier than surgical tracheostomy. Although there is no major difference in mortality risk, it has been found that early tracheostomy resulted in decreased ventilator days. Less infection and bleeding have also been given as advantages over the standard procedure performed in the operating room.[25]

BOX 25-17 PATIENT SAFETY

Complications of Tracheostomy

- Acute hemorrhage at the site
- Air embolism
- Aspiration
- Tracheal stenosis
- Erosion into the innominate artery with exsanguination
- Failure of the tracheostomy cuff
- Laryngeal nerve damage
- Obstruction of tracheostomy tube
- Pneumothorax
- Subcutaneous and mediastinal emphysema
- Swallowing dysfunction
- Tracheoesophageal fistula
- Infection
- Accidental decannulation with loss of airway
- False placement of cannula (not in trachea)
- Weak voice/hoarseness

The nurse can prevent complications by assessing for them with each patient interaction and during tracheostomy care. Proper fixation of the tracheostomy tube reduces the movement of the tube in the airway and limits friction injury to the tracheal wall or larynx. Maintaining the cuff pressure at the minimum required to prevent air leak on the ventilator reduces the risk for tissue breakdown due to excessive pressure on the trachea wall. The tracheostomy tube must be firmly secured. The ventilator tubing should have enough length to allow movement without pulling on the tracheostomy and to allow for procedures. A tracheostomy swivel connector, with or without flex tubing, reduces the tension on the tracheostomy while the patient is on the ventilator. A confused or very mobile patient can easily self-decannulate; patient restraints may be needed to prevent accidental decannulation. Orienting the patient to the need for an artificial airway and providing pain control and sedation are measures that are taken before resorting to restraint application. If restraints are needed, it is necessary to obtain a physician's order, with regular review of continued need. The nurse must monitor the patient closely for potential injury and must perform circulatory checks with removal of restraints frequently.

Tracheostomy care includes frequent changing of tracheal ties and dressing, although initial ties are not changed until at least 24 to 48 hours after placement to allow for hemostasis of the site. The sutures from either a percutaneous or surgical tracheostomy are left in place for 48 to 72 hours or even up to a week (per hospital protocol) to prevent decannulation. As with retaping of the ETT, changing of tracheostomy ties should be a two-person procedure. The ties should be tied so that one to two fingers can be inserted between the ties and the skin, allowing minimal movement of the tracheostomy tube but maintaining comfort. It is mandatory to maintain a midline position for the tracheostomy to prevent pressure on surrounding tissue. The stoma is cleansed with half-strength hydrogen peroxide, followed by rinse with sterile saline solution, and observed for wound healing, bleeding, and signs of infection The routine practice of inner cannula cleaning or changes may not be necessary with a disposable inner cannula that can be changed daily. The routine care for tracheostomy is cleaning the tracheostomy site at least every 8 to 12 hours and as needed, changing the inner cannula daily (or according to facility policy), and changing soiled tracheostomy ties as needed, progressing to daily and as-needed care. This longer care interval usually occurs after 7 to 10 days or when secretion and tracheostomy drainage are minimal. The routine care of tracheostomies is always performed as a sterile procedure while in the hospital.

If decannulation occurs within the first 7 days of tracheostomy insertion, the patient may be reintubated with an ETT if emergent tracheostomy tube replacement cannot be done safely. An obturator and a new, appropriately sized

tracheostomy tube are kept at the bedside. If inadvertent decannulation occurs after a tract has developed, the tube is carefully replaced using the obturator.

Tube Cuff Pressure Monitoring

Tube cuff pressures are monitored every shift to prevent overdistention and excess pressure on the tracheal wall mucosa, which can cause complications such as tracheal stenosis. If a patient is on the ventilator, the best pressure is the lowest possible pressure without having a loss of inspiratory volume. Physiologically, pressures of about 20 to 30 mm Hg obliterate capillary circulation to the tracheal mucosa. If a cuff leak is suspected, auscultation at the neck for the sound of air escaping above the cuff can determine whether the seal is adequate.

One method used to inflate a cuff is called the minimal occluding volume. Air is injected slowly into the pilot balloon during ventilator inspiration while auscultation is performed over the trachea. When the harsh "squeak" of air escaping is no longer audible, the minimal occluding volume has been reached, and the tube cuff is occluding the airway without excessive pressure on the trachea. Extra air should not be added. In the ICU, the best practice is actual measurement of cuff pressure using a manometer. This device is attached to the ETT pilot balloon to obtain a reading, which should ideally be 20 to 25 mm Hg. If a leak is still present above this level of inflation, slight repositioning of the ETT within the patient's airway may correct the problem. Changing to a larger or longer ETT may be necessary with increasing pressures to seal the airway. The cuff pressure is assessed with the manometer every 6 to 8 hours and, when a leak is noted, to help prevent aspiration of subglottic secretions. Whenever a cuff leak is found, the medical team and respiratory care practitioner should be notified. Recurrent cuff leaks may indicate the need for an extra long tube or a larger size to provide for ventilation.

Discharge Planning and Patient Teaching

Discharge planning is necessary for patients who will be discharged to home with tracheostomies. Rationales for tracheostomy care include promotion of ostomy healing, prevention of infection, maintenance of a patent airway, and increased patient comfort.

Teaching the patient and family care giver tracheostomy care allows for independence and self-care. This is an essential component of discharge teaching. Communication about the procedure and reassurance during the training process reduce anxiety and improve cooperation.

Nutritional Support

Respiratory muscles, like all other body muscles, need energy to work. If energy needs are not met, muscle fatigue occurs, leading to discoordination of respiratory muscles and a decrease in tidal volume. Hypomagnesemia and hypophosphatemia have been implicated in muscle fatigue caused by depleted levels of adenosine triphosphate. Electrolyte imbalances must be corrected and monitored daily for optimal muscle functioning during ventilator weaning. In prolonged starvation, the body cannibalizes the intercostal and diaphragmatic muscles for energy.

Metabolic needs in critically ill patients are much higher than in normal subjects. Basic caloric requirements are usually increased by 25% for hospital activity and stress associated with treatment. Adequate nutrition is a prerequisite for weaning from mechanical ventilation; nutritional support should be instituted early. If the gastrointestinal tract is intact, enteral nutrition is preferred and can be provided through a small-bore feeding tube.

Initial tube feeding is started slowly, with close monitoring of blood glucose and electrolyte levels. The nurse observes the patient for signs of intolerance, such as diarrhea and hyperosmolar dehydration. If the patient tolerates feedings, the rate is gradually increased until the goal rate is achieved. If tube feedings cannot be tolerated, parenteral hyperalimentation should be considered (see Chapter 40).

Patients who require long-term mechanical ventilation typically need additional protein and calories per day. When available, metabolic cart testing (also called indirect calorimetry) or a 24-hour urine nitrogen test can assess individual nutritional requirements. The monitoring of the prealbumin level may give an indication of recent nutritional state. Nutritionists are invaluable in determining the caloric needs of critically ill patients.

Eye Care

Eye care of the ventilator patient is important. Many patients in the ICU are comatose, sedated, or chemically paralyzed and therefore have lost the blink reflex or ability to close their eyelids completely. This can lead to corneal dryness and ulceration.

Few studies have established the efficacy of one eye care measure over another. Current practices include instillation of lubricating drops or ointment, taping the eyes, applying eye shields, or applying a moisture chamber. Eye care should be scheduled and not on an as-needed basis to ensure 24-hour application. Scleral edema is common in the ventilated patient. Raising the HOB may help reduce scleral edema.

Oral Care

Frequent oral care must be performed on all mechanically ventilated patients. See Evidence-Based Practice Highlight 25-2. Oral care not only increases comfort but also preserves the integrity of the oropharyngeal mucosa. An intact mucosa helps prevent infection and colonization of organisms that leads to VAP. As noted in the VAP discussion, evidence-based studies note the use of oral care protocols for ventilated adult patients in preventing VAP.[26] Nursing skill manuals do present guidelines for oral care in patients with and without teeth as well as in those who are incapacitated. However, these general oral care guidelines are not suitable for patients with an ETT and do not promote VAP prevention. The current literature includes oral care guidelines using every 2-, 4-, and 8-hour interventions with specific interventions of tooth brushing, oral and subglottic suctioning, moisturizer, and oral rinses. The CDC recommends that every ICU implement a complete oral care program with use of an antimicrobial oral rinse to prevent oral colonization.[27] What is still needed is a definitive research study regarding the optimal frequency, products, type of

EVIDENCE-BASED PRACTICE HIGHLIGHT 25-2

Oral Care for Patients at Risk for Ventilator-Associated Pneumonia

△ Expected Practice

- Develop and implement a comprehensive oral hygiene program for patients in critical care and acute care settings who are at high risk for VAP.
  - Brush teeth, gums, and tongue at least twice a day using a soft pediatric or adult toothbrush. (Level E)
  - Provide oral moisturizing to oral mucosa and lips every 2 to 4 hours.
  - Use an oral chlorhexidine gluconate (0.12%) rinse twice a day during the perioperative period for adult patients who undergo cardiac surgery. (Level D)
  - Routine use of oral chlorhexidine gluconate (0.12%) in other populations is not recommended at this time.

△ Supporting Evidence

- Colonization of the oropharynx is a critical factor in the development of nosocomial pneumonia.[1–3] Growth of potentially pathogenic bacteria in dental plaque provides a nidus of infection for microorganisms that have been shown to be responsible for the development of VAP.[2–4] Dental plaque provides a microhabitat for organisms and provides opportunity for adherence either to the tooth surface or to other microorganisms. These microorganisms in the mouth translocate and colonize the lung, which can result in VAP.[3,5] Dental plaque can be removed by brushing.
  - There are no data associated with critically ill patients; however, the American Dental Association recommends that healthy people brush teeth twice daily to remove plaque from all tooth surfaces.[6]
  - The use of an oral care protocol (brushing with a pediatric toothbrush, mouthwash, and moisturizing gel) reduces oral inflammation and improves oral health.[7]
- Chlorhexidine oral rinse reduced respiratory infections in cardiac surgery patients who received chlorhexidine before intubation as well as postoperatively[8] and reduced nosocomial pneumonia in patients who were intubated for more than 24 hours.[9] However, when chlorhexidine was tested in a more varied ICU population, no difference was observed in VAP mortality or length of stay. Although oropharyngeal colonization by VAP pathogens was reduced with chlorhexidine, its efficacy was insufficient to reduce the incidence of respiratory infections.[10,11] A 2005 meta-analysis of chlorhexidine trials found that use of chlorhexidine did not result in significant reduction in the incidence of nosocomial pneumonia, nor in alteration of the mortality rate.[12] The CDC (Centers for Disease Control and Prevention) guidelines recommend use of chlorhexidine only during the perioperative period for adult patients undergoing cardiac surgery; routine use in other critically ill populations is not recommended.[13]
- Several studies tested intervention bundles that included oral care as one of the interventions.[14–19] The studies demonstrate that bundled interventions decreased nosocomial respiratory infections; however, the contribution of oral care to the results could not be determined.
  - In addition to brushing, providing oral moisturization to oral mucosa and lips every 2 to 4 hours is often a component of the oral care protocols.[20]
- To date, data have been published from large, well-controlled clinical trials of oral care interventions in at-risk patients other than chlorhexidine studies. There are clinical reports of infection rates before and after changes in oral care procedures, but few have been published in referred journals. Some reports show a positive effect; however, the role of oral care in reducing nosocomial pneumonia is not clearly established by such projects, and it is possible that other changes in care occurred in the units and affected the results.[21–22]

AACN Evidence Leveling System

Level A Meta-analysis of quantitative studies or metasynthesis of qualitative studies with results that consistently support a specific action, intervention, or treatment

Level B Well-designed, controlled studies with results that consistently support a specific action, intervention, or treatment

Level C Qualitative studies, descriptive or correlational studies, integrative review, systematic reviews, or randomized controlled trials with inconsistent results

Level D Peer-reviewed professional organizational standards with clinical studies to support recommendations

Level E Multiple case reports, theory-based evidence from expert opinions, or peer-reviewed professional organizational standards without clinical studies to support recommendations

Level M Manufacturer's recommendations only

oral rinse, and materials to provide oral care for adult ventilated patients. Including the oral care guideline as part of VAP prevention may help reduce VAP by educating nurses and implementing practice changes, along with continuing quality improvement by monitoring the effectiveness of oral care and VAP protocols. Every ICU should either review its oral care guideline or create one with the current evidence-based research and available protocols. ICUs should follow the AACN Practice Alert on Oral Care in the critically ill.[28] Suggested guidelines may include the following:

1. Systematic assessment of the oral mucosa performed daily and with each cleaning
2. Handwashing before and after every nursing intervention
3. Routine brushing of teeth to remove dental plaque every 8 hours
4. Cleansing of the mouth every 2 hours and as needed
5. Use of an alcohol-free or antimicrobial (chlorhexidine) oral rinse every 8 or 12 hours to reduce oropharyngeal colonization
6. Suctioning the mouth and subglottic pharynx to minimize aspiration risk and provide a cover for the suction set with replacement every 8 or 24 hours
7. Applying a water-based mouth moisturizer to prevent mucosal drying and maintain integrity of the oral mucosa

Commercial kits are available that provide the suction catheters, covered tonsil-tip suction, toothbrushes with suction, and toothpaste for brushing in individually wrapped sets to prevent contamination.

Psychological Care

The ventilated patient is subjected to extreme physical and emotional stress in the ICU environment. Psychological distress can be caused by sleep deprivation, sensory overstimulation, sensory deprivation for familiar cues, pain, fear, inability to communicate, and commonly used pharmacological agents. Often, treatments can seem dehumanizing.

Feelings of helplessness and lack of control can be overwhelming. The patient may attempt to gain some element of control through constant demanding or exhibiting other "inappropriate" behavior. If the patient is incapable of dealing with stress through coping mechanisms, he or she may exhibit depression, apathy, and lack of emotional involvement. These reactions may be exacerbated in patients with a history of psychiatric problems or drug or alcohol abuse.

Assisted ventilation can precipitate a psychological dependence in those with primary respiratory disorders. If, for the first time in years, a patient is receiving enough oxygen to meet metabolic needs and does not have to struggle for air, he or she may be reluctant to give up the ventilator. Weaning can become even more stressful for this patient. Nursing interventions to improve sleep with quiet time, psychiatric consultation, and alternative therapy, such as music or massage, in addition to encouraging family support, will benefit the stressed patient. Taking the patient outside on the ventilator, sitting up in a chair, and ambulating on an MRB can improve the patient's mental health. Pet therapy, visiting with family and friends, and using a calendar for long-term patients can help keep them oriented. Resumption of home psychotropic medications, especially for depression or other disorders, is essential when compatible with the ongoing medical plan.

Facilitating Communication

A number of interventions can facilitate communication with the patient who has an endotracheal or tracheostomy tube. Before assessing the patient's ability to communicate, provide the patient with his or her eyeglasses or hearing aid (if applicable). Complete explanations from staff members regarding any procedures may help decrease the patient's stress. The care giver can use verbal and nonverbal communication skills. Nonverbal communication may include sign language, gestures, or lip reading. If the patient is unable to use these forms of nonverbal communication, helpful devices include pencil and paper, clipboard or dry erase boards, picture or alphabet boards, electronic communication boards, and even a computer.

Once the patient is off the ventilator and tolerating the tracheostomy collar, the tracheostomy patient can communicate by using a cap or speaking valves that occlude the tracheostomy tube. These allow for the passage of air around the tracheostomy to the vocal chords as long as the cuff is deflated. The tracheostomy may be capped for 24 to 48 hours before decannulation, and the patient breathes and speaks around the tracheostomy. The cap is the final test to ensure airway protection by the patient. Two other options to the cap are the Passy-Muir valve and the Shiley speaking valve. The Passy-Muir and Shiley speaking valves are one-way valves that allow air to enter during inspiration and then close to allow the air to flow over the vocal chords with exhalation. These valves each have a side port for oxygen tubing to be attached, providing oxygen support in addition to the humidified air from a tracheostomy collar. The tracheostomy collar should be used nearly continuously to prevent the accumulation of secretions and the drying of the airway mucosa. Neither speaking valve should be used during sleep to prevent aspiration with a deflated cuff. Patients with copious secretions are at risk for obstruction of these valves. They must be monitored very closely. In addition, patients at high risk for aspiration, especially those with laryngeal or pharyngeal dysfunction, should be carefully assessed before one of these devices is used. The nurse should store these valves in a container clearly identified with the patient's name for safekeeping because each type of valve is relatively costly. The patient should be taught to remove the valve with excessive sputum during cough and call for assistance to clean the valve before reuse. The tracheostomy patient with a speaking valve is at increased risk for aspiration because the cuff must be deflated for the patient to communicate.

Caring for the Family

Family members must deal with a strange environment, a critically ill loved one, and the financial strain imposed by the illness. Nursing support is given by familiarizing the family with the physical surroundings, supplying information about visitation policies, and providing frequent progress reports on the patient's condition.

Studies show improvement in patient outcomes from increased presence of loved ones during hospitalization. Based on these findings and on increased patient and family satisfaction, many ICUs have instituted open visitation policies and increased involvement of family members in patient care. Critical care patients and especially the elderly benefit from increased visitation, and the families benefit from improved communication when they are the decision makers.[29] Nurses increasingly recognize the importance of family visitation for the patient. The presence of family during invasive procedures or during a code has been associated with positive outcomes, and studies show family and care givers reported the benefit of being at the bedside.[30]

The nurse establishes open communication with the patient and family, proactively arranges for visits, and provides the family with information. Promoting spiritual and cultural support, scheduled family communication conferences, nursing education on visitation, and open communication assists the family with coping and reduces stress.[31] A system that includes liberal visitation policies and flexibility for individual patient and family needs promotes a healing environment and supports the family as partners in the care plan.

Weaning From Mechanical Ventilation

As soon as mechanical ventilation starts, plans begin for weaning the patient from mechanical support. The process to achieve this goal includes correcting the cause of respiratory failure, preventing complications, and restoring or maintaining physiological and psychological functional status. Patients can be categorized into two groups: those requiring

short-term ventilation (3 days or less) and those requiring long-term ventilation (more than 3 days).

Each patient is evaluated daily for readiness to wean by performing a spontaneous breathing trial. Boxes 25-18 and 25-19 present guidelines for weaning from short-term ventilation and long-term ventilation, respectively. It is important to perform this assessment and address weaning impediments before initiating weaning trials. Many weaning indices have been advocated for use in predicting weaning readiness. Some look exclusively at respiratory factors, such as muscle strength and endurance (eg, negative inspiratory pressure [NIP], PEP weaning index, or rapid shallow breathing index as the ratio of frequency to tidal volume). Others are integrated indices that look at a broad range of physiological factors that influence weaning readiness. Many of these factors individually lack predictability, and often several factors are assessed for weaning readiness.

In addition to controversy concerning weaning indices, there is disagreement and lack of evidence regarding which approach to weaning is best. Some clinicians maintain total ventilatory support up until the time of weaning trials; others use intermittent trials of increasing frequency and duration. The theoretical advantages of a gradual approach to weaning support include the following: (1) over time, the patient on partial rather than full ventilation is exposed to lower levels of pressure and volume, therefore reducing the risk for complications; and (2) a weaning approach that requires the patient to perform some level of work to breathe imposes an "exercise" regimen that should reduce deconditioning and atrophy of the muscles used in respiration.

The performance of the diaphragm, as well as accessory muscles of respiration, depends on both the endurance and strength of the muscles. The effectiveness of diaphragmatic contraction is a function of both the resting length of muscle

BOX 25-18 Guidelines for Weaning From Short-Term Ventilation

Patients are often intubated electively for surgical or other procedures or more urgently owing to respiratory distress related to underlying pulmonary disease or traumatic injury. The other common reason for intubation is the need for airway protection because of airway swelling (eg, as a result of acute inhalation injury) or significant change in mental status (eg, as with cerebrovascular accident or head injury). Once the procedure is completed or the patient is stabilized, the goal should be extubation as soon as the patient is able to protect the airway. The weaning process in this setting may proceed rapidly, based on individual patient response to reducing ventilatory support.

Readiness Criteria

- Hemodynamically stable, adequately resuscitated, and not requiring vasoactive support
- SaO_2 greater than 90% on FiO_2 40% or less, PEEP 5 cm H_2O or less
- Chest radiograph reviewed for correctable factors; treated as indicated
- Metabolic indicators (serum pH, major electrolytes) within normal range
- Hematocrit more than 25%
- Core temperature more than 36°C and less than 39°C
- Adequate management of pain/anxiety/agitation
- No residual neuromuscular blockade
- ABG values normalized or at patient's baseline

Weaning Intervention

- Reduce ventilator rate, then convert to pressure-support ventilation (PSV) only.
- Wean PSV as tolerated to 10 cm H_2O or less.
- If patient meets tolerance criteria for at least 2 hours on this level of support *and* meets extubation criteria (see later), may extubate.
- If patient fails tolerance criteria, increase PSV or add ventilator rate as needed to achieve "rest" settings (consistent respiratory rate <20 breaths/min) and review weaning criteria for correctable factors.
- Repeat wean attempt on PSV 10 cm after rest period (minimum, 2 hours). If patient fails second wean trial, return to rest settings and use "long-term" ventilation weaning approach.

Tolerance Criteria

If the patient displays any of the following, the weaning trial should be stopped and the patient returned to "rest" settings.

- Sustained respiratory rate greater than 35 breaths/min
- SaO_2 less than 90%
- Tidal volume 5 mL/kg or less
- Sustained minute ventilation greater than 200 mL/kg/min
- Evidence of respiratory or hemodynamic distress:
  - Labored respiratory pattern
  - Increased anxiety, diaphoresis, or both
  - Sustained heart rate greater than 20% higher or lower than baseline
  - Systolic blood pressure exceeding 180 mm Hg or less than 90 mm Hg

Extubation Criteria

- Mental status: alert and able to respond to commands
- Good cough and gag reflex and able to protect airway and clear secretions
- Able to move air around ETT with cuff deflated and end of tube occluded

Adapted from evidence-based practice guidelines used in the Surgical/Trauma Intensive Care Unit, University of Virginia Health System, Charlottesville, Virginia.

BOX 25-19 Guidelines for Weaning From Long-Term Ventilation

Patients on mechanical ventilation for longer than 72 hours or those having failed short-term weaning often display significant deconditioning as a result of acute or chronic complex illness, or both. These patients usually require a period of "exercising" respiratory muscles to regain the strength and endurance needed for successful return to spontaneous breathing. Goals for this process are:

- To have the patient tolerate two to three daily weaning trials of reduction in ventilatory support without exercising to the point of exhaustion
- To rest the patient between weaning trials and overnight on ventilator settings that provide diaphragmatic rest, with minimal or no work of breathing for the patient

Readiness Criteria

- Same as for short-term ventilation (see Box 25-18), with emphasis on hemodynamic stability, adequate analgesia/sedation (record scores on flow sheet), and normalizing volume status

Weaning Intervention

- Transfer to PSV mode, adjust support level to maintain patient's respiratory rate at less than 35 breaths/min.
- Observe for 30 minutes for signs of early failure (same tolerance criteria as with short-term ventilation; see Box 25-18).
- If tolerated, continue trial for 2 hours, then return patient to "rest" settings by adding ventilator breaths or increasing PSV to achieve a total respiratory rate of less than 20 breaths/min.
- After at least 2 hours of rest, repeat trial for 2 to 4 hours at same PSV level as previous trial. If the patient exceeds the tolerance criteria (listed in Box 25-18), stop the trial and return to "rest" settings. In this case, the next trial should be performed at a higher support level than the "failed" trial.
- Record the results of each weaning episode, including specific parameters and the time frame if "failure" observed, on the bedside flow sheet.
- The goal is to increase the length of the trials and reduce the PSV level needed on an incremental basis. With each successive trial, the PSV level may be decreased by 2 to 4 cm H_2O, the time interval may be increased by 1 to 2 hours, or both, while keeping the patient within tolerance parameters. The pace of weaning is patient specific, and tolerance may vary from day to day. Review readiness criteria for correctable factors daily *and* each time the patient "fails" a weaning trial.
- Ensure nocturnal ventilation at "rest" settings (with a respiratory rate of <20 breaths/min) for at least 6 hours each night until the patient's weaning trials demonstrate readiness to discontinue ventilatory support.

Discontinuing Mechanical Ventilation

The patient should be weaned until ventilator settings are FiO_2 40% or more, PSV 10 cm H_2O or less, and PEEP 5 cm H_2O or less. Once these settings are well tolerated, the patient should be placed on continuous positive airway pressure 5 cm H_2O or (if tracheostomy in place) on tracheostomy collar. If the patient meets tolerance criteria over the first 5 minutes, the trial should be continued for 1 to 2 hours. If clinical observation and ABG values indicate that the patient is maintaining adequate ventilation and oxygenation on this "minimal" support, the following options should be considered:

- If the patient meets extubation criteria (see Box 25-18), this step should be attempted.
- If the patient is on tracheostomy collar, the trials should be continued two to three times per day with daily increases in time on tracheostomy collar by 1 to 2 hours per trial until total time off the ventilator reaches 18 h/d. At this point, the patient may be ready to remain on tracheostomy collar for longer than 24 hours unless the tolerance criteria are exceeded.
- Ventilator weaning is considered successful once the patient achieves spontaneous ventilation (extubated or on tracheostomy collar) for at least 24 hours.

Adapted from evidence-based practice guidelines used in the Surgical/Trauma Intensive Care Unit, University of Virginia Health System, Charlottesville, Virginia.

fibers and the speed with which they contract. Both of these factors are affected by physiological changes that change the resting position of the diaphragm. With COPD, the resting length is shorter (weakening force of contraction), and with diaphragmatic distention, ascites, or morbid obesity, the diaphragm must push down abdominal contents as it contracts. Reactive airway disease increases the resistance to airflow, with increased workload for muscles of respiration. Any of these abnormalities can lead to significant fatigue of these muscles and respiratory distress.

Respiratory muscle fatigue impedes weaning. It may take as long as 24 hours of complete rest (the mechanical ventilator assumes all of the work of breathing for the patient) for recovery of fatigued respiratory muscles. Therefore, it is common practice to increase ventilatory support at night to ensure rest. This can be accomplished with any of the "resting" modes, so long as the patient's respiratory rate is less than 20 breaths/min. The intent here is to promote and simulate the normal decrease in rate and work of breathing that occurs during each person's sleep–rest cycle. Newer ventilator modes, such as APRV, may be useful to allow gradual reduction of support and increased patient work of breathing.[32]

Weaning trials are discontinued if signs of fatigue or respiratory distress develop. The weaning tolerance criteria and observations are summarized in Boxes 25-18 and 25-19. During physical therapy and activities, it is necessary to monitor the patient for fatigue with use of accessory muscles, increased respiratory rate, and decreased oxygen saturation that indicates respiratory muscle fatigue. The approach to prolonged mechanical ventilation includes aggressive physical therapy and activity to promote muscle conditioning and strength. The use of sedatives and narcotics during weaning should be limited to only the level of medication clearly needed to control pain or anxiety. Special considerations for weaning an older patient from a ventilator are given in Box 25-20.

Regardless of the mode or approach, certain factors have been found to influence weaning success positively. These include the use of collaborative, multidisciplinary teams to

BOX 25-20 CONSIDERATIONS FOR THE OLDER PATIENT

Overcoming Barriers to Ventilator Weaning

An elderly patient on mechanical ventilation poses a unique challenge to care givers. Successful weaning requires effective nursing interventions to address the patient's basic care needs.

- **Sleep Deprivation:** Learn the patient's normal sleep habits, establish a restful environment, and minimize interruptions for at least 6 hours each night and 2 hours of midday rest. Consult the pharmacist or doctor for sleep medication as needed at bedtime.
- **Imbalanced Nutrition: Less Than Body Requirements; and Risk for Fluid Volume Imbalance:** Consult the registered dietitian and begin delivery of recommended nutrition as soon as possible. Assess patient tolerance and increase to goal rate per order. Evaluate fluid balance each shift (input and output, weight, clinical examination) and discuss changes in intake and the possible need for diuretics with the physician.
- **Acute Pain; Anxiety; and Acute Confusion:** Administer analgesia per order, assessing need and effect of intervention by pain scale or physiological parameters. Carefully evaluate possible etiology of anxiety or agitation; when pharmacological intervention is indicated, titrate to achieve desired response using standardized sedation scale to limit sedation. Nonpharmacological interventions are essential in the elderly patient (eg, orientation to place, date, and time; spiritual; massage). Adjust care for hearing impairment or for other sensory limitations that may contribute to confusion or anxiety.
- **Risk for Constipation; and Diarrhea:** Learn the patient's "usual" elimination pattern if possible; start with similar intervention and add more aggressive bowel regimen as needed to establish regular bowel movements. Evaluate factors (eg, medications or narcotics) that may alter bowel function, and ensure adequate hydration by enteral route if possible.
- **Risk for Activity Intolerance; and Impaired Bed Mobility or Impaired Physical Mobility:** Consult the physical or occupational therapist to evaluate functional capacity and initiate appropriate therapy. Begin getting patient out of bed as soon as possible, and encourage active range-of-motion exercises and participation in activities of daily living.

formulate comprehensive plans of care based on assessment of individual patients, the use of standardized weaning protocols that are assigned to each patient based on individual assessment, and the use of critical pathways. The interplay of these strategies, all designed to promote consistency of and rationale for practice, truly leads to outcomes showing that the whole (process) is greater than the sum of its parts.

Short-Term Ventilation Weaning

Patients typically intubated for a short time include those who are intubated for surgical procedures, for an acute exacerbation of an underlying lung disease that can be easily reversed, and for airway protection during an acute neurological event (eg, drug overdose). It is important to evaluate the reason the patient was initially intubated to be certain that mechanical ventilation is no longer indicated. Weaning within a short period of time is desirable because physiological changes caused by the mechanical ventilation begin within 72 hours (see Box 25-18, p. 544).

Frequently used predictive criteria for short-term weaning success are an NIP of less than or equal to −20 cm H_2O (more negative as −30 cm H_2O), PEP of greater than or equal to +30 cm H_2O (more positive as +45 cm H_2O), and spontaneous minute volume of less than 12 L/min. NIP and PEP give an indication of respiratory muscle strength. The choice of weaning method does not appear to be important.

Weaning procedures may vary slightly from hospital to hospital, but general guidelines remain the same. For instance, weaning is generally initiated in the morning when the patient is rested. The patient is made comfortable, and the nurse elevates the HOB. Pharmacological agents for comfort, such as bronchodilators or sedatives, are administered as indicated. Sedation should be minimized to provide best odds for a successful weaning trial. By explaining the procedure, the nurse helps the patient through some of the discomfort and apprehension. Before a weaning trial, the nurse ensures a patent airway and provides suction if necessary.

Support and reassurance help the patient through the discomfort and apprehension as the nurse remains with the patient following initiation of the weaning process. The nurse also evaluates and documents the patient's response to weaning.

Long-Term Ventilation Weaning

The process of long-term weaning often takes weeks. It incorporates gradual and progressive conditioning for respiratory and body muscles using a multidisciplinary team approach. Success with whole body conditioning with emphasis on upper body strength and respiratory muscle function has improved ventilator liberation, and aggressive physiotherapy is necessary. Usually, the entire process is complicated, and it involves multiple delays and setbacks. During long-term weaning, the patient may fail a weaning trial and should then be rested on the ventilator up to 24 hours before another trial is attempted. The rest period allows for recovery of the respiratory muscles. Patients who fail a weaning trial often exhibit rapid, shallow breathing patterns consistent with their respiratory muscle weakness. Regular reevaluation of the weaning plan by the multidisciplinary team, coupled with continuous communication with the patient and family, is necessary (see Box 25-19).

Methods of Ventilator Weaning

Various methods have been studied for weaning from the ventilator. Controversies exist about which methods are best. Some of the most common weaning methods include T-piece, CPAP trials, and gradual PSV reduction to minimal settings. Comprehensive assessment of the patient's needs and progress toward weaning, monitoring of the weaning parameters, and following established goals promote successful weaning. Multidisciplinary and comprehensive approaches to weaning based on health care professional's monitoring and implementing a weaning plan with continuity promote positive outcomes.

T-Piece Trial

The T-piece is connected to the patient at the desired FiO_2 (usually slightly higher than the previous ventilator setting).

The patient's response and tolerance to the trial are continuously observed. The duration of T-piece trials is not standardized, and some clinicians extubate if an initial trial of 30 minutes ends with acceptable ABG values and patient response. Increasing frequency and duration of T-piece trials builds the patient's endurance, with periods of rest on the ventilator between extended trials. When the latter method is used, the patient is generally deemed ready to be extubated after 24 successive hours on a T-piece.

Synchronized Intermittent Mandatory Ventilation Mode

The SIMV mode was initially heralded as the optimal weaning mode, allowing some spontaneous breathing (to prevent respiratory muscle atrophy) while providing a backup rate. Weaning with the SIMV method entails a gradual reduction in the number of delivered breaths until a low rate is reached (usually 4 breaths/min). The patient is then extubated if all other weaning criteria are met. However, low levels of SIMV (fewer than 4 breaths/min) may result in a high level of work and fatigue. SIMV plus PSV, called synchronized pressure-support ventilation (SPSV), may be used to decrease the work of breathing associated with spontaneous breaths. Use of the SPSV mode can easily progress to PSV alone when the patient initiates all breaths by dialing down the ventilator breaths. As a result, PSV "stand-alone" mode is often preferred for weaning trials.

Continuous Positive Airway Pressure Method

CPAP entails breathing through the ventilator circuit with a small amount of (or zero) positive pressure. The use of CPAP instead of the use of a T-piece for weaning is controversial. Often, the decision to use one over the other is determined by observing the patient's response or is simply based on the clinician's preference.

Pressure-Support Ventilation Mode

Low levels of PSV decrease the work of breathing associated with ETTs and ventilator circuits. Weaning using the PSV mode entails a progressive decrease in IPL to 5 to 10 cm H_2O based on the patient maintaining an adequate tidal volume (6 to 12 mL/kg) and a respiratory rate of fewer than 25 breaths/min. PSV is associated with less work of breathing than with volume modes, so longer weaning trials may be tolerated. The 5-cm H_2O IPL is thought to overcome the work of breathing through the ETT and ventilator tubing. Typically, the IPL is reduced by 2 cm H_2O daily or twice daily following the patient's response to the ventilator change. Tolerance of PSV weaning is assessed as any weaning mode by assessing the patient's response to changes in respiratory rate, SaO_2, and heart rate, along with observing for fatigue (see Box 25-18, p. 544; Box 25-19, p. 545). There is support for use of CPAP, T-piece, or even PSV during a spontaneous breathing trial before extubation because each is an effective method for the weaning readiness trial.[33]

Adjuncts to Weaning

Several adjuncts to long-term weaning are used to improve weaning tolerance and patient comfort. The mode on newer ventilators that allows for the regulation of pressure support for the size and type of tube, endotracheal or tracheostomy, adjusts for the type of tube resistance to allow less work of breathing. Called automatic tube compensation (ATC) on some ventilators, this is another tool to consider during weaning. The fenestrated tracheostomy tube provides for communication during weaning periods, improving patient interaction. The fenestrated tracheostomy tube has an opening in the outer cannula but not the inner cannula. With the inner cannula in place and the cuff inflated, mechanical ventilation is easy. During the weaning process, the inner cannula is removed, the cuff deflated, the outer cannula capped, and supplemental oxygen supplied by nasal cannula. This system permits air to pass the vocal cords, allowing verbal communication by the patient. The cuff should never be inflated while the inner cannula is capped because the patient will be unable to breathe. The speaking valves provide communication during weaning periods for patients with nonfenestrated tracheostomy tubes, which are generally used more frequently. These valves provide less resistance than the fenestrated tracheostomy tube, and each type of speaking valve allows for supplemental oxygen through a side port. Humidified air with a tracheostomy collar is required to keep the airway moist and prevent secretions from drying, especially at night when speaking valves should be removed for sleep. Use of a large ETT (>7.0 mm) decreases resistance to breathing and decreases the work of breathing. A larger ETT also supports bronchoscopy and the removal of secretions when needed. Tracheostomy in many instances is more comfortable for patients and allows for improved oral care, better communication, and tracheostomy collar trials for weaning.

Extubation Criteria

Whichever mode or combination of modes is used for weaning, extubation cannot occur until several criteria are met based on short-term or long-term ventilation (see Box 25-18, p. 544; Box 25-19, p. 545). Before extubation, the patient must be able to maintain his or her own airway, as evidenced by an appropriate level of consciousness and the presence of cough and gag reflexes. In all patients, but especially in those with a history of difficult intubation or reactive airway disease, the cuff-leak test should be performed before extubation. This entails deflation of the tube cuff (after suctioning of the oropharynx) and a brief period of occluding the ETT in order to demonstrate an air leak with patient inspiration. Absence of a leak can indicate edema and may predict laryngeal stridor after extubation. If the cuff-leak test fails, the patient may be given corticosteroids to reduce edema for 24 to 48 hours and then be reassessed for cuff leak. A direct visualization of the trachea with a bronchoscope may be performed before extubation to determine whether the edema has resolved.

Extubation should never occur unless a qualified person is available to reintubate emergently if the patient does not tolerate extubation. After explaining the procedure and preparing the patient, the nurse or respiratory therapist suctions the patient's tube and posterior oropharynx. Equipment includes an MRB and mask at bedside. The ETT securing device or tape is loosened and the cuff is deflated. The ETT is removed quickly while having the patient cough. The patient's mouth

is suctioned, and humidified oxygen is applied immediately. The patient is evaluated for immediate signs of distress: stridor, dyspnea, and decrease in SaO_2. Treatment of stridor includes inhaled racemic epinephrine and sometimes administration of IV steroids (because steroids do not work immediately, they are given before extubation in those at risk). If these interventions fail, immediate reintubation may be necessary.

Home Care and Mechanical Ventilation

Certain patients requiring invasive mechanical ventilation may be candidates for home care. These patients may require full or partial invasive mechanical ventilation because of neuromuscular weakness, neurogenic hypoventilation, or cardiopulmonary diseases that result in ineffective gas exchange. Conditions that may warrant home care ventilator management include:

- Neurological disorders (eg, ALS, Guillain-Barré syndrome, multiple sclerosis, muscular dystrophy, myasthenia gravis, poliomyelitis, polymyositis, spinal cord injury)
- Restrictive disorders (eg, interstitial pulmonary fibrosis, kyphoscoliosis, obesity, sarcoidosis)
- Obstructive disorders (eg, bronchiectasis, bronchiolitis obliterans, bronchopulmonary dysplasia, chronic bronchitis and emphysema, cystic fibrosis, obesity, sleep apnea syndromes)

New Frontiers and Challenges for Ventilated Patients

Ventilated patients present major challenges to nurses because they are prone to iatrogenic complications with higher mortality and morbidity. It is important that nurses apply current evidence-based research and practice to patient care so that clinical and financial outcomes may improve. Research on the use of low-volume ventilation, high-frequency ventilation, and the appropriate fluid management in ARDS presents new challenges for nurses responsible for implementing the changes in clinical practice. Ventilator weaning by use of weaning teams, outcome managers, and weaning protocols shows promise for future improvement in outcomes, lowering hospital costs, and effective weaning from ventilators with decreased mortality.[34] These system approaches continue to demonstrate reduction of ventilator days, length of stay, and complications. They will continue to be popular initiatives for hospitals that are attempting to find the best outcomes, quality, and cost-effective solutions for complex patients.

Nurses can use current journals and the Internet to search for information about the most up-to-date information and research. The new nurse should seek access to a health science library database to obtain the most current research for his or her area of practice as well as subscribe to nursing journals. Three excellent sources for the new nurse for advanced topics are (1) the *AACN Procedure Manual for Critical Care*, (2) the *AACN Protocols for Practice: Care of the Mechanically Ventilated Patient*, and (3) the journal titled *AACN Advanced Critical Care*. These resources provide more in-depth coverage of topics related to ventilators, pathophysiology, and patient care.

The new frontiers of nursing and health care will continue to require that nurses keep abreast of rapidly changing practice by continually updating their knowledge. The key to excellent nursing care is evidence-based practice. The goal for new nurses is to integrate the best evidence-based practice, knowledge, therapies, and clinical skills of ventilator care into all aspects of clinical practice. The ever-changing technology and research of the 21st century will provide nurses with continued challenges to update their clinical practice with the latest evidence-based practice and research to provide the respiratory patient with the highest quality care.

▲ Clinical Applicability Challenges

CASE STUDY

Mr. S. is an 85-year-old man who developed a hospital-acquired pneumonia after cervical fusion surgery related to a motor vehicle crash. He has been hospitalized for 20 days. He developed hypoxia respiratory failure and was subsequently intubated. He has been receiving appropriate antibiotic coverage for 7 days. He has remained on mechanical ventilation for 7 days. His vital signs have remained stable. Current vital signs include temperature, 99.0°F; heart rate, 94 beats/min; respiratory rate, 22 breaths/min; and blood pressure, 147/68 mm Hg. Current ventilator settings include assist control, rate 15, tidal volume (TV) 350 mL, PEEP 5, FiO2 40%. He is in no acute distress. He has a small amount of thin white secretions. Current issues include hypoxia respiratory failure, bilateral pleural effusions, renal insufficiency, volume overload, deconditioning, and malnutrition. He has no family support. He is currently alert and able to make his own decisions concerning his care.

1. Explain the criteria that Mr. S. meets to perform ventilator weaning.
2. What factors will likely decrease Mr. S.'s chances of successful weaning?
3. What are the major priorities of nursing care for Mr. S.?

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Compare the etiology, pathophysiology, assessment, management, and prevention of community-acquired, hospital-acquired, and health care–associated pneumonia.
2. Describe the etiology, pathophysiology, assessment, and management of a patient with severe acute respiratory syndrome.
3. Discuss the pathophysiology, assessment, and management of pleural effusion.
4. Describe the pathophysiology, assessment, and management associated with pneumothorax.
5. Discuss the pathophysiology, assessment, management, and prevention of pulmonary embolism.
6. Explain the pathophysiology, assessment, management, and prevention of chronic obstructive pulmonary disease.
7. Compare the pathological processes, signs and symptoms, and management of chronic bronchitis and emphysema.
8. Describe the pathology, assessment, and management of a patient at various points on the asthma continuum, from mild attack to status asthmaticus.
9. Explain the key characteristics of hypoxemic acute respiratory failure and hypercapnic acute respiratory failure in terms of pathophysiology, assessment, and management.

Pneumonia remains a common infection found in both the community and hospital, even though there have been advances in identifying people at risk and implementing preventive measures. Critical care nurses encounter pneumonia when it complicates the course of a serious illness or leads to acute respiratory distress.

▲ Pneumonia

In the United States, pneumonia is the leading cause of death from infectious disease, the second most common nosocomial (hospital-acquired) infection, and the eighth leading cause of death.[1] In 2006, 56,326 people died as a result of pneumonia or influenza at a rate of 2.6% as compared to 2005 when pneumonia and influenza caused 63,001 deaths per 100,000 population.[1] Community-acquired pneumonia (CAP) is the leading cause of death from an infectious disease in the United States. CAP results in 500,000 hospitalizations and approximately 45,000 deaths in the United States. It is one of the most common causes of admissions to the intensive care unit (ICU). The mortality rate from severe CAP in the ICU can be as high as 58%. Little improvement has occurred in the mortality rate over the past several years.[2] According to some estimates, approximately 915,000 cases of CAP occur in individuals who are 65 years of age or older. The incidence of CAP requiring hospitalization is four times higher in elderly patients (over 65 years of age) than it is in those 45 to 64 years of age.[3]

CAP is defined by the Infectious Diseases Society of America (IDSA) as an acute infection of the pulmonary parenchyma that is associated with either an acute infiltration on chest x-ray or by auscultation of breath sounds that are consistent with pneumonia. CAP can be diagnosed only in individuals who have not been hospitalized or have not resided in a long-term care facility for more than 14 days before the onset of symptoms. There are no cardinal hallmarks of pneumonia.[2] In the outpatient setting, CAP has a low mortality rate (1% to 5%). However, the mortality rate climbs to 14% in patients requiring hospitalization and to 40% in those requiring admission to the ICU.[4]

Two sets of guidelines for treating patients with pneumonia have been issued. In the first set, issued by the Pneumonia Patient Outcomes Research Team (PORT), the initial site of treatment should be selected based on three criteria, which include (1)

*The views of the authors are their own and do not reflect the official policy or position of the Department of the Army, the Department of Defense, or the United States Government.

assessment of any preexisting conditions that compromise the safety of the patient being cared for at home, (2) calculation of the Pneumonia Severity Index (PSI), and (3) clinical judgment.[5] The PSI stratifies patients into five risk categories. The higher the score, the higher the risk for death, admission to the ICU, or readmission, and the longer the length of stay.[6] Patients in risk classes I, II, and III are at low risk for death and can most likely be treated safely in the outpatient setting. Patients in risk classes IV and V should be hospitalized, with those in class V being admitted to the ICU (Box 26-1).[6] In the second

BOX 26-1 Patient Outcomes Research Team (PORT) Pneumonia Severity Index

Pneumonia Patient Outcomes Research Team (PORT) Severity Index[44]

Step 1: Answer questions 1, 2, and 3. If the response is "no" to all three questions, assign patient to risk class I and institute outpatient treatment. If the response is "yes" to any one of the three questions, proceed to step 2 to determine the patient's risk class (II–V).

1. **Is the patient older than 50 years of age?**
2. **Does the patient have a history of any of the following coexisting conditions*?**
   Neoplastic disease, congestive heart failure (CHF), cerebrovascular disease, renal disease, liver disease
3. **Does the patient have any of the following abnormalities on physical examination?**
   Altered mental status†, pulse more than 125/min, respiratory rate more than 30 breaths/min, systolic blood pressure <90 mm Hg, temperature <35°C or >40°C

Step 2: Assess the following characteristics

Characteristic	Points assigned	Score
Demographic factor		
Age		
Men	Age (y)	
Women	Age (y) –10	
Nursing home resident	+10	
Coexisting illnesses*		
Neoplastic disease	+30	
Liver disease	+20	
Congestive heart failure	+10	
Cerebrovascular disease	+10	
Renal disease	+10	
Physical examination findings		
Altered mental status†	+20	
Respiratory rate >30 breaths/min	+20	
Systolic blood pressure <90 mm Hg	+20	
Temperature <35°C (95°F) or >40°C (104°F)	+15	
Pulse > 125 beat/min	+10	
Laboratory and radiographic findings (if study performed)		
Arterial blood pH < 7.35	+30	
Blood urea nitrogen (BUN) level >30 mg/dL	+20	
Sodium level <130 mmol/L	+20	
Glucose level >250 mg/dL	+10	
Hematocrit <30%	+10	
Partial pressure of arterial O_2 < 60 mm Hg Or Sat < 90%‡	+10	
Pleural effusion	+10	
Total score is the sum of points to identify the severity score and determine the patient's risk class.		

*Neoplastic disease is defined as any cancer—except basal- or squamous-cell cancer of the skin—active at time of presentation or diagnosed within 1 year of presentation. Liver disease is defined as a clinical or histologic diagnosis of cirrhosis or another form of chronic liver disease, such as chronic active hepatitis. CHF is defined as systolic or diastolic ventricular dysfunction documented by history, physical examination, and chest x-ray, echocardiogram, multiple-gated acquisition scan, or left ventriculogram. Cerebrovascular disease is defined as a clinical diagnosis of stroke or transient ischemic attack or stroke documented by magnetic resonance imaging or computed tomography. Renal disease is defined as a history of chronic renal disease or abnormal BUN or creatinine.

†Altered mental status is defined as disorientation with respect to person, place, or time that is not known to be chronic, stupor, or coma.

‡In the Pneumonia PORT cohort study, an oxygen saturation <90% on pulse oximetry or intubation prior to admission was also considered abnormal.

Step 3: Determine the patient's risk class

Total Score	Risk Class	Mortality*	Recommended Site of Treatment
None (see Step 1)	I	0.1%	Outpatient
<70	II	0.6%	Outpatient
71–90	III	0.9%	Outpatient
91–130	IV	9.3%	Inpatient
>130	V	27%	Inpatient

From Miskovich-Riddle L, Keresztes P: CAP management guidelines. Nurse Pract 31(1):43–53, 2006.

BOX 26-2 American Thoracic Society Criteria for Diagnosis of Severe Community-Acquired Pneumonia

Major Criteria
- Invasive mechanical ventilation
- Septic shock with the need for vasopressor

Minor Criteria
- Respiratory rate more than 30 breaths/min
- PaO_2/FiO_2 ratio less than 50
- Multilobar infiltrates
- Confusion/disorientation
- Uremia (BUN level 20 or more mg/dL)
- Leukopenia (WBC count <4,000 cells/mm^3)
- Hypothermia (core temperature <36°C)
- Hypotension requiring aggressive fluid resuscitation

BUN, blood urea nitrogen; PaO_2/FiO_2 ratio, arterial oxygen pressure/fraction of inspired oxygen; WBC, white blood cell.

From American Thoracic Society: Guidelines for the management of adults with community-acquired pneumonia. Am J Respir Crit Care Med 163:1730–1754, 2001, with permission; Mandell LA, et al. Infectious Disease Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults. Clin Infect Dis 44(Suppl 2) S27–S72, 2007.

set of guidelines developed by the American Thoracic Society (ATS), patients with severe CAP require admission to the ICU. Severe CAP is defined as the presence of one of two major criteria or the presence of two of three minor criteria (Box 26-2).[7]

Hospital-acquired pneumonia (HAP), ventilator-associated pneumonia (VAP), and health care–associated pneumonia (HCAP) continue to be important causes of morbidity and mortality despite advances in antimicrobial therapy and advanced supportive measures.[8] HAP is defined as pneumonia occurring more than 48 hours after admission to a hospital, which excludes infection that is incubating at the time of admission.[9] HAP occurs at a rate of 5 to 10 cases per 1,000 hospital admissions, and the incidence increases by 6- to 20-fold in patients receiving mechanical ventilation.[10] VAP is defined as the occurrence of pneumonia more than 48 to 72 hours after intubation. If a person experiences a severe episode of HAP requiring intubation and mechanical ventilation, that person should then be managed like a patient with VAP.[9] HCAP is defined as pneumonia in any patient who has been hospitalized in an acute care hospital for 2 or more days within 90 days of infection; has lived in a nursing home or long-term care facility; has received recent intravenous antibiotic therapy, chemotherapy, or wound care within the past 30 days of the current infection; or has received treatment at a hospital or hemodialysis clinic.[8]

The ATS HAP guidelines state that the criteria defining severe CAP can also be used to define severe HAP.[6] Severe HAP may occur in the ICU, with patients receiving mechanical ventilation being at the greatest risk, or it may precipitate admission to the ICU.[7] HAP independently contributes to mortality in critically ill patients; the attributable mortality rate is 33% to 50%.[9]

Etiology

Bacteria, viruses, mycoplasmas, other infectious agents such as fungi, and foreign material can all cause pneumonia. The specific etiology varies greatly depending on the type of pneumonia (CAP or HAP).[10] *Streptococcus pneumoniae* (pneumococcus) is the predominant pathogen associated with CAP, accounting for 30% to 60% of all occurrences of CAP. It is the most common cause of CAP identified in patients requiring hospitalization. Other organisms considered to be causative agents in CAP include *Haemophilus influenzae*, *Staphylococcus aureus*, and other Gram-negative bacilli.[5] Even in the approximately 50% of cases of CAP in which the causative organism is not identified, *S. pneumoniae* is believed to predominate.[5] Drug-resistant *S. pneumoniae* is frequently seen in individuals older than 65 years of age.[5] Pathogens that should be considered in severe CAP requiring admission to the ICU include *S. pneumoniae*, *Chlamydia pneumoniae*, *S. aureus*, *Mycobacterium tuberculosis*, *Legionella* species, respiratory viruses, and endemic fungi.[11]

Etiologic factors may be used to classify pneumonia as typical or atypical. Typical pneumonia, caused by pathogens such as *S. pneumoniae*, *Streptococcus pyrogenes*, and *Staphylococcus aureus*, is the result of the bacteria multiplying in the alveoli, causing inflammation and accumulation of fluid within the alveoli.[3] Atypical pneumonia is caused by pathogens such as *Mycoplasma pneumoniae*, *C. pneumoniae*, influenza virus, adenovirus, and *Legionella* species that give rise to inflammatory changes in the alveolar septa and lung interstitium.[3,10]

Time of onset of pneumonia is an important factor in determining the specific pathogens and outcomes in patients with HAP and VAP.[9] HAP and VAP occurring within 4 days of admission are more likely to be caused by bacteria sensitive to antibiotics. HAP and VAP occurring later on are more likely to be caused by resistant organisms.[9] HAP may be polymicrobial, and common causative pathogens include aerobic Gram-negative bacilli, such as *Escherichia coli*, *Klebsiella pneumoniae*, and *Pseudomonas aeruginosa*, as well as Gram-positive cocci such as *S. aureus*.[9] Polymicrobial HAP is particularly common (>50%) in patients receiving mechanical ventilation (VAP). Highly resistant Gram-negative organisms (eg, *P. aeruginosa*, *Acinetobacter* species) and methicillin-resistant *S. aureus* are frequently seen in late-onset HAP but may occur in early-onset HAP in patients with risk factors for these pathogens.[9,11] The spectrum of potential pathogens can be defined by assessment of a variety of factors, including the severity of the pneumonia, comorbidities, prior therapy (including antibiotics), and length of hospitalization.[9]

Pathophysiology

Pneumonia is an inflammatory response to inhaled or aspirated foreign material or the uncontrolled multiplication of microorganisms invading the lower respiratory tract. This response results in the accumulation of neutrophils and other proinflammatory cytokines in the peripheral bronchi and alveolar spaces.[11] The body's defense system, which includes anatomical, mechanical, humoral, and cellular defenses, is designed to repel and remove organisms entering the respiratory tract. Many systemic diseases increase the patient's risk for pneumonia by altering the respiratory defense mechanism. Pneumonia develops when normal pulmonary defense mechanisms are either impaired or overwhelmed, allowing microorganisms to multiply rapidly. The severity of pneumonia depends on the amount of material aspirated, the virulence of the organism, the amount of bacteria in the aspirate, and the host defenses.[11]

The means by which pathogens enter the lower respiratory tract include aspiration, inhalation, hematogenous spread from a distant site, and translocation. Risk factors that predispose an individual to one of these mechanisms may be categorized as (1) conditions that enhance colonization of the oropharynx, (2) conditions favoring aspiration, (3) conditions requiring prolonged intubation, and (4) host factors.[5] Colonization of the oropharynx (colonization is the presence of microorganisms other than the normal flora in the absence of clinical evidence of infection) has been identified as an independent factor in the development of HAP. Gram-positive bacteria and anaerobic bacteria normally live in the oropharynx, and they occupy bacterial binding sites in the oropharyngeal mucosa. When normal oropharyngeal flora is destroyed, these binding sites are susceptible to colonization by pathogenic bacteria. Risk factors associated with oropharyngeal colonization include previous antibiotic therapy, increased age, dental plaque, smoking, and chronic diseases, such as chronic obstructive pulmonary disease (COPD), gastroesophageal reflux disease, alcoholism, diabetes mellitus, and malnutrition.[11,12] The exact role the stomach plays in the development of pneumonia is controversial. In healthy individuals, the stomach is normally sterile because of the bactericidal activity of hydrochloric acid. However, when gastric pH increases above normal (pH > 4), as occurs with the use of histamine-2 antagonists and antacids for stress ulcer prophylaxis, microorganisms are able to multiply.[9] Gastric colonization increases retrograde colonization of the oropharynx and increases the risk for pneumonia. Individuals at risk for gastric colonization include the elderly; those with achlorhydria, ileus, or upper gastrointestinal disease; and those receiving antacids, histamine-2 antagonists, or enteral feedings.[2,5] The Gram-negative or pathogenic Gram-positive organisms that have colonized the oropharynx are readily available for aspiration into the tracheobronchial tree.

Aspiration occurs frequently in healthy individuals while they sleep. The risk for clinically significant aspiration is increased in individuals who are unable to protect their airways (eg, in patients with alcohol abuse, a depressed level of consciousness, or dysphagia; in those who have endotracheal or enteral tubes; or in those receiving enteral feedings). Aspiration of bacteria found in dental plaques is receiving increased attention as a significant source of pneumonia.

Inhalation of bacteria-laden aerosol devices from contaminated respiratory equipment is another potential source of pneumonia-causing bacteria. Condensate that collects in the ventilator tubing can become contaminated with secretions and serve as a reservoir for bacterial growth.[12] Inhalation is an effective entry mechanism for *Legionella* species, M. *tuberculosis*, certain viruses, and fungi. Organisms are carried through small inhaled droplets from the tracheobronchial tree into the lower respiratory tract.[12]

Hematogenous spread serves as a mechanism for the development of pneumonia; the pulmonary circulation provides a potential portal of entry for microbes. The pulmonary capillaries form a dense network in the walls of the alveoli that is ideal for gas exchange. Hematogenous microbes from distant sites of infection can migrate through this network and cause pneumonia. (Pneumonia can also cause bacteremia. Secondary bacteremia after pneumonia has been reported in 6% to 20% of pneumonia cases.) Finally, translocation of bacterial toxins from the gut lumen to the mesenteric lymph nodes and eventually to the lungs may possibly cause bacterial pneumonia. However, translocation has not yet been confirmed as a pathophysiological mechanism.[9]

Assessment

History

Knowledge of risk factors and symptoms can assist in identifying potential pathogens causing CAP and HAP. Hemoptysis implies tissue necrosis and is more common with pyogenic streptococcal pneumonia, anaerobic lung abscesses, *S. aureus*, necrotizing Gram-negative organisms, and invasive *Aspergillus* species.[11] Extrapulmonary symptoms may indicate specific pathogens; diarrhea and abdominal discomfort are present with *Legionella* species, and otitis media and pharyngitis are present with M. *pneumoniae*.[12] The clinical presentation in the older adult may vary somewhat from what is "typical" in a younger person (Box 26-3).

Historical information may also be extremely helpful in diagnosis of CAP and HAP. It is important to include information about contact with animals, especially birds, bats, rats, and rabbits, which can assist with the diagnosis of histoplasmosis, psittacosis, tularemia, and plague. In addition, a complete history that includes dental hygiene history and place of residence may assist in the differential diagnosis.[11] Diseases that may mimic pneumonia include heart failure, atelectasis, pulmonary thromboembolism, drug reactions, pulmonary hemorrhage, and acute respiratory distress syndrome (ARDS).

Physical Findings

A comprehensive cardiovascular and pulmonary assessment should be completed, with a focus on the ATS major and minor criteria (see Box 26-2, p. 552). The nurse assesses for signs of hypoxemia (duskiness or cyanosis) and dyspnea. Patients presenting with new-onset respiratory symptoms (eg, cough, sputum production, dyspnea, pleuritic chest pain) usually have an accompanying fever and chills. Inspection of

BOX 26-3 CONSIDERATIONS FOR THE OLDER PATIENT

Pneumonia

- **Presentation.** The usual symptoms (fever, chills, increased white blood count) may be absent. Confusion and tachypnea are common presenting symptoms in older patients with pneumonia. Other symptoms in the older patient include weakness, lethargy, failure to thrive, anorexia, abdominal pain, episodes of falling, incontinence, headache, delirium, and nonspecific deterioration.
- **Prevention.** People 65 years of age and older should receive both the pneumococcal vaccine (a one-time vaccination) and yearly influenza vaccines. The Health Care Financing Agency has approved the use of standing orders to give the vaccines to Medicare patients.

the chest includes assessing respiratory pattern and respiratory rate, observing the patient's posture and work of breathing, and inspecting for the presence of intercostal retractions. Percussion of the chest frequently reveals dullness with lobar pneumonia. Decreased breath sounds are heard on auscultation. Crackles or bronchial breath sounds are heard over the area of consolidation.

Extrapulmonary symptoms may include myalgia and gastrointestinal symptoms. Confusion may be a subtle symptom in elderly patients.[12,13]

Diagnostic Studies

The workup for severe CAP and HAP is similar. Diagnostic tests are ordered for two reasons: to determine whether the pneumonia is the cause of the patient's symptoms and to determine the pathogen when pneumonia is present.[9] Table 26-1 summarizes the current ATS recommendations. The diagnostic evaluation must be performed rapidly to prevent delays in initiation of antibiotic therapy.

All patients should have a chest radiograph (posteroanterior and lateral views) to identify both the presence and location of infiltrates. The chest radiograph is helpful in differentiating pneumonia from other conditions and identifying severe pneumonia, which is indicated by the presence of multilobular, rapidly spreading, or cavitary infiltrates.

The value of examining lower respiratory secretions with Gram stain and culturing sputum is controversial. The ATS does not recommend routine use of Gram stain and sputum culture and advises that results must be interpreted cautiously.[7,9] However, the IDSA recommends routine Gram stain and culture of deep-cough specimens.[5] Lower respiratory secretions can be easily obtained in intubated patients using endotracheal aspiration. Nonquantitative endotracheal aspiration cultures may assist in excluding certain pathogens and may be helpful in modifying initial empirical treatment.[5] Routine use of quantitative invasive diagnostic techniques (bronchoscopy with protected specimen brush [PSB] or bronchoalveolar lavage [BAL]) in severe pneumonia is not recommended by the ATS, the Centers for Disease Control and Prevention (CDC), or the IDSA.[5–7] Current guidelines suggest that BAL or PSB be used only in selected circumstances, such as in nonresponse to antimicrobial therapy, immunosuppression, suspected tuberculosis in the absence of a productive cough, pneumonia with suspected neoplasm or foreign body, or conditions that require lung biopsy.[5–7] The IDSA recommends HIV testing for people age 15 to 54 years as well.[5] Pneumococcal urinary antigen assay is being recommended as an addition to blood culture testing. The advantage of this test is the rapidity with which results are obtained (within 15 minutes).[5]

Table 26-1 Diagnostic Studies in Patients With Severe Community-Acquired Pneumonia or Severe Hospital-Acquired Pneumonia

Study	Rationale
Chest radiograph (anterior–posterior and lateral)	For evaluation of patient who are likely to have pneumonia, to aid in differentiating diagnosis To assess for pleural effusion
Pretreatment blood samples for culture (two sets of blood cultures from separate sites): Not necessary for community-acquired pneumonia (CAP), except for those with intensive care unit (ICU) admission, failure of outpatient antibiotic therapy, cavitary infiltrates, leukopenia, active alcohol abuse, severe liver disease, asplenia, positive pneumococcal urinary antigen test (UAT) result, and pleural effusion	To evaluate possible cause of severe CAP because of higher yield, great possibility of the presence of pathogen not covered by the usual empirical antibiotic therapy, and to narrow antibiotic treatment to treat the pathogen
Complete blood count Serum electrolytes Renal and liver function	To document the presence of multiple-organ dysfunction To evaluate for leukopenia that is associated with high incidence of bacteremia To help define severity of illness
Arterial blood gases (ABGs)	To define severity of illness To determine need for supplemental oxygen and mechanical ventilation
Thoracentesis (if pleural effusion is >10 mm identified on lateral decubitus film) Pleural fluid studies, including: White blood count with differential Gram stain and acid-fast stain Culture for bacteria, fungi, and mycobacteria	To rule out empyema
Pretreatment Gram stain and culture of expectorated sputum	Gram stain results will help broaden initial empirical coverage for less common pathogens and validate sputum culture results.
Obtain UAT for *Legionella pneumophila* and *Streptococcus pneumoniae*	To rule out *Legionella* and *Streptococcus*

Management

Antibiotic Therapy

Antibiotic therapy is the cornerstone of treatment for both CAP and HAP. Patients should initially be treated empirically, based on the severity of disease and the likely pathogens.[9] Table 26-2 presents ATS guidelines for treatment of severe CAP, and Table 26-3 presents guidelines for treatment of HAP and VAP. Initial therapy should be instituted rapidly. Data show that hospitalized patients with CAP who receive their first dose of antibiotic therapy within 8 hours of arrival at the hospital have reduced mortality at 30 days.[7] Double antibiotic coverage is necessary for people with severe CAP.[11] Initial therapy should not be changed within the first 48 to 72 hours unless progressive deterioration is evident or initial microbiological (blood or respiratory) cultures indicate a need to modify therapy.[7,9]

Factors to consider when determining the duration of therapy include concurrent illness, bacteremia, severity of pneumonia at the onset of antibiotic therapy, infecting pathogens, risk for multidrug resistance, and rapidity of clinical response.[7,9] Recommended duration of therapy is 7 to 10 days for *S. aureus* or *H. influenzae*; 10 to 14 days for *M. pneumoniae* or *C. pneumoniae*; and 8 to 14 days for *P. aeruginosa*, *Acinetobacter* species, multilobar involvement, malnutrition, or a necrotizing Gram-negative bacillus.[11]

Supportive Therapy

Common nursing diagnoses for a patient with a respiratory disorder (such as pneumonia) are given in Box 26-4. Oxygen therapy may be required to maintain adequate gas exchange. Mechanical ventilation to correct hypoxemia is frequently required in both severe CAP and HAP. Humidified oxygen should be administered by mask or endotracheal tube to promote adequate ventilation. Aggressive pulmonary toilet is indicated to mobilize secretions, open closed alveoli, and promote oxygenation. Adequate nutritional support is critical. In addition, a nutritional consult should be initiated with implementation of appropriate enteral or parenteral therapy.

Prevention

Because pneumonia is the seventh leading cause of death in the United States, prevention of both CAP and HAP is essential. Primary measures to prevent CAP include the use of influenza and pneumococcal vaccines.[7,9] All immunocompetent patients 50 years of age or older should receive the injected form of the inactivated influenza vaccine. The live attenuated intranasal influenza vaccine is an alternative for people 5 to 49 years of age without chronic disease. The pneumococcal vaccine is recommended for people older than 65 years of age and those with chronic illnesses, such as cardiovascular disease, COPD (but not asthma), diabetes mellitus, alcoholism, chronic liver disease, cerebrospinal fluid leaks, and functional or anatomic asplenia; those who belong to special populations, such as Alaska natives or other Native Americans; or those who live in special social settings, such as long-term care facilities.[7,9] The ATS recommends influenza vaccine for three target groups: persons at a high risk for influenza compli-

Table 26-2 Recommended Therapy for Community-Acquired Pneumonia, Inpatients*

Type of Patient	Therapy†,‡
Non-ICU inpatient	A respiratory fluoroquinolone A beta-lactam *plus* macrolide
ICU patient	A beta-lactam (cefotaxime, ceftriaxone, or ampicillin/sulbactam) *plus* either azithromycin or a respiratory fluoroquinolone (for penicillin-allergic patient, a fluoroquinolone and aztreonam are recommended)
At risk for *Pseudomonas aeruginosa*	Selected intravenous antipseudomonal beta-lactam (cefepime, imipenem, meropenem, piperacillin/tazobactam) plus intravenous antipseudomonal quinolone (ciprofloxacin or levofloxacin) or Selected intravenous antipseudomonal beta-lactam (cefepime, imipenem, meropenem, piperacillin/tazobactam) plus intravenous macrolide (azithromycin) and aminoglycoside or Selected intravenous antipseudomonal beta-lactam (cefepime, imipenem, meropenem, piperacillin/tazobactam) *plus* aminoglycoside and intravenous antipneumococcal fluoroquinolone (for penicillin-allergic patients, substitute aztreonam for above beta-lactam)
At risk for CA-methicillin-resistant *Staphylococcus aureus* (MRSA)	Add vancomycin or linezolid

*Excludes patients at risk for HIV.

†Combination therapy required.

‡In no particular order.

Table 26-3 Antibiotic Therapy for Patients With Hospital-Acquired or Ventilator-Associated Pneumonia

Initial Empiric Antibiotic Therapy for Hospital-Acquired Pneumonia or Ventilator-Associated Pneumonia in Patients With No Known Risk Factors for Multidrug-Resistant Pathogens, Early Onset, and Any Disease Severity

Potential Pathogen	Recommended Antibiotic
*Streptococcus pneumoniae**	Ceftriaxone
Haemophilus influenzae	*or*
Methicillin-sensitive *Staphylococcus aureus*	Levofloxacin, moxifloxacin, or ciprofloxacin
Antibiotic-sensitive enteric Gram-negative bacilli	*or*
Escherichia coli	Ampicillin/sulbactam
Klebsiella pneumoniae	*or*
Enterobacter species	Ertapenem
Proteus species	
Serratia marcescens	

*The frequency of penicillin-resistant *S. pneumoniae* and multidrug-resistant *S. pneumoniae* is increasing; levofloxacin and moxifloxacin are preferred to ciprofloxacin, and the role of other new quinolones, such as gatifloxacin, has not been established.

Initial Empiric Therapy for Hospital-Acquired Pneumonia, Ventilator-Associated Pneumonia, and Health Care–Associated Pneumonia in Patients With Late-Onset Disease or Risk Factors for Multidrug-Resistant Pathogens and All Disease Severity

Potential Pathogens	Combination Antibiotic Therapy*
Pathogens listed in above table and MDR pathogens	Antipseudomonal cephalosporin (cefepime, ceftazidime)
Pseudomonas aeruginosa	*or*
Klebsiella pneumoniae (ESBL+)†	Antipseudomonal carbapenem (imipenem or meropenem)
Acinetobacter species‡	*or*
	β-Lactam/β-lactamase inhibitor (piperacillin/tazobactam) *plus*
	Antipseudomonal fluoroquinolone† (ciprofloxacin or levofloxacin)
	or
	Aminoglycoside (amikacin, gentamicin, or tobramycin) *plus*†
MRSA	Linezolid or vancomycin
Legionella pneumophila†	

*Initial antibiotic therapy should be adjusted or streamlined on the basis of microbiologic data and clinical response to therapy.

†If MRSA risk factors are present or there is a high incidence locally.

‡If an ESBL+ strain, such as *K. pneumoniae,* or an *Acinetobacter* species is suspected, a carbapenem is a reliable choice. If *L. pneumophila* is suspected, the combination antibiotic regimen should include a macrolide (eg, azithromycin) or a fluoroquinolone (eg, ciprofloxacin or levofloxacin) should be used rather than an aminoglycoside.

cations, persons who may transmit influenza to high-risk patients (eg, health care workers), and any person who wishes to decrease the chance of becoming infected with influenza.[9] High-risk patients include people older than 65 years of age, residents of long-term care facilities, patients with chronic cardiovascular or pulmonary disease, patients who required regular medical care or hospitalization during the preceding year, and pregnant women in the second or third trimester during influenza season. Because cigarette smoking is a risk factor for both HAP and CAP pneumonia, smoking cessation, particularly in patients who have previously had pneumonia, is an important preventive strategy.[9]

A complete understanding of the pathogenesis of HAP enables the critical care nurse to develop strategies about interventions that prevent the onset of pneumonia. The CDC, IDSA, and ATS consider education the cornerstone of an effective infection control program and the prevention of HAP.[5,9] Targets of opportunity in the prevention of HAP include strict infection control, handwashing using an alcohol-based disinfectant, surveillance for pathogens, and early removal of invasive lines.[9] The American Association of Critical-Care Nurses (AACN) has published guidelines for preventing VAP as part of their AACN Practice Alerts (see Chapter 25). According to the evidence-based directive from AACN, in all patients receiving mechanical ventilation as well as those at high risk for aspiration (1) the head of the bed should be elevated at 30 to 45 degrees unless medically contraindicated, (2) endotracheal tubes should have dorsal lumens above the cuff to allow drainage and continuous tracheal secretions, and (3) patient ventilator circuits should be changed based on need because of contamination rather than by routine.[14] The CDC has published comprehensive guidelines on the prevention of

BOX 26-4 EXAMPLES OF NURSING DIAGNOSES

For the Patient With a Respiratory Disorder

- Ineffective Airway Clearance related to pulmonary secretions
- Anxiety related to impaired breathing function
- Impaired Gas Exchange related to ventilation–perfusion imbalance
- Risk for Deficient Fluid Volume related to dyspnea and fever
- Activity Intolerance related to imbalanced oxygen supply and demand
- Ineffective Breathing Pattern related to respiratory muscle fatigue
- Deficient Knowledge related to disease process and treatment
- Imbalanced Nutrition: Less Than Body Requirements related to decrease in appetite secondary to medical treatment and fatigue
- Risk for Infection
- Disturbed Sleep Pattern related to dyspnea
- Ineffective Peripheral Tissue Perfusion related to decrease in cellular exchange
- Social Isolation related to change in physical well-being

HAP.[9] Internet access to the CDC guidelines is available at http://www.cdc.gov.

▲ Severe Acute Respiratory Syndrome

Severe acute respiratory syndrome (SARS), a viral illness of the lower respiratory tract, is caused by the SARS-associated coronavirus (SARS-CoV).[15] First cases were reported in Guangdong Province, China, in November 2002, and subsequently identified in Hong Kong, Vietnam, Thailand, Taiwan, Switzerland, Germany, Singapore, and Canada.[15,16] A total of 8,098 people who became sick with SARS, resulting in 774 deaths, were reported to the World Health Organization (WHO) between November 2002 and July 2003.[15] The illness has not been as prevalent in the United States, with only eight people having been hospitalized with evidence of the SARS-CoV.[15] What these people had in common was international travel to a SARS-affected region within 10 days of hospital admission.

The SARS virus is transmitted from person to person by droplets, direct or indirect contact, or viral shedding in feces and urine.[15,17] Droplets spread when an infected person coughs or sneezes and droplets land on the mucous membranes of the mouth, nose, or eyes of a person who is usually located within a distance of 3 ft. Direct or indirect contact results when a person touches a surface contaminated with droplets and then touches his or her eyes, nose, or mouth.[15] The virus spreads quickly, and medical personnel are among those commonly infected.[15,17]

The period from exposure to the onset of symptoms, or prodromal phase of SARS, is usually 2 to 7 days, although it may be as long as 10 to 14 days. The first symptoms are fever (>38°C), chills, and rigor.[15,17,18] Other symptoms include headache, malaise, and myalgias. Mild respiratory symptoms may be present. Inspiratory crackles may be heard at the bases of the lungs. Chest radiographs may be normal, or focal airspace infiltrates may be present in the peripheral lung zones (Fig. 26-1). Initial blood counts indicate lymphopenia, although the neutrophil count and monocyte count are often normal.[16,17] Sputum and blood cultures are obtained to rule out the other causes of atypical pneumonia to include *M. pneumoniae*, *C. pneumoniae*, human cytomegalovirus, adenoviruses, respiratory syncytial virus, and influenza viruses.[17]

After 3 to 7 days, the lower respiratory phase begins, as evidenced by a dry, nonproductive cough and dyspnea that may be accompanied by progressive hypoxemia.[17] In up to 20% of the cases, the respiratory illness is severe enough to require intubation and mechanical ventilation.[19] The focal infiltrates progress to more generalized, interstitial infiltrates, and significant consolidation is evident.[16] Findings of ground-glass opacification in the periphery are typical on thoracic computed tomography (CT) scan.[16] Laboratory findings include leukopenia, lymphopenia, and thrombocytopenia on the complete blood count. Serum alanine aminotransferase, creatinine kinase (CK), and lactate dehydrogenase (LDH) may be elevated, indicating extensive lung injury.[16,17] Advanced age, male gender, high peak CK, high LDH, high neutrophil count, and low serum sodium have been found to be predictive of significant illness, ICU admission, and death.[16,17]

Until SARS is specifically identified, the treatment plan for a patient with a suspected diagnosis of SARS includes empiric therapy using antibiotics effective against typical and atypical pathogens.[18] Antiviral agents such as ribavi-

rin and corticosteroids may be administered as well.[20] In an analysis of 110 patients with SARS, 61% had an incident of hemolytic anemia, 57% hypocalcemia, and 46% hypomagnesemia.[20] Ventilatory support may be provided either through noninvasive positive-pressure ventilation or, as patient condition dictates, intubation with mechanical ventilation.

Because SARS is a virulent pathogen, a key part of the care of the patient is the institution of strict infection control measures. Droplet and contact precautions are a necessity. Personal protective equipment, including a gown, gloves, surgical mask or N95 disposable particulate respirator, and face shield, should be worn by those in contact with the patient.[17] A private room with negative air flow is recommended.[21] Strict handwashing and decontamination of any equipment used in patient care are a must (Fig. 26-2).[21] When patients are discharged, they should be instructed to limit their interactions outside the home and not go to any public places until 10 days after fever and respiratory symptoms resolve.[17]

▲ Pleural Effusion

The pleural space is a space between the visceral pleural that lines the lungs and parietal pleurae that lines the interior chest wall. This space is lubricated with 15 mL of serous

fluid.[22] The fluid originates from the parietal pleura and is eventually absorbed by the pulmonary lymphatics.

Pathophysiology

Pleural effusion is the accumulation of pleural fluid due to an increased rate of fluid formation, a decreased rate of fluid removal, or both.[23] This is caused by at least one of the five following mechanisms:[23]

- Increased pressure in pulmonary capillaries (eg, heart failure, massive PE)
- Increased capillary permeability (eg, pneumonia, malignancy, infection, pancreatitis)
- Decreased plasma osmotic pressure (eg, hypoalbuminemia, hypoproteinemia, cirrhosis)
- Increased intrapleural negative pressure (eg, atelectasis, trapped lung)
- Impaired lymphatic drainage of the pleural space (eg, pleural malignancy or infection)

Transudates

Transudative pleural effusions, unilateral or bilateral, are an ultrafiltrate of plasma, indicating that the pleural membranes are not diseased.[24] Systemic factors cause the fluid accumulation in transudative pleural effusion. Over 1 million cases of pleural effusion occur each year, half of which are caused by heart failure.[23] In heart failure, an increase in pulmonary venous pressure contributes to the formation of pleural effusions. Treatment focuses on reducing afterload and improving cardiac output with diuretics and/or inotropes.[24] Another cause of transudative pleural effusions is atelectasis, which may cause pleural fluid to accumulate because of a decrease in pleural pressure. The fluid continues to accumulate until the pleural–parietal pleural interstitial pressure gradient returns to normal.[25] Other causes of transudative pleural effusions include cirrhosis, nephrotic syndrome, malignancy, and peritoneal dialysis.

Exudates

The most common pleural effusion is exudative. Exudative pleural effusions result from local factors, such as pleural inflammation, increased pleural membrane permeability, or lymphatic obstruction.[26] Exudative pleural effusions satisfy any one of the following criteria, known as Light's criteria:[24,27]

- Pleural fluid-to-serum protein ratio greater than 0.5
- Pleural fluid-to-serum LDH ratio greater than 0.6
- Pleural fluid LDH that is two thirds of the upper normal limit for serum LDH

Four million Americans are affected by bacterial pneumonia, 20% of which require hospitalization. Forty percent of these hospitalized patients develop effusions.[26] Malignancies are the second most common cause of exudative pleural effusions. If a massive effusion opacifies, an entire hemithorax, metastatic disease, or chylothorax should be suspected. Other causes of exudative pleural effusion are tuberculosis, trauma, pancreatitis, mesotheliomas, and esophageal perforation.[24]

A hemothorax is a bloody exudative pleural effusion and is diagnosed by a pleural fluid/blood hematocrit ratio greater than 50%.[28] Trauma is the most common cause of a hemothorax (see Chapter 55). Other causes are invasive procedures (placement of central venous catheter, thoracentesis) and anticoagulation therapy. Empyema refers to gross pus in the pleural cavity and requires drainage with a chest tube or surgery. Chylothorax refers to the presence of chyle or a fatty substance in the pleural space.[28] The most common causes of chylothorax are malignancies, surgery, and trauma.[28]

Assessment

History and Physical Findings

Subjective findings include shortness of breath and pleuritic chest pain, depending on the amount of fluid accumulation. Objective findings include tachypnea and hypoxemia if ventilation is impaired, dullness to percussion, and decreased breath sounds over the involved area.

Diagnostic Studies

Diagnosis can be made by chest radiograph, ultrasound, or a CT scan; however, a lateral decubitus chest radiograph is the best demonstration of free pleural fluid. As little as 20 mL of pleural fluid can be seen in the decubitus position.[23] When a pleural effusion is suspected on the basis of physical examination and is confirmed radiologically, obtaining a sample of pleural fluid is necessary for diagnosis by aspiration of fluid from the pleural space. The laboratory tests performed on the pleural fluid obtained by thoracentesis are listed in Table 26-4. Evaluation of the pleural fluid is necessary to distinguish transudative from exudative effusions. When the distance between the pleural fluid line to the inside of the chest wall on lateral decubitus view is less than 1 cm, the pleural effusion is difficult to obtain by thoracentesis and not likely to be clinically significant.[23] In addition, the associated risk for pneumothorax outweighs the benefit of the thoracentesis.[29]

Management

Treatment of the underlying cause of the pleural effusion is necessary. Removal of the pleural effusion by thoracentesis, chest tube placement, or surgery may be indicated depending on the etiology and size of effusion. The primary indication for therapeutic thoracentesis is relief of dyspnea.

▲ Pneumothorax

A pneumothorax occurs when air enters the pleural space between the visceral and parietal pleurae, producing partial or complete lung collapse.

Pathophysiology

During spontaneous breathing, two opposing forces generate negative pleural pressures. Pressure in the airways is positive during expiration and negative during inspiration.[29] However, pleural pressure remains subatmospheric on both inspiration and expiration.[28] Therefore, airway

Table 26-4 Assessment of Pleural Fluid

Test	Comment
Red blood cell count < 100,000/mm^3	Trauma, malignancy, pulmonary embolism
Hematocrit >50% of peripheral blood	Hemothorax
White blood cell count (WBC)	
>50,000–100,000/mm^3	Grossly visible pus, otherwise total WBC less useful than WBC differential
>50% neutrophils	Acute inflammation or infection
>50% lymphocytes	Tuberculosis, malignancy
>10% Eosinophils	Most common: hemothorax, pneumothorax; also benign
>5 % Mesothelial cells	Asbestos effusions, drug reaction, paragonimiasis; tuberculosis *less likely*
Glucose < 60 mg/dL	Infection, malignancy, tuberculosis, rheumatoid, hemothorax, paragonimiasis, Churg-Strauss syndrome
Amylase >200 units/dL	Pleuritis, esophageal perforation, pancreatic disease, malignancy, ruptured ectopic pregnancy Isoenzyme profile: salivary–esophageal disease, malignancy (especially lung)
pH < 7.0	Complicated parapneumonic effusion
pH < 7.2	Systemic acidosis, esophageal rupture, rheumatoid pleuritis, tuberculous pleuritis, malignant pleural disease, hemothorax, paragonimiasis, or Churg-Strauss syndrome.
Triglyceride >110 mg/dL	Chylothorax
Microbiological studies	Etiology of infection
Cytology	Diagnostic of malignancy (adenocarcinoma, benign or malignant mesothelial cells)

Adapted from Light RW: Physiology of pleural fluid production. In Shield TW, LoCicero J, Reed CE, et al (eds): General Thoracic Surgery, 7th Ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, pp 763–770.

pressure remains higher than pleural pressure throughout the respiratory cycle. Sudden communication of the pleural space with either alveolar or external air allows gas to enter (Fig. 26-3). When the pleural pressure rises, the elasticity of the lung causes it to collapse. The lung continues to collapse until either the pressure gradient no longer exists or the pleural defect closes.[28] The main consequence of lung collapse is both decrease in vital capacity and arterial PO_2. In addition, patients with low arterial PO_2 also have an increase in the alveolar–arterial partial pressure of oxygen (PAO_2–PaO_2) gradient, a decreased ventilation–perfusion ratio, and an intrapulmonary shunt resulting in hypoxemia.[28]

There are two types of pneumothorax: spontaneous and traumatic. Spontaneous pneumothorax is any pneumothorax that develops without any trauma. There are two types of spontaneous pneumothorax: primary pneumothorax, which occurs in the absence of underlying lung disease, and secondary, which occurs as a result of underlying lung disease, such as COPD.[28] Primary spontaneous pneumothorax occurs primarily in young (early 20s to 30 years of age, rarely after age 40), tall, and thin men.[28] Family history (Birt-Hogg-Dube syndrome—an autosomal dominant disease) and cigarette smoking are important risk factors.[30,31] Secondary spontaneous pneumothorax most commonly occurs in patients who have COPD, *Pneumocystis carinii* pneumonia, cystic fibrosis, and tuberculosis.[32] Other less common causes include asthma, Marfan syndrome, lung cancer, necrotizing pneumonia, rheumatoid arthritis, sarcoidosis, lymphangioleiomyomatosis, and histiocytosis X.[28,33]

The most common causes of a traumatic pneumothorax in critically ill patients are invasive procedures and barotrauma.[28,34] (See Chapter 55 for a discussion of blunt and penetrating trauma as causes of pneumothorax.) Accidental entry of air into the pleural space during an invasive

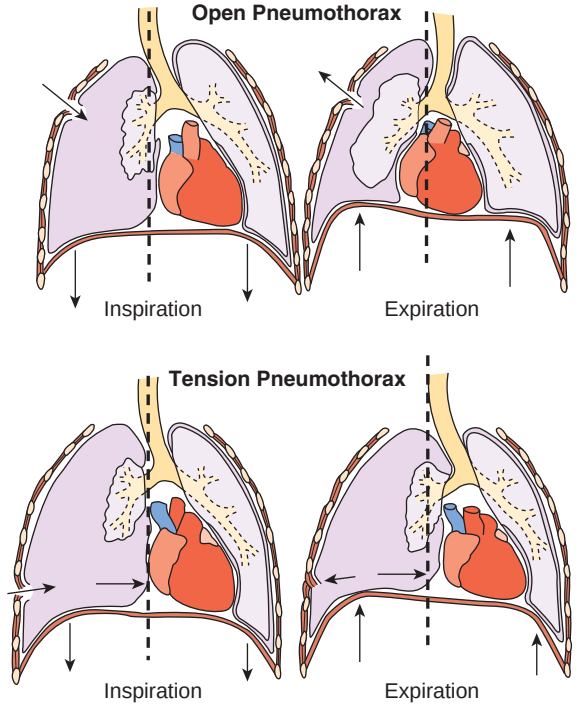

FIGURE 26-3 ▲ Open or communicating pneumothorax (**top**) and tension pneumothorax (**bottom**). In an open pneumothorax, air enters the chest during inspiration and exits during expiration. There may be slight inflation of the affected lung due to a decrease in pressure as air moves out of the chest. In tension pneumothorax, air can enter but not leave the chest. As the pressure in the chest increases, the heart and great vessels are compressed, and the mediastinal structures are shifted toward the opposite side of the chest. The trachea is pushed from its normal midline position toward the opposite side of the chest, and the unaffected lung is compressed. (From Porth C: Essentials of Pathophysiology, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2011, p 571.)

procedure causes iatrogenic pneumothorax. Central line catheter insertions cause approximately 36,000 pneumothoraces per year, which affect 1% to 3.1% of the patients receiving central line catheters.[28,34] Pulmonary barotrauma occurs in approximately 1% to 15% of patients receiving positive-pressure mechanical ventilation and in 25% to 78% of patients with ARDS.[28] Barotrauma includes parenchymal interstitial gas, pneumomediastinum, subcutaneous emphysema, pneumoperitoneum, and pneumothorax.[28] Pulmonary interstitial gas or emphysema is the initial radiographic indication of barotrauma. The mechanically ventilated patient is at risk for development of a tension pneumothorax. A tension pneumothorax occurs when the pressure of air in the pleural space exceeds atmospheric pressure. As pressures in the thorax increase, the mediastinum shifts to the contralateral side, placing torsion on the inferior vena cava and decreasing venous return to the right side of the heart[28] (see Fig. 26-3).

Assessment

History and Physical Findings

The patient complains of sudden onset of acute pleuritic chest pain localized to the affected lung. The pleuritic chest pain is usually accompanied by shortness of breath, increased work of breathing, and dyspnea. Chest wall movement may be uneven because the affected side does not expand as much of the healthy side. Breath sounds are distant or absent. Chest percussion produces a hyperresonant sound. Tachycardia occurs frequently in all types of pneumothorax. Tension pneumothorax is a life-threatening condition manifested by respiratory distress (Box 26-5).

Diagnostic Studies

To detect a pneumothorax, a chest radiograph should be obtained with the patient in the upright or decubitus position. The chest film shows contralateral (opposite side) mediastinal shift, ipsilateral (same side) diaphragmatic depression, and ipsilateral chest wall expansion in the patient with tension pneumothorax.[29] To confirm the size of the pneumothorax, a chest CT maybe obtained.[29,35] When clinical symptoms of tension pneumothorax are present in a patient on mechanical ventilation, treatment should not be delayed to obtain radiographic confirmation. Arterial blood gas (ABG) findings are used to assess for hypoxemia and hypercapnia.

BOX 26-5 PATIENT SAFETY

Signs and Symptoms of Tension Pneumothorax

- Hypoxemia (early sign)
- Apprehension
- Respiratory distress (severe tachypnea)
- Increasing peak and mean airway pressures, decreasing compliance, and auto–positive end-expiratory pressure (auto-PEEP) in patients receiving mechanical ventilation
- Cardiovascular collapse (heart rate >140 beats/min with any of the following: peripheral cyanosis, hypotension, pulseless electrical activity)

Management

Supplemental oxygen should be administered to all patients with pneumothorax because oxygen accelerates the rate of air resorption from the pleural space.[28,35] If the pneumothorax is 15% to 20%, no medical intervention is required, and the patient is placed on bed rest or limited activity.[35] If the pneumothorax is greater than 20%, then a chest tube is placed in the apical and anterior aspect of the pleural space to assist air removal. Connecting the chest tube to underwater seal drainage alone is usually adequate to resolve the pneumothorax. Initially placing the chest tube to suction risks reexpansion pulmonary edema resulting from rapid reinflation of the collapsed lung.[28] If the pneumothorax persists after 12 to 24 hours of underwater seal drainage, 15 to 20 cm H_2O suction should be applied to facilitate closure.[35] In approximately one third of patients with COPD, persistent air leaks require multiple chest tubes to evacuate the pneumothorax.[35]

A tension pneumothorax is a life-threatening condition requiring immediate treatment; if untreated, it leads to cardiovascular collapse. If a chest tube is not immediately available, a large-bore (16- or 18-gauge) needle should be placed into the anterior second intercostal space. After needle insertion, a chest tube is placed and connected to underwater seal drainage. When the tension pneumothorax is relieved, the effect is rapid and occurs as an improvement in oxygenation, a decrease in heart rate, and an increase in blood pressure.

▲ Pulmonary Embolism

Most incidents of pulmonary embolism occur when a thrombus, which has broken loose and migrated to the pulmonary arteries, obstructs part of the pulmonary vascular tree (Fig. 26-4).[36] A pulmonary embolism usually results from a deep vein thrombosis (DVT) that has formed in the lower extremities. Other sites of clot formation include the right sight of the heart (as in untreated atrial fibrillation) and other deep vessels of the pelvic region.[37] In North America, venous thromboembolism occurs for the first time in approximately 100 of every 100,000 people.[38] Of these, approximately one third have a symptomatic pulmonary embolus. Major risk factors include age, recent surgery, cancer, and thrombophilia.[37] Risk factors that increase the incidence of venous thromboembolism are listed in Box 26-6. Nonthrombotic causes of pulmonary embolism include fat, air, and amniotic fluid but are much less common than thromboembolism.[37]

Pathophysiology

A cascade of events begins the process of thromboembolus development. Virchow's triad (venous stasis, hypercoagulability, vein wall damage) has long been acknowledged in the pathophysiology of venous thromboembolism. Venous return from the lower extremities is usually facilitated by contraction of the muscles of the lower extremities during activity. Conditions such as immobility, heart failure, dehydration, and varicose veins contribute to decreased venous return, increased retrograde pressure in the venous system, and stasis of blood with resultant thrombus formation.[39]

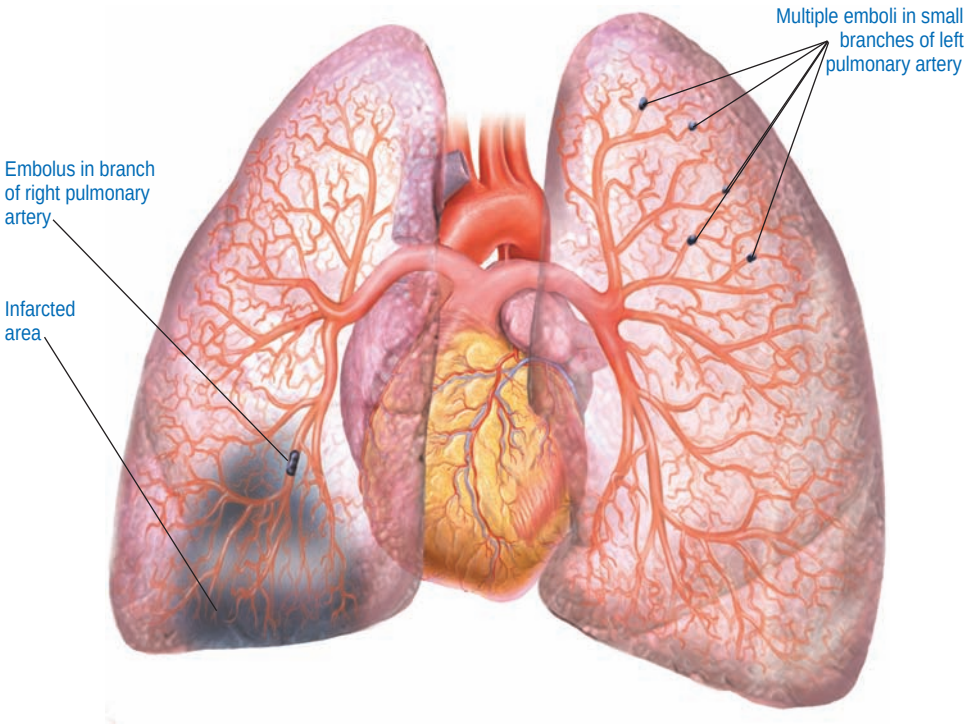

FIGURE 26-4 ▲ Sites of pulmonary emboli. (From Anatomical Chart Company: Atlas of Pathophysiology. Springhouse, PA: Lippincott Williams & Wilkins, 2010, p 107.)

Normally, there is a balance between activation of clotting factors and the fibrinolytic system that prevents thrombus formation. Hypercoagulability may occur in the presence of trauma, surgery, malignancy, pregnancy, or use of oral contraceptives. In these instances, coagulation may be initiated by contact of factor XII with collagen on exposed subendothelium of damaged vessels, by exposure of blood to tissue factor available as a result of vascular wall damage, by activated monocytes migrating to areas of vascular injury, and by release of activated platelets in response to injury. Factor X may be activated by substances from malignant cells and by substances released from hypoxic endothelial cells.[39]

BOX 26-6 Risk Factors for Thromboembolism

For Venous Thromboembolism

Strong Risk Factors
Fracture of the hip, pelvis, or leg
Hip or knee replacement
Major general surgery, major trauma
Spinal cord injury

Moderate Risk Factors
Arthroscopic knee surgery
Central venous lines
Malignancy
Heart or respiratory failure
Hormone replacement therapy, oral contraceptives
Paralytic stroke
Postpartum period
Previous venous thromboembolism
Thrombophilia

Weak Risk Factors
Bed rest for more than 3 days
Immobility due to sitting
Increasing age
Laparoscopic surgery
Obesity
Antepartum period
Varicose veins

Risk Stratification of Thromboemboli for Patients Undergoing Surgery

Low Risk
Uncomplicated surgery in patients aged less than 40 years with minimal immobility postoperatively and no risk factors

Moderate Risk
Any surgery in patients aged 40 to 60 years
Major surgery in patients aged less than 40 years and no other risk factors
Minor surgery in patients with one or more risk factors

High Risk
Major surgery in patients aged more than 60 years
Major surgery in patients aged 40 to 60 years with one or more risk factors

Very High Risk
Major surgery in patients aged more than 40 years with previous venous thromboembolism, cancer, or known hypercoagulable state
Major orthopedic surgery
Elective neurosurgery
Multiple trauma or acute spinal cord injury

From Blann AD, Lip GYH: Venous thromboembolism. BMJ 332(7535):215–219, 2006.

Damage to the vessel wall causes adhesion and aggregation of platelets and contributes to the activation of clotting factors.

Thrombus formation is frequently bilateral and often asymptomatic. Although most thrombi form in the calf, most pulmonary emboli (80% to 90%) arise from venous thrombi that extend into the proximal veins (popliteal and iliofemoral) of the lower extremities.[38] Proximal venous thrombi pose an approximately 50% risk for embolism.[38]

Occlusion of a pulmonary artery by an embolus produces both pulmonary and hemodynamic changes. Alveoli are ventilated but not perfused, producing areas of mismatched ventilation and perfusion. As a result, well-ventilated alveoli are underperfused, and gas exchange is compromised (increased respiratory dead space). Pulmonary vascular constriction resulting from a lack of carbon dioxide, which is normally present in pulmonary arterial blood, shifts ventilation from the underperfused alveoli. Accompanying physiological changes include increased minute ventilation, decreased vital capacity, increased airway resistance, and decreased diffusing capacity.[37]

The severity of hemodynamic change in pulmonary embolism depends on the size of the embolus and degree of pulmonary vascular obstruction as well as on the preexisting status of the cardiopulmonary system. In patients with no previous cardiopulmonary disease, there is a relationship between the degree of pulmonary artery obstruction and the pulmonary artery pressure. Increased right ventricular afterload results from obstruction of the pulmonary vascular bed by embolism. In patients with no preexisting cardiopulmonary disease, obstruction of less than 20% of the pulmonary vascular bed produces compensatory events that minimize adverse hemodynamic consequences.[37] Cardiac output is maintained by increases in both right ventricular stroke volume and heart rate, and recruitment and distention of pulmonary vessels occur, producing normal or near-normal pulmonary artery pressure and pulmonary vascular resistance.[37] When the degree of pulmonary vascular obstruction exceeds 30% to 40%, increases in pulmonary artery pressure occur, followed by modest increases in right atrial pressure.[37] As the degree of pulmonary artery obstruction exceeds 50% to 60%, compensatory mechanisms are overcome, producing a decrease in cardiac output and dramatic increases in right atrial pressure.[37] Patients with preexisting cardiopulmonary disease have degrees of pulmonary hypertension that are disproportionate to the degree of embolic obstruction.[37] Severe pulmonary hypertension may develop from a relatively small reduction of pulmonary blood flow.

Assessment

Pulmonary embolism is difficult to diagnose because of its nonspecific signs and symptoms. Pulmonary embolism should be suspected with patient with new worsening dyspnea or sustained hypotension without other explanation. However, it is also common that a DVT or embolus produces no significant symptoms and may be an incidental finding when the patient undergoes imaging for other reasons.[37]

Clinical evaluation may indicate a need for further studies but is not reliable for confirmation or exclusion of the diagnosis of pulmonary embolism.[37] A diagnostic algorithm for the evaluation of patients with suspected pulmonary embolism is presented in Figure 26-5. When a patient has either renal failure or allergy to contrast dye, ventilation–perfusion (VQ) scans are often used instead of CT angiogram of the chest. Transthoracic echocardiogram is often used to confirm diagnosis of a pulmonary embolism in the main pulmonary artery. Signs and symptoms of pulmonary embolism are listed in Box 26-7. Dyspnea is the most frequent symptom in patients with angiographically confirmed pulmonary embolism. Other signs and symptoms (in order of frequency) are pleuritic chest pain, cough, apprehension, leg swelling, and pain.[36]

Management

Heparin and thrombolytic agents are used to treat pulmonary embolism. Guidelines developed by the American College of Chest Physicians (ACCP) for the treatment of venous thromboembolism are shown in Table 26-5.[40]

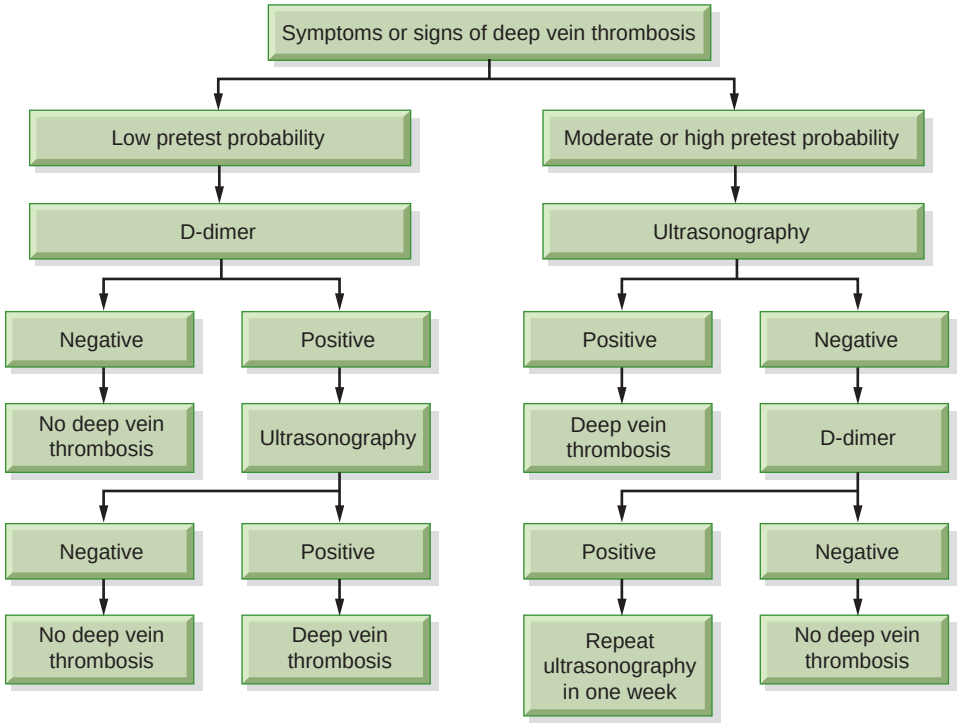
Patients with DVT or pulmonary embolism should be treated with unfractionated intravenous heparin or adjusted-dose subcutaneous heparin. Though adjusted-dose subcutaneous heparin is an option for treatment of PE, it is not commonly used due to the decreased bioavailability of heparin when given subcutaneously.

Low-molecular-weight heparin (LMWH) can be substituted for unfractionated heparin in patients with DVT and in stable patients with pulmonary embolism. Treatment with heparin or LMWH should continue for at least 5 days, overlapped with oral anticoagulation for at least 4 to 5 days (grade A1).[40]

The recommended length of anticoagulation therapy varies, depending on the patient's age, comorbidities, and the likelihood of recurrence of pulmonary embolism or DVT. In most patients, anticoagulation therapy with warfarin should be continued for 3 to 6 months.[40] The first episode of idiopathic DVT should be treated for at least 6 months.[40] Patients with new-onset DVT and a risk factor (eg, cancer, inhibitor deficiency state) or recurrent venous thrombosis should be treated indefinitely.[40] Patients with massive pulmonary embolism or severe iliofemoral thrombosis may require a longer period of heparin therapy.[40] Anticoagulation using full-dose subcutaneous heparin for several months is effective in patients who have contraindications to warfarin (eg, pregnant women) but who can safely take heparin.[40]

Thrombolytic therapy is only recommended for patients with acute massive pulmonary embolism who are hemodynamically unstable and not prone to bleeding.[40] All thrombolytic agents act systemically and have the potential to lyse a fresh platelet–fibrin clot anywhere and cause bleeding at that site.[40] Intracranial disease, recent surgery, trauma, and hemorrhagic disease are contraindications to thrombolytic therapy. Urokinase, streptokinase, and recombinant tissue plasminogen activator are the thrombolytic agents approved for treating pulmonary embolism and venous thromboembolism. Heparin therapy is not administered concurrently with thrombolytics; however, thrombolytic therapy is followed by administration of heparin, then warfarin.

An inferior vena cava filter is recommended to prevent pulmonary embolism in patients with contraindications to heparin therapy (risk for major bleeding or drug sensitivity).[40] Placement of an inferior vena cava filter is also recommended in patients with recurring thromboembolism despite adequate anticoagulation, chronic recurrent embolism and pulmonary hypertension, and concurrent surgical pulmonary embolectomy or pulmonary endarterectomy procedures.



For assessment of pretest probability of suspected deep vein thrombosis:

- Score 1 point each for following: tenderness along entire deep vein system; swelling of entire leg, >3 cm difference in calf circumference; pitting edema; collateral superficial veins; risk factors present (active cancer, prolonged immobility or paralysis, recent surgery, or major medical illness)
- Subtract 2 points for alternative diagnosis likely (for example, ruptured Baker's cyst in rheumatoid arthritis, superficial thrombophlebitis, or infective cellulitis)

Result >3 = high probability; 1-2 = moderate probability; ≤0 = low probability

FIGURE 26-5 ▲ Diagnostic algorithm for evaluation of patients with symptoms suggestive of acute pulmonary embolism. (From Blann AD, Lip GYH: Venous thromboembolism. BMJ 332(7535):215–219, 2006.)

BOX 26-7 PATIENT SAFETY

Signs and Symptoms of Pulmonary Embolism

Small to Moderate Embolus

- Dyspnea
- Tachypnea
- Tachycardia
- Chest pain
- Mild fever
- Hypoxemia
- Apprehension
- Cough
- Diaphoresis
- Decreased breath sounds over affected area
- Rales
- Wheezing

Massive Embolus

A more pronounced manifestation of the above signs and symptoms, plus the following:

- Cyanosis
- Restlessness
- Anxiety
- Confusion
- Hypotension
- Cool, clammy skin
- Decreased urinary output
- Pleuritic chest pain: associated with pulmonary infarction
- Hemoptysis: associated with pulmonary infarction

Signs of Pulmonary Embolism in Intensive Care Patients

- Worsening hypoxemia or hypocapnia in a patient on spontaneous ventilation
- Worsening hypoxemia and hypercapnia in a sedate patient on controlled mechanical ventilation
- Worsening dyspnea, hypoxemia, and a reduction in $PaCO_2$ in a patient with chronic lung disease and known carbon dioxide retention
- Unexplained fever
- Sudden elevation in pulmonary artery pressure or central venous pressure in a hemodynamically monitored patient

Table 26-5 American College of Chest Physicians Recommendations for Treatment of Venous Thromboembolism

Anticoagulation Guidelines for	Recommended Therapy
Unfractionated Heparin (UFH)	
Suspected VTE	• Obtain baseline aPTT, PT, CBC. • Check for contraindications to heparin therapy. • Give heparin 5,000 units IV. • Order imaging study.
Confirmed VTE	• Re-bolus with heparin 80 units/kg IV or 5,000 units, and start maintenance infusion at 18 units/kg/h or 1,300 units/h. • Check aPTT at 6 h; maintain a range corresponding to a therapeutic heparin level. • Start warfarin therapy on day 1 at 5 mg; adjust subsequent daily dose according to INR. • Stop heparin after 4–5 d of combined therapy, when INR is >2.0 (2.0–3.0) for 24 h. • Anticoagulate with warfarin for at least 3 mo (target INR 2.5; 2.0–3.0).
Low-Molecular-Weight Heparin (LMWH)	
Suspected VTE	• Obtain baseline aPTT, PT, CBC. • Check for contraindication to heparin therapy. • Give UFH, 5,000 units IV. • Order imaging study.
Confirmed VTE	• Give LMWH (enoxaparin), 1 mg/kg subcutaneously every 12 h. • Start warfarin therapy on day 1 at 5 mg; adjust subsequent daily dose according to the INR. • Consider checking platelet count between days 3 and 5. • Stop LMWH after at least 4–5 d of combined therapy, when INR is >2.0 on 2 consecutive days. • Anticoagulate with warfarin for at least 3 mo (goal INR 2.5; 2.0–3.0), then it is recommended to continue with low intensity therapy (INR range 1.5–1.9) with less frequent monitoring over stopping treatment.

VTE, venous thromboembolism; aPTT, activated partial thromboplastin time; PT, prothrombin time; INR, international normalized ratio; CBC, complete blood count.

From American College of Chest Physicians: Eighth ACCP consensus conference on Antithrombotic and Thrombolytic Therapy. Chest 133:454S–545S, 2008.

Prevention

Prevention of venous thromboembolism is essential to decreasing the morbidity and mortality associated with pulmonary embolism. Prophylactic measures are based on the patient's specific risk factors.[41] See Table 26-6 for preventive measures recommended by the ACCP.

▲ Chronic Obstructive Pulmonary Disease

COPD is a disease state characterized by airflow limitation that is not fully reversible. The airflow limitation is usually both progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases (primarily cigarette smoke) or an inherited deficiency of α_1-antitrypsin (see Spotlight on Genetics 26-1).[42] COPD includes two diseases: emphysema and chronic bronchitis.[42] COPD is a major cause of chronic morbidity and mortality, ranking as the fourth leading cause of death in the United States.[42]

The WHO estimates that COPD shares fourth place as a single cause of death (behind coronary heart disease, cerebrovascular disease, and lower respiratory infection), and unlike some of the other diseases, the death rates from COPD have increased. The WHO estimates that COPD will be the third leading cause of death by 2020 in the burden of disease caused worldwide.[43]

Pathophysiology

In COPD, pathologic changes occur in the central airways, peripheral airways, lung parenchyma, and pulmonary vasculature.[43] As the disease progresses, pathophysiological changes usually occur in the following order: mucous hypersecretion, ciliary dysfunction, airflow limitation, pulmonary hyperinflation, gas exchange abnormalities, pulmonary hypertension, and cor pulmonale.[43] The peripheral airways become the major site of obstruction in patients with COPD. The structural changes in the airway wall are the most important cause of the increase in peripheral airway resistance. Inflammatory changes, such as airway edema and hypersecretion of mucus, also contribute to narrowing of the peripheral airways.[43] Mucal hypersecretion is caused by the stimulation of the enlarged mucus-secreting glands and the increased number of goblet cells by inflammatory mediators such as leukotrienes, interleukins, and tumor necrosis factor.[43] Ciliated epithelial cells undergo squamous metaplasia, leading to impaired mucociliary clearance, which is usually the first physiological abnormality to occur in COPD.[43] This abnormality may be evident for many years before any other abnormalities develop.[43]

Table 26-6 American College of Chest Physicians Recommendations for Prevention of Venous Thromboembolism

Patient Population	Recommended Therapy	Grade*
Low-risk general surgery	Early and frequent ambulation	A1
Moderate-risk general surgery	LMWH, LDUH, or fondaparinux	A1
Higher-risk general surgery	LMWH, LDUH three times a day, or fondaparinux	A1
High-risk general surgery with multiple risk factors	LDUH three times a day, LMWH, fondaparinux combined with graduated compression stockings, and/or intermittent pneumatic compression	C1
Total hip replacement surgery	LMWH, started 12 h before surgery or 12–24 h after surgery, or 4–6 h after surgery at half usual high-risk dose and then increasing to usual high-risk dose of following day or Fondaparinux (2.5 mg started 6–24 h after surgery) or Adjusted-dose warfarin, started preoperatively or the evening of the surgical day (INR target 2.5; INR range, 2.0–3.0)	A1
Total knee replacement surgery	LMWH (at the usual high-risk dose), fondaparinux, warfarin (INR target, 2.5; INR range, 2.0–3.0); Intermittent pneumatic compression	A1 B1
Acute spinal cord injury	LMWH Elastic stockings and intermittent pneumatic compression and either LDUH or LWMH	B1 B1 C1
Trauma patients with identifiable risk factor for thromboembolism	LMWH, as soon as safe or LMWH and Intermittent pneumatic compression. For high-risk patients with suboptimal prophylaxis, mechanical thromboprophylaxis with intermittent pneumatic compression or possibly with graduated compression stocking alone can be used.	A1 B1 B1
Myocardial infarction	UFH or LMWH or bivalirudin or fondaparinux Intermittent pneumatic compression or elastic stockings when heparin is contraindicated	A1 C1
Ischemic stroke and lower extremity paralysis	Low-dose SC heparin or LMWH For patients with contraindication for anticoagulants, intermittent pneumatic compression, or elastic stockings	A1 B1
Medical patients with risk factors for VTE (including heart failure and chest infections)	LDUH, LMWH, or fondaparinux	A1
Patients with long-term indwelling central vein catheters	Recommended that clinicians NOT use either prophylactic doses of LMWH or minidose warfarin to try to prevent catheter-related thrombosis	B1
Patients receiving a spinal puncture or epidural catheter placement	Use appropriate patient selection and caution when using anticoagulant thromboprophylaxis	A1

*A1: Methods strong, results consistent—randomized clinical trials (RCTs), no heterogeneity, effect clear that benefits do (or do not) outweigh risks. A2: Methods strong, results consistent—RCTs, no heterogeneity, effect equivocal—uncertain whether benefits outweigh risks. B1: Methods strong, results inconsistent—RCTs, heterogeneity present, effect clear that benefits do (or do not) outweigh risks. B2: Methods strong, results inconsistent—RCTs, heterogeneity present, effect equivocal—uncertain whether benefits outweigh risks. C1: Methods weak—observational studies, effect clear that benefits do (or do not) outweigh risks. C2: Methods weak—observational studies, effect equivocal—uncertain whether benefits outweigh risks.

LDUH, low-dose unfractionated heparin; LMWH, low-molecular-weight heparin.

SPOTLIGHT ON GENETICS 26-1

ALPHA-1 ANTITRYPSIN DEFICIENCY

- This disorder affects about 1 in 1,500 to 3,500 individuals with European ancestry. It is uncommon in people of Asian descent but is commonly observed in COPD patients.
- Mutations in the *SERPINA1* gene cause alpha-1 antitrypsin deficiency. This gene provides instructions for making a protein called alpha-1 antitrypsin, which protects the body from a powerful enzyme called neutrophil elastase.
- Leads to a deficiency of alpha-1 antitrypsin or an abnormal form of the protein that cannot control neutrophil elastase. Without enough functional alpha-1 antitrypsin, neutrophil elastase destroys alveoli and causes lung disease.
- There are numerous genetic tests available for the detection of alpha-1 antitrypsin deficiency.

Genetic Home Reference—Available at http://ghr.nlm.nih.gov. Accessed July 14, 2011.

Janciauskiene SM, Bals R, Koczulla R, et al: The discovery of α1-antitrypsin and its role in health and disease. Respir Med 105(8):1129–1139, 2011.

Expiratory airflow limitation is an essential finding in COPD. As the disease process progresses, forced expiratory volume in 1 second (FEV_1) and forced vital capacity (FVC) decrease; this is related to the increased thickness of the airway wall, loss of alveolar attachments, and loss of lung elastic recoil. Frequently, the first sign of developing airflow limitation is a decrease in the FEV_1/FVC ratio.[43] According to the 2009 Global Initiative for Chronic Obstructive Lung Disease (GOLD), the presence of a postbronchodilator FEV_1 less than 80% of the predicted value, in combination with an FEV_1/FVC ratio less than 70%, confirms the presence of airflow limitation that is not fully reversible (Table 26-7).[43] In severe COPD, air is trapped in the lungs during forced expiration, leading to an abnormally high functional residual capacity (FRC). Increasing FRC leads to pulmonary hyperinflation.[44]

In advanced COPD, peripheral airway obstruction, parenchymal destruction, and pulmonary vascular irregularities reduce the lung's capacity for gas exchange, resulting in hypoxemia (low blood oxygen) and hypercapnia (high blood carbon dioxide).[43] A VQ ratio mismatch is the driving force behind hypoxemia in patients with COPD, regardless of the stage of the disease. Chronic hypercapnia usually indicates inspiratory muscle dysfunction and alveolar hypoventilation.[43] As hypoxemia and hypercapnia progress late in COPD, pulmonary hypertension often develops, which causes hypertrophy of the right ventricle, better known as cor pulmonale.[43] Right-sided heart failure leads to further venous stasis and thrombosis that may potentially result in pulmonary embolism and further compromise the pulmonary circulation. Last, COPD is associated with systemic inflammation and skeletal muscle dysfunction that may result in limitation of exercise capacity and decline of health status.[43]

Table 26-7 Spirometric Classification of COPD Severity Based on Postbronchodilator FEV_1 and the Recommended Treatment

Stage	Characteristics	Recommended Treatment
I: Mild COPD	• FEV_1/FVC < 70% • FEV_1 80% or more predicted • With or without symptoms	• Active reduction of risk factors: influenza vaccination • Short-acting bronchodilator when needed
II: Moderate COPD	• FEV_1/FVC < 70% • 50% or less FEV_1 > 80% predicted • With or without symptoms	• Active reduction of risk factors: influenza vaccination • Short-acting bronchodilator when needed • Add regular treatment with one or more long-acting bronchodilators • Add rehabilitation
III: Severe COPD	• FEV_1/FVC < 70% • 30% FEV_1or less more than 50% predicted	• Active reduction of risk factors: influenza vaccination • Short-acting bronchodilator when needed • Regular treatment with one or more long-acting bronchodilators • Rehabilitation • Inhaled glucocorticosteroids if significant symptoms and lung function response or if repeated exacerbations
Stage IV: Very Severe	• FEV_1 /FVC < 70% • FEV_1 < 30% predicted or • FEV_1 < 50% predicted plus chronic respiratory failure	• Active reduction of risk factors: influenza vaccination • Short-acting bronchodilator when needed • Regular treatment with one or more long-acting bronchodilators • Rehabilitation • Inhaled glucocorticosteroids if significant symptoms and lung function response or if repeated exacerbations • Add long-term oxygen therapy if respiratory failure • Consider surgical treatments

Patients must be taught how and when to use their treatment, and treatments being prescribed for other conditions should be reviewed. Beta-blocking agents (including eye-drop formulations) should be avoided.

FEV_1, forced expiratory volume in 1 s; FVC, forced vital capacity.

Assessment

History

A detailed medical history of a new patient with known or suspected COPD should include the following:

- Exposure to risk factors, such as smoking, and occupational or environmental exposures to pollutants
- Past medical history, including asthma, allergy, sinusitis or nasal polyps, respiratory infections in childhood, and other respiratory diseases
- Family history of COPD or other chronic respiratory disease
- Pattern of symptom development. COPD typically develops in adults, and most patients are aware of the occurrence of increased breathlessness, increased frequency of winter "colds," and some social restriction for a number of years before seeking medical attention.
- History of exacerbations or previous hospitalizations for respiratory disorder. Patients may be conscious of periodic worsening of symptoms even if these episodes have not been identified as acute exacerbations of COPD. Indications for hospital assessment or admission for acute exacerbation of COPD are listed in Box 26-8.
- Comorbidities such as heart disease and rheumatic disease, which may also contribute to restriction of activity
- Appropriateness of current medical treatments, such as beta blockers, commonly prescribed for heart disease. Beta blockers are usually contraindicated in COPD.
- Impact of disease on patient's life, including limitation of activity, missed work and economic consequences, effect on family routines, or feelings of depression or anxiety
- Social and family support
- Possibilities for reducing risk factors, especially smoking cessation[42,43]

Physical Findings

Two patterns of disease are evident in advanced COPD (Table 26-8). These patterns may become increasingly apparent as the disease progresses.[43] A physical examination is rarely diagnostic in COPD, although it remains an important aspect of patient care.[43] The physical examination should include inspection, palpation, percussion, and auscultation.

Table 26-8 Patterns of Disease in Advanced Chronic Obstructive Pulmonary Disease

Feature	Type A	Type B
Commonly used name	Pink puffer	Blue bloater
Disease association	Predominant emphysema	Predominant bronchitis
Major symptom	Dyspnea	Cough and sputum
Appearance	Thin wasted, not cyanotic	Obese, cyanotic
PO_2	↓	↓↓
PCO_2	Normal or ↓	Normal or ↑
Elastic recoil of lung	↓	Normal
Diffusing capacity	↓	Normal
Hematocrit	Normal	Often ↑
Cor pulmonale	Infrequent	Common

Adapted from Toung D: COPD: General Anesthesia. In Modak RJ, et al (eds): Anesthesiology Keyword Review, 1st ed. Philadelphia, PA: Lippincott William & Wilkins, 2008, p 115.

BOX 26-8 Indications for Hospital Assessment or Admission for Acute Exacerbation of Chronic Obstructive Pulmonary Disease*

Marked increase in intensity of symptoms, such as sudden development of resting dyspnea
Severe background COPD
Onset of new physical signs (eg, cyanosis, peripheral edema)
Failure of exacerbation to respond to initial medical management
Significant comorbidities
Frequent exacerbations
Newly occurring dysrhythmias
Diagnostic uncertainty
Older age
Insufficient home support

*Local resources need to be considered.

Inspection

- Central cyanosis or bluish discoloration of the mucosal membranes. This feature may be present but is difficult to detect in artificial light and in many racial groups.
- Common chest wall abnormalities, which reflect the pulmonary hyperinflation seen in COPD, including relatively horizontal ribs, barrel-shaped chest, and protruding abdomen
- Flattening of the hemidiaphragms, which may be associated with paradoxical indrawing of the lower rib cage on inspiration, reduced cardiac dullness, and widening xiphisternal angle
- Resting respiratory rate, which is often increased to more than 20 breaths/min; breathing may be shallow.
- Pursed-lip breathing, which may serve to slow expiratory flow and permit more efficient lung emptying
- Resting muscle activation, which may be indicative of respiratory distress. While lying supine, patients with COPD often use the scalene and sternocleidomastoid muscles.
- Ankle or lower leg edema, which may be an indication of right-sided heart failure

Palpation and Percussion

- Palpation and percussion, which are often unhelpful in COPD
- Heart apex beat, which may be difficult to detect due to pulmonary hyperinflation
- Pulmonary hyperinflation, which also leads to downward displacement of the liver and an increase in the ability to palpate this organ without it actually being enlarged

BOX 26-9 Indications for ICU Admission for Patients With Acute Exacerbation of Chronic Obstructive Pulmonary Disease*

Severe dyspnea that responds inadequately to initial emergency therapy
Confusion, lethargy, coma
Persistence of worsening hypoxemia (PaO_2 < 6.7 kPa, 50 mm Hg), or severe/worsening hypercapnia ($PaCO_2$ > 9.3 kPa, 70 mm Hg), or severe/worsening respiratory acidosis (pH < 7.30) despite supplemental oxygen and noninvasive positive-pressure ventilation

*Local resources need to be considered.

Auscultation

- Reduced breath sounds. Patients with COPD often have reduced breath sounds.
- Wheezing. Occurrence during quiet breathing is a useful indicator of airflow limitation. However, wheezing heard only after forced expiration is of no diagnostic significance.
- Inspiratory crackles, which occur in some patients with COPD but are of little assistance diagnostically
- Heart sounds, which are best heard over the xiphoid area

Symptoms of COPD include cough, sputum production, and shortness of breath on exertion. Indications for ICU admission for patients with acute exacerbation of COPD are listed in Box 26-9.[42]

Diagnostic Studies

Laboratory and diagnostic tests in COPD are summarized in Table 26-9.

SPIROMETRY Expiratory airflow limitation is the hallmark diagnostic sign of COPD. Because spirometry is the most reproducible and objective measure of airflow limitation, it remains the gold standard for diagnosing COPD and monitoring its progression.[43,44] Spirometry is performed in patients with chronic cough and sputum production even without dyspnea. Spirometry measures the maximal volume of air forcibly exhaled from the point of maximal inspiration (FVC) and the volume of air exhaled during the first second of this exercise (FEV_1). The ratio of these two measurements (FEV_1/FVC ratio) is then calculated.[43,44] Another measurement of significant value from a pulmonary function test is the DLCO, or the diffusion capacity of the lung for carbon monoxide. This value is indicative of the amount of gas exchange that is occurring in the lung. When one takes the data from the FEV_1 and the DLCO, one can determine the true respiratory status of a patient. Spirometry measurements are evaluated by comparison of the results with appropriate reference values based on age, height, sex, and race.

Figure 26-6 demonstrates a normal spirogram and a spirogram characteristic of a patient with COPD with mild to moderate airflow limitation. Patients with COPD have decreased FEV_1 and FVC, and the degree of spirometric abnormality generally reflects the severity of the disease[43,44] (see Table 26-8). By itself, the FEV_1/FVC ratio is the most sensitive measure of airflow limitation, and an FEV_1/FVC ratio less than 70% is considered an early sign of airflow limitation in patients whose FEV_1 remains normal (80% or more of the predicted value).

Table 26.9 Laboratory and Diagnostic Tests for Patients With Chronic Obstructive Pulmonary Disease

Test	Rationale
Spirometry	Measures FVC and FEV_1; gold standard for diagnosing disease and monitoring progression
Bronchodilator reversibility	Performed once during diagnosis stage and useful for the following reasons: • To rule out an asthma diagnosis (If FEV_1 returns to predicted normal range after administration of bronchodilator, airflow limitation is likely due to asthma.) • To establish a patient's best attainable lung function at that point in time
Chest radiography	Bullous disease may be evident Radiological changes seen include: • Flattened diaphragm on lateral chest film • Increased volume of retrosternal air space (signs of hyperinflation) • Hyperlucency of the lungs • Rapid tapering of vascular markings
Computed tomography (CT) and ventilation–perfusion scanning	Assessment of surgical patient to visualize airway and parenchymal disease May assist with differential diagnosis
ABGs	Performed if FEV_1 is <50% predicted or if signs of respiratory failure or right-sided heart failure are present
$Alpha_1$-antitrypsin deficiency screening	Indicated for patients in whom COPD develops at <45 years of age or who have a strong family predisposition ($alpha_1$-antitrypsin serum level below 15%–20% of normal value is highly suggestive of homozygous $alpha_1$-antitrypsin deficiency)

FEV_1, forced expiratory volume in 1 s; FVC, forced vital capacity.

Adapted from Roisin RR, et al: Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease (Updated 2009) Available at http://www.goldcopd.com/download.asp?intId=552.

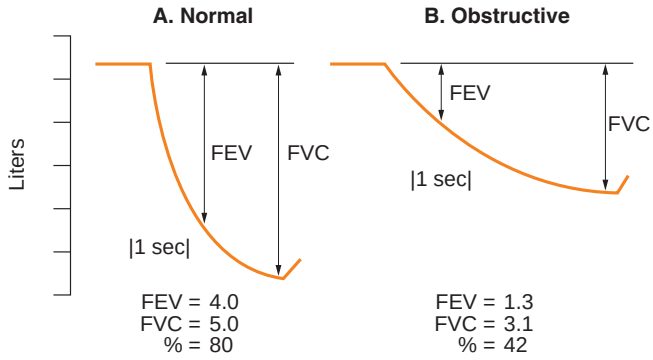

FIGURE 26-6 ▲ Normal, obstructive, and restrictive patterns of a forced expiration. (FVC, forced vital capacity; FEV, forced expiratory volume.) (From West JB: Pulmonary Pathophysiology: The Essentials, 7th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2008.)

ARTERIAL BLOOD GASES. ABG measurements should be performed in all patients in moderate and severe stages of the disease (FEV_1 < 40% predicted) or when clinical signs of respiratory failure or right-sided heart failure are present (ie, central cyanosis, ankle swelling, increase in jugular venous pressure).[42] Respiratory failure is indicated by a partial pressure of arterial oxygen (PaO_2) of 60 mm Hg with or without a partial pressure of arterial carbon dioxide ($PaCO_2$) of 45 mm Hg while breathing air at sea level.[42] Several precautions must be taken to ensure accurate results. First, it should be noted if the patient is currently receiving an oxygen source and the amount of oxygen delivered to the patient during the blood gas sample time. Second, if the fraction of inspired oxygen (FiO_2) has been changed, a period of 20 to 30 minutes should elapse before gas tensions are rechecked.[43]

Management

Several different treatment modalities, ranging from exercise training, nutrition counseling, and education, to drug therapy, oxygen use, and surgery, may be effective in COPD treatment. See Table 26-7 on page 567 for therapeutic guidelines for the various stages of COPD. Box 26-10 provides a collaborative care guide for the patient with COPD.

Nonpharmacological Therapy

The main goals of pulmonary rehabilitation are to decrease symptoms, improve quality of life, and increase physical and emotional participation in day-to-day activities.[43] The 2009

BOX 26–10 *COLLABORATIVE CARE GUIDE For the Patient With Chronic Obstructive Pulmonary Disease*

Outcomes	Interventions
Oxygenation/Ventilation	
Patient has arterial blood gases (ABGs) within normal limits and pulse oximeter value >90%.	• Assess respiratory rate, effort, and breath sounds every 2–4 h. • Obtain ABGs per order or signs of respiratory distress. • Monitor arterial saturation by pulse oximeter. • Provide supplemental oxygen by nasal cannula or face mask using lowest possible FiO_2 and flow rate. • Provide humidification with oxygen. • Provide intubation and mechanical ventilation as necessary (refer to Collaborative Care Guide for the Patient on Mechanical Ventilation, Chapter 25 on pages 538–539).
Patient maintains normal rate and depth of respiration.	• Monitor respiratory rate, pattern, and effort (eg, use of accessory muscles). • Assess respirations during sleep; note sleep apnea or Cheyne-Stokes patterns.
Patient has clear chest x-ray.	• Obtain chest x-ray daily
Patient has clear breath sounds.	• Monitor breath sounds for crackles, wheezes, or rhonchi every 2–4 h. • Administer diuretics per order. • Administer bronchodilators and mucolytics as indicated.
There is no evidence of atelectasis or pneumonia.	• Encourage nonintubated patients to use incentive spirometer, cough, and deep breathe every 2–4 h and PRN. • Assess quantity, color, and consistency of secretions. • Turn side to side every 2 h. • Mobilize out of bed to chair.
Circulation/Perfusion	
Blood pressure, heart rate, and hemodynamic parameters are within normal limits.	• Monitor vital signs every 1–2 h. • Monitor pulmonary artery pressures and right atrial pressure every 1 h and cardiac output, systemic venous resistance, and peripheral venous resistance every 6–12 h if pulmonary artery catheter is in place. • Assess for signs of right ventricular dysfunction (eg, increased central venous pressure, neck vein distention, peripheral edema).
Patient is free of dysrhythmias.	• Maintain patent intravenous access. • Monitor for atrial dysrhythmias due to right atrial dilation and ventricular dysrhythmias due to hypoxemia and hypoxia.
Serum lactate will be within normal limits.	• Monitor lactate daily until it is within normal limits. • Administer red blood cells, positive inotropic agents, colloid infusion as ordered to increase oxygen delivery.

(*continued on page 571*)

BOX 26–10 *COLLABORATIVE CARE GUIDE For the Patient With Chronic Obstructive Pulmonary Disease (continued)*

Outcomes	Interventions
Fluids/Electrolytes	
Renal function is maintained as evidenced by urine output more than 30 mL/h, normal laboratory values.	• Monitor intake and output every 1–2 h. • Monitor blood urea nitrogen, creatinine, electrolytes, Mg, PO_4. • Replace potassium, magnesium, and phosphorus per order or protocol. • Weigh daily.
Patient is euvolemic.	• Administer fluid volume and diuretics based on vital signs, physical assessment, secretion viscosity as ordered.
Mobility/Safety	
There is no evidence of loss of muscle tone or strength.	• Promote standing at bedside, sitting up in chair, ambulating with assistance as soon as possible. • Establish activity program. • Monitor response to activity.
Patient maintains joint flexibility.	• Consult with physical therapist. • Use passive and active range of motion every 4 h while awake.
There is no evidence of infection. WBC counts are within normal limits.	• Monitor systemic inflammatory response syndrome criteria: increased WBC count, increased temperature, tachypnea, tachycardia. • Use strict aseptic technique during procedures and monitor others. • Maintain invasive catheter tube sterility. • Per hospital protocol, change invasive catheters, culture blood, line tips, or fluids.
There is no evidence of deep vein thrombosis (DVT).	• Initiate DVT prophylaxis within 24 h of admission. • Monitor for leg pain, redness, or swelling.
Skin Integrity	
There is no evidence of skin breakdown.	• Turn side to side every 2 h. • Remove self-protective devices from wrists, and monitor skin per hospital policy. • Assess risk for skin breakdown using objective tool (eg, Braden scale). Consider pressure relief/reduction mattress.
Nutrition	
Caloric and nutrient intake meets metabolic requirements per calculation (eg, Basal Energy Expenditure).	• Provide parenteral, enteral, or oral nutrition within 48 h. • Consult dietitian or nutritional support service. • Avoid high-carbohydrate load if patient retains CO_2. • Monitor albumin, prealbumin, transferrin, cholesterol, triglycerides, glucose.
Comfort/Pain Control	
Patient is comfortable and evaluates pain as <4 on the pain scale.	• Assess pain/comfort every 4 h. • Administer analgesics and sedatives cautiously, closely monitoring respiratory rate, depth, and pattern. • Differentiate between agitation caused by discomfort or caused by hypoxia before medication administration. • Elevate head of bed to improve breathing comfort.
Psychosocial	
Patient demonstrates decreased anxiety.	• Assess vital signs during treatments, discussions, and so forth. • Cautiously administer sedatives. • Consult social services, clergy as appropriate. • Provide for adequate rest and sleep. • Provide support during periods of dyspnea.
Teaching/Discharge Planning	
Patient/significant others understand procedures and tests needed for treatment.	• Prepare patient/significant others for procedures such as chest physical therapy, bronchoscopy, pulmonary artery catheter insertion, or laboratory studies.
Significant others understand the severity of the illness, ask appropriate questions, anticipate potential complications.	• Explain the causes and effects of COPD and the potential for complications, such as pneumonia or cardiac dysfunction. • Encourage significant others to ask questions related to the ventilator, pathophysiology, monitoring, treatments, and so forth.
In preparation for discharge to home, patient understands activity levels, dietary restrictions, medication regimen, metered inhaler.	• Make appropriate referrals and consults early during hospitalization. • Initiate family education regarding proper use of metered inhaler, signs and symptoms of respiratory failure, and appropriate actions.

GOLD guidelines for the diagnosis, management, and prevention of COPD recommend a comprehensive pulmonary rehabilitation program.

PULMONARY REHABILITATION. In recent years, the value of pulmonary rehabilitation in managing COPD is being realized. Studies have shown muscle fatigue rather than dyspnea is likely the primary cause of deconditioning in patients with COPD.[43] Pulmonary rehabilitation does not improve lung function but rather helps patients optimize their functional status as well as their quality of life within the limitations of their pulmonary disease process. Pulmonary rehabilitation has been shown to increase exercise tolerance, reduce dyspnea, decrease anxiety and depression, improve quality of life, improve cognitive function, and provide the patient with a feeling of empowerment, meaning that they have control over their disease process.[43,44] Pulmonary rehabilitation programs consist of three to four hourly supervised sessions per week lasting for 6 to 12 weeks.

NUTRITIONAL COUNSELING. Malnutrition is a common problem in patients with COPD and is present in more than 50% of patients with COPD admitted to the hospital. The incidence of malnutrition varies with the degree of gas exchange abnormality. Malnutrition results in wasting of respiratory muscles and further respiratory muscle weakness.[43] A complete nutritional assessment should be conducted to identify strategies to maximize the patient's nutritional status. Improving the nutritional state of weight-losing patients with COPD can lead to increased respiratory muscle strength.[43]

SMOKING CESSATION. Smoking cessation is the single most effective method of reducing the risk for development of COPD. The value of smoking cessation cannot be underestimated in slowing the progression of COPD. In addition, it is the most cost-effective method. A brief (3-minute) counseling session to encourage a smoker to quit results in smoking cessation rates of 5% to 10%. Every smoker should have such a counseling session at every visit to a health care provider.[43] The effectiveness of smoking cessation is gained only when the patient is mentally ready to stop smoking. Numerous effective pharmacotherapies exist today for smoking cessation. These therapies consist of nicotine replacement products in various forms (inhalation, oral, sublingual, or transdermal). One of the most effective pharmacotherapies that have proved effective in smoking cessation is varenicline, which is an alpha-4-beta-2 neuronal nicotinic acetylcholine receptor partial agonist. Many clinical trials are ongoing in regard to varenicline. However, studies show that varenicline therapy in conjunction with counseling is very effective in diminishing withdrawal symptoms and helping patients achieve smoking cessation and that this therapy is superior to therapy with nicotine replacement products or bupropion (Wellbutrin).[43] The current treatment guidelines consist of a 12-week course of therapy.

Pharmacological Therapy

The goal of pharmacotherapy for COPD is to prevent and decrease symptoms, to reduce the frequency and severity of exacerbations, as well as to improve exercise tolerance and improve health status. According to the 2009 GOLD guidelines, pharmacological treatment for stable patients with COPD consists of bronchodilators, beta agonists, anticholinergics, and inhaled glucocorticosteroids.[43] These medications can be administered alone or in combination depending on the response to therapy as well as the severity of the disease. A combination of agents may produce greater effects than single-agent therapy, and the inhaled route is the preferred route of delivery.[43] Other pharmacological treatments that have been used in the past, such as systemic glucocorticoid, mucoactive agents, and chronic antibiotic therapy, are no longer being used for treating stable COPD patients.[43]

BRONCHODILATORS. Bronchodilators, primarily beta agonists and anticholinergics, along with inhaled glucocorticoids[43,44]are the mainstay of pharmacological management of stable COPD. These medications are sometimes used as single agents or in combination. Bronchodilators offer long-term improvement in symptoms, exercise capacity, and quality of life. However, these medications, as well as any other pharmacological agents, have not been shown to reverse the progression of COPD. Patients are usually on a combination of long-acting bronchodilator, such as tiotropium bromide (Spiriva), which is a long-acting anticholinergic, along with a short-acting bronchodilator, such as albuterol (Ventolin), which is a beta agonist, for rescue inhaler.[43,45] Long-acting anticholinergics are preferred over long-acting beta agonists because they have been shown to decrease hyperinflation, decrease COPD exacerbation, and improve dyspnea.[46] They increase the FEV_1 by widening the smooth muscle tone of the airways rather than by altering the elastic recoil properties of the lung.[46] Long-acting bronchodilators are the most convenient. The choice of the particular form of bronchodilator therapy depends on availability and the patient's response in terms of symptom relief and side effects. Combination therapy, rather than an increased dose of a single agent, may lead to improved efficacy and a decreased risk for side effects.

GLUCOCORTICOIDS. COPD is a disease that is characterized by systemic and airway inflammation.[42] The aim of inhaled glucocorticoids is to reduce the inflammation.[42] Studies have shown that inhaled glucocorticoids decrease COPD exacerbations but have little to no impact on overall mortality or improvement of lung function.[42] Inhaled glucocorticoids should always be used in conjunction with long-acting bronchodilators and never as a single agent.[43,45] Regular treatment with inhaled glucocorticosteroids for COPD is appropriate only for patients with GOLD stage III–IV who have FEV_1/FVC less than 70% of predicted value and with increased symptoms and repeated exacerbations on optimal bronchodilator therapy.[43]

OTHER PHARMACOLOGICAL AGENTS. Several other drugs may be useful but are not universally recommended. One such medication is theophylline. Studies have shown that theophylline decreases dyspnea and improves gas exchange.[45] However, several problems exist with using theophylline.[43] Theophylline is a medication that requires monitoring of blood levels. Theophylline is metabolized by the liver, so if there is anything that interferes with an individual's liver function, then the individual can have changes in the theophylline blood level, which leads to toxicity. Theophylline also interacts with a lot of other medications. It is for these reasons that using theophylline in the standard

management of COPD has lost favor.[43] Antibiotics should not be used in COPD except for treating infectious exacerbations and other bacterial infections.[43] Patients with COPD are more susceptible to seasonal flu and pneumonia; therefore, they should be routinely immunized with the seasonal flu vaccine and the pneumonia vaccine. Current research indicates that mucolytic agents have minimal overall benefits, and their widespread use is not recommended. *N*-acetylcysteine, a drug with mucolytic and antioxidant properties, has been shown to cause bronchoconstriction when inhaled. The antioxidant properties were not able to be demonstrated in studies; therefore, it is no longer used in the management of COPD.[43]

Oxygen Therapy

Oxygen therapy is one of the principal nonpharmacological treatments for patients with severe COPD. Oxygen therapy improves the quality of life, cognitive performance, as well as long-term survival of patients in a hypoxic state.[43] Oxygen therapy can be administered as long-term continuous therapy, during exercise, nocturnally, and in the relief of acute dyspnea. The goal of long-term oxygen therapy is to produce an oxygen saturation as measured by pulse oximetry (SpO_2) of at least 90% at rest, sleep, and exercise.[43] Supplemental oxygen therapy is recommended for individuals who are hypoxic as a result of COPD progression or in individuals recovering from an exacerbation with a PaO_2 at or below 60 mm Hg or an SaO_2 at or less than 90%, with or without hypercapnia.[43] Supplemental oxygen therapy is also indicated in individuals when PaO_2 is between 55 and 60 mm Hg or when SaO_2 is below 90% and there is evidence of cor pulmonale or polycythemia despite optimal medical management.[43]

Historically, there has been hesitation to administer oxygen to patients with COPD. However, in the face of acute exacerbation, prevention of tissue hypoxia overrules any concern regarding CO_2 retention.[43] If successful oxygenation (SaO_2 of 90% or more) is not obtained without a progression of respiratory acidosis, intubation and mechanical ventilation are usually performed.[43]

Surgical Therapy

Surgical intervention may include lung volume reduction surgery (LVRS), bullectomy, and lung transplantation. Hopefully, the benefit of these procedures for a select group of patients with COPD is improvement in lung volumes, exercise tolerance, dyspnea, pulmonary function tests, quality of life, and survival.[43]

LUNG VOLUME REDUCTION SURGERY. LVRS is a surgical procedure in which parts of the nonfunctioning or scarred lung, usually the upper lobes, are resected, thereby reducing the lung volume. LVRS can be performed via a median sternotomy or video-assisted thoracoscopic surgery. A rationale as to why LVRS works is that removal of the nonfunctioning or scarred part of the upper lung lobes improves the mechanical functioning of the diaphragm and intercostal muscles. This is achieved by decreasing the FRC and returning the diaphragm to its more normal curvature and lengthening configuration.[43] Therefore, this surgery improves the mechanics of breathing and hopefully decreases the work of breathing.

In the United States in the late 1990s, a multicenter national clinical trial called the National Emphysema Treatment Trial (NETT) compared LVRS to medical management of severe emphysema. An analysis of the data upon conclusion of this trial revealed several things regarding which individuals with emphysema should have LVRS. The data identified five groups. The group that was considered as poor candidates for this surgery had extremely poor pulmonary function (FEV_1 of 20% or less of predicted value and DLCO, or diffusion capacity, of 20% or less of predicted value) and homogenous emphysema. This group was at very high risk for LVRS. The second group had nonhomogenous upper lobe predominant emphysema with low exercise capacity after preoperative pulmonary rehabilitation. The third group had predominately upper lobe emphysema with a high exercise capacity after preoperative pulmonary rehabilitation. The fourth group consisted of individuals with homogenous emphysema and low postrehabilitation exercise capacity. The last group had homogenous emphysema and low postpulmonary rehabilitation exercise capacity.[47] Analysis of the data revealed that the individuals who gained the most benefit from LVRS when compared to medical management were the individuals who were in the group that had nonhomogenous emphysema with upper lobe predominance and limited exercise tolerance after preoperative pulmonary rehabilitation. These individuals had a lower mortality rate, better exercise tolerance, and improved health status. The individuals with predominantly upper lobe emphysema and good postrehabilitation exercise tolerance along with the individuals with homogenous emphysema and low postpulmonary rehabilitation exercise tolerance did gain some benefit in terms of improvement in exercise tolerance and health status but not to the extent as the abovementioned group.[47]

The NETT trial revealed the importance of pulmonary rehabilitation in the management of emphysema. The NETT trial also concluded that LVRS improves the quality of life of the patient with emphysema but does not improve overall survival advantage over medical management.[47] For patients awaiting eventual lung transplantation, LVRS provides a means of managing their symptoms while awaiting transplantation.

OTHER SURGICAL PROCEDURES. Patients with severe COPD (stage III) may also consider bullectomy and lung transplantation.[42,43] Bullectomy is a surgical procedure for bullous emphysema, which is effective in alleviating dyspnea and improving overall lung function.[42,43] Patients with very advanced COPD are candidates for lung transplantation. Lung transplantation has been shown to improve quality of life, exercise capacity, and functional capacity; however, long-term survival is still questionable.[47]

Prevention

Influenza vaccines reduce serious illness and death by about 50% in patients with COPD.[43] Vaccines containing killed or live, inactivated viruses are recommended because they are more efficacious in elderly patients with COPD. Vaccines are administered either once (autumn) or twice (autumn and winter) each year. Some experts do recommend pneumococcal vaccine administration once each year for

patients with COPD and chronic bronchitis and every other year for asplenic patients or patients at risk for decreased antibody levels (eg, in transplantation or in chronic renal failure).[42,43]

Chronic Bronchitis

Chronic bronchitis is defined as the presence of a productive cough for at least 3 months per year over 2 consecutive years, in the absence of other medical causes.[48] During an exacerbation or episode of acute infection, a patient with chronic bronchitis may present with airflow obstruction similar to that of a patient with asthma. However, the difference lies in the fact that, with chronic bronchitis, the primary cause of airflow obstruction is not due to airway hyperreactivity, and there are residual clinical symptoms even when the patient returns to baseline function.[12]

Pathophysiology

Airway obstruction is caused by inflammation of the major and small airways in chronic bronchitis (Fig. 26-7). Subsequently, edema and hyperplasia of submucosal glands and excess mucous excretion into the bronchial tree occur, resulting in a chronic productive cough.[12] Cigarette smoking is the major causal factor in the development of chronic bronchitis.[12] Other causes of chronic airway irritation include air pollutants and occupational exposure to nitrogen, sulfur oxides, or endotoxin.[12] Nonspecific pathological changes in the lung, including infiltration of airway mucosa and submucosa with neutrophils and mononuclear cells, smooth muscle hypertrophy, and enlargement of the submucosal secretory glands, may also contribute to the development of chronic bronchitis.[12]

Once the airway lumen is occluded by secretions and narrowed by a thickened wall, patients develop airflow obstruction and COPD. Acute bacterial or viral infection in patients with existing chronic bronchitis can increase airway and parenchymal damage, impair mucociliary clearance, obstruct bronchioles, and contribute to chronic epithelial damage and bacterial colonization that further exacerbate symptoms and airway obstruction.[12] Common bacteria isolated from the secretions of patients with chronic bronchitis include *H. influenzae*, *Haemophilus parainfluenzae*, *S. pneumoniae*, and *Moraxella catarrhalis*.[12] Even in nonsmoking patients, acute viral infection may lead to the chronic airway inflammation and chronic sputum production characteristic of chronic bronchitis.[12] In contrast to emphysema, chronic bronchitis may have a reversible component if the source of chronic infection or irritation is treated. These patients normally do not have hyperinflation or abnormal diffusion test results.

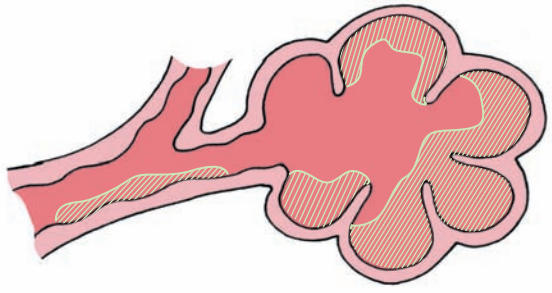

FIGURE 26-7 ▲ Bronchitis: inflammation and thickening produce narrowing of airways. *Lined areas* indicate secretions.

Assessment

Excessive bronchial secretions and subsequent airway obstruction and vasoconstriction lead to ventilation–perfusion mismatching. Patients do not compensate by increasing their ventilation and, therefore, develop hypoxemia, cyanosis, and eventually cor pulmonale with peripheral edema.[43] Common physical signs and symptoms may include:[11]

- Copious sputum expectoration arising from sleep
- Sputum that is usually mucoid, often with brownish discoloration
- Increased sputum volume or changes in color from whitish to yellow or green (signs of an endobronchial infection)
- Hemoptysis occurring during acute exacerbations
- Decreased breath sounds, wheezes, or rhonchi
- Resting respiratory rate greater than 16 breaths/min
- Prolonged forced expiratory time (greater than the normal 4 seconds)

Often, patients wait to seek medical treatment until they are in severe distress. Manifestations of severe exacerbations of chronic bronchitis are listed in Box 26-11.

Management

Patients with chronic bronchitis without airflow obstruction require no specific pharmacological treatment. An

BOX 26-11 Manifestations of Severe Exacerbations of Chronic Bronchitis

Constitutional Signs
Temperature frequently subnormal
White blood cell count varies—may be slightly ↑, normal, or ↓

Central Nervous System Disturbances
Headache
Confusion
Hallucinations

Blood pressure varies: normal, ↑, or ↓
Vasoconstriction initially followed by vasodilation

Neuromuscular Signs
Fine tremors
Asterixis
Flaccidity
Convulsions

essential prophylactic measure involves rigorous bronchial hygiene to promote the clearance of secretions, which provide an ideal medium for bacterial growth in peripheral airways. It is important to prevent the development of an acute inflammatory process to avoid exacerbations. Other preventive measures include smoking cessation, immunization against influenza virus and *S. pneumoniae*, and prompt antibiotic treatment for acute exacerbations caused by bacterial tracheobronchitis.[12]

Chronic bronchitis with airflow obstruction does require pharmacological treatment. The major goals of drug therapy in chronic bronchitis with COPD are to reverse or slow the progression of airway obstruction and mucosal edema, decrease secretion volume, alleviate bronchial smooth muscle spasm, and decrease airway inflammation.[42,43] Primary agents include inhaled bronchodilators (beta$_2$-adrenergic agents, anticholinergic agents, corticosteroids) and theophylline.[42,43] An effective treatment regimen may include using a combination of drugs. By combining drugs with different mechanisms of action and duration of effect (long acting, short acting), more effective bronchodilation may occur with less incidence of side effects, such as tachycardia, restlessness, or toxicity. Although excessive cough and mucous production are common symptoms, regular use of antitussives and mucolytic agents is not indicated.[45]

Emphysema

The ATS defines emphysema as a loss of lung elasticity and abnormal, permanent enlargement of the airspaces distal to the terminal bronchioles with destruction of the alveolar walls and capillary beds without obvious fibrosis (Fig. 26-8).[42] Most patients with COPD have a combination of chronic bronchitis (mucous hypersecretion) and emphysema rather than "pure" bronchitis or emphysema.[42]

There are three types of emphysema: centrilobular emphysema, panacinar emphysema, and paraseptal emphysema (Fig. 26-9). Centrilobular emphysema is most common in smokers and often localizes in the upper lung zones. Panacinar emphysema is most frequently found in patients with alpha$_1$-protease inhibitor deficiency and is often localized in the lower lobes. Paraseptal emphysema is also most common in smokers and is localized peripherally, with possible formation of large bullae.[12]

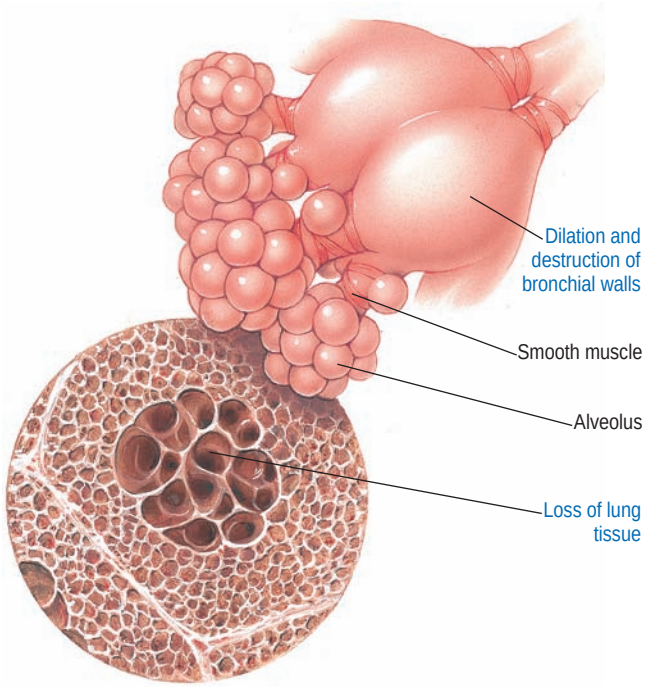

FIGURE 26-8 ▲ Lung changes in emphysema. Airspaces are enlarged in the emphysematous lung. (From Anatomical Chart Company: Atlas of Pathophysiology. Springhouse, PA: Lippincott Williams & Wilkins, 2010, p 91.)

Pathophysiology

The enlargement of the airspaces in emphysema results in hyperinflation of the lungs and increased total lung capacity.[12] Emphysema is believed to result from the breakdown of elastin by enzymes, called proteases, which digest proteins. These proteases, especially elastase, are released from neutrophils, alveolar macrophages, and other inflammatory cells.[44] Two recognized conditions that cause emphysema are smoking and inherited alpha$_1$-antitrypsin deficiency. Smoking contributes to increased inflammatory cells in the alveoli, enhanced release of elastase from neutrophils, increased elastase activity in macrophages, and activation of mast cells that release mast cell elastases.[44] Alpha$_1$-antitrypsin usually protects the lung from the destructive inflammatory cells; however, the elastic tissue–destructive process continues unabated in patients with an inherited alpha$_1$-antitrypsin deficiency.[44]

Almost all people who develop emphysema before 40 years of age have an alpha$_1$-antitrypsin deficiency. Evidence has shown that cigarette smoking decreases levels of alpha$_1$-antitrypsin and increases the number of macrophages in the alveolar walls. This vicious cycle promotes increased numbers of neutrophils. A hereditary deficiency in alpha$_1$-antitrypsin is responsible for about 1% of all cases of COPD.[44] Smoking and repeated respiratory tract infections further decrease alpha$_1$-antitrypsin levels, adding to the risk for emphysema in people with low alpha$_1$-antitrypsin levels.[44]

A common phenomenon in emphysema is spontaneous pneumothorax related to rupture of thinned parenchyma.[12] Patients may experience acute severe dyspnea and respiratory failure depending on the amount of pulmonary reserve (see the discussion of barotrauma in the section on Pneumothorax).

Assessment

Patients with pulmonary emphysema are referred to as "pink puffers" because their oxygen levels are usually satisfactory, and their skin remains pink.[12] There is a proportionate loss of ventilation and perfusion area in the lung. In severe COPD, air is trapped in the lungs during forced expiration, leading to abnormally high residual volume.[12] These patients develop a puffing style of breathing. Common physical examination findings in emphysema include increased basal respiratory rate; barrel-shaped chest; decreased breath sounds; soft, dry crackles in lung bases; right-sided S_3 gallop auscultated substernally; supraclavicular wasting and nasal flaring; and

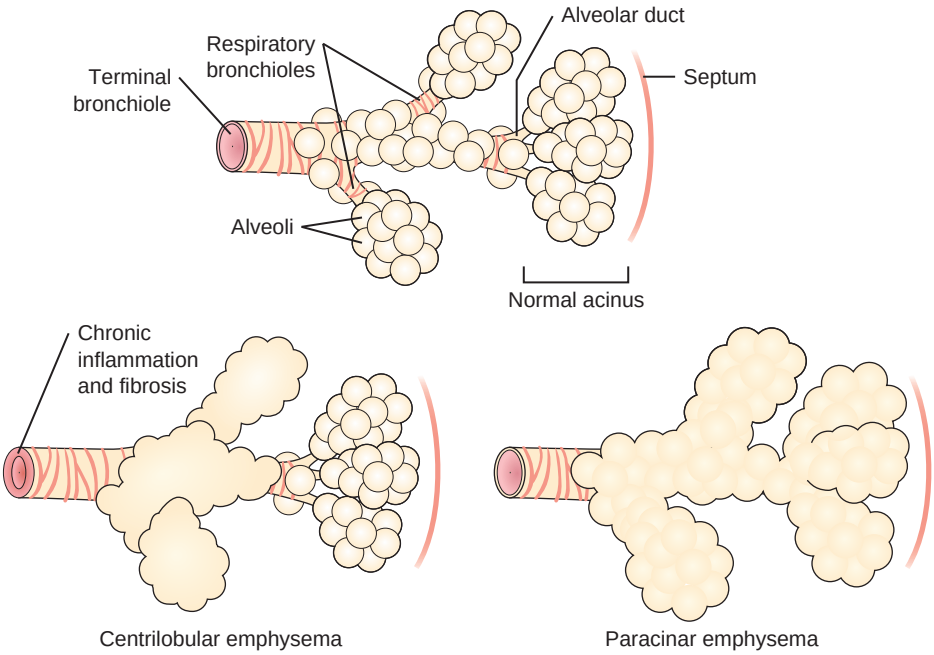

FIGURE 26-9 ▲ Types of emphysema. The acinus, the gas-exchanging structure of the lung distal to the terminal bronchiole, consists of the terminal bronchiole, respiratory bronchioles, alveolar ducts, alveolar sacs, and alveoli. In centrilobular (proximal acinar) emphysema, the respiratory bronchioles are mainly involved. In paraseptal (distal acinar) emphysema, the alveolar ducts are mainly affected. In panacinar (panlobular) emphysema, the acinus is uniformly damaged.

evidence of pulmonary hypertension, including an increased second heart sound, jugular venous distention, and right ventricular heave.[12] Cyanosis may be present in advanced cases of emphysema.

Management

The medical and surgical therapies described for COPD also pertain to patients with emphysema (see section on COPD, Management, pp. 570–573). Preventive measures include an annual influenza vaccine and a pneumococcal vaccine every 5 to 10 years. Medical therapy involves smoking cessation, pulmonary rehabilitation, and oxygen therapy in all patients who are hypoxemic (PaO_2 < 55 mm Hg or SaO_2 < 88%).[44] Pharmacological therapy includes bronchodilators ($beta_2$-agonists, anticholinergics, and theophylline), possibly mucolytics, and $alpha_1$-protease inhibitor replacement in young patients with homozygous disease. In addition, adequate nutrition is important. Patients with advanced emphysema (FEV_1 < 750 mL) may experience significant weight loss related to a variety of factors, including increased energy expended during breathing secondary to the use of accessory muscles, performing activities of daily living, and reduced caloric intake.[42] Patients who are overweight and hypercapnic should strive to lose weight to diminish the respiratory workload.[44]

Three surgical treatments available for patients with emphysema are LVRS, bullectomy, and lung transplantation. Currently, LVRS is the only recognized therapy that can increase respiratory function (FEV_1, FVC, ABG values, and exercise capacity) in moderate to severe emphysema.[47] For end-stage emphysema, the only definitive surgical treatment is single-lung transplantation. Because of the short supply of donor lungs, lung transplantation is usually reserved for younger patients (<60 years of age) with $alpha_1$-protease inhibitor deficiency.[43] Studies have indicated improvements in exercise performance and ABG values after lung transplantation.[44]

▲ Thoracic Surgery

Thoracic surgery is indicated as part of the management plan for a variety of diseases involving the lungs and the associated structures. Specific surgeries involving removal of part of the lung include wedge resection, lobectomy, pneumonectomy, lung volume reduction, and lung transplantation. Wedge resection or segmentectomy is performed for the removal of benign or malignant lesions; segmentectomy is the preferred method when patients are a poor risk with limited pulmonary reserve.[44,48] Bleeding may be extensive following the surgery, and two chest drains are usually in place to drain air or blood. Lobectomy may be performed as a treatment for malignant or benign tumors and infections such as bronchiectasis, tuberculosis, or fungal infection. Pneumonectomy is performed to remove one lung, usually because of primary carcinoma or significant infection. LVRS involves the excision of 20% to 30% of the volume of each lung to improve elastic recoil and diaphragmatic function in the patient with moderate to severe emphysema.[44,48] Lung transplantation may involve one lung or both lungs, or it may be inclusive as part of a heart–lung transplantation. To be considered a viable candidate for lung transplantation, a patient should

have advanced lung disease that is unresponsive to other medical therapy and minimal comorbidities. Significant areas of concern involved in this surgery include primary graft failure, lifelong immunosuppressive therapy, and organ rejection.[44]

▲ Acute Asthma

Asthma is a chronic inflammatory disease of the airways characterized by airway hyperresponsiveness to a variety of stimuli, reversible airflow limitation, and chronic inflammation of the airway submucosa.[49] It is manifested as variable airway obstruction that resolves either spontaneously or after bronchodilator administration.[49] Based on symptoms and lung function, the National Asthma Education and Prevention Program (NAEPP) has classified asthma as mild intermittent, mild persistent, moderate persistent, or severe persistent (Table 26-10). According to the CDC, asthma is a worldwide epidemic. Asthma affects 7% of the population or 17 million adults and children in the United States.[50] Asthma accounts for 2 million emergency department visits, 500,000 hospital admissions, and 5,000 deaths annually in the United States. Most cases are believed to be preventable.[50]

Pathophysiology

Inflammation may be present throughout the bronchial tree, from large airways to the alveoli. This inflammation is characterized by mast cell activation, inflammatory cell infiltration, edema, denudation and disruption of the bronchial epithelium, collagen deposition beneath the basement membrane, goblet cell hyperplasia (which contributes to mucous hypersecretion), and smooth muscle thickening (Fig. 26-10). This inflammatory process contributes to airway hyperresponsiveness, airflow limitation, pathological damage, and associated respiratory symptoms (ie, wheezing, shortness of breath, and chest tightness).[12]

Factors contributing to the airflow limitation in asthma include acute bronchoconstriction, airway mucosal edema, chronic formation of mucous plugs, and airway remodeling.[12]

The T lymphocytes (helper T [Th] cells) are believed to play a crucial role in the inflammation process.[51] Th1 cells serve a protective role against airway inflammation, and Th2 cells promote development of chronic airway inflammation. Recent studies suggest that possible early childhood viral and bacterial infections may contribute to Th2 cell stimulation and result in asthma pathogenesis.[51]

The etiology and pathogenesis of asthma are not fully understood. Inhaled irritants, such as cigarette smoke, inorganic dusts, and environmental pollutants, are common precipitants. These irritants stimulate the irritant receptors in the walls of the larynx and large bronchi, which initiate a reflex arc that travels to the central nervous system and back through the vagus nerve. This in turn induces bronchoconstriction.[12] The most common precipitant of an acute asthmatic exacerbation is an upper respiratory tract viral infection. The proposed mechanism of action is through epithelial damage and airway inflammation.[12] Other potential infectious causal factors include infection with *C. pneumoniae*, tracheobronchitis related to herpes simplex, and exposure to aspirin or other nonsteroidal anti-inflammatory cyclooxygenase-1 inhibitors, which can lead to life-threatening asthmatic reactions in selected patients.[49] The mechanism of action in exercise-induced asthma is less clear but thought to be related to hyperemia and stimulation of irritant receptors following the rewarming of cooled airways. Common triggers of asthma exacerbations are given in Box 26-12.

Assessment

History and Physical Findings

The medical history should address the following areas:[49,51]

- Symptoms and symptom patterns
- Precipitating and aggravating factors
- Development of disease

Table 26-10 Classification of Asthma Severity by Clinical Features Before Treatment

	Symptoms	Nighttime Symptoms	Lung Function
Intermittent	Symptoms once a week or less Brief exacerbations	Two or less times a month	FEV_1 or PEF 80% or more predicted PEF or FEV_1 variability 20% or less.
Mild persistent	Symptoms once a week but less than once a day Exacerbations may affect activity and sleep	More than two times a month	FEV_1 or PEF > 80% predicted PEF or FEV_1 variability 20%–30%
Moderate persistent	Symptoms daily Daily use of inhaled short-acting β_2-agonist Exacerbations affect activity and sleep	More than once a week	FEV_1 or PEF, or >60% to <80% predicted PEF or FEV_1 variability >30%
Severe persistent	Symptoms daily Frequent exacerbations Limitation of physical activities	Frequent nocturnal asthma symptoms	FEV_1 or PEF 60% or less predicted PEF or FEV_1 variability >30%

FEV_1, forced expiratory volume in 1 s; PEF, peak expiratory flow.

BOX 26-12 Common Triggers of Asthma

Factors Influencing the Development and Expression of Asthma,

Host Factors

Genetic, for example,
- Genes predisposing to atopy
- Genes predisposing to airway hyperresponsiveness

Obesity
Sex

Environmental Factors

Allergens
- Indoor: Domestic mites, furred animals (dogs, cats, mice), cockroach, allergen, fungi, molds, yeasts
- Outdoor: Pollens, fungi, molds, yeast

From Global Initiatives for Asthma (GINA) Guidelines: Global strategy for asthma management and prevention. Available at www.ginasthma.org. Accessed December 2010.

- Current treatment
- Effect of symptoms on activities of daily living
- Impact of asthma on the patient and family
- Perceptions of the disease by the patient and family (parent, if appropriate)

The physical examination should focus on the following areas:[49,51]

- Vital signs
- Height, weight, and a comparison of normal values for age
- Inspection of skin for evidence of atopic dermatitis or eczema
- Mouth breathing
- Dark discoloration beneath the lower eyelids ("allergic shiners")
- Edematous or pale nasal mucosa
- Clear nasal discharge
- Hypertrophy of tonsils and adenoids

- Presence of tearing and periorbital edema
- Lung auscultation for wheezing
- Hyperexpansion of the thorax
- Use of accessory muscles
- Presence of tachypnea

Signs and symptoms vary with the degree of bronchospasm. Patients may complain of shortness of breath associated with wheezing, especially during the late night and early morning hours, along with disruption of sleep.[51] According to the NAEPP guidelines, asthma symptoms may be classified as mild intermittent, mild persistent, moderate persistent, or severe persistent depending on frequency, duration, timing, and associated lung function level (see Table 26-10). Additional findings, including tachycardia, retractions, restlessness, anxiety, inspiratory or expiratory wheezing, hypoxemia, hypercapnia, cough, sputum production, expiratory prolongation, cyanosis, and an elevated pulsus paradoxus (systolic blood pressure in expiration exceeding that in inspiration by >10 mm Hg), may be observed in patients who have severe attacks.[50] The severity of an acute asthma exacerbation is evaluated using patient symptoms, physiologic signs, and lung function results and can be classified as mild, moderate, severe, and impending failure (Table 26-11).

Diagnostic Studies

Objective measures in the diagnosis and measurement of asthma severity consist of spirometry and pulmonary function testing. Allergy testing may be performed to ascertain precipitating allergens.[51,52] Spirometry measurements of the FVC, FEV_1, and FEV_1/FVC ratio are performed before and after the patient inhales a short-acting bronchodilator, which determines whether airflow obstruction is present and whether it is reversible. An increase of at least 12% and 200 mL in FEV_1 after inhaling a short-acting bronchodilator indicates significant reversibility and confirms the presence of asthma.[51,52] The FEV_1/FVC ratio is less than 65% predicted. Airway resistance is increased, so FEV is reduced out of proportion to FVC reduction. Portable peak flow meters are used to monitor ongoing lung function. Patients are instructed how to measure peak expiratory flow, an indicator of the degree of airflow obstruction in the large airways, by using the peak flow meter on a regular basis.[51,52]

Management

The level of treatment is based on the patient's level of asthma severity, which changes with time, age, and compliance with

Table 26-11 Classification of Severity of Asthma Exacerbations

	Mild	Moderate	Severe	Impending Respiratory Failure
Symptoms				
Breathlessness	Walking Can lie down	Talking Prefers sitting	At rest Hunched forward	At rest
Talks in	Sentences	Phrases	Words	
Alertness	May be agitated	Usually agitated	Usually agitated	Confused or drowsy
Signs				
Respiratory rate	Increased	Increased	Often more than 30 breaths/min	
Use of accessory respiratory muscles	Usually not	Commonly	Usually	Paradoxical thoracoabdominal movement
Breath sounds	Moderate wheezing, often end expiratory	Loud wheezes	Usually loud wheezes	Absence of wheezes
Heart rate (beats/min)	<100	100–120	>120	Bradycardia
Pulsus paradoxus (mm Hg)	Absent or <10	May be present, 10–25	Often present, >25	Often absent
Functional Assessment				
PEF (% predicted or personal best)	>80%	Approximately 60%–80%	<60% predicted or personal best or response to therapy lasts <2 h	
SaO_2 (%, room air)	>95	91–95	<90	
PaO_2 (mm Hg, room air)	Normal	>60	<60	
$PaCO_2$ (mm Hg)	<45	<45	>45

treatment.[51,52] Frequent reassessments of the level of severity are necessary to provide adequate therapy. The overall goals of therapy are to prevent chronic and troublesome symptoms, prevent exacerbations of symptoms, maintain normal activity levels, maintain normal pulmonary function, optimize pharmacotherapy and minimize side effects, and satisfy the patient's and the family's expectations and goals for asthma care.[52] A stepwise pharmacological approach is recommended in treating patients with asthma. The main goal is to gain control quickly and to "step down" to the lowest medication level required to maintain asthma control.[52] A list of quick-relief asthma medications is presented in Table 26-12. A flow chart outlining the stepwise approach is shown in Figure 26-11.

Asthma education and self-management training are critical to helping the asthmatic patient control airway inflammation. The 2009 Global Initiatives for Asthma guidelines describe the critical components of asthmatic patient education.[52] An important aspect of asthmatic patient education programs is training in the necessary management skills. These skills include proper medication administration, understanding the need for maintenance medications, knowing the early

Table 26-12 Drug Therapy in Asthma

	Examples	Possible Routes of Administration	Mechanism of Action
Bronchodilators			
$Beta_2$ agonist Short acting	Fenoterol Levalbuterol Salbutamol (albuterol) Terbutaline reproterol	Inhaled, oral, parenteral (depending on particular drug)	↑ cAMP via stimulation of adenylate cyclase, which results both in bronchodilation and inhibition of mediator release in immediate hypersensitivity reaction
Long acting	Terbutaline Salbutamol Bambuterol Formoterol		
Xanthines	Theophylline	Oral	Adenosine antagonism and induction on histone deacetylase, which decreases proinflammatory cytokines
Short-acting anticholinergics	Ipratropium	Inhaled	Blockade of cholinergic (bronchoconstrictor) effect on airways by diminishing cyclic guanosine monophosphate concentration and inhibit vagal efferent pathway
Anti-Inflammatory Drugs			
Corticosteroids	Prednisone Prednisolone Hydrocortisone Methylprednisolone	Systemic (oral or parenteral, depending on particular drug)	Direct and indirect inhibitory effects on multiple inflammatory genes
	Beclomethasone Triamcinolone Flunisolide Fluticasone Budesonide Ciclesonide	Inhaled	
Cromones	Sodium cromoglycate Nedocromil	Inhaled	Inhibition of mediator release from mast cells
Drugs Directed at Specific Targets			
5-Lipoxygenase inhibitors	Zileuton	Oral	Decreased production of leukotrienes
Leukotriene antagonists	Zafirlukast Montelukast Pranlukast	Oral	Cysteinyl-leukotriene 1 receptor antagonism
Anti-IgE antibody	Omalizumab	Parenteral	Binds circulating IgE

cAMP, cyclic adenosine monophosphate.

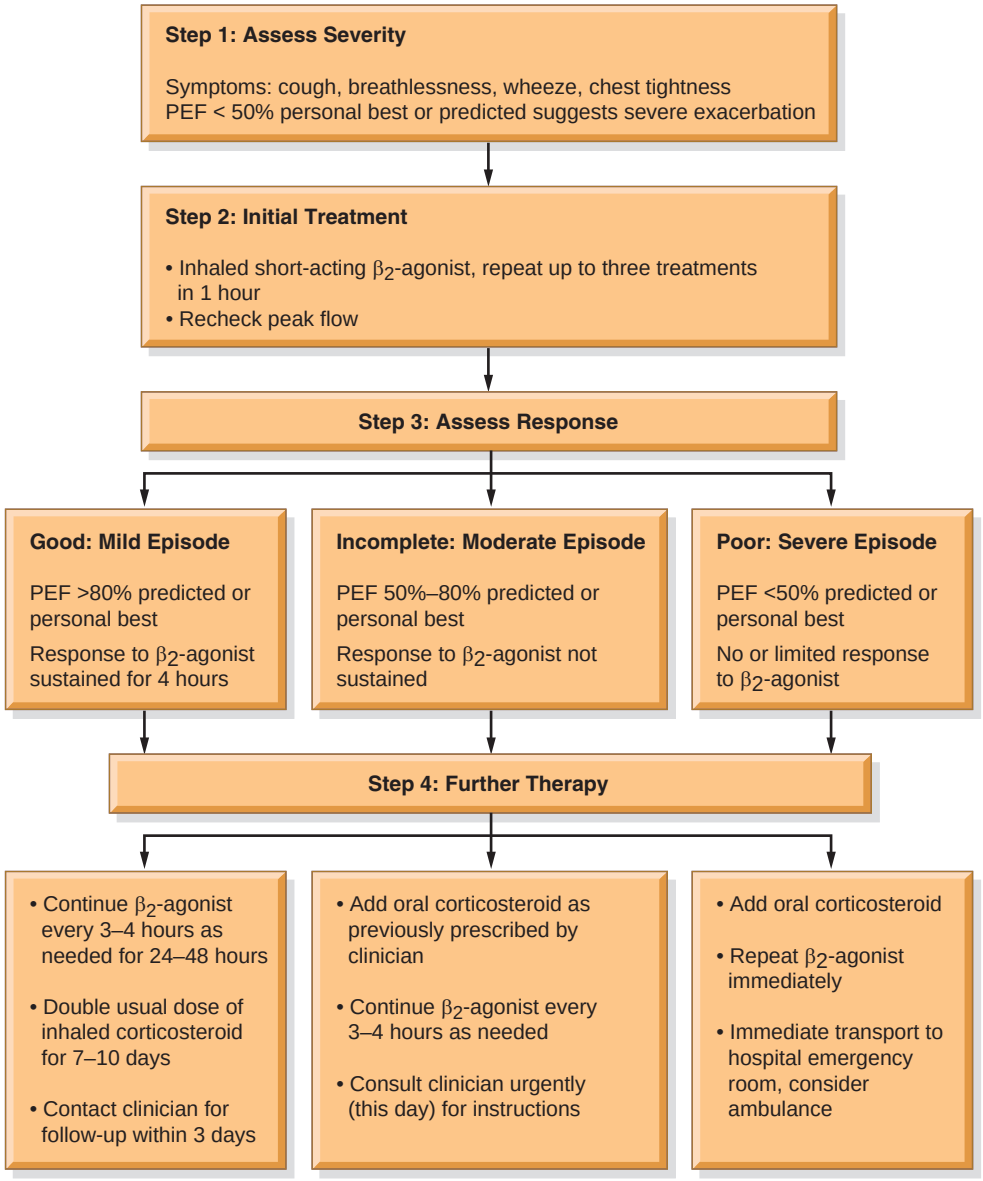

FIGURE 26-11 ▲ Management of Asthma Exacerbation in Acute Care Settings. PEF, peak expiratory flow. (From GINA report, Global Initiatives for Asthma (GINA) Guidelines: Global Strategy for Asthma Management and Prevention. Available at www.ginasthma.org. Accessed December 2010.)

warning signs of an asthma attack, making decisions on the basis of self-monitoring of symptoms and peak flow results, and maintaining control of environmental asthma triggers (ie, dust mites, fur-bearing animals).[52] Recent studies have confirmed that appropriate therapy, coupled with structured asthma education, significantly improves short-term compliance with therapy and decreases asthma morbidity.[52] Long-term asthma management requires regular follow-up care with a clinician experienced in long-term asthma to maintain optimal asthma control and avoid preventable complications.[52]

Status Asthmaticus

Status asthmaticus is a medical emergency. It is an acute refractory asthma attack that has not responded to rigorous therapy with beta$_2$-adrenergic compounds or intravenous theophylline. Patients present with a dramatic picture of acute anxiety, markedly labored breathing, tachycardia, and diaphoresis. Deterioration of pulmonary function results in alveolar hypoventilation with subsequent hypoxemia, hypercapnia, and acidemia. A rising $PaCO_2$ in a patient with an acute asthmatic attack is often the first objective indication of status asthmaticus.[50]

The treatment of status asthmaticus involves the institution of multiple therapeutic modalities. All patients with status asthmaticus demonstrate hypoxemia and require oxygen therapy. Patients are also usually dehydrated and require fluid resuscitation. Pharmacological agents include methylxanthines, sympathomimetic amines, and corticosteroids.[50,52] If pulmonary function cannot be improved and respiratory

failure ensues, patients may require intubation and assisted ventilation (see Chapter 25). A spontaneous pneumothorax may occur during severe acute asthmatic attacks, as well as during positive-pressure mechanical ventilation (see section on Pneumothorax, Management, p. 561).

▲ Acute Respiratory Failure

Acute respiratory failure is a sudden and life-threatening deterioration in pulmonary gas exchange, resulting in carbon dioxide retention and inadequate oxygenation.[53] Acute respiratory failure remains a major cause of morbidity and mortality in the intensive care setting, despite the technological advances in diagnosis, monitoring, and management that have been made in the past four decades.[54] A study of more than 1,400 patients found that 44% of patients diagnosed with acute respiratory failure who required admission to the ICU died in the hospital; in the past 20 years, this statistic appears not to have changed significantly.[55,56] However, a recent analysis of past studies on the mortality of patients with acute respiratory failure showed that there have been improvements due to more lung protective ventilatory therapies.[57] Acute respiratory failure may be responsible for as many as 10% to 15% of admissions to medical ICUs and for as many as 50% to 75% of those patients who require ICU hospital stays longer than 7 days.[54]

Pathophysiology

Acute respiratory failure is defined as a PaO_2 of 55 mm Hg or less, a $PaCO_2$ greater than 50 mm Hg, and an arterial pH less than 7.35.[56,58] This definition is valid only in cases in which baseline ABG values are assumed to be normal.[58] In patients with established chronic hypoxemia or hypercapnia, acute respiratory failure is indicated by the acute deterioration of blood gases relative to their previous levels rather than their absolute values.[58] In patients with chronic lung disease, ABG values associated with classic acute respiratory failure may not be present because these patients have adapted to blood gas levels outside this range, consistent with their disease process.[58]

Acute respiratory failure may be caused by a variety of pulmonary and nonpulmonary diseases (Box 26-13). Respiratory failure may result from malfunction of the respiratory center, abnormal respiratory neuromuscular system, chest wall diseases, airway obstruction, or parenchymal lung disorders.[59] Many factors may precipitate or exacerbate acute respiratory failure (Box 26-14).

A vicious positive feedback mechanism characterizes the deleterious effects of continued hypoxemia and hypercapnia. Hypoxemia affects every organ and tissue, and hypercapnia impairs cellular functions.[58] Hypoxemia in respiratory failure may be caused by any of these conditions, separately or in various combinations; Table 26-13 lists the

BOX 26-13 Causes of Acute Respiratory Failure

Intrinsic Lung/Airway Diseases

Large Airway Obstruction
- Congenital deformities
- Acute laryngitis, epiglottitis
- Foreign bodies
- Intrinsic tumors
- Extrinsic pressure
- Traumatic injury
- Enlarged tonsils and adenoids
- Obstructive sleep apnea

Bronchial Diseases
- Chronic bronchitis
- Asthma
- Acute bronchiolitis

Parenchymal Diseases
- Pulmonary emphysema
- Pulmonary fibrosis and other chronic diffuse infiltrative diseases
- Severe pneumonia
- Acute lung injury from various causes (acute respiratory distress syndrome)

Cardiovascular Disease
- Cardiac pulmonary edema
- Massive or recurrent pulmonary embolism
- Pulmonary vasculitis

Extrapulmonary Disorders

Diseases of the Pleura and the Chest Wall
- Pneumothorax
- Pleural effusion
- Fibrothorax
- Thoracic wall deformity
- Traumatic injury to the chest wall: flail chest
- Obesity

Disorders of the Respiratory Muscles and the Neuromuscular Junction
- Myasthenia gravis and myasthenia-like disorders
- Muscular dystrophies
- Polymyositis
- Botulism
- Muscle-paralyzing drugs
- Severe hypokalemia and hypophosphatemia

Disorders of the Peripheral Nerves and Spinal Cord
- Poliomyelitis
- Guillain-Barré syndrome
- Spinal cord trauma (quadriplegia)
- Amyotrophic lateral sclerosis
- Tetanus
- Multiple sclerosis

Disorders of the Central Nervous System
- Sedative and narcotic drug overdose
- Head trauma
- Cerebral hypoxia
- Cerebrovascular accident
- Central nervous system infection
- Epileptic seizure: status epilepticus
- Metabolic and endocrine disorders
- Bulbar poliomyelitis
- Primary alveolar hypoventilation
- Sleep apnea syndrome

BOX 26-14 PATIENT SAFETY

Precipitating Factors Leading to Acute Respiratory Failure

- Changes of tracheobronchial secretions
- Infection: viral or bacterial
- Disturbance of tracheobronchial clearance
- Drugs: sedatives, narcotics, anesthesia, oxygen
- Inhalation or aspiration of irritants, fumes, smoke, vomitus, foreign body
- Cardiovascular disorders: heart failure, pulmonary embolism, shock
- Mechanical factors: pneumothorax, pleural effusion, abdominal distention
- Trauma, including surgery
- Neuromuscular abnormalities
- Allergic disorders: bronchospasm
- Increased oxygen demand: fever, infection
- Inspiratory muscle fatigue

From Farzan S: Respiratory failure. In Farzan S (ed): A Concise Handbook of Respiratory Diseases, 4th ed. Stamford, CT: Appleton & Lange, 1997, pp 371–386, with permission.

causes of hypoxemia.[56,58,59] Hypercapnia results from alveolar hypoventilation and ventilation–perfusion mismatching when there is no compensation by increased ventilation of well-perfused regions.[59] In acute hypercapnia, arterial blood pH is decreased, indicating acute respiratory acidosis. Patients with advanced COPD and chronic hypercapnia may exhibit an acute rise of $PaCO_2$ to a high level, a decrease of blood pH, and a significant increase in serum bicarbonate during the onset of acute respiratory failure.[59]

Hypoxemia and hypercapnia may have precipitous effects, which include the following:[55]

- Increased pulmonary vascular resistance
- Cor pulmonale
- Right-sided heart failure
- Impaired left ventricular function
- Reduced cardiac output
- Cardiogenic pulmonary edema
- Diaphragmatic fatigue from increased workload of respiratory muscles

Classification

Acute respiratory failure is classified as acute hypoxemic respiratory failure, acute hypercapnic respiratory failure, or combined hypoxemic and hypercapnic respiratory failure.[59] Acute hypoxemic respiratory failure is a direct defect in oxygenation. Acute hypercapnic respiratory failure is a direct defect in ventilation. Historically, acute hypoxemia respiratory failure and acute hypercapnia were discussed in literature as type I and type II, respectfully, respiratory failure. Current literature discusses these pathologies as ARDS.

Acute Hypoxemic Respiratory Failure

Acute hypoxemic respiratory failure is the result of abnormal oxygen transport secondary to pulmonary parenchymal disease, with increased alveolar ventilation resulting in a low $PaCO_2$.[60] The principal problem in this respiratory failure is the inability to achieve adequate oxygenation, as evidenced by a PaO_2 of 60 mm Hg. The most common cause of hypoxemia is decreased FiO_2, hypoventilation, diffusion impairment (low DLCO), ventilation–perfusion mismatch, and shunt. Careful analysis of the ABGs and calculation of an alveolar–arterial gradient (*A-a*) will assist in evaluating the severity of the hypoxemia.[60] The major causes of this type of respiratory failure are listed in Table 26-14.

Acute Hypercapnic Respiratory Failure

Acute hypercapnic respiratory failure, or ventilatory failure, is the result of inadequate alveolar ventilation and is characterized by marked elevation of carbon dioxide with relative preservation of oxygenation.[56] Hypoxemia results from

Table 26-13 Causes of Hypoxemia in Acute Respiratory Failure

Mechanism	Predominant Gas Exchange Abnormality
Controller dysfunction—nervous system: sedative medications, chronic obstructive or interstitial lung disease, toxic overdoses, hypothermia postoperatively, brainstem strokes	Hypoxemia and hypercarbia
Musculature (pump) dysfunction: medications—paralytics, aminoglycosides, steroids, botulism; myopathy; myositis; metabolic abnormalities (hypothyroidism, hypophosphatemia); myasthenia gravis	Hypercapnia
Airway dysfunction: asthma, emphysema/chronic bronchitis, bronchiolitis, endobronchial tumor, mass or stricture	Mild: hypoxemia and hypocarbia Severe: hypoxemia and hypercarbia
Alveolar dysfunction: pneumonia, pulmonary edema, pulmonary hemorrhage, ARDS, drug reaction, pulmonary contusion	Hypoxemia and hypercarbia
Pulmonary vasculature dysfunction: acute pulmonary embolism, pulmonary hypertension, AVM or intracardiac shunt	New-onset hypoxemia with or without hypercarbia Exertional hypoxemia Hypoxemia that is refractory to oxygen therapy

Table 26-14 Evaluation and Management of Causes of Acute Respiratory Failure

Etiology	Key Clinical Findings	Key Diagnostic Tests	Specific Therapy
Respiratory Failure Caused by Central Nervous System Dysfunction*			
CNS-depressant drugs	History of drug overdose, head trauma, or anoxic encephalopathy Pupillary changes, needle marks	Response to naloxone Toxicology screen Electrocardiogram	Antidotes for the drugs taken Neurological evaluation
Hypothyroidism	Myxedema	Thyroid function test	Cautious thyroid replacement
Starvation	Cachexia Diarrhea	↓Albumin ↓Cholesterol	Nutrition
Metabolic alkalosis	Lethargy Confusion	ABGs Serum electrolytes	Treat underlying causes
Structural brain stem damage	Localizing neurologic findings	CT, MRI, cerebrospinal fluid cytology	Radiation, chemotherapy
Neoplasm	Headache		
Infection	Headache, fever	CT, MRI, cardiac echo	Antimicrobial therapy
Primary alveolar hypoventilation (Ondine's curse)	Daytime hypersomnolence, headache, rarely dyspneic, polycythemia, cor pulmonale	Blunted or absent ventilatory response to ↑CO_2, ↓O_2 in inspired gas Normal pulmonary function test	Nighttime ventilatory support Electrophrenic pacing Medroxyprogesterone acetate Supplemental oxygen
Central sleep apnea	Same as primary alveolar hypoventilation	Polysomnography: apnea without respiratory effort Normal CO_2, O_2 response curves while awake	Nighttime ventilatory support Electrophrenic pacing Supplemental oxygen
Respiratory Failure Caused by Peripheral Nervous System Dysfunction*			
Spinal cord disease	Above C5, diaphragm, intercostal, and abdominal activity abolished	Spinal x-ray film, CT, MRI	Supportive, vital capacity tends to improve more than 3 mo in traumatic lesions C5 and below
Traumatic	Below C5, diaphragm preserved, intercostal and abdominal activity abolished		Phrenic nerve pacing for high cervical cord lesions with intact phrenic nerve
Strychnine	Intense muscle spasms Apnea Metabolic acidosis	Toxicology screen Clinical picture	Supportive Gastric lavage, charcoal
Hyperthyroidism	Thyrotoxicosis heat intolerance, tachycardia, hyperreflexia	TSH, TFT	Propylthiouracil, methimazole
Hypothyroidism	Myxedema, cold intolerance Hyporeflexia, bradycardia	TSH, TFTs	Replace thyroid hormone
Respiratory Failure Caused by Respiratory Muscle Dysfunction*			
Muscle dystrophies	Proximal muscle weakness and atrophy Hereditary	Muscle biopsy Elevated CPK Genetic analysis	Supportive Duchenne: prednisone
Periodic paralyses	Hypokalemic, hyperkalemic, or normokalemic Genetic Muscle weakness associated with exercise, emotional upset, cold, alcohol	Serum potassium Family history	Avoid precipitating factors Carbonic anhydrase inhibitor

(*continued on page 585*)

Table 26-14 Evaluation and Management of Causes of Acute Respiratory Failure (continued)

Etiology	Key Clinical Findings	Key Diagnostic Tests	Specific Therapy
Respiratory Failure Caused by Chest Wall, Pleural, and Upper Airway Diseases*			
Kyphoscoliosis	Spinal curvature ≥120 degrees Progressive dyspnea on exertion over several years	Spinal x-ray films Restriction on PFTs	Nighttime ventilatory support
Flail chest	Multiple rib fractures, paradoxical respiration ± pleuritic chest pain	Chest film	Mechanical positive-pressure ventilation
Ankylosing spondylitis	Limited chest expansion Apical pulmonary fibrosis Limited lumbar mobility Chronic lower back pain	PFTs (↑functional residual capacity, ↓total lung capacity) HLA-B27 Spine and sacroiliac x-ray films	Anti-inflammatory agents Flexibility exercises
Angioedema/anaphylaxis	Stridor in setting of Hymenoptera sting, contrast media, or drug administration	Other evidence of angioedema/anaphylaxis; complement levels	Epinephrine parenterally Cricothyroidotomy
Foreign body aspiration	Unable to speak Stridor or apnea	X-ray film helpful when foreign body below vocal cords	Heimlich maneuver Bronchoscopy Cricothyroidotomy
Respiratory Failure by Intrapulmonary Causes			
Cardiogenic pulmonary edema†	Rales, diaphoresis	Chest x-ray: pulmonary edema Echocardiogram	Fluid management for adequate peripheral perfusion (diuresis/fluid) Reduce LVEDP
Adult respiratory distress syndrome†	Rales PaO_2 < 55 mm Hg with FiO_2 more than 60% PaO_2/FiO_2 200 mm Hg or less (regardless of PEEP) Fever	CXR: bilateral infiltrates CBC Pulmonary artery catheter: PAOP 18 mm Hg or less when measured OR no clinical evidence of left atrial hypertension	Treat underlying cause Pulmonary vasodilators Corticosteroids Mechanical ventilation Surfactant replacement
Acute lung injury (caused by sepsis, blood transfusion, pneumonia, aspiration, and/or multiple traumas)†	Dyspnea PaO_2/FiO_2 ≤ 300 mm Hg (regardless of PEEP)	CXR: Bilateral airspace disease, CT: Pulmonary edema from increased permeability ABG Pulmonary artery catheter: PAOP 18 mm Hg or less when measured OR no clinical evidence of left atrial hypertension	Increase FiO_2 PEEP Bronchodilation Inhaled nitric oxide Antibiotics
COPD‡	Dyspnea on exertion Prolonged forced expiratory time Wheezing Decrease in breath sounds Hyperinflation New onset of paradoxical respiratory motion or respiratory alternans	PFTs ABG CXR CT scan	Oxygen therapy Bronchodilators Antibiotics Corticosteroids Nutritional support Smoking cessation

reduced alveolar pressure of oxygen (PaO_2) and is proportionate to hypercapnia.[60] Three factors contribute to hypercapnia: increased exercise, overfeeding, hyperthyroidism, burns, fever, sepsis, and decreased elimination of carbon dioxide (lack of respiratory drive, muscular disorder, and increased respiratory compliance).[60] Increased work of breathing most commonly occurs in COPD (increased dead space) or asthma (elevated airway resistance), and it may also result from thoracic abnormalities (restriction on lungs), such as pneumothorax, or pleural effusions.[60] The major causes of this type of respiratory failure are listed in Table 26-14.[60]

Assessment

History

A complete medical and social history should be obtained from the patient or a family member to determine the patient's baseline respiratory status on admission (see Chapter 24, Box 24-1, p. 486). Data from a comprehensive assessment are used in goal setting, intervention, and evaluation to ensure that patients receive high-quality health care.[61] Self-management categories address the patient's capacity for self-care (physical, cognitive, psychosocial, socioeconomic, and environmental). The health care professional will find this a valuable tool in the continual assessment process of patients with pulmonary disorders.

Physical Findings

Presentation of acute respiratory failure may vary, depending on the underlying disease, precipitating factors, and degree of hypoxemia, hypercapnia, or acidosis.[58–60] It is essential to determine whether intubation and positive-pressure ventilation are required as emergency measures; this is the most critical assessment objective.[54] Typically, intubation and ventilation are necessary in patients with depressed mental status or coma, severe respiratory distress, extremely low or agonal respiratory rate, obvious respiratory muscle fatigue, peripheral cyanosis, or impending cardiopulmonary arrest.[54,60] Patients with altered mental status are at risk for aspiration of gastric contents. In any of these situations, immediate intervention is vital and should not be postponed pending the results of ABG studies or chest radiography.[54,60]

The classic symptom of hypoxemia is dyspnea, although this may be completely absent in ventilatory failure resulting from depression of the respiratory center.[60] Other presenting symptoms of hypoxemia include cyanosis, restlessness, confusion, anxiety, delirium, tachypnea, tachycardia, hypertension, cardiac dysrhythmias, and tremor.[60] Peripheral cyanosis of the skin, lips, or nail beds suggests the presence of profound arterial hypoxemia, usually with a PaO_2 less than 50 mm Hg.[54]

The cardinal symptoms of hypercapnia are dyspnea and headache.[60] Other clinical manifestations of hypercapnia include peripheral and conjunctival hyperemia, hypertension, tachycardia, tachypnea, impaired consciousness, papilledema, and asterixis.[60] Uncorrected carbon dioxide narcosis leads to diminished alertness, disorientation, increased intracranial pressure, and ultimately unconsciousness.[54] Other physical findings on examination may include use of accessory muscles of respiration, intercostal or supraclavicular retraction, and paradoxical abdominal movement if diaphragmatic weakness or fatigue is present.[56]

Diagnostic Studies

Because the signs and symptoms of acute respiratory failure are nonspecific and insensitive, the physician must request an ABG analysis to determine the exact level of PaO_2, $PaCO_2$, and blood pH in cases of suspected acute respiratory failure. Only determination of the blood gases and pH can confirm the diagnosis.[60] Other diagnostic tests necessary to determine the etiology of acute hypoxemic respiratory failure include chest radiography, sputum examination, pulmonary function testing, angiography, ventilation–perfusion scanning, CT, toxicology screen, complete blood count, serum electrolytes, cytology, urinalysis, bronchogram, bronchoscopy, electrocardiography, echocardiography, and thoracentesis.[60] See Table 26-14 for more details about the use of these diagnostic tests in acute respiratory failure.

Management

Treatment of acute respiratory failure warrants immediate intervention to correct or compensate for the gas exchange abnormality and identify the cause.[60] Therapy is directed toward correcting the cause and alleviating the hypoxia and hypercapnia.[60] Although the recommended therapeutic intervention may vary according to the specific disease's pathological process, general management principles are applicable to every patient with acute respiratory failure. See Table 26-15 for specific therapies for managing common causes of acute respiratory failure.[60]

If alveolar ventilation is inadequate to maintain PaO_2 or $PaCO_2$ levels related to respiratory or neurological failure, endotracheal intubation and mechanical ventilation may be lifesaving.[58,60] The initial assessment and the decision to initiate mechanical ventilation should be performed rapidly to minimize the life-threatening complications associated with extended hypoxemia (eg, cardiac dysrhythmias, anoxic encephalopathy).[60] Controlled oxygen therapy and mechanical ventilation are used to increase PaO_2 by increasing FiO_2 and to normalize pH by increasing minute ventilation.[60] See Chapter 25 for further information on airway management and care of the patient on a ventilator.

Patients with acute hypoxemic respiratory failure should receive immediate treatment with rapidly increased FiO_2 and continuous pulse oximetry monitoring until an SaO_2 of 90% or higher is obtained.[60] Correction of hypoxemia in the acute setting takes precedence over possible attenuation of hypoxic respiratory drive.[60] Therefore, once hypoxemia is reversed, oxygen is titrated to the minimum level necessary for correction of hypoxemia and prevention of significant carbon dioxide retention.[60]

Patients with acute hypercapnic respiratory failure should be immediately assessed for either an impaired central respiratory drive associated with sedative or narcotic therapy or for underlying bronchospasm secondary to an asthma exacerbation or COPD.[60] Reversal agents (opiate antagonists, eg, naloxone) are used in the case of impaired central respiratory drive, and inhaled bronchodilators and systemic corticosteroids are used in the case of underlying bronchospasm.[60]

Table 26-15 Management of Respiratory Failure

Management Principle	Therapeutic Intervention
Establishment and maintenance of an adequate airway	• Use oropharyngeal or nasopharyngeal tubes for upper airway obstruction during transient loss of consciousness. • Tracheal intubation may be necessary to prevent aspiration, maintain airway patency, and provide effective suctioning. • Strictly adhere to adequate tracheobronchial toilet (ie, deep breathing, coughing, tracheobronchial suctioning).
Oxygenation	• Increase the inspired oxygen (FiO_2) concentration by administration of oxygen via a Venturi mask or nasal cannula. • Improve cardiac output, correct anemia, and reduce metabolic rates (fever) to improve tissue oxygenation. • Consider continuous positive airway pressure or expiratory positive airway pressure via a nasal or facial mask for alert and cooperative patients. • Mechanical ventilatory support may be needed in more severe cases with refractory and progressive hypoxemia.
Correction of acid–base disturbance	• Correct pH disturbances: in acute hypercapnia with acidosis, improve alveolar ventilation by providing mechanical ventilatory support, establishing and maintaining an adequate airway, treating bronchospasm, and controlling heart failure, fever, and sepsis. • Consider bicarbonate administration in acute respiratory acidosis or metabolic acidosis.
Restoration of fluid and electrolyte balance	• Prevent excessive intravenous fluid administration and, conversely, poor fluid intake. • Monitor fluid intake and output closely. • Perform daily body weight measurement. • Prevent and treat promptly hypokalemia and hypophosphatemia.
Optimization of cardiac function	• Maintain adequate cardiac output. • Consider use of pulmonary artery catheter for accurate hemodynamic monitoring.
Identification and treatment of underlying correctable conditions and precipitating causes	• Prevent or treat respiratory tract infections (viral, bacterial, or fungal). • Prevent potential airway obstruction by maintenance of proper tracheobronchial hygiene; recognize increased tracheobronchial secretions, changes in their characteristics, or difficulty in their elimination due to various factors. • Identify and treat heart failure appropriately. • Recognize and treat bronchospasm with bronchodilators and corticosteroids. • Assess for organic or metabolic disorder affecting the central nervous system or neuromuscular function. • Assess tolerance to sedative, hypnotic, and narcotic drugs in patients with chronic ventilatory insufficiency. In case of a narcotic drug overdose, a proper antidote may be administered. • Avoid indiscriminate use of oxygen; it may potentiate carbon dioxide retention or result in carbon dioxide narcosis. • Remove air or fluid in the pleural cavity. • Prevent and treat abdominal distention by insertion of a nasogastric tube. • For trauma and surgical patients, assess limitation of the thoracic wall movement, ineffective cough, immobility, and lack of deep breathing. • Control fever and other causes of increased metabolism. • Assess diaphragmatic fatigue; if present, mechanical ventilatory support is indicated to rest these muscles and restore their contractility. • Promptly identify and adequately treat hypophosphatemia, hypokalemia, and hypocalcemia.
Prevention and early detection of potential complications	• Most of these complications occur in mechanically ventilated patients (see Chapter 25).
Nutritional support	• Enteral alimentation is preferred over parenteral feeding because bowel wall integrity is maintained. • Recommend high-lipid formulas over high carbohydrates to limit carbon dioxide production.
Periodic assessment of the course, progress, and response to therapy	• Perform frequent ABG measurements. • Monitor arterial oxygen saturation by pulse oximetry.
Determination of a need for mechanical ventilatory support	• Continuously assess the patient's respiratory status and need for ventilator support (see Chapter 25).

▲ Clinical Applicability Challenges

CASE STUDY

A 42-year-old Caucasian female, Ms. R., presents to the emergency room 4 days after being knocked down by a wave at the beach. When she was knocked down, she did not lose consciousness. However, she did develop some back pain as well as some dyspnea on exertion. These symptoms did not worsen over the past 4 days nor did they improve. For this reason, she presented to the emergency room.

Upon further discussion with the patient, we learn that Ms. R. had a pneumothorax in 2008 when she had a very severe pneumonia. Her past medical history consists of hypertension, allergy-related asthma, and recurrent right-sided pneumothoraces. In terms of her medication, she takes hyzaar/hydrochlorothiazide. She is allergic to ACE inhibitors that cause facial numbness.

Her social history consists of no alcohol or illicit drug use. She did smoke a pack of cigarettes a day from the age of 17 to age of 32; therefore, she smoked for 15 years. She has the following vital signs: temperature of 99.4°F, heart rate of 110, respiratory rate of 30 breaths/min, blood pressure of 164/84 mm Hg, height of 168 cm, weight of 88.7 kg, and pulse oximetry of 88% on room air. Her physical examination findings are benign with the exception of her respiratory examination. She has some increased work of breathing. Her breath sounds are clear upon auscultation on the left lung fields. On the right lung fields, her breath sounds are clear in the right lower and middle lobes and somewhat diminished in her right upper lobe. She also complains of pleuritic pain with deep inspiration.

A posteroanterior (PA) and lateral chest x-ray was performed that revealed no pulmonary infiltrates but did show slight white-out in the right upper lung field on the PA view. In the lateral view, the x-ray film showed an air level in the upper lung field.

1. What additional diagnostic tests would be useful?
2. What medical treatment options are there for Ms. R.?
3. Is there a role for surgical treatment? If so, what are the options?

Acute Lung Injury and Acute Respiratory Distress Syndrome

Paul A. Thurman, Mary van Soeren, and Christina Hurlock-Chorostecki

27

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Compare and contrast the causes, definition, assessment findings, and outcomes between acute lung injury (ALI) and acute respiratory distress syndrome (ARDS).
2. Relate the assessment and diagnostic findings of ARDS to the pathophysiological processes.
3. Describe mechanical ventilation strategies used to prevent ventilator-associated lung injury (VALI).
4. Explain the management of patients with ARDS and rationales for the interventions.
5. Review the use of critical care "bundles" as they relate to the care and treatment of patients with ARDS.
6. Discuss potential complications of ARDS and the related interventions.

Acute respiratory distress syndrome (ARDS) represents a complex clinical syndrome (rather than a single disease process) and carries a high risk for mortality. The severity of the clinical course, the uncertainty of the outcome, and the reliance on the full spectrum of critical care resources for treatment mean that the entire health care team is challenged. Since the 1960s, researchers and clinicians have investigated the nature of the pathological process and explored treatment options with the goal of improving outcome. Through this application of research to practice, we know that some previous strategies have been ineffective, and innovations in mechanical ventilation, sedation, nutrition, and pharmacological intervention remain important research initiatives. A key role for the critical care nurse is early detection and prevention of ARDS. Therefore, with respect to ARDS, it is essential that critical care nurses be knowledgeable about risk factors, assessment tools and protocols, and prevention strategies.

ARDS was first described in 1967 and was termed *adult* (rather than *acute*) respiratory distress syndrome because of a misconception that the syndrome occurred only in adults. Recognition of the prevalence of this syndrome in younger patients led to the current terminology. ARDS is at the extreme end of a continuum of hypoxic acute lung injury (ALI) that results in respiratory failure. In 1994, the American-European Consensus Conference members issued definitions of ALI and ARDS that are widely used by researchers today[1] (Table 27-1).

▲ Etiology, Diagnostic Criteria, and Incidence

The causes of ARDS are many and diverse. The syndrome may be precipitated by direct or indirect pulmonary injury, possibly in previously healthy people who are exposed to an insult (Box 27-1). ARDS is acute in onset, and symptoms typically develop over 4 to 48 hours after the inciting insult, making a cause-and-effect association somewhat difficult. Recently, several related respiratory disorders have been found presenting with clinical signs of ALI. These disorders may ultimately lead to development of ARDS and include severe acute respiratory syndrome (SARS), discussed in Chapter 26, and transfusion-related acute lung injury (TRALI).

TRALI is the leading cause of transfusion-related mortality in the United States.[2] It is theorized that an interaction occurs between the recipient's blood and the donor's, among the bioactive compounds produced during blood storage, or a combination of both.[3] Clinical presentation is the sudden onset of respiratory distress within 1 to 2 hours after a transfusion of red blood cells or thawed plasma.[3] Peak airway pressures are elevated, airway secretions may be frothy, and the chest radiograph shows patchy infiltrates. Management of the patient is supportive and involves the same principles of mechanical ventilation used in ARDS and avoidance of aggressive diuresis. The blood bank should be notified of a TRALI case, and the patient should not receive further blood products from that donor.

Diagnostic criteria for ARDS have been difficult to define because ARDS closely resembles other conditions. Diagnostic testing is used to "rule out" these conditions, yet the final diagnosis of ARDS is largely based on clinical presentation. No one test, including radiographic evidence, a plasma brain natriuretic peptide less than 500 pg/mL, or a pulmonary artery occlusion pressure (PAOP, formerly

Table 27-1 Comparison of Acute Lung Injury (ALI) and Acute Respiratory Distress Syndrome (ARDS)

Criterion	ALI	ARDS
PaO_2:FiO_2 ratio,* regardless of PEEP level	<300	<200
Chest x-ray	Bilateral infiltrates	Bilateral infiltrates
Pulmonary artery occlusion pressure	<18 mm Hg or no indication of left atrial hypertension	<18 mm Hg or no indication of left atrial hypertension

*Ratio of arterial oxygen to inspired oxygen.

PEEP, positive end-expiratory pressure.

Adapted from Bernard GR, Artigas A, Brigham KL, et al: The American-European Consensus conference on ARDS: Definitions, mechanisms, relevant outcomes, and clinical trials co-ordination. Am J Respir Crit Care Med 149:818–824, 1994.

known as pulmonary artery wedge pressure [PAWP]) less than 18 cm H_2O, is truly indicative of ARDS. However, an early feature of ARDS is diffuse alveolar damage (DAD), and recent research findings have shown promise in diagnosing DAD with cytological examination of bronchoalveolar fluid.[4]

Approximately 190,600 cases of ARDS occur each year in the United States, of which 74,500 result in death.[5] The patients most at risk for development of ARDS are older than 65 years, with a severe acute illness on presentation, such as sepsis or a preexisting chronic disorder. Although sepsis is the most common cause of ARDS, any person with one of the potential precipitating causes of ARDS is susceptible, and nurses need to be vigilant for early warning signs (Box 27-1). Most patients with ARDS require a period of mechanical ventilation support for days to weeks.

▲ Pathophysiology

In 1967, Ashbaugh and others described ARDS in case reports of 12 patients presenting with acute tachypnea, decreased lung compliance, diffuse pulmonary infiltrates on chest radiograph, and hypoxemia.[1] Later researchers used histological examination of lungs of patients with ARDS to show lung fibrosis that was unlike other diseases. This led to new understanding that the pathological process was not limited to the lung endothelium but was a result of alterations of lung epithelium and vascular tissue as well as the development of hyaline membranes. Pathological changes in lung vascular tissue, increased lung edema, and impaired gas exchange are hallmarks of the pathophysiology. The pathological pulmonary alterations of ARDS are directly related to a cascade of events resulting from release of cellular and biochemical mediators. The activation, interactions, and multisystem actions of biological mediators are extremely complex.

Pathological Changes in ARDS

Mediators released as a result of either direct or indirect injury can precipitate acute respiratory distress syndrome (ARDS), including lipopolysaccharide in gram-negative bacterial sepsis. There is a relationship between clinical presentation (severe acute hypoxemia resistant to improvement with supplemental oxygen, tachypnea, and dyspnea),

BOX 27-1 Causes and Predisposing Conditions for Acute Respiratory Distress Syndrome (ARDS)

Genetic predisposition

Direct injury
- Aspiration (gastric fluids, near-drowning)
- Infectious pneumonia
- Lung contusions with trauma
- Toxic inhalation
- Upper airway obstruction (relieved)
- Severe acute respiratory syndrome (SARS) coronavirus
- Neurogenic pulmonary edema
- Acute eosinophilic pneumonia*
- Bronchiolitis obliterans with organizing pneumonia (BOOP)*
- Miliary tuberculosis*

Indirect pulmonary injury
- Sepsis
- Burns
- Trauma
- Blood transfusion (TRALI)
- Lung or bone marrow transplantation
- Drug or alcohol overdose
- Drug reaction
- Cardiopulmonary bypass
- Acute pancreatitis
- Multiple fractures
- Venous air embolism
- Amniotic fluid embolism
- Pancreatitis

Systemic Inflammatory Response Syndrome (SIRS) Criteria

SIRS is manifested by two or more of the following:
- Temperature greater than 100.4°F (38°C) or less than 96.8°F (36°C)
- Heart rate greater than 90 beats/min
- Respiratory rate greater than 20 breaths/min or an arterial carbon dioxide tension ($PaCO_2$) less than 32 mm Hg
- White blood cell count greater than 12,000 cells/mm^3 or less than 4,000 cells/mm^3 OR more than 10% immature (band) forms.

*Specific treatment required.
TRALI, transfusion-related acute lung injury.

Table 27-2 Examples of Pathological Responses to Biological Mediators

Response	Biological Mediators
Persistent inflammatory response	Cytokines: interleukins (IL-1, IL-6), interferon-γ (INF-γ), tumor necrosis factor-α (TNF-α), complement, thromboxane
Endothelial membrane disruption	Complement, thromboxane, kinins, TNF-α, toxic oxygen metabolites, leukotrienes, prostaglandins (PGE_1 and PGE_2)
Selective vasoconstriction	Thromboxane, TNF-α, platelet-activating factor (PAF), toxic oxygen metabolites
Systemic vasodilation	Complement, prostaglandins, TNF-α, IL-1, IL-6
Myocardial depression	Complement, leukotrienes, TNF-α, myocardial depressant factor
Bronchoconstriction	Complement, thromboxane, leukotrienes, PAF

mediator release (interleukins [ILs], tumor necrosis factor-α [TNF-α], and platelet-activating factor [PAF]), and pathological changes (microvascular permeability, pulmonary hypertension, and pulmonary endothelial damage). Some primary mediators responsible for lung damage in ARDS and their major actions as they relate to ARDS are listed in Table 27-2.[6,7]

Adequate pulmonary gas exchange depends on open, air-filled alveoli, intact alveolar–capillary membranes, and normal blood flow through the pulmonary vasculature. The pathogenesis of ARDS is illustrated in Figure 27-1. Diffuse alveolar–capillary membrane damage occurs and increases membrane permeability, thus allowing fluids to move from the vascular space into the interstitial and alveolar space. Air spaces fill with bloody proteinaceous fluid and debris from degenerating cells, causing interstitial and alveolar edema. As a result, oxygenation is impaired. Inflammatory mediators cause vasoconstriction of the pulmonary vascular bed. Pulmonary hypertension and reduced blood flow to portions of the lung result. Because of the reduced blood flow and decreased hemoglobin in capillaries, there is a decrease in oxygen available for diffusion and transport, further impairing oxygenation.

The pathological changes affect pulmonary blood vessels, gas exchange, and lung and bronchial mechanics (Fig. 27-2). Ventilation is impaired because of a decrease in lung compliance and an increase in airway resistance. Lung compliance is reduced as a result of the stiffness of fluid-filled, nonaerated lung. The presence of these fluid-filled alveoli alongside collapsed alveoli gives the chest radiograph the classic "patchy" or "ground glass" appearance. Surfactant, a substance that normally decreases the surface tension of alveoli, is lost, resulting in alveolar collapse. Mediator-induced bronchoconstriction causes airway narrowing and increased airway resistance, restricting the flow of air into the lungs.

Systemic Inflammatory Response Syndrome

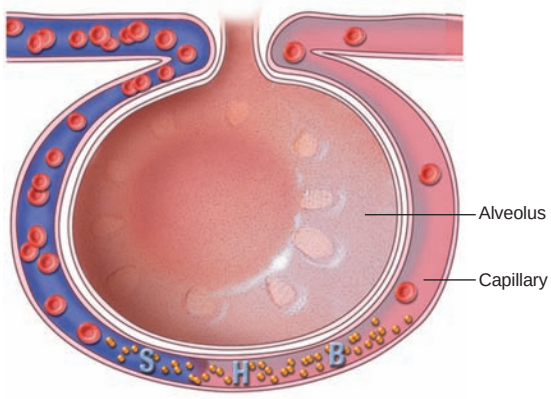
Systemic inflammatory response syndrome (SIRS) describes the inflammatory response occurring throughout the body as a result of some systemic insult. Most patients with ARDS manifest the symptoms that define SIRS (see Box 27-1), and the respiratory system may be the earliest and most common organ system to be involved in the systemic response. Thus, an understanding of the pathophysiology of SIRS and knowledge of the interventions used for SIRS are important in relation to ARDS. Often, patients with SIRS develop multisystem organ dysfunction (MODS), primarily in the liver and kidney. As endothelial damage progresses and tissue hypoxia ensues from the severely impaired gas exchange, the inflammatory response is perpetuated, and the SIRS cascade intensifies (up-regulates) with the release of more mediators. ARDS and MODS are therefore part of a vicious cycle and the continuum of SIRS. Determination of the triggers for SIRS and ARDS that are present in some individuals but not others and investigations of how to stop the cascade pathways are the subjects of ongoing research. For a more detailed discussion of SIRS and MODS, see Chapter 54.

Stages of ARDS

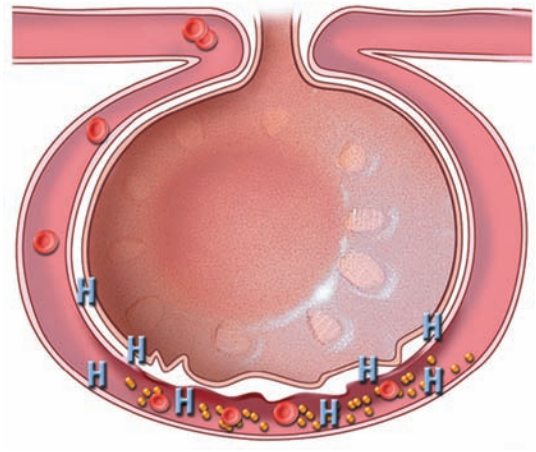
There is progression in the pathological changes associated with ARDS, starting with increasing pulmonary edema in the early stages and progressing to inflammation, fibrosis, and impaired healing in the later stages (Table 27-3, p. 595). Recognizing the dynamic nature of the morphological changes involved with ARDS enables the nurse to understand the changes in physical assessment, mechanical ventilation strategies, treatment, and management that occur throughout the patient's critical care stay.

In stage 1, diagnosis is difficult because the signs of impending ARDS are subtle. Clinically, the patient exhibits increased dyspnea and tachypnea, but there are few radiographic changes. At this point, neutrophils are sequestering; however, there is no evidence of cellular damage. Within 24 hours (a critical time for early treatment), the symptoms of respiratory distress increase in severity, with cyanosis, coarse bilateral crackles on auscultation, and radiographic changes consistent with patchy infiltrates. A dry cough or chest pain may be present. It is at this point (stage 2) that the mediator-induced disruption of the vascular bed results in increased interstitial and alveolar edema. The endothelial and epithelial beds are increasingly permeable to proteins. This is referred to as the "exudative" stage. The hypoxemia is resistant to supplemental oxygen administration, and mechanical ventilation will most likely be commenced in response to a worsening ratio of arterial oxygen to fraction of inspired oxygen (PaO_2:FiO_2 ratio).

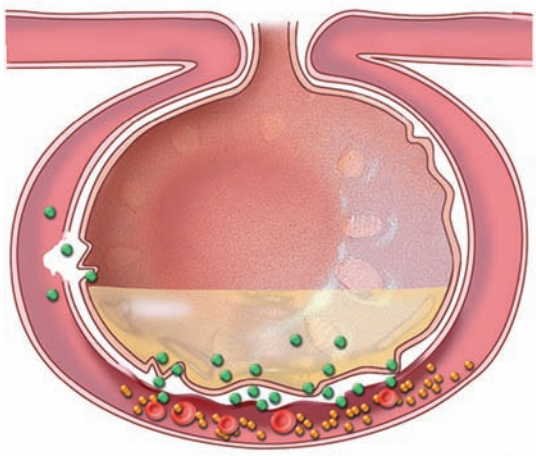
Stage 3, the "proliferative" stage, develops from the 2nd to the 10th day after injury. Evidence of SIRS is now present, with hemodynamic instability, generalized edema, possible



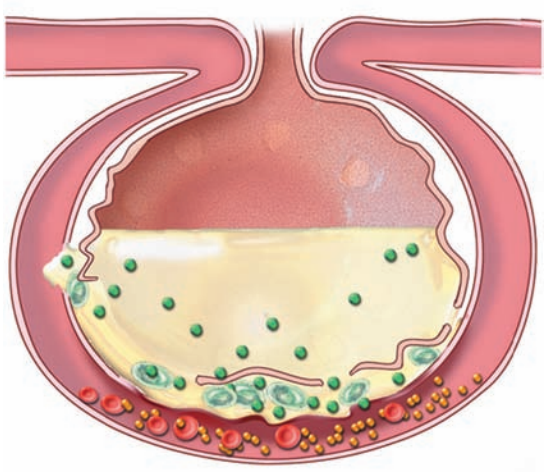
Phase 1. Injury reduces normal blood flow to the lungs. Platelets aggregate and release histamine (H), serotonin (S), and bradykinin (B).



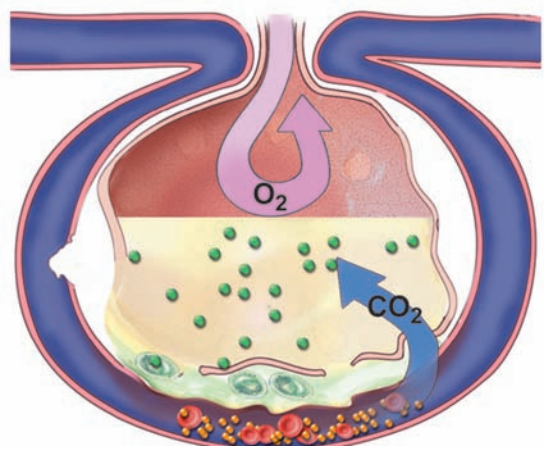
Phase 2. Those substances, especially histamine, inflame and damage the alveolar–capillary membrane, increasing capillary permeability. Fluids then shift into the interstitial space.



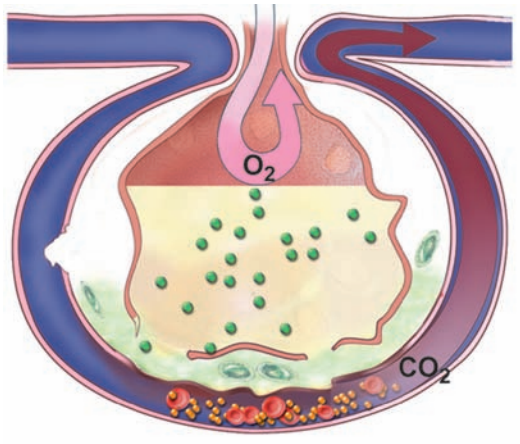
Phase 3. As capillary permeability increases, proteins and fluids leak out, increasing interstitial osmotic pressure and causing pulmonary edema.



Phase 4. Decreased blood flow and fluids in the alveoli damage surfactant and impair the cell's ability to produce more. As a result, alveoli collapse, impeding gas exchange and decreasing lung compliance.



Phase 5. Sufficient oxygen cannot cross the alveolar–capillary membrane, but carbon dioxide (CO_2) can and is lost with every exhalation. Oxygen (O_2) and CO_2 levels decrease in the blood.



Phase 6. Pulmonary edema worsens, inflammation leads to fibrosis, and gas exchange is further impeded.

FIGURE 27-1 ▲ Pathogenesis of acute respiratory distress syndrome (ARDS). Changes in lung epithelium and vascular endothelium result in fluid and protein movement, changes in lung compliance, and disruption of the alveoli with accompanying hypoxia. (From Anatomical Chart Company: Atlas of Pathophysiology, 3rd ed. Ambler, PA: Lippincott Williams & Wilkins, 2010, pp 81, 83.)

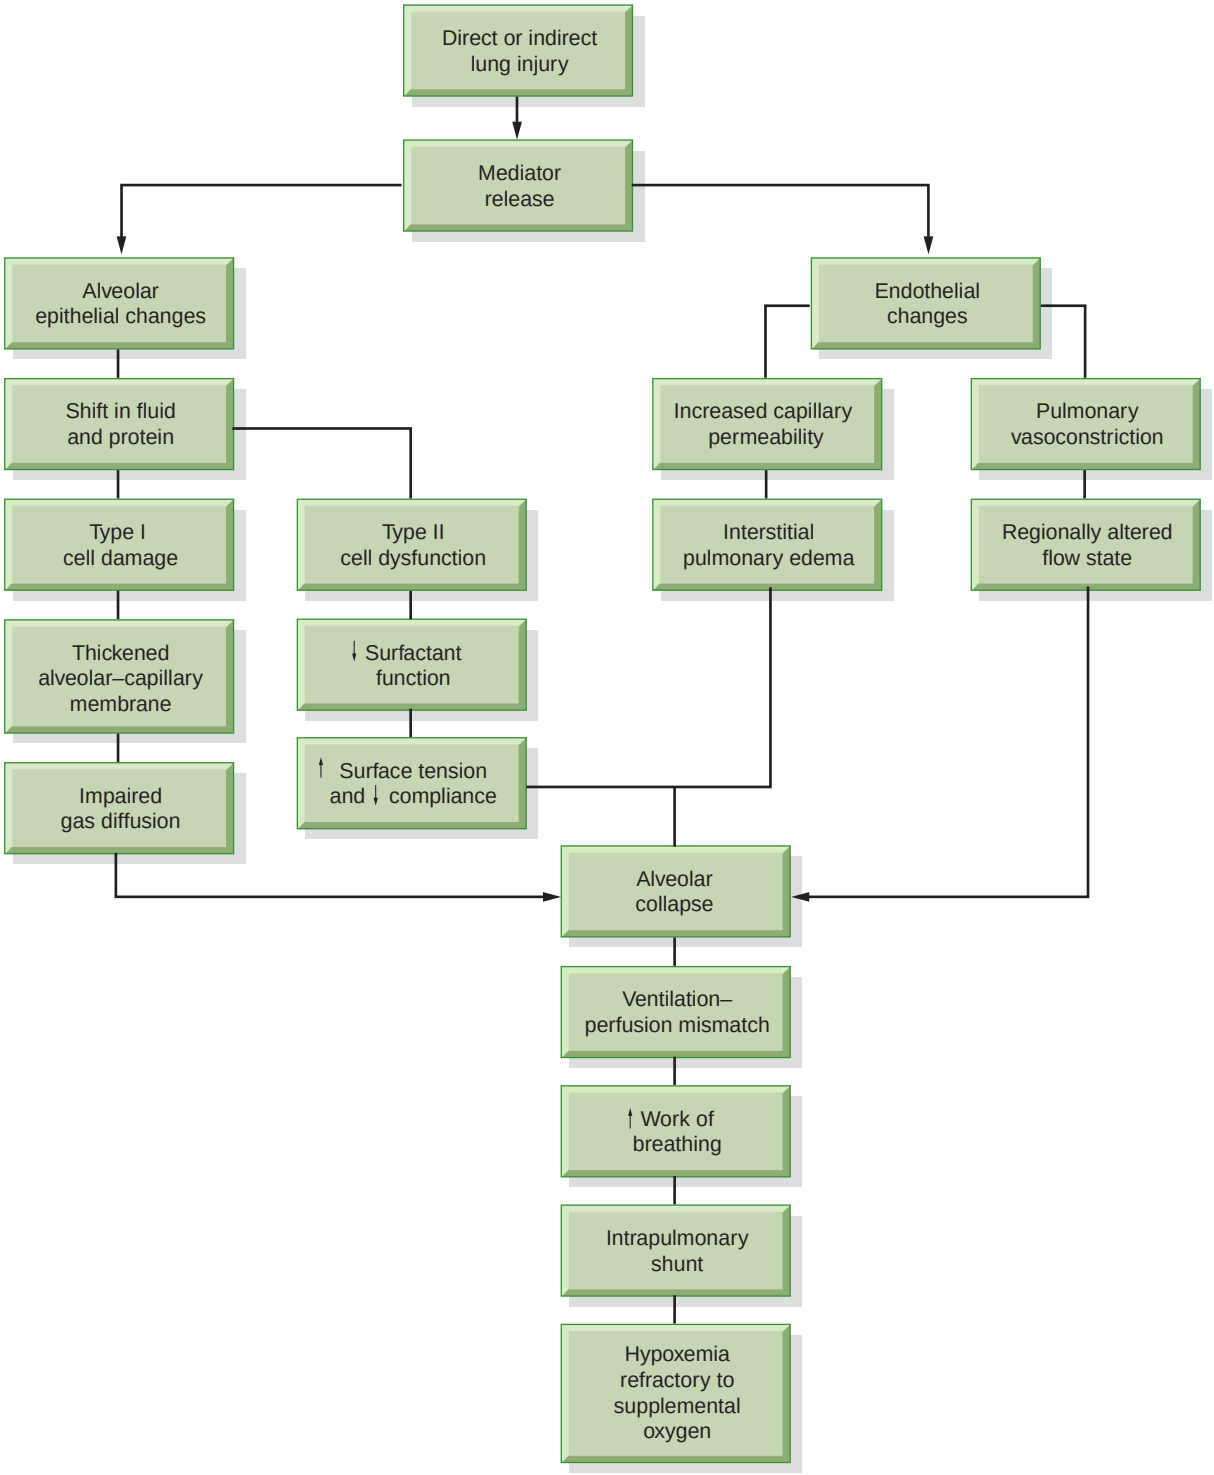


FIGURE 27-2 ▲ Pathophysiological cascade is initiated by injury resulting in mediator release. The multiple effects result in changes to the alveoli, vascular tissue, and bronchi. The ultimate effect is ventilation–perfusion mismatching and refractory hypoxemia.

onset of nosocomial infections, increased hypoxemia, and lung involvement. Air bronchograms may be evident on chest radiography as well as decreased lung volumes and diffuse interstitial markings.

Stage 4, the "fibrotic" stage, develops after 10 days and is typified by few additional radiographic changes. There is increasing multiorgan involvement, SIRS, and increases in the arterial carbon dioxide tension ($PaCO_2$) as progressive lung fibrosis and emphysematous changes result in increased dead space. Fibrotic lung changes result in ventilation management difficulties, with increased airway pressure and development of pneumothoraces.

Table 27-3 Clinical Presentation and Pathological Changes During Acute Respiratory Distress Syndrome

Radiographic Change	Clinical Presentation	Pathological Change
Stage 1 (first 12 h): Normal chest x-ray	Dyspnea, tachypnea	Neutrophil sequestration, no evidence of cellular damage
Stage 2–Exudative (24 h): Patchy alveolar infiltrate, primarily in dependent lung areas; normal heart size	Dyspnea, tachypnea, cyanosis, tachycardia, coarse crackles, hypoxemia	Neutrophil infiltration, vascular congestion, fibrin strands, increased interstitial and alveolar edema
Stage 3–Proliferative (2–10 d): Diffuse alveolar infiltrates, possibly air bronchograms, decreased lung volume, normal heart size	Hyperdynamic hemodynamic parameters, SIRS presentation	Type II cell proliferation, microemboli formation, increased interstitial and alveolar inflammatory exudate, early deposition of collagen
Stage 4–Fibrotic (more than 10 d): Persistent infiltrates, new pneumonic infiltrates, recurrent pneumothorax	Multiple organ involvement, difficulty maintaining adequate oxygenation, sepsis, pneumonia	Type II cell hyperplasia, thickening of interstitial wall with fibrosis, macrophages, fibroblasts, remodeling of arterioles, cyst formation

▲ Assessment

History

The need for a complete and accurate history for the patient presenting with ARDS is important. The history may provide information that allows for removal of the precipitating cause, interrupting the ensuing mediator response. However, a thorough history may be difficult to obtain because of the critical presentation of the patient and problems associating a remote event with the ALI. Because the outcome is uncertain and often involves a long critical care admission, the health care team plays a large role in providing support to both the patient and the family. Developing a relationship early (eg, by taking the time to obtain a thorough history) may assist with care throughout the course of admission.

All health care team members contribute information to the history. Information about past relevant incidents (medications, blood transfusions, radiographic contrast agents), the use of medical and complementary therapies, and social factors may be helpful for the person's care. Items of importance include assessment of risk factors for the development of ARDS (see Box 27-1), a social history to assess risk behaviors (eg, human immunodeficiency virus status, smoking, substance abuse), medications (including over-the-counter medications), and complementary therapies (all exogenous substances, including inhalations). This information is obtained in addition to the history of the present illness and presenting signs and symptoms.

Physical Examination

Acute respiratory failure initially may present within a few hours to several days, depending on the initial insult, and does not always progress to ARDS. Monitoring patients who meet the SIRS criteria (see Box 27-1, p. 591) may aid identification of those who are at risk for development of ARDS. No unexplained change in respiratory rate should be taken lightly because there are few reliable early indicators of impending ALI or ARDS. Vital signs throughout the progression of ARDS vary, but the general trend is hypotension, tachycardia, and hyperthermia or hypothermia. Respiration, initially rapid and labored, varies once mechanical ventilation is instituted.

Early signs and symptoms of respiratory failure include tachypnea, dyspnea, and tachycardia. Breath sounds often are clear in this phase (Table 27-4). Patients with acute respiratory failure may exhibit neurological changes, such as restlessness and agitation associated with impaired oxygenation and decreased perfusion to the brain. Use of accessory respiratory muscles is evident. The cardiovascular response is tachycardia to improve cardiac output as compensation for poor tissue oxygenation. These attempts to reduce hypoxia represent an adaptive sympathetic nervous system response. In both ALI and ARDS, these attempts to reduce hypoxia are likely to be ineffective because mediators are already circulating and triggering a cascade of systemic responses.

As the pathological changes progress, lung auscultation may reveal crackles secondary to an increase in secretions and narrowed airways; however, the bubbling crackles of cardiogenic pulmonary edema may be minimal. Assessment must be considered in the context of the presenting or initiating disease. For example, pneumonia, one risk factor for ARDS, may confound the ability to diagnose early-stage lung sound changes. The patient may be increasingly restless and confused secondary to hypoxia. Decreases in arterial oxygen saturation (SaO_2) are early signs of impending decompensation.

The ability to compensate decreases with increasing pathological changes to the lung, pulmonary vasculature, and bronchi. Dependent lung fields have decreased breath sounds as fluid accumulates and alveoli collapse. Agitation may give way to lethargy, an ominous sign in which interventions to

Table 27-4 Integrated Assessment of the Patient With Acute Respiratory Distress Syndrome

Stage	Physical Examination	Diagnostic Test Results
Stage 1 (first 12 h)	• Restlessness, dyspnea, tachypnea • Moderate to extensive use of accessory respiratory muscles	• *ABG:* Respiratory alkalosis • *CXR:* No radiographic changes • *Chemistry:* Blood results may vary depending on precipitating cause (eg, elevated white blood cell count, changes in hemoglobin) • *Hemodynamics:* Elevated PAP, normal or low PAOP
Stage 2 (24 h)	• Severe dyspnea, tachypnea, cyanosis, tachycardia • Coarse bilateral crackles • Decreased air entry to dependent lung fields • Increased agitation and restlessness	• *ABG*: Decreased Sa_{O_2} despite supplemental oxygen administration • *CXR:* Patchy bilateral infiltrates • *Chemistry:* Increasing acidosis (metabolic) depending on severity of onset • *Hemodynamics:* Increasingly elevated PAP, normal or low PAOP
Stage 3 (2–10 d)	• Decreased air entry bilaterally • Impaired responsiveness (may be related to sedation necessary to maintain mechanical ventilation) • Decreased gut motility • Generalized edema • Poor skin integrity and breakdown	• *ABG:* Worsening hypoxemia • *CXR:* Air bronchograms, decreased lung volumes • *Chemistry:* Signs of other organ involvement: decreased platelets and hemoglobin, increased white blood cell count, abnormal clotting factors • *Hemodynamics:* Unchanged or becoming increasingly worse
Stage 4 (more than 10 d)	• Symptoms of MODS, including decreased urine output, poor gastric motility, symptoms of impaired coagulation **OR** • Single-system involvement of the respiratory system with gradual improvement over time	• *ABG:* Worsening hypoxemia and hypercapnia • *CXR:* Air bronchograms, pneumothoraces • *Chemistry:* Persistent signs of other organ involvement: decreased platelets and hemoglobin, increased white blood cell count, abnormal clotting factors • *Hemodynamics:* Unchanged or becoming increasingly worse

ABG, arterial blood gas; CXR, chest radiograph; MODS, multisystem organ dysfunction syndrome; PAP, pulmonary artery pressure; PAOP, pulmonary artery occlusion pressure.

support ventilation and oxygenation are required quickly. Other later stages of progression result from tissue hypoxia and include dysrhythmias, chest pain, decreased renal function, and decreased bowel sounds. These are indications of multisystem involvement as highly perfused organ systems respond to decreased oxygen delivery with diminished function.

In the later stages of ARDS, mechanical ventilation support is required. Consolidation of the lungs with fluid reduces breath sounds. Lung compliance decreases, and increasing difficulties maintaining ventilation in the face of increasing resistance ensue. Unexplained changes in ventilation (such as decreased PaO_2 or increased peak inspiratory pressure) cannot be minimized because development of spontaneous pneumothoraces is a frequent complication of ARDS in the later stages. Transmitted sounds, poor air entry throughout all lung fields, and diffuse crackles coupled with ventilation make breath sounds difficult to assess. A further complicating event is myocardial depression, a mediated response. Therefore, despite persistent tachycardia, cardiac output decreases, and hypotension results.

Diagnostic Studies

Throughout the stages of ARDS, the reliance on diagnostic tests is important (see Table 27-4). In the early stages, the need to establish cause may require specific tests, such as blood cultures, bronchoalveolar lavage cultures, and computed tomography (CT) for abscess (eg, abdominal abscesses). In later stages, further vigilance is required to intervene for early management of any nosocomial infections. Ongoing monitoring of routine blood gas values, chemistry, and hematology is performed to ensure stability in metabolic parameters and optimization of existing function. Other laboratory studies are generally nonspecific and may include leukocytosis and lactic acidosis.

Blood Gas Analysis

Deterioration of arterial blood gas (ABG) values, despite interventions, is a hallmark of ARDS. Initially, hypoxemia (an arterial oxygen tension, or PaO_2, of <60 mm Hg) may improve with supplemental oxygen; however, refractory hypoxemia (no improvement of PaO_2 with supplemental oxygen) and a persistently low SaO_2 eventually develop. Early in acute respiratory failure, dyspnea and tachypnea are associated with a decreased $PaCO_2$. Hypercarbia develops as gas exchange, and ventilation becomes increasingly impaired. Arterial pH in the early phase may be high (>7.45), a finding that is consistent with respiratory alkalosis secondary to rapid respirations and a low $PaCO_2$. The arterial pH measurements in ARDS are typically lower because of respiratory and ventilatory failure and tissue hypoxia, anaerobic metabolism, and

subsequent metabolic acidosis. Base excess and deficit follow a similar trend, depending on the degree of tissue and organ hypoxia.

Measurement of arterial lactate is commonly ordered as an indication of tissue hypoxia and anaerobic metabolism. An elevated blood lactate concentration is common in early ARDS and resolves as oxygenation improves. Lactate measurement is not performed routinely once adequate, although perhaps not optimal, oxygenation has been achieved.

Radiographic Studies

In the early phase of ARDS, the chest radiographic changes are usually negligible. Within a few days, the chest radiographic findings show patchy bilateral alveolar infiltrates, usually in the dependent lung fields. This may be mistaken for cardiogenic pulmonary edema. Over time, these patchy infiltrates progress to diffuse infiltrates, consolidation, and air bronchograms. CT of the chest also shows areas of infiltrates and consolidation of lung tissue. Daily chest radiographs are important in the continuing evaluation of the progression and resolution of ARDS and for ongoing assessment of potential complications, especially pneumothoraces.

Intrapulmonary Shunt Measurement

An intrapulmonary shunt is a type of ventilation–perfusion mismatch. It may be defined as the percentage of cardiac output that is not oxygenated owing to pulmonary blood flowing past collapsed or fluid-filled and nonventilated alveoli (a physiological shunt), absence of blood flow to ventilated alveoli (alveolar dead space), or a combination of both of these conditions (silent unit [alveoli with no ventilation and no perfusion]; see Chapter 23, Fig. 23-16). Normally, an intrapulmonary shunt of 3% to 5% is present in all people. Advanced respiratory failure and ARDS are associated with a shunt of 15% or more because of the pathological changes in blood flow, endothelial disruption, and alveolar collapse. As the intrapulmonary shunt increases to 15% and greater, more aggressive interventions, including mechanical ventilation, are required because this level of shunt is associated with profound hypoxemia and may be life threatening.

The intrapulmonary shunt fraction (Qs/Qt) is calculated using the arterial oxygen content (CaO_2), the mixed venous oxygen content (CvO_2), and the capillary oxygen content (CcO_2). Oxygen content is determined by hemoglobin (Hgb), oxygen saturation (SO_2), and partial pressure of oxygen (PO_2), measured by calculating the oxygen content in the pulmonary capillary bed, in the systemic arterial system, and in the mixed venous blood from the pulmonary artery. The intrapulmonary shunt fraction may be estimated using a simple calculation, the ratio of arterial oxygen to inspired oxygen (ie, the PaO_2:FiO_2 ratio). In general, a PaO_2:FiO_2 ratio greater than 300 is normal, a value of 200 is associated with an intrapulmonary shunt of 15% to 20%, and a value of 100 is associated with an intrapulmonary shunt of more than 20%.

Lung Compliance, Airway Resistance, and Pressures

Lung mechanics are altered in ARDS, resulting in reduced alveolar ventilation and pulmonary gas exchange. Lung compliance, or distensibility, decreases as the alveoli fill with fluid or collapse. More effort and greater pressure are required to move air into the lungs as they become increasingly "stiff." In addition, the resistance to airflow into and out of the lungs increases with the accumulation of secretions and mediator-induced bronchoconstriction. Because the patient with ARDS requires mechanical ventilation to support oxygenation and ventilation, lung compliance and airway resistance can be evaluated by assessing ventilator pressures and tidal volume changes.

Close monitoring of airway pressures, including the mean airway pressure, the peak inspiratory pressure, and the plateau pressure, is an important component of patient assessment in ARDS. Increases in these pressures as tidal volumes are maintained to achieve a normal $PaCO_2$ indicate reduced compliance and increased resistance to airflow. As airway pressures rise, the lung epithelium is traumatized, resulting in further lung tissue damage. Volutrauma (lung epithelial damage) from persistently elevated airway pressures thus has additional deleterious effects on ventilation and oxygenation.

Possible nursing diagnoses for a patient with ARDS are given in Box 27-2.

BOX 27-2 EXAMPLES OF NURSING DIAGNOSES

For the Patient with Acute Respiratory Distress Syndrome

- Impaired Gas Exchange related to refractory hypoxemia and pulmonary interstitial/alveolar leaks found in alveolar capillary injury states
- Ineffective Airway Clearance related to increased secretion production and decreased ciliary motion
- Ineffective Breathing Patterns related to inadequate gas exchange, increased secretions, decreased ability to oxygenate adequately, fear, or exhaustion
- Anxiety related to critical illness, fear of death, role changes, or permanent disability
- Risk for Infection related to invasive monitoring devices and endotracheal tube

▲ Management

Therapeutic modalities to actually treat ARDS have remained elusive. Although there are multiple potential causes of ARDS, management principles are similar. Treatment is supportive; that is, contributing factors are corrected or reversed, and while the lungs heal, care is taken so that treatment does no further damage.

In addition, extensive work has gone into creating "bundles," which are elements of care considered core to the management and treatment of specific critical illnesses in intensive care units (ICUs). Box 27-3 lists essential critical care bundles that apply to managing ARDS. These treatments span prevention at early stages of disease onset, such as early goal-directed fluid resuscitation and longer-term prevention of complications, such as sedation protocols. Regardless, one of the most important roles for critical care nurses is ensuring attention to all these elements to prevent mortality and to promote recovery.

BOX 27-3 Care "Bundles" in Critical Care

Ventilator: ventilator-associated pneumonia (VAP) "bundle" basics
- Elevated head of the bed 30 to 45 degrees
- Daily weaning assessment (spontaneous breathing trials)
- Daily sedation withholding
- Weaning protocol
- Deep vein thrombosis (DVT) prophylaxis
- Peptic ulcer prophylaxis

Sepsis "bundle" basics
- Appropriate antibiotic therapy
- Early goal-directed fluid resuscitation
- Steroid administration
- Activated protein C
- DVT prophylaxis
- Peptic ulcer prophylaxis

Other protocols that may be added
- Tight glucose control
- Postpyloric feeding
- Subglottic suctioning
- Electrolyte replacement

Oxygenation and Ventilation

Oxygen Delivery

Refractory hypoxemia is one of the hallmarks of ARDS; therefore, attention to improving oxygen delivery is paramount. Strategies have attempted to optimize normal oxygen delivery parameters, including hemoglobin, cardiac output, and oxygen saturation. Oxygen delivery (DaO_2) is the amount of oxygen delivered to the tissues and organs every minute and depends on the flow of oxygenated blood through the tissue beds. Parameters that determine DaO_2 are hemoglobin, arterial oxygenation, and cardiac output.

Adequate DaO_2 (>800 mL O_2/min) is essential to meet tissue requirements for oxygen, thereby preventing anaerobic metabolism and hypoxia, which can trigger and perpetuate SIRS. Critically ill patients with ARDS have high demands for oxygen to maintain organ function.

Hemoglobin combines with oxygen to form oxyhemoglobin; therefore, sufficient amounts of hemoglobin are necessary to carry oxygen to the cells. There is little research to support the intuitive concept that normal or increased hemoglobin is required to promote oxygen delivery in patients with SIRS or ARDS. Studies on transfusion requirements indicate that values of approximately 8.0 g/dL are sufficient for critically ill patients, except for those with cardiac disease.

Cardiac output is typically altered in ARDS because of the SIRS, the effect of hypoxemia on the myocardium, and the decrease in venous return induced by mechanical ventilation. Evaluation of the cardiac output is important so that oxygen delivery can be assessed and appropriate interventions initiated. Therapies to optimize cardiac output are directed toward enhancing preload and contractility and normalizing afterload. Routine use of a thermodilution pulmonary artery catheter to assess oxygen delivery and consumption for patients with ARDS has decreased over the last decade, but may be used to ensure that appropriate interventions are instituted. There are other less-invasive methods to measure cardiac output utilizing the patient's transduced arterial blood pressure, as well as utilizing the patient's central venous catheter to measure the venous oxygen content. These techniques are less accurate, but able to be used for trending.

Fluid management has been used for many years in an effort to balance the type of fluid needed to manage the hallmark edema and decompensation associated with ARDS. At the onset of the disease, early goal-directed fluid resuscitation is recommended. Diuretics and reduced fluid administration have been studied to reduce lung edema. Conservative fluid management with diuresis, plus albumin for hypoproteinemic patients, is associated with modest improvements in oxygenation.[8]

Positive inotropic agents, such as dobutamine, are used to enhance contractility and increase cardiac output; however, care must be taken with these agents as they may cause systemic vasodilation worsening hypotension. Vasoconstrictors, such as norepinephrine, may be added to the therapies to counteract the vasodilation induced by SIRS. Vasoconstricting agents must be administered cautiously because many vascular beds, especially in the lungs, are constricted, also as a result of SIRS mediators and hypoxia. Patients receiving inotropic or vasoactive medications require continuous arterial blood pressure monitoring and may require evaluation of cardiac output and other hemodynamic measures.

Mechanical Ventilation

The goal of therapy is to improve tissue oxygenation and ventilation. Methods to deliver appropriate levels of oxygen and allow for removal of carbon dioxide include types of mechanical ventilation and positioning. Lung-protective ventilation strategies limit ventilator-associated (or ventilator-induced) lung injury (VALI); these include low tidal volumes (<6 mL/kg predicted body weight), the use of adequate positive end-expiratory pressure (PEEP) to reduce the risk of using a high FiO_2 and precipitating oxygen toxicity, and limiting plateau pressures to 30 cm H_2O.[9,10] All other ventilation therapies, including high-frequency oscillation ventilation (HFOV),[11] and extracorporeal lung-assist technology,[8] have not demonstrated consistent improvements in patient outcomes in ARDS, but may be life saving in refractory hypoxemia.

Multiple modes of mechanical ventilation are available to support the patient with respiratory failure. (See Chapter 25 for a complete discussion of mechanical ventilation.) In general, the principle of "do no harm" includes use of the lowest FiO_2 to achieve adequate oxygenation and use of small tidal volumes to minimize airway pressures, thus preventing or reducing lung damage (volutrauma). Permissive hypercapnia may be necessary to prevent an increased respiratory rate in the face of lower tidal volumes. PEEP prevents collapse and recruits alveoli, allowing diffusion of gases across the alveolar–capillary membrane. Recommended values for PEEP are 10 to 15 cm H_2O, but values in excess of 20 cm H_2O are acceptable to reduce inspired oxygen requirements or maintain adequate oxygenation.[9,10,12]

Permissive hypercapnia is a strategy that allows the $PaCO_2$ to rise slowly above normal through reduction of tidal volume, therefore limiting the plateau and peak airway pressures. A $PaCO_2$ between 55 and 60 mm Hg and a pH of 7.25 to 7.35 are tolerated when achieved gradually. It is necessary

to monitor the increase in $PaCO_2$ to prevent too rapid a rise, and overall values should be no greater than 80 to 100 mm Hg because of the potential effects on cardiopulmonary function. These techniques are not used for patients with cardiac or neurological involvement.

Several modes of mechanical ventilation are directed toward minimizing airway pressures and iatrogenic lung injury, associated with conventional volume-controlled mechanical ventilation. Pressure-controlled ventilation limits the peak inspiratory pressure to a set level (as opposed to volume-controlled ventilation, which delivers a set tidal volume despite the pressure required to move the set volume into the lungs). Pressure-controlled ventilation also uses a decelerating inspiratory airflow pattern to minimize the peak pressure while delivering the necessary tidal volume. Patients on pressure-controlled ventilation mode may require sedation to prevent dyssynchrony with the ventilator. Inverse-ratio ventilation is another strategy thought to improve alveolar recruitment. Reversal of the normal inspiratory–expiratory ratio (I:E ratio) to 2:1 or 3:1 prolongs inspiration time, preventing complete exhalation. An inverse I:E ratio is achieved through manipulation of the mechanical ventilator. This increased end-expiratory volume creates auto-PEEP (intrinsic PEEP) that is added to the applied extrinsic PEEP. The theoretical advantages include reduced alveolar pressures and overall PEEP levels. This therapy requires patients to be sedated and given paralytics to improve tolerance. Airway pressure release ventilation similarly inverses the I:E ratio but with the advantage of allowing the patient to initiate breaths. These patients do not require the same level of sedation or paralysis to achieve pressure-limited ventilation and may have improved recruitment of alveoli.

Novel Ventilation Strategies

HFOV uses very low tidal volumes (1 to 4 mL/kg) delivered at rates of 3 to 15 Hz or cycles/second rather than breaths/minute, resulting in lower airway pressures and reduced volutrauma. Deleterious effects of HFOV include increased trapping of air in the alveoli (auto-PEEP) and increased mean airway pressures to high levels in some patients. HFOV requires sedation and paralysis as any change in airway pressure will cause oscillation to cease.

Extracorporeal lung-assist technology involves the use of large vascular cannulas to remove blood from the patient. A pumping device and circuit circulate the blood, and one or two "artificial lungs" remove carbon dioxide and oxygenate the blood. Extracorporeal membrane oxygenation and extracorporeal carbon dioxide removal ($ECCO_2R$) may potentially be effective in managing ARDS, but at present their use is controversial.[8] These highly invasive, high-risk technologies allow the lungs to "rest" because near-apneic ventilation or ventilation with small tidal volumes and slow respiratory rates greatly reduces airway pressures while gas exchange takes place in the artificial membrane lungs. The need for intensive resources and personnel with a high degree of expertise, coupled with the potential for devastating complications (particularly intracranial hemorrhage) and a lack of conclusive benefits for patients with ARDS, make extracorporeal lung-assist technology of limited use.

Positioning

Frequent position change is well established as a means to prevent and reverse atelectasis and to facilitate removal of secretions from the airways. Although not a treatment for ARDS, elevating the head of the bed greater than 30 degrees is considered necessary care for preventing ventilator-associated pneumonia (VAP).

Prone positioning, either in the patient's bed, using a Stryker frame or Roto-Prone™ therapy system, improves pulmonary gas exchange, facilitates pulmonary drainage in the dorsal lung regions, and aids resolution of consolidated dependent alveoli (in the supine position), particularly in the dorsal lung regions. The evidence for the effectiveness of prone positioning, now a common intervention with ARDS, is variable.[13] There are alternative explanations for the improved oxygenation associated with prone positioning, and the question of whether the improvement in oxygenation persists beyond a short time remains controversial. The associated risks include loss of airway control through accidental extubation, loss of vascular access, facial edema and development of pressure areas, and difficulties with cardiopulmonary resuscitation. Recommendations on the steps involved in prone positioning appear in Box 27-4.

Pharmacological Therapy

Antibiotic therapy is appropriate in the presence of a known microorganism but should not be used prophylactically. The signs of SIRS are similar to those of infection

BOX 27-4 Summary of Key Steps to Consider for Prone Positioning

1. Evaluate with the interdisciplinary team the patient's condition and determine whether a trial of prone positioning is warranted.
2. Organize the team to ensure familiarity with the procedure and patient care while prone.
   - Use your hospital's evidence-based procedure
   - Equipment on site
   - Assign and clarify team roles during prone positioning
3. Prepare the patient for the procedure.
   - Provide explanation to patient and family
   - Consider insertion of feeding tube, nasogastric tube, or both as necessary
4. Assess and document the patient's preprone positioning status.
   - Hemodynamic and ventilatory parameters, skin or wound condition, and so forth
5. Protect and maintain the patient's airway.
   - Secure endotracheal tube
   - Apply in-line suction if not already in place
6. Use safety precautions to ensure body position will be maintained during the prone positioning procedure.
7. Administer adequate sedation and analgesic medication.
8. Complete the procedure as per protocol. Note: Risks for inadvertent extubation or line displacement are high during the procedure.
9. Assess, evaluate, and monitor the patient's condition.
10. Implement preventive care for pressure areas, eyes, and skin.

(ie, tachycardia, fever, increased white blood cell count), thus creating the temptation to treat the patient with SIRS with antimicrobial therapy. It is essential to identify a source of infection (isolation of specific bacteria through blood, wound, pulmonary, and other cultures) before initiating antibiotics. Prophylactic antibiotic therapy has not been shown to improve outcome. Emphasis is on prevention of infection, especially nosocomial infection related to the use of invasive vascular catheters and ventilators (eg, VAP).

Bronchodilators and mucolytics are useful in ARDS to assist in maintaining airway patency and reducing the inflammatory reaction and accumulation of secretions in the airways. The response to therapy is evaluated by monitoring airway resistance and pressures and lung compliance.

Administration of intravenous corticosteroids in low-to-moderate doses for prolonged duration has been associated with improved oxygenation when initiated, less than 14 days after onset of ARDS; this has been recommended by an international group of experts.[8] In a meta-analysis, the use of low-dose corticosteroids was associated with improved mortality and morbidity outcomes without increased adverse reactions. The consistency of results in both study designs and all outcomes suggests that they are an effective treatment for ALI or ARDS.[14]

Nitric oxide is an inhaled gas that causes selective pulmonary vasodilation and therefore reduces the deleterious effects of pulmonary hypertension. To date, nitric oxide has not been shown to improve mortality or oxygenation beyond the first 24 hours of therapy.[8] Nitric oxide should be reserved for those patients with life-threatening refractory hypoxemia after mechanical ventilation has been maximized. Inhaled prostacyclin has also produced pulmonary vasodilation similar to nitric oxide and may be considered.[8]

Sedation

Effective use of sedation to promote comfort and reduce respiratory effort, thus decreasing oxygen demand, is an important consideration for nurses dealing with patients with ARDS. Neuromuscular blocking agents and general anesthetics, such as propofol, although not sedatives, are all used to decrease the work of breathing and facilitate ventilation for patients with ARDS. Neuromuscular blocking agents require concurrent use of sedation to prevent patients who are chemically paralyzed from being alert but unable to move. Frequent assessment of adequacy of both neuromuscular blockade and sedation is an important nursing intervention. Neuromuscular blocking agents have been associated with critical illness polyneuropathy and polymyopathy, especially when concurrently administered with corticosteroids.

Pain, anxiety, and delirium are all possible reasons for needing pharmacological treatment, and it is important to distinguish between them because each requires a different pharmacological intervention. It is vital to understand why each is being given, what the goals of therapy are, and what the long-term implications of overuse can be. These considerations are balanced with the need to decrease oxygen demand and provide comfort for patients requiring intensive ventilation management and undergoing potentially uncomfortable procedures.

Nutritional Support

Early initiation of nutritional support is essential for patients with ARDS because nutrition plays an active therapeutic role in recovery from critical illness. There are two major theoretical reasons to use early enteral feeding as a therapeutic intervention in SIRS and ARDS. Mediators (TNF-α and IL-1 in particular) stimulate release of proteolytic enzymes that stimulate protein catabolism from skeletal muscle. Persistent protein loss is compounded by interstitial loss through capillary leak and down-regulation of messenger RNA production of intravascular proteins, such as albumin. Earlier in this chapter, reference was made to changes in circulatory patterns resulting from hypoxic sympathetic nervous system reactions. In this way, there is decreased perfusion to the gut. After resuscitation, increases in neutrophil release further damage the injured, reperfused colon through increased vascular endothelial permeability, thus releasing normal gut bacteria into the systemic circulation and leading to increases in the incidence of peritonitis, pneumonia, and sepsis. The mechanism through which enteral feeding improves outcome remains unproved, but the reduction in mortality in the critically ill who receive enteral feedings indicates that this practice is of general benefit.

A diet with a balanced caloric, protein, carbohydrate, and fat intake is calculated based on metabolic needs, with particular attention paid to specific amino acids, lipid, and carbohydrate intake. Patients with SIRS or ARDS usually require 35 to 45 kcal/kg/d. High-carbohydrate solutions are avoided to prevent excess carbon dioxide production. Recent innovations in amino acid supplementation are being reviewed because of the role of amino acids in the immune response. The role of antioxidants and omega-3 fatty acids is still being investigated as to their use in improving outcomes in ARDS patients.[8]

The problem facing the practitioner is the ability to deliver enteral nutrition in the face of decreased gut motility. Insertion of small bowel feeding tubes may be considered. The role of total parenteral nutrition is controversial, and some clinicians rarely use it, either alone or in combination with enteral nutrition.[8] The risk for aspiration associated with enteral feeding needs to be appreciated, and careful monitoring of absorption and gut function is essential.

A collaborative care guide for the patient with ARDS is given in Box 27-5.

▲ Prevention of Complications

Complications of ARDS are primarily related to SIRS, VALI, and immobility imposed by critical illness. The most serious of these is the development of MODS due to hypoxemia, hypoxia, and the persistent inflammatory response. An entire spectrum of potential complications exists for the critically ill patient. Critical care forums have compiled evidence-based protocols into bundles for two major critical care situations: VAP and

BOX 27–5 COLLABORATIVE CARE GUIDE for the Patient With Acute Respiratory Distress Syndrome

Outcomes	Interventions
Oxygenation/Ventilation	
Patent airway will be maintained. A PaO_2:FIO_2 ratio of 200 to 300 or more will be maintained, if possible.	• Auscultate breath sounds every 2–4 h and as required. • Intubate to maintain oxygenation and ventilation and to decrease work of breathing. • Suction endotracheal airway when appropriate (see Chapter 25, Box 25-16, Collaborative Care Guide for the Patient on Mechanical Ventilation). • Hyperoxygenate before and after each suction pass.
Lung-protective ventilation strategies will be used. Maintain a low tidal volume (<6 mL/kg), a plateau pressure ≤30 cm H_2O, and positive end-expiratory pressure (PEEP) levels titrated to pressure–volume curve.	• Monitor airway pressures every 1–2 h. • Monitor airway pressures after suctioning. • Administer bronchodilators and mucolytics. • Obtain a PEEP study to determine optimal oxygen delivery. • Consider a change in ventilator mode to prevent volutrauma.
The risk for atelectasis, ventilator-associated pneumonia (VAP), and volutrauma will be reduced and oxygenation will be improved.	• Turn patient side-to-side every 2 h. • Perform chest physiotherapy every 4 h, if tolerated. • Elevate head of bed 30 degrees. • Monitor chest x-ray daily.
Oxygenation will be maximized (a PaO_2 of 55 to 80 mm Hg or a SaO_2 of 88% to 95%).	• Monitor pulse oximetry and end-tidal carbon dioxide. • Monitor arterial blood gas values as indicated by changes in noninvasive parameters. • Monitor intrapulmonary shunt (Qs/Qt and PaO_2:FIO_2 ratio). • Increase PEEP and FIO_2 to decrease intrapulmonary shunting, using lowest possible FIO_2. • Consider permissive hypercapnia to maximize oxygenation. • Monitor for signs of volutrauma, especially pneumothorax. • Consider risk for prolonged hyperoxia and decrease FIO_2 to <65% as soon as able.
Circulation/Perfusion	
Blood pressure, cardiac output, central venous pressure (CVP), and pulmonary artery pressures remain stable related to mechanical ventilation.	• Assess hemodynamic effects of initiation of mechanical ventilation (eg, decreased venous return and cardiac output). • Monitor electrocardiogram (ECG) for dysrhythmias related to hypoxemia. • Assess hemodynamic effects of changes in inspiratory pressure settings, tidal volume, PEEP, and ventilatory modes. • Assess effects of ventilator setting changes on cardiac output and oxygen delivery. • Administer intravascular volume to maintain preload.
Blood pressure, heart rate, and hemodynamic parameters are optimized to therapeutic goals.	• Monitor vital signs every 1–2 h. • Monitor pulmonary artery pressures and right atrial pressure every hour and cardiac output, systemic vascular resistance, peripheral vascular resistance, DaO_2, and oxygen consumption (VO_2) every 6–12 h, if pulmonary artery catheter is in place. • Administer intravascular volume agents as indicated by real or relative hypovolemia, and evaluate response.
Serum lactate level will be within normal limits.	• Monitor lactate level as required until it is within normal limits. • Administer red blood cells, positive inotropic agents, and colloid infusion as ordered to increase oxygen delivery.
Fluids/Electrolytes	
Patient is euvolemic. Urine output is >0.5 mL/kg/h.	• Monitor hydration status to reduce viscosity of lung secretions. • Monitor intake and output. • Avoid use of nephrotoxic substances and overuse of diuretics. • Administer fluids and diuretics to maintain intravascular volume and renal function.
There is no evidence of electrolyte imbalance or renal dysfunction.	• Replace electrolytes as ordered. • Monitor urine output, blood urea nitrogen (BUN), creatinine, creatinine clearance, serum osmolarity, and urine electrolytes as required.

(continued on page 602)

BOX 27–5 *COLLABORATIVE CARE GUIDE for the Patient With Acute Respiratory Distress Syndrome (continued)*

Mobility/Safety	
There is no evidence of complications related to bed rest and immobility.	• Initiate deep venous thrombosis (DVT) prophylaxis. • Reposition patient frequently. • Mobilize patient to chair when hemodynamic stability and hemostasis are achieved. • Consult physiotherapist. • Conduct range-of-motion and strengthening exercises when able.
Physiological changes are detected and treated without delay.	• Monitor mechanical ventilator alarms and settings and patient parameters (eg, tidal volume) every 1–2 h. • Ensure appropriate settings and narrow limits for hemodynamic, heart rate, and pulse oximetry alarms.
There is no evidence of infection; white blood cell count is within normal limits.	• Monitor for systemic inflammatory response syndrome (SIRS) criteria (increased white blood cell count, increased temperature, tachypnea, tachycardia). • Use strict aseptic technique during procedures, and monitor others. • Maintain sterility of invasive catheters and tubes. • Change chest tube and other dressings and invasive catheters. • Culture blood and other fluids and line tips when they are changed.
Skin Integrity	
Skin will remain intact.	• Assess skin every 4 h and each time patient is repositioned. • Turn patient every 2 h. • Consider pressure relief/reduction mattress, kinetic therapy bed, or prone positioning. • Use Braden Scale to assess risk for skin breakdown.
Nutrition	
Caloric and nutrient intake will meet metabolic requirements per calculation (eg, basal energy expenditure).	• Provide enteral nutrition within 24 h. • Consult dietitian or nutritional support service. • Consider small bowel feeding tube if gastrointestinal motility is an issue for enteral feeding. • Monitor lipid intake. • Monitor albumin, prealbumin, transferrin, cholesterol, triglyceride, and glucose levels.
Comfort/Pain Control	
Patient will be as comfortable as possible as evidenced by stable vital signs or cooperation with treatments or procedures.	• Objectively assess comfort/pain using a pain scale. • Provide analgesia and sedation as indicated by assessment. • Monitor patient cardiopulmonary and pain response to medication. • If patient is receiving neuromuscular blockade for ventilatory control: • Use peripheral nerve stimulator to assess pharmacological paralysis. • Provide continuous or routine (every 1–2 h) intravenous sedation and analgesia.
Psychosocial	
Patient demonstrates decreased anxiety.	• Assess vital signs during treatments, discussions, and the like. • Cautiously administer sedatives. • Consult social services, clergy, as appropriate. • Provide for adequate rest and sleep.
Teaching/Discharge Planning	
Patient/significant others understand procedures and tests needed for treatment.	• Prepare patient/significant others for procedures, such as bronchoscopy, pulmonary artery catheter insertion, or laboratory studies. • Explain the causes and effects of ARDS and the potential for complications, such as sepsis, volutrauma, or renal failure.
Significant others understand the severity of the illness, ask appropriate questions, and anticipate potential complications.	• Encourage significant others to ask questions related to the ventilator, the pathophysiology of ARDS, monitoring, and treatments.

BOX 27-6 CONSIDERATIONS FOR THE OLDER PATIENT

Acute Respiratory Distress Syndrome

- People who are 65 years of age or older are at increased risk for multisystem organ involvement with less chance of recovering from ARDS; therefore, the mortality rate rises in this population.
- Because of increased immunosuppression with aging, the elderly are at greater risk for infection; therefore, nosocomial infections, such as urinary tract infections and ventilator-associated pneumonia, are more common.
- Hemodynamic instability adds metabolic insults to already-decreased renal function, thus predisposing this group to renal failure.
- Decreased stroke volume; possible coronary artery disease (CAD), atherosclerosis, or both; and increased systolic blood pressure and peripheral vascular resistance alter hemodynamic recovery.
- Decreased maximal oxygen uptake associated with decreased lung volumes puts elderly patients at greater risk for ventilator-associated lung injury.
- Decreased muscle mass associated with aging makes recovery from prolonged immobility more difficult. Therefore, an elderly person with ARDS may require prolonged rehabilitation.
- Generalized peripheral edema, multiple invasive tests, and prolonged bed rest, combined with the decreased skin integrity associated with old age, increase the elderly patient's potential for development of pressure ulcers and skin tears.
- Elderly patients with ARDS are at risk for not receiving the same quality and quantity of treatment and care as younger patients, due to the effects of ageism. The patient's age is one factor to consider in outcome and prognosis, but not the only one.
- The incidence of comorbid conditions, especially non–insulin-dependent diabetes mellitus and CAD, increases with age. Research findings indicate that comorbid conditions increase the risk for death in patients with ARDS.
- Based on previously expressed wishes, the patient and family may request no initiation of, or early removal from, life support. A person's life experience or vision of risk related to prolonged illness with high possibility of mortality may influence this decision, and these wishes should be respected.

sepsis (see Box 27-3, p. 598). The introduction of care bundles into critical care supports application of evidence to reduce major complications. The implementation of care bundles has been shown effective in reducing length of stay and reducing ventilator days, but consistent application requires teamwork and monitoring.

Mechanical ventilation with high levels of PEEP, high tidal volumes, and volume-controlled modes predisposes the patient with ARDS to volutrauma, as previously described. Volutrauma may present as a pneumothorax, pneumomediastinum, or subcutaneous or interstitial emphysema. Prompt chest tube insertion is required for a pneumothorax. Prevention of volutrauma by maintaining the lowest possible airway pressures, PEEP, and tidal volumes may be achieved through the use of pressure-limiting modes of mechanical ventilation.

Prevention or reduction in the incidence of VAP can be accomplished through using in-line suction catheters. The use of endotracheal tubes that allow for the removal of pooled subglottic secretions have been shown to reduce VAP. Sinusitis is also associated with VAP. The critical care nurse needs to monitor for nasal secretions and ensure that devices such as nasotracheal or feeding tubes are removed from the nose when these occur. Oral care is an essential component in the prevention of VAP, as it decreases the amount of organisms in the mouth, which may migrate to the lungs (see Evidence-Based Practice Highlight 25-2, p. 542). Elevating the head of the bed 30 degrees and feeding the critically ill patient with a postpyloric feeding tube have been shown to reduce microaspiration and VAP.

Immobility caused by bed rest, sedation, or pharmacological paralysis has multisystem effects. Not infrequently, nosocomial pneumonia is acquired from accumulated secretions in the airways and atelectasis secondary to immobilization, with bacterial access through and around the endotracheal tube. As discussed, frequent repositioning accompanied by chest physiotherapy will help to reduce stasis of secretions and facilitate removal.

Deep venous thrombosis (DVT) and subsequent pulmonary embolus may be life-threatening complications of immobility. Initiation of DVT prophylaxis within 48 hours of admission minimizes the risk for development of DVT. Low-dose heparin, graded elastic stockings, external pneumatic compression devices, frequent mobilization, and ambulation have been useful in reducing DVT formation.

The physiological aging process compounds the severity of the metabolic insults and complications of ARDS (Box 27-6).

▲ Clinical Applicability Challenges

CASE STUDY

P.F., a 52-year-old woman with a history of cholelithiasis, is admitted to the hospital for acute pancreatitis. She progresses to necrotizing pancreatitis and develops shock. She is transferred to the intensive care unit (ICU).

After arrival in the ICU, the patient develops cardiorespiratory failure and is intubated and placed on vasoactive support of vasopressin, 0.04 units/min, and norepinephrine, 10 mcg/min. She is having multiple episodes

(continued on page 604)

CASE STUDY *(Continued)*

of oxygen desaturation requiring an FiO_2 of 1.00. She is placed on assist-control ventilation of 20 breaths/min, a tidal volume of 6 mL/kg with positive end-expiratory pressure (PEEP) of 10 cm H_2O. Her breath sounds are clear with no crackles or wheezes. Her temperature is 101.1°F (38.4°C). A bronchial lavage is performed, and no pus, fluid, or blood is seen in the airways. As the day progresses, P.F. becomes difficult to ventilate and is sedated with a fentanyl infusion and midazolam (Versed) infusion. She also requires neuromuscular blockade with cisatracurium (Nimbex). Her cardiac index is 4.0, heart rate is 120 beats/min, central venous pressure is 8 mm Hg, PAOP is 10 mm Hg, and systemic vascular resistance index is 900 dynes/s/m^2/cm^5. Arterial blood gas (ABG) values show PaO_2 of 68 mm Hg, $PaCO_2$ of 39 mm Hg, pH of 7.36, HCO_3 of 18 mEq/L, and O_2 saturation of 95.5%.

The following day, P.F. continues to decline on 100% FiO_2. She has developed a mild to moderate bilateral wheeze in his chest. Chest radiography shows small bilateral effusions but is otherwise clear. PaO_2 remains low at 65 mm Hg. Blood, sputum, and urine specimens are sent to the laboratory for culture. Empiric broad-spectrum antibiotics are started. With no improvement in the ABGs and the rising pulmonary arterial pressures (47/16 mm Hg), nitric oxide is started at 10 ppm.

Computed tomography (CT) of the thorax is performed the following day to rule out pulmonary embolus and shows bilateral airspace opacity. This is visible on a chest radiograph the following day. A postpyloric feeding tube is inserted, and enteral feedings are started while P.F.'s lipase levels are monitored.

Seven days after admission, FiO_2 remains at 100%, and nitric oxide continues at 10 ppm with no improvement in oxygenation. Temperature remains elevated at 102°F (39.1°C) with a white blood cell count of 12,000/mm^3. All cultures remain negative. Chest radiography shows fluffy white opacities bilaterally and a collapsed right upper lung lobe. A bronchoscopy is performed to examine the right upper lobe, and copious secretions are removed. Several short attempts at lung recruitment to expand the lungs are performed, and because there is still no improvement, P.F. is placed in the prone position. Once in the prone position, her oxygenation improves.

Over the next few days, P.F. makes small steps forward with her oxygenation yet continues to require high levels of oxygen. A transbronchial biopsy is performed and demonstrates DAD and organizing pneumonia without evidence of infection. At this time, low-dose corticosteroids are started intravenously and continued for 3 weeks. The dose is tapered off over a 3-month period.

P.F. does well after corticosteroids are initiated. However, she has several episodes of VAP before becoming free of the ventilator.

After almost 4 months in hospital, P.F. is discharged home. On a follow-up examination, she had recovered to about 60% of her prehospital status. Her pulmonary function test shows only mild impairment. CT of her thorax shows scarring and fibrosis in nondependent lung zones and some bronchiectasis in dependent lung zones. This is interpreted as ventilator-acquired (induced) lung injury with stretch injury in the nondependent areas and airway trauma in the dependent airways.

1. What symptoms were presented early in P.F. that indicated the onset of ARDS?

2. Early enteral feeding was used to support P.F. For what other care should the nurse advocate to reduce complications in Ms P.F.?

3. What is the evidence that corticosteroids have a positive benefit in treating a patient with ARDS?

PART 7

RENAL SYSTEM

28

Anatomy and Physiology of the Renal System

Kara Adams Snyder and Kimberli Haas

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Describe the impact of afferent and efferent blood supply on renal function.
2. Discuss the structures comprising the nephron: glomerulus, proximal tubule, loop of Henle, and distal and collecting tubules.
3. Differentiate the functions of the nephron, including glomerular filtration, active and passive transport, and tubular secretion.
4. Compare normal fluid pressures in the nephron and how they affect glomerular filtration rate.
5. Explain the relationship of antidiuretic hormone, renin, and aldosterone to fluid regulation by the kidneys.
6. Explain the mechanisms used by the kidneys to help achieve clearance of substances and maintain homeostasis.
7. Describe the physiological roles of the predominant electrolytes.

With each contraction of the heart, the kidneys receive 21% of the cardiac output. This means that approximately 1.2 liters of blood passes through the kidneys each minute, and the body's entire blood volume is filtered through the kidneys 340 times per day.[1] Given this large volume of blood, the kidneys have a dominant role in filtration and a minor role in metabolism. Therefore, the kidneys have a large requirement for pressure and a relatively smaller requirement for oxygen. The regulation and maintenance of the concentration of solutes in the extracellular fluid (ECF) of the body are the primary functions of the kidney. The kidneys remove metabolic waste products and excess concentrations of constituents and conserve substances present in normal or low quantities.

▲ Macroscopic Anatomy of the Renal System

The kidneys are bean-shaped organs that lie in a retroperitoneal position in the abdomen, one on each side of the vertebral column (Fig. 28-1). The kidneys are partially protected by the last pair of ribs, with the right kidney slightly lower than the left because of the location of the liver. A tough, fibrous coat, known as the renal capsule, surrounds each kidney. The adrenal glands, which are discussed in more detail in Chapter 42, cap the kidneys.

The adult kidneys are approximately 12 cm long, 6 cm wide, and 2.5 cm thick. The kidney weighs about 150 g, the

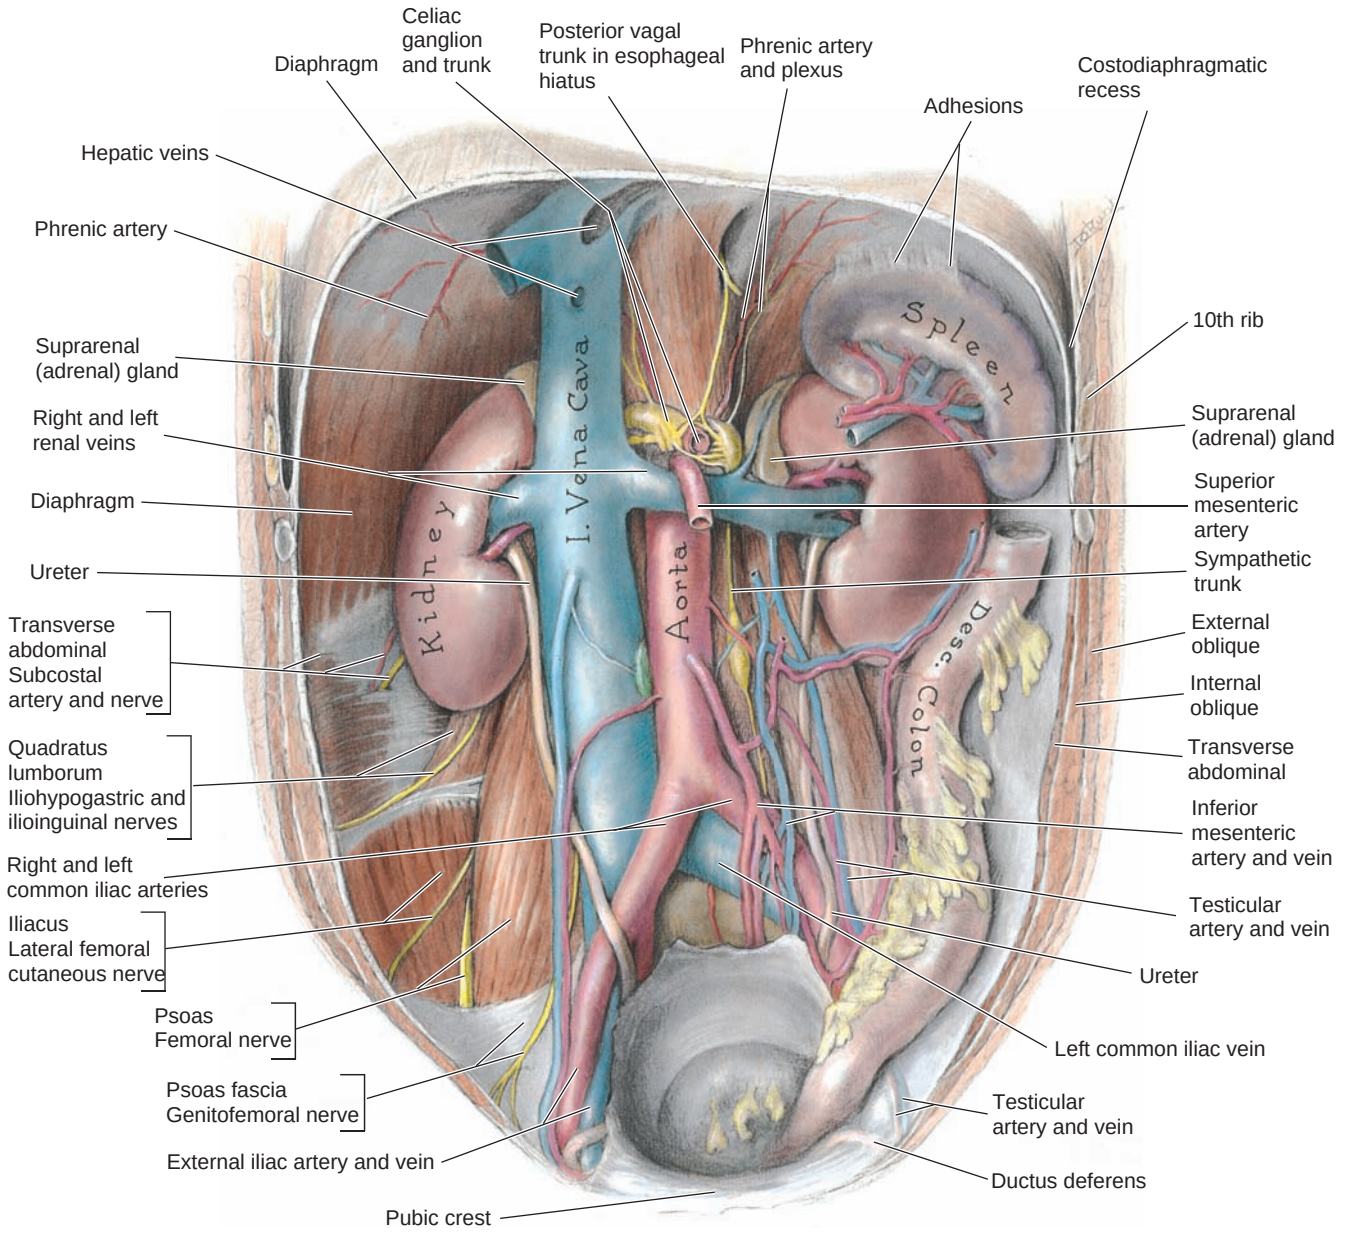

FIGURE 28-1 ▲ Anatomy of the kidneys and urinary system. (From Moore KL, Dalley AF, Agur AMR: Clinically Oriented Anatomy, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 290.)

size of a clenched fist. The size and weight of the kidneys are clinically valuable indicators in ultrasound-guided differential diagnosis of renal failure (see Chapter 29).

There are two distinct layers of the kidney: the renal cortex and the renal medulla (Fig. 28-2). The renal cortex is the outer portion of the kidney and has two regions: the cortical region and the juxtamedullary ("next to the medulla") region. The cortex contains the glomeruli, the proximal tubules, the cortical loops of Henle, the distal tubules, and the cortical collecting ducts. The inner layer, the medulla, in addition to the cortical structures, contains the renal pyramids. The renal cortex receives 90% of the total renal blood flow, and only 5% to 10% reaches the outer medulla. The pyramids contain the medullary loops of Henle and the medullary portions of the collecting ducts, which join to form a minor calyx. Minor calyces come together to form a major calyx. The renal calyces further join to become the conduit for directing urine into the ureter.

Urine exits the kidney at an oblique angle through a fibromuscular structure, the ureter. Peristalsis helps maintain the flow of urine through the ureter. The ureter enters the bladder in the trigone region. The trigone region of the bladder is so called for the three structures that form the shape of a triangle: the two ureters and the urethra. The peristaltic actions in the ureter and the angle of entry at the bladder help prevent the reflux of urine. Urine exits the bladder through the urethral orifice via the urethra. The male urethra is about 20 cm long; the female urethra is about 3 to 5 cm long.[1]

On the medial aspect of each kidney, there is an indentation known as the hilum. It is through this indentation

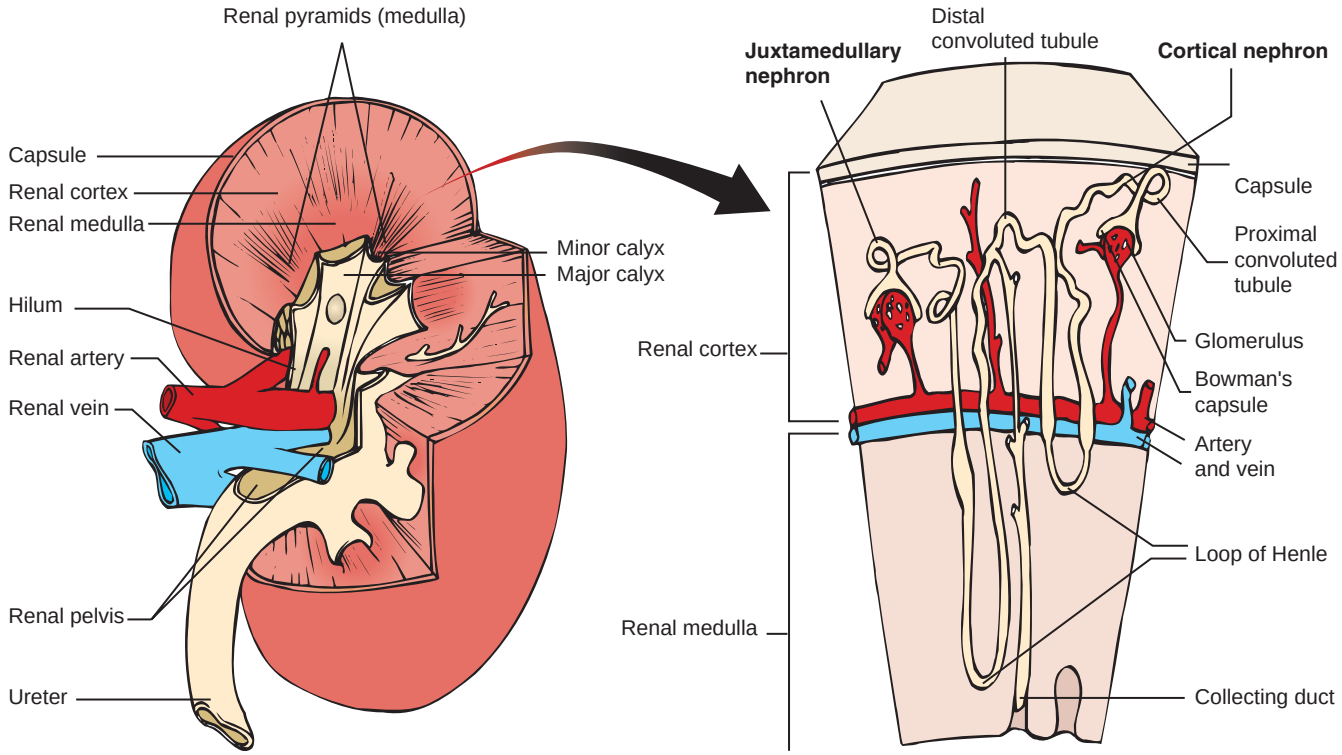

FIGURE 28-2 ▲ Macroscopic anatomy of the kidney.

that the renal arteries and nerves enter and the renal veins, lymphatics, and ureters exit (see Fig. 28-2).

The kidneys receive their blood supply from the renal artery, a branch of the descending aorta. The renal artery divides into several smaller branches known as the interlobular arteries (Fig. 28-3). Further branching produces numerous afferent arterioles. Each afferent arteriole forms a tuft of capillaries, known as the glomerulus, where blood is filtered. Leaving the glomerulus is the efferent arteriole. The efferent arteriole branches to form a second capillary bed, known as the peritubular capillaries (see Fig. 28-3). The peritubular capillaries surround the loop of Henle to reabsorb more water and solutes as needed for homeostasis. Reconnecting, this vast network of vessels eventually returns to the central circulation through the renal veins. The renal blood flow per weight unit is higher than any other major organ in the body.

The glomerular filtration rate (GFR) is relatively stable over a wide range of arterial blood pressures. The concept of "autoregulation" offers the kidneys such stability: the afferent arterioles adjust their diameter in response to the pressure of blood coming to them. If the blood pressure decreases, the smooth muscles of the afferent arterioles relax, vasodilation occurs, and perfusion increases, thereby maintaining the GFR at its normal rate. Conversely, with an increase in blood pressure, these vessels constrict. In healthy persons, autoregulation maintains homeostasis quite nicely when mean blood pressure falls approximately within a range of 80 to 180 mm Hg. Outside of this range, autoregulation is limited and GFR is proportional to renal perfusion. For example, if the systemic blood pressure falls greatly, such as in shock, the GFR falls to near zero, thereby producing near anuria.

▲ Microscopic Anatomy of the Renal System and Normal Renal Physiology

Urine, the end product of kidney function, is formed from the blood by the smallest unit of the kidney, the nephron (see Fig. 28-3). Each human kidney consists of about 1 million nephrons, all of which function identically; therefore, kidney function can be explained by describing the function of one nephron (Table 28-1, p. 611). A nephron is composed of a glomerulus, a proximal tubule, a loop of Henle, and a distal tubule. Several distal tubules drain into a collecting duct.

Approximately 80% of the filtrate is returned to the bloodstream by reabsorption in the proximal tubule.[1] In a healthy person, all the filtered glucose and amino acids, much sodium, chloride, hydrogen, and other electrolytes, uric acid, and urea are all reabsorbed here. The proximal tubule cells also secrete substances (eg, some drugs, organic acids, and organic bases) into the filtrate.

In the loop of Henle, the filtrate (urine) becomes highly concentrated. This part of the nephron is composed of a thin-walled descending portion and a thick-walled ascending portion. Loops of Henle belonging to juxtamedullary nephrons dip into the medulla of the kidney, which contains a highly concentrated interstitial fluid (ISF). The thin walls of the descending portion are quite permeable. This permeability, together with the high concentration of the ISF at this point, causes water to move by osmosis from the filtrate into the ISF. This makes the filtrate quite concentrated by the time it reaches the ascending limb of the loop.

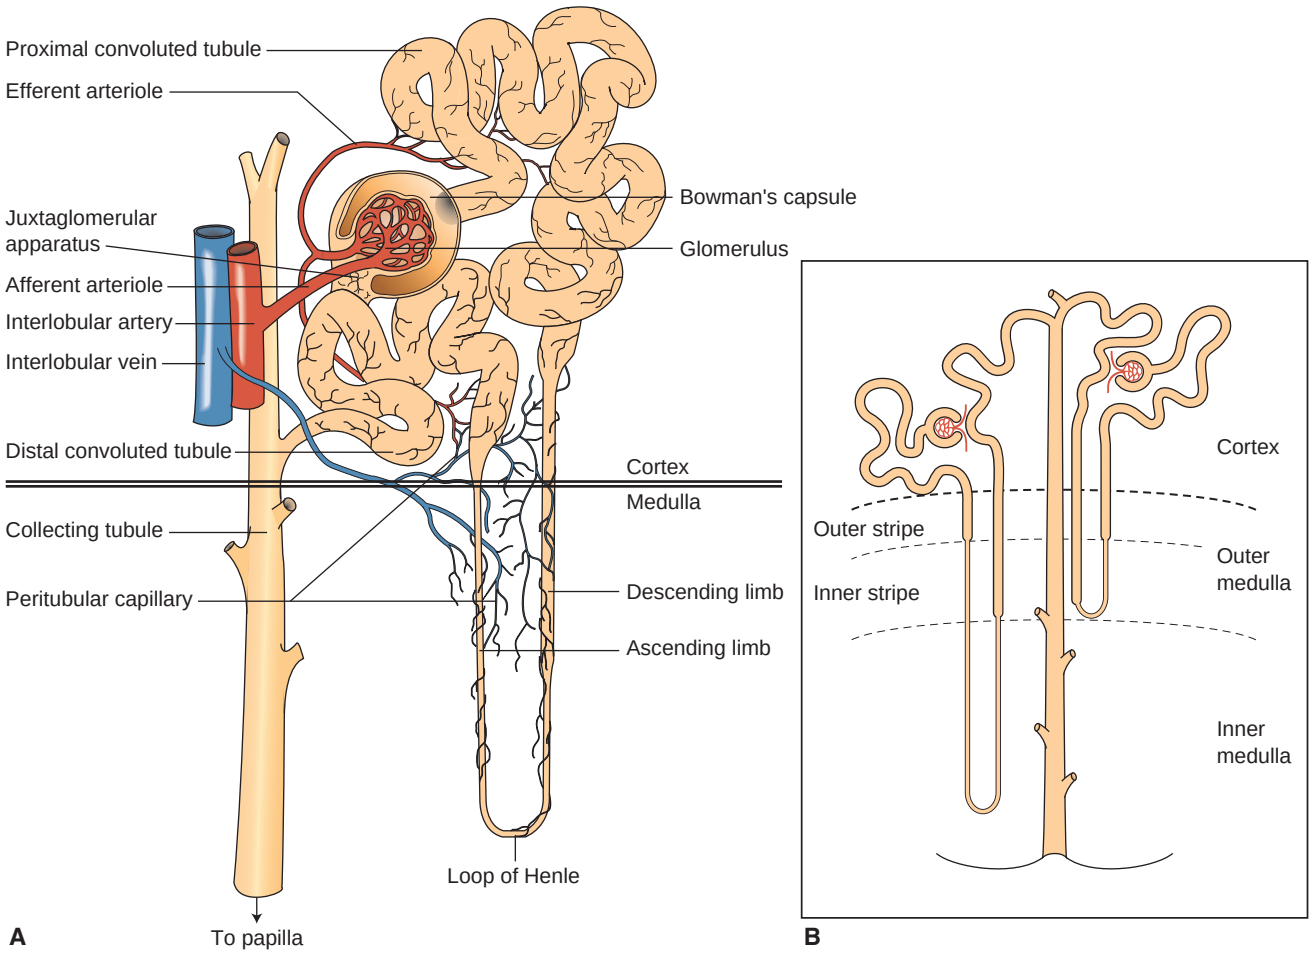

FIGURE 28-3 ▲ **A:** Nephron, showing the glomerular and tubular structures along with the blood supply. **B:** Comparison of differences in location of tubular structures of the cortical and juxtamedullary nephrons. (From Porth CM: Pathophysiology: Concepts of Altered Health States, 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 743.)

The thicker-walled ascending limb is relatively impermeable to water. It contains ion carriers that actively transport chloride ions out of the filtrate, which creates an electrochemical gradient that "pulls" the positively charged sodium ions from the filtrate. This exit of electrolytes without water now makes the filtrate more dilute than before.

In the distal tubule, sodium again is reabsorbed by active transport, and hydrogen, potassium, and uric acid can be added to the urine by tubular secretion.

The collecting ducts receive the contents from many distal tubules. At this point, there is no further electrolyte reabsorption or secretion. In the well-hydrated person, there is also no further water reabsorption. Water reabsorption without electrolyte reabsorption can occur in the collecting ducts under the stimulus of antidiuretic hormone (ADH).

Juxtaglomerular Apparatus

The nephron is arranged so that the initial portion of the distal tubule lies at the juncture of the afferent and efferent arterioles, which is very near the glomerulus. Here, macula densa cells of the distal tubule lie in approximation to the juxtaglomerular cells of the wall of the afferent arteriole. Both these cell types (juxtaglomerular and macula densa cells) plus some connective tissue cells constitute the juxtaglomerular apparatus (Fig. 28-4). A major function of the juxtaglomerular cells is to secrete renin, which thereby initiates the renin–angiotensin–aldosterone system.[2] When a decrease in sodium chloride concentration is sensed, the macula densa cells initiate two signals: one signal to reduce afferent arteriole tone (increasing afferent arteriole hydrostatic pressure) and a second to increase renin release from the juxtaglomerular cells.[2] In this manner, the juxtaglomerular apparatus helps maintain and promote glomerular filtration.

Glomerulus

The glomerulus consists of a tuft of capillaries fed by the afferent arteriole and drained by the efferent arteriole. The glomerulus is surrounded by Bowman's capsule. High hydrostatic pressure in the afferent arteriole causes rapid filtration. Fluid that is filtered from the capillaries into this capsule then flows into the tubular system, which is divided into four

Table 28-1 Nephron Functions

Nephron Structure	Function	Concentration of Filtrate Along the Nephron
Glomerulus	Free filtration of blood through Bowman's capsule to produce filtrate Hydrostatic and osmotic pressure forces create net filtration pressure	Isosmotic
Proximal convoluted tubule	Reabsorbs sodium, potassium, calcium, glucose, ketone bodies, and amino acids by active transport Reabsorbs chloride and bicarbonate by electromechanical gradient Reabsorbs water by osmosis Reabsorbs urea by diffusion	Isosmotic
Loop of Henle		
Thin descending limb	Reabsorbs sodium by active transport Further reabsorbs chloride by electromechanical gradient Reabsorbs water by osmosis Reabsorbs urea by diffusion	Isosmotic
Thick ascending limb	Reabsorbs sodium and chloride by active transport Blocks water reabsorption at thick ascending limb Reabsorbs bicarbonate by electromechanical gradient	Hypo-osmotic
Distal tubule	Reabsorbs sodium by active transport and aldosterone Reabsorbs water by osmosis Reabsorbs phosphorus, chloride, and bicarbonate by electromechanical gradient	Hypo-osmotic
Collecting tubule	Antidiuretic hormone promotes selective water reabsorption Secretes or reabsorbs bicarbonate and hydrogen ions to maintain pH Secretes potassium and hydrogen ions depending on body requirements or effects of drugs Secretes some creatinine Actively reabsorbs potassium	Depends on body requirements for fluid

sections: the proximal tubule, the loop of Henle, the distal tubule, and the collecting duct (see Fig. 28-3). Lower hydrostatic pressure in the efferent circulation allows reabsorption. Most of the water and electrolytes are reabsorbed into the blood in the peritubular capillaries that surround the tubular structures. The end products of metabolism remaining in the tubules pass into the urine.

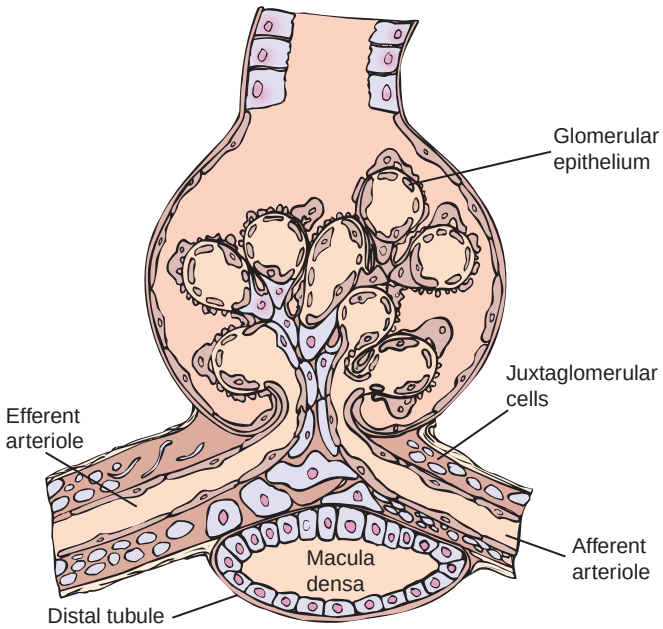

FIGURE 28-4 ▲ The juxtaglomerular apparatus. The macula densa cells lie in close proximity to the afferent and efferent arterioles, which help to regulate nephron functions.

Glomerular filtration is determined by net filtration pressure. Hydrostatic pressure and osmotic pressure forces are major factors. Hydrostatic pressure is driving or "pushing" pressure. Osmotic pressure is the pressure exerted by water (or any solvent) on a semipermeable membrane as it attempts to cross the membrane into an area containing more molecules that cannot cross the semipermeable membrane. The pores in the glomerular capillary make it a semipermeable membrane that permits smaller molecules and water to cross but prevents larger molecules (eg, plasma proteins) from crossing. Protein concentrations are the greatest factors in determining an osmotic pressure, and therefore, osmotic pressure is often referred to as colloid osmotic pressure. Four forces are considered when determining net filtration of fluid. (Fig. 28-5).

The rate at which the filtrate is formed is the GFR. Major clinical factors that influence the GFR are the blood hydrostatic pressure and the filtrate osmotic pressure. Hypoproteinemia, as in starvation, lowers filtrate osmotic pressure and increases the GFR.[3] The GFR decreases with severe hypotension because of a drop in blood hydrostatic pressure, when autoregulatory control may be lost. Other factors that decrease the hydrostatic pressure (and therefore the GFR) are afferent arteriole constriction and renal artery stenosis.

From the 20% to 25% of the cardiac output that goes to the kidneys in a resting adult, about 125 mL of filtrate is pro-

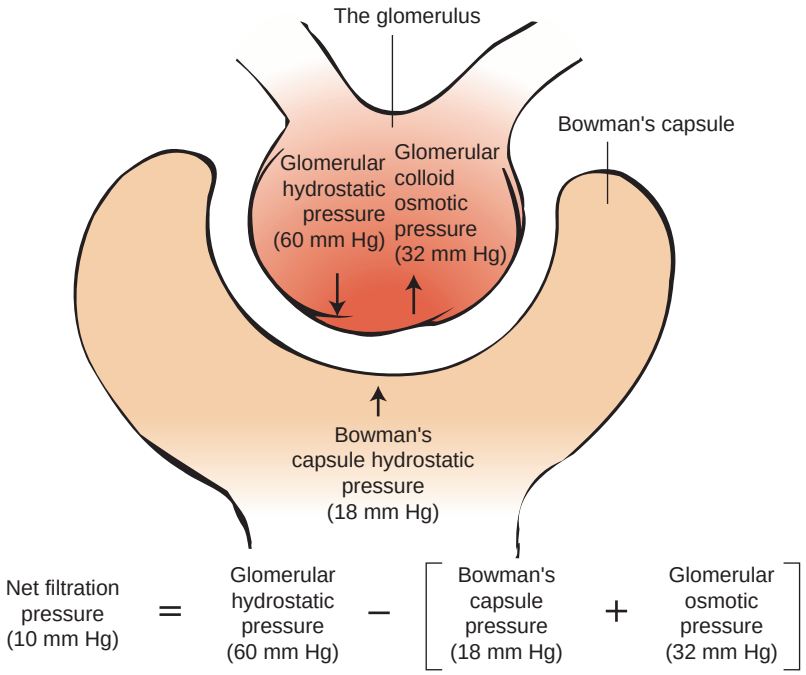

FIGURE 28-5 ▲ Interaction of hydrostatic and osmotic forces for glomerular filtration at Bowman's capsule.

duced each minute. This totals 180 L/d and is about 4.5 times the total amount of fluid in the body. Obviously, not all this filtrate can be excreted as urine. As this filtrate passes from Bowman's capsule through the remainder of the nephrons, all but about 1.5 L/d returns to the bloodstream. Similarly, at plasma glucose levels of less than 200 mg/dL, none of the filtered glucose is found in the urine when it enters the collecting tubules. The volume and content of the urine are the result of tubular reabsorption and tubular secretion.

Tubules

Tubular Reabsorption

Reabsorption is accomplished by active transport, osmosis, and diffusion. It occurs in all parts of the nephron as substances moving from the lumen into the peritubular capillaries.

ACTIVE TRANSPORT. Active transport involves the binding of a molecule of a substance to a carrier, which then moves the molecule from one side of the membrane to the other against the concentration gradient of that substance. Because it helps molecules to move in a direction opposite the one they would move by simple diffusion, the carrier acts like a pump. Many processes for active transport use the sodium–potassium pump. Therefore, the small oxygen requirements of the kidneys are closely linked to the active transport processes that occur in the nephron.

In tubular cells, the carrier is located in the cell membrane nearest the peritubular capillaries, and it transports material out of the tubular cell into the peritubular fluid. This lowers the intracellular concentration of the type of molecule being transported. The decreased concentration enables more of those molecules to diffuse from the urine (filtrate) into the tubule cell. These molecules, in turn, exit the cell and enter the peritubular fluid by active transport. The movement of molecules increases the peritubular fluid concentration of the molecule, and this increase stimulates the diffusion of the molecule into the peritubular capillaries. In the nephrons, reabsorption by active transport removes molecules from the filtrate (urine) back to the bloodstream.

Because active transport involves carrier molecules and energy exchanges, there is an upper limit to the number of molecules of a substance that can be transported at one time. This maximal limit for reabsorption rates is called T_{max}. Glucose is an example of a molecule that appears in the same concentrations that it appears in the blood. As serum glucose rises, filtrate glucose also rises. The renal tubules reabsorb the filtered glucose at faster and faster rates, until all of this molecule's active transport mechanisms are being used. At this T_{max}, more glucose is appearing in the filtrate than can be reabsorbed, and glucose is excreted in the urine. This "spilling" of glucose into the urine indicates serum levels higher than T_{max}.

OSMOSIS. The active transport of sodium is responsible for the osmotic reabsorption of water from the filtrate in the proximal (and later, in the distal) tubule. As sodium ions are actively transported out of the cell and into the peritubular fluid, they make the osmotic pressure of this peritubular fluid higher than that of the cellular or tubular fluid. Water is thereby osmotically "pulled out" of the tubular fluid. Both water and sodium then diffuse into peritubular capillaries and are returned to the bloodstream. This movement of positively charged sodium ions also creates an electrochemical gradient that draws negatively charged ions (especially chloride) out of the tubular fluid and back into the bloodstream.

DIFFUSION. Urea is an example of a molecule that is reabsorbed by diffusion. Under the high pressures in the glomerular capillaries, urea is filtered. In the tubules, as water is reabsorbed into the bloodstream, urea follows by simple diffusion. No selective permeability prevents its return to the bloodstream, and no transport mechanism is required. The

reabsorption rates of urea range from 40% to 60% of what is filtered and depend entirely on water reabsorption rates.

Tubular Secretion

Secretion involves active transport and is performed only by distal tubule cells. Substances move from the peritubular capillaries through tubule cells into the filtrate. Many substances that are secreted do not occur naturally in the body (eg, penicillin). Naturally occurring bodily substances that are secreted include uric acid, potassium, and hydrogen ions.

In the distal tubule, the active transport of sodium uses a carrier system that is also involved in the tubular secretion of hydrogen and potassium ions. In this relationship, every time the carrier transports sodium out of the tubular fluid, it also carries either a hydrogen ion or a potassium ion into the tubular fluid on its "return trip." Thus, for every sodium ion reabsorbed, a hydrogen or potassium ion must be secreted, and vice versa. The choice of cation to be secreted depends on the ECF concentration of these ions (hydrogen and potassium).

This cation exchange system in the distal tubule helps explain some of the relationships that these electrolytes have with one another. For example, it is clear why an aldosterone blocker (such as spironolactone) may cause hyperkalemia. The aldosterone blocker reduces sodium reabsorption. Such reduced reabsorption of sodium also reduces the tubular secretion of either hydrogen or potassium. The hydrogen excess can be buffered by bicarbonate, but the potassium simply rises to above-normal levels, leading to hyperkalemia. Similarly, the cation exchange system helps explain why there can be an initial decrease in plasma potassium in alkalosis or as severe acidosis is corrected therapeutically. In severe acidosis, the nephrons attempt to compensate by increasing hydrogen ion secretion. But as acidosis is therapeutically corrected (eg, by sodium bicarbonate administration), potassium ions are secreted. As hydrogen ions no longer need to be secreted, potassium ions become the sole exchange for sodium ions, leading, it is thought, to a reduction in plasma potassium.

▲ Hormonal Influences

Through the reabsorption of sodium and the passive "following" of water and chloride, it is possible to make urine of the same osmolality as blood. However, under conditions of dehydration, urine is very concentrated, whereas if a great deal of water is consumed, urine is more dilute than blood. This final regulation of urine (and, therefore, serum osmolality and volume) is under the influence of three hormones: ADH, renin, and aldosterone.

Antidiuretic Hormone

Osmoreceptors in the hypothalamus are sensitive to serum osmolality. During dehydration, when serum osmolality rises, osmoreceptors in the hypothalamus respond by stimulating the hypothalamus to secrete ADH, which increases the permeability of collecting tubule cells to water. This permits the reabsorption of water alone (without electrolytes), which in turn decreases the concentration of the ECF. Negative feedback loops regulate ADH secretion. This means that as the concentration of the ECF returns to normal, the stimulus for ADH secretion disappears, and ADH secretion stops.

Renin

Another hormone that influences urine concentration is renin. When the GFR falls because of dehydration or blood loss, the juxtaglomerular apparatus secretes renin.[1] Subnormal sodium levels in the filtrate also stimulate renin secretion. Renin converts angiotensinogen, which is secreted by the liver, into angiotensin I. Pulmonary capillary cells in turn convert angiotensin I into angiotensin II with angiotensin converting enzyme (ACE) (see Chapter 42, Fig. 42-9). Angiotensin II constricts the smooth muscle surrounding the arterioles. This increases blood pressure, which increases the GFR.

Aldosterone

Angiotensin II also triggers the secretion of aldosterone by the adrenal cortex (see Chapter 42, Fig. 42-9). Aldosterone is the third substance that influences urine osmolality. By increasing sodium reabsorption in distal tubule cells, aldosterone causes an increase in renal water reabsorption. This increases blood pressure and decreases serum osmolality. Simultaneously, potassium is excreted in the urine in exchange for the sodium reabsorption. Therefore, aldosterone also is secreted in response to subnormal serum sodium and elevated potassium levels.

▲ Functions of the Renal System

Renal Clearance

From the previous discussion, an important concept in renal function emerges: clearance. As the filtrate moves along the nephron, it contains a large proportion of metabolic end products. These products are removed (cleared) from the blood and exit the body in the urine. Indeed, of each 125 mL of glomerular filtrate formed per minute, about one half, or 60 mL, returns to the blood without urea, and about one half is excreted with urea. Stated another way, 60 mL of plasma is "cleared" of urea each minute in normally functioning kidneys. In the same way, the 125 mL of plasma is also cleared of creatinine, uric acid, potassium, sulfate, phosphate, and so forth each minute. It is possible to calculate renal clearance by simultaneously sampling urine and plasma. By dividing the quantity of substance found in each milliliter of plasma into the quantity found in the urine, the milliliters cleared per minute can be calculated. This method is used as one means of testing kidney function.

Other methods of assessing renal function involve chemicals that are known to be filtered only, or both filtered and secreted. The polysaccharide, inulin, for example, is filtered only and neither absorbed nor secreted. Therefore, the clearance of inulin provides a measure of glomerular filtration. The sodium concentration in the urine can also serve as an index of tubular health in certain situations. For example,

in acute renal failure, an increased clearance of sodium can indicate acute tubular necrosis. Accordingly, supernormal blood levels of filtered substances (creatinine and other nitrogenous wastes) indicate a decrease in glomerular filtration and therefore in nephron health.

Regulation

In addition to excreting nitrogenous wastes as urea and other by-products of metabolism, the kidneys help regulate the electrolyte concentration and the pH of the ECF (ie, the blood and ISF of the body).

Electrolyte Concentration

Electrolytes are substances that, when in water, disassociate and become charged. When charged, the solution is capable of carrying an electrical current. Positively charged electrolytes are cations; negatively charged electrolytes are anions. Most electrolytes are dissolved in body fluids, although some are bound to proteins or deposited as solids to form bones and teeth.

Despite the complex physiology associated with electrolytes, they have four main functions in homeostasis:

1. Cell metabolism and contribution to body structures
2. Facilitation of water movement between body compartments
3. Help in the maintenance of acid–base balance
4. Maintenance and production of membrane potentials in nerve and muscle cells

The functions of individual electrolytes are given in Table 28-2. For normal functions to occur, the concentration of electrolytes must be carefully maintained. Energy, usually in the form of adenosine triphosphate (ATP), is often required to maintain this balance. As described earlier in this chapter, the kidneys play a crucial role in electrolyte balance. In addition to being lost in the urine, electrolytes are lost from the gastrointestinal tract in the stool and emesis and through the skin in sweat.

SODIUM. The sodium content of a normal adult is approximately 142 mEq/L of ECF. As the most abundant extracellular electrolyte, sodium exerts an extracellular osmolality, thereby regulating movement of body fluids. Sodium plays a role in nerve impulses through active transport and the sodium–potassium pump. The balance of sodium is carefully regulated by the kidneys, with influences of aldosterone and ADH. Regulation occurs primarily through reabsorption (or excretion) in the proximal tubule under the influence of aldosterone.

POTASSIUM. In contrast to sodium, potassium is the most abundant intracellular electrolyte, with an approximate plasma concentration of only 4.5 mEq/L. Potassium, among other substances and factors, is critical in the maintenance of nervous and impulse conduction in the heart. Because of the small plasma concentration, potassium plays little role in osmotic regulation. Although some potassium may be lost in sweat and feces, the kidneys excrete approximately 80% to 90% of the potassium lost by the body. In cases of hyperkalemia, aldosterone release facilitates increased potassium excretion. Potassium also assists with acid–base regulation through the cellular exchange with hydrogen ions.

Table 28-2 Electrolyte Functions

Electrolyte	Normal Range	Functions
Sodium (Na^+)	135–145 mEq/L	Exerts an extracellular osmolality, thereby regulating movement of body fluids Facilitates nerve impulses through active transport and the sodium–potassium pump
Potassium (K^+)	3.5–5 mEq/L	Maintains nervous impulse conduction in the heart Promotes skeletal muscle function Plays small role in osmotic regulation Assists with acid–base regulation
Chloride (Cl^-)	100–110 mEq/L	Maintains electroneutrality by passively following the positively charged ions Helps regulate osmotic pressure differences between intracellular and extracellular fluid compartments Regulates body water balance with sodium Combines with H^+ in gastric mucosal cells to make hydrochloric acid
Calcium (Ca^{2+})	8.5–10.0 mg/dL (total) 4.4–5.4 mg/dL (ionized)	Major structural component of bones and teeth Plays role in blood coagulation Promotes muscle contraction and nervous impulse transmission Decreases neuromuscular irritability
Phosphorus (PO_4^-)	2.5–4.5 mg/dL	A structural component of bones and teeth Helps maintain acid–base balance Energy production (adenosine triphosphate) Delivery of oxygen to tissues as a component of 2,3-diphosphoglycerate
Magnesium (Mg^{2+})	1.8–2.5 mEq/L	Ensures the cross-membrane transport of sodium and potassium in the sodium–potassium pump Promotes neuromuscular excitability Plays role in heart contraction Facilitates transmission of central nervous system impulses Part of many enzymatic reactions for carbohydrate and protein metabolism

CHLORIDE. Chloride is the most abundant extracellular anion. Negatively charged, chloride passively follows the positively charged sodium to maintain electroneutrality. Chloride plays an important role in electroneutrality because all positive charges and negative charges must be in equilibrium. Therefore, chloride passively follows the secretion or reabsorption of the predominant cations, sodium and potassium. A large amount of chloride is also found in the gastric mucosal cells in the form of hydrochloric acid.

CALCIUM. Calcium has both structural and functional roles in homeostasis. In the form of calcium phosphate, it is the major structural component of bones and teeth. In the free, plasma form, calcium has a function in clotting, muscle contraction, and nervous impulse transmission. In the ionized form, about half is bound to plasma proteins, such as albumin.

Unlike the other electrolytes, calcium is absorbed from the small intestine under the influence of vitamin D, with the remaining ingested calcium lost in the feces. Excretion also occurs in the proximal convoluted tubule of the kidneys.

Parathyroid hormone (PTH) is produced and released by the parathyroid glands. A low calcium concentration stimulates its release. PTH facilitates the shift of calcium in its solid form (calcium phosphate, found in the bones) to its ionized form. PTH also increases the calcium absorbed from the intestine by signaling the kidneys to activate vitamin D. Reabsorption of calcium at the renal tubules is also increased under the influence of PTH. Calcitonin, secreted by the thyroid gland, is another hormone that plays a comparatively small role in calcium regulation. Calcitonin acts in opposition to PTH in an effort to reduce plasma calcium levels.

PHOSPHORUS. Like calcium, phosphorus has both structural and functional roles. Approximately 85% is found in the organic form in bones and teeth. The remaining phosphorus is in the inorganic, ionized forms, HPO_4^{2-} and $H_2PO_4^-$. Carried in two forms, phosphate is able to accept or donate an ion, thereby assisting with acid–base balance. The intracellular ionized form plays a role in many critical metabolic processes, with its primary function being the formation of ATP. Phosphorus is required for the delivery of oxygen to tissues because it is the primary substrate for 2,3-diphosphoglycerate.

PTH regulates phosphorus, with effects directly opposite those of calcium. PTH causes an increase in calcium plasma concentration and promotes excretion of phosphorus. PTH also causes release of phosphorus in the bones and shifts it to the ECF. Presumably, this would cause an increase in phosphorus; however, PTH also decreases the transport of phosphate ions by the kidney tubules, so more phosphate ions are lost in the urine.

MAGNESIUM. Magnesium is a predominantly intracellular ion. Magnesium ensures the cross-membrane transport of sodium and potassium in the sodium–potassium pump. In addition, magnesium functions in the maintenance of neuromuscular excitability and in the transmission of central nervous system impulses. It also plays a role in enzymatic reactions for carbohydrate and protein metabolism. Often, reactions requiring calcium require magnesium as well.

pH. If respiratory buffers for pH regulation are insufficient, the kidneys begin to take part, although much more slowly than the lungs. Although respiratory control of carbon dioxide, and therefore hydrogen ion levels, can take only seconds to achieve, 48 to 72 hours may pass before the renal system can change the serum acid–base balance significantly.

Alkalosis occurs as a result of too few hydrogen ions or too many bicarbonate ions. To compensate, the body must conserve hydrogen ions. In renal compensation for alkalosis, tubular reabsorption of hydrogen ions is increased and secretion is decreased. This increases the hydrogen ion concentration of the ECF and thereby decreases the alkalosis.

Acidosis occurs as a result of too many hydrogen ions or too few bicarbonate ions. To compensate, the body must secrete hydrogen ions. Renal compensation for acidosis involves increasing the hydrogen ion secretion of the tubule cells, especially in the distal tubule cells. In this case, bicarbonate and sodium ions are continually being filtered from the glomerulus. Also, hydrogen ion secretion by distal tubule cells causes an increase in sodium reabsorption. Such sodium reabsorption can increase bicarbonate reabsorption electrochemically. Therefore, as hydrogen ions are being eliminated from the ECF, sodium and bicarbonate ions are being added to it. Both serve to decrease the acidosis (Fig. 28-6).

Urine can be acidified (by hydrogen ion secretion) only to a pH level of 4.0 to 4.5. If the tubular secretion of hydrogen ions was the only mechanism operating, only a few hydrogen ions could be secreted before the critical shut-off level of 4.0 was reached. This would occur because hydrogen would combine with urinary chloride to make hydrochloric acid. Not many of these strong hydrochloric acid molecules are needed to make the urine pH 4.0. The formation of hydrochloric acid would then stop tubular hydrogen ion secretion before sufficient compensation for acidosis could be obtained. This does not occur because tubule cells deaminate certain amino acids and secrete the nitrogenous component as ammonia. This ammonia combines with hydrogen in the urine to form ammonium. Because tubule membranes are not permeable to ammonium, much of it is secreted in this form. Some ammonia combines with chloride to form ammonium chloride.

Fluid Balance

The body contains about 60% water in most individuals.[4] This percentage may vary between 50% and 70%, depending on a person's fat content. Adipose tissue has very low water, and therefore people with more fat have a lower percentage of body weight as water. Women have a tendency to have higher body fat percentages than men and therefore have lower total-body water (usually around 50%).[4]

Water is distributed among the two main compartments in the body: intracellular fluid (ICF) and ECF. The ICF is the amount of volume within the cell and makes up about two thirds of the total-body water, or about 40% of the body weight. Primarily, the ICF is a solution of ions, including potassium, proteins, and organic ions. The ECF represents the remaining one third of the body water, or about 20% of the body weight. The solution primarily contains sodium chloride and bicarbonate. Figure 28-7 illustrates the different body water compartments.

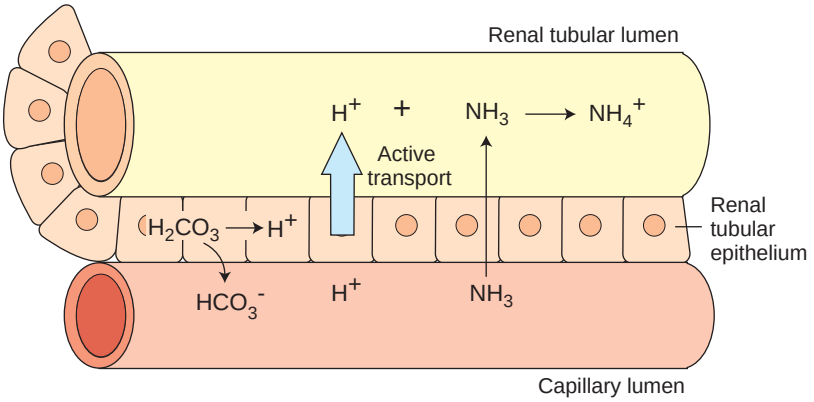

FIGURE 28-6 ▲ Renal compensation for acidosis. Hydrogen (H^+) is moved from blood into the filtrate by active transport and exits in the urine as ammonium (NH_4^+). HCO_3^-, bicarbonate; NH_3, ammonia.

There are three subcompartments to the ECF: the ISF, the plasma, and the transcellular fluid. ISF surrounds the cells but does not circulate. This subcompartment makes up about three fourths of the ECF. The second subcompartment of the ECF is the plasma, which circulates as the extracellular component of blood. Plasma makes up about one fourth of the ECF.

The third subcompartment of ECF is called transcellular fluid. This fluid is neither in the plasma nor in the interstitium; instead, it is the fluid that makes up the digestive juices, cerebrospinal fluid, synovial fluid, pericardial fluid, and mucus. Although the transcellular fluid is only about 1 to 2 L in total (<1 pound), it plays a very important role in homeostasis. Transcellular fluid helps cushion the heart with each beat, makes joint movement smooth, carries critical oxygen and glucose to the brain, and removes bacteria and antigens from the respiratory tract.

There is a constant movement of water between body compartments. For example, in diseases in which there is a lack of plasma oncotic pressure (eg, liver disease), there may be excessive movement of fluid from the plasma to the interstitium. This additional ISF is reabsorbed by the lymph for recirculation; however, the volume that the lymph system is capable of holding becomes overwhelmed. This then causes edema formation. During times of dehydration, hormonal influences are recruited to pull additional ICF, ISF, and transcellular water into the plasma to maintain effective circulating volume.

Several factors may influence body water. Body water moves between compartments and is regulated by hormones, such as ADH, aldosterone, and atrial natriuretic peptide. Approximately 2.5 L of water are lost each day through normal bodily functions, such as urination, defecation, respiration, and sweating. This volume of water lost must be replaced. As people age, there is a decrease in total-body water as the ratio of muscle to fat changes. As fat increases, total-body water decreases. In part, this physiological change accounts for the older adult's propensity for dehydration.

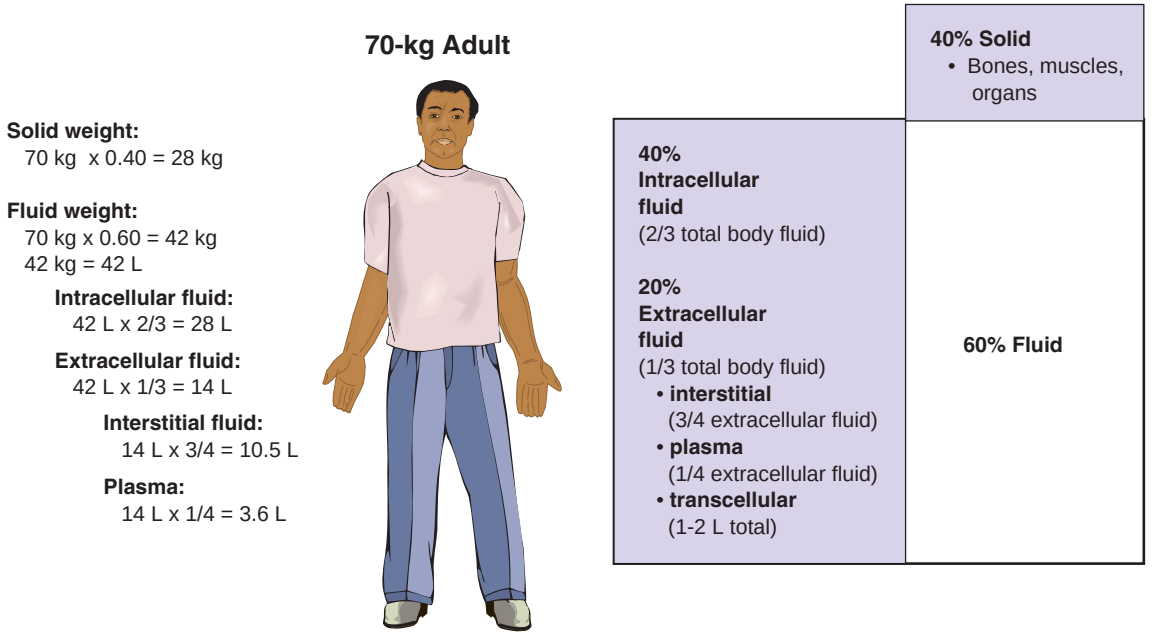

FIGURE 28-7 ▲ Body water compartments.

Other Renal Functions

Renal interstitial (not nephron) cells manufacture and secrete two hormones, calcitriol (vitamin D) and erythropoietin, the actions of which are unrelated to urine formation. Calcitriol is a hormone that increases plasma calcium concentration by increasing intestinal absorption of calcium, promoting bone resorption, and stimulating the renal tubular reabsorption of calcium. Erythropoietin is a glycoprotein hormone that stimulates the bone marrow to produce red blood cells. Any process that decreases the oxygen content in the blood, such as bleeding or hypoxemia, is sensed by the kidney and initiates the release of erythropoietin. This increases the arterial oxygen content required to maintain cell integrity.

The kidneys also activate vitamin D. Ingested with food, vitamin D is absorbed in an inert form. The kidneys activate vitamin D so that it may assist in the absorption of calcium, which occurs in the intestines. Calcium has many functions as discussed earlier in this chapter. If renal failure occurs, there is a marked reduction in vitamin D and subsequently bioavailable calcium, thereby putting the patient at risk for bone diseases (such as osteoporosis) and bleeding.

▲ Clinical Applicability Challenges

SHORT ANSWER QUESTIONS

1. Describe the role of the macula densa in autoregulation.
2. A 65-year-old patient is admitted to your unit. On your health history, you note a history of elevated blood glucose levels. The patient states that his primary provider has him checking his urine for "sugar" on office visits, but he cannot understand why he needs to do that since he was told that he had elevated sugar levels in the blood. Describe the physiological processes involved in using the urine glucose level as an estimate for serum glucose level.

29 Patient Assessment: Renal System

Kara Adams Snyder and Kelley Caldwell Crusius

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Formulate a plan for collecting history and physical examination data for patients with renal disorders and fluid and electrolyte imbalance.
2. Describe diagnostic and laboratory blood tests used to evaluate renal and electrolyte status.
3. Discuss methods to evaluate fluid balance.

Assessment of the renal system involves determining how well the kidneys perform their many functions. It also includes gathering information about other systems. A careful assessment of the history and physical findings, with interpretation of laboratory and diagnostic test results, provides early clues to the diagnosis of disorders of water and volume imbalance and other complications of renal dysfunction in the critically ill patient.

▲ History

The patient history provides important information that helps determine the cause, severity, treatment, and management of renal dysfunction. It involves gathering information about the present illness, past health history, family history, personal history, and social history. In addition, relevant information about the status of other body systems is gathered through a review of systems. A guide for renal assessment is summarized in Box 29-1.

▲ Physical Examination

The physical examination provides objective data that are used to substantiate and clarify the history. The nurse begins the physical examination by observing the patient's overall appearance, including facial expression, height and weight, position in bed, grooming, personal hygiene, and signs of distress. The nurse observes the patient's level of responsiveness, cognition, and interaction with people, including positive, negative, or unusual responses.

Because patients with renal problems usually have significant problems with fluid and electrolyte balance, the nurse evaluates the patient's volume status throughout the examination. The nurse begins by taking the vital signs. Particular attention is paid to the blood pressure, noting pulse pressure and presence of a positive pulse paradoxus. An elevated temperature may indicate an infection.

Throughout the physical examination, the nurse inspects the skin on the extremities and trunk for color and evidence of excoriation, bruising, or bleeding; palpates for moistness, dryness, temperature (using the back of the fingers), and edema; and checks mobility and turgor by lifting a fold of skin and noting the ease (mobility) and speed with which it returns into place (turgor). To assess hydration further, the nurse inspects the tongue and mucous membranes in the mouth and looks for a saliva pool under the tongue. Additional volume status assessment is done when examining the neck, as the nurse observes for jugular vein distention and determines the need to measure jugular venous pressure.

The anterior and posterior chest is inspected for respiratory rate, rhythm, depth, and effort. Deformities of the thorax, shape of chest, or bulging of interspaces during expiration are noted. The precordial area is observed and palpated for heaves, pulsations, and thrills. The nurse listens for heart rate and rhythm, extra heart sounds, murmurs, clicks, and pericardial friction rub. Fluid overload often results in the presence of a third or fourth heart sound.

Anterior and posterior lung fields are auscultated. The nurse notes the quality of vesicular breath sounds and the presence of adventitious breath sounds (crackles, wheezes, rubs), which may indicate volume overload.

After auscultating the posterior chest, the nurse can assess kidney tenderness. To do this, the nurse places one hand over the posterior costovertebral angle (CVA). Then, using the fist of the second hand, the nurse gently percusses the CVA and notes whether the patient has discomfort (Fig. 29-1), which is known as CVA tenderness (CVAT).

The nurse inspects the abdomen and then listens for bowel sounds. In addition to auscultating bowel sounds, the nurse auscultates the renal arteries for bruits by placing the stethoscope above and to the left and right of the umbilicus (Fig. 29-2). A bruit is an abnormal sound that resembles a blowing or swishing noise, similar to the sound of a cardiac

BOX 29-1 HEALTH HISTORY for Renal Assessment

Chief Complaint
- Patient's description of the problem

History of the Present Illness
- Complete analysis of the following signs and symptoms (using the NOPQRST format, see Chapter 17, Box 17-1, p. 207).
- Frequency
- Urgency
- Hesitancy
- Burning
- Dysuria
- Hematuria
- Incontinence
- Lower back pain
- Pain with urination
- Change in color, odor, or amount of urine
- Thirst
- Change in weight
- Edema

Past Health History
- Relevant antenatal history and immunizations: prematurity; antenatal use of angiotensin-converting enzyme inhibitors, angiotensin-receptor blockers, or nonsteroidal antiinflammatory drugs (NSAIDs; eg, ibuprofen); ensuring antenatal vaccination against rubella; screening for cytomegalovirus or toxoplasmosis
- Past acute and chronic medical problems, including treatments and hospitalizations: renal failure; renal calculi; renal cancer; glomerulonephritis; Wegener's granulomatosis; polycystic kidney disease; dialysis, including type, frequency, and duration; urinary tract infections; systemic lupus erythematosus; sickle cell anemia; cancer; AIDS; hepatitis C; heart failure; diabetes; hypertension
- Risk factors: age; trauma; heavy use of ibuprofen, naproxen, or acetaminophen; use of heroin or cocaine
- Past surgeries: kidney transplantation, placement of dialysis fistula
- Past diagnostic tests and interventions: urinalysis, cystoscopy, intravenous pyelography, ultrasound of kidneys, renal biopsy, magnetic resonance imaging, diagnostic tests that have used contrast dyes
- Medications: diuretics, aminoglycosides, antibiotics, NSAIDs
- Allergies and reactions: radiographic contrast media
- Transfusions

Family History
- Health status or cause of death of parents and siblings: hereditary nephritis, polycystic kidney disease, diabetes, high blood pressure

Personal and Social History
- Tobacco, alcohol, and substance use
- Family composition
- Occupation and work environment: exposure to nephrotoxic substances such as organic acids, pesticides, lead, and mercury
- Living environment: exposure to nephrotoxic substances such as organic acids, pesticides, lead, mercury
- Diet
- Sleep patterns
- Exercise
- Cultural beliefs
- Spiritual and religious beliefs
- Coping patterns and social support systems
- Leisure activities
- Sexual activity
- Recent travel

Review of Systems
- Skin: dryness, itching
- HEENT: periorbital edema
- Cardiovascular: hypertension, heart failure, vascular disease
- Respiratory: Goodpasture's syndrome
- Gastrointestinal (GI): hepatitis, cirrhosis
- Endocrine: diabetes mellitus
- Neurological: numbness, tingling, burning, tremors, memory loss
- Hematological: sickle cell anemia
- Immune: systemic lupus erythematosus
- Musculoskeletal: rhabdomyolysis, muscle weakness

murmur. The presence of a renal bruit may indicate renal artery stenosis, which means there may be diminished blood flow to the kidney. This diminished blood flow may result in acute or chronic renal dysfunction.

Next, the nurse percusses and palpates the abdomen and then palpates the liver border to determine enlargement. If ascites is suspected, the nurse measures abdominal girth and may check for a fluid wave or shifting dullness. During the abdominal examination, the right and left kidneys are palpated by placing one hand under the patient's flank and placing the other examining hand in the quadrant just below the costal margin at the mid-clavicular line. The kidneys are normally not palpable. An enlarged kidney may be palpable, and the enlargement may be due to a cyst, tumor, or hydronephrosis (Fig. 29-3). If indicated by history, the nurse may palpate and percuss the bladder. The bladder cannot be palpated unless it is distended above the symphysis pubis. When palpated, the dome of the distended bladder feels smooth and round. For palpation and percussion of the bladder, the nurse begins at the symphysis pubis and moves upward and outward to estimate the bladder size. A full bladder is dull to percussion (Fig. 29-4).

If the patient is at risk for excess vascular volume, the nurse looks for hypertension; pulmonary edema; crackles; engorged, elevated neck veins; liver congestion and enlargement; heart failure; and shortness of breath. Signs and symptoms related to excess extravascular volume include pitting edema of feet, ankles, hands, and fingers; periorbital edema; sacral edema; and ascites. Table 29-1 presents a scale used to document levels of pitting edema.

While examining the extremities, the nurse can check the quality of the peripheral pulses; observe for tremors; test for paresthesia, numbness, and weakness; and palpate fingernails and toenails, checking for color, shape, and capillary refill time.

If the patient has an arteriovenous graft or fistula for dialysis, the nurse assesses it for patency and for adequate circulation to the extremity distal to the access. Palpating for a thrill and auscultating for a bruit help to assess patency of the graft. If assessment reveals a change, the physician or practitioner must be notified urgently because the graft may be saved through radiological or surgical intervention. If the patient has temporary dialysis access, the exit site is inspected for signs of inflammation or infection. Often the lumens of the

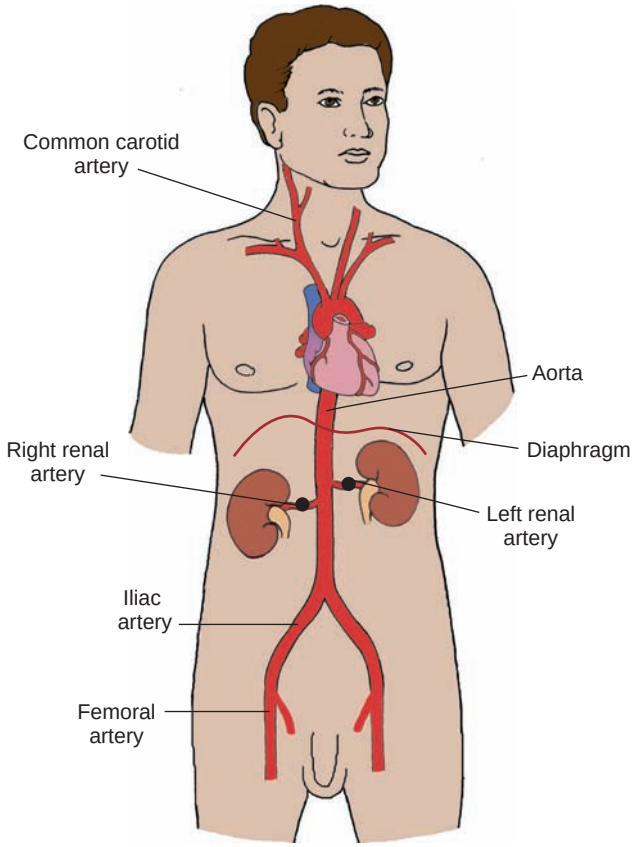

FIGURE 29-2 ▲ Sites for auscultation of renal bruits.

temporary access have high doses of heparin to maintain patency, so flushing or use of the device is clarified with the physician or practitioner before any manipulation or use of the catheter.

Patients with renal impairment may be at risk for hypocalcemia, hypomagnesemia, or both. Physical assessment of these electrolyte changes can be achieved by checking for Chvostek's and Trousseau's signs. Chvostek's sign occurs when there is facial irritability after tapping the facial nerve in front of the auditory meatus with the finger. Trousseau's sign occurs when there is spasm of the hands and feet (carpopedal spasm) in response to arm compression (eg, as with a blood pressure cuff).

During the history and examination, the critical care nurse continuously observes the patient's level of consciousness and mental status. If more data are needed, the nurse may use tools such as the Glasgow Coma Scale and Folstein Mini-Mental Examination.

Laboratory Studies

Urine Studies

URINALYSIS. The nurse inspects the urine for color, clarity, and odor. Normally, the urine is clear and yellow to straw-colored and smells of ammonia. Changes in the characteristics of the urine can indicate kidney damage, infection, excretion of drugs, or the kidney's compensation for systemic homeostatic imbalance. Cloudy urine may indicate infection, whereas very clear and colorless urine may be a sign of diuresis, either induced pharmacologically or by diabetes insipidus. Blood in the urine may appear bright red or dark brown. If hematuria is present, additional evaluation and follow-up with specialists may be considered to investigate the presence of a malignancy.[1] Urinalysis is used to identify more specifically the components of the urine. Table 29-2 summarizes the components of the urinalysis.

URINE VOLUME. The difference between the glomerular filtration rate (GFR) and the amount of water reabsorbed determines the urine volume. A patient with normal renal function, filters 180 L daily and must reabsorb approximately 179 L. This is the equivalent of roughly greater than 99% of filtered volume. Patients with renal disease and impairment may actually excrete an appropriate amount of urine. For example, a patient with severe renal disease may have a GFR of 10 L but still filter 1 liter or 90% reabsorption. Thus, urine volume is of little diagnostic importance in this setting. However, urine volume is important in the setting of acute anuria. In acute anuria, a patient may be making normal volume and experience an abrupt change in pattern. Causes of acute anuria include:

- Complete bilateral obstruction (ie, abdominal compartment syndrome)
- Glomerulonephritis
- Bilateral vascular occlusion

However, trends in urine production can provide important clues to the body's recruitment of important compensatory responses, as in hypovolemia. The body initiates the renin–angiotensin–aldosterone system to maintain the crucial water balance (see Chapter 28).

URINE pH. Normal urinary pH is acidic, with a range between 5.0 and 6.5, depending primarily on dietary intake. The kidneys play a tremendous role in acid–base balance (see Chapter 28). Clinically, urinary pH is important in two settings. First, an alkaline urinary pH (above 7.5) suggests the presence of a urinary tract infection. Second, a low, or acidic, pH indicates that the kidney may be compensating for a serum acidosis. Physiologically, in this state, the kidneys reabsorb more bicarbonate and excrete more hydrogen ions to buffer the serum acidosis. The urine becomes increasingly acidic (lower pH) when the body is attempting to conserve sodium, as in states of dehydration.

URINE PROTEIN. Most proteins are large molecules and under normal conditions should not penetrate Bowman's capsule. Normal urinary protein levels, therefore, are zero to trace. Proteinuria usually indicates damage to the capillary structures, as in the case of glomerular diseases (glomerulonephritis) and intrarenal acute kidney injury. For diagnostic purposes, a 24-hour sample of urine is used to assess for proteinuria. Single dipstick measurements are not as sensitive and may lead to false-positive values.

Table 29-1 Assessing Pitting Edema

Scale	Description	Depth of Indentation (mm)	Return to Baseline
4+	Severe	8	2–5 min
3+	Moderate	6	1–2 min
2+	Mild	4	10–15 s
1+	Trace	2	Disappears rapidly

Table 29-2 What Urinalysis Findings Mean

Test	Normal Values or Findings	Abnormal Findings	Possible Causes of Abnormal Findings
Color and odor	• Straw color	Clear to black	Dietary changes; use of certain drugs, metabolic inflammatory, or infectious disease
	• Slightly aromatic odor	Fruity odor	Diabetes mellitus, starvation, dehydration
	• Clear appearance	Turbid appearance	Renal infection
Specific gravity	• Between 1.005 and 1.030, with slight variations from one specimen to the next	Below-normal specific gravity	Diabetes insipidus, glomerulonephritis, pyelonephritis, acute renal failure (ARF), alkalosis
		Above-normal specific gravity	Dehydration, nephrosis
		Fixed specific gravity	Severe renal damage
pH	• Between 4.5 and 8.0	Alkaline pH (above 8.0)	Fanconi's syndrome (chronic renal disease) urinary tract infection, metabolic or respiratory alkalosis
		Acidic pH (below 4.5)	Renal tuberculosis, phenylketonuria, acidosis
Protein	• No protein	Proteinuria	Renal disease (such as glomerulosclerosis, acute or chronic glomerulonephritis, nephrolithiasis, polycystic kidney disease, and acute or chronic renal failure)
Ketones	• No ketones	Ketonuria	Diabetes mellitus, starvation, conditions causing acutely increased metabolic demands and decreased food intake (such as vomiting and diarrhea)
Glucose	• No glucose	Glycosuria	Diabetes mellitus
Red blood cells (RBCs)	• 0–3 RBCs/high-power field	Numerous RBCs	Urinary tract infection, obstruction, inflammation trauma, or tumor; glomerulonephritis; renal hypertension; lupus nephritis; renal tuberculosis; renal vein thrombosis; hydronephrosis; pyelonephritis; parasitic bladder infection; polyarteritis nodosa; hemorrhagic disorder
Epithelial cells	• Few epithelial cells	Excessive epithelial cells	Renal tubular degeneration
White blood cells (WBCs)	• 0–4 WBCs/high-power field	Numerous WBCs	Urinary tract inflammation, especially cystitis or pyelonephritis
		Numerous WBCs and WBC casts	Renal infection (such as acute pyelonephritis and glomerulonephritis, nephrotic syndrome, pyogenic infection, and lupus nephritis)
Casts	• No casts (except occasional hyaline casts)	Excessive casts	Renal disease
		Excessive hyaline casts	Renal parenchymal disease, inflammation, glomerular capillary membrane trauma
		Epithelial casts	Renal tubular damage, nephrosis, eclampsia, chronic lead intoxication
		Fatty, waxy casts	Nephrotic syndrome, chronic renal disease, diabetes mellitus
		RBC casts	Renal parenchymal disease (especially glomerulonephritis), renal infarction, subacute bacterial endocarditis, sickle cell anemia, blood dyscrasias, malignant hypertension, collagen disease
Crystals	• Some crystals	Numerous calcium oxalate crystals	Hypercalcemia
		Cystine crystals (cystinuria)	Inborn metabolic error
Yeast cells	• No yeast crystals	Yeast cells in sediment	External genitalia contamination, vaginitis, urethritis, prostatovesiculitis
Parasites	• No parasites	Parasites in sediment	External genitalia contamination
Creatinine clearance	• Male (age 20): 90 mg/min/173 m^2 of body surface	Above-normal creatinine clearance	Little diagnostic significance
	• Female (age 20): 84 mL/min/1.73 m^2 of body surface	Below-normal creatinine clearance	Reduced renal blood flow (associated with shock or renal artery obstruction), acute tubular necrosis, acute or chronic glomerulonephritis, advanced bilateral renal lesions (as in polycystic kidney disease, renal tuberculosis, and cancer), nephrosclerosis, heart failure, severe dehydration
	• Older patients: normally decreased concentrations by 6 mL/min/decade		

From Critical Care Nursing Made Incredibly Easy, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2008, pp 505–506.

URINE GLUCOSE AND KETONES. Glucose, like most proteins, is not present in the urine under normal conditions. Unlike proteins, however, glucose is freely filtered but is reabsorbed in the proximal tubule. Glucose becomes detectable if the serum glucose is elevated (>200 mg/dL) as the filtered load exceeds the kidney's reabsorptive abilities. Findings of glucosuria should be confirmed with serum or capillary blood glucose measurement.

Ketone bodies are byproducts of fat metabolism and are formed in states of insulin deficiency. Three ketone bodies are formed: β-hydroxybutyric acid (the primary ketone formed), acetoacetic acid, and acetone. The latter two ketone bodies are detected in the urine. Acetone may be measured in the serum. A urine sample that is positive for ketones may indicate diabetic ketoacidosis.

URINARY SEDIMENT. Sediment is particulate matter that, when examined, can reveal certain physiological conditions in the renal system. Sediment in general refers to casts, red cells, white cells, epithelial cells, and crystals. Casts are the breakdown products of cellular material formed in the collecting tubules. Urinary stasis, as in prerenal disease, may promote cast formation. Casts can be made up of different types of cells, and thus, the shape, composition, and size of the casts can help in identifying the presence and etiology of a disease.

Red Blood Cells. Red blood cells (RBCs) may be microscopic (microscopic hematuria) or grossly visible (macroscopic hematuria). RBCs enter the urine anywhere along the urinary tract. Any injury or damage to the structures making up the urinary tract can cause hematuria. Kidney stones, trauma, and prostatic disease are examples of extrarenal causes of hematuria (ie, not related to the kidneys).

Microscopic bleeding can be present in glomerular diseases, such as glomerulonephritis. When assessing the results of the urinalysis, take note of the presence of RBC casts and the RBC morphology. Glomerular bleeding is often associated with some type of fragmentation of the RBC, whereas extrarenal bleeding often leaves the cell intact. The presence of RBC casts is virtually diagnostic of glomerulonephritis.

Myoglobin in the urine makes the urine appear red; however, when the urine is inspected under the microscope, there is no evidence of RBCs. Myoglobin is a component of skeletal muscle breakdown, or rhabdomyolysis. Crush injuries or protracted down times are the greatest predictors of this disease. When muscle begins to break down, it releases the myoglobin, which is similar in chemical structure to hemoglobin. Because of its large molecular size, myoglobin blocks the renal tubules, placing patients at very high risk for intrarenal acute kidney injury.

White Blood Cells. White blood cells (WBCs) in the urine (pyuria) usually indicate infection anywhere along the urinary tract. Leukocyte esterase is an enzyme produced by WBCs along the urinary tract that can be detected in the urine. This enzyme is present along the urinary tract as a component of the local immune response. High levels of this enzyme can indicate infection. The presence of nitrites may also aid in the diagnosis of a bacterial infection along the urinary tract.

SPECIFIC GRAVITY AND OSMOLALITY. The specific gravity of the urine tests the kidneys' ability to concentrate and dilute the urine. The specific gravity measures the buoyancy of a solution compared with water and depends on the number of particles in the solution and their size and weight. Three methods are used to obtain this measurement in clinical practice: a multiple-test dipstick that has a reagent area for specific gravity, the urinometer, and the refractometer (TS meter). The multiple-test dipstick has a poor sensitivity and can therefore miss problems that are actually present. The urinometer has been in clinical use for many years and requires enough urine to float the urinometer. Its results are questionable. The refractometer gives highly reproducible results and requires only one drop of urine for the measurement. In addition, this instrument can be used to measure the total solids in plasma (hence the name, TS meter), which is a good indicator of the plasma protein concentration and can be a useful indicator of a patient's fluid balance (especially if serial determinations are done).

The normal kidney has the capacity to dilute the urine to a specific gravity of 1.001 and to concentrate the urine to at least 1.022. For reference, the specific gravity of water is 1.000. Normally, a person's water balance determines whether the urine is concentrated or dilute; dilute urine is an indicator of water excess, and concentrated urine indicates water deficit. In many renal diseases, the ability of the kidneys to form concentrated urine is lost, and the specific gravity can become "fixed" at approximately 1.010. Often, this finding is seen in acute tubular necrosis, acute nephritis, and chronic renal disease. A falsely high specific gravity can be seen when high-molecular-weight substances, such as protein, glucose, mannitol, and radiographic contrast material, are present in the urine. Therefore, a greater degree of accuracy can be obtained by checking the urine osmolality in these cases.

Osmolality measures the osmoles of solute particles present per kilogram of solvent. The main determinants of osmolality are the sodium, urea, and glucose. In states of volume depletion or excess, several neuroendocrine responses interact to maintain homeostasis, thereby affecting the urinary osmolality. Because of this dynamic interaction, particularly in critical illness, single measurements of the osmolality are of little diagnostic importance. The urinary osmolality is often followed for the evaluation of patients with hyponatremia.

Normal urine osmolality ranges from 300 to 900 mOsm/kg/24 h. Because of this wide range, more information about renal function is obtained when simultaneous serum and urine samples are collected and interpreted. In renal disease, one of the first functions to be lost is the ability to concentrate urine. This can result in the urine osmolality becoming fixed within 150 mOsm of the simultaneously determined serum osmolality.

URINARY SODIUM CONCENTRATION. The urinary sodium excretion is used as an indicator of renal function in differentiating the oliguria associated with acute kidney injury from other prerenal causes. States of poor kidney perfusion are usually associated with a decrease in urinary sodium concentration (usually <10 mEq/L). This is a compensatory reaction generated by the activation of the renin–angiotensin–aldosterone system. Activation of this neuroendocrine response allows for increased reabsorption of sodium (reduced excretion) with a subsequent increase in water reabsorption. The root cause of kidney hypoperfusion can be anything that causes a reduction in effective circulating volume: Volume depletion and heart failure are two examples. Acute kidney injury may develop if hypoperfusion persists. In acute kidney injury, urine sodium concentration usually is greater than 30 to 40 mEq/L despite oliguria because of damage to the

tubular transport mechanisms. However, when the urine pH is alkaline, urine sodium concentration does not reflect sodium balance accurately, and the chloride concentration becomes a better indicator of volume status.

FRACTIONAL EXCRETION OF SODIUM TEST. The fractional excretion of sodium (FE_{Na}) test gives a more precise estimation of the amount of filtered sodium that remains in the urine and is more accurate in predicting tubular injury than the urinary sodium concentration.[2] One benefit of the FE_{Na} compared with the urinary sodium is that it removes the confounding effect of water. It can be calculated by using the following formula:

$$FE_{Na} = \frac{U_{Na} \times P_{Cr}}{P_{Na} \times U_{Cr}}$$

where U and P are the urinary and plasma concentrations of sodium and creatinine, respectively. (Although volume measurements are necessary to derive the absolute urinary excretion of both sodium and creatinine, these cancel out in deriving the formula.)

The FE_{Na} test requires the determination of both serum and urinary sodium and creatinine concentrations on simultaneously obtained samples. Values less than 1% indicate transient acute kidney injury, typically caused by underperfusion. Values greater than 1% (and frequently >3%) are indicative persistent acute kidney injury. Some situations render a falsely low (<1%) FE_{Na}, including glomerulonephritis, myoglobinuric renal failure, contrast nephropathy, renal transplant rejection, acute interstitial nephritis, and acute urinary tract obstruction.[2] FE_{Na} is also a poor indicator of renal function in patients who have received diuretic therapy.[2]

Blood Studies

CREATININE AND CREATININE CLEARANCE. Creatinine is a byproduct of normal muscle metabolism and is excreted in the urine primarily as the result of glomerular filtration, with a small percentage secreted into the urine by the kidney tubules. Therefore, creatinine is currently the most useful indicator of GFR. The amount of creatinine excreted in the urine is directly related to muscle mass and normally remains constant unless significant muscle wasting (a catabolic state) occurs. Normal serum values for creatinine are 0.6 to 1.2 mg/dL.

The creatinine clearance can be defined as the amount of blood that is cleared of creatinine in 1 minute and is an excellent clinical indicator of renal function. As renal function diminishes, creatinine clearance decreases. To obtain an accurate creatinine clearance, the nurse collects all urine made in a 24-hour period and obtains a blood specimen at some point during the urine collection. Thus, it is essential for the nurse to communicate to other team members that a 24-hour collection is in progress. For consistency, the blood sample is usually collected at the midpoint of the urine collection. It is important to note the exact beginning and ending times of the urine collection.

The actual creatinine clearance is calculated by the following formula:

$$CrCl = \frac{U_{Cr} \times V}{P_{Cr}}$$

where U is the urine creatinine concentration, V the urine volume, and P the plasma creatinine concentration.

The product U multiplied by V tells how much creatinine appears in the urine during the period of collection. This can be converted readily to milligrams per minute, which is the standard reference point. Dividing this value by the plasma creatinine concentration (which must be converted from milligrams per 100 mL to milligrams per milliliter) tells the minimal number of milliliters of plasma that must have been filtered by the glomeruli to produce the measured amount of creatinine in the urine. The final result is usually expressed in milliliters per minute. The normal range varies between 80 and 120 mL/min, depending on the person's size, age, and sex. The results can be adjusted to a standard body size of 1.73 m^2 (body surface area [BSA]), which can be derived from standard tables if the patient's height and weight are known; it averages between 120 and 125 mL/min/1.73 m^2 BSA. After age 40 years, normal creatinine clearance values generally decrease 6.5 mL/min per decade because of a decline in GFR.

There are also formulas that estimate creatinine clearance based on a single serum creatinine level. An estimate may be made when there is difficulty collecting a 24-hour urine sample or when spot-checking the creatinine clearance will assist prompt treatment (as in the case of drug nephrotoxicity). The estimate may be accurate only in patients with chronic renal failure with stable renal function who are not edematous or extremely overweight. The following is the Cockcroft-Gault formula for estimating creatinine clearance:

$$\text{Creatinine Clearance} = \frac{(140 - \text{age}) \times \text{weight (kg)}}{72 \times xP_{Cr}\ (\text{mg/dL})}$$

where P_{Cr} is plasma creatinine; for women, the final result is multiplied by 0.85. Many labs are now routinely reporting the GFR using estimate formulas for creatinine clearance.

When the kidneys are damaged by a disease process, the creatinine clearance decreases, and the serum creatinine concentration rises. The urine creatinine excretion decreases initially until the blood level rises to a point at which the amount of creatinine appearing in the urine is equal to the amount being produced by the body. Because men tend to have a higher proportion of muscle than women, the creatinine and creatinine clearance can be higher in men than women. A healthy person with a serum creatinine concentration of 1 mg/dL and a creatinine excretion of 1 mg/min has a creatinine clearance of 100 mL/min. When the person experiences a 50% loss of renal function, the serum creatinine rises to 2 mg/dL, and the person will continue to excrete 1 mg/min of creatinine in the urine when balance is restored. When the person has rapidly changing renal function and oliguria (eg, acute kidney injury), the creatinine clearance is less reliable. Until renal function stabilizes, serum creatinine levels provide a better indication of the rate and direction of change. In patients with rhabdomyolysis, the serum creatinine is elevated out of proportion to the reduction of GFR as the result of chemical conversion of muscle creatine to creatinine. In this situation, the serum creatinine is less reliable as an indicator of renal function.

BLOOD UREA NITROGEN. The blood urea nitrogen (BUN) level has been used for many years as an indicator of kidney function, but unlike the serum creatinine, the BUN level can be influenced by many factors. At low urine flow rates, more

sodium and water, and consequently more urea, are reabsorbed. Therefore, when the patient is volume depleted, the BUN tends to increase out of proportion to any change in renal function. A normal value for the BUN is considered to be 8 to 20 mg/dL.

Increased urea production can result from increased protein intake (tube feedings and some forms of hyperalimentation), increased tissue breakdown (as with crush injuries), febrile illnesses, steroid or tetracycline administration, and reabsorption of blood from the intestine in a patient with intestinal hemorrhage. The BUN may also be elevated in the dehydrated patient, because the lack of fluid volume causes a concentrated value. The patient in shock and the patient with heart failure may have an elevated BUN secondary to decreased renal perfusion. The opposite is true for patients with decreased protein intake or liver disease (both of which reduce urea production) and for patients with large urine volumes secondary to excessive fluid intake.

However, the BUN can be of significant value when used as a comparison with the serum creatinine concentration. Normally, there is a urea/creatinine ratio of 10:1. Discrepancies in this ratio might suggest a potentially correctable situation, as Box 29-2 shows.

OSMOLALITY. The osmolality of a solution is an expression of the total osmoles per kilogram (Osm/kg) of solvent and is independent of the size, molecular weight, and electrical charge of the molecules. All substances in solution contribute to the osmolality. For example, 1 mol (gram molecular weight) of sodium chloride (NaCl) dissociates incompletely into sodium (Na) and chloride (Cl) ions and produces 1.86 Osm when dissolved in 1 kg of solvent (such as plasma). A mole of nonionic solute (eg, glucose or urea) produces only 1 Osm when dissolved in 1 kg of solvent. The total concentration of particles in a solution equals the osmolality and is normally reported in units of osmoles per kilogram of solvent. In the clinical setting (because of much smaller concentrations), the osmolality is reported in milliosmoles (thousandth of an osmole, abbreviated mOsm) per kilogram of solvent (plasma or serum).

The normal serum osmolality consists primarily of sodium and its accompanying anions, with urea and glucose contributing about 5 mOsm each. Therefore, when the serum sodium, urea, and glucose concentrations are known, the osmolality of plasma can be calculated by the following formula:

$$\text{Osmolality} = 2(\text{Na}) + \frac{\text{Glucose}}{18} + \frac{\text{BUN}}{2.8}$$

BOX 29-2 Factors Affecting the Serum Urea: Creatinine Ratio

Decreased Urea/Creatinine Ratio (<10:1)
- Liver disease
- Protein restriction
- Excessive fluid intake

Increased Urea/Creatinine Ratio (>10:1)
- Volume depletion
- Decreased "effective" blood volume
- Catabolic states
- Excessive protein intake

The normal adult average osmolality is 280 to 290 mOsm/kg and remains quite constant. Because water can move freely between the blood, interstitial fluid, and tissues, any change in the osmolality of one body compartment produces a shift in body fluids. Therefore, the osmolality of the plasma is the same as that of other body compartments except in rapidly changing conditions, when a slight lag may occur.

A decrease in the serum osmolality can occur only when the serum sodium is decreased. An increase in the serum osmolality can occur whenever the serum sodium, urea, or glucose is elevated or when abnormal compounds are present in the blood, such as drugs, poisons, or metabolic waste products, such as lactic acid. Symptoms usually do not occur until the osmolality exceeds 350 mOsm/kg. Coma can occur when the osmolality is 400 mOsm/kg or greater.

The calculated osmolality normally is within 10 mOsm of the measured osmolality. Comparing the calculated and measured osmolality can be useful in determining potential substances present. An elevated osmolar gap provides evidence for the presence of a significant amount of abnormal solutes. Ethanol, methanol, and ethylene glycol are three examples of solutes that, when present in appreciable amounts, cause an elevated osmolar gap. If ingestion of one of these substances is suspected, calculate the osmolar gap.

NONSPECIFIC STUDIES. Changes in hematocrit, hemoglobin, platelets, and uric acid levels may be indications of a disorder.

Hematocrit and Hemoglobin. The normal hemoglobin for men is 13.5 to 17.5 g/dL and is 12 to 16 g/dL for women. The normal hematocrit should be 40% to 52% for adult men and 37% to 48% for adult women. False elevations of hematocrit can be seen with dehydration or after dialysis. Low hematocrits may be a dilutional value due to hypervolemia. The kidney is the primary site for the production of erythropoietin. It stimulates the bone marrow to release mature RBCs. Many patients with CKD produce insufficient amounts of erythropoietin, which can result in chronic anemia.

Platelets. Patients with uremia are particularly susceptible to platelet dysfunction. Gastrointestinal (GI) bleeding may be a presenting symptom. The bleeding time, indicative of platelet function, may be prolonged. One mechanism of platelet dysfunction is that uremic platelets tend to synthesize less thromboxane-A2, the chemical that gives platelets their sticky function.

Uric Acid. Uric acid is a nitrogenous end product of protein and purine metabolism. Humans produce only small quantities of uric acid under normal conditions, and the normal uric acid serum level is between 2 and 8.5 mg/dL. Uric acid is excreted primarily by the kidneys, with some in the stool. The value may be elevated because of excessive production from cell breakdown or inadequate excretion by the kidney.

Diagnostic Studies

Radiological Studies

Radiological studies of the kidneys that may be useful in evaluating renal abnormalities include roentgenography, ultrasonography, and radionuclide studies. Table 29-3 summarizes these studies and their purposes.

Table 29-3 Radiological Study of Kidneys

Diagnostic Test	Definition	Purpose
Roentgenography		
Radiograph of kidney–ureter–bladder	Also known as abdominal x-ray. Standard x-rays capture image.	Detects abnormal calcifications and renal size
Tomography	Standard x-rays capture series of cross-sectional scans made along single axis of bodily structure or tissue. Computer software is used to construct three-dimensional image of that structure.	Determines renal outlines and abnormalities
Intravenous pyelography (IVP)	X-ray of renal structures using contrast material. Images are captured on real-time basis. Contrast material is injected intravenously and then collected in renal system; this turns areas bright white, allowing assessment of anatomy and function of kidneys and lower urinary tract.	Detects anatomical abnormalities of kidneys and ureters
Retrograde pyelography	Similar to IVP, with use of x-ray and contrast material. Contrast material is injected through urinary catheter. This test is typically performed at the same time as cystoscopy.	Assesses renal size, evaluates ureteral obstruction, and localizes and diagnoses tumors as well as obstructions
Antegrade pyelography	Similar to IVP and retrograde pyelography, this x-ray test uses contrast material to visualize structures of urinary tract. Contrast dye, however, is injected into ureter. Thus, structures of upper urinary tract are well visualized.	Distinguishes cysts from hydronephrosis
Renal arteriography and venography	Vessel (artery or vein) is accessed and contrast dye is injected to visualize structures "downstream."	Evaluates possible renal arterial stenosis, renal mass lesions, renal vein thrombosis, and venous extension of renal cell carcinoma
Digital subtraction angiography	X-ray with a computer technique that compares x-ray image of kidney vessels before and after contrast dye is injected. Tissues and blood vessels on first image are digitally subtracted from second image, leaving clear picture of artery, which can then be studied independently from rest of the body.	Visualizes major arterial vessels
Ultrasonography	Imaging technique that is excellent means of visualizing tissues and organs to assess their size, structure, and possible pathology. Images are created by emission and receiving of sound waves.	Delineates renal outlines Measures longitudinal and transverse dimensions of the kidneys Evaluates mass lesions Examines perinephric area Detects and grades hydronephrosis
Radionuclide scintillation imaging (renal scan)	Nuclear medicine test that uses small amounts of radioactive materials (radioisotopes) to measure kidney function	
Static imaging	Gives information about the size, shape, and position of the kidneys; and whether there are scars on the kidney from a previous infection.	Evaluates location, size, and contour of functional renal tissue; may reveal areas of inhomogeneity or filling defects
Dynamic imaging	Gives information about the blood flow to the kidneys and how well each kidney is functioning for the production of urine	Monitors passage of radiopharmaceutical agent through vascular, renal parenchymal, and urinary tract compartments; also indicates whether there are any obstructions in urine output
Magnetic resonance imaging	Uses nonionizing radiofrequency signals (as opposed to computed tomography, which uses ionizing radiation) to acquire its images and is best suited for noncalcified tissue.	Determines anatomical abnormalities

Table 29-4 Indications for Renal Biopsy

Clinical Condition	Biopsy Indicated	Expected Gain
Orthostatic proteinuria	No	—
Isolated hematuria and/or proteinuria	No*	—
Hematuria and/or proteinuria with ↓ GFR	Yes	D,P,T
Nephrotic syndrome	Yes	D,P,T
Systemic disease with renal abnormalities	Yes†	D,P,T
Classic ARF	No	—
ARF with		
1. Azotemia for >3 wk	Yes	D,P
2. Moderate proteinuria	Yes	D,T
3. Anuria	Yes	D,T
4. Eosinophilia or eosinophiluria	Yes	D,T
Posttransplant ↓ in GFR	Yes	D,P,T

*Biopsy may be indicated for insurance, administrative reasons, and so forth.

†Biopsy may or may not be indicated, depending on clinical picture.

GFR, glomerular filtration rate; D, diagnosis; P, prognosis; T, therapy; ARF, acute renal failure.

Renal Biopsy

Renal biopsy is the most invasive diagnostic test and has been shown to have a good sensitivity and specificity for malignancy (97.7% and 100%, respectively).[3] It is used to define the histological counterpart of the clinical picture, provide etiological clues for diagnosis, assess prognosis, and guide therapy. Table 29-4 lists the indications for renal biopsy. Contraindications to biopsy include serious bleeding disorders, excessive obesity, and severe hypertension.

Renal biopsies are usually performed percutaneously with a biopsy needle, but an open renal biopsy under general anesthesia still is performed. Preparation for a renal biopsy includes obtaining informed consent, prebiopsy clotting studies, preoperative blood typing, and sedation (usually diazepam, 5 to 10 mg). It is necessary to establish intravenous (IV) access to prevent or treat complications. After the biopsy, the patient's vital signs are checked frequently for the first 24 hours as the patient is monitored during the emergency from sedation and for signs of bleeding. The patient's urine is examined for blood. The major complication is bleeding, which can occur either retroperitoneally or into the urinary tract. Other complications that can occur are biopsy of other abdominal viscera such as bowel, pancreas, liver, spleen, or vessels, and tears in the diaphragm or pleura.

Renal Angiography

Assessment of the renal vasculature may be accomplished by ultrasonography. When precise measurements are required, evaluation of renal blood flow through angiography may be used. This procedure may be performed in conjunction with cardiac catheterization. Access is obtained by percutaneous technique: an introducer, or sheath, is inserted into the femoral artery, and a small catheter is passed to the bifurcation of the renal arteries. Contrast medium is injected to provide radiological visualization of blood flow. Preparation for a renal angiogram is similar to that for renal biopsy; it includes obtaining informed consent, preprocedure clotting studies, preoperative blood typing, and sedation, as well as establishing IV access to prevent or treat complications. After the angiogram, the patient's vital signs are checked frequently for the first 24 hours as the patient is monitored for emergence from sedation and for bleeding. Pressure is applied locally when the arterial access is removed. Because the artery has been accessed, life-threatening bleeding can ensue. Therefore, the access site is assessed for bleeding with the same frequency as the vital signs are assessed. Diligence in application of pressure to the site and conducting site assessment is imperative. Watch for development of bradycardia, because pressure applied to the groin area may stimulate the vagus nerve.

▲ Assessment of Electrolytes and Acid–Base Balance

The role of the kidney is central in maintaining fluid volume and ionic composition of body fluids. When the kidneys properly regulate the excretion of water and ions, homeostasis is achieved. When the kidneys fail to adapt adequately, imbalances occur. Table 29-5 summarizes electrolyte values and signs and symptoms of imbalance. The critical care nurse needs to monitor closely all of the electrolytes because minor shifts can be lethal.

Sodium Balance

Serum sodium concentration is normally 135 to 145 mEq/L. It is regulated by the kidneys and depends on the sodium concentration in the extracellular fluid (ECF). When the concentration of sodium rises, antidiuretic hormone (ADH) is secreted from the posterior pituitary gland, and the kidneys retain water in response. When the concentration falls, aldosterone promotes sodium retention by the kidneys (see Chapter 42, Fig. 42-9). When the kidneys malfunction, this balance is not maintained. Low serum sodium usually indicates water intake in excess of sodium and is characterized by an increase in body weight. High serum sodium usually indicates water loss in excess of sodium and is reflected in weight loss. Sodium is essential for maintaining the osmolality of ECFs, neuromuscular function, acid–base balance, and various other cellular chemical reactions.

Hyponatremia is important because it can produce a wide range of neurological symptoms, including death. The severity of symptoms depends on the degree of hyponatremia and the rate at which it has developed. Usually, symptoms do not occur until the serum sodium level is below 120 mEq/L.[2] For patients with hyponatremia, the severity of symptoms encountered depends on how rapidly the sodium concentration was lowered, as well as the value. Hyponatremia requires further evaluation. Figure 29-5 illustrates the etiologies and evaluation for hyponatremia.

Table 29-5 Disorders of Electrolyte Balance

Electrolyte Imbalance	Signs and Symptoms	Diagnostic Test Results
Hyponatremia	• Muscle twitching and weakness • Lethargy, confusion, seizures, and coma • Hypotension and tachycardia • Nausea, vomiting, and abdominal cramps • Oliguria or anuria	• Serum sodium <135 mEq/L • Decreased urine specific gravity • Decreased serum osmolality • Urine sodium >100 mEq/24 h • Increased red blood cell count
Hypernatremia	• Agitation, restlessness, fever, and decreased level of consciousness • Muscle irritability and convulsions • Hypertension, tachycardia, pitting edema, and excessive weight gain • Thirst, increased viscosity of saliva, and rough tongue • Dyspnea, respiratory arrest, and death	• Serum sodium >145 mEq/L • Urine sodium <40 mEq/24 h • High serum osmolality
Hypokalemia	• Dizziness, hypotension, dysrhythmias, electrocardiogram (ECG) changes, and cardiac and respiratory arrest • Nausea, vomiting, anorexia, diarrhea, decreased peristalsis, abdominal distention, and paralytic ileus • Muscle weakness, fatigue, and leg cramps	• Serum potassium <3.5 mEq/L • Coexisting low serum calcium and magnesium levels not responsive to treatment for hypokalemia usually suggest hypomagnesemia • Metabolic alkalosis • ECG changes, including flattened T waves, elevated U waves, depressed ST segment
Hyperkalemia	• Tachycardia changing to bradycardia, ECG changes, and cardiac arrest • Nausea, diarrhea, and abdominal cramps • Muscle weakness and flaccid paralysis	• Serum potassium >5 mEq/L • Metabolic acidosis • ECG changes, including tented and elevated T waves, widened QRS complex, prolonged PR interval, flattened or absent P waves, depressed ST segment
Hypochloremia	• Muscle hyperexcitability and tetany • Shallow, depressed breathing • Usually associated with hyponatremia and its characteristic symptoms, such as muscle weakness and twitching	• Serum chloride <96 mEq/L • Serum pH > 7.45, serum CO_2 <32 mEq/L (supportive values)
Hyperchloremia	• Deep, rapid breathing • Weakness • Lethargy, possibly leading to coma	• Serum chloride > 108 mEq/L • Serum pH < 7.35, serum CO_2 <22 mEq/L (supportive values)
Hypocalcemia	• Anxiety, irritability, twitching around the mouth, laryngospasm, seizures, positive Chvostek's and Trousseau's signs • Hypotension and dysrhythmias due to decreased calcium influx	• Serum calcium <8.5 mg/dL • Low platelet count • ECG changes: lengthened QT interval, prolonged ST segment, and dysrhythmias
Hypercalcemia	• Drowsiness, lethargy, headaches, irritability, confusion, depression, apathy, tingling and numbness of fingers, muscle cramps, and convulsions • Weakness and muscle flaccidity • Bone pain and pathological fractures • Heart block • Anorexia, nausea, vomiting, constipation, dehydration, and abdominal cramps • Flank pain	• Serum calcium >10.5 mg/dL • ECG changes: signs of heart block and shortened QT interval • Decreased parathyroid hormone level • Calcium stones in urine
Hypomagnesemia	• Nearly always coexists with hypokalemia and hypocalcemia • Hyperirritability, tetany, leg and foot cramps, positive Chvostek's and Trousseau's signs, confusion, delusions, and seizures • Dysrhythmias, vasodilation, and hypotension	• Serum magnesium <1.8 mEq/L • Coexisting low serum potassium and calcium levels
Hypermagnesemia	• Central nervous system (CNS) depression, lethargy, and drowsiness • Diminished reflexes, muscle weakness to flaccid paralysis • Respiratory depression • Heart block, bradycardia, widened QRS, and prolonged QT interval • Hypotension	• Serum magnesium >2.5 mEq/L • Coexisting elevated potassium and calcium levels

(continued on page 629)

Table 29-5 Disorders of Electrolyte Balance (continued)

Electrolyte Imbalance	Signs and Symptoms	Diagnostic Test Results
Hypophosphatemia	• Muscle weakness, tremor, and paresthesia • Tissue hypoxia • Bone pain, decreased reflexes, and seizures • Weak pulse • Hyperventilation • Dysphagia and anorexia	• Serum phosphate <2.5 mg/dL • Urine phosphate >1.3 g/24 h
Hyperphosphatemia	• Usually asymptomatic unless leading to hypocalcemia, then evidenced by tetany and seizures • Hyperreflexia, flaccid paralysis, and muscular weakness	• Serum phosphate > 4.5 mg/dL • Serum calcium < 8.5 mg/dL • Urine phosphate < 0.9 g/24 h

From Anatomical Chart Company: Atlas of Pathophysiology, 3rd ed. Ambler, PA: Lippincott Williams & Wilkins, 2010, pp 32–33.

Symptoms of hypernatremia generally are the same as those of hyperosmolality and result from central nervous system (CNS) dehydration. Mental confusion, stupor, seizures, coma, and death may occur, in addition to other signs of dehydration, such as fatigue, muscle weakness and cramps, and anorexia. The serum osmolality usually is above 350 mOsm/L before significant symptoms are noted. This corresponds to a serum sodium level of 165 to 170 mEq/L.

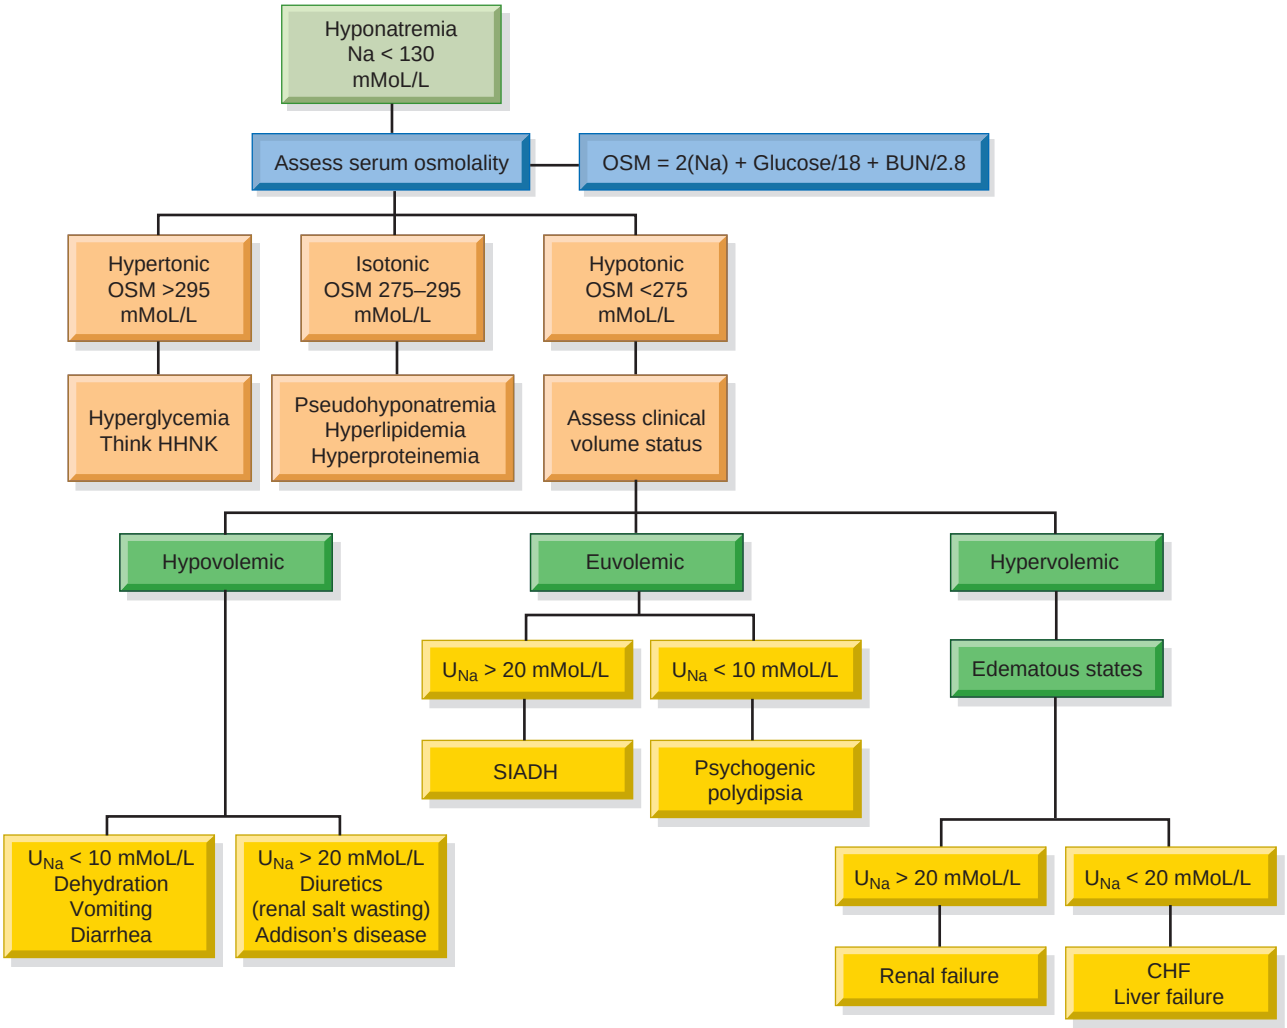

FIGURE 29-5 ▲ Assessing hyponatremia. (BUN, blood urea nitrogen; CHF, congestive heart failure; HHNK, hyperglycemic hyperosmolar nonketotic [coma]; Na, sodium; OSM, osmolality; SIADH, syndrome of inappropriate antidiuretic hormone secretion; UNa, urine sodium.)

Potassium Balance

Potassium is essential for regulating nerve impulse conduction and muscle contraction and is involved in numerous other body functions, including intracellular osmolality and acid–base balance. The normal serum potassium concentration is 3.5 to 5 mEq/L. Potassium balance is maintained by dietary intake and renal excretion. Ninety-eight percent of potassium is located in the skeletal muscle; therefore, the balance of this electrolyte also is strongly tied to the exchanges between the intracellular and extracellular compartments in the body.

Hypokalemia can result from inadequate potassium intake, excessive potassium loss through the kidneys, GI loss, and extracellular-to-intracellular potassium shifts. Also, diuretic therapy can contribute to potassium excretion, further compounding the problem.

Hyperkalemia may be caused by a decrease in the renal excretion of potassium or transcellular shifts of potassium. This is seen most often in acidosis, cell injury or destruction, and hyperglycemia.

Calcium and Phosphate Balance

Calcium and phosphate are regulated reciprocally in the body by vitamin D, parathyroid hormone, and calcitonin. The calcium and phosphate salts are normally deposited in bone. When calcium levels are high, phosphate levels are low. Because in renal failure, the kidneys are unable to eliminate phosphate, patients with renal failure often have high phosphate and low calcium levels.

Calcium's primary function is maintenance of bone and tooth strength. It also plays an important role in myocardial and skeletal contractility. Calcium also maintains cellular permeability and assists in blood coagulation. The normal serum concentration of calcium is 8.5 to 10.5 mg/dL. The total serum calcium is composed of two major fractions: the diffusible or ultrafiltrable (or ionized) calcium and the nondiffusible or protein-bound (primarily to albumin) calcium. Many critically ill patients have low albumin, which will result in low serum calcium. This result does not necessarily mean that the patient's calcium is low. It is necessary to either assess the ionized calcium (if available) or to correct the serum calcium for the albumin level, using the following formula:

$$\text{Corrected calcium} = [0.8 \times (\text{normal albumin} - \text{patient's albumin})] + \text{serum}$$

Phosphate is essential for the formation of adenosine triphosphate. Phosphate also assists in maintaining cell membrane structure, oxygen delivery, and cellular immunity. The normal phosphate level is 3 to 4.5 mg/dL.

Magnesium Balance

The magnesium ion is the second major intracellular ion. The normal serum concentration is 1.4 to 2.1 mEq/L. Magnesium balance is necessary for the functional integrity of the neuromuscular system. The parathyroid glands regulate both magnesium and calcium. Sodium is necessary for magnesium reabsorption. Magnesium can accumulate in the serum, bone, and muscle in renal failure, causing numerous problems.

Acid–Base Balance

A normal acidity or alkalinity (pH 7.35 to 7.45) of the body fluid is essential for life. The body maintains acid–base balance by the buffer system, the respiratory system, and the renal system. The buffer and respiratory systems are able to react quickly to changes in body pH. However, the kidneys take more time to adjust to changes in body pH.

Five major processes are associated with the regulation of acid–base balance by the renal system: hydrogen ion excretion; sodium ion reabsorption; bicarbonate ion generation and reabsorption; phosphate salt and titratable acid excretion; and ammonia synthesis and ammonium excretion. Acid–base imbalances may result when the kidneys are unable to perform those processes adequately. Table 29-6 summarizes acid–base balances.

The Anion Gap

To maintain chemical neutrality, the total concentration of cations and anions in the blood (and other body fluids) must be equivalent in terms of milliequivalents per liter. However, because a number of anions and cations are present in blood but not routinely measured, a "gap" exists between the total concentration of cations and anions and the concentration normally measured in the plasma.

The anion gap is composed primarily of an excess of unmeasured anions, including plasma proteins, inorganic phosphates and sulfates, and organic acids. The unmeasured cations that exist in smaller concentrations are primarily calcium and magnesium.

The anion gap usually is calculated by subtracting the anions (chloride and bicarbonate) from the cations (sodium and potassium) using the following formula:

$$\text{Anion gap} = ([Na^+] + [K]) - ([Cl^-] + [HCO_3])$$

The normal mean is approximately 12 mEq/L (range, 8 to 16 mEq/L). However, departures from this "normal" anion gap may have important diagnostic significance in acid–base disorders, especially metabolic acidoses.

The most common abnormality of the anion gap is an increase that is associated with increased concentrations of lactate, ketone bodies, or inorganic phosphate and sulfate that are found in lactic acidosis, ketoacidosis, and uremia, respectively. Other forms of acidosis associated with ingestion of toxins, such as ethylene glycol, methanol, paraldehyde, and salicylates, also may produce significant increases in the anion gap.

Decreases in the anion gap are less common but equally important. They can occur because of increases in unmeasured cations or because of decreases in unmeasured anions. Table 29-7 lists the causes of altered anion gap.

Table 29-6 Disorders of Acid–Base Balance

Disorder/Causes	Pathophysiology	Signs/Symptoms	Diagnosis
Respiratory Acidosis			
• Airway obstruction or parenchymal lung disease • Mechanical ventilation • Chronic metabolic alkalosis as respiratory compensatory mechanisms try to normalize pH • Chronic bronchitis • Extensive pneumonia • Large pneumothorax • Pulmonary edema • Asthma • Chronic obstructive pulmonary disorder • Drugs • Cardiac arrest • CNS trauma • Neuromuscular diseases • Sleep apnea	When pulmonary ventilation decreases, partial pressure of carbon dioxide in arterial blood ($PaCO_2$) increases and CO_2 level rises. Retained CO_2 combines with water (H_2O) to form carbonic acid (H_2CO_3), which dissociates to release free hydrogen (H^+) and bicarbonate (HCO_3^-) ions. Increased $PaCO_2$ and free H^+ ions stimulate the medulla to increase respiratory drive and expel CO_2. As pH falls, 2,3-diphosphoglycerate accumulates in red blood cells, where it alters hemoglobin (Hgb) to release oxygen. The Hgb picks up H^+ ions and CO_2 and removes them from the serum. As respiratory mechanisms fail, rising $PaCO_2$ stimulates kidneys to retain HCO_3^- and sodium (Na^+) ions and excrete H^+ ions. As the H^+ ion concentration overwhelms compensatory mechanisms, H^+ ions move into cells and potassium (K^+) ions move out. Without enough oxygen, anaerobic metabolism produces lactic acid.	• Restlessness • Confusion • Apprehension • Somnolence • Asterixis • Headaches • Dyspnea and tachypnea • Papilledema • Depressed reflexes • Hypoxemia • Tachycardia • Hypertension/hypotension • Atrial and ventricular dysrhythmias • Coma	• Arterial blood gas (ABG) analysis: $PaCO_2$ > 45 mm Hg; pH <7.35–7.45; and normal HCO_3^- in the acute stage and elevated HCO_3^- in the chronic stage
Respiratory Alkalosis			
• Acute hypoxemia, pneumonia, interstitial lung disease, pulmonary vascular disease, or acute asthma • Anxiety • Hypermetabolic states such as fever and sepsis • Excessive mechanical ventilation • Salicylate toxicity • Metabolic acidosis • Hepatic failure • Pregnancy	As pulmonary ventilation increases, excessive CO_2 is exhaled. Resulting hypocapnia leads to reduction of H_2CO_3, excretion of H^+ and HCO_3^- ions, and rising serum pH. Against rising pH, the hydrogen–potassium buffer system pulls H^+ ions out of cells and into blood in exchange for K^+ ions. H^+ ions entering blood combine with HCO_3^- ions to form H_2CO_3, and pH falls. Hypocapnia causes an increase in heart rate, cerebral vasoconstriction, and decreased cerebral blood flow. After 6 h, kidneys secrete more HCO_3^- and less H^+. Continued low $PaCO_2$ and vasoconstriction increases cerebral and peripheral hypoxia. Severe alkalosis inhibits calcium (Ca^{++}) ionization; increasing nerve/muscle excitability.	• Deep, rapid breathing • Light-headedness or dizziness • Agitation • Circumoral and peripheral paresthesias • Carpopedal spasms, twitching, and muscle weakness	ABG analysis showing $PaCO_2$ < 35 mm Hg; elevated pH in proportion to decrease in $PaCO_2$ in the acute stage but decreasing toward normal in the chronic stage; normal HCO_3^- in the acute stage but less than normal in the chronic stage
Metabolic Acidosis			
• Excessive acid accumulation • Deficient HCO_3^- stores • Decreased acid excretion by the kidneys • Diabetic ketoacidosis • Chronic alcoholism • Malnutrition or a low-carbohydrate, high-fat diet • Anaerobic carbohydrate metabolism • Underexcretion of metabolized acids or inability to conserve base • Diarrhea, intestinal malabsorption, or loss of sodium bicarbonate from the intestines • Salicylate intoxication, exogenous poisoning, or, less frequently, Addison's disease • Inhibited secretion of acid	As H^+ ions begin accumulating in the body, chemical buffers (plasma HCO_3^- and proteins) in cells and extracellular fluid (ECF) bind them. Excess H^+ ions decrease blood pH and stimulate chemoreceptors in the medulla to increase respiration. Consequent fall of partial pressure of $PaCO_2$ frees H^+ ions to bind with HCO_3^- ions. Respiratory compensation occurs but is not sufficient to correct acidosis. Healthy kidneys compensate, excreting excess H^+ ions, buffered by phosphate or ammonia. For each H^+ ion excreted, renal tubules reabsorb and return to blood one Na^+ ion and one HCO_3^- ion. Excess H^+ ions in ECF passively diffuse into cells. To maintain balance of charge across cell membrane, cells release K^+ ions. Excess H^+ ions change the normal balance of K^+, Na^+, and Ca^{++} ions, impairing neural excitability.	• Headache and lethargy progressing to drowsiness, CNS depression, Kussmaul's respirations, hypotension, stupor, and coma and death • Associated gastrointestinal (GI) distress leading to anorexia, nausea, vomiting, diarrhea, and possibly dehydration • Warm, flushed skin • Fruity-smelling breath	• Arterial pH < 7.35; $PaCO_2$ normal or <35 mm Hg as respiratory compensatory mechanisms take hold; HCO_3^- may be <22 mEq/L • Urine pH < 4.5 in the absence of renal disease • Elevated plasma lactic acid in lactic acidosis • Anion gap >14 mEq/L in high–anion gap metabolic acidosis, lactic acidosis, ketoacidosis, aspirin overdose, alcohol poisoning, renal failure, or other disorder characterized by accumulation of organic acids, sulfates, or phosphates • Anion gap 12 mEq/L or less in normal anion gap metabolic acidosis from HCO_3^- loss, GI or renal loss, increased acid load, rapid intravenous (IV) saline administration, or other disorders characterized by HCO_3^- loss

(continued on page 632)

Table 29-6 Disorders of Acid–Base Balance (continued)

Disorder/Causes	Pathophysiology	Signs/Symptoms	Diagnosis
Metabolic Alkalosis			
• Chronic vomiting • Nasogastric tube drainage or lavage without adequate electrolyte replacement • Fistulas • Use of steroids and certain diuretics (furosemide [Lasix], thiazides, and ethacrynic acid [Edecrin]) • Massive blood transfusions • Cushing's disease, primary hyperaldosteronism, and Bartter's syndrome • Excessive intake of bicarbonate of soda, other antacids, or absorbable alkali • Excessive amounts of IV fluids, high serum concentrations of bicarbonate or lactate • Respiratory insufficiency • Low serum chloride • Low serum potassium	Chemical buffers in ECF and intracellular fluid bind HCO_3^- in the body. Excess unbound HCO_3^- raises blood pH, depressing chemoreceptors in the medulla, inhibiting respiration, and raising $PaCO_2$. CO_2 combines with H_2O to form H_2CO_3. Low oxygen limits respiratory compensation. When blood HCO_3^- rises to 28 mEq/L, the amount filtered by renal glomeruli exceeds reabsorptive capacity of the renal tubules. Excess HCO_3^- is excreted in urine, and H^+ ions are retained. To maintain electrochemical balance, Na^+ ions and water are excreted with HCO_3^- ions. When H^+ ion levels in ECF are low, H^+ ions diffuse passively out of cells and extracellular K+ ions move into cells. As intracellular H^+ ion levels fall, calcium ionization decreases, and nerve cells become permeable to Na^+ ions. Na^+ ions moving into cells trigger neural impulses in peripheral nervous system and in CNS.	• Irritability, picking at bedclothes (carphology), twitching, and confusion • Nausea, vomiting, and diarrhea • Cardiovascular abnormalities due to hypokalemia • Respiratory disturbances (such as cyanosis and apnea) and slow, shallow respirations • Possible carpopedal spasm in the hand, due to diminished peripheral blood flow during repeated blood pressure checks	• Arterial blood pH > 7.45; HCO_3^- > 26 mEq/L • Low potassium (<3.5 mEq/L), calcium (<8.9 mg/dL), and chloride (<98 mEq/L)

▲ Assessment of Fluid Balance

The nurse's role in the assessment of problems of fluid balance includes accurate measurement of intake and output, weight, and vital signs. Although vital signs can provide supporting data, they may not be abnormal until significant volume or water deficits occur. Assessment of fluid imbalance needs to be based on keen observation and recognition of pertinent symptoms.

Weight

Weight is one of the single most important tests for critically ill patients. The admission weight is compared with that obtained in the history. Of note is whether the weight has changed significantly over the past 1 to 2 weeks. Weights should be carefully measured at the same time, with the same scale, and with the same linens and clothing daily. Variations in the procedure should be noted and made known to the

Table 29-7 Causes of an Altered Anion Gap

Increased Anion Gap	Decreased Anion Gap
Increased unmeasured anions • Endogenous metabolic acidosis Lactic acidosis Ketoacidosis Uremic acidosis • Exogenous anion ingestion Ethylene glycol Methanol Paraldehyde Salicylates Penicillin Carbenicillin • Increased plasma proteins Hyperalbuminemia Decreased unmeasured cations • Hypokalemia • Hypocalcemia • Hypomagnesemia	Increased unmeasured cations • Normal cations Hypercalcemia Hyperkalemia Hypermagnesemia • Abnormal cations Increased globulins (eg, myeloma) Lithium Decreased unmeasured anions • Hypoalbuminemia

physician. One liter of fluid equals 1 kg of body weight, equivalent to 2.2 pounds. A kilogram scale provides for greater accuracy because drug, fluid, and diet measurements can be calculated easily using the metric system. An increase in weight does not specify where the weight is gained. For example, a patient may be intravascularly volume depleted yet show an increase in weight because of third spacing of fluid (ie, movement of water to the interstitial space).

Rapid daily gains and losses of weight usually are associated with changes in fluid volume and not nutritional factors. Critically ill patients often experience unmeasured insensible losses, such as ventilation and wound losses. Fever can increase the amount of fluid lost through the skin and lungs by as much as 75 mL/1°F above baseline. Serial weights often are more reliable, and weight changes usually detect imbalances before any symptoms are apparent. In addition to the fluid balance perspective, body weights are also used to calculate drug dosages and, for the patient receiving dialysis, determine the amount of fluid to be removed during therapy.

Intake and Output

An accurate intake and output record provides valuable data for evaluating and treating fluid and electrolyte imbalances. It is important that the nurse teach the patient or visitors to assist in this assessment. Intake and output are measured and recorded as they occur and totaled at the end of every shift. In the presence of excessive losses or deterioration of cardiac, hepatic, renal, or respiratory function, more detailed recording of every source of fluid intake and output is necessary, and calculations may be required every 1 to 4 hours.

In the critically ill patient, intake and output are monitored every 1 to 2 hours. The intake and output values are summed to provide an overall balance at the end of a 24-hour period. A net balance is calculated by subtracting the output from the intake:

$$\text{Fluid balance} = \text{total fluid intake} - \text{total fluid output}$$

Depending on the patient's condition, daily therapeutic goals, and response to interventions, the net balance may be neutral, positive, or negative. The 24-hour balance is compared with the daily weight to assess overall balance. If the net daily balance is positive, but the daily weight reflects a loss over the past 24 hours, insensible losses may be the cause of the discrepancy.

Intake should include all liquids, such as water, juices, or soup, and any foods that are high in water content (eg, oranges, grapefruit, gelatin, and ice cream). It is useful to keep a list of equivalents for fruits, ice cubes and chips, and other sources of fluid. Output should include urinary and intestinal losses and estimates of respiratory and cutaneous losses when the patient's temperature or the ambient temperature is high. Also recorded are other sources of fluid loss that are present, such as ileostomy or other enteric drainage, wound drainage, or thoracic drainage.

In severe electrolyte and fluid imbalances, the time and type of fluid intake and the time and amount of each voiding must be recorded. In the event that renal function decreases, this information may aid immeasurably in the diagnosis and possible prevention of prerenal azotemia or acute kidney injury. Box 29-3 gives risk factors for excessive fluid loss.

Hypovolemia and Hypervolemia

The critical care nurse must be continually on the alert to detect early changes in the patient's volume status. Seldom is the diagnosis made on the basis of one parameter. The first clue may be the patient's general appearance; after observing this, the nurse seeks and notes more specific parameters.

Symptoms vary with the degree of imbalance; some are seen early in imbalance states, and others are not evident until severe imbalances are present. Table 29-8 lists the signs and symptoms of hypovolemia and hypervolemia.

In volume depletion, the patient may complain of orthostatic light-headedness when assuming the sitting or standing position (this also can occur from inactivity and autonomic dysfunction). Development of tachycardia on assuming the upright position and a decrease in blood pressure (orthostatic hypotension), as opposed to the normal rise, are frequent early findings. Later, the pulse may become rapid, weak, and thready. There may be early dryness of the skin,

BOX 29-3 PATIENT SAFETY

Risk Factors for Excessive Fluid Loss

- **Fever:** A patient with a body temperature of 40°C (104°F) and a respiratory rate of 40 breaths/min can lose as much as 2,500 mL of fluid in a 24-hour period from the respiratory tract and from the skin.
- **Environment:** Hot, dry climates can increase evaporative sweat losses to 1,500 mL/h to maintain body evaporative heat loss. This can increase to between 2 and 2.5 L/h for short times in acclimatized people exercising in hot climates.
- **Hyperventilation:** Hyperventilation can increase respiratory water losses as a result of either disease or use of nonhumidified respirators or oxygen delivery systems.
- **Gastrointestinal tract:** Vomiting, nasogastric suction, diarrhea, and enterocutaneous drainage or fistulas can increase gastrointestinal losses.
- **Third spacing:** Formation of pleural or peritoneal effusions and edema from liver, renal, or hepatic disease or from the diffuse capillary leak syndrome can result in a loss of effective intravascular volume. Drainage of peritoneal or pleural fluid, when for of these third spaces still is occurring, can result in further effective intravascular losses because of continued fluid shifts from the vascular compartment to the third space.
- **Burns:** Fluid loss into burned tissues can result in a significant decrease in effective intravascular volume. Because both evaporative and transudative losses through the burned skin can result in very large losses of fluid daily, the burned patient requires special attention to maintain fluid and electrolyte balance. Formulas for determining burn area and fluid resuscitation are discussed in Chapter 53.
- **Renal losses:** Inappropriate solute and fluid loss from the kidneys can occur because of renal salt wasting. This is seen in the diuretic phase of acute tubular necrosis, in some rare patients with true renal salt wasting, and as a result of excessive diuretic administration. It also may occur as a result of solute diuresis from high-protein or high-saline enteral and parenteral alimentation and from administration of osmotic agents, such as mannitol and radiocontrast agents. Finally, fluid can be lost during the generation phase of metabolic alkalosis, in which compensatory urinary bicarbonate excretion obligates renal sodium excretion. This frequently results in volume depletion.

Table 29-8 Signs and Symptoms of Hypovolemia and Hypervolemia

Parameters	Hypovolemia	Hypervolemia
Skin and subcutaneous tissues	Dry, less elastic	Warm, moist, pitting edema over bony prominences; wrinkled skin from pressure of clothing
Face	Sunken eyes (late symptom)	Periorbital edema
Tongue	Dry, coated (early symptom); fissured (late symptom)	Moist
Saliva	Thick, scanty	Excessive, frothy
Thirst	Present	May not be significant
Temperature	May be elevated	May not be significant
Pulse	Rapid, weak, thready	Rapid
Respirations	Rapid, shallow	Rapid dyspnea, moist rales, cough
Blood pressure	Low, orthostatic hypotension; small pulse pressure	Normal to high
Weight	Loss	Gain

with loss of elasticity, sunken eyes, loss of axillary sweating, and a dry, coated tongue. When severe volume depletion occurs, thirst, decreased urine volume, and weight loss may be noted; however, weight loss and orthostatic blood pressure and pulse changes may be the only findings.

Laboratory studies, such as a high urine osmolality and low urinary sodium, may facilitate the diagnosis. Other guidelines, such as elevated hematocrit, decreased central venous pressure, and decreased pulmonary wedge pressure, may corroborate the diagnosis.

In fluid overload, the patient, if alert, may complain of puffiness or stiffness in the hands and feet. Later, periorbital edema or puffiness, followed by pitting edema of the dependent parts (feet and ankles if upright; sacral area and posterior thighs if supine) will occur, followed by dyspnea or ascites, depending on etiology (ie, cardiac decompensation and systemic fluid overload versus hepatic disease). Urine volume and urine sodium may be normal, increased, or decreased, depending on the etiology. In most diseases with fluid retention, except for the syndrome of inappropriate ADH secretion, urine sodium is reduced. The hematocrit is decreased, reflecting hemodilution.

The pulse may be rapid, and auscultation of the heart may reveal a third heart sound (S_3), fourth heart sound (S_4), or murmur secondary to volume overload. Respirations may be increased because of pulmonary congestion, and auscultation of the chest may reveal rales. A chest film may reveal pulmonary vascular congestion, increased alveolar lung markings, cardiac dilation, frank pulmonary congestion, and pleural effusions.

All data should be evaluated in the light of other evidence. Trends usually are more significant than isolated values. For example, when a decrease in urine output is noted, a systematic assessment should be done to determine why this is happening and what nursing interventions are most appropriate. Depending on the stability of the patient, the health care team may use advanced physiological monitoring (eg, pulmonary artery catheter) to guide assessment and management. Table 29-9 lists factors affecting water balance.

Table 29-9 Factors Affecting Water Balance

	Water Excess	Water Deficiency
Intake		
Thirst	Decreased thirst threshold Increased osmolality Potassium depletion Hypercalcemia Fever Dry mucous membranes Poor oral hygiene Unmisted O_2 administration Hypotension Psychiatric disorders	Increased thirst threshold Decreased osmolality Lack of access Psychiatric disorders
Parenteral fluids	Excessive D_5W	Deficient replacement Osmotic loads Parenteral nutrition Hyperglycemia Mannitol Radiographic contrast agents

Left-sided preload	Left ventricular failure Mitral/aortic valve disease Left ventricular papillary muscle dysfunction	

Hemodynamic Monitoring

Hemodynamic monitoring offers the clinician an improved assessment of the patient's overall status. For a detailed discussion, refer to Chapter 17. Although physical assessment may provide insight into the volume status, changes in physical assessment are reflected later than changes in hemodynamic assessment parameters, such as central venous pressure. Through improved monitoring, interventions are guided by information on a real-time basis. Table 29-10 provides an overview of the causes of altered parameters for the assessment of preload.

Based on data from the history, physical examination, and laboratory and diagnostic tests, nursing diagnoses are developed for the patient with renal problems. Box 29-4 lists possible nursing diagnoses.

BOX 29-4 EXAMPLES OF NURSING DIAGNOSES

For the Patient with Renal, Fluid, or Electrolyte Problems

- Acute Pain related to urinary retention
- Chronic Pain related to urinary retention
- Acute Pain: Dysuria related to infection
- Acute Pain: Dysuria related to urinary obstruction
- Impaired Urinary Elimination related to urinary tract obstruction
- Disturbed Body Image
- Excess Fluid Volume related to impaired kidney function
- Risk for Deficient Fluid Volume related to impaired kidney function
- Activity Intolerance
- Acute Confusion
- Risk for Electrolyte Imbalance
- Risk for Falls
- Risk for Ineffective Renal Perfusion
- Impaired Gas Exchange

▲ Clinical Applicability Challenges

CASE STUDY

Mr. J. is admitted to the intensive care unit following cardiac bypass surgery. He has a history of diabetes, type 2, and is controlled with oral hypoglycemic agents. His glycalated hemoglobin is 6.5%. He had a preoperative ejection fraction of 20%. His bypass time was 45 minutes with a total surgery time of 3 hours. He received 4 units of packed RBCs. Postoperatively, his hemodynamic profile is as follows:

- Heart rate 63 beats/min
- Blood pressure 115/65
- Pulmonary capillary wedge pressure 22 mm Hg
- Central venous pressure 8 mm Hg
- Cardiac index 1.5 L/min/m^2

Urine output has been 30 to 45 mL/h over the past 4 hours. The next morning, his lab values are as follows:

- Na^+ 135 mEq/L
- K^+ 4.2 mEq/L
- Cl^- 90 mEq/L
- BUN 35 mg/dL
- Cr 1.4 mg/dL

1. Describe the risk factors Mr. J. has for developing acute kidney injury. How can each factor contribute to the development of acute kidney injury?
2. What clinical assessment and physiologic data support the diagnosis for acute kidney injury?
3. What are some additional diagnostic tests that may be performed?
4. Outline the monitoring plan for Mr. J. related to his acute kidney injury.

30 Patient Management: Renal System

Angela C. Muzzy and Kara Adams Snyder

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Explain the physiological principles involved in renal replacement therapy: hemodialysis, continuous renal replacement therapies, and peritoneal dialysis.
2. Analyze the differences in equipment and procedures used in renal replacement therapy.
3. Explain the types of vascular access used in hemodialysis and continuous renal replacement therapies.
4. Compare and contrast the indications, assessment and management, and complications for each renal replacement therapy.
5. Discuss the psychosocial and teaching needs surrounding renal replacement therapy for patients and their families.
6. Describe the nursing assessments and interventions for patients receiving fluid therapy.
7. Analyze the specific fluid therapies chosen based on physiological alterations.
8. Explain the nursing management for patients with selected electrolyte disorders.

Renal function may be replaced by a process called dialysis, which is a life-maintaining therapy used in acute kidney injury and chronic kidney disease (also known as chronic renal failure). Critical care nurses may encounter patients suffering from the effects of acute kidney injury or patients already on some form of chronic dialysis who subsequently become critically ill. Critical care nurses must be familiar with various dialysis therapies to help care for patients with complex illnesses. This chapter discusses the three most common forms of renal replacement therapy: hemodialysis, continuous renal replacement therapies (CRRTs), and peritoneal dialysis. Common fluid and electrolyte imbalances experienced by critically ill patients also are explored.

▲ Physiology

All forms of dialysis make use of the principles of osmosis and diffusion to remove waste products and excess fluid from the blood. A semipermeable membrane is in the dialysis circuit between the blood and the dialysate. Dissolved substances, such as urea and creatinine, diffuse across the membrane from an area of greater concentration (blood) to an area of lesser concentration (dialysate). Water molecules move across the membrane by osmosis to the solution that contains fewer water molecules. Dialysate is formulated with varying concentrations of dextrose or sodium to produce an osmotic gradient, thereby pulling excess water from the circulatory system. This process of fluid moving across a semipermeable membrane in relation to forces created by osmotic and hydrostatic pressures is called ultrafiltration. These basic principles are the foundation of any dialysis therapy. The manner in which they are accomplished varies depending on the therapy.

▲ Extracorporeal Therapies

Hemodialysis and the CRRTs use an extracorporeal (outside the body) circuit. Therefore, they require access to the patient's circulation and anticoagulation of the circuit.

Access to Circulation

The three most common methods used to access a patient's circulation are through a vascular catheter, an arteriovenous fistula, or a synthetic vascular graft. Patients who suddenly need hemodialysis or CRRT have a venous catheter, whereas

BOX 30-1 NURSING INTERVENTIONS

For the Patient With Dialysis Vascular Access

Dual-Lumen Venous Catheter

- If in upper torso, verify central line catheter placement radiographically before use.
- Do not inject IV fluids or medication into the catheter. Both lumens of the catheter may be filled with concentrated heparin.
- Do not unclamp the catheter unless preparing for dialysis therapy. This can cause blood to fill the lumen and clot.
- Maintain sterile technique in handling vascular access.
- Observe catheter exit site for signs of inflammation or catheter kinking.

Arteriovenous Fistula or Graft

- Do not take blood pressure or draw blood from the access limb.
- Listen for bruit and palpate for thrill every 8 hours and before and after accessing.
- Make sure there is no tight clothing or restraints on the access limb.
- Check access patency more frequently when patients are hypotensive. Hypotension can predispose the blood to clotting.
- In the event of postdialysis bleeding from the needle site, apply just enough pressure to stop the flow of blood and hold the pressure until bleeding stops. Do not occlude the vessel.

patients already receiving chronic hemodialysis typically have either an arteriovenous fistula or a synthetic vascular graft. Box 30-1 lists nursing interventions for the patient with dialysis vascular access.

Venous Catheters

Dual-lumen catheters inserted into large central veins are used for acutely ill patients who need hemodialysis, continuous venovenous hemofiltration (CVVH), or continuous venovenous hemofiltration with dialysis (CVVH/D). These catheters are also used for hemodialysis when there is no other means of access to the circulation. Veins commonly used are the femoral, internal jugular, and subclavian. The site chosen depends on the patient's anatomy and vein accessibility and the physician's experience and preference.

Dual-lumen venous catheters are also used temporarily for patients on acute dialysis who are critically ill or patients on chronic dialysis who are waiting for a more permanent access to mature. Tunneled dual-lumen central venous catheters are often used as a permanent means of access for patients in whom all other means of entry into the circulatory system have been exhausted. The tunneled catheter has an implantable cuff around which tissue grows and acts as a barrier against infection. If possible, the catheter should be placed in the right or left internal jugular vein because catheters placed in the subclavian vein can cause stenosis. The stenosis can cause increased venous pressure and edema that may thwart future efforts to create an arteriovenous fistula or place a graft.

Whenever venous catheters are used, care must be taken to avoid accidental slippage and dislodgment during hemodialysis. For safety, catheters are usually secured with sutures as well as tape to avoid movement. The length of time catheters are left in place depends on catheter function and institutional policy. In general, central venous catheters may be used for up to 3 to 4 weeks. To reduce the risk of catheter-related bloodstream infection, the guidelines from the Centers for Disease Control suggest placing a tunneled catheter if hemodialysis is expected to last longer than 3 weeks.[1] More permanent internal jugular vein catheters often function for many months before problems force their removal. Catheters left in place between dialysis treatments usually are filled with a concentrated heparin-saline solution or 0.9% normal saline solution (dependent upon end cap used and institutional policy) after dialysis to prevent clotting. These catheters should never be used for any purpose other than hemodialysis without first checking with dialysis unit personnel. Cleansing and dressing of the insertion site are the same as with other central lines using strict aseptic technique.

If the catheters are removed at the end of dialysis, pressure is applied to the puncture sites until complete clotting occurs. The site is checked for several hours thereafter so that any recurrent bleeding can be detected. Removal of the more permanent tunneled catheter requires use of local anesthetic at the exit site and careful dissection around the cuff to free it from the attached subcutaneous tissue.

Catheter patency must be maintained. Thrombolytics may be used to dissolve clots in venous catheters. Thrombolytics are enzymes derived from streptococcal bacteria that are capable of activating the fibrinolytic system and dissolving intravascular thrombi. These agents can help preserve vascular access and reduce the need for surgery or catheter reinsertion. However, their use is associated with inherent risks and side effects, including bleeding and an allergic response. The key element in catheter patency is in preventing the formation of thrombosis via proper and routine flushing.

In the early days of dialysis, vascular access was created at every treatment by cannulating an artery to remove blood from the body and a vein to return dialyzed blood to the patient. The lines carrying blood to the dialyzer were called arterial lines, and the lines returning blood to the body were called venous lines. The two lumens of the venous catheter used in dialysis are still designated as arterial and venous. The "arterial" lumen is longer than the venous lumen, so it can pull the venous blood flowing by and allow it to be pumped out of the body and to the dialyzer. Blood is returned upstream from the "arterial" lumen to avoid pulling out the blood that has just been dialyzed and returned to the body. The lumens are distinguished by the presence of colored ends: red on the "arterial" lumen and blue on the venous lumen.

Arteriovenous Fistulas

The arteriovenous fistula technique was developed in 1966 in an effort to provide long-term access for hemodialysis. To create the arteriovenous fistula, a surgeon anastomoses an artery and a vein, creating a fistula or artificial opening between them (Fig. 30-1A). Arterial blood flowing into the venous system results in a marked dilation of the vein, which can then be punctured easily with a 15- or 16-gauge dialysis

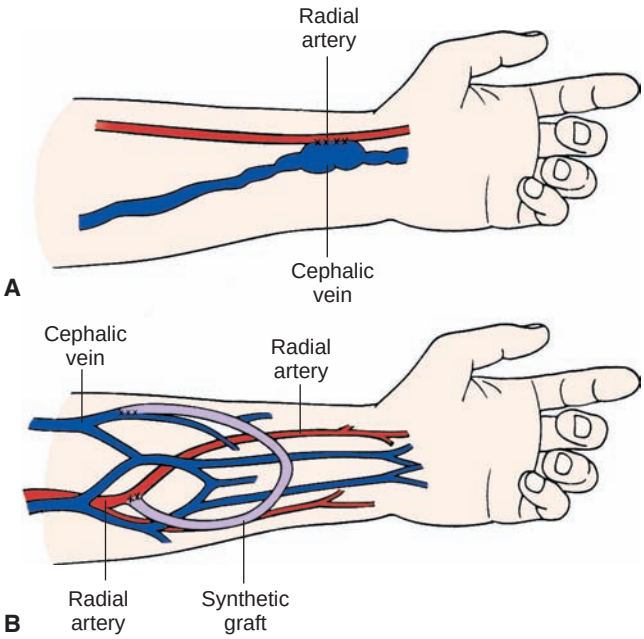

FIGURE 30-1 ▲ Methods of vascular access for hemodialysis. **A:** Arteriovenous fistula. **B:** Synthetic graft.

BOX 30-2 TEACHING GUIDE *Caring for an Arteriovenous Fistula*

- Wash the fistula site with antibacterial soap each day and always before dialysis.
- Refrain from picking the scab that forms after completion of dialysis therapy.
- Check for redness, feeling of excess warmth, or the beginning of a pimple on any area of access.
- Ask the dialysis care team to rotate needles at the time of dialysis treatment.
- Check blood flow several times each day by feeling for a pulse or thrill. If this is not felt, or if there is a change, call your health care provider or dialysis center.
- Refrain from wearing tight clothes or jewelry on the access arm. Also avoid carrying anything heavy or doing anything that will put pressure on the access site.
- Avoid sleeping with your head on the arm where the access site is located.
- Remind care givers and staff not to use a blood pressure cuff on, or draw blood from, the arm where the access site is located.
- Apply only gentle pressure to the access site after the needle is removed. Too much pressure stops flow of blood to the access site.

fistula needle. Two venipunctures are made at the time of dialysis: one for blood outflow and one for blood return.

After the arteriovenous fistula incision has healed, the site is cleansed by normal bathing or showering. To avoid scar formation, excessive bleeding, or hematoma of the arteriovenous fistula, care is taken to avoid traumatic venipuncture, excessive manipulation of the needles, and repeated use of the same site for venipuncture. Adequate pressure must be put on the puncture sites after the needles are removed. In addition, blood pressure measurements and venipunctures should not be performed on the arm with the fistula. For inpatients, a sign posted above the patient's head of bed is advisable regarding these precautions. This aids in ensuring communication regarding the fistula precautions.

Most arteriovenous fistulas are developed and ready to use 1 to 3 months after surgery. After initial healing has occurred, patients are taught to exercise the arm to assist in vessel maturation. They also are encouraged to become familiar with the quality of the "thrill" felt at the site of anastomosis so that they can report any change in its presence or strength. A loud, swishing sound termed a *bruit* plus a palpable thrill indicates a functioning fistula. Box 30-2 presents a patient teaching guide for the care of arteriovenous fistulas.

Although arteriovenous fistulas usually have a long life, complications may occur. These include thrombosis, aneurysm or pseudoaneurysm, or arterial insufficiency causing a "steal syndrome." Steal syndrome occurs when shunting of blood from the artery to the vein produces ischemia of the hand, causing pain or coldness in the hand. Surgical intervention can remedy these problems and restore adequate fistula flow.

Synthetic Grafts

The synthetic graft is made from polytetrafluoroethylene (PTFE), a material manufactured from an expanded, highly porous form of Teflon. The graft is anastomosed between an artery and a vein and is used in the same manner as an arteriovenous fistula (see Fig. 30-1B).

For many patients whose own vessels are not adequate for fistula formation, PTFE grafts are extremely valuable. PTFE segments are also used to patch areas of arteriovenous grafts or fistulas that have stenosed or developed areas of aneurysm. It is best to avoid venipuncture in new PTFE grafts for 2 to 4 weeks while the patient's tissue grows into the graft. When tissue growth progresses satisfactorily, the graft has an endothelium and wall composition similar to the patient's own vessels.

The procedures for preventing complications in grafts are the same as those used for arteriovenous fistulas. However, certain complications are seen more frequently with grafts than with fistulas, including thrombosis, infection, aneurysm formation, and stenosis at the site of anastomosis.

Anticoagulation

Blood in the extracorporeal system, such as the dialyzer and blood lines, clots rapidly unless some method of anticoagulation is used. Heparin is most commonly used because it is simple to administer, it increases clotting time rapidly, it is monitored easily, and its effect may be reversed with protamine. Citrate solutions may also be used for anticoagulation during dialysis. This agent chelates calcium, thereby inactivating the clotting cascade. Evidence suggests that the use of citrate in CRRTs is associated with fewer life-threatening bleeding complications than heparin.[2,3]

Specific anticoagulation procedures vary, but the primary goal of all methods is to prevent clotting in the dialyzer with the least amount of anticoagulation. Two methods of heparinization commonly used are intermittent and continuous infusion. Regardless of the type of anticoagulation used, close monitoring of appropriate laboratory values is necessary to ensure patient safety.

Systemic Anticoagulation

Typically, the circuit is initially primed with a dose of heparin, followed by smaller intermittent doses of anticoagulant or heparin administered at a constant rate by an infusion pump. This results in systemic anticoagulation, in which the clotting times of the patient and the dialyzer essentially are the same.

Definitive guidelines are difficult to provide because methods and dialyzer requirements vary. The normal clotting time of 6 to 10 minutes may be increased to 30 to 60 minutes. The effect of heparin is generally monitored by the activated partial thromboplastin time (aPTT).

The patient's need for heparinization and an appropriate beginning heparin dose should be assessed routinely before dialysis, especially in the critically ill patient who may be actively bleeding or at risk for bleeding. In addition, there is also a need to assess for the development of heparin-induced thrombocytopenia with the administration of all heparin products (refer to Chapter 49 for a discussion of hematologic abnormalities), and there is evidence that the use of argatroban for CRRT may be of benefit.[4] The patient's platelet count, serum calcium level, and results of coagulation studies are valuable in assessing current function of the clotting process. Often, little or no heparin may be used when the patient has serious alterations in one or more factors needed for effective clotting.

Regional Anticoagulation

Regional anticoagulation is another option to maintain blood flow during extracorporeal therapies. Regional anticoagulation is where the patient's clotting time is kept normal while the clotting time of the dialyzer is increased. This is accomplished by infusing the anticoagulant at a constant rate into the dialyzer and simultaneously neutralizing its effects with its antidote before the blood returns to the patient. Typical combinations include heparin/protamine sulfate or trisodium citrate/calcium.

Regional anticoagulation has no associated standard ratios of anticoagulants to antidotes. Frequent monitoring of the clotting times with adjustment of the antidote rate is the best way to achieve effective regional anticoagulation. One patient safety concern is bleeding secondary to overanticoagulation. Causes of overanticoagulation include infusion pump malfunction, errors in setting delivery rates, and infrequent monitoring of clotting times. Because of these hazards, anticoagulation delivery must be monitored carefully and frequently, with meticulous checking of pump rates.

Another way to prevent dialyzer clotting and reduce the risk for bleeding from anticoagulation is to administer the anticoagulant with intermittent boluses and use frequent normal saline flushes. Occasionally, saline flushes are used alone.

When regional citrate anticoagulation is used, citrate is infused into the system before the dialyzer binds calcium, obstructing the normal clotting pathway. The patient's sodium levels may rise because the citrate is administered in the form of sodium citrate.[3] Citrate has a higher pH, and therefore, patients may also develop metabolic alkalosis.

▲ Intermittent Hemodialysis

In hemodialysis, water and excess waste products are removed from the blood as it is pumped by the dialysis machine (Fig. 30-2) through an extracorporeal circuit (Fig. 30-3) into a device called a dialyzer or artificial kidney. The blood is in one compartment, and the dialysate is in another compartment. There, the blood flows through a semipermeable membrane. The semipermeable membrane is a thin, porous sheet made of cellulose or a synthetic material. The pore size of the membrane permits diffusion of low-molecular-weight substances such as urea, creatinine, and uric acid. In addition, water molecules are small and move freely through the membrane, but most plasma proteins, bacteria, and blood cells are too large to pass through the pores of the membrane. The difference in the concentration of the substances in the two compartments is called the concentration gradient.

FIGURE 30-2 ▲ Hemodialysis delivery unit, which includes an automatic blood pressure cuff, heparin infusion pump, and blood pump. This machine displays a continuous readout of ultrafiltration goal, rate, and total fluid removed and monitors dialysate temperature and conductivity. It can vary the sodium concentration of the dialysate. (Courtesy of Fresenius 2008T Fresenius VSA, Inc., Concord, CA.)

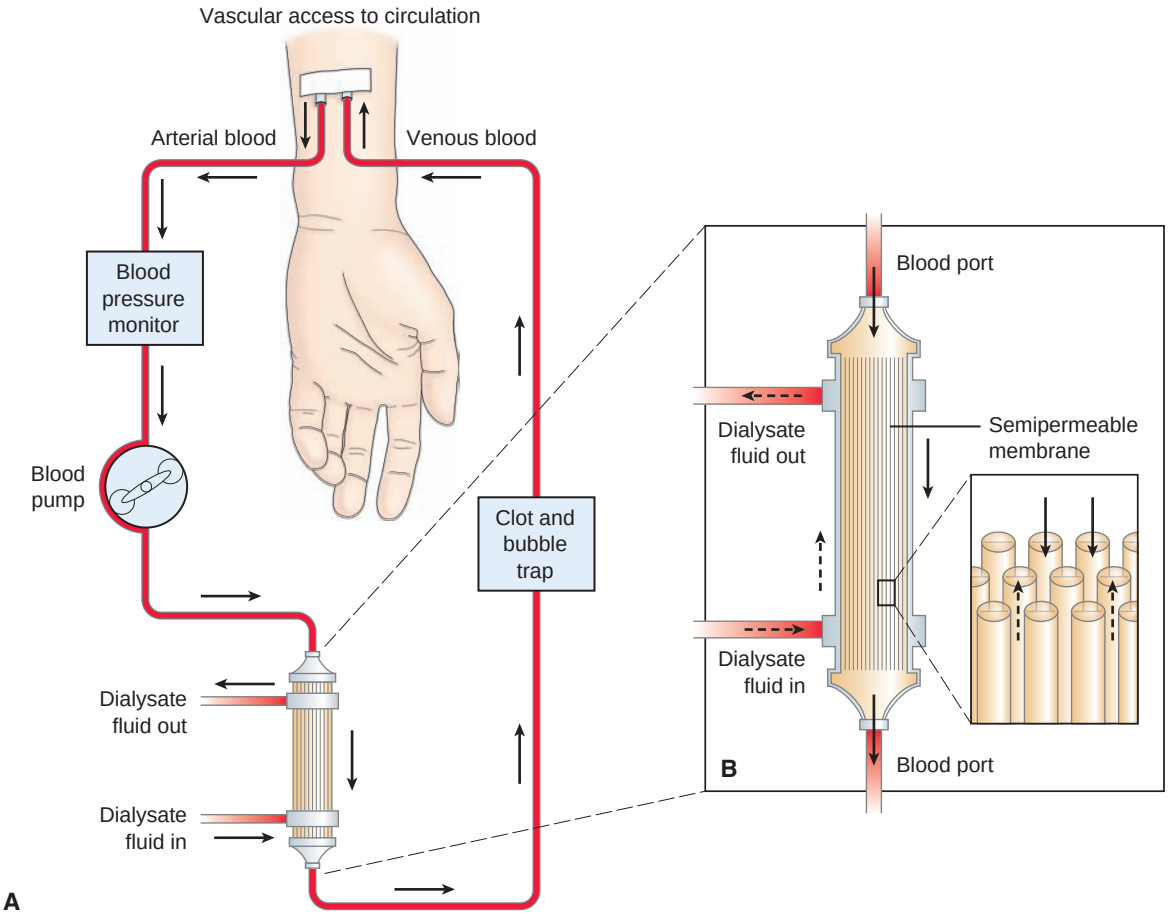

FIGURE 30-3 ▲ Hemodialysis system. **A:** Blood from an artery is pumped into a dialyzer (**B**), where it flows through the cellophane tubes, which act as the semipermeable membrane (**inset**). The dialysate, which has the same chemical composition as the blood except for urea and waste products, flows in around the tubules. The waste products in the blood diffuse through the semipermeable membrane into the dialysate. (From Smeltzer SC, Bare BG, Hinkle JL, Cheever KH: Brunner & Suddarth's Textbook of Medical-Surgical Nursing, 12th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 1334.)

The blood, which contains waste products such as urea and creatinine, flows into the blood compartment of the dialyzer, where it comes into contact with the dialysate, which contains no urea or creatinine. A maximal gradient is established so that these substances move from the blood to the dialysate. These waste products fall to more normal levels as the blood passes through the dialyzer repeatedly at a rate ranging from 200 to 400 mL/min over 2 to 4 hours.

Excess water is removed by a pressure differential created between the blood and fluid compartments. This pressure differential is aided by the action of the dialyzer pump and usually consists of positive pressure in the blood path and negative pressure in the dialysate compartment. This is the process of ultrafiltration.

In summary, hemodialysis:

- Removes by-products of protein metabolism, such as urea, creatinine, and uric acid
- Removes excess water
- Maintains or restores the body's buffer system
- Maintains or restores electrolyte levels in the body.

Indications for Hemodialysis

Hemodialysis is indicated in chronic renal failure and for complications of acute kidney injury. These include uremia, fluid overload, acidosis, hyperkalemia, and drug overdose. Table 30-1 compares hemodialysis, CRRT, and peritoneal dialysis, and Box 30-3 lists indications for dialysis.

Contraindications to Hemodialysis

Hemodialysis may be contraindicated in patients with coagulopathies because the extracorporeal circuit needs to be heparinized. Intermittent hemodialysis may also be difficult to perform in patients who are hypotensive, have extremely low cardiac output, or are sensitive to abrupt changes in volume status. For these critically ill patients in these situations, CRRT may be the optimal choice. In addition, intermittent hemodialysis may not keep up with the metabolic needs of a highly catabolic patient. In this case, CRRT would likely be chosen as the dialysis method. Patients treated chronically for renal failure may be given the choice to undergo hemodialysis or peritoneal dialysis.

Table 30-1 Comparison of Hemodialysis, Continuous Renal Replacement Therapy, and Peritoneal Dialysis

	Hemodialysis	CRRT	Peritoneal Dialysis
Access	Arteriovenous fistula or graft; dual-lumen venous catheter	Dual-lumen venous catheter	Temporary or permanent peritoneal catheter
Anticoagulation requirements	Systemic heparinization or frequent saline flushes	Systemic anticoagulation with heparin or trisodium citrate may be indicated depending on patient's coagulation studies before starting therapy	May only need heparin intraperitoneally Not absorbed systemically
Length of treatment	3–4 h, three or more times per week, depending on patient acuity and need	Continuous throughout day; may last as many days as needed	Continuous (cycled) or intermittent exchanges; time between exchanges = 1–6 h
Advantages	Quick, efficient removal of metabolic wastes and excess fluid Useful for drug overdoses and poisonings	Best choice for patient who is hemodynamically unstable because less blood is outside body than with hemodialysis and blood flow rates are slower; amount of fluid removed can still be achieved but over a much longer period of time Good for hypercatabolic patients who receive large amounts of IV fluids	Continuous removal of wastes and fluid Better hemodynamic stability Fewer dietary restrictions
Disadvantages	May require frequent vascular access procedures Places strain on a compromised cardiovascular system Potential blood loss from bleeding or clotted lines Requires specially skilled staff to perform therapy Risk of bloodstream infection	Requires vascular access procedures; potential blood loss from clotting or equipment leaks; uses an extra piece of equipment Requires specially skilled staff to perform therapy Costly Risk of bloodstream infection	Contraindicated after abdominal surgery or in presence of many scars Waste products may be removed too slowly in a catabolic patient Danger of peritonitis Abdominal discomfort

Assessment and Management

The degree and complexity of problems arising during hemodialysis vary among patients and depend on many factors. Important variables are the patient's diagnosis, stage of illness, age, other medical problems, fluid and electrolyte balance, prior experience with hemodialysis, and emotional state. Because an increasing number of older adults are receiving dialysis, it is also important to consider the normal renal and urinary system changes resulting from the aging process (Table 30-2).

Preprocedure

A predialysis assessment is the first step in managing the patient receiving hemodialysis. It consists of a review of the patient's history and clinical findings, response to previous dialysis treatment, laboratory results (such as electrolytes), consultation with other care givers, and the nurse's direct assessment of the patient.

BOX 30-3 Indications for Dialysis

- Anuria secondary to acute/chronic kidney failure
- Symptomatic pulmonary edema unresponsive to diuretic therapy
- Severe electrolyte disturbances (ie, hyperkalemia and hyperphosphatemia refractory to medical therapy)
- Metabolic acidosis
- Uremic complications involving other organs (ie, pericarditis, encephalopathy)
- Drug/toxin overdoses that are dialyzable (ie, salicylates)
- Evolving use of hemodialysis in the literature: Treatment of sepsis

The nurse evaluates fluid balance before dialysis so that corrective measures may be initiated at the beginning of the procedure. Blood pressure, pulse, weight, intake and output, tissue turgor, and other symptoms assist the nurse in estimating fluid overload or depletion. Monitoring tools, such as pulmonary artery catheters and central venous pressures, also help determine cardiovascular fluid load.

The term *dry weight* or *ideal weight* is used to express the weight at which fluid volume is in a normal range for a patient who is free of the symptoms of fluid imbalance. It provides a guideline for fluid removal or replacement. The figure is not absolute. It requires frequent review and revision, especially in patients receiving dialysis in whom frequent weight changes occur.

After reviewing the data and while consulting with the physician and the bedside nurse (as applicable), the dialysis nurse establishes objectives regarding fluid removal and restoration of electrolyte balance for the dialysis treatment. The objectives vary from one dialysis to the next in the patient whose condition may change rapidly. For example, fluid removal may take precedence over correction of an electrolyte imbalance or vice versa.

Anxiety and apprehension, especially during the first dialysis, may contribute to change in blood pressure, restlessness, and gastrointestinal upset. The presence of a competent and

Table 30-2 Renal and Urinary System Changes Resulting From the Aging Process

Pathophysiologic Changes	Physiologic Effects	Nursing Implications
Decrease in number and function of nephrons	Decreased ability to concentrate urine and conserve water. At risk for dehydration; dry mouth.	Provide routine oral care and offer fluids liberally (as ordered).
Decreased GFR	Decreased secretion of sodium, water, urea, ammonia, and drugs. Increased risk for confusion, dry skin, thirst. Less clearance of renally eliminated drugs leading to toxicity.	Fall precautions as needed. Thorough skin assessments with position changes every 2 h. Review medications/prescriptions with multidisciplinary team to ensure appropriate medications and doses for age.
Decline in kidney efficiency	Predisposes to hypernatremia, fluid overload, drug reactions.	Routine assessment for heart failure symptoms (crackles, edema, S3 heart tones). Daily weights and I&O as ordered.
Reduction in bladder tonicity and capacity	Increased residual urine, nocturnal urination. Risk for incontinence and associated skin breakdown. Increased risk of falls associated with incontinence.	Monitor for incontinence and skin breakdown. Provide skin protection as appropriate. Offer toileting program. Call bell in reach at all times. Teach Kegel exercises.
Decreased regulatory functions such as sensation of thirst, secretion of aldosterone, calcium absorption, response to vasopressin	Increased risk for dehydration. Less ability to conserve sodium and excrete potassium. Altered bone formation. Risk for injury. Increased needs for supplements. Risk for hypotensive episodes.	Provide adequate fluid intake and encourage as appropriate. Monitor for fluid and electrolyte imbalances. Assess gait and balance, place on fall precautions if indicated.

caring nurse during dialysis may increase the patient's sense of security enough to avoid the need for an antianxiety drug that might precipitate changes in vital signs.

A basic explanation of the procedure and its place in the total plan of care for the patient may also allay some of the anxiety experienced by the patient and family. They must understand that dialysis is being used to support normal body function rather than to "cure" the kidney disease process.

Procedure

The nurse begins the procedure by checking the equipment (Box 30-4). After predialysis preparation and a safety check of equipment, the nurse is ready to begin hemodialysis. Access to the circulatory system is gained by one of several options: a dual-lumen catheter, an arteriovenous fistula, or a graft. The dual-lumen catheter is opened under aseptic conditions according to institutional policy. Two large-gauge (15- or 16-gauge) needles are needed to cannulate a graft or fistula.

BOX 30-4 NURSING INTERVENTIONS

For Checking Hemodialysis and Continuous Venovenous Hemofiltration With Dialysis Equipment

- Prime lines and dialyzer or filter to expel all air before starting treatment.
- Test all alarms before connecting the patient to the circuit.
- Respond to all alarms immediately.
- Replace wet pressure transducers if they interfere with transmission of pressure reading.
- Inspect and tighten all connections before initiating treatment.

Figure 30-3 on page 641 illustrates the hemodialysis circuit. After vascular access is established through strict aseptic technique, blood begins to flow, assisted by the blood pump. The part of the disposable circuit before the dialyzer is designated the arterial line, both to distinguish the blood in it as blood that has not yet reached the dialyzer and in reference to needle placement. The arterial needle is placed closest to the arteriovenous anastomosis in a graft or fistula to maximize blood flow. A clamped bag of saline solution is always attached to the circuit just before the blood pump. In episodes of hypotension, blood flow from the patient can be clamped while the bag of saline solution is opened and allowed to infuse rapidly to correct blood pressure. Blood transfusions and plasma expanders also can be attached to the circuit at this point and allowed to drip in, assisted by the blood pump. Heparin infusions may be located either before or after the blood pump, depending on the equipment in use.

The dialyzer is the next important component of the circuit. Blood flows into the blood compartment of the dialyzer, where exchange of fluid and waste products takes place. Blood leaving the dialyzer passes through an air detector that shuts down the blood pump if any air is detected. At this point in the pathway, any medications that can be given during dialysis are infused through a medication port. However, unless otherwise ordered, most medications are withheld until after dialysis.

Blood that has passed through the dialyzer returns to the patient through the venous (postdialyzer) line. After the prescribed treatment time, dialysis is terminated by clamping off blood from the patient, opening the line for saline solution, and rinsing the circuit to return the patient's blood.

A dialysis nurse is in constant attendance during acute hemodialysis. Blood pressure and pulse are recorded at least every half hour when the patient's condition is stable. All

machine pressures and flow rates are checked and recorded on a regular basis. The nurse assesses the patient's responses to fluid and solute removal and the condition and function of the patient's vascular access. Gloves are always worn by the nurse performing hemodialysis because of the risk for exposure to blood. The dialysis nurse and critical care nurse work together to care for the patient because they must coordinate their specific patient care responsibilities.

Postprocedure

The results of a dialysis treatment can be determined by assessing the amount of fluid removed (as assessed by postdialysis weight) and the degree to which electrolyte and acid–base imbalances have been corrected. Blood drawn immediately after dialysis may show falsely low levels of electrolytes, urea nitrogen, and creatinine. The process of equilibration is thought to continue for some time after dialysis because these substances move from inside the cell to the plasma. To ensure accuracy of laboratory data after dialysis, a minimum of 2 to 3 hours should elapse before samples for laboratory tests are taken from the patient.

Complications

Dialysis Dysequilibrium

Uremia must be corrected slowly to prevent dysequilibrium syndrome, which is a set of signs and symptoms ranging from headache, nausea, restlessness, and mild mental impairment to vomiting, confusion, agitation, and seizures. This is thought to occur as the plasma concentration of solutes, such as urea nitrogen, is lowered. Blood urea and nitrogen play a role in calculating the serum osmolarity. Because of the blood–brain barrier, solutes are removed much more slowly from brain cells. Therefore, plasma becomes hypotonic in relation to the brain cells. This results in a shift of water from plasma to the brain cells and causes cerebral edema and symptoms of dysequilibrium syndrome. This syndrome can be avoided by dialyzing patients for short periods, such as 1 to 2 hours on 3 or 4 consecutive days.

Hypovolemia

Fluid overload is treated during dialysis by removing excess water. Because this removal depends on shifting fluid from other body compartments to the vascular space, clinicians must take care to avoid removing fluid so rapidly during dialysis that it leads to volume depletion. Excessive fluid removal may lead to hypotension, and little is gained if intravenous (IV) fluids are given to correct the problem. Therefore, it is better to reduce the volume overload over two or three dialyses, unless pulmonary congestion is life threatening.

Hypotension

Generally, normal saline solution in bolus amounts of 100 to 200 mL is used to correct hypotension. Dialysis machines now aid in preventing hypotension because the amount of ultrafiltration is controlled at the push of a button. It is also possible to vary the sodium concentration of dialysate. A higher sodium level in the dialysate means that less sodium is removed from the blood. A higher serum sodium assists the body as it shifts fluid from the interstitial to the intravascular compartment. Blood volume expanders, such as albumin, are sometimes used in patients with a low serum protein.

The use of antihypertensive drugs in patients who undergo dialysis may precipitate hypotension during dialysis. To avoid this, standard practice in many dialysis units is to omit antihypertensive drugs 4 to 6 hours before dialysis. Restriction of fluids and sodium before and during the dialysis phases is a more desirable method for controlling hypertension. Sedatives and tranquilizers also may cause hypotension and should be avoided, if possible.

Hypertension

Fluid overload, dysequilibrium syndrome, renin response to ultrafiltration, and anxiety are the most frequent causes of hypertension during dialysis. Hypertension during dialysis is usually caused by sodium and water excess. This can be confirmed by comparing the patient's present weight to his or her ideal or dry weight. If fluid overload is the cause of hypertension, ultrafiltration usually brings about a reduction in the blood pressure.

Some patients who may be normotensive before dialysis become hypertensive during dialysis. The blood pressure rise may occur either gradually or abruptly. The cause is not well understood, but it may be the result of renin production in response to ultrafiltration and an increase in renal ischemia. Patients must be carefully monitored because the vasoconstriction caused by the renin response is limited. Once a decrease in blood volume surpasses the ability to maintain blood pressure through vasoconstriction, hypotension can occur precipitously.

Muscle Cramps

Muscle cramps may occur during dialysis as a result of excess fluid removal, which results in diminished intravascular volume and reduced muscle perfusion. During dialysis, cramps may be treated by lowering the rate of ultrafiltration and administering hypertonic solutions, normal saline solution boluses, mannitol, or glucose in an attempt to increase perfusion to the muscles.

Dysrhythmias and Angina

Dysrhythmias and angina may occur in patients with underlying cardiac disease in response to fluid and electrolyte removal. Decreasing the rate of fluid removal may help. Medication may be needed to control the patient's cardiac rhythm.

▲ Continuous Renal Replacement Therapies

In continuous renal replacement therapy (CRRT), blood circulates outside the body through a highly porous filter similar to that used with hemodialysis. The process is similar to hemodialysis in that water, electrolytes, and small to medium-sized molecules are removed by ultrafiltration. CRRT is accompanied by a simultaneous reinfusion of a physiological solution, and it occurs continuously for an extended period. A pump, slightly different from that used in hemodialysis,

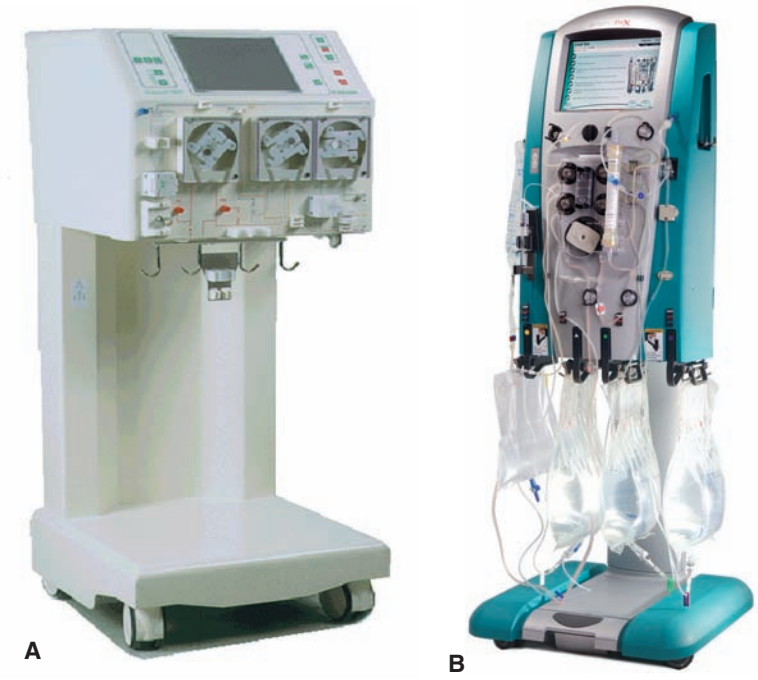

FIGURE 30-4 ▲ Devices for administering continuous renal replacement therapy (CRRT) offer an integrated fluid warmer for the heating of infusion and dialysate fluids, a weighing system to reduce the possibility of error in assessing fluid balance, and a battery backup that allows treatments to continue when the patient is moved.
A: Diapact pump. (Courtesy B-Braun McGraw Corporation.)
B: PRISMAFLEX. (Courtesy of Gambro Renal Products, Inc.)

is used and often incorporates a weighing system so that fluids can be intricately balanced hour to hour (Fig. 30-4).

The most common types of CRRTs include CVVH, CVVH/D, and slow continuous hemofiltration (Table 30-3). This discussion focuses primarily on CVVH and CVVH/D because these therapies are replacing previous arteriovenous procedures. Access to the circulation for CVVH and CVVH/D is generally a large-bore dual-lumen central venous catheter designed for helodialysis. The extracorporeal circuit is similar to the hemodialysis circuit (Fig. 30-5). A pump is added to assist blood flow. The rate of blood flow is typically much slower than in hemodialysis (mimicking the patient's

Table 30-3 Continuous Renal Replacement Therapies

Type of Therapy	Mechanism of Action	Indications
Continuous venovenous hemodialysis (CVVHD)	Blood is driven from the access port through the low-permeability dialysis filter; there is a countercurrent flow of dialysis solution into the dialysate compartment and to the ultrafiltrate bag. There is hydrostatic pressure pushing molecules (electrolytes and toxins) and fluid and osmotic pressure pulling additional molecules (electrolytes and toxins) across the filter. Both actions create the effluent which drains into the ultrafiltrate collection bag. Solute clearance is mainly achieved by diffusion; replacement solution is not needed. Efficiency of clearance is limited to small molecules.	Fluid and solute clearance
Continuous venovenous hemofiltration (CVVH)	Blood is driven from the access port through the high-permeability dialysis filter; replacement fluid is added to the system, typically just prior to the filter This results in a "push-only" phenomena: there is hydrostatic pressure pushing molecules (electrolytes and toxins) and fluid across the filter. The addition of replacement fluid will increase this hydrostatic pressure to help facilitate clearance. The effluent created then drains into the ultrafiltrate collection bag. Fluid removed may or may not be replaced depending upon the needs of the patient. Ultrafiltration is in excess of patient weight loss; replacement solution is needed.	Fluid and solute clearance
Continuous venovenous hemofiltration with dialysis (CVVHD)	Both replacement fluid and dialysate are used. Blood is driven through highly permeable dialyzer, and countercurrent flow of dialysis solution is delivered on the dialysate compartment. Replacement fluid is added typically just prior to connection to the filter. Solute clearance is obtained both by diffusion and convection; replacement solution is needed to obtain fluid balance (sometimes referred to as "push–pull" dialysis). natural blood flow). The ultrafiltration rate is titrated to reach an hourly goal and is based on the patient's cardiac and pulmonary status.

When CVVH is used, a replacement fluid is ordered and is connected either before or after the filter, depending on patient characteristics and institutional practice. When dialysis is added to the CVVH process, it is called CVVH/D. Adding the dialysate increases the ability to remove wastes. Therefore, it is used when uremia must be aggressively managed, such as with the highly catabolic patient. CVVH and CVVH/D can be performed and managed by the critical care nurse. Typically, didactic training, competency assessment, and validation are performed before the nurse cares for patients receiving CRRT.

Indications for Continuous Renal Replacement Therapy

CRRT is indicated in the following circumstances: in patients with a high risk for hemodynamic instability who do not tolerate the rapid fluid shifts that occur with hemodialysis, in those who require large amounts of hourly IV fluids or parenteral nutrition, and in those who need more than the usual 3- to 4-hour hemodialysis treatment to correct the metabolic imbalances of acute renal failure. CVVH is used when patients primarily need excess fluid removed, whereas CVVH/D is used when patients also need waste products removed because of uremia. For a comparison of CRRT with hemodialysis and peritoneal dialysis, see Table 30-1 on page 642.

Contraindications to Continuous Renal Replacement Therapy

CRRT is contraindicated when patients become hemodynamically stable or no longer require continuous therapy, and intermittent hemodialysis should be used. It may be difficult to achieve access to circulation in some patients with coagulopathies, which may prolong initiation of therapy. Patient and family discussion is imperative before initiation of therapy; patients may not wish to receive CRRT, and it is essential that patient wishes be considered.

Equipment

A typical CVVH/D setup is shown in Figure 30-5. Blood exits the body through the arterial limb of the vascular access. The first infusion line shown is for anticoagulation. Located just before the blood pump is a line that measures pressure in the prefilter portion of the circuit, known as the arterial pressure. The blood pump, which propels blood into the filter, is next. An infusion port just after the blood pump is usually connected to normal saline solution for flushing the circuit or for attaching the replacement fluid. A bag of dialysate is shown flowing through the filter and surrounding the hollow fibers in which the blood travels. As the dialysate exits the filter, it passes through a sensor that detects microscopic amounts of blood, thereby warning of filter rupture. The dialysate and excess fluid removed from the patient are collected in a graduated/weighed collection device for easy measurement. Meanwhile, the blood exits the filter and passes into a drip chamber, where air and foam are trapped instead of entering the patient's circulation. The drip chamber also contains a line to which a syringe can be attached to raise and lower the blood level and another line that measures pressure in the postfilter section of the circuit, known as venous pressure. A clamp is located after the drip chamber and automatically engages if air tries to pass through it. The arterial and venous pressure transducers are protected by a disposable filter. As blood returns to the body, replacement fluid is infused. In some systems, the line for replacement fluid is placed before the blood pump so that it can be infused before the blood reaches the filter. The total amount of blood in the circuit is about 150 to 200 mL.

Assessment and Management

Preprocedure

Baseline hemodynamics, vital signs, laboratory values (ie, electrolytes and coagulation results), and weight are obtained before initiation of therapy. The potential exists for uncontrolled losses of a large amount of fluid. Because of this, an hourly fluid balance goal is set by the physician. Fluid is either removed or replaced each hour in varying amounts to achieve the fluid balance goal (Box 30-5).

Procedure

Before therapy is initiated, the equipment is checked (see Box 30-4, p. 643). The lines and filter are primed to expel air from the circuit. Arterial and venous lines are connected to the corresponding port of the access catheter, and the blood pump is turned on. Blood starts to flow through the tubing. Ultrafiltration begins to produce plasma water (ultrafiltrate) that starts to flow into the collection device. Blood flow rates through the circuit average 30 to 60 mL/min and up to 200 mL/min for optimal clearance. Substances are adequately cleared when ultrafiltration produces 500 to 600 mL/h of ultrafiltrate.

Anticoagulation, if indicated, is administered as therapy begins. Low-dose heparin is the standard anticoagulant used, and aPTT values should be monitored frequently. It may also be used along with saline flushes to prevent circuit clotting, which is the most common mechanism for interruption of CRRT. Saline flushes without low-dose heparin may be used when the patient has a low platelet count. A typical protocol is to flush 50 to 100 mL through the circuit every hour. Another method of anticoagulation is to infuse citrate before the filter. This anticoagulates only the extracorporeal part of the circuit. It chelates calcium, which is then replaced through infusion through the venous return line or peripherally to maintain normal ionized calcium levels.[4] Therefore, the patient needs to be closely monitored to prevent hypercalcemia or hypocalcemia.

Hourly maintenance of the CVVH/D system includes measuring blood and dialysate flows, calculating net ultrafiltration and replacement fluid, titrating anticoagulants, assessing the integrity of the vascular access, and monitoring hemodynamic parameters and blood circuit pressures. In consultation with the interdisciplinary team, the nephrologist sets a goal for hourly fluid balance, and the critical care nurse is responsible to see that it is met. Box 30-6 lists nursing interventions in monitoring fluid and electrolyte balance. By comparing total intake and output, the hourly net fluid balance is calculated. The amount of replacement fluid is determined by the difference between desired and net fluid balance. Fluid balance and replacement should be carefully documented in the patient's intake and output record.

In CVVH, replacement fluid may be infused before or after the filter. Both techniques have advantages and disadvantages. Fluid given before the filter decreases blood viscosity and increases blood flow through the filter. This enhances ultrafiltrate (plasma fluid) production and solute removal and decreases the frequency of clotting. The disadvantage is the increased need for fluid replacement. If replacement fluid is given after the filter, there is less total fluid loss and less need

BOX 30-5 Example Showing Hourly Fluid Goal With Intake and Output in Fluid Replacement in CVVH/D

1. The patient needs to have 100 mL of fluid removed per hour.
2. The patient receives 450 mL/h of IV fluid (eg, a blood transfusion and IV medications).
3. The patient has 100 mL of chest tube drainage and 50 mL of nasogastric drainage in 1 hour.
4. Dialysate is added at the rate of 1,000 mL/h to increase clearance.
5. The total amount of fluid in the collecting bag at the end of 1 hour is 1,500 mL. (Remember, 1,000 mL is 1 liter dialysate, so 500 mL has been filtered from the patient's plasma.)

To calculate the amount of replacement fluid, add the input fluid of 450 mL of IV fluid and 1,000 mL of dialysate. Output is the 500 mL that has been filtered from the patient's plasma, 50 mL of nasogastric drainage, and the 100 mL of chest tube drainage. Total output is 1,650 mL, and the total input is 1,450 mL. The difference is 200 mL. The hourly fluid removal goal of 100 mL is subtracted, indicating 100 mL has been removed in excess of the goal and needs to be replaced this hour.

BOX 30-6 NURSING INTERVENTIONS

For Monitoring Fluid and Electrolyte Balance During CVVH/D

- Monitor and record patient weight daily—preferably with the same scale and at the same time.
- Draw blood for electrolyte, blood urea nitrogen, and creatinine analysis before initiating treatment and then at least twice daily.
- Assess vital signs, central pressure readings (if available), intake, and output before initiating treatment and at least every hour during treatment.
- Collaborate with nephrologist to determine hourly fluid balance.
- Record all intake and output when calculating replacement fluid for the next hour.
- Administer replacement fluid tailored to the patient's electrolytes or obtain custom-mixed dialysate from the pharmacy.
- If hypotension occurs, administer boluses of saline solution as ordered (100 to 200 mL), reduce ultrafiltration and, if necessary, obtain an order for 5% albumin.
- Observe patient for signs of electrolyte imbalances (ie, electrocardiographic changes and muscle weakness, as with hypokalemia).

for replacement fluid. However, there is an increased incidence of filter clotting and decreased filter life. The method chosen depends on the system used and institutional preference.

Electrolytes, urea nitrogen, creatinine, and glucose levels are measured before the procedure is started and then at least every 6 to 12 hours. Electrolyte imbalances can be corrected by altering the composition of the replacement fluid or by custom-mixing the dialysate. Anticoagulation is monitored by checking activated clotting times or prothrombin time (PT) and partial thromboplastin time (PTT). Although frequency is determined by each institution, it is not unusual to check clotting times every 1 or 2 hours to prevent clotting of the filter and blood lines.

No one policy delineates the optimal time to change the circuit. Many institutions put a 24- to 48-hour limit on circuit life, although there are reports of filters lasting an average of 4 days. System performance is monitored by checking the amount of urea nitrogen in the filtrate compared with the amount of urea nitrogen before the filter. A decreasing ratio indicates inadequate performance. A decreasing rate of ultrafiltration and increases in the venous pressure indicate clotting in the filter.

Treatment may be interrupted to transport the patient for a diagnostic test or to fix a mechanical problem with the circuit or vascular access. Treatment may be terminated if the patient shows signs of recovering renal function. When it is determined that continuous therapy can be terminated, the blood is returned to the patient. First, the ultrafiltrate outlet is clamped, and the dialysate is turned off. Then, anticoagulation is turned off, and the blood is returned to the patient through a saline flush. Once the lines are clear, they are disconnected from the vascular access. Then, the vascular access is flushed and locked per unit policy. Documentation includes fluid balance, condition of the access, and the patient's response to treatment. The tubing and filter are disposable. When working with the circuit and ultrafiltrate, the nurse uses Standard Precautions. Box 30-7 lists some nursing diagnoses associated with hemodialysis and CRRT.

BOX 30-7 EXAMPLES OF NURSING DIAGNOSES

For the Patient Undergoing Hemodialysis or Continuous Renal Replacement Therapy

- Excess Fluid Volume related to renal impairment
- Deficient Fluid Volume related to renal replacement fluid removal
- Ineffective Renal Tissue Perfusion as manifested by decreased renal perfusion
- Risk for Infection related to invasive devices, malnutrition

Technical Complications in Continuous Venovenous Hemofiltration With Dialysis

Access Problems

Blood flows used in CVVH/D are much lower than for hemodialysis, making it more likely that a catheter will provide adequate flow. However, poorly functioning access jeopardizes the entire CVVH/D procedure. Depending on the location of the access catheter (especially femoral or internal jugular), the position of the patient can affect blood flow. An obstruction, such as a clot or kink in the arterial lumen of the catheter, results in less blood being delivered to the circuit and manifests as lowered arterial and venous pressures. Clots or kinks in the venous lumen of the catheter raise venous pressures as blood tries to return against an obstruction. The treatment may be temporarily halted while the nurse manually flushes each lumen to determine patency. If blood flow still cannot be established, the physician is notified for further intervention, such as administration of a thrombolytic to restore patency to the dialysis catheter or to replace the catheter.

Clotting

An early sign of filter clotting is a reduced rate of ultrafiltration that cannot be corrected by increasing blood flow. As clotting progresses, venous pressure rises, arterial pressure drops, and the blood lines appear dark. Clotting times are low. A bolus of saline solution may help determine the location and extent of clotting. It may be possible to return some of the patient's blood before changing the circuit, but if clotting is extensive, this should not be attempted. Box 30-8 lists some nursing interventions for maintaining blood flow through a CVVH/D circuit.

Air in the Circuit

If the connections are loose, or a prefilter infusion line runs dry, air disrupts the system by collecting in the drip chamber and setting off the air detector alarm and triggering the clamp on the venous line to close. The nurse assesses the circuit's integrity to detect the source of air. Before resetting the line clamp, the nurse makes sure all bubbles have been tapped out of the drip chamber, all connections are tight, and there is no danger of air getting into the patient's bloodstream.

BOX 30-8 NURSING INTERVENTIONS

For Maintaining Blood Flow Through A Continuous Venovenous Hemofiltration With Dialysis Circuit

- Check clotting times at initiation and at the prescribed intervals throughout treatment.
- Flush system as often as needed with saline solution to assess appearance of filter and circuit.
- Monitor ultrafiltration rates, venous and arterial pressure, and color of blood in circuit.
- If system is clotting, return as much blood as possible to the patient before changing the system.

Blood Leaks

Blood appears in the ultrafiltrate if there is any rupture inside the filter. The blood leak alarm sounds, and the blood pump stops. Testing the ultrafiltrate with a dipstick can verify a microscopic leak. Blood can be safely returned to the patient as long as there is no gross blood in the ultrafiltrate. Then the circuit should be changed. A gross leak is readily identifiable. Blood should not be returned to the patient, and the patient's hematocrit should be checked to determine the need for transfusion.

Physiological Complications in Continuous Venovenous Hemofiltration With Dialysis

Hypotension

If blood pressure and intravascular filling pressures fall below optimal, the nurse can increase the infusion rate of replacement fluid, decrease the amount of fluid removal, give a normal saline bolus, or titrate existing vasoactive IV drips. An infusion of 5% albumin may also help stabilize blood pressure. If this situation persists, the physician is consulted to adjust the net ultrafiltration goal.

Hypothermia

Some patients experience chills and lowered body temperature while their blood is circulating outside the body. If this happens, it may be advisable to use a blood warmer to warm either the dialysis lines, dialysate, or the replacement fluid. Advancements in the technologies used to perform CRRT have improved the precision of fluid balance and reduced the hypothermia that can develop with any extracorporeal therapy. And because hypothermia can cause clotting deficiencies and dysrhythmias, close monitoring of the patient's temperature along with interventions to achieve normothermia is essential.[2]

Psychological Aspects of Renal Replacement Therapies

The psychological impact of short-term renal replacement therapy is different from that of lifelong therapy. Although the patient depends on a machine in both situations, in short-term therapy, there is usually hope that the patient may recover renal function. Therefore, concerns usually focus on the discomfort associated with insertion of the temporary vascular access and the dialysis treatment. Once these situations are handled, the patient and family then must cope with the uncertainty of how long renal failure will last and how long dialysis will be necessary.

Patients who develop chronic renal failure must deal with the fact that renal replacement therapy will be necessary for the rest of their lives. At first, patients usually deny a great deal of what is happening to them. This may continue for some time and prevent some patients from accepting necessary aspects of their treatment regimen. Other patients who feel considerably better after starting dialysis may enter a "honeymoon phase" and appear quite euphoric for a while. Patients should progress through the normal grieving stages and develop healthy coping mechanisms to deal with their long-term treatment.

Hemodialysis Applied to Other Therapies

The technical equipment and knowledge needed to perform hemodialysis are often applied to other therapies that involve an extracorporeal blood process, such as hemoperfusion and therapeutic apheresis. Hemoperfusion is used primarily for treating drug overdose. Blood is pumped from the body and perfused through a column of charcoal or other absorbent materials that bind the drug. This leads to a rapid reduction in serum levels and avoids potential tissue damage caused by an abnormally high drug level. This therapy is particularly useful for drugs that are fat bound or whose molecular structure is too large to be removed by hemodialysis. With this in mind, critical care nurses may need to take the hemodialysis schedules of their patients into consideration when timing administration of medications. For a list of medications that are removed during dialysis, see Box 30-9.

Therapeutic plasma exchange, or apheresis, is another therapy that may be performed using standard hemodialysis equipment in conjunction with a plasma separator cell and replacement fluids. Apheresis is used to treat diseases caused or complicated by circulating immune complexes or their abnormal proteins. During the procedure, the patient's whole blood is separated into its major components, and the offending components are removed.

BOX 30-9 Examples of Medications Commonly Hemodialyzed

Acetaminophen, acyclovir, allopurinol, amoxicillin, ampicillin, aspirin, atenolol
Captopril, cefazolin, cefepime, cefoxitin, ceftazidime, cimetidine, ciprofloxacin
Enalapril, esmolol
Ferrous sulfate, fluconazole
Ganciclovir, gentamicin
Imipenem
Lisinopril, lithium
Mannitol, meropenem, metformin, methotrexate, methylprednisolone, metoprolol, metronidazole, morphine
Nitroprusside
Penicillin, phenobarbital, piperacillin, procainamide
Salsalate, sotalol, streptomycin, sulfamethoxazole
Theophylline, tobramycin

▲ Peritoneal Dialysis

Peritoneal dialysis and hemodialysis accomplish the same objective and operate on the same principle of diffusion. However, in peritoneal dialysis, the peritoneum is the semipermeable membrane, and osmosis is used to remove fluid, rather than the pressure differentials used in hemodialysis. To access the peritoneal cavity, a Tenckhoff (peritoneal) catheter is inserted (Fig. 30-6). Intermittent peritoneal dialysis (IPD) is an effective alternative method of treating acute renal failure when hemodialysis is not available or when access to the bloodstream is not possible. It sometimes is used as an initial treatment for renal failure while the patient is being evaluated for a hemodialysis program. For a comparison of peritoneal dialysis with hemodialysis and CRRT, see Table 30-1 on page 642.

Peritoneal dialysis has the following advantages over hemodialysis:

- The required technical equipment and supplies are less complicated and more readily available.
- There is less training required by personnel.
- The adverse effects associated with the more efficient hemodialysis are minimized. This may be important for patients with severe cardiac disease, who cannot tolerate rapid hemodynamic changes.
- Patients can learn to manage their own peritoneal dialysis at home.

Peritoneal dialysis also has a few disadvantages, which are as follows:

- It requires more time to remove metabolic wastes adequately and to restore electrolyte and fluid balance.
- Repeated treatments may lead to peritonitis.
- Long periods of immobility may result in complications, such as pulmonary congestion and venous stasis.

Because fluid is introduced into the peritoneal cavity, peritoneal dialysis is contraindicated in patients who have existing peritonitis, in those who have undergone recent or extensive abdominal surgery, and in those who have abdominal adhesions. In the event of a cardiac arrest, the patient's abdomen is drained immediately to maximize the efficiency of chest compressions.

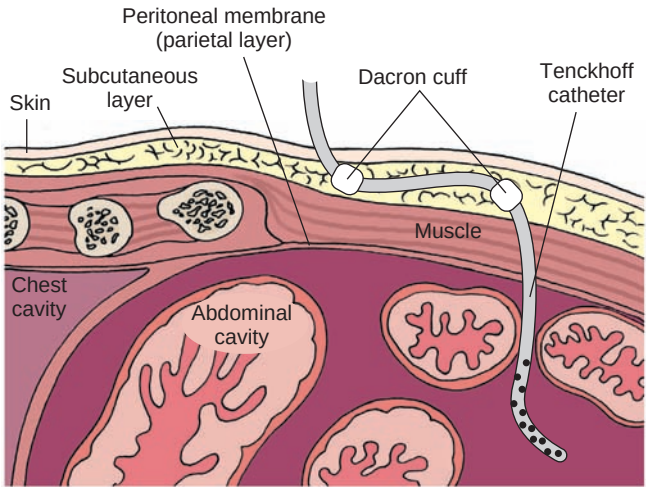

FIGURE 30-6 ▲ A Tenckhoff (peritoneal) catheter is used to access the peritoneal cavity. A Dacron cuff wrapped around the catheter helps to reduce complications related to infection.

Equipment

Solutions

As in hemodialysis, peritoneal dialysis solutions contain "ideal" concentrations of electrolytes but lack urea, creatinine, and other substances that are to be removed. Unlike dialysate used in hemodialysis, solutions must be sterile. Dextrose concentrations of the solutions vary; a 1.5%, 2.5%, or 4.25% dextrose solution can be used. Use of 2.5% or 4.25% solutions usually are reserved for more fluid removal and occasionally for better solute clearance. If peritoneal dialysate does not contain potassium, a small amount of potassium chloride may have to be added to the dialysate to prevent hypokalemia. The patient's serum potassium must be monitored closely to regulate the amount of potassium to be added.

Automated Peritoneal Dialysis Systems

Automated peritoneal dialysis systems have built-in monitors and a system of automatic timing devices that cycle the infusion and removal of peritoneal fluid. For this reason, they are called cyclers, and they may be used in the intensive care setting. They are convenient because they eliminate the need to change solution bags constantly. Most cyclers also have a log that retains cycle-by-cycle information on ultrafiltration. Setting up the cycler requires attaching the appropriate strength of large-volume (5 L) solution bags to the cycler tubing, using aseptic technique. The cycler is programmed to deliver a set amount of dialysate per exchange for a certain length of time. When the time is up, the patient is automatically drained and then refilled. Cyclers are usually used when patients have a permanent peritoneal access device.

Assessment and Management

Preprocedure

Before peritoneal dialysis begins, the nurse must perform the following interventions:

1. If a new catheter is required, prepare the patient for catheter insertion and the dialysis procedure by giving a thorough explanation of the procedure. Depending on hospital policy, a signed consent form may be necessary.
2. Ask the patient to empty his or her bladder just before the procedure.
3. Give a preoperative medication, as ordered, to enhance relaxation during the procedure.
4. Warm the dialyzing fluid to body temperature or slightly warmer, using a device manufactured solely for this purpose. Avoid warming peritoneal dialysate in microwave ovens because of uneven heating of the fluid and inconsistency from one microwave to another.
5. Take and record baseline vital signs, such as temperature, blood pressure, pulse, respirations, and weight. An in-bed scale is ideal for frequent monitoring of the patient's weight.
6. Take the patient's history, identifying abdominal surgery or trauma.
7. Examine the abdomen before inserting the catheter.
8. Follow specific orders, obtained before the procedure, regarding fluid removal, replacement, and drug administration.

Procedure

The following items are needed for the catheter placement procedure:

- Peritoneal dialysis administration set
- Peritoneal dialysis catheter set, which includes the catheter, a connecting tube for connecting the catheter to the administration set, and a metal stylet
- Trocar set of the physician's choice.
- Ancillary drugs: local anesthetic solution (2% lidocaine), aqueous heparin (1,000 units/mL), potassium chloride, broad-spectrum antibiotics

The physician makes a small midline incision just below the umbilicus under sterile conditions. A trocar is inserted through the incision into the peritoneal cavity. The obturator is removed, and the catheter is inserted and secured. The placement of the peritoneal dialysis catheter is ideally performed in a special procedures laboratory or in the operating room.

The dialysis solution flows into the abdominal cavity by gravity as rapidly as possible (5 to 10 minutes; Fig. 30-7). If it flows in too slowly, the catheter may need to be repositioned. When the solution is infused, the tubing is clamped, and the solution remains in the abdominal cavity for 30 to 45 minutes. Next, the solution bottles or bags are placed below the abdominal cavity, and the fluid drains out of the peritoneal cavity by gravity. If the system is patent and the catheter well placed, the fluid drains in a steady, forceful stream. Drainage should take no more than 20 minutes.

This cycle is repeated continuously for the prescribed time, which varies from 12 to 36 hours, depending on the purpose of the treatment, the patient's condition, and the proper functioning of the system. Dialysis effluent is considered a contaminated fluid, and gloves are worn while handling it.

Postprocedure

After the procedure, the nurse must perform the following interventions:

1. Maintain accurate records of intake and output and weights obtained from the same scale for the assessment of volume depletion or overload.
2. Monitor blood pressure and pulse rate. Orthostatic blood pressure changes and increased pulse rate are valuable clues that help the nurse evaluate the patient's volume status.
3. Detect signs and symptoms of peritonitis early. Low-grade fever, abdominal pain, and cloudy peritoneal fluid all are possible signs of infection.
4. Maintain sterility of the peritoneal system. Masks and sterile gloves must be worn while the abdominal dressing is being changed and when the catheter is being accessed or discontinued from the exchange. Solution bags or bottles are changed in as controlled a physical environment

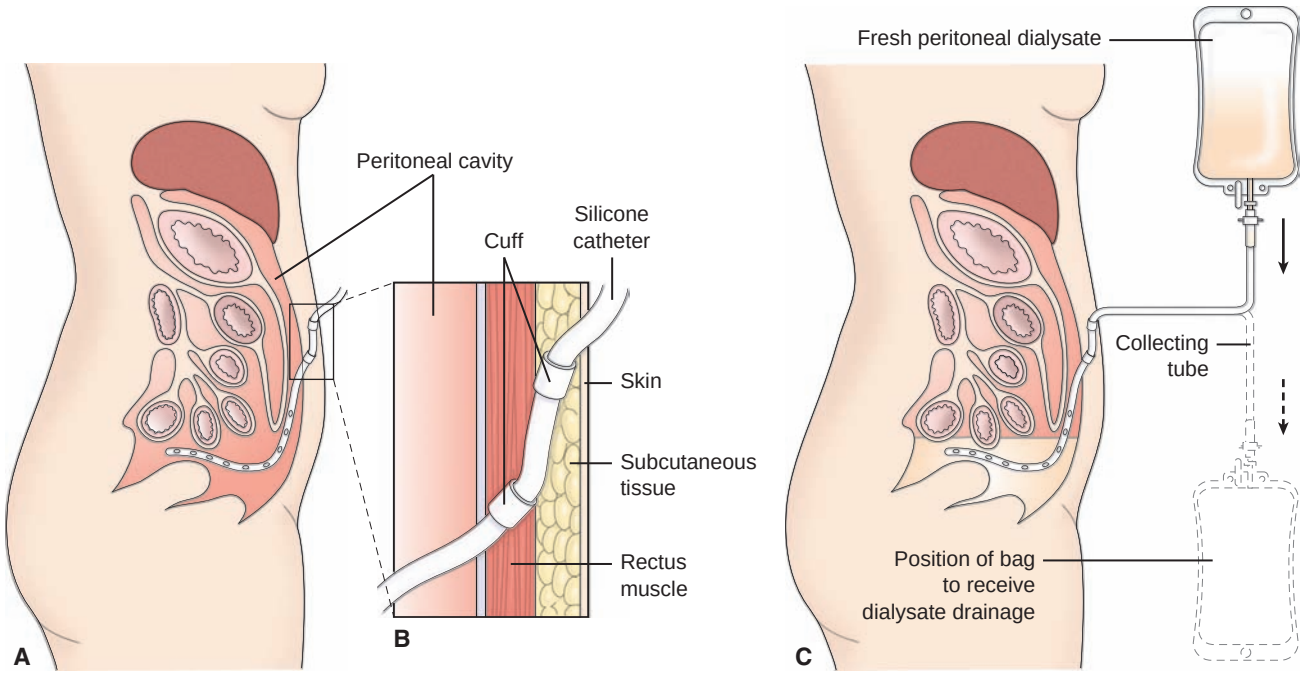

FIGURE 30-7 ▲ Continuous ambulatory peritoneal dialysis. **A:** The peritoneal catheter is implanted through the abdominal wall. **B:** Dacron cuffs and a subcutaneous tunnel provide protection against bacterial infection. **C:** Dialysate flows by gravity into the peritoneal catheter and then into the peritoneal cavity. After a prescribed period of time, the fluid is drained by gravity and discarded. New solution is then infused into the peritoneal cavity until the next drainage period. Dialysis thus continues on a 24-hour-a-day basis during which the patient is free to move around and engage in his or her usual activities. (From Smeltzer SC, Bare BG, Hinkle JL, et al: Brunner & Suddarth's Textbook of Medical–Surgical Nursing, 12th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 1341.)

as possible to avoid contamination (eg, avoiding areas of high traffic and high air flow).
5. Detect and correct technical difficulties early before they result in physiological problems. Slow outflow of the peritoneal fluid may indicate early problems with the patency of the peritoneal catheter.
6. Prevent complications of bed rest and provide an environment that helps the patient in accepting bed rest for prolonged periods.
7. Prevent constipation. Difficult or infrequent defecation decreases the clearance of waste products and causes the patient more discomfort and distention.

Technical Complications

Incomplete Recovery of Fluid

The fluid that is removed should equal or exceed the amount infused. Commercially prepared dialysate contains about 1,000 to 2,000 mL of fluid. If, after several exchanges, the volume drained is less (by 500 mL or more) than the amount infused, an evaluation must be made. Signs of fluid retention include abdominal distention or complaints of fullness. The most accurate indication of the amount of unrecovered fluid is weight.

If the fluid drains slowly, the catheter tip may be buried in the omentum or clogged with fibrin. Turning the patient from side to side, elevating the head of the bed, and gently massaging the abdomen may facilitate drainage.

If fibrin or blood exists in the outflow drainage, heparin needs to be added to the dialysate. The specific dose, which is ordered by the physician, is 500 to 1,000 units/L.

Leakage Around the Catheter

Superficial leakage after surgery may be controlled with extra sutures and a decrease in the amount of dialysate instilled into the peritoneum. Increases in intra-abdominal pressure may also cause dialysate leaks. Therefore, continued vomiting, coughing, and jarring movements should be avoided during the initial postoperative period. The abdominal dressing must be checked frequently to detect leakage. Dialysate leaks can be distinguished from other clear fluids by checking with a dextrose test strip. Dialysate tests positive because of its dextrose content. A leaking catheter must be corrected because it acts as a pathway for bacteria to enter the peritoneum.

BOX 30–10 NURSING INTERVENTIONS

For Preventing Infection During Peritoneal Dialysis

- Maintain aseptic technique throughout dialysis procedure.
- Use sealed plastic dialysate bags.
- Change dialysis tubing regularly per protocol.
- Swab or soak tubing connections and injection ports with bactericidal solution before adding medications or breaking closed system.
- Assess patient continuously for signs and symptoms of peritonitis (pain, cloudy effluent, fever).
- Change exit site dressing daily using aseptic technique until healing occurs. Assess daily for increase in inflammation or drainage.
- If infection is suspected, obtain appropriate culture and begin antibiotic according to protocol or physician's order.

Blood-Tinged Peritoneal Fluid

Blood-tinged peritoneal fluid is expected in the initial outflow but should clear after a few exchanges. Gross bleeding at any time is an indication of a more serious problem and must be investigated immediately.

Physiological Complications

Peritonitis

Peritonitis is a serious, but manageable, complication of peritoneal dialysis. Signs of peritonitis include low-grade fever, abdominal pain when fluid is being inserted, and cloudy peritoneal drainage fluid. Early detection and treatment reduce the patient's discomfort and prevent more serious complications.

Treatment begins as soon as a sample of peritoneal fluid is obtained for culture and sensitivity. The patient is started on a broad-spectrum antibiotic, which is usually added to the dialysate solution, although it also can be given intravenously. Depending on the severity of the infection, the patient's condition should improve dramatically after 8 hours of antibiotic therapy.

Catheter Infection

During the daily dressing change, the nurse examines the exit site closely for signs of infection, such as tenderness, redness, and drainage around the catheter. In the absence of peritonitis, a catheter infection usually is treated with an oral, broad-spectrum antibiotic. Box 30-10 lists nursing interventions for preventing infections during peritoneal dialysis.

Hypotension

Hypotension may occur if excessive fluid is removed. Vital signs are monitored frequently, especially if a hypertonic solution is used. Lying and sitting blood pressure readings are especially useful for evaluating fluid status. Progressive drops in blood pressure and weight are signs of fluid deficit.

Hypertension and Fluid Overload

If all the dialysate solution is not removed in each cycle, hypertension and fluid overload may occur. If there is hypertension and a weight increase, the nurse assesses catheter patency and notes the exact amount of fluid in the dialysate bag. Some manufacturers add 50 mL to a 1,000-mL bag. Over a period of hours, this can make a considerable difference.

The nurse also observes the patient for signs of respiratory distress and pulmonary congestion. In the absence of other symptoms of fluid overload, hypertension may be the result of anxiety and apprehension. Nonpharmacological measures to reduce anxiety are preferable to administering sedatives and tranquilizers.

High Blood Urea Nitrogen and Creatinine Levels

Blood urea nitrogen and creatinine levels are closely monitored because they help evaluate the effectiveness of the dialysis. When levels remain high, it indicates inadequate clearance of these waste products.

Hypokalemia

The serum potassium is monitored closely because hypokalemia is a common complication of peritoneal dialysis. When the serum potassium level is low, potassium chloride is added to the dialysate.

Hyperglycemia

Supplemental insulin can be added to the dialysate to control hyperglycemia. Blood glucose levels should be monitored closely in patients with diabetes mellitus and hepatic disease.

Pain

Patients may experience mild abdominal discomfort at any time during the procedure. It is probably related to the constant distention or chemical irritation of the peritoneum. If a mild analgesic does not provide relief, injecting 5 mL of 2% lidocaine directly into the catheter may help. The patient may be more comfortable if nourishment is given in small amounts, when the fluid is draining out rather than when the abdominal cavity is distended.

Severe pain may indicate more serious problems of infection or paralytic ileus. Infection is not likely in the first 24 hours. Aseptic technique and prophylactic antibiotics minimize the risk for infection. Periodic cultures of the outflowing fluid help in the early detection of pathogenic organisms.

Immobility

Immobility may lead to hypostatic pneumonia, especially in the debilitated or older patient. Deep breathing, turning, and coughing should be encouraged during the procedure. Leg exercises and the use of elastic stockings may prevent the development of venous thrombi and emboli.

Discomfort

Peritoneal dialysis results in slower clearance of waste products than hemodialysis; therefore, it is rarely associated with the dysequilibrium seen with hemodialysis. However, boredom is a frequent problem because the treatment is longer. Nursing measures are directed toward making the patient as comfortable as possible. Diversions such as reading, watching television, and visitors should be encouraged. Educating the patient about peritoneal dialysis and involving the patient in the care may reduce some of the anxiety and discomfort.

Peritoneal Dialysis as a Chronic Treatment

Intermittent peritoneal dialysis (IPD) has been used for chronic therapy for some time, but it requires the patient to remain stationary for up to 10 to 14 hours, three times per week. Because of this inconvenience to the patient and increased staff time needed if this therapy is performed in-center, IPD seldom is used and is not available in many dialysis centers.

Peritoneal dialysis has gained popularity as a chronic form of dialysis therapy, especially since continuous ambulatory peritoneal dialysis (CAPD) has become available. CAPD is easily taught to patients and does not limit ambulation between dialysate fluid exchanges. It uses the dialysis fluid that is continuously present in the peritoneal cavity 24 hours a day, 7 days a week. Dialysis fluid is drained by the patient and replaced with fresh solution three to five times per day. The number of solution exchanges needed per day depends on the patient's individual needs. Although the patient is required to perform dialysis techniques every day, CAPD is attractive to many patients with end-stage renal disease (ESRD) because they can accomplish it easily and independently. CAPD may also be preferred in patients who benefit from a slow, continuous removal of sodium and water, such as in those with refractory congestive heart failure.

Continuous cyclic peritoneal dialysis (CCPD) is another variation of chronic peritoneal dialysis therapy. Patients who choose this form of therapy perform IPD at night during sleep using a cycling machine and in the morning instill dialysis fluid, which remains in the abdomen during the entire day. This is most convenient for patients who require the help of working family members to perform their exchanges.

As with acute peritoneal dialysis, peritonitis is the greatest potential problem associated with chronic forms of dialysis. Peritoneal catheters are permanent and inserted in the operating room. Such catheters have one or two Dacron cuffs that the surgeon sutures to the abdominal wall, subcutaneous tissue, or both to anchor the catheter and provide a permanent seal against invading bacteria. Patients are taught how to recognize any potential problem associated with the catheter or treatment and to seek help from the CAPD team when needed.

Patients who perform IPD, CAPD, or CCPD at home usually visit the dialysis unit every 4 to 8 weeks. At this time, a nursing assessment is performed, techniques are reviewed, and required blood studies are obtained. All health team members, including the physician, nurse, dietitian, and social worker, work together with the patient and family to ensure successful adaptation to the chosen mode of treatment. Box 30-10 presents a discharge planning guide for the patient undergoing chronic peritoneal dialysis.

▲ Pharmacological Management of Renal Dysfunction

When the kidneys fail, treatment such as dialysis may be used to achieve fluid and electrolyte balance. Pharmacological treatment may be initiated to enhance an already functional kidney, attempt to recover renal function, or optimize fluid balance.

Diuretics

Diuretics are drugs that promote fluid removal through increased urine production. There are three major classes of diuretics: loop, thiazide, and potassium sparing. Table 30-4 presents information about the various diuretics. In addition, acetazolamide (a carbonic anhydrase inhibitor) and mannitol (an osmotic diuretic) may be used to promote fluid removal. It may be necessary to use combination therapy to achieve the desired therapeutic end point. Drugs from different classes are chosen to maximize urine production in combination therapy.

Table 30-4 Diuretic Drugs

Drug	Mechanism	Complication(s)	Management and Prevention
Loop diuretics Examples: furosemide (Lasix), ethacrynic acid (Edecrin), bumetanide (Bumex)	Powerful diuretics that act primarily in the thick segment of the medullary and cortical ascending limbs of loop of Henle Cause loss of sodium, chloride, and potassium Increase calcium excretion	Volume depletion Hypokalemia Hyponatremia Hypocalcemia Hypomagnesemia	Monitor daily weights, intake and output, and signs and symptoms of volume depletion. Potassium supplements or extradietary potassium may be necessary when loop diuretics are used routinely. Monitor calcium levels and administer supplemental calcium as indicated. Usually no intervention is required because body stores of magnesium are quite high.
Thiazides Examples: chlorothiazide (Diuril), hydrochlorothiazide	Act by inhibiting sodium reabsorption in distal tubule and, to a lesser extent, inner medullary collecting duct Cause loss of sodium, chloride, and potassium Decrease urinary calcium excretion	Hypercalcemia Hypokalemia Hypomagnesemia	Monitor calcium levels; loop diuretic may be indicated if calcium levels are persistently elevated. Potassium supplements or extradietary potassium may be necessary when these agents are used routinely. Usually no intervention is required because body stores of magnesium are quite high.
Potassium-sparing diuretics Examples: spironolactone (Aldactone), triamterene (Dyrenium), amiloride (Midamor)	Conserve potassium Spironolactone inhibits action of aldosterone, thereby reducing sodium reabsorption while increasing potassium reabsorption Triamterene acts on distal renal tubule to depress exchange of sodium Effects of amiloride are apparently due to inhibition of sodium entry into cell from luminal fluid	Hyperkalemia	Potassium supplements are contraindicated, as are salt substitutes containing potassium. Often combined with thiazides for effective diuresis; hypokalemic tendency of thiazides may offset hyperkalemic tendency of triamterene and spironolactone.
Carbonic anhydrase inhibitors Example: acetazolamide (Diamox)	Decrease proximal tubular sodium reabsorption Not very effective when administered alone Facilitate excretion of bicarbonate	Metabolic acidosis	Monitor pH and bicarbonate.
Osmotic diuretics Example: mannitol	Nonreabsorbable polysaccharide that pulls water into vascular space, thereby increasing glomerular flow	Hyperosmolarity	Monitor serum osmolarity. Withhold mannitol therapy if serum osmolarity is >300–305 mMol/L.

Diuretics may be administered orally or IV. The effect is more immediate with IV therapy. The patient is monitored for breath sounds, hemodynamic value changes, weight, and peripheral edema to determine his or her response to therapy. Careful laboratory assessment of the blood urea nitrogen and creatinine level is required to monitor for development or worsening of acute renal failure. Ideally, the patient's pulmonary status and fluid balance improve while the glomerular filtration rate (GFR) remains normal.

Diuretics have both desirable and undesirable effects (see Table 30-4). Overdiuresis is the most common side effect. The nurse must monitor for fluid volume depletion, especially when diuretic regimens are altered or initiated. Signs of volume depletion are discussed in Chapter 29. Other side effects include hyponatremia, hypokalemia, hyperkalemia, hypocalcemia, hypercalcemia, hypomagnesemia, and acid–base disturbances. A reduction in volume from vomiting, third-spacing of fluid, diuretic therapy, or other conditions may have the same consequences. Box 30-11 lists nursing diagnoses for patients taking diuretics.

Hypokalemia is another common side effect of diuretics, particularly the loop and thiazide diuretics. In general, hypokalemia is a benign condition that can be managed effectively with potassium supplementation. If left untreated, patients may experience harmful, sometimes life-threatening, cardiac dysrhythmias.

BOX 30-11 EXAMPLES OF NURSING DIAGNOSES

For the Patient Undergoing Diuretic Therapy

- Impaired Gas Exchange related to increased pulmonary hydrostatic pressure secondary to congestive heart failure
- Risk for Deficient Fluid Volume related to effect of diuretic therapy
- Risk for Electrolyte Imbalance
- Risk for Acute Confusion related to electrolyte imbalance/fluid shifts

Vasoactive Drugs

Sometimes, the cause of decreased effective circulatory volume is reduced cardiac contractility. In such a case, an inotropic agent (eg, dobutamine or milrinone) may be added to the plan of care to improve the forward flow of the heart, thereby improving the effective circulatory volume and stopping the cascade of counterproductive compensatory mechanisms. A failing heart, such as in congestive heart failure, can cause reduced blood flow to the kidney and potentiate acute renal failure. The same compensatory mechanisms used in volume depletion operate in an attempt to restore renal function. Namely, the renin–angiotensin–aldosterone system is activated to increase sodium and water retention and achieve renal and peripheral vasoconstriction. Other common inotropic agents are described in detail in Chapter 18.

Dopamine is a vasoactive drug at higher doses but can stimulate dopaminergic receptors in the kidneys when infused at lower doses (1 to 3 mcg/kg/min). Stimulation of dopamine receptors increases renal blood flow and promotes natriuresis. Although this practice may sometimes still be used to prevent or treat acute renal failure in some settings, several studies have found that there is no improvement in clinical outcome and a lack of sufficient clinical evidence to support its routine use.[5]

▲ Disorders of Fluid Volume

Critically ill patients often have imbalances in fluid homeostasis related to their primary underlying disease. Fluid imbalance occurs when there is an excess or deficit of fluid and may be either absolute or relative. Medications, such as diuretics, put patients at increased risk for fluid imbalance. Infection increases metabolic demand and insensible loss, and fluid volume deficits may develop. Regardless of patient diagnosis, assessment of fluid balance (see Chapter 29) and careful management are mainstays of patient care in the critical care setting.

Fluid Volume Deficit

When fluid loss exceeds intake, a fluid volume deficit exists. A fluid volume deficit is a physiological situation in which fluids are lost in an isotonic fashion (both fluid and electrolytes are lost together). Dehydration is the loss of water alone, resulting in a hyperosmolar state. Although the critically ill patient typically can have both a fluid volume deficit and dehydration states simultaneously, this discussion is limited strictly to disorders of fluid volume deficit.

Several patient populations are particularly vulnerable to the development of fluid volume deficits. Young children at prespeech developmental levels cannot communicate thirst; therefore, during times when fluid requirements increase, they do not increase their fluid intake of their own accord. Debilitated patients, for example, patients affected by stroke, may have difficulty communicating their needs or have swallowing disturbances and cannot manage their own intake of fluid. Elderly patients are at particular risk for a fluid volume deficit because of the multisystem changes associated with aging. For a review of the changes associated with aging and nursing implications for fluid volume assessment and management, see Table 30-2 on page 643.

Causes

GASTROINTESTINAL LOSS. Physiologically, the body produces approximately 5 L of gastrointestinal fluid. In the gastrointestinal tract, fluids help act as a carrier of important enzymes and buffers to aid in digestion. In the distal small intestine and large intestine, fluid is reabsorbed, leaving only approximately 150 mL lost through the stool daily.

Excess loss from any site from which fluids are ordinarily lost may cause a fluid imbalance. Conditions such as vomiting and diarrhea may cause an increase beyond the typical 150 mL and result in a fluid volume deficit. In addition, surgically placed drainage tubes and nasogastric tubes used for suction may cause such a deficit.

INFECTION. Infection causes fluid deficits in several ways as follows:

1. Infection can increase metabolic demand, increasing insensible water loss. When patients are not critically ill, they often mitigate this imbalance by increasing fluid intake. When they have widespread infections or a self-care deficit, which may occur in elderly people, fluid intake may not be sufficient to restore fluid balance.
2. Mediators are released as part of the immune response. These mediators cause a loosening of the capillary tight junctions, resulting in the third-spacing of fluids.
3. Carbon dioxide production increases due to increased metabolism. To maintain pH balance, tachypnea may develop. Although only a very small amount of fluid is lost daily through the respiratory tract, water loss may become clinically significant when the respiratory rate is greater than 35 breaths/min.

RENAL LOSS. The kidneys filter approximately 180 L/d. However, urine output is only 1% to 2% of total blood volume filtered. Reabsorption of fluid is influenced by a complex regulatory system that includes the actions of aldosterone, angiotensin, and antidiuretic hormone (ADH). A defect in any one of the regulatory functions can cause a disruption in renal fluid balance.

Several endocrine disorders may disrupt the renal regulatory system. Adrenal insufficiency, the absence of glucocorticoids and aldosterone, can reduce the absorption of sodium, thereby promoting water loss. Diabetes insipidus is a profound reduction in ADH, which reduces the amount of fluid reabsorbed at the distal convoluted tubule. Water loss predominates in diabetes insipidus, and therefore, volume imbalance is related to dehydration (see Chapter 44).

Serum osmolarity is predicted by sodium, glucose, and blood urea nitrogen. Normally, glucose does not influence the overall osmolarity. However, in profound hyperglycemia, the influence of glucose increases greatly. Serum osmolarity increases and is sensed by the osmoreceptors, thereby pulling fluids into the vascular space and initiating an osmotic diuresis. Two conditions that pathologically increase glucose are diabetic ketoacidosis (DKA) and hyperglycemic hyperosmolar nonketotic coma. Both of these disorders are discussed in more detail in Chapter 44.

Diuretic therapy is intended to treat fluid volume excess. However, overadministration of diuretics may result in a fluid volume deficit. It is important to recognize the immediate onset that diuretics can have when administered intravenously, initiated for the first time, or adjusted in dosage (see Table 30-4 for more information).

THIRD-SPACING OF FLUID. Third-spacing of fluid is the movement of fluid from the vascular space to the interstitial space. To create a movement of fluid between body compartments, there is an alteration in capillary permeability because of inflammation, ischemia, or injury. Causes of third-spacing of fluids are numerous and include infection; systemic inflammatory response syndrome, such as in pancreatitis; hypoalbuminemia, such as in liver failure; burns; intestinal obstruction; and surgery. The amount of fluid lost depends on the degree of the pathophysiological alteration. Regardless of cause, the fluid lost is not functioning to maintain vascular volume, and therefore, a fluid volume deficit exists. When fluid leaks out of the vascular space, daily weights can increase, paradoxically, despite intravascular volume depletion.

Management: Fluid Volume Replacement

To correct a fluid volume deficit, it is necessary to treat the underlying cause and replace the lost fluid. The main purposes of fluid administration include replacement of lost fluid, maintenance of fluid balance, and replacement of lost electrolytes. Several types of fluids, which have different physiological effects, are available. Administration of fluids may occur using the gastrointestinal tract or an IV or intraosseous route. When chronic replacement is required, such as in patients with long-term tube feeding, the gastrointestinal approach is used. Enteral access is required when patients cannot take fluids by mouth. When rapid restoration of fluid balance is required, the IV route is preferred. Occasionally, both routes are used.

MAINTENANCE FLUIDS. Under normal conditions, the average healthy adult requires about 2.5 L/d. This volume replaces fluids lost through the feces, the respiratory tract, sweating, and the urine. Patients who are unable to consume their usual intake of fluid are often prescribed IV maintenance fluids of 2 to 3 L/d. When determining the rate of administration of maintenance fluid, factors such as medical history (renal failure), age (young or old), confounding water excesses (heart failure), and ongoing assessment parameters (edema formation) must be considered.

REPLACEMENT FLUIDS. Critically ill patients are often unable to consume the additional fluid required to replace the lost fluid. In this case, IV administration beyond baseline maintenance fluids is required for homeostasis. This is achieved either by administering a bolus of fluid or by increasing the total daily fluid intake. When fluid loss occurs acutely, the loss must be replaced immediately to maintain tissue perfusion. The type of fluid given depends on the type of fluid lost. When whole blood is lost, such as in trauma or surgery, blood may be administered. When intravascular volume is depleted, such as in diarrhea, isotonic solutions may be administered. The rate of administration depends on the patient's medical history and amount of volume lost.

Crystalloids Crystalloid solutions are prepared with a specified balance of water and electrolytes. Box 30-12 provides a description of commonly used crystalloid solutions, and although here they are described separately, they are most commonly used in combination. Fluids are classified as hypotonic (osmolarity <250 mEq/L), isotonic (osmolarity approximately 310 mEq/L), or hypertonic (osmolarity > 376 mEq/L).

Dextrose solutions are given to provide free water and some calories to prevent protein catabolism. The 5% solution contains 50 g of dextrose for every liter of fluid and provides approximately 170 cal/L. When pure dextrose solutions, such as 5% dextrose in water (D_5W), are administered, the dextrose is metabolized, resulting in the administration of free water. When given intravenously, free water decreases the plasma osmolarity, thereby promoting the movement of water evenly into all body compartments. Free water does not stay in the vascular space; therefore, pure dextrose solutions should not be used when intravascular replacement of fluids is required.

Saline solutions are commonly used and are available in different strengths, such as 0.9% and 0.45%. Normal saline, or 0.9% saline, is an isotonic solution. Approximately one fourth of the fluid administered remains in the vascular space, and the remaining fluid moves into the extracellular space 1 hour after administration. During critical illness, the amount that exits into the extracellular space can increase as a result of increased capillary permeability.

Half-strength (0.45%) saline solution, in comparison, is a hypotonic solution. Additional free water is administered

BOX 30-12 Common Crystalloid Solutions

5% dextrose in water (D_5W): no electrolytes, 50 g dextrose
- Supplies about 170 cal/L and free water to aid in renal excretion of solutes
- Should not be used in excessive volumes in patients with increased ADH activity or to replace fluids in hypovolemic patients

0.9% NaCl (isotonic saline): Na^+ 154 mEq/L, Cl^- 154 mEq/L
- Isotonic fluid commonly used to expand the extracellular fluid in presence of hypovolemia
- Because of relatively high chloride content, it can be used to treat mild metabolic alkalosis

0.45% NaCl (½ strength saline): Na^+ 77 mEq/L, Cl^- 77 mEq/L
- A hypotonic solution that provides sodium, chloride, and free water (sodium and chloride provided in fluid allow kidneys to select and retain needed amounts)
- Free water desirable as aid to kidneys in elimination of solutes

0.33% NaCl (1/3 strength saline): Na^+ 56 mEq/L, Cl^- 56 mEq/L
- A hypotonic solution that provides sodium, chloride, and free water
- Often used to treat hypernatremia (because this solution contains a small amount of sodium, it dilutes the plasma sodium while not allowing the level to drop too rapidly)

3% Saline Solution
- Grossly hypertonic solution used only to treat severe hyponatremia
- This solution used only in settings where the patient can be closely monitored

Lactated Ringer's solution: Na^+ 130 mEq/L, K^+ 4 mEq/L, Ca^{2+} 3 mEq/L, Cl^- 109 mEq/L, lactate (metabolized to bicarbonate) 28 mEq/L
- Approximately isotonic solution that contains multiple electrolytes in about same concentrations as found in plasma (note that this solution is lacking magnesium and phosphate)
- Used in treating hypovolemia, burns, and fluid lost as bile or diarrhea
- Useful in treating mild metabolic acidosis

with this solution, making it an ideal maintenance fluid. Occasionally, half-strength saline solution is administered to replace fluids lost when there is concurrent hypernatremia.

Saline solutions, such as 3% saline, are hypertonic and may be given to treat symptomatic hyponatremia. The hypertonicity pulls fluid from the extravascular space to the vascular space. Hypertonic solutions should be administered only when patients may be closely monitored because fluid volume excess can develop rapidly. Some studies have shown that hypertonic saline solutions, such as 3% or 7.5% saline, may be beneficial during resuscitation.[6,7]

Colloids. Colloids are high-molecular-weight substances and therefore do not cross the capillary membrane under normal conditions. Table 30-5 describes commonly prepared colloid solutions.

Albumin is the most abundant circulating protein in the body and accounts for 80% of the colloidal oncotic pressure. For therapeutic uses, albumin is prepared from donor plasma. With albumin, there is no risk of bloodborne diseases, such as hepatitis or human immunodeficiency virus infection. Albumin is available in two concentrations, 5% and 25%, and both preparations contain some sodium. The 5% solution is similar in osmolarity to plasma. In contrast, the 25% solution is hypertonic, thereby pulling extravascular water into the vascular space. Both preparations of albumin can cause the intravascular volume to expand beyond the volume of albumin infused because of the increased oncotic pressure generated. Care must be taken when administering albumin to patients at high risk for volume overload. Use of albumin should also be limited in patients with profound capillary leak syndrome (eg, in sepsis, acute respiratory distress syndrome, and pancreatitis[7]). Although albumin is a protein, it is inefficient and expensive when used for malnutrition.

The starches dextran and hetastarch, which differ from each other only slightly, have an oncotic pressure similar to albumin. Both substances are used to expand plasma volume by exerting an oncotic pressure and thereby pulling water from the extravascular space to the vascular space. Hetastarch is metabolized by both the kidneys and liver. The diuresis that may occur with hetastarch is an osmotic diuresis and does not reflect an increase in effective renal circulatory volume. Both dextran and hetastarch may cause coagulopathies; however, dextran has a more profound effect on coagulation.

Fluid Volume Excess

Fluid volume excess occurs when there is retention of sodium, resulting in the reabsorption of water. Electrolytes typically remain unchanged when there is an increase in total body water and electrolytes increase in parallel. Many critically ill patients may have mixed disturbances with manifestations of the confounding compensatory mechanisms. Causes of fluid volume excess include overadministration of fluids, edematous disorders (eg, congestive heart failure, kidney, or liver failure), excessive sodium intake, and medications (eg, steroids, desmopressin acetate).

When the kidneys are functioning normally and regulating fluid balance, the body typically rids itself of excess fluid, and fluid overload is not manifested clinically. When the kidneys sense a decrease in effective circulatory volume, the compensatory mechanisms prevent the excretion of excess water, such as in congestive heart failure.

Management of fluid volume excess is directed toward correcting the underlying disorder. If this is not feasible, efforts are geared to preventing pulmonary compromise by attempting to rid the body of the excess sodium and water. In cases of volume overload, there is an increase in pulmonary hydrostatic pressure, which promotes movement of water into the alveoli, thereby impeding gas exchange. Sodium restriction reduces the amount of water reabsorption but does contribute to acute correction of

Table 30-5 Common Colloid Solutions

Solution	Contents	Indications	Comments
Albumin	Available in two concentrations: 5%: oncotically similar to plasma 25%: hypertonic Both 5% and 25% solutions contain about 130–160 mEq/L of sodium	Used as volume expander in treatment of shock May be useful in treating burns and third-spacing shifts	Cost is ~25–30 times more than for crystalloid solutions. Increased interstitial oncotic pressure in disease states in which there is increased capillary leaking (eg, burns, sepsis) may occur; this may result in increased vascular space loss of fluid. Use caution with rapid administration; watch for volume overload.
Hetastarch	Synthetic colloid made from starch (6%) and added to sodium chloride solution	May be used to expand plasma volume when volume is lost from hemorrhage, trauma, burns, and sepsis	Plasma volume expansion effects decrease over 24–36 h Starch is eliminated by kidneys and liver; therefore, use caution in patients with liver and kidney impairment. Mild, transient coagulopathies may occur. Transient rise in serum amylase may occur.
Dextran	Glucose polysaccharide substance, available as low-molecular-weight dextran (dextran 40) or high-molecular-weight dextran (dextran 70) No electrolyte content	May be used to expand plasma volume when volume is lost from hemorrhage, trauma, burns, and sepsis	Has been associated with greater risk for allergic reaction than albumin or hetastarch. Interference with blood cross-matching may occur. May cause coagulopathy; has more profound effect on coagulation than hetastarch.

volume overload. Diuretics are the mainstay of treatment for acute resolution of fluid volume excess (see Table 30-4).

▲ Management of Electrolyte Imbalances

Electrolyte disorders commonly occur in critically ill patients, typically in combination with other conditions. Management of the underlying problem ensures long-term restoration of balance. However, acute management of electrolyte disorders is often required to maintain cellular integrity.

Sodium

Sodium is the major extracellular cation. It is a major predictor of serum osmolarity and controls movement of water. Disorders of sodium are typically associated with water disorders (Table 30-6).

Table 30-6 Management of Electrolyte Disorders

Electrolyte	Selected Medical Conditions Associated With Disturbance	Collaborative Interventions
Sodium		
Hyponatremia	Congestive heart failure Liver failure Kidney failure Hyperlipidemia Hypoproteinemia SIADH GI loss Adrenal insufficiency Thiazide diuretics Drugs: NSAIDs, tricyclic antidepressants, SSRIs, chlorpropamide, omeprazole Tumors associated with ectopic excessive ADH production: oat cell carcinoma, leukemia, lymphoma Pulmonary disorders: pneumonia, acute asthma AIDS	Review medication profile and patient history. Monitor for sites of fluid losses or gains. Monitor fluid balances and for signs and symptoms of electrolyte disturbance. Attempt to manage underlying cause. Correction of electrolyte may require sodium replacement (3% saline solution) or water restriction, depending on etiology of disorder.
Hypernatremia	Profound dehydration usually in patients not able to ask for water (eg, debilitated elderly or children), in those with impaired thirst regulation (eg, elderly), or in those with heatstroke Hypertonic tube feedings without water supplementation Increased insensible water loss (eg, excessive sweating, second- and third-degree burns, hyperventilation) Excessive administration of sodium-containing fluids (3% saline, sodium bicarbonate) Diabetes insipidus	Assess in patients at particular risk for hypernatremia, including debilitated or elderly patients, acutely or critically ill children, and patients receiving tube feedings. Monitor laboratory values closely in patients with insensible fluid losses and in those receiving parenteral administration of sodium-containing fluids. For comprehensive review of management of diabetes insipidus, see Chapter 44. Administer therapeutic medications, including vasopressin, DDAVP. Administer hypotonic fluids (1/2 saline to free water, D_5W).
Potassium		
Hypokalemia	GI loss: diarrhea, laxatives, gastric suction Renal loss: potassium-losing diuretics, hyperaldosteronism, osmotic diuresis, steroids, some antibiotics Intracellular shifts: alkalosis, excessive secretion or administration of insulin, hyperalimentation Poor intake: anorexia nervosa, alcoholism, debilitation	Monitor laboratory values closely in patients at particular risk for hypokalemia. Pay particular attention to potassium level in patients receiving digoxin. Administer potassium either orally or IV (see Box 30-13, p. 661). Monitor magnesium levels in patients who are refractory to potassium replacement.
Hyperkalemia	Pseudohyperkalemia: prolonged tight application of tourniquet; fist clenching and unclenching immediately before or during blood draws; hemolysis of blood sample Decreased potassium excretion: oliguric renal failure, potassium-sparing diuretics, hypoaldosteronism High potassium intake: improper use of oral potassium supplements; rapid IV potassium administration Extracellular shifts: acidosis, crush injuries, tumor cell lysis after chemotherapy	Ensure that minimal negative pressure is used to obtain all laboratory samples, particularly when drawn through small-gauge needles. Restrict potassium-sparing diuretics. Promote excretion: sodium polystyrene sulfonate orally or rectally, dialysis, potassium-losing diuretics (eg, furosemide) Emergency management measures: calcium IV, sodium bicarbonate, IV insulin with glucose, β_2-adrenergic agonists

(continued on page 659)

Table 30-6 Management of Electrolyte Disorders (continued)

Electrolyte	Selected Medical Conditions Associated With Disturbance	Collaborative Interventions
Calcium		
Hypocalcemia	Surgical hypoparathyroidism Primary hypoparathyroidism Malabsorption (alcoholism) Acute pancreatitis Excessive administration of citrated blood Alkalotic states Drugs (loop diuretics, mithramycin, calcitonin) Hyperphosphatemia Sepsis Hypomagnesemia Medullary carcinoma of thyroid Hypoalbuminemia	Monitor for signs and symptoms associated with low calcium, especially for seizures, and stridor. Administer calcium IV for acute replacement (see Box 30-13, p. 661). Ensure adequate dietary intake for patients at particular risk.
Hypercalcemia	Hyperparathyroidism Malignant neoplastic disease Drugs (thiazide diuretics, lithium, theophylline) Prolonged immobilization Dehydration	Administer bisphosphonates, such as etidronate or mithramycin, especially when disorder is related to malignancy. Administer diuretics, such as loop diuretics, to promote renal excretion. Provide fluid replacement with 0.9% saline solution.
Magnesium		
Hypomagnesemia	Inadequate intake: starvation, total parenteral nutrition without adequate Mg^{2+} supplementation, chronic alcoholism Increased GI loss: diarrhea, laxatives, fistulas, nasogastric tube suction, vomiting Increased renal loss: drugs (loop and thiazide diuretics, mannitol, amphotericin B), diuresis (uncontrolled diabetes mellitus, hypoaldosteronism) Changes in magnesium distribution: pancreatitis, burns, insulin, blood products	Monitor for hypokalemia in patients with low magnesium because kidneys are not able to conserve potassium when magnesium level is low. Administer magnesium IV for acute replacement (see Box 30-13, p. 661). Administer PO preparations for long-term replacement.
Hypermagnesemia	Renal failure Excessive intake of magnesium-containing compounds (eg, antacids, mineral supplements, laxatives)	Avoid administration of magnesium-containing compounds to patients in renal failure. In extreme cases, dialysis may be indicated.
Phosphorus		
Hypophosphatemia	Refeeding syndrome Alcoholism Phosphate-binding antacids Respiratory alkalosis Administration of exogenous insulin IV Burns	Ensure nutritional intake. Monitor phosphorus for the first few days after initiation of enteral or parenteral nutrition. Administer by oral supplementation (Neutra-Phos capsules) or IV (see Box 30-13, p. 661).
Hyperphosphatemia	Renal failure Chemotherapy Excessive administration of phosphate compounds	Prevention is mainstay of therapy; avoid administration of phosphorus to patients in renal failure. Administer calcium acetate. Administer IV fluids to promote renal excretion. In severe cases, administration of high levels of glucose with insulin may help shift phosphorus intracellularly.

ADH, antidiuretic hormone; AIDS, acquired immunodeficiency syndrome; DDAVP, desmopressin acetate; GI, gastrointestinal; NSAID, nonsteroidal anti-inflammatory drug; SIADH, syndrome of inappropriate antidiuretic hormone; SSRI, selective serotonin reuptake inhibitor.

Hyponatremia may be associated with volume excess, such as in edematous disorders (eg, heart, kidney, or liver failure), or with volume deficit, such as when volume loss is exceeded by sodium loss (eg, in gastrointestinal fluid, diuretic overuse, or adrenal insufficiency). Low sodium with euvolemia is manifested as the syndrome of inappropriate antidiuretic hormone secretion (SIADH; see Chapter 44). Pseudohyponatremia may occur in association with hyperlipidemia and hypoproteinemia; the total-body sodium remains unchanged, but the actual sodium measurement is altered.

Management of hyponatremia is aimed at correcting the underlying cause (see Table 30-6). When the hyponatremia is associated with hypervolemia, diuretics may be beneficial. When the disorder is associated with euvolemia, such as in SIADH, water restriction may be useful. In conditions in which there is both sodium loss and water loss, administration of hypertonic saline solution, typically started in symptomatic patients, at slow rates may help improve this clinically significant hyponatremia.

Hypernatremia may occur as an isolated condition when there is a loss of free water, which raises the sodium level. Increased insensible loss of fluid, such as occurs in sweating, hyperventilation, or fever, is the most common cause of this type of hypernatremia. The fluid volume deficit associated with the hypernatremia depends almost entirely on the degree of insensible loss. Endocrine disorders, such as hyperaldosteronism or Cushing's disease, can result in hypernatremia and are associated with total-body water excess. Administration of hypertonic fluids, such as sodium bicarbonate, 3% saline solution, or albumin, may also cause hypernatremia.

Management of hypernatremia is primarily aimed at restoring fluid balance (see Table 30-6). Correcting the underlying cause of the increased sodium is also important.

Potassium

Potassium is the major intracellular ion. Potassium plays a key role in neuromuscular functioning, and high or low levels may result in alterations in the cardiac rhythm. Because of the narrow range of extracellular potassium balance, renal function is essential to regulation of potassium. In critically ill patients, disorders of potassium are common and have numerous causes (see Table 30-6).

Hypokalemia is most commonly caused by an absolute deficiency in potassium. Losses of potassium occur through the kidneys, gastrointestinal tract, sweat, and intracellular shifting. Although relative deficiencies may occur, such as in metabolic alkalosis, they are rare compared with the absolute deficits. Management of hypokalemia involves replacing depleted potassium to restore potassium balance. It may be necessary to check the magnesium level in patients who do not respond to potassium replacement. Box 30-13 presents nursing considerations in potassium replacement.

Hyperkalemia is caused by reduced renal excretion, excessive administration of potassium replacements, transcellular shifts, and measurement error. Patients with chronic renal failure or acute kidney injury are at particular risk. Dialysis is typically used to manage hyperkalemia in patients with ESRD. Noncompliance with dialysis can certainly cause hyperkalemia and is a frequent reason for hospital admission. Potassium replacement therapy, although performed frequently in critical care settings, must be performed carefully; particular attention should be paid to cardiac signs and laboratory reassessments. Acidosis of any cause can potentiate hyperkalemia; therefore, patients who are acidotic must be carefully monitored for potassium shifts. In this situation, the primary goal of management is resolution of the acidosis. Clinically significant hyperkalemia must be resolved using the measures described in Table 30-6. Temporizing measures for hyperkalemia center on stabilization of cell membrane (calcium) and shifting potassium from the extracellular to the intracellular spaces (bicarbonate, insulin). These measures resolve the potassium imbalance temporarily and give clinicians time to address the underlying problem. If it is anticipated that correction of this problem will take some time, the excretion of potassium is facilitated by administering sodium polystyrene, dialysis, and diuretics. Drawing laboratory samples can cause hemolysis of cells, which causes liberation of the abundant intracellular potassium. Evaluating trends and assessing the overall clinical picture prevent unnecessary treatment and therefore prevent hypokalemia.

Calcium

Almost all of the calcium in the body is contained in the bone, and the remaining 1% is either bound to albumin (50% plasma calcium) or in an ionized form. The primary function of calcium is promotion of the neuromuscular impulse. Several clotting factors also depend on calcium.

Hypocalcemia has numerous causes (see Table 30-6). Most hypocalcemia is a relative deficiency; causes include intracellular shifting, decreased circulating protein, and binding with fatty acids (pancreatitis). The relative hypocalcemia that occurs with a massive transfusion of blood is common in the critical care setting. The blood is mixed with citrate to prevent coagulation; when the blood is infused, the citrate binds to calcium, causing a relative calcium deficiency. Citrate used for anticoagulation in CRRT also results in hypocalcemia. Other causes of hypocalcemia include increased renal excretion (loop diuretics) or decreased absorption (malabsorption syndromes).

Calcium is transported in its ionized form, provides some of the structural components in bone, and is also bound to albumin. A low albumin level can therefore be one cause of a low calcium level. The calcium level should be corrected for the low albumin before considering calcium replacement. Replacement of calcium is required to prevent complications of bleeding and decreased impulse transmission. For a review of nursing considerations in calcium replacement, see Box 30-13.

Hypercalcemia, which is less common in the critical care setting, is most often caused by malignancy. Treatment is supportive and involves administration of diuretics and IV fluids, sometimes simultaneously.

Magnesium

About two thirds of the magnesium in the body is in the skeletal system, and the remaining one third is in the intracellular space. About 1% circulates in the extracellular space. Magnesium is a catalyst for hundreds of enzymatic reactions and plays a role in neurotransmission and cardiac contraction. Magnesium is primarily excreted by the kidneys.

Hypomagnesemia is caused by loss of magnesium through the gastrointestinal tract or (less commonly) the kidneys. Alcoholism is a significant cause. The etiological mechanism

BOX 30-13 NURSING INTERVENTIONS

For Intravenous Electrolyte Replacement

Potassium

Dilution

- Do not administer undiluted potassium directly IV.
- Keep all vials of undiluted potassium away from patient care area.
- Dilution of potassium depends on the amount of fluid the patient can tolerate. Highly concentrated potassium solutions can cause irritation, pain, and sclerosing of vein.
- Typical concentrations of potassium are 10 to 40 mEq/100 mL. Premixed bags are available.

Peripheral IV Administration

- In collaboration with prescribing provider, consider the addition of small volume of lidocaine to minimize pain.
- Administer in central vein if available.
- For mild to moderate hypokalemia, rates of 10 to 20 mEq/h are recommended.
- Rates exceeding 40 mEq/h are not recommended.
- Use infusion pump to administer replacement.

Monitoring

- Monitor urinary output, blood urea nitrogen, and creatinine in patients receiving potassium replacement. Patients with impaired renal function or oliguric renal failure may experience transient hyperkalemia. Consider smaller replacement dosages and periodic reevaluation.
- When rate of administration exceeds 10 mEq/h, monitoring of cardiac rhythm is recommended.
- Assess magnesium level because correction of potassium may be refractory to potassium replacement with concurrent hypomagnesemia.

Calcium

Dilution

- Calcium can be delivered as calcium gluconate (4.5 mEq of elemental Ca^{2+}) or calcium chloride (13.5 mEq of elemental Ca^{2+}).
- Calcium can be irritating to veins. If peripheral administration is required, calcium gluconate is recommended because damage can occur to surrounding soft tissues.

Administration

- Administer by slow IV push through central vein or administer by mixing with compatible IV fluids.
- Administer slowly (over 1 to 2 hours) for patients receiving digoxin.

Magnesium

Administration

- Administer with caution to patients with renal failure because magnesium is primarily excreted by the kidneys.
- During emergencies, such as torsades de pointes, magnesium may be injected directly.
- In mild to moderate hypomagnesemia, a rate of infusion of 1 to 2 g over 1 hour is advisable.

Monitoring

- Monitor for hypotension or flushing during administration.
- Monitor deep tendon reflexes periodically during administration.

Phosphorus

- Phosphorus IV replacement is available as sodium or potassium phosphate. Note that phosphorus is dosed in millimoles, whereas sodium and potassium are dosed in milliequivalents.
- Administer sodium phosphate for patients with renal failure.
- Do not administer with calcium.
- Administer over several hours, typically 15 to 30 mmol phosphorus over 4 to 6 hours.

is not completely understood, but it is thought that decreased dietary intake due to malnutrition, decreased absorption, and increased gastrointestinal losses (due to periodic emesis) all play a role. Several drugs may also cause hypomagnesemia, including loop diuretics, aminoglycosides, amphotericin B, *cis*-platinum, cyclosporine, and citrate. For a review of the causes of hypomagnesemia, see Table 30-6.

Magnesium is available in a variety of preparations, including 50%, 20%, or 10% solutions. It is important to pay particular attention to how the replacement preparation is ordered; the replacement solution should be "dosed" in grams instead of milliliters. For a review of nursing considerations in magnesium replacement, see Box 30-13.

Phosphorus

Phosphorus is the major intracellular anion. The source of adenosine triphosphate (ATP), phosphorus is implicated in many life-sustaining processes, such as muscle contraction, neuromuscular impulse conduction, and the regulation of several intracellular and extracellular electrolyte balances.

Hypophosphatemia may be caused by several metabolic disorders, including refeeding syndrome and alcoholism, intracellular shifting due to respiratory alkalosis, binding by medications, such as phosphate-binding magnesium-containing antacids, and excessive excretion of phosphate, such as in DKA (see Table 30-6). Refeeding syndrome occurs when the patient is fed, either enterally or parenterally, after some time of starvation. During starvation, protein catabolism occurs, depleting all of the intracellular phosphorus. When a large glucose load is administered, as occurs with refeeding, it is thought that the insulin response shifts the phosphorus intracellularly.

Management of hypophosphatemia may be problematic, particularly for patients on a mechanical ventilator. Contraction of all muscles, including the diaphragm, depends on ATP. Replacement of phosphorus is indicated in critically ill patients to achieve adequate pulmonary function. Once the critical illness abates, the hypophosphatemia typically resolves as well. However, replacement with either sodium or potassium phosphate is indicated in the meantime. For a review of nursing considerations in phosphorus replacement, see Box 30-13.

Hyperphosphatemia is commonly associated with renal failure due to reduced elimination of phosphorus. Because of the inverse relationship with calcium, the high phosphorus may also be associated with hypocalcemia. Administration of phosphate binders and calcium supplementation are indicated.

▲ Clinical Applicability Challenges

CASE STUDY

Mrs. B. is a 68-year-old female with a history of diabetes and hypertension. Two years ago, she was diagnosed with an abdominal aortic aneurysm (AAA). Four days ago, she was admitted to the cardiovascular intensive care unit (CVICU) postoperatively for repair of her AAA. Immediate postoperative data are as follows: temperature, 97.3°F (36.3°C); pulse rate, 120 beats/min; blood pressure, 87/50 mm Hg; respiratory rate, 18 breaths/min; and oxygen saturation by pulse oximetry (SpO_2), 98% (on 50% fraction of inspired oxygen [FiO_2]). Laboratory test on admission included Na^+, 130 mEq/L; K^+, 3.5 mEq/L; Cl^-, 100 mEq/L; CO_2, 18 mmol/L; blood urea nitrogen, 28 mg/dL; creatinine, 1.4 mg/dL; and glucose, 162 mg/dL. This morning, the data included temperature, 101.5°F (38.5°C); pulse rate, 80 beats/min; blood pressure, 127/85 mm Hg; respiratory rate, 16 breaths/min; oxygen saturation by pulse oximetry (SpO_2), 96% (on 2 L/min by nasal cannula); Na^+, 132 mEq/L; K^+, 4.5 mEq/L; Cl^-, 105 mEq/L; CO_2, 17 mmol/L; blood urea nitrogen, 45 mg/dL; creatinine, 2.1 mg/dL; and glucose, 122 mg/dL.

1. Explain the pathophysiological basis of Mrs. B.'s blood urea nitrogen and creatinine values before and after surgery.
2. What are Mrs. B.'s risk factors for developing renal insufficiency?
3. What additional diagnostic tests might you anticipate to be ordered to evaluate Mrs. B.'s renal function?
4. What are some of the nursing care priorities for Mrs. B.? What treatments could you anticipate for her?

31 Renal Failure

Dorene M. Holcombe and Nancy Kern Feeley

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Explain the causes of acute kidney injury (AKI).
2. Describe urine production during the nonoliguric, oliguric, and diuretic phases of acute tubular necrosis.
3. Differentiate between the three types of AKI based on history and physical examination, laboratory values, and diagnostic tests.
4. Discuss the major causes and the clinical stages of chronic kidney disease (CKD).
5. Explain factors that can contribute to the progression of CKD.
6. Discuss the clinical manifestations and management of renal failure.

Previously, acute kidney injury (AKI) was known as acute renal failure (ARF). More than 35 different definitions for ARF were contained in the medical literature. This lack of uniformity resulted in varying reported incidences and conflicting reports regarding morbidity and mortality. This had an adverse effect on research studies.[1] Consequently, in 2004, a group of expert intensivists and nephrologists formed the Acute Dialysis Quality Initiative (ADQI) to develop a consensus definition for ARF/AKI. The resultant consensus definition (formulated by ADQI) is known as the Risk-Injury-Failure-Loss-and End-stage (RIFLE) classification.

▲ Acute Kidney Injury

Acute kidney injury (AKI) occurs in up to 15% to 18% of hospitalized patients and in as many as 66% of the patients treated in intensive care units (ICUs).[1–3] Furthermore, due to increased recognition, the incidence of AKI has dramatically increased over the last decade.[4] Regardless of the underlying etiology, AKI is associated with increased in-hospital morbidity, mortality, and costs along with increased long-term mortality and morbidity.[1,2,4] Patients with AKI who are treated with renal replacement therapy (RRT) have a mortality rate between 50% and 60%; this rate has not changed in the past several decades despite advances in technology and dialysis.[1,3,5] However, the demographics of patients have changed, with patients in general being older and having an increased number of comorbid conditions.[1,6] On an optimistic note, more than 80% of survivors of severe AKI (those requiring RRT) are independent of dialysis by discharge.[1]

AKI is a common clinical syndrome in which there is a sudden onset of reduced renal function that can result in derangements in fluid and electrolyte balance, acid–base homeostasis, calcium and phosphate metabolism, blood pressure (BP) regulation, and erythropoiesis. The hallmark of AKI is a decreased glomerular filtration rate (GFR), reflected by an accumulation of blood urea nitrogen (BUN) and serum creatinine—a condition termed azotemia. Serum creatinine is the better marker because increases in serum creatinine are relatively unaffected by metabolic factors. As defined by the RIFLE classification[7,8] (Table 31-1), there are three increasing grades of severity of AKI (risk, injury, and failure) based on a relative increase in serum creatinine or a period of decreased urine output. Also, two outcome criteria (loss and end-stage kidney disease) are defined by duration of loss of kidney function, 4 weeks and 3 months, respectively.[7]

In 2007, the RIFLE criteria were modified by the Acute Kidney Injury Network (AKIN), which included the ADQI group as well as other representatives from nephrology and intensive care societies. The AKIN-proposed diagnostic criteria for AKI is an abrupt (within 48 hours) increase in the serum creatinine of 0.3 mg/dL or more from baseline, a percentage increase in the serum creatinine concentration of 50% or more, or a urine output of less than 0.5 mL/kg/h for more than 6 hours.[9] Since its creation, the RIFLE criteria has been widely adopted in research and has been validated in clinical settings for predicting patient outcomes.[7,10] In the future, it is likely that functional markers of renal failure (urine output and serum creatinine) will be replaced or augmented by biological injury markers, analogous to how troponin is now used to help diagnose an acute myocardial infarction. Hopefully, such markers of kidney cellular injury

Table 31-1 Acute Kidney Injury Staging Criteria

Stage	Creatinine Criteria	Urine Output Criteria
RIFLE Criteria		
Risk	Creatinine increase of 1.5–2 times baseline value	<0.5 mL/kg/h × 6 h
Injury	Creatinine increase of 2–3 times baseline value	<0.5 mL/kg/h × 12 h
Failure	Creatinine increase of 3 or more times baseline value or a creatinine value >4 mg/dL with an acute increase of 0.5 mg/dL or more	<0.3 mL/kg/h × 24 h or anuria × 12 h
Loss	Persistent ARF for >4 wk	
End-stage kidney disease	Persistent ARF for >3 mo	
AKIN Criteria*		
1	Creatinine increase of 1/5–2 times baseline value or increases in creatinine of 0.3 or more mg/dL	<0.5 mL/kg/h × 6 h
2	Creatinine increase of 2–3 times baseline value	<0.5 mL/kg/h × 12 h
3	Creatinine increase of 3 or more times baseline value or a creatinine value >4 mg/dL with an acute increase of 0.5 mg/dL or more	

*Reduction in renal function must occur within 48 h.

will not only define AKI but will also offer the potential to diagnose the disorder before functional decline.

Urine output patterns in AKI can manifest as oliguria (<400 mL/d), nonoliguria (>400 mL/d), or anuria (<100 mL/d). Categorization of AKI as oliguric or nonoliguric is diagnostically significant because the oliguric form is associated with higher morbidity and mortality rates. This may be mediated in part by the more pronounced fluid retention in oliguric versus nonoliguric patients.[11] Anuria is rare and is most often seen in two conditions: shock and complete bilateral urinary tract obstruction. Any sudden and complete cessation of urinary flow in a patient with a Foley catheter should alert the nurse to inspect, flush, or change the urinary catheter.

Causes of Acute Kidney Injury

Many pathophysiological pathways may lead to the syndrome of AKI. To aid in establishing a diagnostic and management plan, AKI is organized into three general categories according to precipitating factors and the symptoms manifested (Box 31-1).

Prerenal Acute Kidney Injury

Prerenal AKI is characterized by any physiological event that results in renal hypoperfusion. Most commonly, precipitating events include hypovolemia and cardiovascular failure; however, any other event that leads to an acute decrease in "effective renal perfusion" can fall into this category (see Box 31-1). For example, in sepsis, a systemic inflammatory response triggers a cascade of events that results in a vasodilated hypotensive state despite no net loss in body fluids.

Intrarenal Acute Kidney Injury

The intrarenal category of AKI is characterized by actual damage to the renal parenchyma and has many possible associated causes. One way to categorize these causes is by anatomical compartment: glomerular, vascular, interstitial, and tubular. The glomerular etiologies, which result in acute glomerulonephritis, include immune complex–mediated causes (eg, as seen with poststreptococcal glomerulonephritis) and diseases that cause vasculitis, such as Wegener's granulomatosis and antiglomerular basement membrane disease. Interstitial causes include acute allergic interstitial nephritis, usually caused by pharmacological agents, and infectious causes such as pyelonephritis. Vascular etiologies include malignant hypertension as well as microangiopathic processes, such as atheroembolic disease or hemolytic–uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP). Finally, the tubules of the kidney can be primarily affected because of obstruction or acute tubular necrosis (ATN). Obstructive causes include multiple myeloma and acute urate nephropathy.

A common cause of intrarenal hospital-acquired AKI is ATN. ATN results from either a prolonged prerenal condition (ischemic ATN) or the effects of toxins on the tubules (toxic ATN). Examples of potential toxins to the tubules include pharmacological agents, such as aminoglycosides, amphotericin B, and chemotherapeutic agents; heavy

BOX 31-1 Precipitating Causes of Acute Kidney Injury

Prerenal
- Decreased intravascular volume
  - Dehydration
  - Hemorrhage
  - Hypovolemic shock
  - Hypovolemia (gastrointestinal losses, diuretics, diabetes insipidus)
  - Third spacing (burns, peritonitis)
- Cardiovascular failure
  - Heart failure
  - Myocardial infarction
  - Cardiogenic shock
  - Valvular heart disease
  - Renal artery stenosis or thrombosis
- Drugs
  - ACE inhibitors
  - NSAIDs—inhibit prostaglandin-mediated afferent arteriolar vasodilation
  - Calcineurin inhibitors (eg, tacrolimus, cyclosporine)—cause preglomerular vasoconstriction
- Decreased "effective renal perfusion"
  - Sepsis
  - Cirrhosis
  - Neurogenic shock

Intrarenal
- Acute glomerulonephritis
  - Immune complex–mediated (postinfectious, lupus nephritis, cryoglobulinemia, immunoglobulin A [IgA] nephropathy)
  - With vasculitis (Wegener's granulomatosis, antiglomerular basement membrane disease, polyarteritis nodosa)
- Vascular disease
  - Malignant hypertension
  - Microangiopathic hemolytic–uremic syndrome (HUS)
  - Thrombotic thrombocytopenic purpura (TTP)
  - Scleroderma
  - Eclampsia
  - Atheroembolic disease
  - Acute cortical necrosis
- Acute interstitial disease
  - Allergic interstitial nephritis
  - Acute pyelonephritis
- Tubular obstruction
  - Multiple myeloma
  - Acute urate nephropathy
  - Ethylene glycol or methanol toxicity
- Acute tubular necrosis (ATN)
  - Ischemia
  - Nephrotoxins (contrast dye, drugs, heme pigments)
  - Kidney transplant rejection

Postrenal
- Ureteral obstruction
  - Intrinsic (stones, transitional cell carcinoma of the ureter, blood clots, stricture)
  - Extrinsic (ovarian cancer; lymphoma; metastatic cancer of the prostate, cervix, or colon; retroperitoneal fibrosis)
- Bladder problems
  - Tumors
  - Blood clots
  - Neurogenic bladder (spinal cord injury, diabetes mellitus, ischemia, drugs)
  - Stones
- Urethral obstruction
  - Prostate cancer or benign prostatic hypertrophy
  - Stones
  - Stricture
  - Blood clots
  - Obstructed indwelling catheter

metals; organic solvents; heme pigments (eg, myoglobin and hemoglobin); and radiocontrast media (Box 31-2).

Postrenal Acute Kidney Injury

Postrenal AKI accounts for approximately 10% of hospital cases.[10] Any obstruction in the flow of urine from the collecting ducts in the kidney to the external urethral orifice can result in postrenal AKI. Postrenal obstruction can result from ureteral blockage (as with bilateral renal stones), urethral blockage (as from stricture and benign prostatic hypertrophy), or an extrinsic source, such as a retroperitoneal tumor or fibrosis. Another source of postrenal AKI is a dysfunctional bladder (eg, as might be caused by ganglionic blocking agents that interrupt autonomic supply to the urinary system). Elderly men and the young are populations particularly susceptible to postrenal AKI. Children are at risk secondary to congenital anomalies, and elderly men are at risk because of the high prevalence of benign or malignant prostatic hypertrophy.

Pathophysiology of Acute Kidney Injury

Prerenal Acute Kidney Injury

The pathophysiology of prerenal AKI is centered on the kidneys' response to inadequate perfusion. A decrease in renal perfusion results in the release of the enzyme renin from juxtaglomerular cells in the walls of the afferent arterioles. This activates the renin–angiotensin–aldosterone cascade, the end result being the production of angiotensin II and the release of aldosterone from the adrenal cortex. Angiotensin II causes profound systemic vasoconstriction, and aldosterone induces sodium and water retention. These effects help the body preserve circulatory volume to maintain adequate blood flow to essential organs such as the heart and brain. In the kidneys, angiotensin II also helps maintain the GFR by increasing efferent arteriolar resistance and by stimulating intrarenal vasodilator prostaglandins (which dilate the afferent arteriole), increasing hydrostatic pressure in the glomeruli.[12] In this way, the kidneys can preserve the GFR over a wide range of mean arterial pressures. However, when renal perfusion is severely compromised, the capacity for autoregulation is overwhelmed, and the GFR decreases.

Even with moderate hypovolemia or congestive heart failure, certain drugs, such as angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), and nonsteroidal anti-inflammatory drugs (NSAIDs), can overwhelm the kidney's ability to autoregulate. These drugs disrupt some of the autoregulatory mechanisms, such as prostaglandin-mediated afferent arterial vasodilation, in the case of NSAIDs, and increased efferent arteriolar resistance,

BOX 31-2 Common Causes of Acute Tubular Necrosis

Ischemic
Hemorrhagic hypotension
Severe volume depletion
Surgical aortic cross-clamping
Cardiac surgery
Defective cardiac output
Septic shock
Pancreatitis
Immunosuppression (cyclosporine, tacrolimus)
NSAIDs

Nephrotoxic
Drugs, including antimicrobials (aminoglycosides, amphotericin), cyclosporine, anesthetics, chemotherapeutic agents
Heavy metals (mercury, lead, cisplatinum, uranium, cadmium, bismuth, arsenic)
Radiological contrast agents
Heme/pigments (myoglobin, hemoglobin)
Organic solvents (carbon tetrachloride)
Fungicides and pesticides
Plant and animal substances (mushrooms, snake venom)

in the case of ACE inhibitors and ARBs. Predisposing factors for NSAID- and ACE inhibitor–induced prerenal failure are hypovolemia, baseline renal insufficiency, liver disease, heart failure, and diseases of the renal arteries.[12,13]

In prerenal AKI, once autoregulatory capacity is overwhelmed and the GFR decreases, changes in urinary composition and volume occur in a predictable pattern. When the GFR decreases, the amount of tubular fluid is reduced, and the fluid travels through the tubule more slowly. This results in increased sodium and water reabsorption. Because of the reduced renal circulation, the solutes reabsorbed from the tubular fluid are removed more slowly than normal from the interstitium of the renal medulla. This results in increased medullary tonicity, further augmenting water reabsorption from the distal tubular fluid. As a result of these events, the urinary volume is reduced to less than 400 mL/d (<17 mL/h), the urine specific gravity is increased, and the urine sodium concentration is low (usually <5 mEq/L; Fig. 31-1). Because of these characteristic changes associated with renal underperfusion, measurement of urinary volume, urinary sodium, and specific gravity is a simple method of determining the effect of management on renal perfusion.

An increase in systemic BP does not necessarily imply improvement in renal perfusion. This may be especially evident when drugs, such as norepinephrine, are used to correct the hypotension associated with states of volume depletion. These drugs may be associated with further reduction in renal blood flow as a consequence of constriction of the renal arteries. This is manifested by a further fall in urinary volume and rise in specific gravity.

In turn, if the hypoperfusion state is more appropriately and specifically treated by replacement of volume, improvement of cardiac output, correction of dysrhythmias, or a combination of these approaches, the improved renal perfusion is manifested as an increased urinary volume and urine sodium concentration and as a decreased specific gravity of

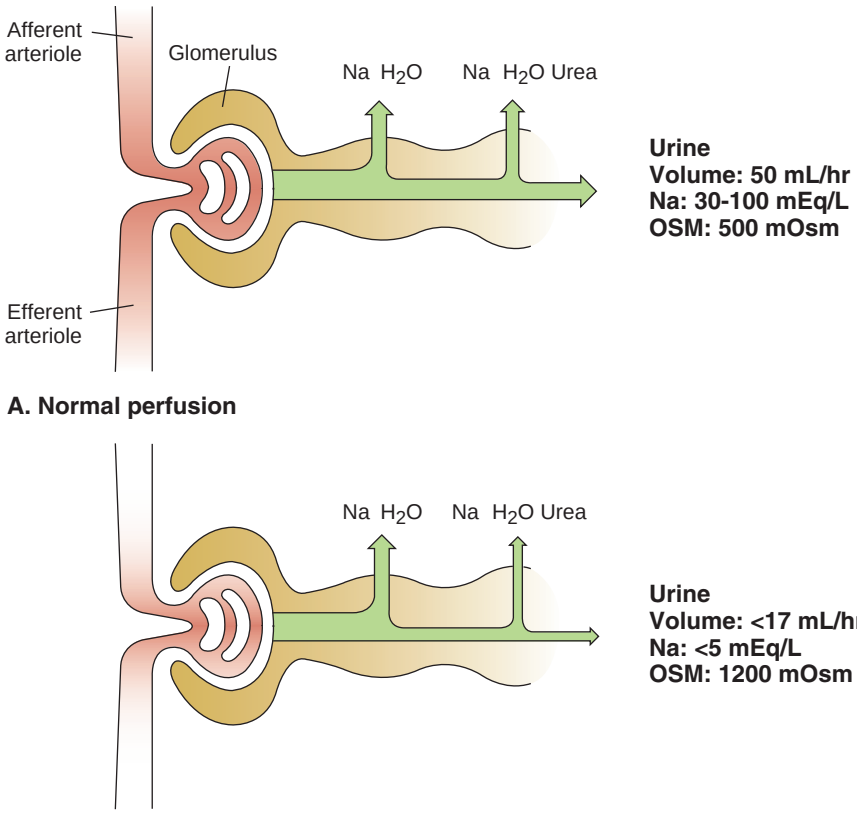

FIGURE 31-1 ▲ Normal perfusion (**A**) of the kidney compared with underperfusion (**B**), as seen in prerenal AKI. Underperfusion of the kidney results in decreased renal blood flow and glomerular filtration, an increase in the fraction of filtrate reabsorbed in the proximal tubule, and low urine flow with low sodium (Na) content and increased concentration. H_2O, water; OSM, osmolarity.

the urine. This ability to reverse prerenal AKI is the key to its diagnosis.

Intrarenal Acute Kidney Injury

Just as there are many causes of intrarenal AKI, there are also many pathophysiological pathways that lead to it (Fig. 31-2). Because ATN is the most common hospital-acquired form of intrarenal AKI, this discussion focuses on the pathophysiology of ATN, which is complex, but intense and ongoing research has increased understanding of the factors contributing to this condition. Ischemia and nephrotoxicity are two major underlying causes of ATN (Fig. 31-3).

Ischemic Acute Tubular Necrosis

Ischemic ATN results from prolonged hypoperfusion. Thus, prerenal AKI and ischemic ATN are actually a continuum, a fact that underscores the importance of prompt recognition and treatment of the prerenal state. When renal hypoperfusion persists for a sufficient time (the exact duration of which is unpredictable and varies with clinical circumstances), renal tubular epithelial cells become hypoxic and sustain damage to the point that restoration of renal perfusion no longer effects an improvement in glomerular filtration. Ischemia results in decreased adenosine triphosphate production in renal cell mitochondria, which robs the cells of a needed energy supply. Part of this energy is used to keep the proper concentration of electrolytes in the cell through electrolyte exchange channels. Some of the cellular electrolyte disturbances from ischemia are decreased intracellular potassium, magnesium, and phosphate and increased intracellular sodium, chloride, and calcium. Increased intracellular calcium specifically has been shown to predispose the cells to injury and dysfunction.[12,14]

During reperfusion, cellular insults also occur from the formation of oxygen free radicals. Eventually, these cellular insults cause the tubular cells to swell and become necrotic. The necrotic cells then slough off and may obstruct the tubular lumen. These sloughed cells also allow back leak of tubular fluid because of altered function of their basement membrane, which contributes to the decreased GFR seen in this disorder.

A final contributor to the pathophysiology of ischemic ATN is profound renal vasoconstriction, which reduces renal blood flow by as much as 50%.[12] These hemodynamic disturbances further compromise renal oxygen delivery and add to the ischemic damage. Vasoconstrictors involved include norepinephrine from sympathetic nervous system activation, angiotensin II, thromboxane A_2, adenosine, leukotrienes C4 and D4, prostaglandin H_2, and endothelin, a powerful vasoconstrictor released by damaged vascular endothelial cells of the kidney.[12]

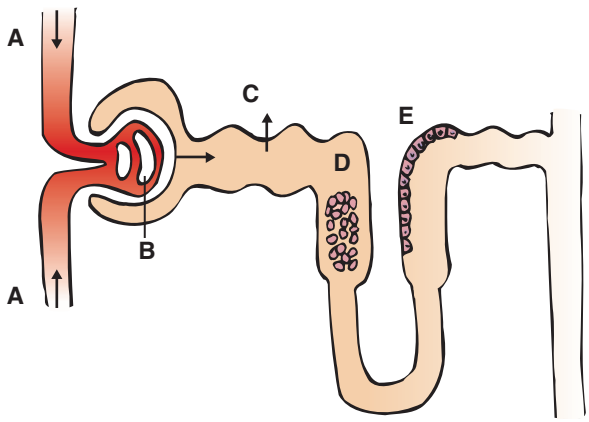

FIGURE 31-2 ▲ Potential mechanisms of intrarenal AKI include decreased filtration pressure because of constriction in the renal arterioles (**A**), decreased glomerular capillary permeability (**B**), increased permeability of the proximal tubules with back leak of filtrate (**C**), obstruction of urine flow by necrotic tubular cells (**D**), and increased sodium delivery to the macula densa (**E**), which causes an increase in renin–angiotensin production and vasoconstriction at the glomerular level.

Toxic Acute Tubular Necrosis

The pathophysiology of toxic ATN begins with a concentration of a nephrotoxin in the renal tubular cells, which causes necrosis. These necrotic cells then slough off into the tubular lumen, possibly causing obstruction and impairing glomerular filtration in a manner similar to that of ischemic ATN. However, there are significant differences between toxic ATN and ischemic ATN. In toxic ATN, the basement membrane of the renal cells usually remains intact, and the injured necrotic areas are more localized. In addition, nonoliguria occurs more often with toxic ATN, and the healing process is often more rapid.

Although the potential nephrotoxins in toxic ATN are many (see Box 31-2), aminoglycoside antibiotics and radiocontrast dye deserve special mention because of the frequency with which they are seen as causes of toxic ATN in hospitalized patients. Nephrotoxicity occurs in 10% to 20% of patients treated with aminoglycosides for 10 days or more.[13,14] The onset of AKI secondary to aminoglycosides is usually delayed, often beginning 5 to 10 days after the onset of therapy. The toxicity of these agents is dose dependent, and because these agents are primarily eliminated by the kidneys, dosage must be adjusted in patients with preexisting renal impairment. To ensure that the correct therapeutic range is being achieved, blood is drawn frequently for peak and trough level analysis. Offending agents (listed in decreasing order of the severity with which they produce dose-dependent proximal tubule damage) are neomycin, gentamicin, amikacin, tobramycin, and streptomycin. Several studies have suggested that a single daily dose of an aminoglycoside may result in less nephrotoxicity than giving the same total amount of medication in three daily doses.[13,15] Besides dosage, increased risk factors for aminoglycoside toxicity are volume depletion, advanced age, concurrent use of other nephrotoxic agents, and hepatic dysfunction.[13,16]

Contrast-induced nephropathy (CIN), the sudden decline of renal function following intravascular injection of contrast media, accounts for a significant number of hospital-acquired cases of AKI. It usually begins within 24 to 48 hours of intravenous (IV) radiocontrast administration and peaks within 5 to 7 days. Typically, CIN is nonoliguric, transient, and reversible; however, in high-risk patients, dialysis may be required on an intermittent or permanent basis.[17,18] Patients at greatest risk for CIN are those with diabetes, especially those with diabetes and underlying renal impairment. In

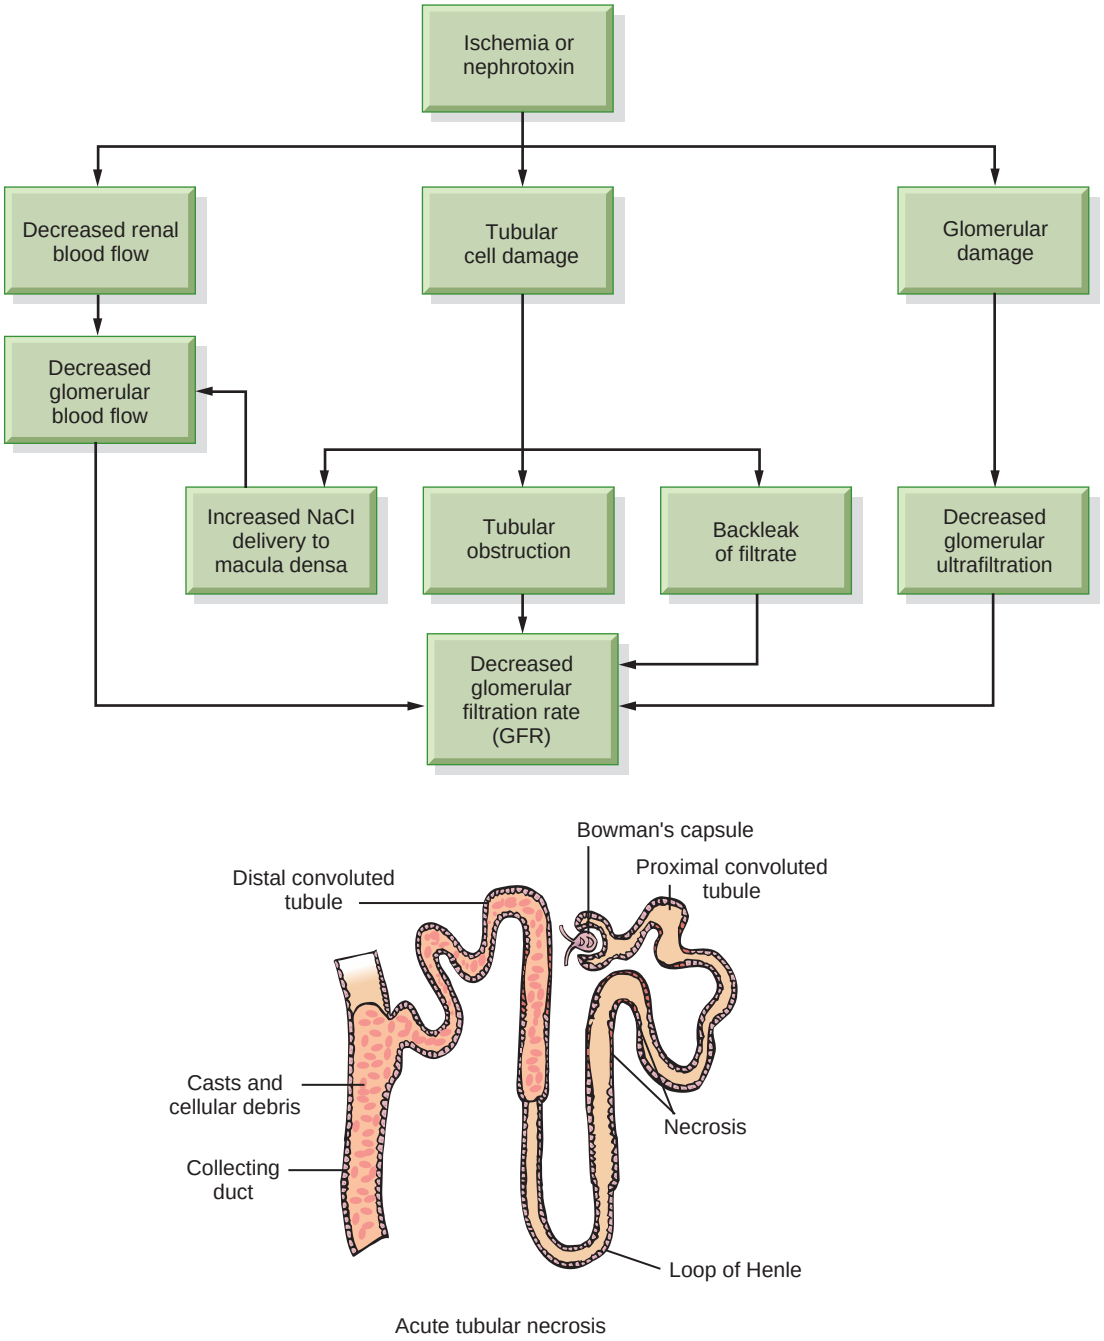

FIGURE 31-3 ▲ Ischemic ATN results from prolonged hypoperfusion. A sequence of pathophysiological processes results in the sloughing off of necrotic cells that block the tubular lumen. Toxic ATN occurs when a nephrotoxin becomes concentrated in the renal tubular cells and causes necrosis. The necrotic cells slough off and obstruct the tubular lumen, similar to ischemic ATN. In toxic ATN, the basement membrane of the renal cells usually remains intact, and the necrotic areas are more localized.

these patients, the incidence of CIN may be as high as 50%.[17] Other patients at risk are elderly patients; those with intravascular volume depletion, congestive heart failure, or anemia; and those who receive a large contrast load.[17,18]

The only proven way to reduce the risk for CIN is by aggressive volume expansion with isotonic crystalloids (normal saline solution) before and after contrast agent administration.[17] Because CIN is believed to involve the production of oxygen free radicals, it is postulated that alkalinization of the urine with sodium bicarbonate may confer greater protection than IV fluids alone. However, two recent meta-analyses of multiple randomized trials have demonstrated no clear evidence of benefit for hydration with sodium bicarbonate versus hydration with saline solution to prevent CIN.[19,20]

Other interventions to reduce the incidence of CIN include using the minimal necessary dose of contrast media, using low or iso-osmolar nonionic contrast media instead of ionic hyperosmolar agents, stopping the intake of nephrotoxic drugs 24 hours before contrast media

injection, and avoiding short intervals between contrast procedures.[17,18] *N*-Acetylcysteine (NAC), an antioxidant and a potent vasodilator, is part of the protocol in many hospitals to prevent CIN based on clinical trials demonstrating its renoprotective effects in patients receiving IV contrast media. However, NAC has been the subject of many meta-analyses, and, overall, there has been insufficient evidence to support the universal use of NAC to prevent CIN.[17,18] Studies have shown that other pharmacological interventions, such as calcium channel blockers, dopamine, mannitol, and atrial natriuretic peptide, do not consistently reduce the incidence of CIN and may even be harmful.

Of course, avoiding any use of iodinated contrast media in high-risk patients is the best prevention, and alternative studies, such as ultrasonography, computerized tomography (CT) scanning without contrast, and contrast-enhanced magnetic resonance imaging (MRI), should be considered. The MRI contrast agents in use are mostly chelates of gadolinium and have been found to be less nephrotoxic than iodinated radiocontrast, particularly when used in small doses.[21] This has led to the use of gadolinium-based contrast agents (GBCAs) as alternatives to iodinated contrast agents for digital subtraction angiography or interventional procedures, especially in patients with iodinated contrast allergies. However, one important caveat regarding the use of GBCA in patients with acute or severe chronic kidney disease (CKD; GFR < 30 mL/min) is the rare but serious risk for developing nephrogenic systemic fibrosis (NSF). NSF, a fibrosing disorder seen only in patients with kidney disease, is characterized by thickening and hardening of the skin overlying the extremities and trunk. Occasionally, fibrosis of deeper structures (such as muscles, the lungs, and the heart) occurs as well. Because the condition can be devastating to a patient (resulting in significant loss of mobility and even death), gadolinium agents should be avoided in patients with a GFR less than 30 mL/min.[21–23] If it is determined that a study using a GBCA must be performed, the Food and Drug Administration recommends that the lowest possible dose of GBCA needed to conduct the study be used and that there be allotted a sufficient period of time for elimination of the agent from the body prior to readministration. In addition, for patients receiving hemodialysis, prompt hemodialysis following GBCA administration is recommended to enhance elimination of the GBCA.[23]

Postrenal Acute Kidney Injury

Obstruction can occur at any point in the urinary tract. When urine cannot get around the obstruction, resulting congestion causes retrograde pressure through the collecting system and nephrons. This slows the rate of tubular fluid flow and lowers the GFR. As a result, the reabsorption of sodium, water, and urea is increased, leading to a lowered urine sodium concentration and increased urine osmolality and BUN. Serum creatinine levels also increase. With prolonged pressure from urinary obstruction, the entire collecting system dilates, compressing and damaging nephrons. This results in dysfunction of the concentrating and diluting mechanism, and the urine osmolality and urine sodium concentration become similar to that of plasma. This circumstance can be avoided by prompt removal of the obstruction.

Because a single well-functioning kidney is adequate to maintain homeostasis, the development of AKI from obstruction requires blockage of both kidneys (ie, urethral or bladder neck obstruction or bilateral ureteral obstruction) or unilateral ureteral obstruction in patients with a single kidney. After relief of the obstruction, there is often a profound diuresis that may be as great as 5 to 8 L/d.[14] If electrolytes and water are not replenished as needed, this diuresis can lead to hemodynamic compromise, dysrhythmias, and ATN.

Clinical Course of Acute Tubular Necrosis

The course of ATN can be divided into four clinical phases: onset phase, oliguric or nonoliguric phase, diuretic phase, and recovery phase.

Onset Phase

The onset (initiating) phase begins with an initial insult and lasts until cell injury occurs. During this phase, injury is evolving, and the health care team members need to attempt to prevent disease progression. The onset phase lasts from hours to days, depending on the cause, and is heralded by an increase in serum creatinine. The major goal during this phase is to determine the cause of the ATN and initiate treatment to prevent irreversible tubular damage.

Oliguric or Nonoliguric Phase

The second phase of ATN is characterized as either oliguric or nonoliguric. Patients who present with oliguric ATN are less likely to recover renal function and have a higher associated mortality rate.[14] This presentation of ATN is most commonly the result of ischemic insult. Oliguric ATN is marked by fluid overload, azotemia, electrolyte abnormalities (ie, hyperkalemia, hyperphosphatemia, and hypocalcemia), metabolic acidosis, and symptoms of uremia. The main goal during this period is to support renal function and keep the patient alive until renal injury heals. Complications during this period are from hyperkalemia, hypoxemia, gastrointestinal bleeding, and infection. Oliguric ATN lasts approximately 7 to 14 days, although it may persist for weeks depending on the extent of renal injury.[14]

The nonoliguric presentation of ATN is most commonly associated with toxic injury (eg, from aminoglycoside antibiotics). It is characterized by a renal concentrating defect rather than the impaired urinary flow seen in oliguric ATN. Urine volume in nonoliguric ATN ranges from normal to as much as 2 L/h.[14] Because of the higher volume of urine output, fluid complications are minimized. However, because potassium excretion parallels that seen in oliguria, hyperkalemia remains a major risk. The duration of nonoliguric ATN is typically short, lasting an average of 5 to 8 days.

Diuretic Phase

The diuretic phase lasts 1 to 2 weeks and is characterized by a gradual increase in urine output as renal function starts to resume. The degree of diuresis, which can exceed

10 L/d, is primarily determined by the state of hydration at the time the patient enters this stage. Thus, patients who are receiving hemodialysis or who are nonoliguric tend to diurese less. The diuresis is thought to result from the osmotic pull of retained substances (ie, urea and sodium), which act as osmotic agents. Although the urine output may be normal or elevated, renal concentrating ability is still impaired. This puts patients at risk for fluid volume deficits and electrolyte abnormalities, such as hyponatremia and hypokalemia. Primary goals during this stage are maintenance of hydration, prevention of electrolyte depletion, and continued support of renal function.

Recovery Phase

The recovery phase of ATN lasts from several months to a year. It is the time it takes for renal function to return to normal or near-normal levels. If significant renal cell damage has occurred, especially to the basement membrane (which cannot regenerate), residual renal impairment may result. Major goals of the health care team in this phase revolve around patient education. To foster and maintain the return of renal function, it is critical that patients and family members understand what precipitated the AKI episode as well as what follow-up care and preventive measures are necessary to prevent a recurrence.

Diagnosis of Acute Kidney Injury

Diagnosis of AKI begins with a determination of whether the AKI is prerenal, intrarenal, or postrenal. The assessment tools used to make this determination include the history and physical examination, laboratory tests, and diagnostic studies. Special considerations for assessing renal function in older patients are given in Box 31-3.[24]

History and Physical Examination

Essential to any assessment is the health history and physical examination. By taking a detailed history, clues to the categorization and exact cause of the AKI can be obtained. Important indications in the history that suggest prerenal AKI include any event or condition that may have contributed to decreased renal perfusion (eg, acute myocardial infarction, cardiovascular surgery, cardiac arrest, high fever, any shock state, and the use of certain drugs, such as NSAIDs). Also, a history of atherosclerotic disease may be a clue to renal artery stenosis, another precipitant of prerenal AKI. Clues to an intrarenal cause provided by the history include any prolonged prerenal event or condition as well as exposure to nephrotoxins, especially aminoglycoside antibiotics and radiocontrast media. It is also important to collect information regarding systemic diseases such as lupus or vasculitis, recent streptococcal infections, and causes for heme pigment toxicity, such as rhabdomyolysis (eg, a history of trauma or a patient found unconscious for an unknown amount of time). In addition, a history of cardiac catheterization, anticoagulation, and thrombolytic therapy increases the possibility of atheroembolic intrarenal diseases. Findings that may point to postrenal AKI include any history of abdominal tumors or calculi, and especially a history of benign prostatic hypertrophy in elderly men. A family history of urolithiasis or benign prostatic hypertrophy may be contributory.

The physical examination, particularly fluid status, is critical to the diagnosis of AKI. In prerenal AKI, a state of decreased renal perfusion related to dehydration or hypovolemia is heralded by poor skin turgor, dry mucous membranes, weight loss, and reduced jugular venous distention. In contrast, when decreased perfusion is related to vasodilation, third spacing, cardiovascular disease (eg, heart failure), liver disease, or a combination of these factors, findings of increased extracellular fluid may be manifested. These findings include edema, ascites, and weight gain. For critical care patients, hemodynamic monitoring values help determine intravascular fluid status as well as cardiac functioning. Surveillance values include central venous pressure (CVP), pulmonary artery occlusion pressure (PAOP), and cardiac output (or cardiac index). By correlating physical examination findings with the history, hemodynamic values, and

BOX 31-3 CONSIDERATIONS FOR THE OLDER PATIENT

Physiological Changes Affecting the Renal System

As the body ages, physiological systemic and kidney-specific changes occur that are important to take into consideration when addressing the kidney.

- Vascular changes: At 30 years of age, arteriosclerosis starts to develop, including in the renal arteries; this can result in significant damage.
- Musculoskeletal changes: In elderly people, there is a decreased muscle mass and body weight. These changes must be kept in mind when assessing renal function because of the possibility of a consequent decreased baseline serum creatinine value. A minimum rise in serum creatinine value in elderly patients, which may be within normal limits for a young adult, may actually signify major renal impairment.
- Kidney-specific changes: With aging, there is a decrease in the total number of functioning glomeruli, a decrease in renal blood flow, and a decrease in GFR of about 0.75 mL/min/1.73 m^2 per year after 30 years of age.[24]

In view of these systemic and kidney-specific changes, an accurate assessment of GFR using a 24-hour urine study or an isotopic study is essential. The Cockroft-Gault formula or the Modification of Diet in Renal Disease (MDRD) formulas below, which take into account gender and age, can also be used. It is important to realize that these formulas are not extensively validated in patients older than 70 years. After true GFR is realized, therapy (eg, drug dosages) can be guided more safely.

Cockcroft-Gault Formula for Creatinine Clearance (mL/min)

Men = (140 – age) × weight in kg/72 × serum creatinine

Women = 0.85 × creatinine clearance for men

MDRD Formula for GFR (adults; mL/min)

175 × Serum creatinine concentration$^{-1.154}$

× Age$^{-0.203}$

× 0.742 (if female)

× 1.210 (if black)

Websites are available to aid in the calculation of the GFR through these formulas. These include http://www.kidney.org and http://www.nephron.com.

laboratory tests, potential prerenal etiologies can be narrowed down.

Although no specific physical examination finding prompts consideration of intrarenal AKI, many examination findings are helpful clues to potential causes of intrarenal AKI. For example, signs of a streptococcal throat infection, lupus (eg, a butterfly mask rash), or embolic phenomena (eg, discolored toes and livedo reticularis, a semipermanent bluish mottling of the skin in the extremities) may all suggest an intrarenal cause. Again, correlation with the history and laboratory studies helps narrow the list of potential causes. Findings on physical examination that may suggest a postrenal cause include a distended bladder, an abdominal mass, an enlarged or nodular prostate gland, and, most obviously, a kinked or obstructed Foley catheter.

Laboratory Studies

Laboratory assessment, critical to the diagnosis and categorization of AKI, includes both serum and urinary values. For a basic comparison of laboratory values in prerenal AKI, postrenal AKI, and ATN, see Table 31-2. In addition to helping differentiate between prerenal, intrarenal, and postrenal AKI, blood and urine tests are also helpful for diagnosing the underlying etiology of the AKI (Box 31-4).

URINARY VALUES. Obtaining a urine specimen for diagnostic evaluations is invaluable in establishing the diagnosis and determining the type of AKI. The urine specimen should be obtained before a diagnostic challenge dose of diuretics is administered because these agents may alter the urine's chemical composition. The urine sodium concentration, osmolality, and specific gravity are especially helpful in distinguishing between prerenal AKI and ATN because these values reflect the concentrating ability of the kidney. In prerenal failure, the hypoperfused kidney actively reabsorbs sodium and water in an attempt to increase circulatory volume. Consequently, the urine sodium level and the fractional excretion of sodium (FE_{Na}) are low (<20 mEq/L and <1%, respectively), whereas the urine osmolality and concentration of nonreabsorbable solutes are high. In contrast, in ATN in which parenchymal damage affects the kidney, the tubular cells can no longer effectively reabsorb sodium or concentrate the urine. As a result, the urine sodium concentration is often greater than 40 mEq/L, the FE_{Na} is greater than 1%, and the urine osmolality is close to that of plasma (isosthenuria). Unfortunately, there is a limit to the usefulness of these indices because of overlap in these values for prerenal AKI and ATN (ie, urine sodium concentration values in the 20- to 40-mEq/L range). Values at the extremes thus are most useful.

Although controversial, one test that may be helpful in distinguishing prerenal AKI from ATN in patients who have already been given diuretics is the fractional excretion of urea nitrogen (FE_{un}). Urea, like sodium, is reabsorbed in a prerenal hypoperfused kidney, but unlike sodium, its reabsorption is primarily dependent on passive forces and is not inhibited by loop and thiazide diuretic administration.[25] In prerenal AKI, the fractional excretion of urea nitrogen is less than 35%, whereas in ATN and normally, it is more than 50%.

The sediment in a urinalysis is also very helpful in diagnosing and distinguishing the types of AKI. In prerenal AKI, the urinary sediment is normal with only a few hyaline casts, whereas in ATN, coarse, muddy-brown granular casts and tubular epithelial cells are typically found. In postrenal AKI, the sediment is often normal but can be helpful in diagnosing kidney stones.

BLOOD UREA NITROGEN AND CREATININE LEVELS. Serum tests for blood urea nitrogen (BUN) and creatinine are essential not only for diagnosing AKI but also for helping to distinguish between prerenal AKI and ATN or postrenal AKI. In prerenal AKI, the BUN-to-creatinine ratio is increased from the normal ratio of 10:1 to more than 20:1. This finding is caused by a state of dehydration and by the fact that as the tubules become more permeable to sodium and water in prerenal AKI, urea is also passively reabsorbed. In ATN and postrenal AKI, when the concentrating ability of the kidneys is impaired, both the BUN and creatinine increase proportionally, maintaining the normal 10:1 ratio.

Diagnostic Studies

One important diagnostic test in the evaluation of AKI is renal ultrasonography. This test is especially useful in ruling out an obstruction and has the advantage of being

Table 31-2 Acute Kidney Injury: Comparison of Laboratory Findings in Prerenal Failure, Postrenal Failure, and Acute Tubular Necrosis

Value	Prerenal	Postrenal	Acute Tubular Necrosis
Urine volume	Oliguria	May alternate between anuria and polyuria	Anuria, oliguria, or nonoliguria
Urine osmolality	Increased (>500 mOsm/kg H_2O)	Varies, increased, or equal to serum	250–300 mOsm/kg H_2O
Urine specific gravity	Increased (>1.020)	Varies	Approximately 1.010
Urine sodium	<20 mEq/L	Varies	>40 mEq/L
Urine sediment	Normal, few casts	Normal, may be crystals	Granular casts, tubular epithelial cells
FE_{Na}	<1%	>1%	>1% (often >3%)
BUN:Cr	>20:1	10:1 to 15:1	10:1 to 15:1

FE_{Na}, fractional excretion of sodium; BUN:Cr, blood urea nitrogen/creatinine ratio.

BOX 31-4 Diagnostic Clues in Acute Kidney Injury

Urine
- Urate crystals: tumor lysis, especially lymphoma (urate nephropathy)
- Oxalate crystals: ethylene glycol nephrotoxicity, methoxyflurane nephrotoxicity
- Eosinophils: allergic interstitial nephritis, especially methicillin
- Positive peroxidase test without red blood cells: hemoglobinuria or myoglobinuria
- Pigmented casts: hemoglobinuria or myoglobinuria
- Massive proteinuria: acute interstitial nephritis, thiazide diuretics, hemorrhagic fevers (eg, Korean, Scandinavian)
- Abnormal urine protein electrophoresis: multiple myeloma
- Anuria: renal cortical necrosis, bilateral obstruction, renal vascular catastrophe

Plasma
- Marked hyperkalemia: rhabdomyolysis, tissue necrosis, hemolysis
- Marked hypocalcemia: rhabdomyolysis
- Hypercalcemia: hypercalcemic nephropathy
- Hyperuricemia: tumor lysis, rhabdomyolysis, toxin ingestion
- Marked acidosis: ethylene glycol, methyl alcohol
- Elevated creatine kinase or myoglobin levels: rhabdomyolysis
- Low complement levels: systemic lupus erythematosus (SLE), postinfectious glomerulonephritis, subacute bacterial endocarditis
- Abnormal serum protein electrophoresis: multiple myeloma
- Positive antibody/glomerular basement membrane ratio: Goodpasture's syndrome
- Positive antineutrophilic cytoplasmic antibody: small vessel vasculitis (Wegener's granulomatosis or polyarteritis nodosa)
- Positive antinuclear antibody or antibody to double-stranded DNA: SLE
- Positive antibodies to streptolysin O: poststreptococcal glomerulonephritis
- Elevated lactate dehydrogenase level, elevated serum bilirubin level, or decreased haptoglobin level: HUS or TTP

noninvasive. With a high-grade obstruction, dilation of the urinary collecting system is detectable on ultrasonography within 1 to 2 days of the onset of the obstruction. Ultrasonography may also reveal proximal renal calculi as a cause of postrenal obstruction. In addition, it can be used to estimate renal size, which is helpful in distinguishing between AKI and advanced CKD. Often in advanced CKD, the kidneys are small (<9 cm) and echogenic.

Other studies may be useful in diagnosing AKI. These include CT and MRI to evaluate for masses, vascular disorders, and filling defects in the collecting system as well as renal angiography to evaluate for renal artery stenosis. It is notable that the iodinated contrast media used in some studies are allergenic and nephrotoxic and that GBCAs can cause NSF in patients with severe kidney disease (GFR < 30 mL/min). If available, alternative technology, such as the use of carbon dioxide gas in digital subtraction angiography, should be considered for patients allergic to iodinated agents or with advanced kidney failure.[26] For any diagnostic test, the benefits of the study must be weighed against potential risks. Finally, renal biopsy may be helpful in patients thought to have intrarenal AKI that is not ATN, especially if significant proteinuria or unexplained hematuria is revealed on urinalysis. In addition to having diagnostic value, the results of a biopsy may help determine prognosis and therapy.

▲ Chronic Kidney Disease

Chronic kidney disease (CKD) is a slow, progressive, irreversible deterioration in renal function that results in the kidney's inability to eliminate waste products and maintain fluid and electrolyte balance. Ultimately, it leads to end-stage renal disease (ESRD) and the need for RRT or renal transplantation to sustain life.

Currently, there are more than 520,000 dialysis and renal transplant recipients in the United States, which is an 18% increase in prevalence since the year 2000. In 2007 alone, more than 110,000 patients were newly diagnosed with ESRD. Among ESRD patients, incidence rates are 24% higher in men than in women and are higher with increasing age. The incidence rates in the African American population are 3.7 times greater than in the white population. Hispanics and Native Americans also have higher incidence rates than whites, but the difference in rates is not as dramatic.[27] These differences in incidence rates are important to remember when considering patient risk factors and populations to which increased health education regarding prevention should be targeted.

Although the exact reason for the increase in ESRD is unclear, it is postulated that changes in the demographics of the population, differences in disease burden among racial groups, underrecognition and undertreatment of earlier stages of CKD, and underrecognition of the risk factors for CKD may partially explain this increase.[28] Increasing evidence shows that early detection and treatment of CKD may prevent or at least delay progression to ESRD.[29–31] Consequently, it is important that opportunities to prevent and treat CKD are not lost secondary to underdiagnosis, undertreatment, or both.

Definition and Classification

In an effort to address the growing public health problem of CKD, the Kidney Disease Outcome Quality Initiative (K/DOQI) of the National Kidney Foundation published clinical practice guidelines for CKD in 2002. The goals of the working group that developed these guidelines were as follows: to define CKD and classify its stages, to evaluate laboratory measurements for clinical assessment of kidney disease, to associate the level of kidney function with the complications of CKD, and to stratify risk for the loss of kidney function and the development of cardiovascular disease.[28]

The K/DOQI defines CKD as either kidney damage with or without decreased GFR for 3 or more months *or* a GFR of less than 60 mL/min/1.73 m^2 for greater than 3 months (Box 31-5). Markers of damage include abnormal findings in the blood or urine tests or imaging studies. Examples are proteinuria, abnormalities in the urine sediment, increased serum creatinine, and multiple renal cysts detected on ultrasound in a patient with a family history of polycystic kidney disease (see Spotlight on Genetics 31-1).

BOX 31-5 Definition of Chronic Kidney Disease

1. Kidney damage for greater than or equal to 3 months as defined by structural or functional abnormalities of the kidney, with or without decreased GFR, manifested by *either:*
   a. Pathological abnormalities; *or*
   b. Markers of kidney damage, including abnormalities in the composition of the blood and urine, or abnormalities in imaging tests.
2. GFR less than 60 mL/min/1.73 m^2, with or without kidney damage

From National Kidney Foundation: K/DOQI clinical practice guidelines for chronic kidney disease: Evaluation, classification, and stratification. Am J Kidney Dis 39(2 Suppl 1): S1–S266, 2002.

A GFR (considered to be the best overall measure of kidney function) of less than 60 mL/min/1.73 m^2 was chosen for two reasons: (1) it represents a loss of half or more of the adult level of normal kidney function, and (2) below this level, the prevalence of complications from CKD increases.

Because predictable complications and management issues are based on the level of kidney dysfunction, regardless of the specific underlying etiology of CKD, the K/DOQI working group also developed a classification system for CKD based on the measured GFR (Table 31-3).[32] This classification system provides a common language for practitioners and patients to improve communication, enhance education, and promote research. Most importantly, it also provides a framework for evaluation and development of a treatment plan for patients with various stages of CKD, as outlined below.[14]

- Stage 1 is characterized by the lack of a clear filtration deficit and is defined as normal or increased kidney function (GFR ≥ 90 mL/min/1.73 m^2) in association with evidence of kidney damage. This damage most often is represented by persistent albuminuria defined as two consecutive spot urine albumin-to-creatinine ratios (mg/g) of greater than 17 mg/g in men and greater than 25 mg/g in women.
- Stage 2 is a mild reduction in kidney function (GFR, 60 to 89 mL/min/1.73 m^2) that occurs in association with kidney damage.
- Stages 3 and 4 are defined as moderately decreased kidney function (GFR, 30 to 59 mL/min/1.73 m^2) and severely decreased kidney function (GFR, 15 to 29 mL/min/1.73 m^2), respectively. These degrees of reduced GFR are classified as CKD regardless of any additional evidence of kidney damage.
- Stage 5 CKD is defined as a GFR of less than 15 mL/min/1.73 m^2 or the need for dialysis therapy. The term ESRD, widely used in regulatory and administrative circles, continues to be used by K/DOQI to represent those patients receiving or eligible for RRT by dialysis or transplantation.

It is important to note (see Table 31-3) that stage 5, which basically correlates to patients who are classified as having ESRD, represents only the tip of the iceberg of the total number of people who have CKD. According to the Third National Health and Nutrition Examination Survey (NHANES III), conducted between 1988 and 1994, which examined the health and nutritional status of 15,625 participants age 20 years or older, the prevalence of adults in the United States with stage 1 to 4 CKD was 19.2 million (11%), and 8.3 million (4.7%) had stages 3 to 5 CKD, with a GFR of less than 60 mL/min/m^2.[33] This is when most of the complications of CKD begin or have already occurred. The most recent NHANES data collected from 1999 to 2004 reveal increasing prevalence estimates for all stages of CKD, with an overall prevalence of 16.9%.[32] Compounding these grave statistics is the fact that CKD is associated with an increased risk of mortality, particularly from cardiovascular disease.

SPOTLIGHT ON GENETICS 31-1

POLYCYSTIC KIDNEY DISEASE

- Polycystic kidney disease is one of the most common disorders caused by mutations in a single gene. It affects about 500,000 people in the United States. The autosomal dominant form of the disease is much more common than the autosomal recessive form. Autosomal dominant polycystic kidney disease affects 1 in 500 to 1,000 people, while the autosomal recessive type occurs in an estimated 1 in 20,000 to 40,000 people. Clusters of fluid-filled sacs, called cysts, develop in the kidneys and interfere with their ability to filter waste products from the blood.
- Mutations in the PKD1, PKD2, and PKHD 1 genes cause polycystic kidney disease.
- Mutations in either the PKD1 or PKD2 gene can cause autosomal dominant polycystic kidney disease. These genes provide instructions for making proteins whose functions are not fully understood. Researchers believe that they are involved in transmitting chemical signals from outside the cell to the cell's nucleus. The two proteins work together to promote normal kidney development, organization, and function. Mutations in the PKD1 or PKD2 gene lead to the formation of thousands of cysts, which disrupt the normal functions of the kidneys and other organs.
- Genetic tests for Autosomal dominant and Autosomal recessive type of polycystic kidney disease are available

Genetic Home Reference: http://ghr.nlm.nih.gov. Accessed July 14, 2011.

Patch C, Charlton J, Roderick PJ, et al: Use of antihypertensive medications and mortality of patients with autosomal dominant polycystic kidney disease: A population-based study. Am J Kidney Dis 57(6):856–862, 2011

Causes

The causes of CKD are numerous (Box 31-6). By far, the two most common causes are diabetes mellitus and hypertension, which account for more than 54% and 33% of incident cases of ESRD, respectively.[27] Other causes include glomerulonephritis (both primary and secondary to systemic diseases), interstitial nephritis, congenital malformations, genetic disorders, neoplasms, hepatorenal syndrome, obstructive uropathy, and microangiopathic etiologies, such as scleroderma and atheroembolic disease.

Pathophysiology

Although many diseases can cause CKD, there appear to be common pathophysiologic pathways for disease progression.

Table 31-3 Stages and Prevalence of Chronic Kidney Disease in the U.S. Adult Population

Stage	Description	GFR (mL/min/1.73 m²)	Prevalence in U.S. Adult Population
1	Kidney damage with normal or increased GFR	90 or more	5.7
2	Kidney damage with mild or decreased GFR	60–89	5.4
3	Moderately decreased GFR	30–59	5.4
4	Severely decreased GFR	15–29	0.3
5	Kidney failure	<15 or dialysis	0.1

GFR, glomerular filtration rate.

Modified from Jacobs C, Opolinsky D. The Little Handbook of Dialysis. Boston, MA: Jones & Bartlett, 2010.

The outstanding common morphologic features seen in CKD include fibrosis, loss of native renal cells, and infiltration by monocytes and macrophages. The mediators of the process are many and include abnormal glomerular hemodynamics, hypoxia, proteinuria, and vasoactive substances, such as angiotensin II.[34,35]

In discussing glomerular hemodynamics, it is important to understand intact nephron theory. Because each of the more than 1 million nephrons in each kidney is an independent functioning unit, as renal disease progresses, nephrons can lose function at different times. When an individual nephron becomes diseased, nephrons in close proximity increase their individual filtration rates by increasing the rate of blood flow and hydrostatic pressure in their glomerular capillaries. This hyperfiltration response in the nondiseased nephrons enables the kidneys to maintain excretory and homeostatic functions, even when up to 70% of the nephrons are damaged. However, eventually, the intact nephrons reach a point of maximal filtration, and any additional loss of glomerular mass is accompanied by an incremental loss in GFR and subsequent accumulation of filterable toxins.

Although hyperfiltration is an adaptive measure to nephron loss, over time it actually can accelerate the loss of nephrons because the hyperfiltration causes endothelial injury, stimulation of profibrotic cytokines, infiltration by monocytes and macrophages, and detachment of glomerular epithelial cells. In addition, hypertrophy of the nondiseased nephrons caused by hyperfiltration leads to increased wall stress and even more injury.[14] This is why many interventions to slow down the progression of renal failure involve measures that reduce glomerular hydrostatic pressure. One such example is the use of ACE inhibitors and ARBs, which prevent angiotensin II–mediated efferent arteriolar vasoconstriction and subsequent nephron hyperfiltration.

Other possible mediators of CKD progression are hypoxia and angiotensin II. In CKD, the loss of peritubular capillaries by various causes results in reduced capillary perfusion of the tubules. The resultant hypoxia favors the release of proinflammatory and profibrotic cytokines, leading to fibrosis and cell injury. Angiotensin II stimulates growth factors and cytokines that contribute to fibrosis aside from its hemodynamic effects on the glomerulus.[11,34,35]

Proteinuria, the result of glomerular hypertension and abnormal glomerular permeability, also contributes to CKD progression. Abnormally filtered protein is reabsorbed by proximal tubular cells through endocytosis and accumulates in the cells, causing the production of cytokines. These proinflammatory factors ultimately cause fibrosis and scarring of the tubulointerstitium.[34,35] Proteinuria is a very strong predictor of CKD progression, consistent with its role in the pathophysiology of CKD.

BOX 31-6 Causes of Chronic Kidney Disease

- Diabetes mellitus
- Hypertension
- Glomerulonephritis
  - Primary (immunoglobulin A nephropathy, postinfectious glomerulonephritis)
  - Secondary (HIV nephropathy, lupus, cryoglobulinemia, Wegener's granulomatosis, Goodpasture's syndrome, polyarteritis nodosa, amyloidosis)
- Interstitial nephritis (allergic interstitial nephritis, pyelonephritis)
- Microangiopathic vascular disease (atheroembolic disease, scleroderma)
- Congenital disease
- Genetic disease (polycystic kidney disease, medullary cystic kidney disease)
- Obstructive uropathy
- Neoplasms or tumors
- Transplant rejection
- Hepatorenal syndrome

Diabetic Nephropathy

Because of the extremely high prevalence of diabetes and hypertension as causes of CKD, an understanding of the renal pathophysiology specific to these entities and knowledge of interventions designed to slow down or even prevent progression to stage 5 CKD is imperative. Diabetic nephropathy is a major complication of diabetes, with an incidence of approximately 20% to 40%.[36]

In diabetes, the microvasculature in the organ systems of the body, including the kidneys, is damaged. In the kidneys, primarily the afferent and efferent arterioles and the glomerular capillaries are affected. Glomerular changes include thickening of the basement membrane, mesangial expansion from overproduction and underdegradation of extracellular matrix proteins, and diffuse glomerulosclerosis. Late in diabetic nephropathy, tubular atrophy and interstitial fibrosis also occur. The exact physiological

mechanism for these structural alterations is unclear, but hyperglycemia is a major contributor. In the classic Diabetes Control and Complications Trial (DCCT)—a prospective, randomized, multicenter trial performed to assess the effectiveness of tight blood glucose control on the complications of type 1 diabetes—researchers found that strict blood glucose control delayed and possibly even prevented the progression of diabetic nephropathy.[37] More recently, the follow-up study to the DCCT, called the Epidemiology of Diabetes Interventions and Complications (EDIC) study, revealed that the benefits of tight control persist for a number of years.[38] In addition, the classic United Kingdom Prospective Diabetes Study (UKPDS) reached conclusions in people with type II diabetes that were similar to those of the DCCT.[39]

At the onset of diabetic nephropathy, patients may have an increased GFR (as high as 140 mL/min) because of hyperfiltration, slightly enlarged kidneys, and microalbuminuria (30 to 300 mg/d of albumin in the urine). Over the course of approximately 10 to 15 years, hypertension and protein leakage increase. Eventually, protein leakage is massive, with consequent hypoalbuminemia and edema as well as mild azotemia. At this point, kidney damage is extensive, often requiring dialysis therapy within a few years.

Hypertensive Nephrosclerosis

The effect of systemic hypertension on the kidneys results in a condition known as nephrosclerosis. Hypertensive nephrosclerosis involves the development of sclerotic lesions in the renal arterioles and glomerular capillaries that cause them to become thickened, narrowed, and eventually necrotic. Hypertensive nephrosclerosis can be benign or malignant. In benign nephrosclerosis, associated with chronic mild or moderate hypertension, renal impairment occurs over many years. Malignant nephrosclerosis, associated with malignant hypertension, can lead to permanent renal failure rapidly if BP is not immediately reduced. Often, symptoms such as blurred vision and a severe headache accompany this crisis situation.

Because hypertensive nephrosclerosis is directly caused by hypertension, its incidence is greater in populations with a higher incidence of primary hypertension (eg, elderly people, African Americans). Among African Americans, the risk for hypertension-induced ESRD is nearly two times that of Caucasians.[40] The signs of hypertensive nephrosclerosis vary depending on the severity of the renal damage and the acuteness of the hypertension. Some signs that may be present include proteinuria, azotemia, and hematuria with red blood cell casts. Unfortunately, like those with hypertension, patients often remain asymptomatic until extensive damage has occurred. To prevent or delay the progression of hypertensive nephropathy, BP control is essential, and often multiple different antihypertensive medications are required. This is an area in which patient education can have a great impact in decreasing the incidence of ESRD. Educating patients about the complications of uncontrolled hypertension is particularly important and may foster the patient's active involvement in controlling his or her BP.

Preventing the Progression of Chronic Kidney Disease

An important characteristic of chronic kidney disease (CKD) is continuous progression. Slowing the rate of progression after CKD is diagnosed is a focus of extensive and ongoing research. Regardless of the primary cause of CKD, specific identifiable secondary insults to the kidney can rapidly accelerate the loss of nephrons. Such secondary insults include an alteration in renal perfusion, as observed in congestive heart failure or intravascular volume depletion; the administration of nephrotoxic agents; urinary obstruction; and urinary infections. Consequently, monitoring for and avoiding these insults or aggressively treating them, if they occur, is paramount.

It is also important to educate patients and their families about the dangers of these insults. Patients and families should be instructed, for instance, about the signs and symptoms and the need for prompt treatment of urinary infections as well as common nephrotoxic drugs to avoid. Common over-the-counter and prescription analgesics, such as NSAIDs, can cause rapid deterioration in renal function and should be avoided in patients with CKD.

Strict control of blood glucose levels is critical to preventing and retarding the progression of renal failure in people with diabetes. The targets for key parameters of glucose control set by the American Diabetes Association for people with diabetes are a glycosylated hemoglobin of less than 7.0%, a preprandial plasma glucose of 70 to 130 mg/dL, and a peak postprandial plasma glucose of less than 180 mg/dL.[36]

BP control is also essential for preventing the progression of renal failure from almost any primary etiology, not just hypertension or diabetes. According to the K/DOQI Clinical Practice Guidelines on Blood Pressure Management and Use of Antihypertensive Agents in Chronic Kidney Disease (2004), the target of therapy is a BP of less than 130/80 mm Hg.[41] Control of hypertension entails lifestyle changes (eg, exercise, salt restriction, smoking cessation, and avoidance of excessive alcohol) as well as pharmacological therapy if necessary. Regarding pharmacological therapy, ACE inhibitors and ARBs have been shown to offer a selective advantage in slowing the progression of diabetic and other proteinuric syndromes. Both drugs have been proved to lower BP, reduce proteinuria, and slow the progression of kidney disease,[29–31] presumably because of their ability to decrease intraglomerular pressure by blocking the effect of angiotensin II on the afferent and efferent arterioles.

A protein-restricted diet as a means to slow the progression of renal failure is controversial, but the evidence appears to support the view that moderate protein restriction of 0.8 g/kg/d in patients may help.[30,31] However, caution with protein restriction, especially in critically ill patients who are in a catabolic state, is important to prevent malnutrition. Malnutrition itself is a major determinant of morbidity and mortality in patients with renal failure.[14,32] Ways to avoid malnutrition include providing protein with high biological value, ensuring that adequate caloric requirements are met, and closely monitoring nutritional assessment parameters (ie, body weight, serum albumin and prealbumin levels, and

total protein levels). Because of the complexity of nutritional requirements in critically ill patients, collaboration with a dietitian is essential.

Finally, controlling serum lipid levels may slow the progression of renal failure. Hyperlipidemia is commonly seen in patients with CKD, particularly those with diabetes and nephrotic syndrome, and is hypothesized to contribute to renal failure.[42] In addition, numerous secondary analyses of data from lipid trials suggest that high lipid levels are associated with a faster rate of progression and that statins slow this rate.[30] The mechanisms by which dyslipidemias may contribute to renal failure are unclear, but the formation of oxygen free radicals, the expression of growth factors and cytokines, the proliferation of mesangial cells, and the inhibition of nitric oxide have been postulated. Besides their lipid-lowering effect, statins have pleiotrophic effects that may directly oppose these mechanisms.[43] Because the use of lipid-lowering statins have favorable side effect profiles in patients with CKD, their use may be prudent, especially because lowering lipid levels decreases the risk for cardiovascular events (the primary cause of mortality in patients with ESRD).

▲ Management of Renal Failure

Although some distinct differences exist between the ways AKI and CKD are managed, many of the clinical manifestations and complications encountered are the same. Thus, the general management of renal failure is addressed here, noting any differences between AKI and CKD as necessary. In either type of renal failure, management begins with treating the primary insult. Common nursing diagnoses for patients with AKI are given in Box 31-7. An overview of the management of patients with AKI is provided in the accompanying Collaborative Care Guide (Box 31-8).

BOX 31–7 *Examples of Nursing Diagnoses*

For the Patient with Acute Kidney Injury

- Excess Fluid Volume related to decreased kidney function
- Decreased Cardiac Output related to fluid volume excess, disturbances in renin–angiotensin system
- Imbalanced Nutrition: Less Than Body Requirements related to anorexia, nausea and vomiting, dietary restrictions, and altered oral mucous membranes
- Risk for Skin Integrity related to poor nutritional status, immobility, and edema
- Anxiety related to unexpected serious illness and uncertain prognosis, unfamiliar environment, and current symptoms
- Activity Intolerance related to shortness of breath, fatigue, anemia, uremia, and dialysis procedure
- Disturbed Sleep Pattern related to fragmented sleep in hospital environment
- Risk for Infection related to decreased functioning of immune system
- Deficient Knowledge related to pathophysiology and etiology of acute episode, dietary restrictions, medications, complications, prognosis, and follow-up care

Managing Fluid Balance Alterations

Clinical management of fluid balance is of primary importance in patients with renal failure and is the area in which differences in the management of AKI and CKD are perhaps most dramatic.

Fluid Balance Changes in Acute Kidney Injury

In prerenal AKI and the early stages of ischemic ATN, the cause of the renal failure is inadequate renal perfusion, often from intravascular volume deficits. After using laboratory, physical assessment, and hemodynamic clues to make a rapid diagnosis of intravascular volume depletion, therapy involves prompt administration of replacement fluids, such as blood and crystalloids. The replacement solutions used should reflect the type of losses (eg, for a patient with a hemorrhagic condition, blood would be the replacement fluid of choice). Often in AKI, even if signs and symptoms of intravascular volume deficits are not present, large boluses of IV fluids are given. Reversal of AKI after such a bolus is therapeutic as well as diagnostic of prerenal AKI.

Fluid administration in AKI is also indicated in the diuretic phase of ATN, when extensive diuresis may occur, and for the prevention or alleviation of tubular obstruction seen in obstructive causes of AKI, including ATN and many postrenal etiologies. However, in any oliguric state, caution must be taken to prevent fluid overload. In a sustained oliguric state, such as the oliguric stage of ATN, fluid is restricted to the previous day's urine output amount plus 500 to 800 mL to account for insensible losses.

Diuretics are often used in AKI to increase urinary flow and thereby help alleviate conditions of fluid overload or to prevent tubular obstruction. Furosemide, a loop diuretic, and mannitol, an osmotic diuretic, are often used with hydration to prevent tubular obstruction in certain obstructive causes of AKI, such as acute urate nephropathy, and in heme pigment nephropathy, such as rhabdomyolysis. In states of fluid overload, such as pulmonary edema and heart failure, diuretics are also useful. Often in these situations, furosemide is administered every 6 hours, with the initial dose ranging between 20 and 100 mg depending on whether the patient has taken furosemide regularly. If within an hour the response is inadequate, the dose may then be doubled. This process may be repeated until adequate urine output is achieved. Sometimes even a continuous furosemide drip is required. In addition, a thiazide diuretic, such as chlorothiazide, may be administered with furosemide because of the synergistic action of these diuretics in promoting urinary excretion.

With the use of diuretics, caution must be taken to avoid complications of dehydration, electrolyte imbalances, and side effects. Tinnitus and hearing impairment (reversible and irreversible) have been reported after IV furosemide administration. Ototoxicity is associated with rapid injection, excessively high doses, or concomitant therapy with other ototoxic drugs. The manufacturer recommends controlled IV infusion (not to exceed 4 mg/min) for high-dose parenteral furosemide therapy.

The use of diuretics to convert oliguria to nonoliguria, unlike the aforementioned uses of diuretics, has not been substantiated in medical research and may even be harmful. Additionally, research has not shown that the use of loop diuretics in AKI

BOX 31-8 *COLLABORATIVE CARE GUIDE for the Patient With Acute Kidney Injury*

Outcomes	Interventions
Coordination of Care	
All appropriate team members and disciplines will be involved in the plan of care.	• Develop the plan of care with the patient, family, primary physician, nephrologist, pulmonologist, cardiologist, registered nurse, advanced practice nurse, social worker, respiratory therapist, physical therapist, occupational therapist, dietitian, chaplain, and dialysis staff.
Oxygenation/Ventilation	

Patient will have adequate gas exchange as evidenced by:
• ABGs within normal limits
• Functional oxygen saturation (SpO_2) >92%
• Clear breath sounds
• Normal respiratory rate and depth
• Normal chest x-ray
	• Monitor ABGs and continuous pulse oximetry.
	• Monitor acid–base status.
	• Monitor for signs and symptoms of pulmonary distress from fluid overload.
	• Provide routine pulmonary toilet, including the following:
	  • Airway suctioning
	  • Chest percussion
	  • Incentive spirometer
	  • Frequent turning
	• Mobilize out of bed to chair.
	• Support patient with oxygen therapy, mechanical ventilation, or both as indicated. Involve respiratory therapist.

Circulation/Perfusion	
Patient's BP, heart rate, and hemodynamic parameters will be within normal limits. Patient will have adequate tissue perfusion as evidenced by: • Adequate hemoglobin levels • Euvolemic status • Optimal urine output depending on phase of AKI • Appropriate level of consciousness	• Monitor vital signs every 1–2 h. • Monitor PAOP, right atrial pressure, cardiac output, systemic vascular resistance, and peripheral vascular resistance every 4 h or as ordered if pulmonary artery catheter is in place. • Assess vital signs continuously or every 15 min during dialysis. • Monitor hemoglobin and hematocrit levels daily. • Assess evidence of tissue perfusion (pain, pulses, color, temperature, and signs of decreased organ perfusion such as an altered level of consciousness, ileus, and decreasing urine output). • Administer intravascular crystalloids or blood products as indicated.
Fluids/Electrolytes	
Patient will be euvolemic. Patient will achieve normal electrolyte balance. Patient will achieve optimal renal function.	• Monitor fluid status, including input and output (fluid restriction), daily weight, urine output trends, vital signs, CVP, and PAOP. • Monitor for signs and symptoms of hypervolemia (hypertension, pulmonary edema, peripheral edema, jugular venous distention, and increased CVP). • Monitor serum electrolytes daily. • Monitor renal parameters, including urine output, BUN, serum creatinine, acid–base status, urine electrolytes, urine osmolality, and urine specific gravity. • Administer fluids and diuretics to maintain intravascular volume and renal function, per order. • Replace electrolytes as ordered. • Treat patient with, and monitor response to, dialysis therapies if indicated. • Monitor and maintain dialysis access for chosen intermittent or continuous dialysis method: *Continuous Veno–Veno Dialysis* • Monitor and regulate ultrafiltration rate hourly based on patient's response and fluid status. • Provide fluid replacements as ordered. • Assess and troubleshoot hemofilter and blood tubing hourly. • Protect vascular access from dislodgment. • Change filter and tubing per protocol. • Monitor vascular access for infection.

(*continued on page 678*)

BOX 31–8 *COLLABORATIVE CARE GUIDE for the Patient With Acute Kidney Injury (continued)*

Outcomes	Interventions
Fluids/Electrolytes	
	Peritoneal Dialysis • Slowly infuse warmed dialysate. • Drain after appropriate dwell time. • Assess drainage for volume and appearance. • Send cultures daily or as ordered. • Assess access site for infection. *Intermittent Hemodialysis* • Assess shunt for thrill and buzzing sound (bruit) every 12 h. • Avoid constrictions (ie, BPs), phlebotomy, and IV fluid administration in arm with shunt. • Assess for infection. • Monitor perfusion of related extremity.
Mobility	
Patient will remain free of complications related to bed rest and immobility.	• Initiate deep venous thrombosis prophylaxis. • Reposition frequently. • Mobilize to chair when possible. • Consult physical therapist. • Conduct range-of-motion and strengthening exercises.
Protection/Safety	
Patient will be protected from possible harm.	• Assess need for wrist restraints if patient is intubated, has a decreased level of consciousness, is unable to follow commands, or is acutely agitated, or for affected extremity during hemodialysis. Explain need for restraints to patient and family members. If restrained, assess response to restraints and check every 1–2 h for skin integrity and impairment in tissue perfusion. Follow hospital protocol for use of restraints. • Use siderails on bed and safety belts on chairs as appropriate. • Follow seizure precautions.
Skin Integrity	
Patient will have intact skin.	• Assess skin integrity and all bony prominences every 4 h. • Turn every 2 h. • Consider a pressure relief/reduction mattress. Use Braden Scale to assess risk for skin breakdown. • Use superfatted or lanolin-based soap for bathing and apply emollients for pruritus. • Treat pressure ulcers according to hospital protocol. Involve enterostomal nurse in care.
Nutrition	
Patient will be adequately nourished as evidenced by: • Stable weight not <10% below, or >20% above, ideal body weight • An albumin level of 3.5 to 4.0 g/dL • A total protein level of 6 to 8 g/dL • A total lymphocyte count of 1,000 to 3,000 × 10^6/L	• Consult dietitian to direct and coordinate nutritional support. • Observe sodium, potassium, protein, and fluid restriction as indicated. • Provide small, frequent feedings. • Provide parenteral or enteral feeding as ordered. • Monitor albumin, prealbumin, total protein, hematocrit, hemoglobin, and white blood cell counts, and monitor daily weights to assess effectiveness of nutritional therapy.
Comfort/Pain Control	
Patient will be as comfortable and as pain free as possible as evidenced by: • No complaints of discomfort • No objective indicators of discomfort	• Monitor for signs and symptoms of respiratory distress related to fluid overload and support oxygenation as needed. Keep head of bed elevated and teach breathing techniques to minimize oxygen distress, such as pursed-lip breathing. • Plan fluid restrictions over 24 h, allowing for periodic sips of water and ice chips to minimize thirst.

(*continued on page 679*)

BOX 31–8 COLLABORATIVE CARE GUIDE for the Patient With Acute Kidney Injury (continued)

Outcomes	Interventions
Comfort/Pain Control	
	• Provide frequent mouth and skin care. • Assess quantity and quality of discomfort. • Provide a quiet environment and frequent reassurance. • Observe for complications that may cause discomfort, such as infection of vascular access device, peritonitis or inadequate draining during peritoneal dialysis, and gastrointestinal disturbances (nausea, vomiting, diarrhea, constipation). • Administer analgesics, antiemetics, antidiarrheals, laxatives (non–magnesium and non–phosphate containing), stool softeners, antihistamines, sedatives, or anxiolytics as needed and monitor response.
Psychosocial	
Patient will demonstrate a decrease in anxiety as evidenced by: • Vital signs within normal limits • Level of consciousness within normal limits • Subjective reports of decreased anxiety levels • Objective assessment of decreased anxiety level	• Assess vital signs. • Explore patient and family concerns. • If the patient is intubated, develop interventions for effective communication. • Arrange for flexible visitation to meet needs of the patient and family. • Provide for adequate rest and sleep. • Provide frequent information and updates on condition and treatment, and explain equipment. Answer all questions. • Consult social services and clergy as appropriate. • Administer sedatives and antidepressants as appropriate and monitor response.
Teaching/Discharge Planning	
Patient and family members will understand procedures and tests needed for treatment during the acute phase and maintenance of a patient with chronic disease. Patient and family members understand the severity of the illness, ask appropriate questions, and anticipate potential complications. In preparation for discharge to home, the patient and family members will demonstrate an understanding of RRT, fluid and dietary restrictions, and the medication regimen.	• Prepare the patient and his or her family members for procedures, such as insertion of dialysis access, dialysis therapy, or laboratory studies. • Explain the causes and effects of renal failure and the potential for complications, such as hypertension and fluid overload. • Encourage family members to ask questions related to the pathophysiology of renal failure, dialysis, and dietary or fluid restrictions. • Make appropriate referrals and consults early during hospitalization. • Initiate family education regarding home care of the patient on dialysis, what to expect, maintenance of renal function, and when to seek medical attention.

reduces mortality, shortens the duration of renal failure, or helps avoid or reduce the requirements for RRT.[44,45] Hence, based on the literature, it is reasonable to use diuretics for a short time for volume control but not for therapy for established oliguric AKI.

Dopamine is another agent that has been traditionally used in AKI because of its ability to theoretically cause renal vasodilation at "renal doses" (1 to 3 mcg/kg/min), thereby increasing renal perfusion. However, the efficacy of this agent to affect the course of AKI has not been substantiated despite many clinical trials, and some studies have even shown deleterious effects.[45,46] Thus, based on current evidence, there is no current role for dopamine in preventing AKI.

If fluid complications arise and cannot be controlled by fluid restrictions and pharmacological agents, dialysis (discussed in detail in Chapter 30) or isolated ultrafiltration may be necessary. This is often the case in oliguric patients who are receiving large amounts of IV fluids hourly in the form of medications and nutritional supplements. People in whom AKI develops secondary to hypoperfusion or tubular injury may have a delayed recovery time, necessitating maintenance dialysis until the tissue repairs itself and normal function returns. For these patients, discharge planning should take into consideration the need for outpatient dialysis therapy (which may last for several weeks to months), the need to modify the person's diet and consumption of fluids, and the psychosocial implications of these measures for the patient and family members.

Fluid Balance Changes in Chronic Kidney Disease

In CKD, fluid and salt restriction is a mainstay of therapy to prevent fluid overload. Sodium is restricted to less than 2,400 mg/d, and fluid intake is limited to 500 mL plus the patient's previous day's 24-hour urine output. Diuretics are also used to manage volume overload. Patients usually are able to respond to diuretics until they reach stage 5 CKD, at which point extensive renal damage prevents an adequate

response. By the time CKD progresses to stage 5, oliguria is typically manifested, and signs and symptoms of fluid overload, such as edema, hypertension, pulmonary edema, heart failure, and jugular vein distention, occur unless dialysis therapy is instituted. In these patients, an ongoing assessment of fluid status, including obtaining accurate intake and output measurements with daily weights and monitoring for fluid complications, is imperative.

Managing Acid–Base Alterations

AKI and CKD typically result in metabolic acidosis because of the nephrons' inability to secrete and excrete hydrogen ions and reabsorb bicarbonate ions as renal failure progresses. In critically ill patients, this acid–base disturbance may be intensified because of concurrent conditions, such as lactic acidosis or diabetic ketoacidosis, and because such patients are in a high-catabolic state, which increases the release of intracellular acids into the circulation. Clinical manifestations of metabolic acidosis include headaches, nausea and vomiting, deep and rapid respirations (Kussmaul respirations), altered mental status, hyperkalemia, and tachycardia. In severe metabolic acidosis, bradycardia and hypotension may manifest because of myocardial depression and vasodilation. There is also a dramatic depression of the patient's level of consciousness, often resulting in stupor or coma.

In CKD, metabolic acidosis begins to manifest as the patient reaches stage 3 and the GFR falls below 60 mL/min/1.73 m^2. Although the metabolic acidosis associated with CKD is usually mild (CO_2, 16 to 22 mEq/L), it is associated with many adverse consequences, including fatigue, protein catabolism, and bone demineralization. The bones become demineralized because bone phosphate and carbonate are used as buffers against excess hydrogen ion.

Laboratory assessments of acid–base status using arterial blood gas (ABG) values and venous carbon dioxide content guide therapy. Patients with a plasma bicarbonate level less than 22 mEq/L warrant treatment. Therapy involves the administration of alkaline medications (eg, Bicitra, sodium bicarbonate tablets), dialysis, or both. When using citrate-containing medications, such as Bicitra, it is important that these medications not be given with aluminum-containing phosphate binders. Using these agents together would put the patient at risk for aluminum toxicity because citrate significantly increases aluminum absorption from the gastrointestinal tract.

The use of IV sodium bicarbonate is reserved for severe acidosis (evidenced by a blood pH < 7.2 or a plasma bicarbonate level <12 to 14 mEq/L) because of potential complications of extracellular volume excess, metabolic alkalosis, and hypokalemia. Intractable acidosis is an indication for dialysis, which removes excess hydrogen ions and adds a buffer to the body. In hemodialysis, the buffer is bicarbonate, and in peritoneal dialysis, it is lactate, which is metabolized to bicarbonate. When correcting metabolic acidosis, caution is advised. Rapid correction may result in a suppressed respiratory drive and hypoventilation. Rapid correction can also lead to acute hypocalcemia and tetany because the amount of ionized calcium decreases in an alkalotic state owing to increased binding of calcium with albumin and inorganic substances such as phosphate. Throughout any kind of acid–base therapy, it is necessary to monitor serum bicarbonate, pH, and calcium and potassium levels closely.

Managing Cardiovascular Alterations

Alterations in the cardiovascular system can cause or accelerate AKI and CKD. In addition, cardiovascular complications can arise as a result of renal failure itself. Common cardiovascular complications in AKI and CKD include hypertension and hyperkalemia. Pericarditis, another cardiovascular complication of renal disease, is primarily seen with CKD.

Hypertension

Hypertension as a complication of renal failure results from excess retention of water and sodium, overactivation of the sympathetic nervous system, and stimulation of the renin–angiotensin–aldosterone system. Because controlling BP is essential to prevent end-organ damage and reduce the risk for life-threatening cardiovascular events, adequate treatment is essential. Management may include fluid and sodium restrictions, diuretic administration, antihypertensive therapy, and dialysis to remove excess fluid. Extensive patient teaching regarding nonpharmacological and pharmacological treatment and the potential complications of uncontrolled hypertension is an integral part of management.

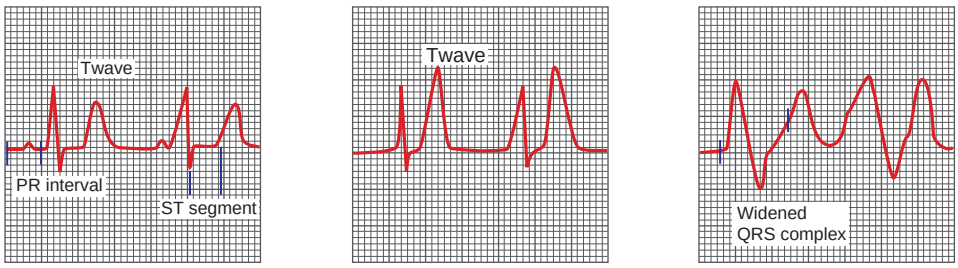
Hyperkalemia

Hyperkalemia is a life-threatening condition seen in patients with AKI and CKD. As the GFR decreases, the ability of the kidneys to excrete excess potassium diminishes. In critically ill patients, this renal impairment is frequently compounded by states of increased catabolism, acidosis, cellular injury, administration of potassium-based medications, and blood transfusions, all of which can raise serum potassium levels. If not recognized and treated, hyperkalemia leads to fatal dysrhythmias.

Assessment of hyperkalemia involves close monitoring of serum potassium levels as well as monitoring the effects of potassium on the electrical conduction system of the heart. Characteristically, electrocardiogram (ECG) changes occur as potassium levels rise (Fig. 31-4). The first ECG changes that occur, usually when serum potassium is in the range of 6 to 7 mEq/L, are the appearance of tall, tented T waves and a prolonged PR interval. Next, there is a loss of the P wave and a slight widening of the QRS complex. At this point, the serum potassium is usually in the range of 8 to 9 mEq/L. From here, the QRS complex continues to widen until a sine wave (wavy line) pattern develops. This ominous sign is closely followed by ventricular fibrillation or standstill.

When evaluating hyperkalemia, note that patients with long-standing elevations in serum potassium are more refractory to its effects on the heart than patients in whom hyperkalemia develops suddenly. Thus, potassium and ECG changes must be evaluated together to determine the acuteness of the situation. Other effects of hyperkalemia that are monitored include paresthesias, hyporeflexia, and muscle weakness (which typically begins in the lower extremities and ascends to the trunk and upper extremities).

Mild hyperkalemia (a serum potassium level <6 mEq/L without ECG changes) may be treated with dietary



A. Peaked T waves, prolonged PR interval, depressed ST segment

B. Lost P wave

C. Widened QRS complex

FIGURE 31-4 ▲ Typical ECG findings indicative of various degrees of hyperkalemia. **A:** When the serum potassium (K^+) level is about 6 to 7 mEq/L, the T waves become peaked, the PR interval is prolonged, and the ST segment is depressed. **B:** At about 8 to 9 mEq/L, the P wave is lost. **C:** At about 10 to 11 mEq/L, the QRS complex widens.

potassium restriction, diuretics, and potassium-binding resins (eg, sodium polystyrene sulfate). Sodium polystyrene is given orally or as an enema. The oral dose of 15 to 30 g in 60 to 120 mL of a 20% sorbitol solution (to prevent constipation) may be repeated every 4 to 6 hours as needed. The rectal dose of 50 g in 50 mL of 70% sorbitol and 150 mL tap water should be retained in the colon for at least 30 to 60 minutes. This drug must be used with caution in critically ill patients with decreased colonic motility, such as postsurgical patients and patients taking large amounts of opiates, because of its association with colonic necrosis in this population. To reduce this risk, a cleansing enema may be given after rectal administration.[14] Sodium polystyrene should never be used in a patient with a gastrointestinal obstruction, and bowel sounds should always be assessed before its administration.

Treatment of life-threatening hyperkalemia entails taking steps to antagonize the effects of potassium on the heart, promote intracellular shifting of potassium, and remove potassium from the body. Antagonizing the effects of potassium on the heart is achieved with IV calcium gluconate or chloride and is the first priority for patients with substantial ECG changes. Intracellular shifting of potassium is done next to bridge the gap until potassium removal from the body can be executed. Means to shift potassium into the cell include IV insulin and dextrose administration and IV bicarbonate administration. β_2-Adrenergic therapy can also effect transcellular potassium shifting but is less commonly used because of the requirement for 10 to 20 times the dose used for reactive airway disease. Removal of potassium from the body entails, as previously mentioned, diuretic administration and the use of potassium exchange resins. If these measures do not control hyperkalemia, dialysis must be initiated. Obviously, in a patient who has stage 5 CKD, and who is likely already receiving dialysis therapy, dialysis is initiated immediately along with other emergent therapy in life-threatening hyperkalemia.

Pericarditis

Pericarditis resulting from uremia (uremic pericarditis) is a complication that can be seen primarily in stage 5 CKD. This type of pericarditis is characterized by an inflammation of the pericardial membrane, which causes the pericardial capillaries to become permeable to fluid, red blood cells, fibrinogen, and albumin. In most cases, the inflammation is aseptic, although it may also result from bacterial or viral infections. The consequent serous or serosanguineous fluid in the pericardial cavity (pericardial effusion) can increase the intrapericardial pressure and compromise ventricular contractility, stroke volume, and cardiac output. Pericardial tamponade, which results when the accumulation of pericardial fluid is so large that adequate cardiac output cannot be maintained, is a life-threatening emergency. The exact etiology of uremic pericarditis is unknown, but it is associated with prolonged inadequate dialysis therapy, uremic toxins, infectious agents, treatment with the antihypertensive agent minoxidil, and heparin administration.

Chest pain, fever, and a pericardial friction rub are the classic triad of findings associated with pericarditis. The chest pain is characteristically sharp and steady and is relieved by sitting forward and intensified by breathing deeply. The pericardial friction rub (a harsh, leathery sound heard over the precordium) may precede the pain, may persist after the pain has subsided, and may disappear when the volume of effusion increases.[14] In addition to these findings, there are typical ECG changes in pericarditis. The most notable are new-onset atrial dysrhythmias and widespread ST elevations with an upward concavity (versus the upward convexity typical in an acute myocardial infarction). In a large pericardial effusion, signs and symptoms are more dramatic and include dyspnea, tachycardia, mental confusion, weakness, increased jugular vein distention, peripheral edema, and a paradoxical pulse greater than 10 mm Hg during inspiration. Tamponade results in distended neck veins, tachypnea, a narrowed pulse pressure, an increased PAOP, muffled heart sounds, diminished peripheral pulses, and a decreased level of consciousness.

Therapy for uremic pericarditis includes aggressive dialysis therapy, usually daily, until symptoms disappear. Also, because anticoagulation during dialysis may precipitate or enhance bleeding into the pericardial space, low-dose, regional, or no heparin may be prescribed. Systemic steroids and NSAIDs, such as indomethacin, may also be used but have variable results. Cardiac tamponade is an emergency that requires urgent pericardiocentesis to relieve the pressure on the heart. For the patient in whom recurrent pericarditis develops or the pericardium becomes constrictive, surgical creation of a pericardial window or pericardiectomy may be necessary.

Cardiovascular Disease in Chronic Kidney Disease

CKD is associated with high cardiovascular morbidity and mortality. In fact, patients with CKD are much more likely to suffer from cardiac disease resulting in cardiovascular death than to eventually require RRT.[47] The predominant cardiac disorders in

CKD are left ventricular hypertrophy (found in 74% of patients on dialysis), coronary artery disease, dysrhythmias, cardiomyopathy, congestive heart failure, and valvular dysfunction.

Because most of these cardiovascular disorders develop over a period of at least a few years, they usually present early in CKD and continue to progress as renal function declines. This association between CKD and cardiovascular disease may occur for the following reasons: (1) cardiovascular disease causes renal dysfunction (ie, heart failure), (2) CKD causes an increased risk for cardiovascular disease, or (3) other factors (eg, hypertension, diabetes mellitus, anemia, or hyperlipidemia) cause or accelerate both renal dysfunction and cardiovascular disease. In any case, monitoring for cardiovascular disease, reducing modifiable risk factors, and treating specific cardiovascular conditions when present are essential to decrease mortality in patients with CKD.

Diagnostic tests useful in assessing for cardiovascular disease in these high-risk patients include routine ECGs, echocardiography, and cardiac stress testing. Pharmacological rather than exercise stress testing is the stress test of choice because patients with CKD are often unable to attain the level of exercise needed to make exercise stress tests useful. More invasive tests for symptomatic patients include a thallium scan and coronary angiography.

Modifiable risk factors that can contribute to cardiovascular disease and that should be addressed as part of managing patients with CKD include hypertension, hyperlipidemia, hypervolemia, anemia, smoking, hyperglycemia, calcium and phosphate imbalances, vitamin D deficiency, hyperhomocysteinemia, and metabolic acidosis.[47,48] Regarding BP control, the Joint National Committee for the Prevention, Detection, Evaluation and Treatment of High Blood Pressure (JNC7) and the K/DOQI Clinical Practice Guidelines recommend strict BP control with a goal of less than 130/80 mm Hg in all patients with CKD.[49,50] Similarly, the K/DOQI Clinical Practice Guidelines recommend that all patients with CKD be included in the highest risk group, justifying strict lipid control with a target low-density lipoprotein cholesterol level of less than 100 mg/dL.[51] As with the general population, disease-specific treatment (eg, antiplatelet therapy and β-blocker administration for coronary artery disease) must be instituted as appropriate.

Managing Pulmonary Alterations

A frequent complication in patients with oliguric AKI or stage 5 CKD is the development of pulmonary edema. This complication results from fluid overload, heart failure, or both. Clinical manifestations include dyspnea; crackles on auscultation; the production of pink, frothy sputum; tachypnea; tachycardia; decreased arterial oxygen saturation (SaO_2); and evidence of fluid overload on chest radiograph. Management involves fluid and sodium restriction, treating underlying cardiac disease, and possibly diuretic medications if the patient's kidneys can respond to them. Frequently, pulmonary edema becomes life threatening, necessitating intubation, emergent dialysis, or both to improve arterial oxygenation and restore fluid balance.

Other pulmonary complications in renal failure include pleural effusions, pleuritic inflammation and pain, uremic pneumonitis, and pulmonary infections. Pleuritic inflammation and uremic pneumonitis occur more frequently with stage 5 CKD and are due to the effect of uremic toxins on the lungs and inadequate dialysis. Pulmonary infections, on the other hand, are common in both AKI and CKD, especially in critically ill patients. Factors associated with renal failure that contribute to pulmonary infections include decreased pulmonary macrophage activity, a generalized immunocompromised state, tenacious sputum, and a depressed cough reflex. Collaborative management includes culturing sputum, administering broad-spectrum antibiotics until organism-specific sensitivities are available, and teaching and encouraging pulmonary hygiene measures (ie, coughing and deep breathing).

Managing Gastrointestinal Alterations

A potentially life-threatening gastrointestinal complication in both AKI and CKD is gastrointestinal bleeding. Proposed etiologies for gastrointestinal bleeding as it relates to renal failure include platelet and blood-clotting abnormalities; anticoagulation with dialysis, access patency, or both; ingestion of irritating drugs (eg, NSAIDs, aspirin); and increased ammonia production in the gastrointestinal tract from urea breakdown. Ammonia is known to be irritating to mucosal surfaces. Physiological stress, especially in critically ill patients, is another proposed contributor. Assessment parameters include examining all vomit and stool for gross and occult blood; monitoring iron, hemoglobin, hematocrit, and red blood cell indices; and paying close attention to signs of intravascular volume depletion. If gastrointestinal bleeding is suspected, radiographic and endoscopic examinations are often required to diagnose and treat specific lesions. Management depends on the specific lesion but often includes volume restoration with crystalloids and blood products as well as administration of histamine-2 receptor (H_2) blockers, proton pump inhibitors (PPIs), or both.

Other gastrointestinal complications associated with renal failure occur primarily in CKD and include anorexia, nausea, vomiting, diarrhea, constipation, gastroesophageal reflux disease (GERD), and oral cavity alterations, such as stomatitis, a metallic taste in the mouth, and uremic fetor (the smell of urine and ammonia on the breath). Oral alterations and symptoms of anorexia, nausea, and vomiting are partially attributable to high levels of uremic toxins, which affect the intestinal mucosa and stimulate vomiting centers in the brain. The reason GERD is common is unclear but may be due to alterations in the hormones that affect lower esophageal sphincter tone and a higher occurrence of hiatal hernias in patients with CKD.[14] Collaborative management involves initiating (or providing) adequate dialysis, providing prophylactic antacids and H_2 blockers or PPIs, and administering antiemetics. Good oral hygiene is also essential.

The complication of constipation is seen frequently in patients with renal failure owing to decreased bulk and fluid in the diet and the administration of oral iron supplements and calcium-based phosphate binders. Diarrhea may also occur as a result of intestinal irritation from uremia. Collaborative management includes increasing dietary bulk; administering bulk-forming laxatives, stool softeners, or both; administering antidiarrheal agents; or a combination of these therapies. For patients with stage 5 CKD, magnesium-containing medications, including cathartics, such as magnesium citrate, should be avoided because of the risk for hypermagnesemia

in these patients. In addition, Fleet enemas, which contain large amounts of phosphate that could be absorbed systemically, should not be used.

Managing Neuromuscular Alterations

Neuromuscular alterations include sleep disturbances, cognitive process disturbances, lethargy, muscle irritability, and peripheral neuropathies, including restless leg syndrome and burning feet syndrome. Restless leg syndrome is characterized by a discomfort in the legs, especially at night, which is sometimes relieved by continuous movement of the extremities. Burning feet syndrome consists of paresthesias and numbness in the soles of the feet and lower parts of the legs. These neuromuscular complications are associated primarily with stage 4 and 5 CKD and are thought to be the result of electrolyte imbalances, metabolic acidosis, and the effect of uremic toxins on motor and sensory nerves. Cognitive process disturbances, such as difficulty concentrating and impaired short-term memory, are linked to elevations of BUN in the cerebral vasculature, which can result in cerebral edema. Extensive cerebral edema can result in seizures, projectile vomiting, and even coma or death.

Frequent assessments for cognitive disturbances, seizure activity, and other neuromuscular alterations are important. In addition to thorough neuromuscular examinations, nerve conduction studies and diagnostic tests, including electroencephalograms and head CT scans, may be used. Collaborative management involves implementing emergency treatment, as in the case of sustained seizure activity; maintaining electrolyte balance; correcting metabolic acidosis; using regular dialysis; and providing extensive patient teaching. Specific points that need to be included during patient teaching are the importance of preventing injury to the extremities by heat or trauma when paresthesias are present and that alterations in neuromuscular function often improve with regular dialysis or transplantation. However, if components of the patient's neuropathies are due to other comorbid conditions, such as diabetes, the problem may respond only minimally to dialysis or renal transplantation.

Cognitive alterations encountered are important to remember during any patient teaching. Because of difficulties in concentrating and impairments in short-term memory, teaching should be provided in short, frequent sessions with reinforcement of material and should include the family as much as possible. These points are especially true for critically ill patients who are, by definition, in a crisis situation.

Managing Hematological Alterations

Hematological system alterations are major complications in AKI and CKD. These alterations include an increased bleeding tendency, an impaired immune system, and anemia.

Increased Bleeding Tendency

The increased bleeding tendency in renal failure is attributable to impaired platelet aggregation and adhesion and an altered platelet response to clotting factor VII (von Willebrand's factor). These alterations are thought to be due to uremia, but their exact pathophysiological mechanisms are unknown. Assessment involves the monitoring of platelet counts and bleeding times, coagulation studies, and assessing for bleeding, especially gastrointestinal bleeding. Collaborative management includes administering blood products as needed, protecting the patient from injury, and avoiding medications that alter platelet function, such as NSAIDs and aspirin. Often heparin (for dialysis) and aspirin (for myocardial infarction prevention) are indicated in patients with renal failure. In such cases, the effects of these medications on platelets must be closely monitored. One potential and serious complication of heparin is heparin-induced thrombocytopenia; the development of this complication mandates discontinuation of the drug.

Impairments in the Immune System

Patients with renal failure are in an immunocompromised state, which sets the stage for infections (a major cause of mortality in AKI and CKD). The impairments in the immune system are thought to be due to malnutrition and the effects of uremia on white blood cells. These effects include, among others, depressed T-cell- and antibody-mediated immunity, impaired phagocytosis and decreased chemotaxis and adherence of white blood cells.[14]

Assessing the patient for infection and monitoring laboratory indicators of infection must be done continuously. Regarding temperature as a gauge of infection, the baseline body temperature in uremic patients is decreased, and thus any increase in temperature above baseline is significant. Collaborative management includes frequent hand washing, removing invasive catheters as soon as possible (or avoiding their use altogether), and culturing blood and other body fluids that may be infected to identify specific organisms and determine appropriate antimicrobial therapy.

Anemia

Anemia associated with renal failure is attributable to three main mechanisms: erythropoietin deficiency, decreased red blood cell survival time, and blood loss from an increased bleeding tendency. Of these three mechanisms, erythropoietin deficiency has the most dramatic effect.

More than 90% of the hormone erythropoietin is produced in the kidneys. It is a glycoprotein that stimulates red blood cell production in response to hypoxia and is essential to maintaining normal red blood cell counts. As kidney disease progresses and nephrons are damaged, this hormone is inadequately synthesized and a hypoproliferative anemia, resulting in normocytic normochromic red blood cells, results. Before the production of erythropoietin by human recombinant techniques, this hormone deficiency caused most patients with CKD to be in a severely anemic state, requiring frequent blood transfusions.

Decreased red blood cell survival time in renal failure occurs in the form of a mild hemolysis. The exact mechanism for this hemolysis is unclear, but it may be related to dialysis therapy or the effect of uremia on red blood cells. The average survival of red blood cells in uremia is only 70 days, which contrasts with the normal 120-day life span of a red blood cell in the general population.

In addition to the three aforementioned mechanisms of anemia, other factors can contribute to anemia in patients with renal failure, particularly those who are critically ill. Examples are malnutrition, frequent laboratory blood sampling, dialyzer

malfunction and sequestration of blood in the dialyzer, and infectious states. Treating anemia in patients with renal failure is extremely important for many different reasons, including increasing the oxygen-carrying capacity of the blood, increasing intravascular volume, and preventing the negative consequences of anemia on the cardiovascular system. Concerning the cardiovascular system, anemia exacerbates myocardial, cerebral, and peripheral ischemia and increases the risk for development (or acceleration) of left ventricular hypertrophy. Correcting anemia has also been shown to have a positive impact on quality-of-life issues in patients with renal failure, including increases in appetite, energy, and work capacity. In addition, CKD anemia is associated with increased hospitalization rates and increased mortality in patients with CKD.[14]

A thorough evaluation of anemia involves diagnostic studies and a history and physical examination. Diagnostic metabolic parameters that should be obtained and monitored include hemoglobin, hematocrit, red blood cell indices, and reticulocyte counts. In addition, the stool or vomit should be tested for occult blood. Iron studies also need to be obtained because iron deficiency itself can cause anemia and because adequate iron stores are needed for erythropoietin to be effective. Specific iron indices that should be obtained include total serum iron, total iron-binding capacity, and serum ferritin levels. Finally, nutritional parameters and levels of folic acid, pyridoxine, and vitamin B_{12}, all of which affect red blood cell production, need to be monitored.

A thorough history and physical examination involves questioning patients about potential sites of bleeding (eg, by asking about stool color), assessing for signs and symptoms of anemia (eg, angina, tachycardia, skin and mucous membrane pallor, appetite suppression, weight loss, decreased energy levels, fatigue), assessing for sources of blood loss, assessing for inflammation or infection, and assessing for other diseases that can cause anemia (eg, lupus, sickle cell anemia).

Collaborative management of anemia includes minimizing blood loss, administering oral or IV iron supplements, providing vitamin supplementation, aggressively treating infections, ensuring adequate nutrition, and administering erythropoietin stimulating agents (ESAs), such as human erythropoietin or darbepoetin, blood products, or both. Goals for iron therapy in the CKD population are a transferrin saturation greater than 20% and serum ferritin levels greater than 100 ng/mL (>200 ng/mL for dialysis patients). These goals and guidelines to achieve them are detailed in the K/DOQI guidelines on anemia.[52] Goals for ESA therapy are less concrete due to potential cardiovascular risks when targeting normal hemoglobin levels. These cardiovascular risks prompted the Federal Drug Administration (FDA) to issue a warning in all package inserts of ESAs. Hemoglobin goals should be individualized, based on patient symptoms and co-morbidities, using the lowest ESA dose to reduce the need for red blood cell transfusions.

Certain points regarding ESA therapy and the management of anemia deserve special mention. One is that the full effect of these medications takes weeks to achieve, and hence in patients with profound anemia, blood administration is indicated. In addition, ESA administration may result in an elevation of BP. In some cases, modification of antihypertensive therapy may be needed. When there is an inadequate response to ESAs despite increased dosages, reasons for erythropoietin resistance need to be explored. These include occult infections, inflammatory states, human immunodeficiency virus infection, hyperparathyroidism, aluminum toxicity, malnutrition, iron deficiency, and bone marrow malignancy.

Important clinical features regarding iron preparations should also be considered by the nurse. One is that oral iron is poorly absorbed if taken with phosphate binders, antacids, H_2 blockers, or PPIs, all of which are commonly prescribed to patients with renal failure. On the other hand, IV iron has much better bioavailability but carries the risk for an allergic, sometimes life-threatening, reaction.

Extensive patient teaching about anemia is crucial. At minimum, teaching should include information about medication therapy; timing of iron supplements; potential causes, signs, and symptoms of worsening anemia; and energy conservation techniques. Instruction about measures to decrease bleeding, such as use of a soft toothbrush and avoidance of NSAIDs, is also helpful.

Managing Alterations in Drug Elimination

Because many pharmacological agents, their metabolites, or both are excreted by the kidneys, extreme caution must be used when administering medication to patients with renal failure. Depending on the patient's GFR, adjustments may need to be made in drug dosage, the interval between drug dosages, or both. Important to consider, especially in AKI, is that the GRF is often unstable, and thus the GFR must be monitored frequently to determine dosages accurately. As in patients without renal failure, monitoring serum levels of certain medications to be sure they are within the therapeutic range is essential. For patients receiving dialysis, the health care team must be cognizant of which drugs are removed during dialysis therapy to ensure appropriate timing of drug administration. For a listing of frequently encountered antimicrobial agents in critical care that are affected by renal failure, hemodialysis, or both, see Table 31-4.

Managing Skeletal Alterations

In renal failure, disturbances in calcium and phosphate balance occur and set the stage for secondary hyperparathyroidism and high-turnover renal osteodystrophy (renal bone disease). As the GFR declines, glomerular filtration of phosphate also decreases, and serum phosphate levels begin to rise. This results in decreased serum ionized calcium levels because of binding of the calcium with the phosphate. Calcium levels also decrease because of the failing kidneys' inability to convert vitamin D to its active form (1,25-dihydroxycholecalciferol, or vitamin D_3), which is needed for adequate intestinal absorption of calcium. In response to decreased ionized calcium levels, elevations in serum phosphorus levels, and reduced vitamin D_3 synthesis, the parathyroid glands secrete parathyroid hormone (PTH). Over time, the continuous PTH stimulation leads to hyperplasia and proliferation of the parathyroid cells, resulting in secondary hyperparathyroidism. PTH causes the reabsorption of calcium and phosphate salts from bones, thus increasing the serum calcium level at the expense of bone density and mass. PTH also causes calcium reabsorption and phosphate excretion in the kidneys; however, as renal failure progresses, this effect of PTH is not realized. Eventually, as calcium and phosphate continue to be reabsorbed from bones, both levels rise in the serum concomitantly. This results in an elevation in the normal calcium–phosphate product (serum calcium

Table 31-4 Impact of Renal Failure and Hemodialysis on Commonly Used Antimicrobials in Critical Care

Drug	Drug Renally Excreted (%)	Adjustment for Renal Failure (GFR [mL/min/1.73 m²]) 10–50	<10	Effect of Hemodialysis
Aminoglycosides*				
Amikacin†	95	100% of normal dose every 24–48 h	100% of normal dose q48–72 h	Dialyzed
Gentamicin†	95	100% of normal dose every 24–48 h	100% of normal dose q48–72 h	Dialyzed
Tobramycin†	95	100% of normal dose every 24–48 h	100% of normal dose every 48–72 h	Dialyzed
Cephalosporins				
Cefazolin†	75–95	100% of normal dose every 12 h	100% of normal dose every 24–48 h	Dialyzed
Cefepime†	85	100% of normal dose every 16–24 h	100% of normal dose every 24–48 h	Dialyzed
Cefotaxime (active metabolite in ESRD)	60	100% of normal dose every 8–12 h	100% of normal dose every 24 h	Dialyzed
Cefotetan	75	50% of normal dose	25% of normal dose	Dialyzed
Ceftazidime	60–85	100% of normal dose every 24–48 h	100% of normal dose every 48 h	Dialyzed
Ceftriaxone	30–65	Normal dose	Normal dose	Dialyzed
Penicillins				
Amoxicillin	50–70	100% of normal dose every 8–12 h	100% of normal dose every 24 h	Dialyzed
Ampicillin	30–90	100% of normal dose every 6–12 h	100% of normal dose every 12–24 h	Dialyzed
Mezlocillin	65	100% of normal dose every 6–8 h	100% of normal dose every 8 h	Not dialyzed
Nafcillin	35	Normal dose	Normal dose	Not dialyzed
Penicillin G	60–85	75% of normal dose	20%–50% of normal dose	Dialyzed
Piperacillin	75–90	100% of normal dose every 6–8 h	100% of normal dose every 8 h	Dialyzed
Ticarcillin†	85	1–2 g every 8 h	1–2 g every 12 h	Dialyzed
Quinolones				
Ciprofloxacin	50–70	50%–75% of normal dose	50% of normal dose	Slightly dialyzed
Levofloxacin	67–87	250 mg every 24–48 h (500 mg initial dose)	250 mg every 48 h (500 mg initial dose)	No data
Tetracyclines				
Doxycycline	35–45	Normal dose	Normal dose	Not dialyzed
Tetracycline†	48–60	100% of normal dose every 12–24 h	100% of normal dose every 24 h	Not dialyzed
Miscellaneous Antibacterials				
Azithromycin	6–12	Normal dose	Normal dose	Not dialyzed
Aztreonam	75	50%–75% of normal dose	25% of normal dose	Moderately dialyzed

Table 31-4 **Impact of Renal Failure and Hemodialysis on Commonly Used Antimicrobials in Critical Care (continued)**

Drug	Drug Renally Excreted (%)	Adjustment for Renal Failure (GFR [mL/min/1.73 m²]) 10–50	<10	Effect of Hemodialysis
Miscellaneous Antibacterials				
Clarithromycin	15–25	75% of normal dose	50%–75% of normal dose	No data; give after dialysis
Erythromycin	15	Normal dose	50%–75% of normal dose	Not dialyzed
Imipenem	20–70	50% of normal dose	25% of normal dose	Dialyzed
Metronidazole	20	Normal dose	50% of normal dose	Dialyzed
Sulfamethoxazole	70	100% of normal dose every 18 h	100% of normal dose every 24 h	Dialyzed
Trimethoprim	40–70	100% of normal dose every 18 h	100% of normal dose every 24 h	Dialyzed
Vancomycin†	90–100	1.0 g every 24–96 h	1.0 g every 4–7d	Not dialyzed
Linezolid‡	30	Normal dose	Normal dose	Not dialyzed
Antifungals				
Amphotericin B	5–10	Normal dose	100% of normal dose every 24–36 h	Not dialyzed
Fluconazole	70	Normal dose	Normal dose	Dialyzed
Ketoconazole	13	Normal dose	Normal dose	Not dialyzed
Antiviral				
Acyclovir	40–75	100% of normal dose every 12–24 h	50% of normal dose every 24 h	Dialyzed
Ganciclovir	90–100	100% of normal dose every 24–48 h	100% of normal dose every 48–96 h	Dialyzed
Antitubercular				
Amantadine†	90	100% of normal dose every 48–72 h	100% of normal dose every 7d	Not dialyzed
Ethambutol	75–90	100% of normal dose every 24–36 h	100% of normal dose every 48 h	Dialyzed
Isoniazid	5–30	Normal dose	Normal dose	Dialyzed
Rifampin	15–30	50%–100% of normal dose	50%–100% of normal dose	Not dialyzed

*Aminoglycosides are nephrotoxic and ototoxic and have a narrow therapeutic window. Serum levels must be monitored frequently for efficacy and toxicity.

†These drugs have adjustment in dose and/or frequency when a patient's GFR is >50 mL/min as well.

‡Metabolites may accumulate in renal failure; significance unknown.

Modified from Aronoff G, Berns J, Brier M, et al: Drug Prescribing in Renal Failure, 5th ed. Philadelphia, PA: American College of Physicians, 2007.

multiplied by serum phosphate) of less than 40 mg/dL. When the product exceeds 55 mg/dL, calcium phosphate crystals can form and precipitate in various parts of the body (a condition known as metastatic calcifications), including the brain, eyes, gums, valves of the heart, myocardium, lungs, joints, blood vessels, and skin. Other insults to bones that can occur in renal disease include bone demineralization in response to metabolic acidosis and low-turnover renal osteodystrophy from aluminum deposits in the bone or overuse of vitamin D_3 therapy. The events related to high-turnover renal osteodystrophy in renal failure are summarized in Figure 31-5.

Complications resulting from renal bone disease include bone pain, fractures, pseudogout from deposits of calcium oxalate in synovial fluid, periarthritis from calcifications of the joints, proximal muscle weakness, spontaneous tendon rupture, and pruritus. Metastatic calcifications can result in calcified blood vessels and valves, skin lesions, red-eye syndrome from crystal deposition in the conjunctiva, and, most seriously, ischemic ulcers. Laboratory data, including levels of calcium, phosphate, aluminum, alkaline phosphatase, and intact PTH, help make the diagnosis. Radiographic findings also may be helpful, particularly in high-turnover bone

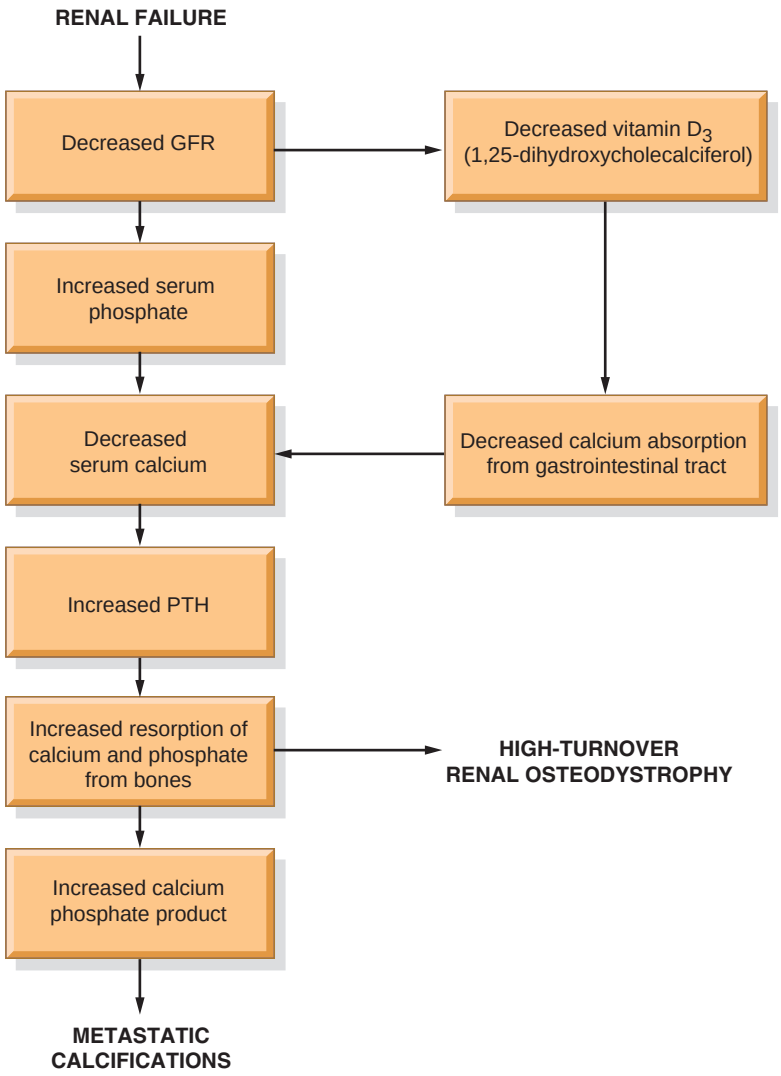

FIGURE 31-5 ▲ Effects of renal failure on the skeletal system.

disease; images may reveal subperiosteal bone thinning, most easily seen in the hands and clavicles. A bone biopsy, considered the gold standard for obtaining a definitive diagnosis of renal bone disease, is not routinely performed secondary to patient discomfort and controversy surrounding the indications for this invasive test.

Management involves phosphate regulation, maintenance of normal calcium levels, treatment of vitamin D deficiency, suppression of PTH, prevention of aluminum toxicity, and control of metabolic acidosis. Measures to control phosphate levels include dietary restrictions and phosphate-binding medications. Commonly used phosphate binders are calcium acetate (Phos-lo), calcium carbonate (Tums), sevelamer hydrochloride (Renagel), and lanthanum carbonate (Fosrenol). Sevelamer and lanthanum carbonate are calcium-free phosphate binders and are preferred over calcium-based binders in patients with high calcium levels because they lessen the risk for hypercalcemia and further elevations in the calcium–phosphate product. Aluminum hydroxide binders, once a mainstay of therapy, are now infrequently used because of the effects of aluminum toxicity on the bones as well as the nervous system. Aluminum toxicity causes erythropoietin resistance as well.

According to the K/DOQI Clinical Practice Guidelines, calcium levels should be maintained in the normal range, preferably toward the lower end of normal (8.4 to 9.5 mg/dL).[53] This is accomplished with diet and calcium supplements. If calcium levels exceed 10.2 mg/dL, therapies that may be contributing to hypercalcemia (eg, administering calcium or vitamin D supplements) should be adjusted to reduce the risk for extraskeletal calcifications.

Vitamin D supplements are administered to suppress PTH secretion. Besides causing a decrease in PTH indirectly through the elevation of serum calcium, active vitamin D also directly inhibits PTH secretion by binding to vitamin D receptors on the parathyroid gland. Active vitamin D may be given orally (calcitriol) or intravenously (Calcijex). In either case, caution must be exercised with the administration of these agents to avoid hypercalcemia and hyperphosphatemia as well as to avoid oversuppression of the parathyroid gland. Two synthetic analogues of active vitamin D that can also be used are paricalcitol (Zemplar) and doxercalciferol (Hectorol). These drugs have the advantage of causing less dramatic increases in serum calcium and phosphate levels while still causing PTH suppression.

The most recent therapeutic agents developed to help suppress PTH and the development of secondary hyperparathyroidism are calcimimetics, which work by increasing the sensitivity of the calcium-sensing receptor in the parathyroid gland to extracellular calcium. In the United States, the Food and Drug Administration approved the calcimimetic cinacalcet hydrochloride (Sensipar) for patients with ESRD. Thus far, it has been shown to be both safe and effective, with the most common side effects being nausea and vomiting and hypocalcemia.[54] Rarely, for patients who are refractory to available treatments for secondary hyperparathyroidism, including vitamin D therapy and calcimimetics, a parathyroidectomy may be necessary.

Patient teaching concerning bone disease and its management is complex and needs to be continually reinforced. Particular areas that should be included are the purpose and timing of medications (eg, phosphate binders must be given with meals to be effective), dietary modifications, and the complications of untreated bone disease.

Managing Integumentary Alterations

Alterations in the integumentary system in renal failure include xerosis (dryness), pruritus, pallor, ecchymosis and purpura, and a pale bronze skin discoloration. Contributing factors to these alterations are anemia, decreased activity of sweat and sebaceous glands, retained skin pigments, platelet dysfunction and capillary fragility, deposition of calcium phosphate crystals into the skin, hyperparathyroidism, hyperphosphatemia, and possibly increased mast cell activity and histamine secretion. In patients with an arteriovenous fistula or graft, pseudo-Kaposi's sarcoma may develop in the area of the fistula, graft, or hands due to overflow of blood or insufficient blood drainage from the area. Patients with stage 5 CKD may also experience bullous lesions and bullous dermatosis, especially male patients who have been on dialysis for long periods.[14] Uremic frost, a white, powdery substance composed of urates on the skin, is due to crystallization of urea. It is usually seen only in severely uremic patients for whom needed dialytic therapy is being withheld. These skin alterations, particularly pruritus and xerosis, may lead to localized infection from excoriation. In addition, substantial patient discomfort and psychological disturbances from skin disfigurement may occur.

Collaborative management for skin alterations includes phosphate regulation, active vitamin D administration, correction of anemia, antihistamine medications, and meticulous skin care and turning to prevent skin breakdown. Dialysis therapy helps as well by removing metabolic waste products. However, because of potential allergies to the dialysis system components, dialysis therapy can also aggravate some conditions, such as pruritus. Patient education should include information on factors contributing to skin alterations, the importance of keeping the skin clean and well moisturized, and ways to avoid excoriation (such as keeping the fingernails trimmed).

Managing Alterations in Dietary Intake

The goals of nutritional therapy in renal failure are to minimize uremic symptoms; reduce the incidence of fluid, electrolyte, and acid–base imbalances; minimize symptoms of anemia; decrease the patient's vulnerability to infections; and limit catabolism. Dietary restrictions related to managing comorbid conditions and reducing cardiovascular risk also need to be considered. Because of the complexity of achieving a nutritional therapy plan that meets these goals, a collaborative health care team approach, including the ongoing participation of a dietitian, is essential. This is particularly the case in critical care, where patients usually are in a catabolic state and are at risk for substantial malnutrition.

Renal diet prescriptions include restrictions in fluid, sodium, potassium, and phosphate intake and may include supplementations of iron, vitamins, and calcium. Calorically, critically ill patients with renal disease need a high-calorie diet with a total of 35 to 45 kcal/kg/d, most of which should come from a combination of carbohydrates and lipids. In addition, adequate protein intake must be administered to prevent catabolism, and at least 50% of protein intake should be of high biological value to ensure that the minimal intake requirements of essential amino acids are met. Protein restriction to decrease symptoms of uremia and slow the progression of renal failure is controversial (refer to the section on preventing the progression of CKD) but may be beneficial. However, protein restriction should never compromise meeting anabolic goals, which would expose the patient to the risk for malnutrition. For patients with CKD, the K/DOQI guidelines recommend a moderate protein restriction of 0.6 to 0.8 g/kg/d in patients not yet receiving dialysis and from 1.2 to 1.3 g/kg/d in patients on dialysis.[55] In critically ill patients, parenteral nutrition may need to be instituted because of impaired bowel function or severe malnutrition. In oliguric patients, the high hourly volume requirements needed for parenteral nutrition often must be offset by dialysis or isolated ultrafiltration.

To determine the effectiveness of nutritional therapy, continual laboratory monitoring of serum protein, cholesterol, albumin and prealbumin, electrolytes, hemoglobin, hematocrit, and urea and creatinine levels is essential. Patient weight, volume status, and energy levels are additional monitoring parameters. Nutritional education, including information on dietary restrictions, the use and timing of phosphate binders, vitamin and mineral supplements, and measures of nutritional status should be provided.

Managing Alterations in Psychosocial Functioning

Patients in AKI and CKD often experience feelings of fear, anxiety, and powerlessness. In addition, patients frequently have an alteration in self-concept as well as body image disturbances because of both physical and functional changes that occur in renal failure. Patients and their families may have difficulty coping owing to stress, limited resources or support, inadequate or ineffective coping mechanisms, interruptions in usual family roles, or a combination of these factors. It is important that the health care team attend to these and other psychosocial complications of renal failure to treat the patient and family holistically. Specific interventions include thorough patient and family teaching, active involvement of the patient and family members in managing the condition, ensuring adequate rest and sleep to the patient, exploring the patient's and family's feelings and concerns, providing support, and obtaining the active involvement of social services and clergy as appropriate.

▲ Clinical Applicability Challenges

CASE STUDY

A 56-year-old white female was admitted to the ICU following a pelvic exenteration at 10 AM. She presented 3 months prior to admission with early satiety and abdominal bloating. Evaluation revealed endometrial cancer and after failed radiation therapy, the patient elected for surgery. Her operative course was prolonged, and there was an estimated blood loss of 4.5 L.

Postoperatively, in the ICU, she remained intubated with an initial BP of 136/86, pulse rate of 120, and respiration rate of 26, and she was afebrile. Initial fluid administration included 2 units of packed red blood cells and lactated Ringer's solution at 125 mL/min.

In the first 6 hours after surgery, her urine output was 20 mL/h. BP remained in the 130/80s and the patient remained tachycardic. IV fluids were increased to 150 mL/h, and an additional 6 hours passed with no increase in urine output. The attending physician ordered Lasix (furosemide) 40 mg IV, which did not improve urinary output.

Midnight laboratory results revealed the following values: sodium 138, potassium 5.3, chloride 105, CO_2 28, BUN 46, and creatinine 2.7. Of note, the patient's preoperative BUN and creatinine values were 23 and 1.1, respectively. An ABG test result showed a pH of 7.47/42/98 (28) while the patient was receiving oxygen therapy (40% of O_2).

Evaluation of her AKI included a renal ultrasound finding of two normal-sized kidneys of normal echotexture without evidence of hydronephrosis.

Urinalysis prior to diuretic administration showed urinary sodium of 42 mg/dL, fractional excretion of sodium of 2.6, and fractional excretion of urea of 66. Analysis of urine obtained from a Foley catheter showed too-numerous-to-count red blood cells, 1+ protein, and muddy brown casts.

1. What is the most likely etiology for this patient's AKI?
2. What special concerns would you have about medication administration in this patient?
3. What electrolyte and acid–base abnormalities may be expected in this patient on subsequent laboratory tests?

PART 8

NERVOUS SYSTEM

32

Anatomy and Physiology of the Nervous System

Mary Ciechanowski, Donna Mower-Wade, and Sandra W. McLeskey

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Describe the cellular units of the nervous system.
2. Explain the characteristics of neurons.
3. Describe the components of the central nervous system.
5. List areas of the cerebrum and their corresponding function.
6. Explain the functions of the thalamus.
7. Define the reticular activating system.
8. Briefly define the sensory system and the motor system.
9. Explain the baroreceptor reflex, and list three spinal cord reflexes.
10. Explain the anatomy and physiology of pain.
11. Explain the concept of homeostasis.
12. Describe the acute stress response.
13. Discuss why the stress response could be helpful or harmful, depending on the situation.

The brain is a central organ that coordinates activity of most, if not all, body systems through its influence on the endocrine and immune systems as well as its more generally appreciated influence on skeletal muscle and autonomic function. Its influence is modulated by sensory perceptions that convey a picture of the external and internal environments and also by internal circuits having to do with emotional state and levels of arousal. Therefore, the brain can be thought of as the integrative organ that drives our responses to environmental influence. Moreover, separation of the brain and spinal cord from the periphery is more anatomical than conceptual, and modern nurses must always keep in mind that the brain has a profound influence on almost everything that happens in the periphery, and vice versa.

Traditionally, the nervous system is discussed with reference to both anatomical and functional divisions. Anatomical components are the central nervous system (CNS), comprising the brain and spinal cord, and the peripheral nervous system (PNS), comprising the cranial and spinal nerves. The nervous system is functionally separated into the sensory, integrative, and motor (somatic and autonomic) divisions. Content in this chapter is ordered according to both divisions. However, cell anatomy and physiology are discussed first.

▲ Cells of the Nervous System

The cellular units are the neuron—the basic functional unit—and its attendant cells, the neuroglia.

Neuroglia

Neuroglia constitute the supportive tissue associated with the neurons. In the CNS, there are four types of neuroglia: microglia, astrocytes, ependymal cells, and oligodendroglia. The microglia are phagocytic cells of the nervous system similar to macrophages in the periphery. The astrocytes are supportive cells of the nervous system and make up the blood–brain barrier. The ependymal cells line the ventricles and aid in the production and circulation of the cerebrospinal fluid (CSF). The oligodendroglia are mostly found in the white matter and produce the myelin that covers nerve fibers in the CNS. In the PNS, the counterpart of the myelin-producing oligodendroglial cell is the Schwann cell.

Under most circumstances, neurons lose their ability to undergo mitosis early in the life of the individual. However, neuroglia retain mitotic abilities throughout a person's life span. Because of this, malignant or benign proliferative lesions originating in the CNS involve neuroglia rather than neurons. However, as the neuroglial tumor enlarges, it adversely affects adjacent neurons—early by exerting pressure and later by promoting an inflammatory reaction along with the pressure.

Neurons

The basic functional unit of the nervous system is the neuron (or nerve cell), and all information and activity, whether sensory, motor, or both, is accomplished by neurons. The neuron consists of a nerve cell body or soma that contains nuclear and cytoplasmic material and processes, either axons or dendrites, that arise from the soma (Fig. 32-1). Axons normally carry nerve impulses away from the cell body, whereas dendrites conduct impulses toward the cell body. Axons and dendrites may be merely microscopic knobs or areas on the cell body surface, or they may be cylindrical processes that can extend to more than 1 m (3.25 ft) long. A specialized structure at the end of the axon is called the axon terminal. This is a bulbous ending (sometimes called a bouton) that forms a synapse with another neuron. The axon terminal contains vesicles of neurotransmitter that is released

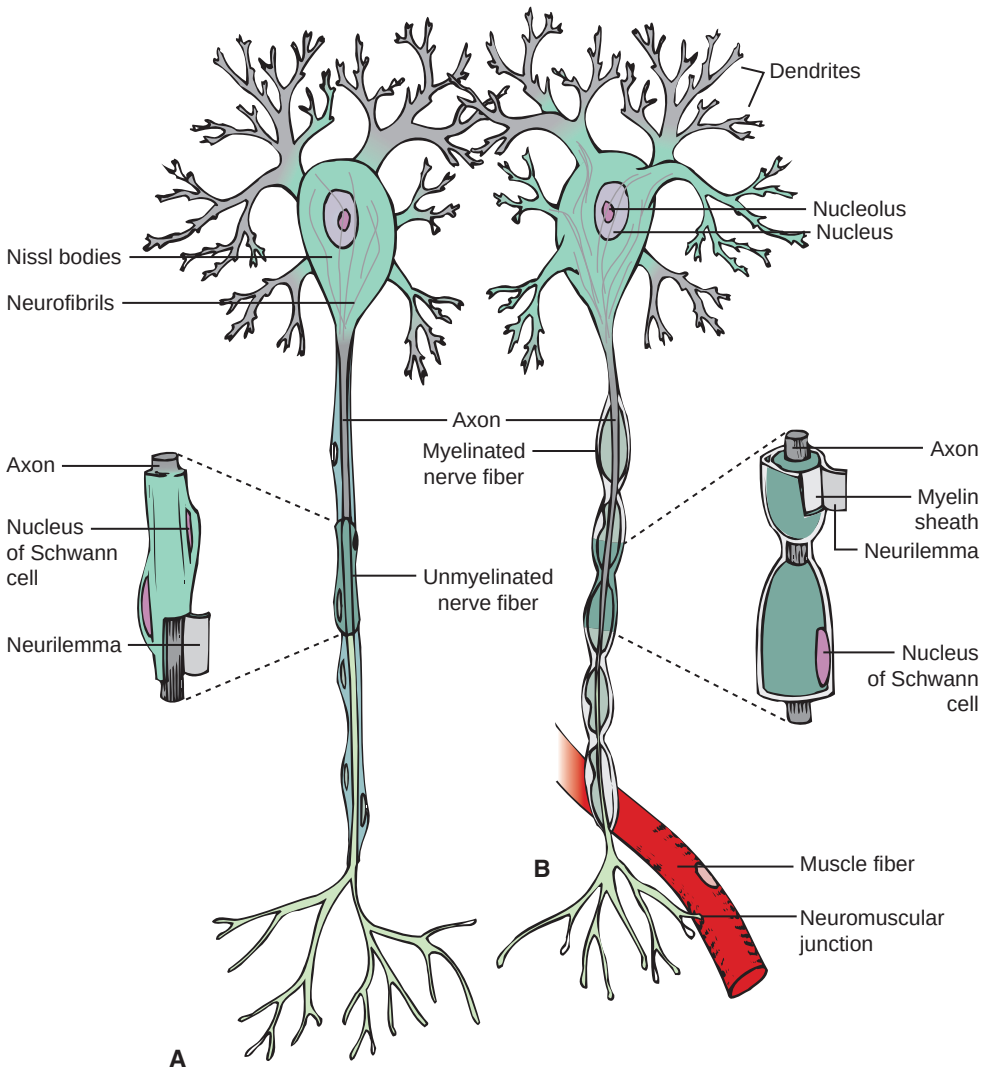

FIGURE 32-1 ▲ Typical efferent neurons. **A**: Unmyelinated fiber. **B**: Myelinated fiber.

into the synapse, diffuses across to the postsynaptic neuron, and binds to specific receptors on the membrane of the postsynaptic cell. Binding of a particular neurotransmitter to its specific receptor on the postsynaptic neuron either depolarizes or hyperpolarizes the postsynaptic neuron in the area of the synapse. Axons and dendrites are referred to collectively as nerve fibers. A bundle of nerve fibers together with their coverings is called a tract in the CNS and a nerve in the periphery.

Some nerve fibers are covered with a white lipid–protein sheath termed the myelin sheath. This covering is what differentiates white matter from gray matter in the CNS. The myelin sheath is formed in the CNS by the oligodendrocytes. Other fibers remain unmyelinated. All nerve fibers in the PNS are covered by a neurilemma. This is a sheath formed by the Schwann cells, which wrap themselves around the fiber. Some Schwann cells around particular fibers secrete myelin; others do not (see Fig. 32-1). The neurilemma of a myelinated fiber comes in contact with the axon at periodic intervals. These periodic constrictions of the neurilemmal sheath are termed the nodes of Ranvier. The nodes of Ranvier produce faster nerve impulse conduction by allowing the impulse to jump from one node to the next (saltatory conduction).

Neurons are very diverse, with many specialized anatomical features that are important to their function. Some neurons are extremely large or may give rise to extremely long nerve fibers. Transmission velocities in long, myelinated fibers may be as high as 100 m/s, whereas unmyelinated neurons with very short, unmyelinated processes demonstrate velocities of 1 m/s. Some neurons connect to many different neurons, perhaps thousands of other neurons, in a "network," whereas others have relatively few connections to other cells of the nervous system.

It is estimated that the human CNS has 12 billion neurons. Three fourths of these neurons are located in the cerebral cortex, where conscious thought and feeling reside, along with integrative processing and smoothing of planned motor movements. This processing includes not only the determination of appropriate and effective responses but also the storage of memory and the development of associative motor and thought patterns.

▲ Characteristics of Neurons

Resting Membrane Potential

As is true of all cells, the neuronal cell membrane contains sodium–potassium pumps that keep the inside of the neuron more negatively charged than the outside interstitial fluid. The cytoplasm of all cells contains anions (negatively charged ions) that are too large to leave the cell. Many ions, including sodium, potassium, and chloride, are small enough to diffuse through tiny pores in the cell membrane. If it were not for the sodium–potassium pump, the concentrations of these ions would be equal on the inside of the cell compared with the outside. However, the sodium–potassium pump in the cell membrane pumps sodium ions out of the cell almost as fast as they enter. For every two sodium ions that are pumped out, one potassium ion is pumped into the cell. Because of this, there is a net positive charge leaving the cell, and the large anions cannot be counterbalanced. Thus, under resting conditions when no impulse is being conducted, the inside of the neuron is negative with respect to the outside. This internal relative negativity is the resting membrane potential of the neuron and typically measures about −85 mV.

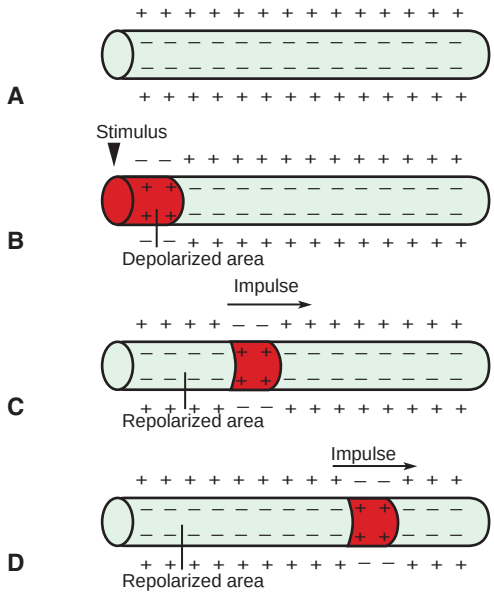

FIGURE 32-2 ▲ Propagation of impulses. **A**: Resting membrane. **B**: Action potential, first stage: stimulation of fiber results in depolarization. **C**: Action potential, second stage: repolarization occurs as the resting potential is restored. **D**: Propagation of impulses continues in direction of *arrow*.

In addition, as a result of activity of the sodium–potassium pump, sodium ion concentration inside the cell is much lower than outside, and potassium ion concentration is much higher inside the cell than outside. These concentration gradients are important for depolarization produced by synaptic transmission and also for conduction of the action potential down the axon (Fig. 32-2).

Synaptic Transmission

Submicroscopic spaces between the axon (or axons) of one neuron and the dendrite (or dendrites) or soma of another are called synapses. Axons or dendrites may branch, enabling the axon of one neuron to synapse with dendrites or somas of several neurons. A synapse consists of a presynaptic axon terminal, a postsynaptic neuron, and the small (150 to 1,000 Å) space between elements called a synaptic cleft (Fig. 32-3A). When an action potential is conducted down the presynaptic axon and depolarizes the axon terminal, vesicles of neurotransmitter fuse with the plasma membrane, releasing neurotransmitter into the synaptic cleft. The molecules of neurotransmitter diffuse across the cleft and bind to specific receptors on the postsynaptic cell membrane. The binding of neurotransmitter to its receptor causes a change in the membrane potential of the postsynaptic cell, either a depolarization or a hyperpolarization.

In very short time (millionths of a second), the neurotransmitter detaches from the receptor site. It may then reattach or be inactivated. Inactivation occurs in two basic ways, depending on the neurotransmitter. For example, the

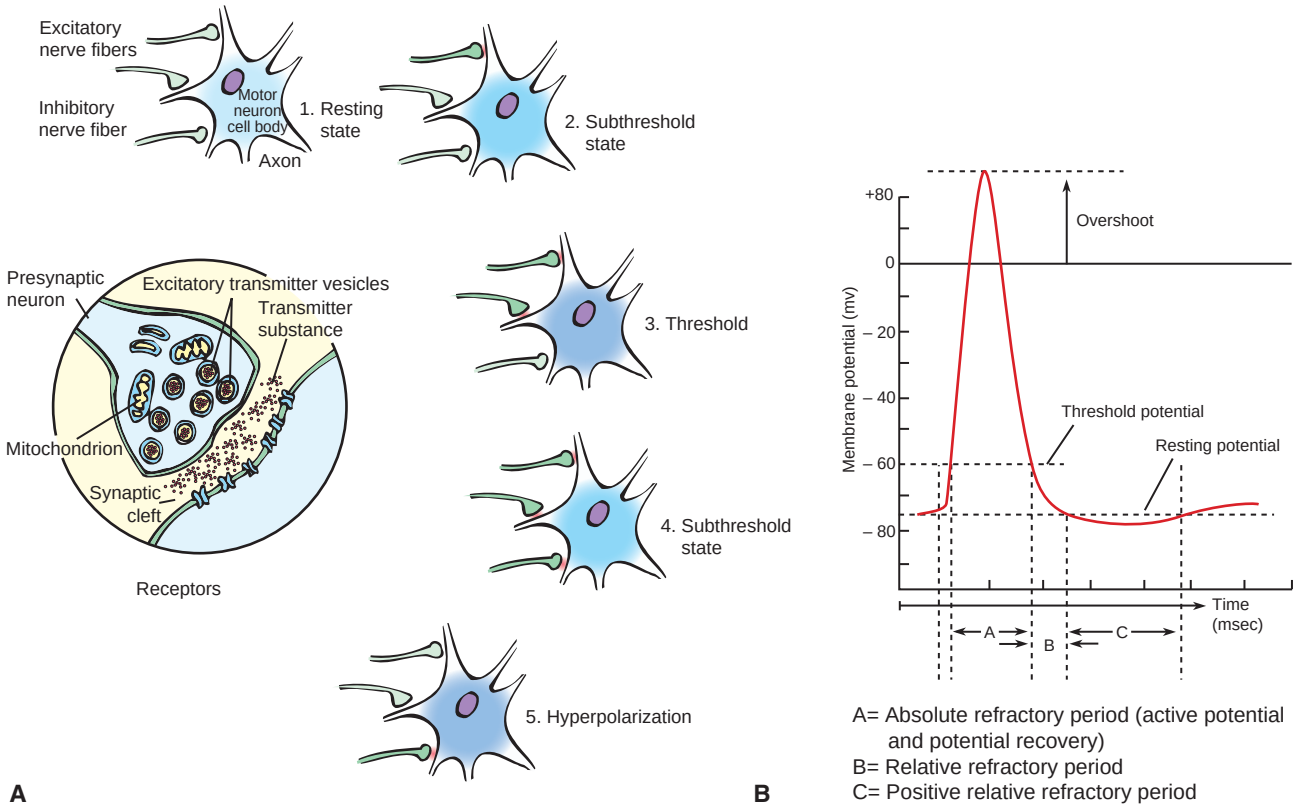

FIGURE 32-3 ▲ Conduction at synapses. **A**: A neuron may be excited or inhibited by transmitter substances liberated by presynaptic nerve fiber endings. Two excitatory fibers and one inhibitory fiber are shown. (1) During the resting state, no impulses are received. (2) During the subthreshold state, impulses from only one excitatory fiber cannot cause the postsynaptic neuron to mount an action potential. (3) The threshold is reached by the addition of impulses from a second excitatory fiber. This enables the postsynaptic neuron to mount an action potential. (4) The subthreshold state is restored by impulses from an inhibitory fiber. (5) When the inhibitory fiber alone is carrying impulses, the postsynaptic neuron is in a state of hyperpolarization and is unable to fire. **B**: The time course of a neural action potential.

catecholamine neurotransmitters and serotonin are taken back into the axon terminal by specific reuptake pumps and are repackaged in vesicles to be reused. In contrast, acetylcholine is destroyed by an enzyme, acetylcholinesterase, present in the synaptic cleft. In either case, the neurotransmitter is available to bind to its receptors on the postsynaptic membrane only for a very short time. Rapid, repetitive, discrete stimulation of neurons is necessary for activity of a neural pathway to continue. In this way, neural pathways can be stimulated over prolonged periods by repeated depolarizations of presynaptic neurons, or activity of a specific pathway can be turned on or off almost instantaneously.

Synaptic transmission is a one-way street—from the axon across the synaptic cleft to the dendrite or soma of the next neuron. It cannot proceed in the opposite direction. Moreover, decreased destruction or decreased reuptake of a transmitter can increase the effect of this transmitter on the postsynaptic membrane. Similarly, increased destruction or increased reuptake of a transmitter reduces its postsynaptic effects. Several classes of pharmacological agents take advantage of these facts. For instance, acetylcholinesterase inhibitors, such as neostigmine, are used to increase the amount of acetylcholine remaining in the synapse of the neuromuscular junction to counteract the effects of paralytic drugs given during anesthesia. Serotonin or norepinephrine reuptake pump inhibitors increase the amount of serotonin or norepinephrine in the synapse and have therapeutic effects in depressed patients.

Each neuron synthesizes and stores only one major neurotransmitter in its axon terminal. Major neurotransmitters include serotonin, acetylcholine, gamma-aminobutyric acid (GABA), glycine, glutamate, and the catecholamines, dopamine, norepinephrine, and epinephrine. Examples of neuropeptide neurotransmitters are the endogenous opioids (endorphins and enkephalins) and substance P, all of which appear to be involved in pain sensation. The endorphins and enkephalins, often described as the body's own morphine, contribute to a decrease in pain sensation. Substance P excites sensory neurons that respond to painful stimuli, so it is thought to be involved in transmission of pain information from the periphery to the CNS.

Each major neurotransmitter has multiple receptors. For instance, epinephrine can bind to α_1, α_2, β_1, and β_2 receptors, and acetylcholine can bind to neuronal nicotinic, skeletal muscle nicotinic, or muscarinic receptors, which are further subdivided into m_1, m_2, and m_3. The postsynaptic membrane of each synapse contains only one receptor type for the particular neurotransmitter synthesized by the presynaptic neuron. The receptor subtype dictates the effects of a neurotransmitter in a particular synapse on the postsynaptic cell

(hyperpolarization or depolarization). Therefore, the same neurotransmitter might be either hyperpolarizing or depolarizing to a given postsynaptic neuron, depending on the receptor subtype present on the postsynaptic cell. However, all GABA receptor types are hyperpolarizing, and GABA is the most important inhibitory neurotransmitter in the nervous system. Likewise, glutamate and glycine are always depolarizing (excitatory) neurotransmitters.

Neuronal Thresholds and the Action Potential

A depolarizing impulse that reaches a neuron's dendrites or soma through action of a neurotransmitter binding to its receptors causes the membrane to depolarize locally through action of the receptor. The local depolarization causes voltage-sensitive sodium channels locally in the membrane to open, and sodium ions are transmitted down their concentration gradient from outside the neuron to inside, causing further local depolarization. If enough sodium channels open locally, the resulting depolarization is large enough to open sodium channels in adjacent areas, depolarizing a larger area of the membrane. Conversely, release of an inhibitory neurotransmitter, such as GABA, at a synapse may cause hyperpolarization of the postsynaptic neuron through receptor action.

As mentioned, for a given nerve cell, typically there are many other neurons that synapse with its soma or dendrites. Some of these synapsing neurons release an excitatory neurotransmitter that interacts with the nerve cell's receptors to depolarize the postsynaptic neuron. Other synapsing neurons release inhibitory neurotransmitters that interact with their receptors to hyperpolarize the postsynaptic neuron. The nerve cell body algebraically sums the positive depolarizing (excitatory) and negative hyperpolarizing (inhibitory) influences. If the depolarizing influences outweigh the hyperpolarizing influences, the membrane potential of the nerve cell body may reach a value called threshold. At that point, an action potential is generated at the point where the axon leaves the soma. The action potential is propagated down the length of the axon by the process of sodium channel openings in the area of the advancing action potential, followed by complete depolarization of that area. After this process, sodium channels close, and the membrane in that area can repolarize through activity of the sodium–potassium pump and through opening of voltage-sensitive potassium channels. As potassium accumulates within the cell, either by entry through the voltage-sensitive potassium channels or the sodium–potassium pump, the membrane potential is reestablished.

The action potential is normally propagated down the entire length of the axon to the axon terminal. At that point, depolarization of the axon terminal causes neurotransmitter to be released, which diffuses across the synapse and binds to specific receptors, causing a depolarizing or hyperpolarizing change in the postsynaptic neuron.

Neuronal activity can be influenced by hormones. For example, thyroxine lowers thresholds of certain neurons, and one sign of hyperthyroidism is the presence of exaggerated spinal reflexes, such as the knee jerk and ankle jerk.

Figure 32-3B depicts the time course of a neuronal action potential as monitored by electrodes inserted into an axon. Compared with cardiac action potentials, neuronal action potentials are quite short, with durations of approximately 5 to 15 ms. Like the cardiac action potential, there are absolute and relative refractory periods during which the neuron cannot easily be reexcited. However, these refractory periods are very short because repeated impulse conduction is necessary to maintain tonic activity of particular neural pathways. For instance, the motor pathways that supply muscles of posture must be tonically active to maintain a steady contraction in these muscles that keep us erect. Other pathways that have tonic activity include the autonomic motor pathways (sympathetic and parasympathetic), as discussed later in this chapter.

The electrical activity of the action potential can be monitored in certain clinical situations. For example, the electroencephalogram depicts multiple action potentials from surface neurons of the brain. Nerve conduction studies can be done on peripheral nerves to diagnose areas of compression or entrapment, which slow action potentials.

Remodeling of Connections in the Nervous System

Although neurons in adults, and all but the youngest children, do not divide to form more neurons, and in fact neurons die throughout our life span, our CNS is in a constant state of remodeling (often referred to as *plasticity*), with formation of new connections between neurons (synapses) and regression of previous connections. This is an area of continuing research, but evidence suggests that sensory information that is communicated to the brain as a result of our experiences is responsible for the remodeling. These alterations in brain circuitry may explain phenomena, such as emotional maturation and motor learning. They may also explain the development of mental illness at certain times in a person's life or the intense cravings that appear with substance abuse disorders.

▲ Nerve Regeneration

If a nerve fiber is severed, the portion distal to the cut dies, and the part still attached to the cell body regenerates. In peripheral neurons, the neurilemma itself provides a channel that can be followed by a regenerating fiber so that it may become reattached to its original anatomical connection (Fig. 32-4). Regeneration also occurs in the absence of a neurilemma, as in the case of CNS neurons. Because there is no channel to ensure correct anatomical reconnection, most such regenerations do not produce recovered function. The regrowing stump may wind aimlessly among other structures or curl into a useless tangle. However, a bigger hindrance to functional regeneration in the CNS has been discovered—an overgrowth of neuroglial cells that occurs in response to injury. This produces a neuroglial thicket that acts as a barrier to the reconnection of severed neuronal networks.

Note that nerve processes, axons, or dendrites that are cut by an injury may regenerate, but if the soma is damaged by injury or the nerve cell is killed by lack of oxygen or a neurotoxin, there will be no regeneration. Moreover, under ordinary circumstances, a neuron that dies cannot be replaced because neurons do not normally undergo mitosis in people older than age 2.

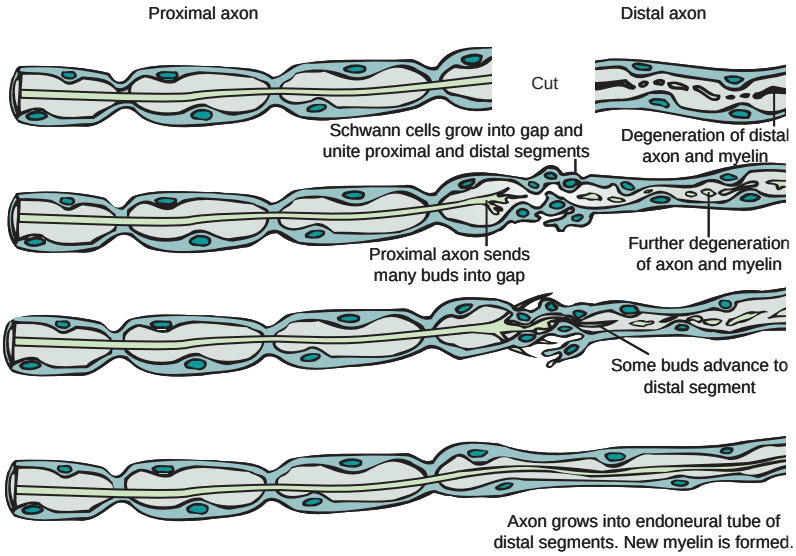

FIGURE 32-4 ▲ Diagram of changes that occur in a nerve fiber that has been cut and then regenerates.

▲ Central Nervous System

The CNS comprises the brain and spinal cord. It receives sensory input through sensory neurons whose dendrites run within spinal and cranial nerves, and it sends out motor impulses through axons of motor neurons that run in these same nerves. The CNS also contains large numbers of neurons that are entirely contained within it. These neurons are termed internuncial neurons, or interneurons, and exist inside the brain or the spinal cord or connect one with the other.

Skull

The skull (cranium) is one of the hardest bones of the body and, along with the facial bones, functions to protect the brain from traumatic injury (Fig. 32-5). The facial bones help protect the brain from injury by absorbing some of the traumatic forces. The skull, which surrounds the soft structures of the brain, is composed of eight bones fused together at suture lines. The bones that compose the main part of the skull are the frontal, parietal, temporal, and occipital bones, and these bones are joined together during early childhood (see Fig. 32-5).

Meninges

The CNS, including the spinal cord, is covered by three layers of tissue collectively called the meninges (Fig. 32-6). The pia mater is the layer that lies next to the CNS. Next is the arachnoid layer, which contains a substantial vascular supply. The last layer is the dura mater, the thickest layer of all, lying next to the bones surrounding the CNS. Between the pia and arachnoid layers lies the subarachnoid space. CSF

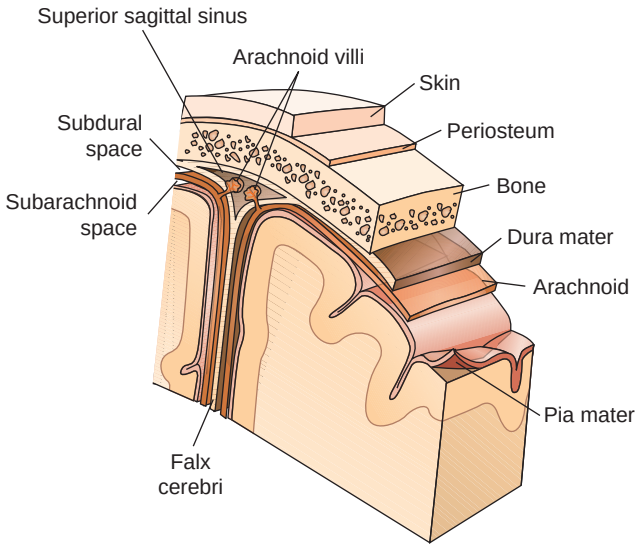

FIGURE 32-6 ▲ The cranial meninges. The arachnoid villi, shown within the superior sagittal sinus, are one site of passage of cerebrospinal fluid (CSF) into the blood. (From Porth CM: Pathophysiology: Concepts of Altered Health States, 8th ed. Philadelphia, PA: Wolters Kluwer Health | Lippincott Williams & Wilkins, 2009, p 1211.)

circulates through the subarachnoid space. In addition, the subarachnoid space contains the cerebral vasculature. When a cerebral vascular abnormality rupture occurs, it bleeds into the subarachnoid space, causing a subarachnoid hemorrhage. The space between the arachnoid and dura mater is named the subdural space. The space between the dura mater and skull bone is known as the epidural space. The epidural space that surrounds the spinal cord is used for epidural pain management.

The CNS is richly supplied with blood vessels that bring oxygen and nutrients to the cells. However, many substances cannot easily be exchanged between the blood and the brain because the endothelial cells of the vessels and the astrocytes of the CNS form extremely tight junctions collectively referred to as the blood–brain barrier. In particular, polar molecules and large molecules, such as proteins, do not cross the blood–brain barrier, but lipid-soluble molecules cross with ease. Many drugs penetrate the brain poorly because they do not have sufficient lipid solubility to cross the blood–brain barrier.

The space between the arachnoid layer and the pia mater, termed the subarachnoid space, contains CSF, which is another means of supplying nutrients, but not oxygen, to the CNS. CSF also serves a protective function by cushioning the brain and spinal cord.

Cerebrospinal Fluid

CSF, a clear, colorless fluid, flows in the ventricles of the brain and the subarachnoid space of the brain and spinal cord. Functioning as a fluid shock absorber, CSF keeps the delicate CNS tissues from being mechanically injured by surrounding bony structures. CSF is actually a plasma filtrate that is exuded by the capillaries in the roofs of each of the four ventricles of the brain. As such, it is similar to plasma without the large plasma proteins, which stay behind in the bloodstream. Red blood cells, which contain the hemoglobin that is responsible for most oxygen transport in blood, are not present in CSF. Therefore, the CSF is a poor source of oxygen, although it contains glucose, amino acids, and other nutrients that might be needed by the cells of the CNS.

Most of the CSF is made in the lateral ventricles, which are located in each cerebral hemisphere. The choroid plexus produces approximately 500 mL of CSF each day, or 25 mL/h. The CSF moves from there through the ducts into the third ventricle of the diencephalon (Fig. 32-7). From there, it travels through the aqueduct of Sylvius of the midbrain and enters the fourth ventricle in the medulla oblongata. Most of it then passes through holes (foramina) in the roof of this ventricle and enters the subarachnoid space. A small amount diffuses down into the spinal canal. In the subarachnoid space, the CSF is reabsorbed into the bloodstream at certain structures called the arachnoid villi.

The formation and reabsorption of CSF is governed by the same hydrostatic and colloid osmotic forces that regulate the movements of fluid and small molecules between the plasma and interstitial fluid compartments. Briefly reviewed, the action of these forces is as follows. Two opposing push–pull forces influence the movement of water and small molecules through the semipermeable capillary membranes. One force is composed of plasma oncotic pressure and CSF hydrostatic pressure. It favors movement of water and small molecules from the CSF compartment into the plasma. The movement of water and small molecules in the opposite direction is influenced by the force of plasma hydrostatic pressure and CSF oncotic pressure. These two opposing forces are exerted simultaneously and continually. In the lateral ventricles, the flow of CSF out of the ventricles reduces CSF hydrostatic pressure. This tips the influence in favor of the movement

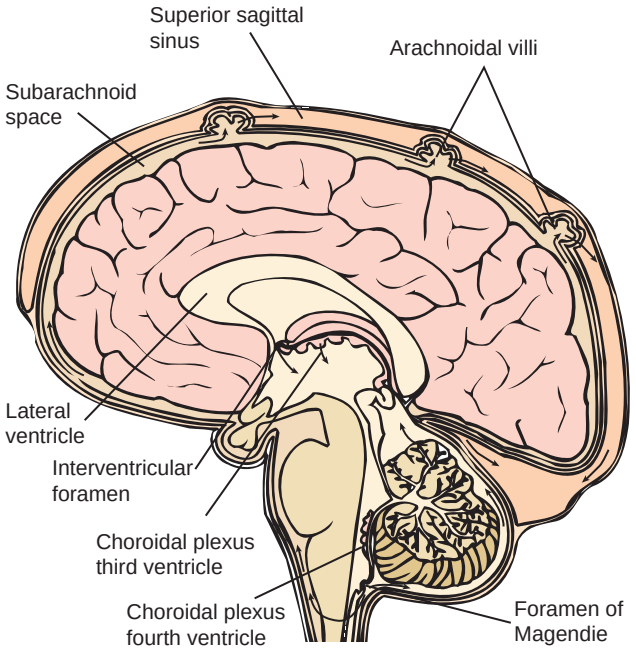

FIGURE 32-7 ▲ Diagram of the flow of CSF from the time of its formation from blood in the choroid plexuses until its return to the blood in the superior sagittal sinus. (Adapted from Hickey JV: The Clinical Practice of Neurological and Neurosurgical Nursing, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 52.)

of water and small molecules from plasma to the ventricles. The low plasma hydrostatic pressure of blood in the venous sinuses next to the arachnoid villi tips the scales in favor of the movement of water and solute from the CSF compartment back into the bloodstream. These forces are modulated by death of cells lining the CSF compartment, which releases proteins into the CSF. This elevates CSF oncotic pressure and retards reabsorption (while also hastening CSF formation if the damage is in ventricle walls). Increased CSF proteins from this or other causes can provoke or exacerbate a condition of excess CSF called hydrocephalus. If at any time the arachnoid villi become blocked or the flow of CSF is otherwise disrupted, hydrocephalus occurs.

Because the CSF is formed in the ventricles and must travel to the arachnoid to be reabsorbed, any impediment to its flow impairs its absorption. The aqueduct of Sylvius or the foramina in the roof of the fourth ventricle may become clogged by adhesions from an infection (meningitis), clots from a subarachnoid hemorrhage, a tumor, or a congenital abnormality. This produces an obstructive hydrocephalus with increased pressure in the CSF. Communicating hydrocephalus, caused by infection or subarachnoid hemorrhage, occurs when CSF cannot be reabsorbed by the arachnoid villi.

Cerebral Vasculature

Because the brain requires a continuous supply of oxygen and glucose to survive, it receives about 20% of the cardiac output at a rate of approximately 750 mL/min. Two major sets of vessels supply the brain with blood: the two internal carotid arteries and the two vertebral arteries. The left common carotid artery arises from the aortic arch, and the right common carotid artery is formed from the bifurcation of the short brachiocephalic trunk, which arises from the aorta. Each carotid artery bifurcates to form the internal and external carotid arteries. The internal carotid arteries supply most of the cerebrum and upper portion of the diencephalon, and the external carotid artery supplies the face and scalp. The vertebral arteries arise from the subclavian arteries. After entering the foramen magnum, the vertebral arteries join to form the basilar artery, which sends branches to the cerebellum, brainstem, and posterior diencephalon. The basilar artery joins the circle of Willis by bifurcating to form the two posterior cerebral arteries.

The circle of Willis, located in the subarachnoid space, is the area in which the branches of the basilar and internal carotid arteries unite (Fig. 32-8). This area is composed of the two anterior cerebral arteries, the anterior communicating artery, the two posterior cerebral arteries, and the two posterior communicating arteries. These arteries send branches to supply the various lobes of the cerebral cortex. This circular network permits blood to circulate from one hemisphere to the other and from the anterior to the posterior areas of the brain. The anterior circulation consists of the middle and anterior cerebral arteries and one anterior communicating cerebral artery. The posterior circulation consists of posterior and posterior communicating cerebral arteries and one basilar artery. This system allows for collateral circulation if one vessel is occluded.

It is not unusual for a vessel in the circle of Willis to be atrophic or even absent. This accounts for different clinical presentations among patients with the same lesion. For example, a person with an occluded carotid artery and a fully patent circle of Willis may be totally asymptomatic, but a patient in whom the circle of Willis is incomplete may demonstrate a massive cerebral infarction.

Brain

The basic anatomy of the brain is illustrated in Figure 32-9. The parts of the brain, in descending order, are the cerebral

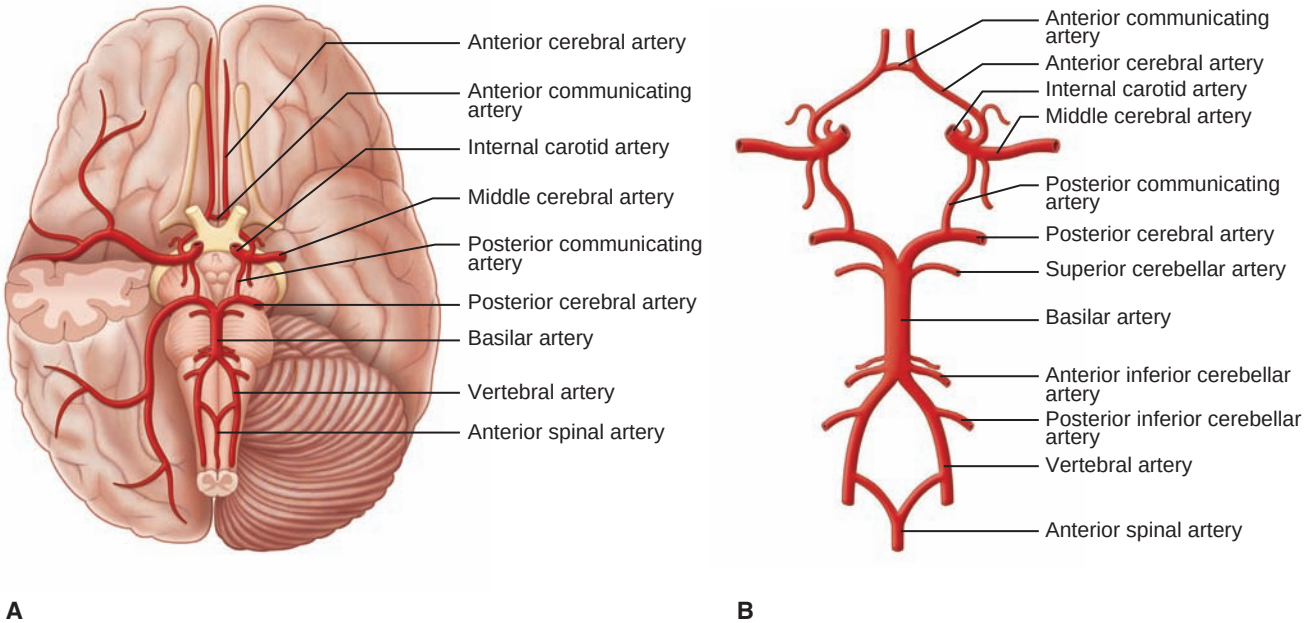

FIGURE 32-8 ▲ Circle of Willis (arterial blood supply to the brain). **A**: The circle of Willis seen from below the brain. **B**: Schematic of the circle of Willis.

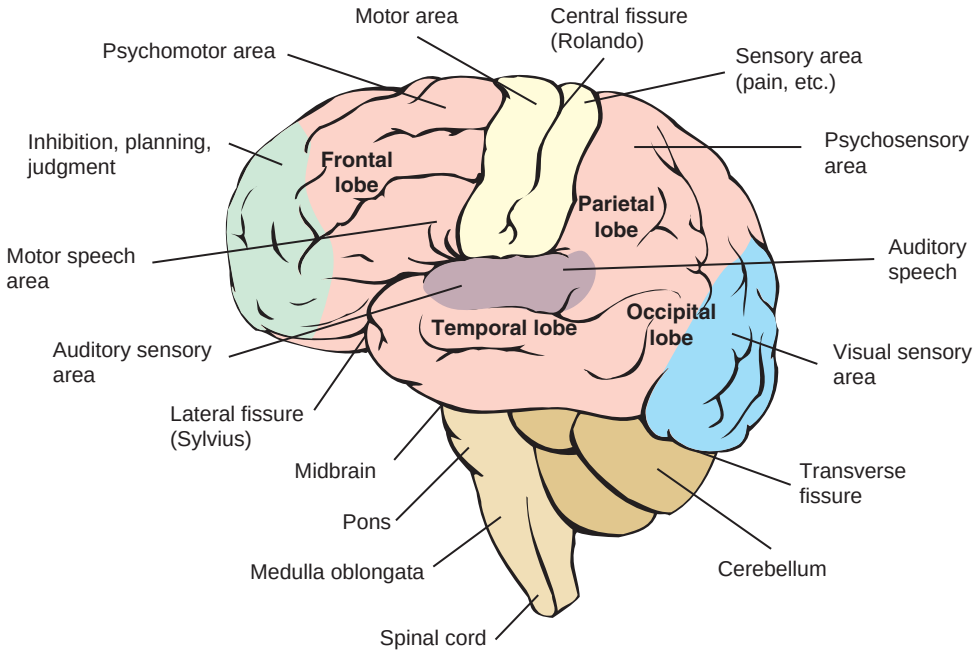

FIGURE 32-9 ▲ The human brain, showing the lobes and fissures of the cerebrum. Major functional areas are also indicated. The cortex is comprised of the frontal lobe, the parietal lobe, the temporal lobe, and the occipital lobe.

hemispheres (the cerebrum), diencephalon, midbrain, pons varolii (usually called the pons), medulla oblongata (usually called the medulla), and cerebellum.[4] The general appearance of the brain can be viewed as a stem extending upward from the spinal cord with an inferior small flowering overgrowth (cerebellum) covering the lower part of the stem and a large superior flowering overgrowth (cerebrum) covering most of the upper portion of the stem. The medulla, pons, and midbrain compose the brainstem.

Cerebrum

Each of the two cerebral hemispheres (left and right) has a layer of cortex covering the surface. This cortical layer consists of several different types of neurons with accompanying neuroglia arranged in six distinctive layers according to cell type and function. Some of these neurons project myelinated axons deeper into the cortex with ultimate destinations lower in the CNS or in the opposite cortex. Areas of myelinated axons appear as white matter. Gray matter is made up of nerve cell bodies that are vascular in nature and have a gray appearance. Deep within each hemisphere is a lateral ventricle containing CSF, along with several collections of nerve cell bodies, termed the basal ganglia. The left and right hemispheres are connected and communicate with each other by a transverse band of white matter termed the corpus callosum, formed by myelinated axons traveling between each side of the cortex. For the most part, each hemisphere serves the contralateral side of the body (fibers cross over in the CNS). However, one notable exception is Broca's speech area. This area of the cortex subserves all motor speech functions and is located in a posterolateral area of the left frontal lobe for all right-handed and most left-handed people. Damage to this area in an adult produces motor dysphasia, which includes dysarthria (difficulty with spoken words) and dysgraphia (difficulty with written words).

Each hemisphere has four lobes that are named for the skull bones that cover them: frontal, parietal, temporal, and occipital. Primary functions of each lobe are as follows. The frontal lobes perform high-level cognition, memory, and voluntary motor movement. The parietal lobes deal mostly with sensation. The temporal lobes are primarily responsible for a variety of sensory functions such as learning, memory, emotion, and visual stimuli. The occipital lobes primarily function to interpret.

Many areas of the cerebrum operate together to produce coordinated human function. The process of communication provides a good example of this coordination. Verbal communication depends on the ability to interpret speech and translate thought into speech. Ideas usually are communicated between people by either the spoken or the written word. With the spoken word, the input of sensory information occurs through the primary auditory cortex. In auditory association areas, the sounds are interpreted as words and the words as sentences. These sentences are then interpreted by a common integrative area of the cortex as thoughts.

The common integrative area also develops thoughts to be communicated. Letters seen by the eyes are associated with words and sentences in the visual association areas and then integrated into thought in the common integrative area. Operating in conjunction with facial regions of the somesthetic sensory area, the common integrative area initiates a series of impulses, each representing a syllable or word, and transmits them to the secondary motor area controlling the larynx and mouth. The speech center, in addition to controlling motor activity of the larynx and mouth, sends impulses to the respiratory center of the secondary motor cortex to provide appropriate breath patterns for the speech process.

Cortex

As mentioned, the cortex is the most superficial layer of the cerebrum. It is responsible for all higher mental functions, such as judgment, language, memory, creativity, and abstract thinking. It also functions in the perception, localization, and interpretation of all sensations and governs all voluntary

motor activities (see Fig. 32-9). Various areas of the cortex have been identified as having different motor and sensory functions, but some of these areas are being implicated in other functions as well. For example, the occipital area, which usually takes sensory impulses from the eyes and integrates them into visual images, is now known to function in some learning processes of blind people.

Basal Ganglia

The basal ganglia function in cooperation with other lower brain parts in providing circuitry for basic and subconscious bodily movements. They provide the necessary background muscle tone for discrete voluntary movements, smoothness and coordination in functions of muscle antagonists, and the basic automatic subconscious rhythmic movements involved in walking and balance. Lesions of the basal ganglia produce various clinical abnormalities, such as chorea, hemiballismus, and Parkinson's disease.

Diencephalon

The diencephalon, a major division of the cerebrum, lies below the cerebral hemispheres. The diencephalon is a paired structure on each side of the third ventricle, directly above the brainstem. The most important areas of the diencephalon are the thalamus and the hypothalamus, described in the following sections. The subthalamus is the ventral portion of the thalamus, and the epithalamus is an area that contains the pineal gland, thought to play an important role in diurnal rhythms (Fig. 32-10).

Thalamus

The thalamus (see Fig. 32-10) functions as a sensory and motor relay center. Its neurons receive sensory impulses from synapsing neurons that originate at lower levels in the spinal cord or brainstem and relay sensory input, including sight, sound, and touch, to the sensory cortex. The thalamus also functions in the gross awareness of certain sensations, most notably pain. Discrete localization and the finer perceptual details of sensations are cortical functions, but awareness occurs at the thalamic and even midbrain areas. Finally, the thalamus is involved in the reticular activating system (RAS), the neural system that promotes wakefulness and consciousness and possibly some aspects of attention.

Hypothalamus

The hypothalamus is the seat of neuroendocrine interaction. It has a part in controlling visceral, autonomic, endocrine, and emotional function. It is connected to the reticular formation of the brainstem as well as the diencephalon, the cortex, and the pituitary gland. This area of the brain also contains some of the centers for coordinated parasympathetic and sympathetic stimulation, as well as those for temperature regulation, appetite regulation, regulation of water balance by antidiuretic hormone (ADH), and regulation of certain rhythmic psychobiological activities (eg, sleep).

Brainstem

A major subdivision of the brain, the brainstem consists of the midbrain, pons, and medulla and contains respiratory and autonomic control centers, as well as many tracts of myelinated motor axons that are passing through on their way down to the spinal cord or sensory axons passing through on their way up to the thalamus. In addition, areas of the brainstem are important in coordinating activity of the cerebellum with the rest of the brain. Also, 10 of the 12 cranial nerves originate from this area (Fig. 32-11).

Midbrain

The midbrain lies between the diencephalon and the pons. It contains the aqueduct of Sylvius, many ascending and descending nerve fiber tracts (white matter), and centers for auditory and visually stimulated nerve impulses. The Edinger-Westphal nucleus in the midbrain contains the autonomic reflex centers for pupillary accommodations

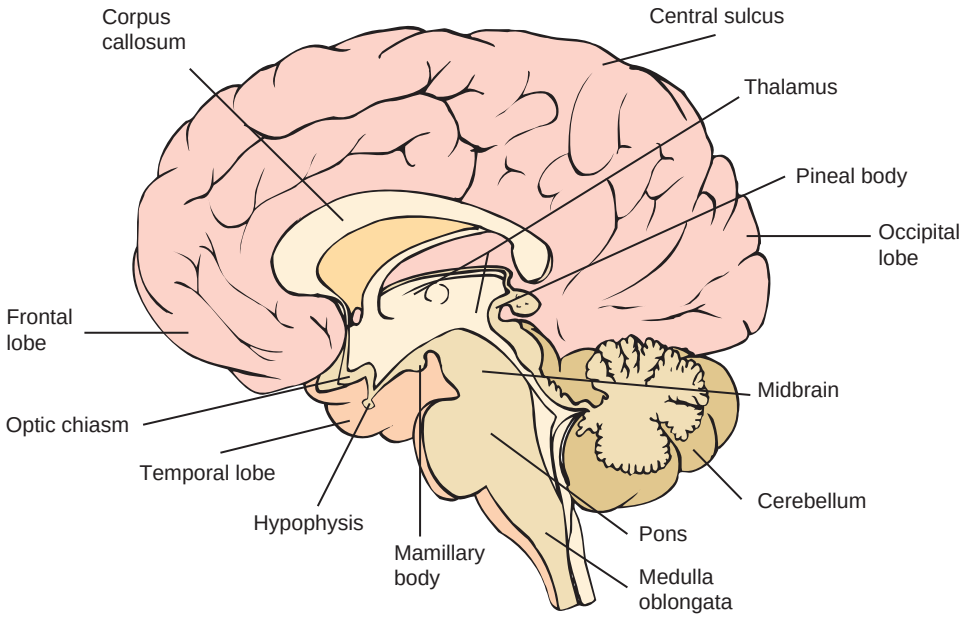

FIGURE 32-10 ▲ Lateral view of the human brain, showing the parts of the brainstem, the cerebellum, and other major landmarks. (From Cohen H: Neuroscience for Rehabilitation, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 1999.)

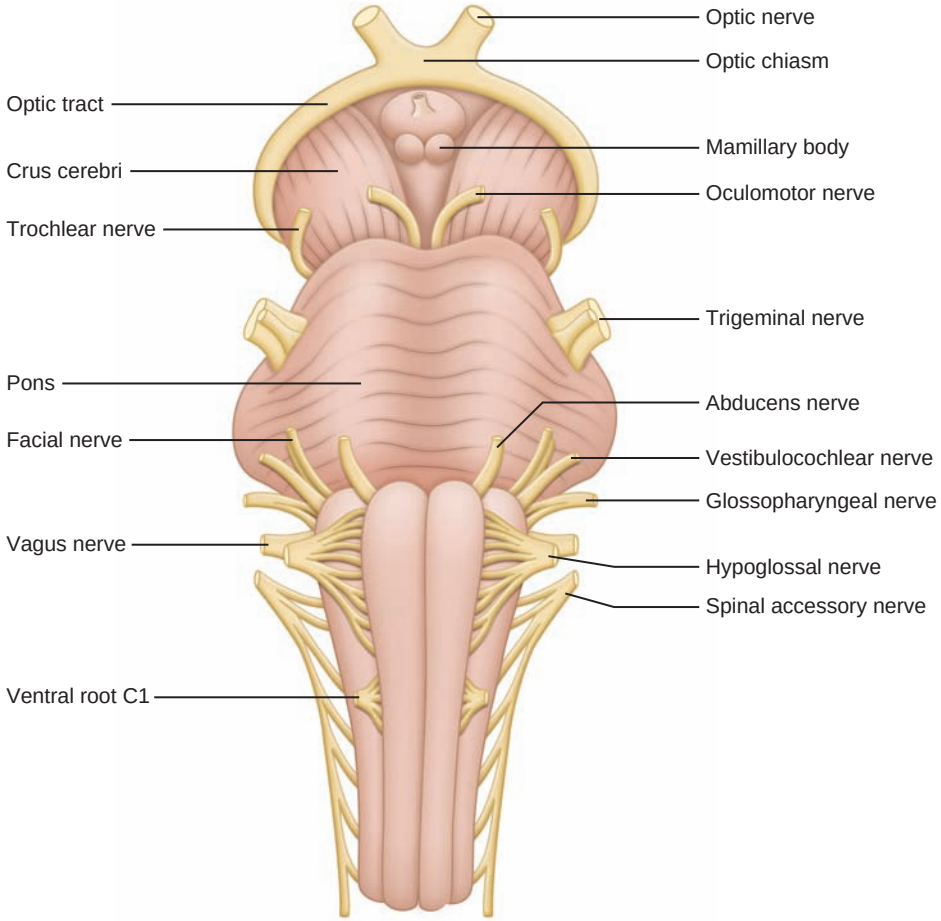

FIGURE 32-11 ▲ Anterior surface of the brainstem, showing the emergence and entrance of most of the cranial nerves.

to light. It receives sensory fibers from the retina through cranial nerve II and sends motor impulses by way of sympathetic and parasympathetic fibers (cranial nerve III) to the smooth muscles of the iris. Impaired pupillary accommodation means that at least one of these inputs or outputs is damaged or that the midbrain is suffering insult (often from tentorial herniation or stroke). Cranial nerve IV also originates in the midbrain.

Pons

The pons lies between the midbrain and the medulla and has cell bodies of fibers contained in cranial nerves V, VI, VII, and VIII. It contains respiratory centers and fiber tracts connecting higher and lower centers, including the cerebellum.

Medulla Oblongata

The medulla lies between the pons and the spinal cord. It contains centers that regulate vital functions, such as breathing, cardiac rate, and vasomotor tone, as well as centers for swallowing, vomiting, gagging, coughing, and sneezing reflex behaviors. It also contains the fourth ventricle. Cranial nerves IX, X, XI, and XII originate in the medulla. Impairment of any of the vital functions or reflexes involving these cranial nerves suggests medullary damage.

Functionally Integrated Brainstem Systems

Four networks of neurons in the brainstem should be mentioned. They are the integrated systems responsible for posture and equilibrium, consciousness, emotional reactions, and sleep.[7]

BULBORETICULAR FORMATION. The bulboreticular formation is a network of neurons in the brainstem that helps maintain balance and erect posture. This area receives sensory information from a variety of sources, including the peripheral sensory receptors that are relayed from the spinal cord, the cerebellum, the inner ear vestibular apparatus, the motor cortex, and the basal ganglia. Therefore, the bulboreticular formation is an integrative network for sensory information and motor information that has to do with body posture and balance. Output from the bulboreticular formation travels down descending fibers to internuncial neurons in the spinal cord, which synapse with motor neurons. This output alters the tonus of muscles maintaining balance and erect posture and positions of major body parts (trunk, appendages) necessary for the performance of discrete actions (eg, writing at a table, walking).

RETICULAR ACTIVATING SYSTEM. The RAS is an ascending nerve fiber system originating in the midbrain and thalamus. The RAS is stimulated by sensory impulses from various sources. These include input from the optic and acoustic cranial nerves, somesthetic impulses from the dorsal

column and spinothalamic pathways, and fibers from the cortex. Therefore, the RAS is an integrative system that receives sensory information concerning light, sound, and touch that may indicate a need for alertness. Excitatory output of the RAS extends to a variety of higher centers, including the cortex. In this way, the RAS can stimulate these centers to maintain alertness. The stimulation of the cortex by the RAS seems to be the major physiological basis for consciousness, alertness, and attention to various environmental stimuli. Decreased activity of the RAS produces decreased alertness or levels of consciousness, including stupor and coma. Inactivation of the RAS can result from anything that interrupts the entry of a critical amount of sensory input or from any damage that prevents the RAS fibers from sending impulses to the cortex.

LIMBIC SYSTEM. The hypothalamus, the cingulate gyrus of the cortex, the amygdala and hippocampus in the temporal lobes, and the septum and interconnecting nerve fiber tracts among these areas compose a functional unit of the brain called the limbic system. This system provides a neural substrate for emotions (eg, terror, intense pleasure, eroticism). This region of the brain is involved in emotional experience and in the control of emotion-related behavior. Also, it is here that neural pathways provide a connection between higher brain functioning and endocrine or autonomic activities.

SLEEP CENTERS. The release of stored serotonin from axon terminals in the diencephalon, medulla, thalamus, and a small forebrain area, collectively called DMTF, results in inactivation of the RAS and activation of the DMTF. DMTF activity results in the four stages of sleep. During sleep stages III and IV, parasympathetic activity (with decreased heart rate, respiratory rate, and so forth) predominates, and sleepwalking, sleep talking, and nocturnal enuresis occur.

Rhythmic discharges (about four to eight times per night, from 10 to 20 minutes per episode) from the pontine nuclei during sleep result in rapid eye movement sleep, during which approximately 80% of all dreaming occurs and sympathetic nervous system activity predominates. Based on circadian rhythmicity and decreasing cerebral serotonin levels, the RAS is reactivated in the morning, after 6 to 8 hours of sleep. See Chapter 2, Box 2-2, on page 19 for a review of the stages and characteristics of sleep.

Cerebellum

The cerebellum (see Fig. 32-10) is located just superior and posterior to the medulla. It receives "samples" of all ascending somesthetic sensory input and all descending motor impulses. Use of these connections enables the cerebellum to match intended motor stimuli (before they reach the muscles) with actual sensory data. This ensures an optimal match for voluntary motor "intention" with actual motor action, with time to alter the motor message in case of error. It sends its own messages to the basal ganglia and cortex and to parts of the brainstem.

The cerebellum functions to produce smooth, steady, harmonious, and coordinated skeletal muscle actions; maintain equilibrium; and control posture without any jerky or uncompensated movements or swaying. The cerebellum is also involved in motor learning and is responsible for reflexive activities that occur when motor learning is complete, such as correcting one's balance when riding a bike. Cerebellar disease can produce typical symptoms, the most prominent of which are disturbances of gait, equilibrium ataxia (overstability or understability of the walk), inability to perform rapid repetitive movements, and characteristic intention tremors.

Spinal Cord

The spinal cord lies within the neural canal of the vertebral column for protection from traumatic injury. The bony structures of the spine, along with those of the skull, are one mechanism for protection of the delicate structures of the CNS (see Fig. 32-5, p. 696 and Fig. 32-12). The vertebral column of the spine is composed of 33 vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 sacral (fused into one), and 4 coccygeal (fused into one). Each vertebra is composed of two essential parts, an anterior body

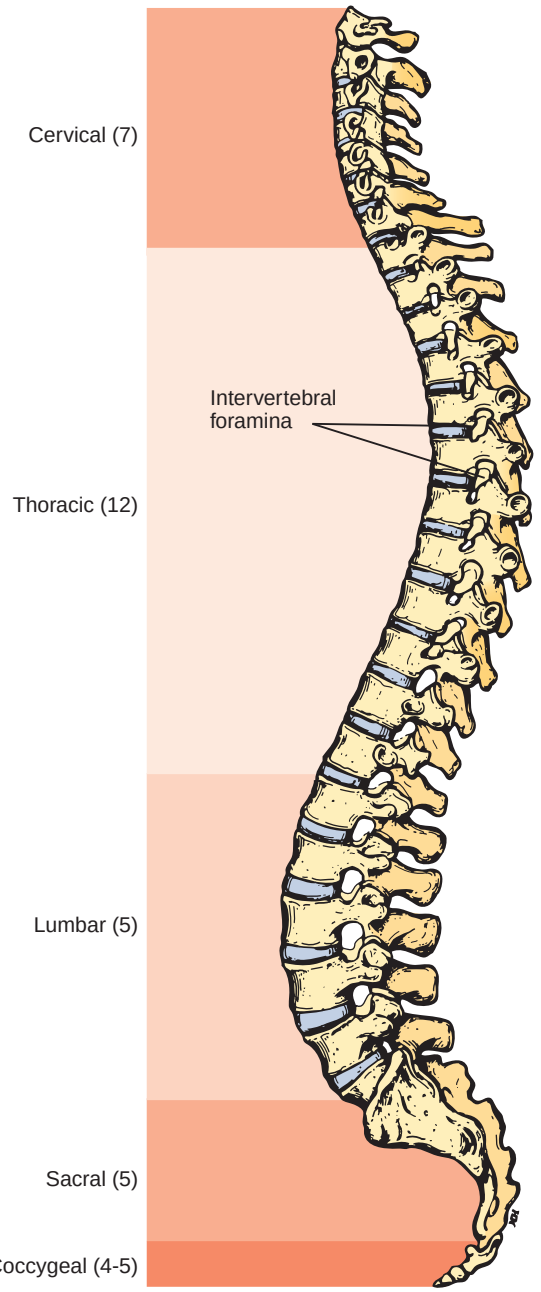

FIGURE 32-12 ▲ Lateral view of the adult vertebral column. (From Hickey JV: The Clinical Practice of Neurological and Neurosurgical Nursing, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 48.)

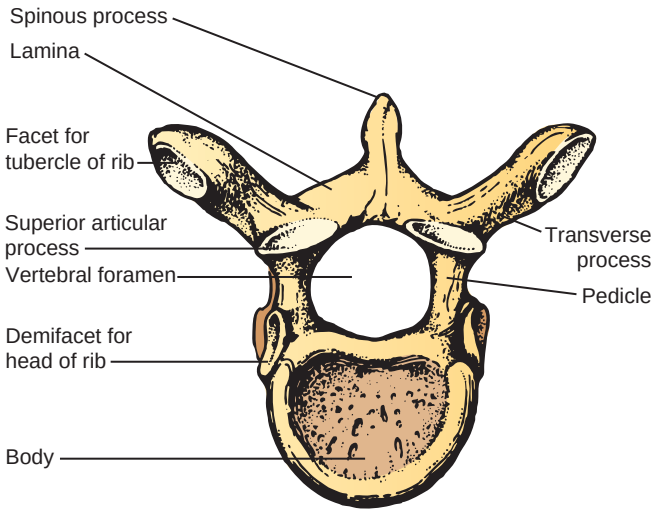

FIGURE 32-13 ▲ The sixth thoracic vertebra with anatomical markings. The vertebral foramen is the site of the spinal cord, and the spinous and transverse processes serve as places for attachments for muscles. The articular processes form synovial joints between the vertebrae. The vertebral body is opposed to superior and inferior intervertebral disks. (From Hickey JV: The Clinical Practice of Neurological and Neurosurgical Nursing, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 416.)

and a posterior arch, which form a protective ring (vertebral foramen) around the spinal cord. The arch has two pedicles and two laminae to support seven processes (four articular, two transverse, and one spinous), on which muscles and ligaments can attach (Fig. 32-13). The first cervical vertebra, the atlas, supports the weight of the head by articulating with the occiput of the skull. The second cervical vertebra, the axis, has a perpendicular projection called the odontoid process that the atlas sits on; this allows for lateral rotation of the head (Fig. 32-14).

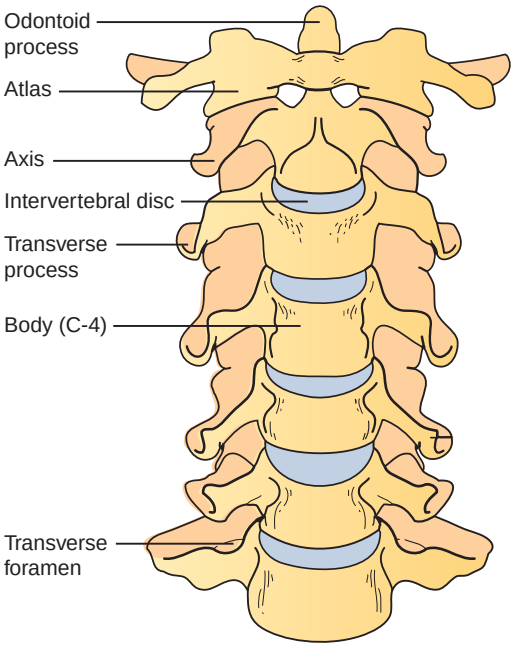

FIGURE 32-14 ▲ The cervical spine. Note odontoid process of C2 and the atlas, C1, positioned on top of C2. (Adapted from Hickey JV: The Clinical Practice of Neurological and Neurosurgical Nursing, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 50.)

In addition to the bony structures of the spinal column, ligaments and the intervertebral disks also protect the spinal cord by providing support and stability to the vertebral column. The anterior longitudinal ligament and the posterior longitudinal ligament hold the disks and vertebral bodies in position. The intervertebral disks are fibrocartilaginous, disk-shaped structures located between the vertebral bodies from the second cervical vertebra to the sacrum. These disks, which act as shock absorbers between the vertebrae, have a central core known as the nucleus pulposus surrounded by a fibrous capsule known as the anulus fibrosus (Fig. 32-15).

The spinal cord extends down and fills the neural canal to the level of about the second lumbar vertebra in an adult. Over the entire length of the vertebral column, a pair of spinal nerves exits between adjacent vertebrae at its respective level (eg, C5, T11, L1, S1). However, because the cord is shorter than the spinal column, the level of the cord that gives rise to a particular pair of spinal nerves is above the vertebra of that level. For instance, the two spinal nerves that leave the spinal column between the L4 and L5 vertebrae have to travel down the neural canal from the cord level L4, which is actually up at about vertebral level T12. Below the point at which the cord terminates, the neural canal is filled with descending spinal nerves collectively

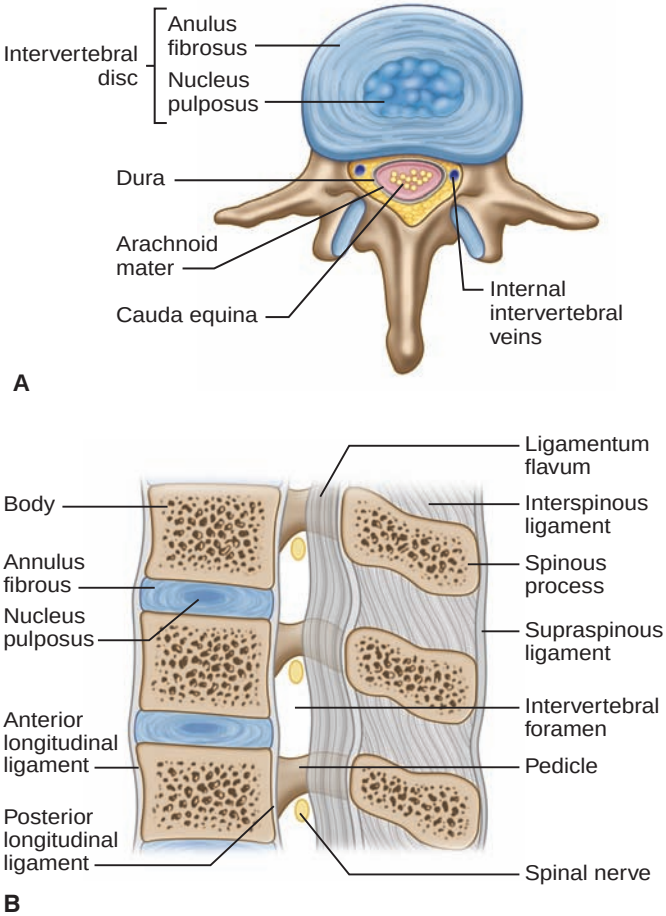

FIGURE 32-15 ▲ **A**: Third lumbar vertebra seen from above, showing the intervertebral disk. **B**: Sagittal section through three lumbar vertebrae, showing the ligaments and the intervertebral disks. (Adapted from Hickey JV: The Clinical Practice of Neurological and Neurosurgical Nursing, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 49.)

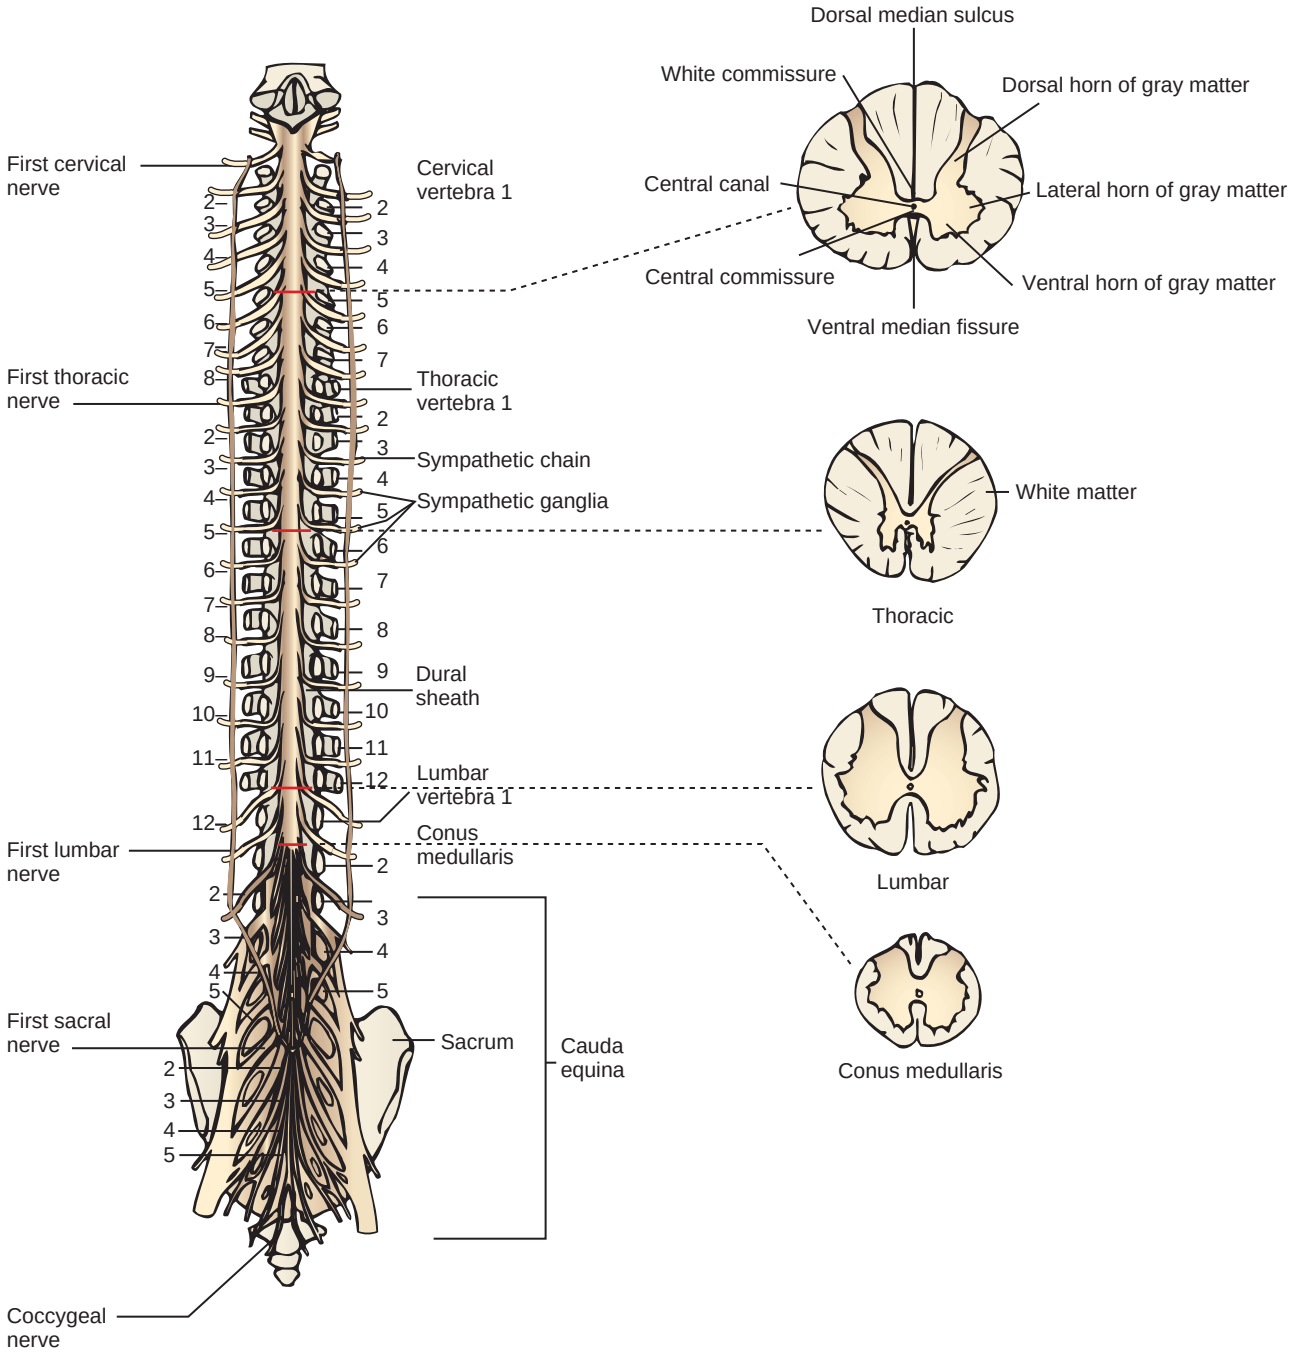

FIGURE 32-16 ▲ The spinal cord within the vertebral canal. The spinal canal and meninges have been opened. The spinal nerves and vertebrae are numbered on the left. Cross (transverse) sections with regional variations in gray matter and increasing proportions of white matter as the cord ascends appear on the right. (Adapted from Hickey JV: The Clinical Practice of Neurological and Neurosurgical Nursing, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 69.)

known as the cauda equina (horse's tail), which exit the neural canal at the vertebra that corresponds to the cord level from which they arose (Fig. 32-16). Because neurons occupy less space in the canal at lower lumbar levels, it is here that spinal taps may be performed safely. This anatomical fact also explains why injuries to lumbar and lower thoracic vertebrae can produce impairment at disproportionately lower body levels.

Within the cord lie ascending sensory fibers and descending motor fibers, many of which are myelinated and appear as white matter. Interneurons, and the nerve cell bodies and dendrites of the second-order somatic (voluntary) and first-order autonomic motor neurons, are not myelinated and appear as gray matter. The central area of the cord contains nerve cell bodies and internuncial neurons (ie, nerve cells contained entirely within the cord) and also appears as gray matter. The gray matter has left and right dorsal and ventral projections (Fig. 32-17). Nerve cell bodies of motor neurons supplying skeletal muscles lie in the ventral horns. Nerve cell bodies of the sympathetic preganglionic neurons lie in left and

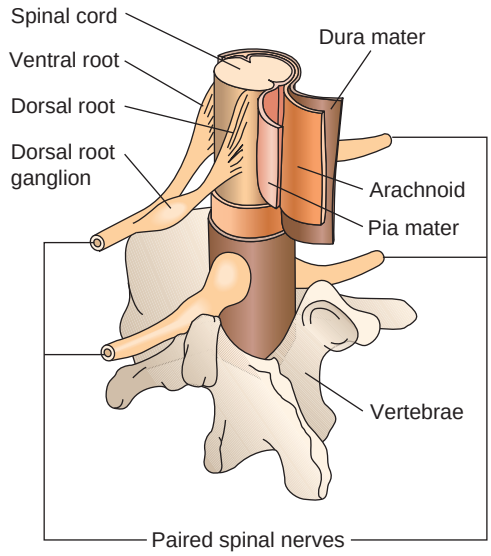

FIGURE 32-17 ▲ Spinal cord and meninges. (From Porth CM: Pathophysiology: Concepts of Altered Health States, 8th ed. Philadelphia, PA: Wolters Kluwer Health: Lippincott Williams & Wilkins, 2009, p 1211.)

right lateral projections or horns of gray matter referred to as the intermediolateral cell column in the thoracic and upper lumbar cord.

It is important to realize that the spinal cord is really an extension of the brain and contains many integrative and processive functions. For instance, the substantia gelatinosa contains nerve terminals of descending neurons, and also interneurons, which function to moderate ascending pain impulses (see later section on Pain, pp. 716–718).

▲ Peripheral Nervous System

The PNS consists of 12 pairs of cranial nerves and 31 pairs of spinal nerves and includes all neural structures lying outside the pia mater of the spinal cord and brainstem. The parts of the PNS inside the neural canal and attached to the ventral and dorsal surfaces of the cord are called the spinal nerve roots. Those attached to the ventrolateral surface of the brainstem are the cranial nerve roots.

Functionally, the PNS is separated into sensory and motor divisions. The sensory division includes sensory neurons that innervate the skin, muscles, joints, and viscera and provide sensory information about the environment outside and inside the body to the CNS. The motor division includes motor neurons that innervate skeletal muscles and the autonomic nervous system (ANS) that innervates smooth and cardiac muscle and glands. The ANS is responsible for regulating the ongoing functions of many organ systems, such as blood pressure, heart rate, and gastrointestinal activity.

Cranial Nerves

The 12 pairs of cranial nerves supply motor and sensory fibers mostly to the structures of the head, neck, and upper back, although cranial nerve X, the vagus nerve, supplies the viscera to about the level of the waist (Table 32-1). Most cranial nerves originate in the brainstem (see Fig. 32-11, p. 701), except cranial nerves I and II, which originate in the diencephalon. Cranial nerves are classified as either sensory, motor, or mixed (carrying both sensory and motor signals). They bring input from the special senses (vision, hearing, smell) and somatic sensory input from the face and head into the brain. They also send motor commands out to the muscles and glands of the head and neck to control facial expression, eye movements, movements of the structures in the mouth and throat, movements of the head and neck, and autonomic functions of the eyes, salivary glands, and viscera in the chest and upper abdomen. Most cranial nerves contain fibers of more than one functional type; thus, most cranial nerves are associated with more than one nucleus in the brainstem (see Table 32-1).

Spinal Nerves

Spinal nerves are attached to the spinal cord in pairs; there are 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal pair of spinal nerves (see Fig. 32-16). In the cervical spine, the spinal nerves exit above the vertebrae. At C7, an extra spinal nerve exists below C7, giving rise to the C8 spinal nerve. All of the rest of the spinal nerves (ie, the thoracic, lumbar, sacral, and coccygeal spinal nerves) exit below the vertebrae. Spinal nerves contain both sensory and motor fibers. Each spinal nerve attaches to the cord by a dorsal and a ventral root. The dorsal root houses the nerve cell bodies of sensory neurons. Motor axons, whose nerve cell bodies lie in the gray matter of the ventral horn of the cord, traverse the ventral root. Thus, damage to the dorsal root may impair sensory function without impairing motor function, and vice versa. However, a spinal nerve injury distal to the roots could damage both sensory and motor functioning. A dermatome is the area of skin innervated by sensory fibers from a particular spinal nerve emanating from a particular segment of the spinal cord (see Chapter 37, Fig. 37-3, p. 829).

Sensory Division

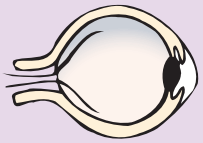
The sensory division of the nervous system is composed of sensory receptors, sensory neurons whose axons form sensory pathways, and perceptive areas of the brain.

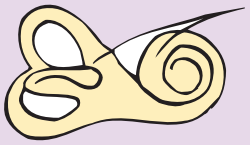
Sensations and Sensory Receptors

Sensations often are divided into the special senses (eg, vision, hearing, and smell) and those termed somesthetic sensations (eg, pain, touch, and stretch). In this section, only somesthetic sensations are discussed. Such sensations provide information about, for example, body position and conditions of the external and internal environment. These are called proprioceptive, exteroceptive, and visceral sensations, respectively.

Proprioceptive sensations describe the physical position state of the body, such as muscle tension, joint flexion or extension, tendon tension, and deep pressure in dependent parts, such as the feet while one is standing or the buttocks while one is sitting. Exteroceptive sensations monitor conditions on the body surface, such as temperature and pain.

Table 32-1 The Cranial Nerves

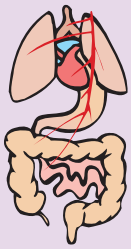
Cranial Nerve	Tract(s)	Function	Location of Origin
			
I. Olfactory	Sensory	Sense of smell	Diencephalon
			


II. Optic	Sensory	Vision	Diencephalon
			
III. Oculomotor	Parasympathetic Motor	Pupillary constriction Elevation of upper eyelid and four of six extraocular movements	Midbrain
IV. Trochlear	Motor	Downward, inward movement of the eye (superior oblique)	Midbrain
			
V. Trigeminal	Motor Sensory	Muscles of mastication and opening jaw Tactile sensation to the cornea, nasal and oral mucosa, and facial skin	Pons
VI. Abducens	Motor	Lateral deviation of eye (lateral rectus)	Pons
			
VII. Facial	Parasympathetic Motor Sensory	Secretory for salivation and tears Movement of the forehead, eyelids, cheeks, lips, ears, nose, and neck to produce facial expression and close eyes Tactile sensation to parts of the external ear, auditory canal, and external tympanic membrane Taste sensation to the anterior two thirds of the tongue	Pons
			


VIII. Vestibulocochlear (also known as acoustic or cochlear)	Sensory	*Vestibular branch:* Equilibrium *Cochlear branch:* Hearing	Pons

(continued on page 707)

Table 32-1 The Cranial Nerves (continued)

Cranial Nerve	Tract(s)	Function	Location of Origin
IX. Glossopharyngeal	Parasympathetic	Salivation	Medulla
	Motor	Voluntary muscles for swallowing and phonation	
	Sensory	Sensation to pharynx, soft palate, and posterior one third of tongue Stimulation elicits gag reflex	
			


X. Vagus	Parasympathetic	Autonomic activity of viscera of thorax and abdomen	Medulla
	Motor	Involuntary activity of visceral muscles of the heart, lungs, and digestive tract Innervation of striated muscles of the soft palate, pharynx, and larynx for voluntary swallowing	
	Sensory	Sensation to the auditory canal, pharynx, larynx, and viscera of the thorax and abdomen	
XI. Spinal accessory	Motor	Sternocleidomastoid and trapezius muscle movements	Medulla
			
XII. Hypoglossal	Motor	Tongue movements	Medulla

Artwork from Evans MJ: Neurologic Neurosurgical Nursing, 2nd ed. Springhouse, PA: Springhouse, 1995, pp 7–8.

Visceral sensations are similar to exteroceptive sensations, except that they originate from within the body and monitor pain, pressure, and fullness from internal organs.

The sensory receptors for somesthetic sensations are basically dendrites, which can have the form of free nerve endings or specialized receptors. Free nerve endings are nothing more than small, filamentous branches of dendrites. They detect crude sensations of touch, pain, heat, and cold. The precision is crude because different neurons have overlapping distributions of their dendrites. These nerve endings are the most widely distributed and most numerous of sensory receptors and perform the general discriminatory functions. The more specialized sensory receptors discriminate between very slight differences in degrees of touch, pain, heat, and cold. Indeed, the special exteroceptive end organs for detecting light touch, warmth, and cold differ structurally from one another and are specific in their function. The physiological basis for this specific function has not been determined but is presumed to be based on some specific physical effect on the receptor itself.

Sensation from the internal organs may come from specialized sensory receptors, such as baroreceptors and chemoreceptors that reside in arterial walls, or stretch receptors in sphincters. In contrast, visceral pain is the result of stimulation of unmyelinated, raw sensory nerve endings, usually by stretch, as might happen during swelling or distention, or by pressure on the organ as might happen from compression by a tumor. For both specialized and unspecialized visceral receptors, the sensory fibers run within the autonomic nerves (sympathetic or parasympathetic) back to CNS centers that are closely associated with autonomic motor responses. For this reason, these sensory fibers are sometimes referred to as autonomic afferent fibers. This is a somewhat misleading name because the ANS is purely a motor system (see later), and the name refers only to the anatomical location of sensory fibers within the nerves that also carry autonomic motor fibers.

Stimulation of a sensory receptor initiates an electrical charge (generator potential) that depolarizes the sensory dendrite, causing a series of nerve impulses to travel along the sensory dendrite to the cell body. As mentioned, the sensory neuron cell body is contained in the dorsal root ganglion just outside the spinal cord. The sensory neuron sends axons into the spinal cord (or brain in the case of cranial nerves), where it synapses with projection neurons in either brain or spinal cord that carry impulses to the appropriate centers in the brain, including the thalamus, where the sensation finally may be perceived consciously. The projection neuron may synapse in the thalamus with another neuron, which relays the sensory impulse to the sensory cortex.

When the sensation first stimulates the sensory receptor in the periphery, there is a burst of impulses; if the stimulus persists, the frequency of impulses transmitted begins to decrease. All sensory receptors show this phenomenon of adaptation to varying degrees and at different rates. Adaptations to light touch and pressure occur in a few seconds, whereas pain and proprioceptive sensations adapt very little, if at all, and at a very slow rate. This adaptation results in our being unaware of the touch of our clothing to our skin or the pressure on our buttocks while we are seated. Determination of the intensity of the sensation is made on a relative rather than an absolute basis.

Although there are structurally different receptors for detecting each type of sensation, the area of the brain to which the information is transmitted determines the modality, or type of sensation, a person feels. The thalamus and sensory cortex operate together to attribute various sensory qualities and intensities to nerve impulse information they receive.

Sensory Pathways

As mentioned, sensory neurons that enter the cord synapse with projection neurons that carry the sensory information up the spinal cord. There are a number of pathways by which sensory information is transmitted up the cord by axons of the projection neurons. Depending on the type of somesthetic receptor involved, fibers of sensory neurons may, on entering the cord, do one of three things.

First, they may send axons up the cord to the medulla on the same side of the body as the sensory receptor. This tract of myelinated axons (white matter) is called the dorsal column. In the medulla, the sensory neurons synapse with projection neurons that cross over to the opposite side of the brain and travel to the thalamus. This tract is called the medial lemniscus (Fig. 32-18). It is used for conducting impulses originating from stimulation of joint, muscle, and tendon proprioceptors; vibration-sensitive receptors; and receptors in the skin involved in precise localization of touch.

Second, the sensory neurons may synapse immediately on entering the cord with projection neurons that immediately cross over to the opposite side of the cord. Fibers from these projection neurons then travel up the white matter of the cord to the thalamus. This is called the spinothalamic pathway (see Fig. 32-18). It conducts impulses concerned with pain, temperature, poorly localized touch, and sex organ sensations. Both the dorsal column–medial lemniscus pathway and the spinothalamic pathway involve crossing of the sensory information from each side of the body to the opposite side of the CNS. Therefore, sensations on each side of the body are perceived by the thalamus and sensory cortex on the opposite side. In the thalamus, neurons of both the dorsal column pathway and the spinothalamic pathway synapse with other neurons that transmit impulses to the appropriate area of the sensory cortex. Because of their final destination in the cortex, impulses from either pathway give rise to consciously perceived sensations. The sensory homunculus (Fig. 32-19) is a pictorial representation of the number of neurons in the sensory cortex that are devoted to receiving sensations from various areas of the body. It should be noted that very sensitive areas, such as the lips, have a large representation in the sensory cortex, whereas less sensitive areas, such as the trunk, have a smaller representation.

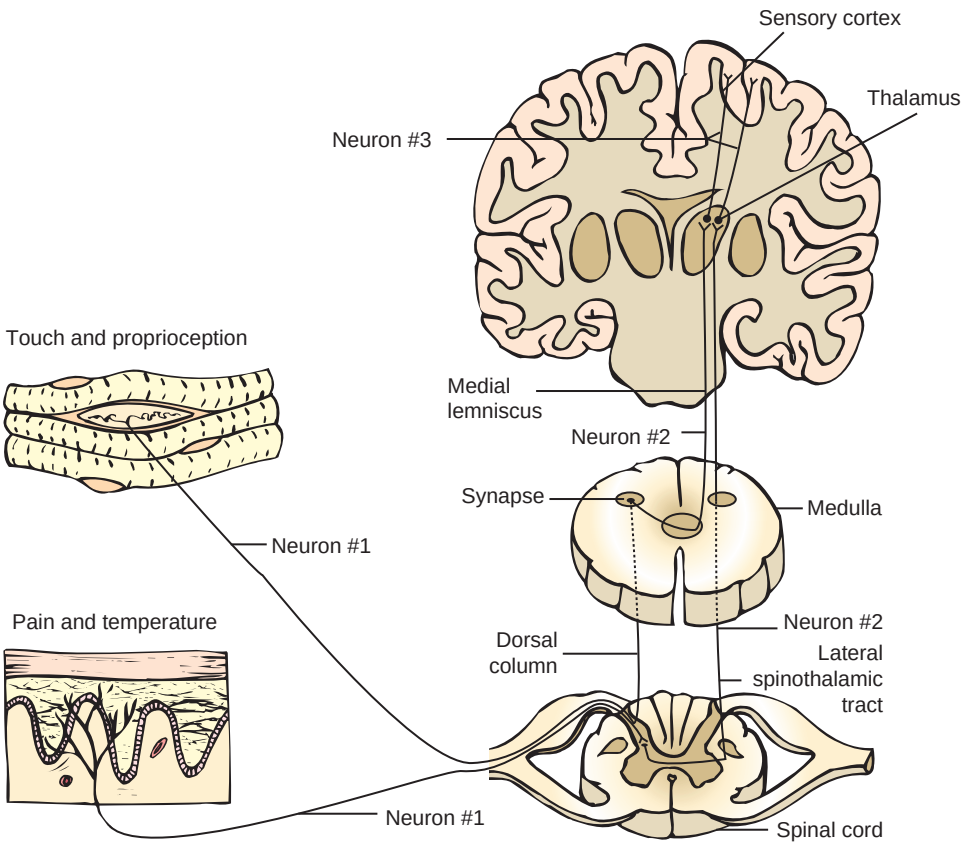


FIGURE 32-18 ▲ Pathways of ascending tracts. Sensory neurons enter the cord at the dorsal horn. Axons of sensory neurons for touch and proprioception ascend in the dorsal columns to the medulla, where they synapse with second-order projection neurons that cross (decussate) to the opposite side before ascending to the thalamus in the tract called the medial lemniscus. First-order neurons for pain and temperature enter the dorsal gray matter of the cord, where they synapse with second-order projection neurons that cross to the opposite side and ascend in the lateral spinothalamic tract to the thalamus. Third-order neurons connect both pathways from thalamus to the sensory cortex.

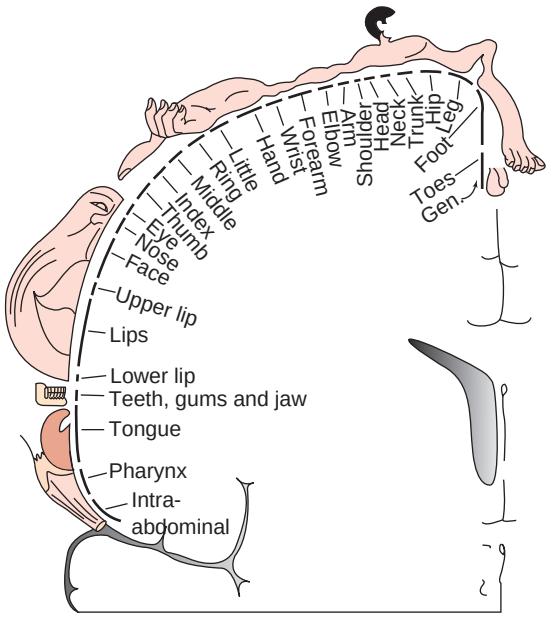

FIGURE 32-19 ▲ The sensory homunculus, a representation of the relative extent of the somatosensory cortex devoted to various body regions, as determined by stimulation studies on the human somatosensory cortex during surgery. (From Penfield E, Rasmussen T: The Cerebral Cortex of Man. New York, NY: Macmillan, 1955. Copyright © by MacMillan Publishing Co., Inc., renewed 1978 by Theodore Rasmussen.)

Third, certain sensory neurons may synapse with a projection neuron belonging to the spinocerebellar pathway. Spinocerebellar neurons do not cross over. They carry impulses only as far as the cerebellum (and possibly lower brainstem). This pathway carries impulses originating from stimulation of joint, muscle, and tendon proprioceptors. Because this pathway ends at the cerebellum, it transmits sensory information that is not perceived consciously. Instead, these data are used in reflex postural adjustments.

Motor Division and the Neuromuscular Junction

The motor division comprises the areas of the brain, descending fiber tracts, and motor neurons involved in producing or altering movement or adjusting tonus of skeletal, cardiac, and smooth muscles and in regulating the secretions of the various exocrine and certain endocrine gland cells. Muscle and glandular tissues are referred to as the effector organs of this system.

The motor division can be divided on the basis of motor neurons and effector organs into somatic and autonomic subdivisions (Fig. 32-20). The former involves skeletal muscles and the motor neurons innervating them. The latter is composed of smooth muscle, cardiac muscle, and gland cells plus the sympathetic and parasympathetic fibers innervating them.

Somatic Motor Division

Figure 32-21 depicts the major descending fiber tracts from motor areas of the cortex. The most prominent of these tracts is the corticospinal tract, often called the pyramidal tract because it originates from pyramid-shaped nerve cell bodies in the cortex. The corticospinal tract is heavily myelinated and appears as white matter in the brain and spinal cord. The fibers cross to the opposite side in an area of the medulla referred to as the decussation (crossing over) of the pyramids. Several other motor tracts originate in the cortex or in the cerebellum. These tracts may cross over in the brain or in cord centers. Motor fibers from the brain ultimately stimulate somatic motor neurons, the nerve cell bodies of which lie in the anterior (ventral) horn of the gray matter in the

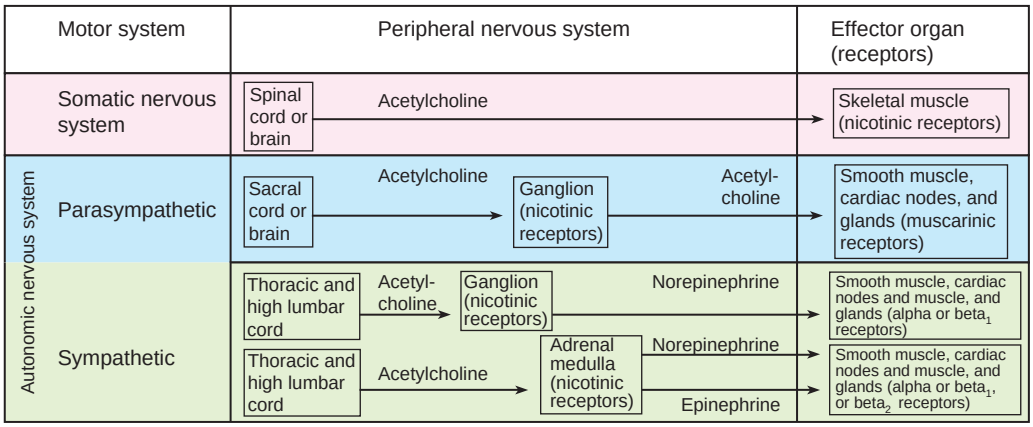

FIGURE 32-20 ▲ A comparison between the divisions of the motor systems. The somatic nervous system (*pink*) sends cholinergic motor axons from the spinal cord or brain to the skeletal muscles. Acetylcholine released from these axon terminals binds to nicotinic receptors on skeletal muscles to cause contraction. The autonomic nervous system (ANS) is composed of parasympathetic (*blue*) and sympathetic (*green*) divisions. For both divisions, preganglionic cholinergic neurons originate in the brain or spinal cord and send their axons to ganglia in the periphery, where they synapse with postganglionic neurons having ganglionic nicotinic receptors. Postganglionic neurons of the parasympathetic division are cholinergic and synapse with muscarinic receptors on end organs. Postganglionic neurons of the sympathetic division are noradrenergic and synapse with α or β_1 receptors on end organs. The adrenal medulla is innervated by preganglionic sympathetic neurons. Acetylcholine released by these neurons binds to ganglionic nicotinic receptors on cells of the adrenal medulla, causing them to release norepinephrine and epinephrine into the bloodstream.

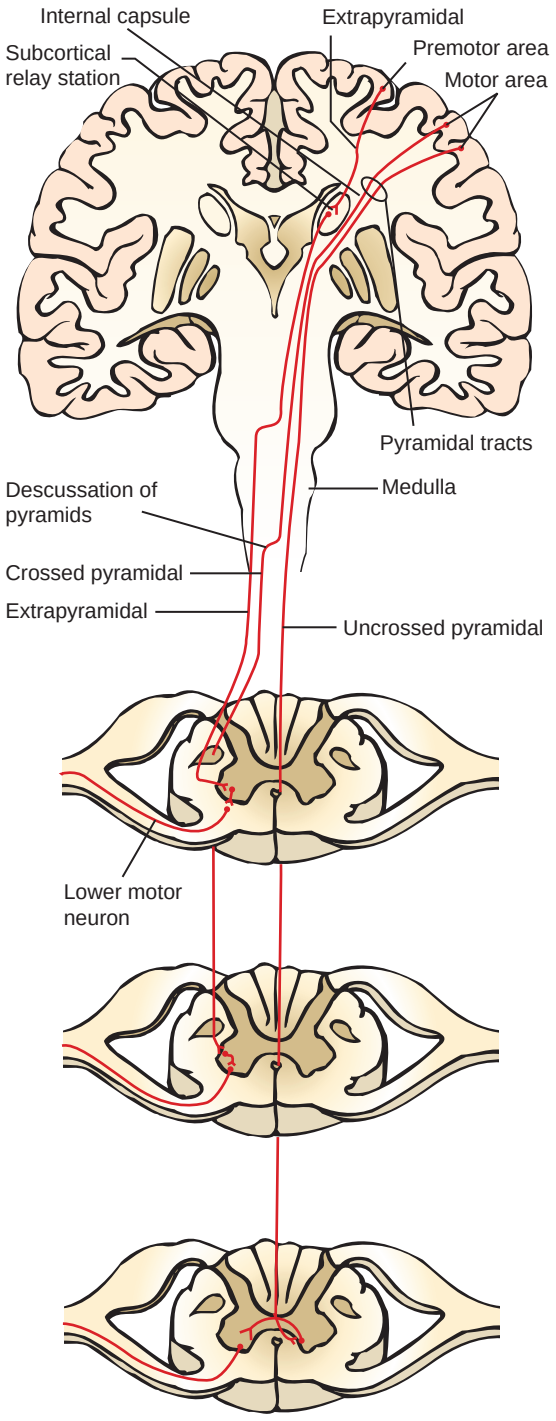

FIGURE 32-21 ▲ Diagram of motor pathways between the cerebral cortex, one of the subcortical relay centers, and lower motor neurons in the spinal cord. Decussation (crossing) of fibers dictates that each side of the brain controls skeletal muscles on the opposite side of the body.

cord. The axons of these motor neurons travel within spinal nerves and terminate at the neuromuscular junction, the synapse between the somatic motor neuron axon and the muscle cell. When a motor neuron depolarizes, acetylcholine is released into the synapse at the neuromuscular junction. It binds to nicotinic receptors on the skeletal muscle membrane, causing depolarization of the muscle cell, which stimulates contraction.

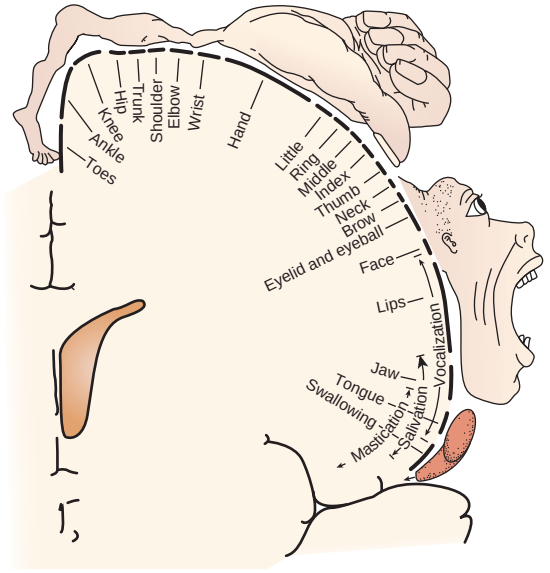

FIGURE 32-22 ▲ The motor homunculus, a representation of the relative extent of the primary motor cortex devoted to various body regions. (From Penfield E, Rasmusen T: The Cerebral Cortex in Man: A Clinical Study of Localization of Function. New York, NY: MacMillan, 1968.)

Figure 32-21 also shows several extrapyramidal (not part of the pyramidal [corticospinal] tracts) tracts arising from the brainstem centers (eg, bulboreticular formation, midbrain). Some of these cross over; others do not. Fibers in these tracts descend the cord and ultimately stimulate either somatic motor neurons, which stimulate skeletal muscle contraction, or other motor neurons (gamma efferent) that alter the tensions of stretch receptor organelles (muscle spindles) in the skeletal muscles. Alteration of spindle tension provokes a spinal reflex arc that efficiently alters skeletal muscle tonus. These extrapyramidal pathways conduct impulses that produce the automatic coordinated alterations in skeletal muscle tonus and movement that are necessary for gross motor movements (eg, walking) and for appropriate posture for conduction of finer movements (eg, sitting at a desk with arm flexed in preparation for writing).

Not shown in Figure 32-21 are descending fiber tracts that stimulate motor neurons responsible for the movement of skeletal muscles of the head (eg, tongue, face, jaw). The general pattern and myoneural transmitter are the same, except the somatic motor neuron nerve cell bodies lie in particular areas of the brain and exit through cranial nerves. These fibers must also cross over from the opposite side before synapsing with the motor neurons.

The motor homunculus (Fig. 32-22) is a pictorial representation of the number of neurons in the motor cortex devoted to each area of the body. It should be noted that areas of the body capable of fine motor movement, such as the fingers and the thumb, have abundant representation in the motor homunculus, whereas those areas not involved with fine motor movement, such as the thigh or trunk, have less abundant representation.

Neuromuscular Junction

As mentioned, motor neurons whose cell bodies are in the ventral horn of the spinal cord at each level send axons out

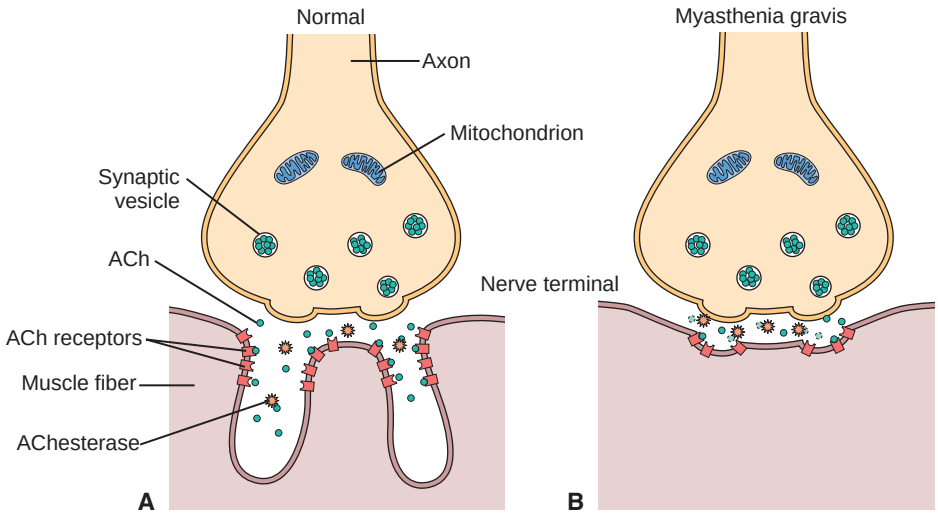

FIGURE 32-23 ▲ The neuromuscular junction. **A**: Acetylcholine (ACh), released from the motor neurons in the myoneural junction, crosses the synaptic space to reach receptors that are concentrated in folds of the endplate of the muscle fiber. Once released, ACh is rapidly broken down by the enzyme acetylcholinesterase (AChesterase). **B**: Decrease in Ach receptors in myasthenia gravis. (From Porth CM: Essentials of Pathophysiology, 3rd ed. Philadelphia, PA: Wolters Kluwer Health | Lippincott Williams & Wilkins, 2011, p 901.)

of the ventral root into each spinal nerve and innervate specific skeletal muscles. Similarly, cranial nerves that innervate skeletal muscles of the head, neck, and shoulders contain axons of motor neurons that originate in nuclei of the brainstem and pons. The axon terminals of these motor neurons end in specialized synapses with skeletal muscle cells, termed the neuromuscular junction.

Motor neurons may innervate several muscle fibers. The combination of axon terminals and the corresponding muscle fibers innervated by one motor neuron is referred to as a motor unit. The axon terminals reach into invaginations on the skeletal muscle fiber, called motor end plates, and form the highly structured synapses that compose the neuromuscular junctions (Fig. 32-23). The cell membrane of the skeletal muscle contains abundant nicotinic skeletal muscle receptors concentrated in the area of the motor end plate. These receptors bind acetylcholine, which is released from the motor neuron in response to an arriving action potential. These nicotinic receptors are slightly different from those located at ganglionic synapses of the ANS, making it possible to design drugs that bind only to skeletal muscle nicotinic receptors, not ganglionic ones. These drugs, such as tubocurarine, are used for neuromuscular blockade during anesthesia or in the intensive care unit.

Also located within the neuromuscular junction, similar to other cholinergic synapses, are many molecules of acetylcholinesterase, an enzyme that degrades acetylcholine into acetate and choline with great rapidity. This enzyme is responsible for terminating the activity of acetylcholine in the synapse. Following the degradation of acetylcholine, choline is quickly taken back up into the motor nerve terminal and used to resynthesize acetylcholine. Acetate can be used for fuel by body cells by conversion to acetyl coenzyme A. Acetylcholinesterase inhibitors are drugs that can be used to prolong the activity of acetylcholine. This may be helpful, as in the reversal of neuromuscular blockade with drugs such as neostigmine, or harmful, as in "nerve gases," such as soman, and organophosphate insecticides, such as malathion.

Myasthenia gravis is a disease of the neuromuscular junction in which antibodies develop to nicotinic skeletal muscle receptors (see Chapter 35). Immune attack of these receptors decreases the number available for activation by acetylcholine, rendering the muscle contraction weaker than normal. Lambert-Eaton syndrome, a similar condition prevalent in cancer patients, is due to decreased release of acetylcholine into the neuromuscular junction.

Autonomic Motor Division

The autonomic division contains both sympathetic and parasympathetic motor fibers. They are responsible for contraction and relaxation of smooth muscle, rate and strength of contraction of cardiac tissue, secretion by exocrine glands, and secretion by the adrenal medulla. They also influence the secretion by the islets of Langerhans in the pancreas.

The sympathetic and parasympathetic sections differ on the basis of the anatomical distribution of nerve fibers, the secretion of two different neurotransmitters by the postganglionic fibers of the two divisions, and the antagonistic effects of the two divisions on some of the organs they innervate. Figure 32-24 shows the anatomy of the sympathetic and parasympathetic nervous systems. The CNS center immediately responsible for sympathetic outflow resides in the thoracic cord. In contrast, 80% of parasympathetic activity originates in the brain and travels through cranial nerve X (the vagus nerve), and approximately 20% originates in the sacral cord and travels through pelvic nerves.

Both the sympathetic and parasympathetic motor pathways are composed of a chain of two neurons carrying nerve impulses from the CNS to the effector organ. The first neuron in the chain is the preganglionic neuron; the second is the postganglionic neuron. (A ganglion is a group of cell bodies.) Nerve cell bodies of preganglionic sympathetic neurons lie in the lateral horns of the gray matter of the thoracic and high lumbar segments of the cord (the intermediolateral cell columns); their axons exit the cord in the spinal nerve roots. The nerve cell bodies of preganglionic parasympathetic neurons lie either in certain areas of the brain and send their axons down cranial nerve X or in the lateral horns of gray matter in the sacral cord and send their axons down the pelvic nerves.

As mentioned, axons of preganglionic sympathetic neurons exit the cord and enter the ventral roots of spinal nerves. They then leave the spinal nerve to enter a nearby sympathetic ganglion by a connecting pathway termed a

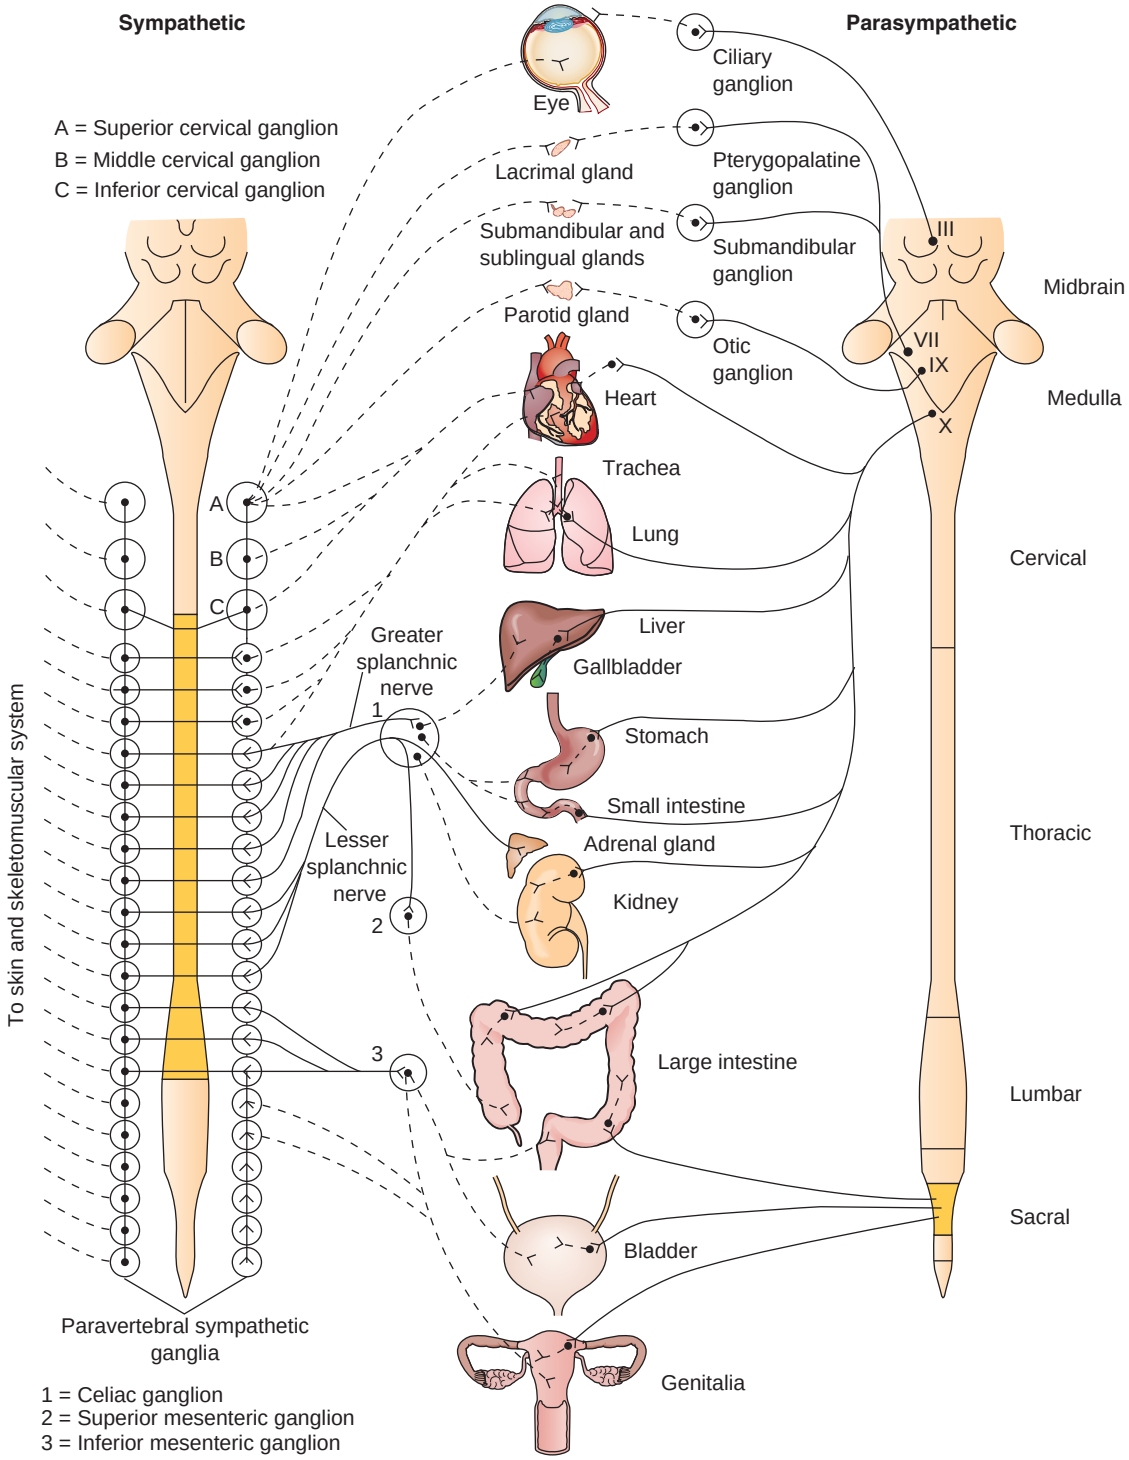

FIGURE 32-24 ▲ The ANS and the organs it affects. The **left side** illustrates the actions of the sympathetic nervous system. The **right side** illustrates the parasympathetic nervous system. (From Porth CM: Pathophysiology: Concepts of Altered Health States, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009.)

ramus. In a sympathetic ganglion, the preganglionic neuron synapses with a postganglionic one. The postganglionic sympathetic neuron then may reenter the spinal nerve or exit the ganglion by a special sympathetic nerve and travel to the effector organ. Preganglionic sympathetic neurons may also send axons up or down the sympathetic ganglion chain, where they synapse with postganglionic sympathetic neurons at different levels. In this way, the sympathetic nervous system maintains communication between its different levels up and down the cord. This anatomy makes possible unitary activation of the sympathetic system so that all sympathetic end organs are stimulated maximally at the same time. This type of activation is important for the total sympathetic response involved in flight or fight. In contrast, the parasympathetic system is more diffuse, with more indirect communication between vagal parasympathetic centers in the brain

and sacral parasympathetic centers, and relative independence of activity.

Axons of preganglionic parasympathetic neurons leave the CNS by certain cranial or spinal nerves and travel to the effector organ. At or near the effector organ, they synapse with the postganglionic neuron, which innervates the effector organ.

Acetylcholine is the neurotransmitter synthesized by all preganglionic autonomic neurons—both sympathetic and parasympathetic (see Fig. 32-20, p. 709). Neurons that use acetylcholine as their neurotransmitter are called cholinergic neurons. When an action potential is conducted down the axon of a preganglionic autonomic neuron, acetylcholine is released into the synapse between the axon terminal and the membrane of the postganglionic neuron. It diffuses across the synapse and binds to nicotinic receptors on the membrane of the postganglionic neuron, depolarizing that membrane and possibly causing the postganglionic neuron to develop an action potential. The nicotinic acetylcholine receptors on the postganglionic neuron at its synapse with the preganglionic neuron are similar to, but slightly different from, the nicotinic acetylcholine receptors on the skeletal muscle membrane at the neuromuscular junction. This is why drugs such as vecuronium and tubocurarine are able to block the skeletal muscle nicotinic receptors without affecting ganglionic nicotinic receptors at normal doses.

Acetylcholine also is the neurotransmitter synthesized by the axons of postganglionic parasympathetic neurons (see Fig. 32-20, p. 709). An action potential conducted down the axon of a postganglionic parasympathetic neuron as the result of a strong depolarizing influence received from the preganglionic neuron causes acetylcholine to be released from the axon terminal into the synapse. The acetylcholine diffuses across the synapse and binds to muscarinic acetylcholine receptors on the parasympathetic end organ. These receptors cause changes in the end organ cell that result in smooth muscle contraction, glandular secretion, hyperpolarization of the sinoatrial node of the heart (causing a decrease in heart rate), or slowing in the speed of conduction in the atrioventricular node of the heart. As noted previously, the activity of the acetylcholine is terminated by acetylcholinesterase, an enzyme in the synapse. Because muscarinic receptors are structurally different from nicotinic receptors, although both can bind acetylcholine, drugs have been developed that affect only muscarinic receptors and not nicotinic receptors. An example of such a drug is atropine, which blocks muscarinic receptors and prevents the binding of acetylcholine. This and similar drugs are called muscarinic antagonists (also known as anticholinergics), and their effects are opposite to those of acetylcholine at muscarinic receptors.

Most postganglionic sympathetic neurons synthesize norepinephrine, also called noradrenaline. For this reason, they and other neurons that use norepinephrine as their neurotransmitter are called noradrenergic neurons. When an action potential is conducted down a postganglionic sympathetic neuron because of a strong depolarizing influence received from the preganglionic neuron, norepinephrine is released from the axon terminal into the synapse. It diffuses across the synapse and binds to receptors on the cell membrane of the effector organ. These receptors may be α or β receptors; α receptors may be α_1 or α_2 receptors, and β receptors may be β_1 or β_2 receptors. The heart has mostly β_1 receptors, and the smooth muscle of the arteries and veins has mostly α_1 and α_2 receptors. The sympathetic nervous system innervates organs with α_1, α_2, and β_1 receptors, and norepinephrine activates these receptors to cause changes in the effector organs that have them. For instance, activation of β_1 receptors in the sinoatrial node by norepinephrine released from sympathetic axon terminals results in depolarization of the sinoatrial node and an increase in heart rate. Activation of α_1 or α_2 receptors in the arteries results in increased contraction by arteriolar smooth muscle and an increase in blood pressure.

The adrenal medulla is innervated by the sympathetic nervous system through preganglionic (cholinergic) sympathetic neurons. When an action potential is conducted down their axons, these neurons release acetylcholine from their axon terminals into their synapses. The acetylcholine diffuses across the synapse and binds to nicotinic receptors on the cell membranes of the adrenal medullary cells, triggering the release of some norepinephrine but mostly epinephrine from the adrenal cells into the bloodstream. Circulating norepinephrine and epinephrine can both bind to α and β receptors on sympathetic effector organs, similar to synaptic norepinephrine that is released from sympathetic nerve terminals. However, there is one important difference between norepinephrine and epinephrine. As mentioned, β_2 receptors are not innervated by the sympathetic nervous system, and norepinephrine does not bind or activate β_2 receptors to any degree. However, epinephrine is a powerful stimulator of β_2 receptors, which it reaches through the bloodstream after being secreted by the adrenal medulla. Thus, dilation of bronchiolar smooth muscle and dilation of blood vessels in skeletal muscles are important effects of β_2 receptors that are mediated by circulating epinephrine rather than by norepinephrine released from sympathetic nerve terminals or the adrenal medulla.

Although the sympathetic nerves originate in the thoracic and high lumbar cord, and parasympathetic nerves originate with nuclei that send axons down various cranial nerves or sacral spinal nerves, inputs into the patterns of autonomic function are regulated or triggered by centers in the hypothalamus, medulla, and bulboreticular formations. These centers in the CNS send impulses along descending fibers to the appropriate preganglionic autonomic neuron. In the cord, such fibers travel by special descending tracts in the white matter until they reach the appropriate level of the cord. Thus, any interruption of these descending fibers (eg, transection of cervical tracts) impedes or prevents stimulation of preganglionic autonomic neurons in the thoracic, lumbar, and sacral regions of the cord.

Inputs into the centers in the brainstem and hypothalamus that regulate sympathetic or parasympathetic outflow come from diffuse areas throughout the brain, including visual or auditory centers and areas of the brain associated with conscious thought or planning. Therefore, when we see an alarming sight, such as a car bearing down on us, or hear a frightening noise, sympathetic centers are stimulated and sympathetic outflow increases. Conversely, if we smell food, parasympathetic outflow might increase to prepare the digestive glands for secretion.

In many organ systems, the sympathetic and parasympathetic systems are antagonistic. For instance, the sympathetic system increases the rate of firing of the sinoatrial node and increases the speed of conduction in the atrioventricular node of the heart, whereas the parasympathetic system does

the opposite. The parasympathetic system activates the gastrointestinal tract, whereas the sympathetic system inhibits it. Although this is a recurring theme, it is not an absolute rule. Thus, sympathetic stimulation constricts blood vessels (through α receptors), but blood vessels are not innervated by the parasympathetic system, so an opposite effect is not produced by the parasympathetic system. The sympathetic system stimulates cardiac ventricular contractility (through β_1 receptors), but the ventricles are not innervated by the parasympathetic system, so contractility is not affected by it. The two systems actually work together in the male genitalia, where the parasympathetic system mediates erection while the sympathetic system mediates ejaculation.

Both the sympathetic and parasympathetic systems are tonically active most of the time. One or the other may be more active at a given time, but it is rare that either of them is completely silent. Therefore, a person's heart rate at any given time is a summation of the positive effects of the sympathetic system and the negative effects of the parasympathetic system. At rest, parasympathetic influence is strongest, and the heart rate is slow. With exertion or strong emotion, sympathetic activation increases, and the heart rate speeds up.

▲ Reflexes

Basically, a reflex is a motor response to a sensory input. Reflexes have three components. There is a sensory component, which may consist of only one sensory input or multiple inputs. There is an integrative CNS component that processes the sensory component and "decides" whether it is strong enough to warrant a motor response. Finally, the motor component executes the response. The motor component can consist of one motor nerve and one muscle, or several motor nerves and several muscles. The three components together constitute a "reflex arc." Reflexes are mediated by lower areas of the brain or by the spinal cord, so that they happen without conscious thought. We become aware of the sensory input and the motor response when they are communicated to our cortex, but by then, the reflex is over. However, if we know that a reflexive action is likely, such as when we see someone about to strike our knee with a reflex hammer, we can often suppress a reflex by willing ourselves not to perform the motor action. This capability illustrates that the cortex has input into the integrative CNS component of the reflex. If higher centers are damaged, the reflex still occurs. For example, people with spinal cord transections still have reflexes in areas supplied by spinal nerves below the transection. Of course, they are unaware that these reflexes are taking place because they cannot receive sensory input to their cortex from below the level of the transection.

Brain Reflexes

Brain reflexes include those involving the cardioregulatory and vasomotor centers of the medulla, plus the pupillary adjustment center, which involves the midbrain. Additional reflexes mediated by brain centers include the gag reflex, blink reflex, vomiting, and swallowing.

Because of its importance to critical care, the baroreceptor reflex will be used as an illustration of a brain reflex. The sensory components of the baroreceptor reflex are stretch receptors in various arteries, the most important of which are in the carotid sinuses and the aortic arch. These stretch receptors are actually specialized dendrites of sensory nerves that sense the stretch in the arterial wall produced by the pulse. If the blood pressure is high, the stretch receptors are highly stimulated, whereas if the blood pressure is low, the stretch receptors are not stimulated very much. The stretch receptors send nerve impulses down their dendrites to sensory ganglia near the brain in their respective nerves (cranial nerve IX—the glossopharyngeal nerve—in the case of the carotid sinuses, and cranial nerve X—the vagus nerve—in the case of the aortic arch) that are proportional to the degree of stretch. This information is communicated by sensory axons to autonomic centers in the medulla that process the information and compare it with a "set point" that represents the degree of stimulation they should receive if blood pressure were normal. If the medullary centers receive too little stimulation from the baroreceptors, they send impulses to sympathetic centers to increase sympathetic outflow. This stimulates sympathetic nerves supplying the heart to increase their release of norepinephrine, which binds to β_1 receptors in the sinoatrial node to increase heart rate and β_1 receptors in the ventricles to increase contractility. Sympathetic nerves supplying the veins release norepinephrine, which binds to α receptors, causing constriction of the veins, which increases venous return to the heart. Sympathetic nerves supplying the arteries release norepinephrine, which binds to α receptors, causing constriction of the arteries, which raises the blood pressure. The combination of increased venous return to the heart, increased heart rate, and increased contractility raises the cardiac output, which also increases the blood pressure. Finally, sympathetic nerves supplying the juxtaglomerular apparatus in the kidney release norepinephrine, which binds to β_1 receptors there, stimulating renin release. Through a series of events, renin stimulates the formation of angiotensin II, which is a potent arterial constrictor, increasing blood pressure directly; it also acts on the kidney (through aldosterone) to cause sodium and water retention. Increased retention of sodium and water further increases venous return to the heart, causing additional increased cardiac output and blood pressure. Therefore, activation of the sympathetic nervous system in response to decreased stimulation of the baroreceptors produces many consequences at the effector organs, all of which separately and together cause a rise in blood pressure. If the stretch on the baroreceptors is too high (according to the normal set point), the sympathetic nervous system is inhibited, sympathetic outflow decreases, and consequences at the effector organs are diminished.

Spinal Cord Reflexes

In one type of cord reflex, the sensory component of the reflex is the sensory neurons that send their axons to the cord through one of the spinal nerves, the CNS integrative component is the spinal cord, and the motor component is the motor neurons that supply skeletal muscles. Deep tendon reflexes belong in this classification, as does the withdrawal reflex (Fig. 32-25A). These reflexes are present at each level of the spinal cord, bilaterally.

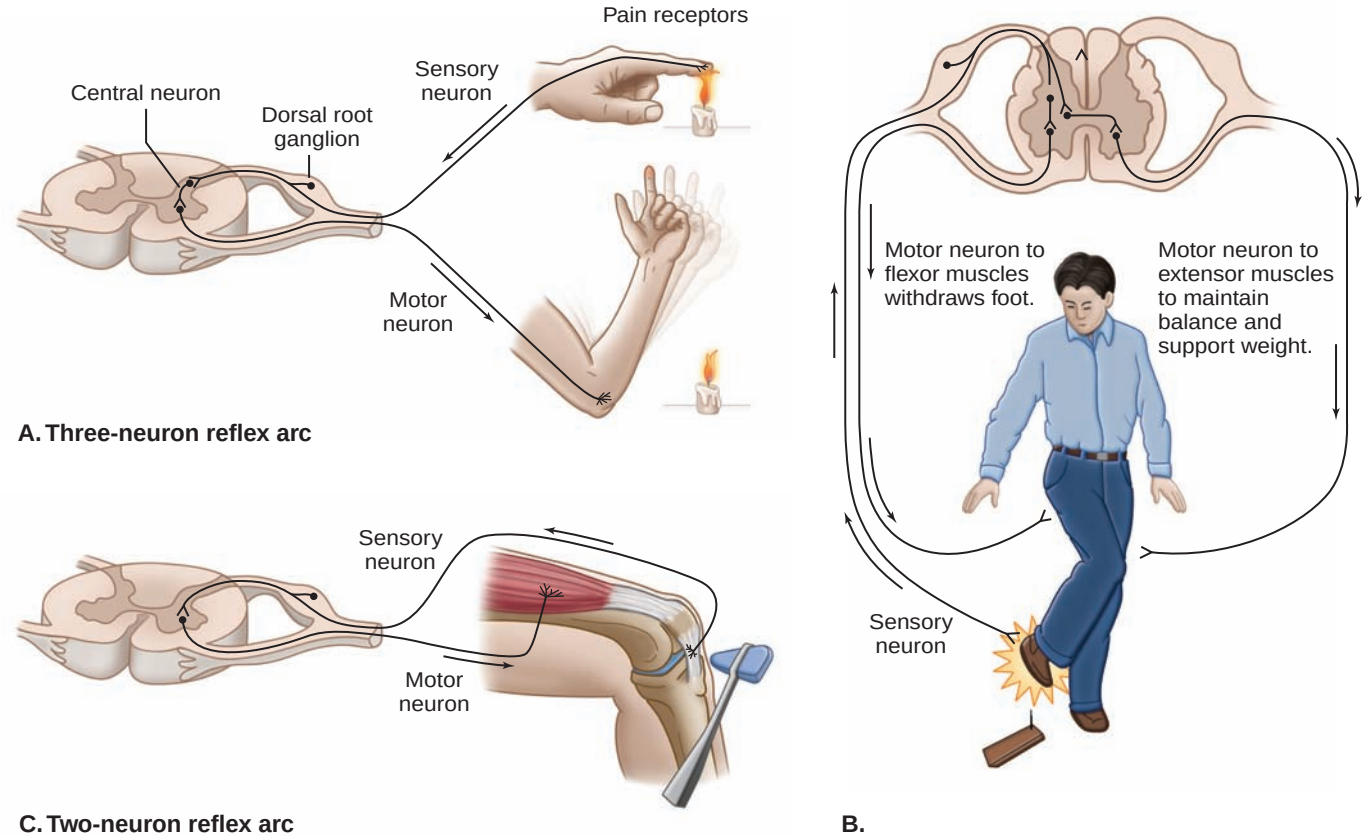

FIGURE 32-25 ▲ Reflex arcs showing pathways of impulses in response to a stimulus. **A**: The withdrawal reflex involves a three-neuron reflex arc: sensory, central, and motor neurons. **B**: The flexor and crossed extensor reflexes. **C**: Example of a stretch reflex, involving only a two-neuron reflex arc: sensory and motor neurons.

The sensory component of the withdrawal reflex is pain that originates in nociceptors, specialized dendrites of sensory neurons. Impulses are conducted through dendrites of the sensory neurons to the dorsal root ganglia next to the spinal cord and from there along sensory axons into the cord. These impulses stimulate cord interneurons, which, if the sensory input is strong enough, stimulate motor neurons whose axons innervate skeletal muscles, causing contraction. When contracted, the skeletal muscles produce withdrawal of the body part from the painful stimulus. The withdrawal reflex depends on the appropriate anatomical connections between sensory neurons, interneurons, and motor neurons in the cord. If these become nonfunctional (eg, spinal shock or physical trauma), this and other spinal reflexes do not occur.

The withdrawal reflex of one foot is associated with another reflex, the crossed extensor reflex (see Fig. 32-25B). This reflex involves stimulation of various extensor muscles in the opposite leg so that a person's weight is fully supported by the other leg while one lower extremity is withdrawn from a painful stimulus. Such a reflex is complex and involves many levels of the cord. Any imbalance, however slight, during the operation of this reflex in a normal person triggers the occurrence of additional reflexes involving the bulboreticular formation, cerebellum, and various muscles of arms and trunk to maintain balance and posture.

Another cord reflex is the stretch reflex or deep tendon reflex, most commonly illustrated by the clinical test of the knee jerk response (see Fig. 32-25C). In the deep tendon reflex, the sensory component is a specialized sense organ, the muscle spindle, which sends its signals along a spinal nerve to the dorsal horn of the spinal cord. The CNS component is a single synapse of the sensory axon terminal with the motor nerve cell body. The motor component is the motor axon supplying the skeletal muscle. In the knee jerk test, a reflex hammer blow stretches the quadriceps tendon, which stretches the muscle spindle, which sends impulses through the dendrite and axon of its nerve cell to release neurotransmitter from the axon terminal. This causes the motor neuron cell body in the spinal cord to depolarize. If the depolarization is strong enough, an action potential is conducted down the axon of the motor neuron to depolarize the muscle through release of acetylcholine into the synapse at the neuromuscular junction, as discussed previously. This causes contraction of the quadriceps, which causes the lower leg to kick forward. Other deep tendon reflexes of clinical importance are the ankle jerk and the biceps and triceps reflexes. All work similarly to the knee jerk.

An important feature of all cord reflexes involving skeletal muscles is reciprocal inhibition, which occurs in the antagonist muscle of the one stimulated. For example, when a flexor reflex stimulates the biceps, it also inhibits its antagonist, the triceps, and provides for more efficient performance of motor activities in the upper arm.

Spinal cord activities also include autonomic reflex circuits, which aid in the control of visceral functions of the body. Sensory input arises from visceral sensory receptors and

is transmitted to the spinal cord, where reflex patterns appropriate to the sensory input are determined. The signals are then transmitted to autonomic motor neurons in the gray matter of the spinal cord, which send impulses to the sympathetic nerves innervating visceral motor end organs.

A most important autonomic reflex is the peritoneal reflex. Tissue damage in any portion of the peritoneum results in the activation of this reflex, which slows or stops all motor activity in nearby viscera, such as the intestine. Other autonomic cord reflexes are capable of modifying local blood flow in response to cold, pain, and heat. This vascular control by autonomic reflexes in the spinal cord can operate as a backup mechanism for the usual brainstem control patterns in patients with transectional injuries at the brainstem. Alternatively, because the autonomic reflexes arising lower in the cord of a patient with a cervical transectional injury are not modulated by brainstem centers as they are in patients without a transection, sensory input to autonomic centers in the cord can cause extreme motor responses, similar to the development of clonus with unmodulated deep tendon reflexes. However, these motor reflexes are sympathetic, and their out-of-control state in spinal injury patients is called autonomic hyperreflexia.

Also included in the autonomic reflexes of the spinal cord are those causing the emptying of the urinary bladder and the rectum. These reflexes are mediated by the sacral parasympathetic system. When the bladder or bowel becomes distended, sensory signals from stretch receptors in the bladder or bowel wall are transmitted by sensory neurons to the internuncial neurons of the upper sacral and lower lumbar segments of the cord. These neurons in turn stimulate parasympathetic motor neurons innervating the smooth muscle in the wall of the bladder or bowel, and their respective internal smooth muscle sphincters also are reflexively inhibited by the internuncials. The result is a reflex contraction of bladder or bowel and an opening of the respective smooth muscle sphincter, thereby permitting micturition or defecation.

In addition to their smooth muscle sphincters, both the bladder and bowel have skeletal muscle sphincters that are controlled by motor neurons. Descending motor fibers from the cortex synapse with the motor neurons, and, in toilet-trained people, keep the skeletal muscle sphincters in a state of contraction, inhibiting the reflex emptying of bladder or bowel at times or places deemed inappropriate. When an appropriate time and place is reached, the person can consciously relax the skeletal muscle sphincter and either void or defecate reflexively. Toilet training of infants must await the functional maturation of these descending motor fibers. Cord transection or other damage above the level of the cord housing the neurons for the bladder or bowel evacuation reflexes interrupts some or all of these descending fibers. This produces a condition in which the patient cannot consciously control (prevent) the emptying of the bladder or bowel, or both. As long as the sacral cord and associated spinal nerves are functioning, voiding or defecation proceeds reflexively in such a patient. Damage to or interrupted function of the level of the cord housing the anatomical neuronal connections for these reflexes (as in, eg, spina bifida, spinal shock, or severe injuries to the lower sacral or lumbar cord) or damage to the spinal nerves supplying the bladder or rectum prevents reflex evacuation of bladder or bowel, or both. Such a patient may exhibit retention with overflow and does not possess any effective mechanism for emptying the bladder or bowel.

▲ Pain

The sensation of pain warrants special consideration because it plays such an important protective role. Whenever there is tissue damage, pain receptors, called nociceptors, are stimulated and send impulses back to the spinal cord. These impulses are transmitted up to the brain, where they are perceived, as previously explained. Stimulation of the nociceptors is caused by the release of substances from damaged tissue and from activation of the inflammatory response. Damaged cells release potassium and hydrogen ion, both of which can stimulate nociceptors. However, the inflammatory response that is evoked in response to tissue damage is responsible for much of the stimulation of nociceptors. For instance, histamine can stimulate nociceptors and prostaglandins, and leukotrienes can sensitize nociceptors to other stimuli. All of these substances are released by inflammatory cells (macrophages, neutrophils, and other white blood cells) that are attracted to the area of tissue injury. In addition, activated platelets participating in clot formation in response to tearing of blood vessels release serotonin, which also stimulates nociceptors. Finally, the nociceptor itself may release substance P when it is stimulated, which sensitizes it to other activating substances. Thus, pain may be due to actual tissue injury or to the inflammatory response evoked by the injury.

Pain Pathways and Their Modulation

The sensation of pain is transmitted to the spinal cord and up to the brain in the same manner as previously described for sensations in general. To review, the nociceptor is actually a specialized dendrite of a sensory neuron, whose cell body is in the dorsal root ganglion of the spinal nerve. When the nociceptor is stimulated enough to mount an action potential, the impulse travels to the dorsal root ganglion, and then down the sensory nerve's axon into the dorsal horn, where it synapses with one or more projection neurons. The projection neurons carry the pain message to the thalamus, where pain is first perceived. The projection neurons synapse in the thalamus with neurons that carry the message to the sensory cortex, where the pain is perceived as a localized sensation.

However, there is an important difference in how pain messages are transmitted to the thalamus and cortex compared with other sensations. This difference is in the way the pain impulse can be modulated by spinal influences before it ascends the cord. In brief, gating mechanisms exist in an area in the gray matter called the substantia gelatinosa at all levels of the dorsal cord. These mechanisms are capable of regulating the number of pain impulses that can enter the ascending tracts and travel to the brain.

To regulate ascending pain impulses, an area of the brainstem called the periaqueductal gray sends axons to the nucleus raphe magnus in the medulla. These axons synapse with neurons that send axons from the nucleus raphe magnus back down to all levels of the cord in the substantia gelatinosa. These neurons regulate the ability of pain-stimulated sensory

neurons to stimulate projection neurons of the spinothalamic tract. Thus, the descending fibers of the substantia gelatinosa control the entry of pain impulses into the spinal pain conduction system at the level of the cord where the particular sensory neuron enters (Fig. 32-26). Sensory stimuli cannot be conducted and, at least to the thalamus, cannot be perceived.

How do the descending fibers modulate stimulation of the projection neurons by the sensory neurons? When researchers answered this question, we also obtained the answer to another perplexing question: How do the opioid drugs relieve pain? The neurons that descend from the nucleus raphe magnus in the medulla, as well as the modulating internuncial neurons, use previously undiscovered small protein neurotransmitters collectively referred to as the endogenous opioid peptides:[7]

- Leucine-enkephalin
- Methionine-enkephalin
- β-Endorphin
- Dynorphin
- α-Neoendorphin

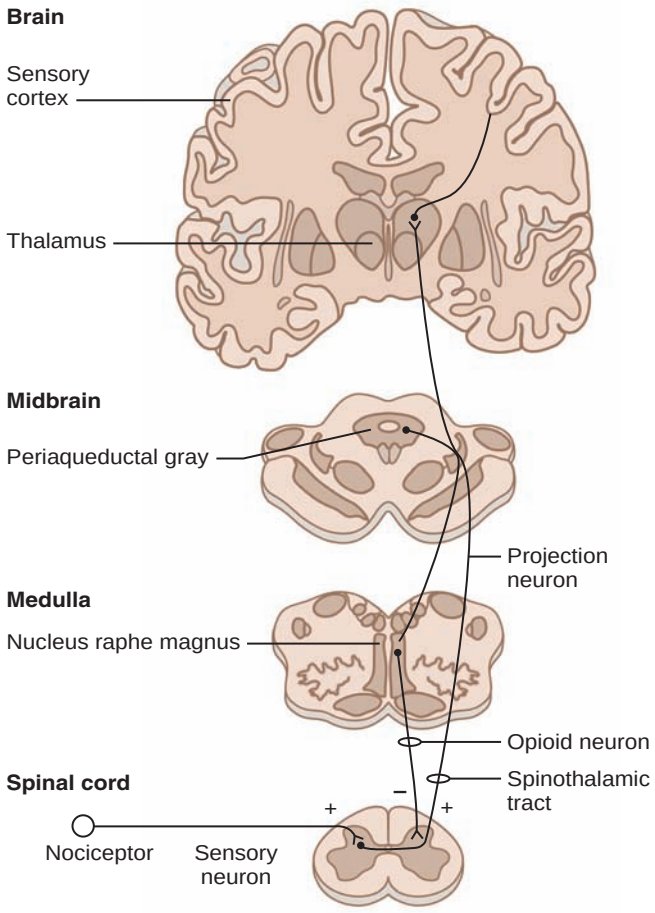

FIGURE 32-26 ▲ Modulation of ascending pain impulses by descending opioid neurons with origins in the nucleus raphe magnus and input from the periaqueductal gray. The sensory neuron's influence on the projection neuron is stimulatory (depolarizing), designated by the plus sign, but the influence of the opioid neuron is inhibitory (hyperpolarizing), designated by the minus sign. Therefore, if the strength of impulses descending in the opioid neuron is high, the projection neuron will experience fewer action potentials and send fewer pain impulses up to the thalamus.

When the endogenous opioid peptides are released into a synapse and bind to their receptors on the postsynaptic cell, they produce hyperpolarization of the postsynaptic cell. As explained previously, that makes the postsynaptic cell less likely to be able to conduct an action potential along its axon. Therefore, the descending fibers that synapse with the projection neurons can produce hyperpolarization in the projection neurons, lessening or perhaps even eliminating the pain messages that would otherwise be conducted upward by the projection neurons. Therefore, the endogenous opioid neurotransmitters, by binding to their receptors on the projection neurons, lessen the perception of pain in the thalamus and cortex. Under extreme circumstances, these descending pathways may be so inhibitory to projection neurons that they eliminate all ascending pain messages, producing complete analgesia to pain. This phenomenon is sometimes seen in victims of automobile crashes or in wounded soldiers, who continue to function, oblivious to their wounds.

What stimulates areas of the periaqueductal gray and nucleus raphe magnus to send these descending inhibitory messages to the substantia gelatinosa, resulting in the release of opioid neurotransmitters and diminution of ascending pain signals? Unfortunately, very little is known about this, but it is possible that acupuncture and electrical stimulation devices for pain control are stimulating these pathways, causing inhibition of the projection neurons by the descending neurons' release of opioid neurotransmitters.

The opioid drugs work in the same way as the endogenous opioid neurotransmitters. They bind to opioid receptors on the projection or internuncial neuron, producing hyperpolarization and a decrease in the amount of pain stimulus reaching the thalamus and the cortex. There are neurons that use the endogenous opioids as neurotransmitters in the brain as well, and opioid drugs also bind to the receptors that these neurons supply. These effects may increase the analgesic effects of the drug, or they may be responsible for other effects, such as the somnolence or dizziness that opioid drugs produce. In addition, there are opioid receptors in the intestinal tract that are stimulated by endogenous opioids and by opioid drugs. These receptors inhibit peristalsis in the intestinal tract, and this effect is responsible for the constipation and nausea often seen with opioid drugs.

Pain is a complex sensation. There is great variation in pain thresholds among different people and within the same person at different times. These variations can partly be explained by the modulation of pain pathways by endogenous opioid neurotransmitters. In addition, the amount of tissue injury and presence of chemical mediators can increase the pain experience qualitatively, quantitatively, temporally, and spatially. However, pain perception is also influenced by expectations and by cultural influences. It is helpful to remember that pain is a perception and that we have to take a person's word in describing that perception to us. It is impossible to judge a patient's pain by his or her appearance or actions, or physical or laboratory signs. The complexity of the pain pathways can make the clinical management of pain difficult, but every patient's description of his or her pain should be taken seriously. Opioid addiction is practically unknown in patients without a history of drug abuse who receive opioids for pain relief. Pain medication should be administered to most patients based on their own self-report of their pain.

Referred Pain

Referred pain is pain perceived as arising from a site that is different from its true point of origin. The "true point of origin" for this type of pain usually is some visceral organ or deep somatic structure, and the "point of reference" is some area of the body surface. Well-known examples include the referring of pain from severe cardiac ischemia to the left arm or the referring of diaphragmatic pain to the neck and shoulder.

The most generally accepted theory for referred pain is that the two sensory neurons, one from the region of the true point of origin and one from the point of reference, enter the same segment of the spinal cord and synapse with the same projection neuron. There is no way for the cortex to know whether a given projection neuron was originally stimulated by pain from the true point of origin or from the referred area. In localizing the source of the pain stimulus, the cortex relies on prior experience regarding the person's geographical knowledge of his or her own body. Because surface areas are more familiar to a person than the locations of the visceral or deep somatic structures, the referred locale is used preferentially over the more unfamiliar but true point of origin (Fig. 32-27).

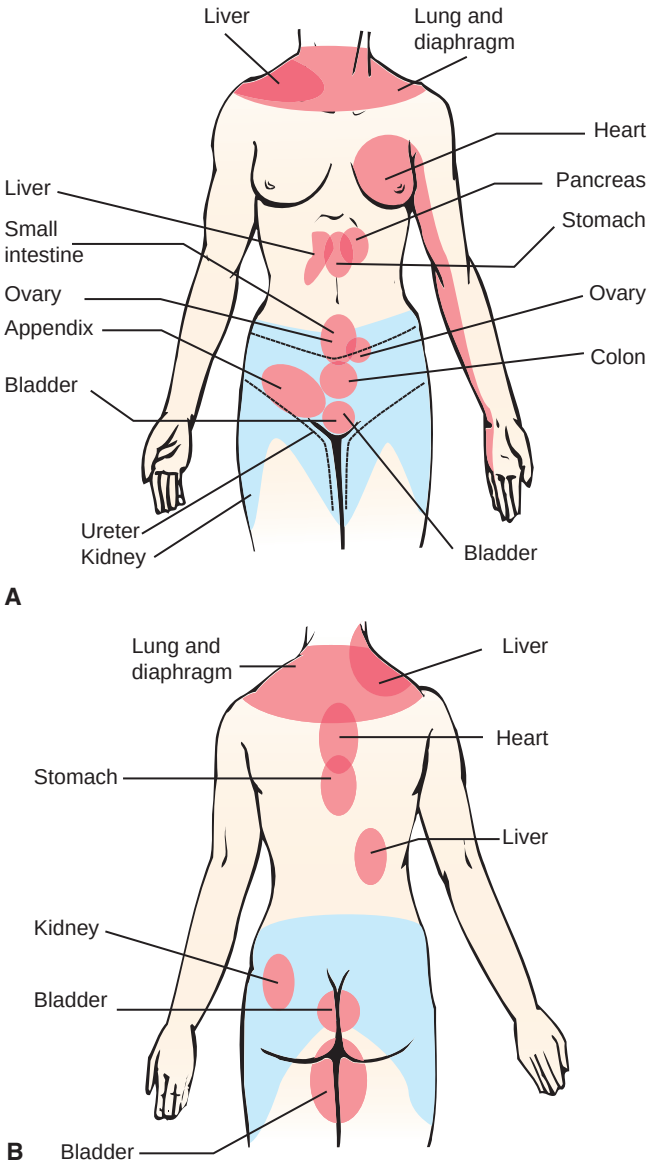

FIGURE 32-27 ▲ Areas of referred pain. **A**: Anterior view. **B**: Posterior view.

▲ The Neurohormonal Stress Response

Homeostasis

In the middle of the 19th century, the French physiologist Claude Bernard (1813–1878) coined the term milieu intérieur to mean the internal environment to which body cells are exposed. He stated that to maintain proper cell functioning, the milieu intérieur must be constant and proper.[1,2]

> The living body, though it has need of the surrounding environment, is nevertheless relatively independent of it. This independence which the organism has of its external environment, derives from the fact that in the living being, the tissues are in fact withdrawn from direct external influences and are protected by a veritable internal environment which is constituted, in particular, by the fluids circulating in the body.
>
> *Opening lecture in general physiology given to the* College de France, *as quoted in Scultz SG: The internal environment. In Johnson LR (ed): Essential Medical Physiology, 2nd ed. New York, Raven Press, 1998.*

Although Bernard thought the blood constituted the milieu intérieur, we now realize that each tissue and cell type probably has its own environment that may be different from that of other tissues or cell types. However, the idea of a constant and appropriate internal environment remains valid to this day. Bernard was the first to advance the concept that bodily processes are constantly responding to the external environment with mechanisms that maintain constancy of the milieu intérieur: "The constancy of the internal environment requires such a perfection in the organism that external variations are instantly compensated for and balanced."[1] The concept of a constant internal environment was expanded by Walter Canon in the early 20th century to include all bodily process and structures and was termed homeostasis.

Homeostasis is defined as the situation in which attributes of the body, such as blood pressure, level of alertness, and muscle tone, remain constant or change appropriately for different situations. The constant nature of these attributes is due to the right balance between stimulatory and inhibitory neuronal and hormonal influences. In addition, structural components, such as the composition of blood, composition of extracellular fluid, and bones, tendons, muscles, and internal organs, remain essentially constant even though their components are being constantly degraded and resynthesized. Again, this structural constancy is maintained through a combination of neural and hormonal mechanisms. Homeostasis is a dynamic equilibrium—dynamic because of the constant degradation and renewal, or stimulation and inhibition, and an equilibrium because there is a balance between these opposing processes such that conditions remain constantly the same. When stressors disturb the dynamic equilibrium, compensatory mechanisms return it to its previous steady state.

Disruption of Homeostasis

Although each of us is continually exposed to psychological and physiological stressors, we are usually able to maintain a state of emotional and physical health through compensatory mechanisms that maintain homeostasis. In fact, it has been shown that some level of stress is beneficial to health. However, in the event of stress that overwhelms compensatory mechanisms, we can become ill. Overwhelming stressors may become so because of their large magnitude over time, or because of their sudden onset. People who present as patients in critical care settings have usually experienced recent, severe physiological stressors, but these are superimposed on their level of chronic physiological and psychological stress. In addition, the patient is exposed to continuous stressors that are by-products of the critical care setting, such as monitoring devices, invasive procedures, and the continual presence of devices for intravenous access, endotracheal intubation, and others.[3]

Although others, especially Walter Cannon (who also coined the term homeostasis), presented some of these theories earlier, Dr. Hans Selye[5,6] was the most prolific researcher and author on the topic of stress. Stress is "any external or internal factor that affects the normal state of dynamic equilibrium in an individual." These factors, or stressors, can be either physical or psychological. Regardless of whether the person consciously perceives a threat, the body responds with certain intrinsic reactions. When the effects are realized by the conscious mind, the person perceives a stressful experience. The stress response is how a person reacts to the stressors that he or she encounters (ie, the person's physiological adaptation or psychological coping mechanisms). One person may have compensatory mechanisms with a large capacity to handle stressors, whereas another person may not. Therefore, exposure to a given stressor does not elicit the same response in all people. This difference may be based on internal conditioning factors, such as age, sex, and genetics, and on external factors, such as culture, previous life events, exposure to this or similar stressors, diet and nutrition, and medications.

Stressors may be either psychological or physiological in origin. Psychological stressors are additive in nature (eg, life events, such as a job change, divorce, marriage) and have a physiological impact. Physiological stressors, such as injury or infection, disrupt homeostasis, eliciting the stress response in an attempt to restore it. If homeostasis is not restored quickly, illness results.

General Adaptation Syndrome

Selye and his collaborators noted commonalities in responses to different stressors in different individuals. They termed these commonalities the general adaptation syndrome. Although this term has fallen from favor, and the changes they noted are probably not as general as they thought, the concept of a generalized response to stress remains. They also defined the three basic stages of the stress syndrome as the alarm reaction, stage of resistance, and stage of exhaustion.

- *Alarm reaction.* During this initial stage, the threat is perceived, either consciously or subconsciously, and body processes are modified to counteract it. The sympathetic nervous system is stimulated by the stressor, and there is a subsequent response through the release of norepinephrine and epinephrine. Additionally, adrenocorticotropic hormone (ACTH) and ADH are released by the anterior and posterior pituitary. Stimulation of the sympathetic nervous system raises heart rate and blood pressure and stimulates the renin–angiotensin–aldosterone system, which results in sodium and water retention, increasing the blood pressure further. ACTH stimulates the release of cortisol by the adrenal cortex, which produces numerous adaptations to stress, outlined below. ADH raises blood pressure mainly by causing the kidney to retain water. These effects are additive to those elicited by the sympathetic nervous system and the renin–angiotensin–aldosterone system.
- *Stage of resistance.* During the second stage, the stress is being compensated for by increased activity of the stress responses evoked during the alarm phase. Cortisol secretion, the sympathetic nervous system, and other mechanisms triggered in the alarm reaction may continue to be activated at a lower, more constant level. This phase may continue for a long time, even years, if the increased levels of stress response mechanisms are maintained. However, the increased levels of stress response mechanisms come at a price—the use of additional resources of energy and nutrients. It is during this stage that symptoms of disease may become chronic if the compensatory responses are not adequate to control them.
- *Stage of exhaustion.* The ability to mount a stress response has limits. Therefore, the stress response can be activated only for a finite time or to a finite degree. If the stressor is not removed or adaptation does not occur, the person is no longer able to resist the stressor. At this point, homeostasis is no longer achievable. A shock state may occur (see Chapter 54), and without appropriate intervention, organ failure and death may rapidly ensue.

The Stress Response

ACUTE STRESS. Consider a prehistoric man walking on the African veldt. Suddenly, a lion springs from behind some vegetation. The man's eyes capture an image of the lion, which is communicated to the visual areas in his occipital cortex. From there, the image is sent to and processed by his prefrontal and frontal cortex and perceived as a threat. This information of threat is communicated to many centers in his brain, including those supplying the ANS. Immediately, sympathetic outflow is greatly increased by activation of brainstem sympathetic centers and through unitary activation of the sympathetic nervous system (remember the autonomic ganglia that communicate with each other at all levels of the spinal cord), increasing the rate of firing of his sympathetic nerves, releasing norepinephrine into sympathetic synapses. At the same time, parasympathetic outflow is greatly inhibited, decreasing activity of the gastrointestinal system and the need of those organs for blood. The man's heart rate and cardiac contractility (β_1 receptors) are greatly increased, both of which increase his cardiac output, and his resistance arterioles constrict (α receptors). Increased cardiac output and increased arteriolar resistance raise his blood pressure. At the same time, veins also constrict (α receptors), increasing venous return to his heart and increasing cardiac output still more. The adrenal medulla is stimulated by sympathetic outflow (neuronal nicotinic receptors) to secrete some norepinephrine, but mostly

epinephrine, into the bloodstream. The epinephrine stimulates α and β_1 receptors all over the man's body, causing the same effects as norepinephrine does at those receptors. It also stimulates β_2 receptors on his bronchiolar smooth muscle, causing relaxation and dilation of the bronchioles, enabling him to inspire and expire greater volumes of air. In addition, it stimulates β_2 receptors on arterioles in his skeletal muscle beds, causing profound dilation, increasing the capacity of these beds for blood flow. Because arterioles to digestive and other internal organs are constricted by virtue of α-receptor activation, the greatly increased cardiac output is directed to skeletal muscle beds, supplying the muscle cells with increased amounts of oxygen and glucose to sustain increased contraction. Blood flow to the brain is also greatly increased by the increased cardiac output because arterioles supplying the brain have few α receptors, so they remain fully dilated. Stimulation of β_1 receptors in the juxtaglomerular apparatus of the kidney by norepinephrine (from sympathetic nervous system nerve terminals and the adrenal medulla) and epinephrine (from the adrenal medulla) causes the release of renin, which activates the renin–angiotensin–aldosterone system. Renin acts on circulating angiotensinogen to angiotensin I, which is further converted to angiotensin II by angiotensin-converting enzymes. Angiotensin II causes additional arteriolar constriction, increasing blood pressure still further. It also causes the release of aldosterone, which causes the kidney to retain sodium and water. Sodium and water retention increases the preload to the heart, increasing cardiac output still further.

In addition, communication of the threatening sight to the hypothalamus activates many neurohormonal mechanisms controlled by the pituitary. We consider only three of these. First, the hypothalamus increases its synthesis and release of ADH from the posterior pituitary. ADH causes the kidney to retain water, further increasing the preload and thereby the cardiac output. Second, the hypothalamus increases its secretion and release of corticotropin-releasing hormone, which causes the anterior pituitary to secrete additional ACTH, which in turn causes the adrenal cortex to release increased quantities of cortisol. Cortisol has far-reaching effects on many organs that increase their ability to respond to stress. Third, through increased synthesis and release of growth hormone–releasing hormone by the hypothalamus, growth hormone (GH) synthesis and release by the anterior pituitary is increased. Like cortisol, GH has many far-reaching effects on many organs, but its overall effect is to increase the activity of tissue repair mechanisms and utilization of nutrients.

Finally, the man's immune system is activated by the stress response. This activation is achieved by multiple influences, only a few of which are mentioned here. First, GH increases the ability of many cells of the immune system, such as neutrophils and T and B lymphocytes, to carry out their functions, including phagocytosis, antigen presentation, and antibody production. In addition, the physiologically high levels of cortisol affect the immune system's ability to respond to foreign antigens. (Levels produced by pharmacological doses of corticosteroids are much higher than those produced by stress and are immunosuppressive.) The effects of physiologically elevated levels of cortisol in response to stress on immune function are complex and may involve effects on the ability of immune cells to exit the circulation and go to sites of tissue injury, or their ability to respond to antigen presentation. Finally, catecholamines also affect the immune system's ability to respond to tissue injury or foreign antigens. The net response of the immune system to acute influences of the stress response is generally considered to be an increased ability to mount an inflammatory response and respond to a foreign antigen. Figure 32-28 summarizes the effects on various body systems.

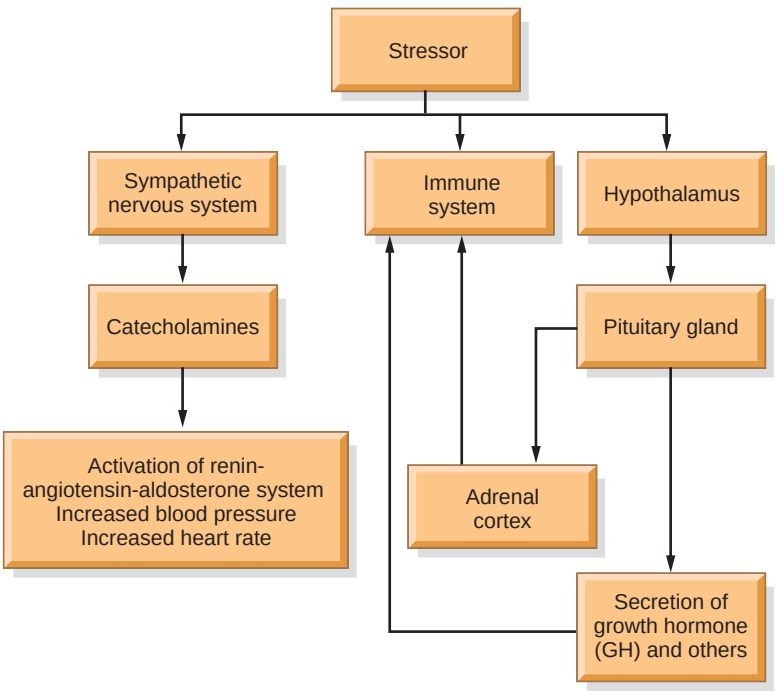

FIGURE 32-28 ▲ The stress response induces increased activity in the sympathetic nervous system, including the adrenal medulla, which activates the renin–angiotensin–aldosterone system and increases the blood pressure and heart rate, among other things. The stress response also activates the pituitary gland, which secretes increased growth hormone; the adrenal cortex, which secretes increased cortisol; and the immune system.

Returning to our prehistoric man threatened by a lion, the changes produced in his body by the threatening sight of a lion all have the effect of increasing the ability of his muscles to help him run faster or fight harder to escape the lion and increasing his ability to respond to tissue injury that might result from his encounter with the lion. These changes constitute the alarm reaction characterized by Selye. The lion threat represents an acute stressor that would end very quickly, because the man either escaped or was killed. If the man was successful in escaping the lion, the stress response would extinguish itself very rapidly, and his physiological state would gradually return to normal.

The question that arises for modern humans is, "How are the changes of the alarm reaction beneficial for stresses encountered in modern times?" If one is running to get away from a dangerous situation or to catch a bus, is injured in an automobile crash, or contracts an acute illness, the acute stress response is very likely still beneficial. However, if one undergoes an acute emotional stress, such as an intense argument or the death of a loved one, the alarm reaction is invoked, the same as it would be for a more physiologically oriented stress. In such circumstances, we do not need increased ability to fight or run away, decreased activity of our gastrointestinal system, or increased ability for tissue repair. Therefore, in these circumstances, the acute stress response is at best superfluous and at worst consumes resources and unnecessarily creates wear and tear on body systems.

CHRONIC STRESS. Selye's "stage of resistance" describes our ability to handle chronic stress. Chronic stressors that affected prehistoric humans included starvation or extreme heat or cold. Responses to these stressors included some of the same mechanisms as outlined earlier for acute stress but at diminished levels that are more sustainable over a long period. However, responses to these stressors also included additional mechanisms that conserve body stores of nutrients and energy. These responses include cortisol, but also insulin, glucagon, and GH. The chronic stress response in prehistoric times probably did not include response to diseases. Because disease processes could not be treated, affected people quickly died during the acute stress response. The mechanisms that evolved prehistorically to handle chronic stress may or may not be appropriate to handle modern stressors such as chronic disease or the chronic emotional stress associated with constant deadlines or commuting in heavy traffic. Moreover, with modern medical care, we now have the ability to maintain people with extremely high levels of chronic stress due to disease, their emotional state, and the stress induced by our interventions. In intensive care units, we measure many aspects of homeostasis, such as electrolyte levels, blood cell counts, cardiac functioning, and hormonal levels, and adjust our care to preserve homeostasis (a proper milieu intérieur).

In many such situations, the chronic stress responses as they have been handed down to us from prehistoric times may actually be counterproductive and decrease our ability to maintain homeostasis. In addition, increased activity of stress responses may increase the likelihood of degenerative diseases of the circulatory system, such as atherosclerosis, leading to vascular events in the heart, periphery, or brain; disorders of glucose metabolism that lead to type 2 diabetes; or, perhaps, disorders of the immune system that lead to inflammatory diseases. These types of diseases are all the result of a complex interplay between a person's genetic makeup, his or her life experiences (including exposure to antigens and infectious diseases), and level of both physiological and psychological stress.

▲ Age-Related Changes

Because of age-related changes in the nervous system, older people are at higher risk for injury and have less chance for survival after a severe injury. Impairment of sensation, proprioception, gait, vision, and hearing and delayed response time are a few factors that predispose older people to injury. Considerations for the older patient are given in Box 32-1.

BOX 32-1 CONSIDERATIONS FOR THE OLDER PATIENT

Anatomical and Physiological Changes in the Nervous System That Occur With Aging

- Cerebral atrophy results in a decrease in total brain weight and volume, especially in the frontal and temporal lobes; enlargement of the ventricles; and a loss of gray matter.
- Cerebral atrophy causes the dura mater and bridging veins to become tightly adherent to the skull; thus, they are easily torn with significant movement of the cranial contents, leading to subdural hematoma formation.
- Cerebral atrophy creates more space for intracranial blood to be concealed, so the older patient may manifest only subtle symptoms, which may lead to a delay in diagnosis.
- Axonal loss or decreases in myelination result in a loss of white matter.
- There is atrophy of the hippocampus, which correlates with a decline in learning and memory and cognitive impairments.
- A decreased number of neuronal cells and degeneration of dendrites and dendritic spines in cortical pyramidal cells lead to declining synaptic transmission and slowed impulse conduction.
- There is decreased production, release, and metabolism of neurotransmitters.
- Altered circulation in the inner ear and fewer functional cochlear cells lead to reduced hearing.
- A decreased number of olfactory cells in nasal mucosa lead to a reduced sense of smell.
- There is an increase in wakefulness and arousal from sleep and a decrease in slow-wave sleep, leading to changes in sleep patterns.
- The odontoid process in the cervical spine is most commonly fractured because of osteoporosis and degenerative joint disease.
- Central cord syndrome occurs more frequently because of spinal stenosis.
- The patient is more prone to severe brain injury and may have less reserve to survive a severe injury.
- The incidence of dementia somewhat increases. Those who develop dementia have a decline in cognitive and emotional abilities, which can affect memory, language, visuospatial skills, complex cognition, emotion, and personality.

▲ Clinical Applicability Challenges

SHORT ANSWER QUESTIONS

1. A 55-year-old man is brought to the emergency department after having a seizure. A CT scan of the brain reveals a large left frontoparietal mass. The patient is neurologically intact. The patient is taken to the operating room for resection of the mass. Explain the symptoms this patient could experience postoperatively.

2. A 38-year-old female is brought to the emergency department after developing the worst headache of her life. CT scan of the brain revealed a subarachnoid hemorrhage. CT angiography (CTA) of the brain confirmed the presence of a left middle cerebral aneurysm (MCA). The patient was taken to the interventional radiology suite for coiling of the MCA aneurysm. After the procedure, the patient is neurologically intact. On day 3, the patient becomes lethargic and restless. Explain what complications this patient could be experiencing. How would these complications best be treated?

3. A 21-year-old male is brought to the emergency department after diving into shallow water. Now he is unable to move his extremities. The patient is found to have a C5 fracture/dislocation resulting in traumatic quadriplegia. The patient is experiencing bradycardia, hypotension, and hypothermia. Explain why neurogenic shock occurs and differentiate it from spinal shock.

33 Patient Assessment: Nervous System

Genell Hilton

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Perform a comprehensive neurological assessment.
2. Describe abnormal assessment findings consistent with neurological compromise.
3. Analyze assessment findings and identify potential nursing diagnoses.
4. Evaluate the effect of neurological dysfunction on the patient.
5. Discuss preprocedure and postprocedure nursing interventions appropriate to selected neurodiagnostic tests.

Assessment and care of a patient with a neurological problem constitute one of the biggest challenges for critical care nurses. Basic nursing education and critical care courses may not address the assessment of the nervous system to the depth or complexity observed with other body systems. In addition, a comprehensive neurological assessment involves the use of techniques not commonly performed in the assessment of other body systems. Therefore, it is not uncommon for even the experienced nurse to feel uncertain when gathering data about the nervous system.

There are four major objectives in the nursing assessment of a patient with a real or potential neurological problem. The first objective is to gather data about the functioning of the nervous system in an unbiased and orderly manner, avoiding inconsistencies in data collection or inadequate data collection. It is essential that examination results be recorded clearly so that changes in findings can be easily identified. A standard neurological check sheet should be used by all the nursing staff, with clearly defined grading scales or terms listed as appropriate.

The second objective of neurological assessment is to follow the data over time, discovering correlations and trends. For such correlations to be of value, it is necessary to interrelate the results of history, physical assessment, and diagnostic tests. Use of a patterned format helps establish medical and nursing diagnoses and guides the nurse in choosing and evaluating therapy.

The third objective of neurological assessment is to analyze the data to develop a list of potential or actual diagnoses. Minor changes in neurological status may be the first indication that the patient's physical condition is worsening. The nurse providing care to the patient is responsible to recognize these changes, correlate these findings to the pathophysiological process, and intervene appropriately.

The fourth objective of the neurological nursing assessment is to determine the effect of dysfunction on the patient's daily living and ability to perform self-care. Up to this point, the goals of physicians and nurses in the care of a patient with a neurological problem have been similar. Each discipline uses many of the same questions and techniques to determine normal and abnormal nervous system functioning. The focus of nursing is to help patients cope with real or potential changes in daily living and self-care.

These objectives of neuroassessment are the same for all patients. In older patients, it is necessary to take the normal changes of aging into account when assessing for neurological problems. Older adults are at increased risk for certain medical conditions that predispose them to neurological problems. These same medical conditions or their prescribed treatment may also alter neurological assessment findings. Special considerations for older adults are given in Box 33-1.

▲ History

Neurological assessment begins with the first patient encounter. Conversation with the patient and family is a vital source of data needed to evaluate overall functioning. The nurse ascertains the reason for the patient's visit and obtains data regarding symptoms and evaluates the patient's past medical history, family history, and personal and social history. A comprehensive review of systems is also performed as part of the initial assessment (Box 33-2).

▲ Physical Examination

A comprehensive neurological evaluation of the critically ill patient includes assessment of mental status, motor function, pupillary response, cranial nerve function, reflexes, and sensation. Findings are correlated with the vital signs.

BOX 33-1 CONSIDERATIONS FOR THE OLDER PATIENT

Neuroassessment

When assessing an older adult, it is necessary to ascertain the person's previous level of functioning to adequately assess the person's status. The following should be taken into consideration when the nurse assesses an older adult's neurological function:

- Motor function may be affected by decreased strength, alterations in gait, changes in posture, and increased tremors.
- Vision may be decreased, pupils may be less reactive, color discrimination may be decreased, gaze may be impaired, and night vision may be diminished.
- Hearing may be diminished and changes in Rinne test findings may be noted. The nurse should bear in mind that an undetected hearing impairment can lead to the erroneous assumption that a person has more neurological deficits than he or she actually has.
- Changes in sensory function may include decreased reflexes, decreased vibratory and position sense, and decreased two-point discrimination.
- Older adults are at increased risk for depression, nutritional abnormalities, stroke, transient ischemic attacks, and dementia.
- Older adults may have impaired sleep patterns.

Mental Status

The mental status examination includes tests to evaluate level of consciousness and arousal, orientation to the environment, and thought content. The quality of a patient's level of consciousness is the most basic and critical parameter requiring assessment. Level of consciousness evaluates the functioning of the cerebral hemispheres as well as that of the reticular activating system, which is responsible for arousal. The degree of a patient's awareness of, response to, and interaction with the environment is the most sensitive indicator of nervous system dysfunction. Responsivity may be categorized according to the patient's arousal to external stimuli, and gradations of response include terms such as lethargic, stuporous, and semicomatose (Box 33-3).

Orientation to the environment involves assessing not only the patient's ability to respond but also the content of his or her response. This is assessed by asking the patient

BOX 33-2 HEALTH HISTORY for Neurological Assessment

Chief Complaint

- One-sentence description, in patient's own words, of why the patient is seeking care

History of Present Illness

- Complete analysis of the following signs and symptoms (using the NOPQRST format; see Chapter 17, Box 17-1, p. 207)
- Dizziness, syncope, or seizures
- Headaches
- Vision or auditory changes, including sensitivity to light and tinnitus
- Difficulty swallowing or hoarseness
- Slurred speech or word finding difficulty
- Confusion, memory loss, or difficulty concentrating
- Gait disturbances
- Motor symptoms, including weakness, paresthesia, paralysis, decreased range of motion, and tremors

Past Health History

- Relevant childhood illnesses and immunizations: febrile seizures, birth injuries, physical abuse or trauma, meningitis
- Past acute and chronic medical problems, including treatments and hospitalizations: tumors, traumatic head injuries, hypertension, thrombophlebitis or deep venous thrombosis, coagulopathies, sinusitis, meningitis, encephalitis, diabetes, cancer, psychiatric disorders
- Risk factors: diabetes, smoking, hypercholesterolemia, hypertension, drug use, alcohol use, cardiovascular disease
- Past surgeries: peripheral vascular surgeries; carotid endarterectomy; aneurysm clipping; evacuation of hematoma; head, eyes, ears, nose, or throat (HEENT) procedures
- Past diagnostic tests and interventions: electroencephalography, brain scan, carotid Doppler, head and neck computed tomography, magnetic resonance imaging, thrombolytic therapy, cardiac catheterization
- Medications: anticonvulsants, anticoagulants, psychotropic agents, oral contraceptives, b-blockers, calcium channel blockers, antihyperlipidemics, hormone replacement therapy
- Allergies and reactions: contrast medium, medications
- Transfusions including type and date

Family History

- Health status or cause of death of parents and siblings: coronary artery disease, peripheral vascular disease, cancer, hypertension, diabetes, stroke, hyperlipidemia, coagulopathies, seizures, psychiatric disturbances

Personal and Social History

- Tobacco, alcohol, and substance use
- Family composition
- Occupation and work environment: exposure to chemicals and toxins
- Living environment: physical, verbal, and emotional abuse
- Diet
- Sleep patterns
- Exercise
- Cultural beliefs
- Spiritual and religious beliefs
- Coping patterns and social support systems
- Leisure activities
- Sexual activity
- Recent travel

Review of Systems

- HEENT: visual changes, tinnitus, headache
- Cardiovascular: hypertension, syncope, palpitations, intermittent claudication
- Respiratory: shortness of breath, infections, cough, dyspnea
- Gastrointestinal: weight loss, change in bowel habits, nausea/vomiting/diarrhea
- Genitourinary: change in bladder habits, painful urination, sexual dysfunction
- Musculoskeletal: sensitivity to temperature changes, varicosities, loss of hair on extremities, change in sensation

BOX 33-3 Clinical Terminology for Grading Responsiveness

Alert (full consciousness): normal
Awake: may sleep more than usual or be somewhat confused on first awakening, but fully oriented when aroused
Lethargic: drowsy but follows simple commands when stimulated
Obtunded: arousable with stimulation; responds verbally with a word or two; follows simple commands; otherwise drowsy
Stuporous: very hard to arouse; inconsistently may follow simple commands or speak single words or short phrases; limited spontaneous movement
Semicomatose: movements are purposeful when stimulated; does not follow commands or speak coherently
Comatose: may respond with reflexive posturing when stimulated or may have no response to any stimulus

questions such as, "What is your name? Where are you right now? What is the month/year/date/time?" An increase in the number of wrong answers indicates increasing confusion and possible deterioration in neurological status. Likewise, an increase in the number of correct answers may indicate neurological improvement.

In instances in which brain injury is suspected, the Glasgow Coma Scale (GCS) has proved a reliable tool for assessing arousal and level of consciousness (Box 33-4). The GCS allows the examiner to record objectively the patient's response to the environment in three major areas: eye opening, verbalization, and movement. In each category, the best response is scored. The GCS uses two responses, best eye-opening response and best verbal response, to assess arousal and level of consciousness. Best eye-opening response is scored from 1 to 4, with 1 as no response and 4 as spontaneous eye opening. Best verbal response addresses orientation and ranges from 1 to 5, with 1 again indicating no response and 5 indicating a fully oriented patient. The intubated patient is usually noted to have a verbal score of 1T, which should be added into the total score. In this way, recognition is given to the patient's inability to speak secondary to the presence of the endotracheal tube. Best motor responses ranges from 1 to 6, with 1 indicating no motor response and 6 representing a patient with movement of all extremities to command.

BOX 33-4 The Glasgow Coma Scale

Best Eye-Opening Response	Score
Spontaneously	4
To speech	3
To pain	2
No response	1
Best Verbal Response	**Score**
Oriented	5
Confused conversation	4
Inappropriate words	3
Garbled sounds	2
No response	1
Best Motor Response	**Score**
Obeys commands	6
Localizes stimuli	5
Withdrawal from stimulus	4
Abnormal flexion (decorticate)	3
Abnormal extension (decerebrate)	2
No response	1

A total score of 3 to 8 suggests severe impairment, 9 to 12 suggests moderate impairment, and 13 to 15 suggests mild impairment.

The maximal total score for a fully awake and alert person is 15. A minimal score of 3 is consistent with complete lack of responsiveness. An overall score of 8 or below is associated with coma. If maintained over time, a low GCS score may be a predictor of poor functional recovery. This scoring system was designed as a guide for rapid evaluation of the acutely ill or severely injured patient whose status may change quickly. It is not useful as a guide for evaluation of patients in long-standing comas or during prolonged recovery from severe brain injury.

More complex information about nervous system functioning can be obtained by gathering data about the patient's ability to integrate attention, memory, and thought processes (Table 33-1). Such a mental status examination also may uncover clues about additional problems affecting the patient's lifestyle. The Mini-Mental State Examination (MMSE) is a widely used cognitive assessment tool that is easy and rapid to administer and has good interrater reliability. It is frequently used to monitor disease progression in patients with dementia or other progressive disease states. The MMSE is composed of questions related to orientation, recall/memory, attention, calculation, language, and spatial insight. Points are assigned for correct answers, with a maximum of 30 points. Scores of less than 20 may indicate neurological disease. Examples of specific deficits are presented in Table 33-2.

When gathering such a wealth of data, assessment of the patient's ability to communicate becomes paramount. Use of language requires comprehension of verbal and nonverbal symbols and the ability to use those symbols to communicate with others. Evaluation of the patient's understanding normally is accomplished through the spoken word. However, speech dysfunctions can make such evaluations exceedingly difficult (Table 33-3). Use of an interpreter to ensure accurate assessment of orientation may be indicated in patients whose primary language is other than English.

Motor Function

Evaluation of motor function includes assessment of motor response to stimuli, as well as motor strength and coordination. Assessment of motor response involves evaluating the type of stimuli necessary to elicit a motor response. This gives the health care team information regarding the level of awareness necessary to obtain a motor response as well as the patient's ability to follow commands. Evaluation of motor strength and coordination assesses motor neuron pathways within the brain, from the primary motor cortex to the spinal cord, as well as multiple other areas involved in coordination, such as the cerebellum and basal ganglia.

Motor Response to Stimuli

The nurse first attempts to elicit a motor response by asking the patient to move an extremity against gravity. If no response is

Table 33-1 Mental Status Examination

Functions	Test	Implications
Orientation	*Time:* state year, month, date, season, day of week *Place:* indicate state, county, city of residency; state hospital name, floor or room number	May be altered by a multitude of neurological conditions
Attention	Digit span; serial 7's; recitation of months of the year in reverse order	May be impaired in delirium, frontal lobe damage, and dementia
Memory	*Short-term:* recall of three items after 5 min *Long-term:* recall of such items as mother's maiden name, events of previous day	May be impaired in conditions such as dementia, cerebrovascular accident, and delirium
Language	*Naming:* point to three objects and have patient name them *Comprehension:* give simple and complex commands *Repetition:* repeat phrases such as "no if's, ands, or buts" *Reading:* have patient read and explain a short passage *Writing:* have patient write a brief sentence	Requires integration of visual, semantic, and phonological aspects of knowledge Dysfunction may be associated with lesions of Broca's area; may be dependent on educational level
Spatial/perceptual	Copy drawings such as cross or square; draw a clock face Point out right and left side of self Demonstrate such actions as putting on a coat or blowing out a match	May be associated with parietal lobe lesions

Table 33-2 Selected Deficits in Higher Intellectual Function

Type	Characteristics
Anomia	Inability to name objects or recognize written or spoken names of objects
Phonemic paraphasia	Substitutes parts of words (eg, pan opener instead of can opener)
Semantic paraphasia	Substitutes whole words (eg, apple for orange)
Dyslexia	Inability to recognize and comprehend written words
Alexia	Reading letter by letter instead of whole words
Neglect dyslexia	Omissions or substitutions of letters confined to initial part of the word
Surface dyslexia	Difficulty reading words with irregular spelling
Dysgraphia	Difficulty with writing
Central dysgraphia	Affects both written and oral spelling
Neglect dysgraphia	Misspelling the initial part of the word
Agnosia	Failure to recognize objects despite intact sensory input; may be visual, auditory, or sensory
Prosopagnosia	Inability to recognize familiar faces
Achromatopsia	Inability to discriminate colors
Acalculia	Inability to read, write, and comprehend numbers

forthcoming, the patient may be unable to comprehend or to respond to verbal commands. In this instance, noxious stimuli should be used to elicit a motor response. When noxious stimuli are needed to evoke a response, the nurse pays careful attention to where the painful stimulus is applied. Noxious stimuli can involve either central or peripheral stimulation. Central stimulation involves pinching of the trapezius muscle, pressure on the supraorbital ridge, or a sternal rub while peripheral stimulation response may be elicited by compression of the nail bed. However, be aware that a misplaced examiner's hand may cause serious skin or tissue injury. Areas to avoid include the skin of the nipples and genital area. When stimulating the supraorbital ridge, one should take care not to compress the eye itself.

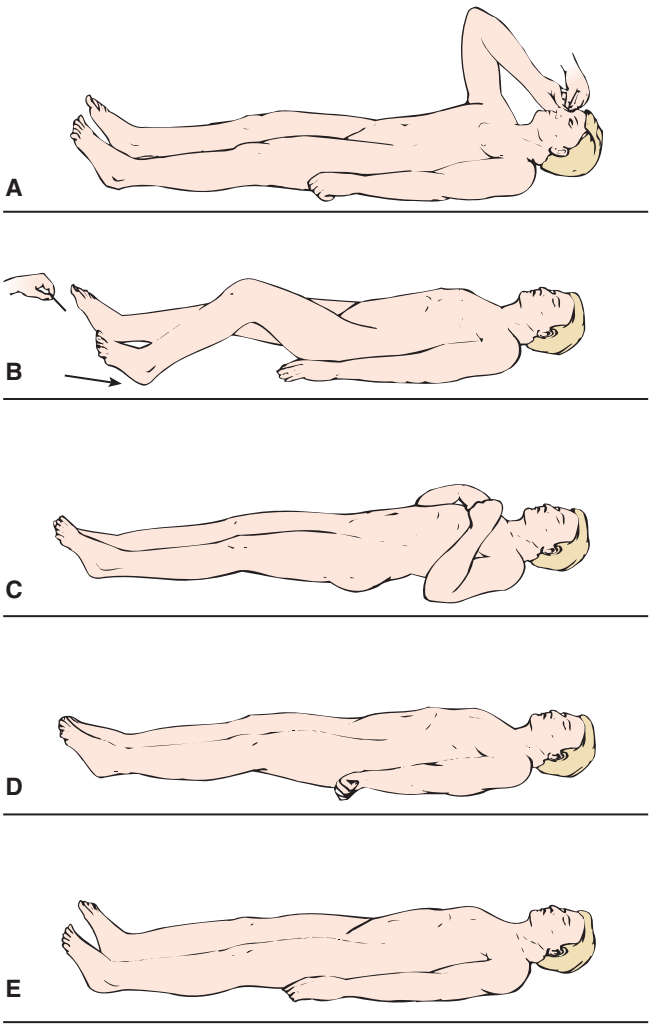
Localization to painful stimuli is characterized by an organized attempt to remove the stimulus, which entails movement of the extremity across midline. This contrasts to withdrawal, in which the patient simply pulls away from the noxious stimulus, rather than attempting to remove it (Fig. 33-1). Appropriate responses, such as localization or withdrawal, infer that the sensory and corticospinal pathways are functioning (see Fig. 33-1A,B). There may be monoplegia or hemiplegia, indicating that the corticospinal pathways are interrupted on one side.

Inappropriate responses include decorticate rigidity and decerebrate rigidity. Flexion of the arms, wrists, and fingers; adduction of the upper extremities; and extension, internal rotation, and plantar flexion of the lower extremities characterize decorticate rigidity (see Fig. 33-1C). Such rigidity results from lesions of the internal capsule, basal ganglia, thalamus, or cerebral hemisphere, interrupting corticospinal pathways.

Table 33-3 Patterns of Speech Deficits

Type	Deficit Locations	Speech Patterns
Fluent dysphasia	Left parietal–temporal lobes (Wernicke's area)	• Fluent speech that lacks coherent content • Impaired understanding of spoken word despite normal hearing • May have normal-sounding speech rhythm but no intelligible words • May use invented, meaningless words (neologism), word substitution (paraphasia), or repetition of words (perseveration, echolalia)
Nonfluent dysphasia	Left frontal area (Broca's area)	• Slow speech with poor articulation • Inability to initiate sounds • Comprehension usually intact • Usually associated with impaired writing skills
Global dysphasia	Diffuse involvement of frontal, parietal, and occipital areas	• Nonfluent speech • Inability to understand spoken or written words
Dysarthria	Corticobulbar tracts; cerebellum	• Loss of articulation, phonation • Loss of control of muscles of lips, tongue, palate • Slurred, jerky, or irregular speech but with appropriate content

Decerebrate rigidity consists of extension, adduction, and hyperpronation of the upper extremities and extension of the lower extremities, with plantar flexion of the feet (see Fig. 33-1D). Many times, the person also has clenched teeth. Injury to the midbrain and pons results in decerebration. At times, the inappropriate responses of decortication and decerebration may switch back and forth. If there is no response to noxious stimuli or only very weak flexor



(A) Localizing pain. An appropriate response is to reach up above shoulder level toward the stimulus. Remember, a focal motor deficit such as hemiplegia may prevent a bilateral response.

(B) Withdrawal. An appropriate response is to pull the extremity or body away from the stimulus. As brainstem involvement increases, your patient may respond by assuming one of the following postures. Each one shows more advanced deterioration.

(C) Decorticate posturing. One or both arms in full flexion on the chest. Legs may be stiffly extended.

(D) Decerebrate posturing. One or both arms stiffly extended. Possible extension of the legs.

(E) Flaccid. No motor response in any extremity.

FIGURE 33-1 ▲ Motor responses to pain. When a painful stimulus is applied to an unconscious patient's supraorbital notch, the patient responds in one of these ways.

responses (ie, flaccidity), the patient likely has extensive brainstem dysfunction (see Fig. 33-1E). Additional abnormal motor responses in a comatose patient include tonic contraction, which is consistent muscular contraction, and clonus, which is alternating muscle spasticity and relaxation.

Motor Strength and Coordination

The second component of the motor assessment addresses strength and coordination. Muscle weakness is a cardinal sign of dysfunction in many neurological disorders. The nurse tests extremity strength by offering resistance to various muscle groups, using his or her own muscles or gravity. As a quick test to detect weakness of the upper extremities, have the patient hold the arms straight out with palms upward and eyes closed and observe for any downward drift or pronation of the forearms. This is referred to as pronator drift. A similar test for the lower extremities involves having the patient lie in bed and raise the legs, one at a time, straight off the bed against the examiner's resistance. Weakness noted in any of these tests can indicate damage to the motor neuron pathways of the pyramidal system, which transmits commands for voluntary movement. Motor function for each extremity is reported as a fraction, with 5 as the denominator, as shown in Box 33-5.

Muscle groups are assessed individually, initially without resistance and then against resistance, to obtain a thorough evaluation. Upper extremity muscle strength is evaluated by asking the patient to shrug the shoulders (trapezius and levator scapulae muscles), raise the arms (deltoid muscle), flex the elbow (biceps muscle), extend the arm (triceps muscle), and extend the wrist (extensor carpi radialis longus muscle). Lower extremity muscle strength is evaluated by asking the patient to raise the leg (iliopsoas muscle), extend the knee (quadriceps muscle), dorsiflex and plantarflex the foot (anterior tibialis and gastrocnemius muscles, respectively), and flex the knee (hamstring muscle group consisting of the biceps femoris, semitendinosus, and semimembranosus muscles).

Assessment of movement and strength in a patient who cannot follow commands or is unresponsive can be difficult because participating in muscle strength testing against gravity requires the patient's understanding and cooperation. Unless the patient is able to mount a motor response secondary to painful stimuli, the nurse may not have the opportunity to test for muscle strength in any sort of reliable manner. Therefore, for comatose patients, it is important to note what, if any, stimuli initiate a response and to describe or grade the type of response obtained.

BOX 33-5 A Motor Function Scale

Score	Interpretation
0/5	No muscle contraction
1/5	Flicker or trace of contraction
2/5	Moves but cannot overcome gravity
3/5	Moves against gravity but cannot overcome resistance of examiner's muscles
4/5	Moves with some weakness against resistance of examiner's muscles
5/5	Normal power and strength

The nurse may also assess each extremity for size, muscle tone, and smoothness of passive movement. Abnormal responses may indicate problems in the basal ganglia (also called the extrapyramidal system). These pathways normally suppress involuntary movements through controlled inhibition. Assessment findings may include the "clasp-knife" phenomenon, in which initially strong resistance to passive movement suddenly decreases. Alternatively, "lead-pipe" rigidity may be present, which is steady, continuous resistance to passive movement and is characteristic of diffuse hemispheric damage. "Cogwheel" rigidity, which is a series of small, regular, jerky movements felt on passive movement, is characteristic of Parkinson's disease. The nurse also should be alert to involuntary movements, from mild fasciculation (muscle twitching) to violent, flailing movement of an extremity. Descriptive terms for involuntary movements are given in Box 33-6.

Hemiparesis (weakness) and hemiplegia (paralysis) are unilateral symptoms resulting from a lesion contralateral to the corticospinal tract. Paraplegia results from a spinal cord lesion below the first thoracic vertebrae or from peripheral nerve dysfunctions. Quadriplegia (also known as tetraplegia) is associated with cervical spinal cord lesions, brainstem dysfunction, and large bilateral lesions in the cerebrum.

The cerebellum is responsible for smooth synchronization, balance, and ordering of movements. It does not initiate any movements, so a patient with cerebellar dysfunction is not paralyzed. Instead, ataxia, dysmetria, and lack of synchronization of movement are common manifestations. Some of the more common tests for cerebellar synchronization of movement with balance include the following:

- **Romberg test.** This test is performed by having the patient stand with his or her feet together, first with the eyes open, then with the eyes closed. The nurse looks for sway or direction of falling and is prepared to catch the patient if necessary.

BOX 33-6 Types of Voluntary Movements

Tremor	Purposeless movement
Resting	Lesion in basal ganglia
Intention	Lesion in cerebellum
Asterixis	Metabolic derangement
Physiological	Due to fatigue or stress
Fasciculation	Twitching of resting muscles due to peripheral nerve or spinal cord lesion or to metabolic influences such as cold or anesthetic agents
Clonus	Repetitive movement; elicited with stretch reflex and implies lesion of the corticospinal tracts
Myoclonus	Nonrhythmic movement; single jerk-like movements; symmetrical; unknown etiology
Hemiballismus	Flailing movement of extremity; violent movement; not present during sleep; lesion in subthalamic nuclei of basal ganglia
Chorea	Irregular movements; involves limbs and facial muscles; asymmetrical movements at rest; involuntary movements may increase when purposeful movement is attempted
Athetosis	Slow, writhing movements

- **Finger-to-nose test.** This test is performed by having the patient touch one finger to the examiner's finger, then touch his or her own nose. Overshooting or past-pointing the mark is called dysmetria. Both sides are tested individually.
- **Rapidly alternating movement (RAM) test.** The patient's ability to perform RAMs is checked on each side by having the patient oppose each finger and thumb in rapid succession or by performing rapid pronation and supination of the hand on the leg. Inability to perform RAMs is termed adiadochokinesia; performing RAMs poorly or clumsily is termed dysdiadochokinesia.
- **Heel-to-shin test.** This test is performed by having the patient extend the heel of one foot down the anterior aspect of the shin, moving from the knee to the ankle.

Pupillary Changes

Assessment of pupillary response is an important component of the neurological examination. Pupils are examined for size (specified in millimeters) and shape (Fig. 33-2). The patient focuses on a distant point in the room. To isolate the eye being examined, the examiner places the edge of one hand along the patient's nose. A bright light is directed into one eye, and the briskness of pupillary constriction (direct response) is noted. The other pupil also should constrict (consensual response). The procedure is then repeated with the other eye. Anisocoria (unequal pupils) is normal in a small percentage of the population but can also indicate neural dysfunction. If it is a normal variant, the difference in pupil size should be less than 1 mm.

Pupil reactivity is also assessed with respect to accommodation. To test accommodation, an object is held 8 to 12 inches in front of the patient's face. The patient focuses on the object as the examiner moves it toward the patient's nose. The pupils should constrict as the object gets closer, and the eyes turn inward to maintain a clear image. The normal response to testing is documented as PERRLA, or **p**upils **e**qual, **r**ound, **r**eactive to **l**ight and **a**ccommodation.

Some important pupillary abnormalities are shown in Figure 33-3. Causes of small, reactive pupils include metabolic abnormalities and bilateral dysfunction in the diencephalon. Large, fixed pupils (5 to 6 mm) that may show slight rhythmic constriction and dilation when stimulated may indicate midbrain damage. Midposition, fixed pupils (4 to 5 mm) also may indicate midbrain dysfunction, involving interruption of the sympathetic and parasympathetic pathways. Pinpoint, nonreactive pupils are seen after damage to the pons area of the brainstem (thus the phrase "pontine pupils are pinpoint"), with selected eye medications, and with opiate administration. A unilaterally dilated, nonreactive ("blown") pupil is seen with third cranial (oculomotor) nerve damage when the uncal portion of the temporal lobe herniates through the tentorium. When structures are compressed around the opening in the tentorium or fold of dura that separates the cerebrum from the cerebellum and brainstem, loss of functioning of the parasympathetic nerves to the pupil on that side results in ipsilaterally (same side) dilated pupils. A quick guide to changes in pupil size is given in Box 33-7.

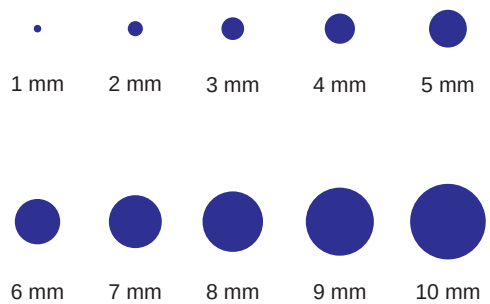


FIGURE 33-2 ▲ Pupil size chart.

The assessment of pupillary response for comatose patients is the same as for conscious patients. Pupil reactivity to light, by direct and consensual response, is easily obtained. It may be impossible to ascertain reactivity to accommodation because the patient may be unable to cooperate.

Cranial Nerve Function

The performance of a cranial nerve assessment varies depending on whether the patient is conscious or unconscious. Assessment of the cranial nerves in the unconscious patient is important because it provides data regarding brainstem function, however many components may need to be eliminated or adapted. For specific physiological information about the cranial nerves, see Chapter 32.

Cranial Nerve I (Olfactory Nerve)

The first cranial nerve contains sensory fibers for the sense of smell. This test usually is deferred unless the patient complains of an inability to smell. The nurse tests the nerve, with the patient's eyes closed, by placing aromatic substances near the nose for identification. Items that have a distinct smell (eg, soap, coffee, or cinnamon) should be used. Ammonia should not be used because the patient will respond to irritation of the nasal mucosa rather than to the odor. Each nostril is checked separately by closing off one nostril at a time. Loss of smell may be caused by a fracture of the cribriform plate or a fracture in the ethmoid area. The patient may also have anosmia (loss of sense of smell) from a shearing injury to the olfactory bulb after a basilar skull fracture or from cerebrospinal fluid (CSF) leak.

Cranial Nerve II (Optic Nerve)

Assessment of the optic nerve involves evaluation of visual acuity and visual fields. Gross visual acuity is checked by having the patient read ordinary newsprint, noting the patient's preinjury need for corrective lenses. Visual fields are tested by having the patient look straight ahead with one eye covered. The examiner moves a finger from the periphery of each quadrant of vision toward the patient's center of vision. The patient should indicate when the examiner's finger is seen. This is done for both eyes, and the results are compared with the examiner's visual fields, which are assumed to be normal

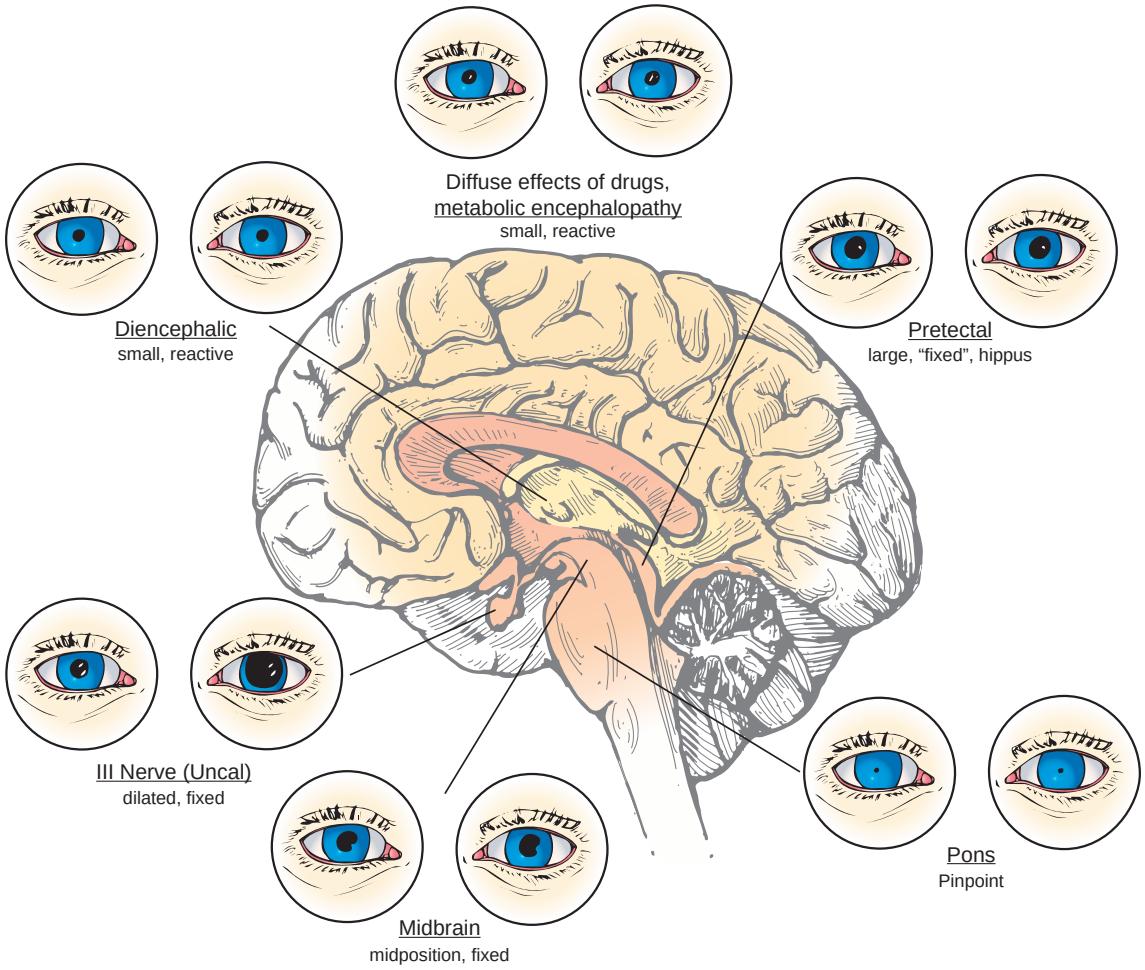

FIGURE 33-3 ▲ Abnormal pupils. (Adapted from Saper C: Brain stem modulation of sensation, movement, and consciousness. In Kandel ER, Schwartz JH, Jessel TM (eds): Principles of Neural Science, 4th ed. New York, NY: McGraw-Hill, 2000, pp 871–909, with permission from McGraw-Hill.)

(Fig. 33-4). Damage to the retina produces a blind spot. An optic nerve lesion produces partial or complete blindness on the same side. Damage to the optic chiasm results in bitemporal hemianopsia, blindness in both lateral visual fields (Table 33-4). Pressure on the optic tract can cause homonymous hemianopsia, half-blindness on the opposite side of the lesion in both eyes. A lesion in the parietal or temporal lobe may produce contralateral blindness in the upper or lower quadrant of vision, respectively, in both eyes (quadrant deficit). Damage in the occipital lobe can cause homonymous hemianopsia with central vision sparing.

BOX 33-7 Quick Guide to Causes of Pupil Size Change

Pinpoint Pupils
- Drugs: opiates
- Drops: medications for glaucoma
- "Nearly dead": damage in the pons area of the brainstem

Dilated Pupils
- Fear: panic attack, extreme anxiety
- "Fits": seizures
- "Fast living": cocaine, crack, phencyclidine

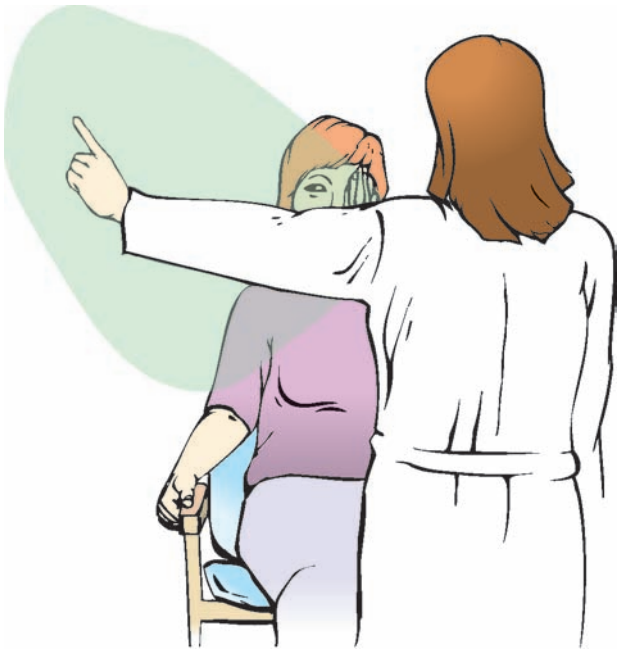

FIGURE 33-4 ▲ Confrontational method of testing visual fields.

Table 33-4 Visual Field Defects Associated With Defects of the Visual System

Visual Field Defect	Left	Right	Description
Anopsia			Blindness in one eye; due to complete lesion of the right optic nerve
Bitemporal hemianopsia (central vision)			Blindness in both lateral visual fields; due to lesions around the optic chiasm such as pituitary tumors or aneurysms of the anterior communicating artery. Affected fibers originate in the nasal half of each retina.
Homonymous hemianopsia			Half-blindness involving both eyes with loss of visual field on the same side of each eye; due to lesion of temporal or occipital lobe with damage to the optic tract or optic radiations (blindness occurs on the side opposite the lesion; here, the lesion occurred in the right side of the brain, resulting in loss of vision in the left visual field of both eyes)
Quadrant deficit			Blindness in the upper or lower quadrant of vision in both eyes, resulting from a lesion in the parietal or temporal lobe

Cranial Nerves III (Oculomotor Nerve), IV (Trochlear Nerve), and VI (Abducens Nerve)

Cranial nerves III, IV, and VI are assessed together because they all innervate extraocular muscles involved in eye movement. The parasympathetic fibers of the oculomotor nerve are responsible for lens accommodation and pupil size through control of the ciliary muscles. This is the nerve tested when a nurse elicits a pupillary response. The motor fibers of the oculomotor nerve innervate the muscles that elevate the eyelid and those that move the eyes up, down, and medially. These include the superior rectus, inferior oblique, inferior rectus, and medial rectus muscles. The trochlear nerve innervates the superior oblique muscle to move the eyes down and in. The lateral rectus muscle moves the eyes laterally and is innervated by the abducens nerve. Diplopia, nystagmus, conjugate deviation, and ptosis may indicate dysfunction of these cranial nerves. In the conscious patient, these nerves are tested by having the patient follow the examiner's finger as he or she moves it in all directions of gaze (Fig. 33-5).

Ocular position and movement are among the most useful guides to the site of brain dysfunction in the comatose person. When observing the eyes at rest, it is not uncommon to note a slight divergence of gaze. If both eyes are conjugately deviated to one side, there is possible dysfunction either in the frontal lobe on that side or in the contralateral pontine area of the brainstem. Downward deviation suggests a dysfunction in the midbrain.

Although the unconscious patient cannot participate in the examination by voluntarily moving the eyes through fields of gaze, the examiner still can test the range of ocular movement by assessing the oculocephalic ("doll's eyes" test) and oculovestibular (caloric ice-water test) reflexes.

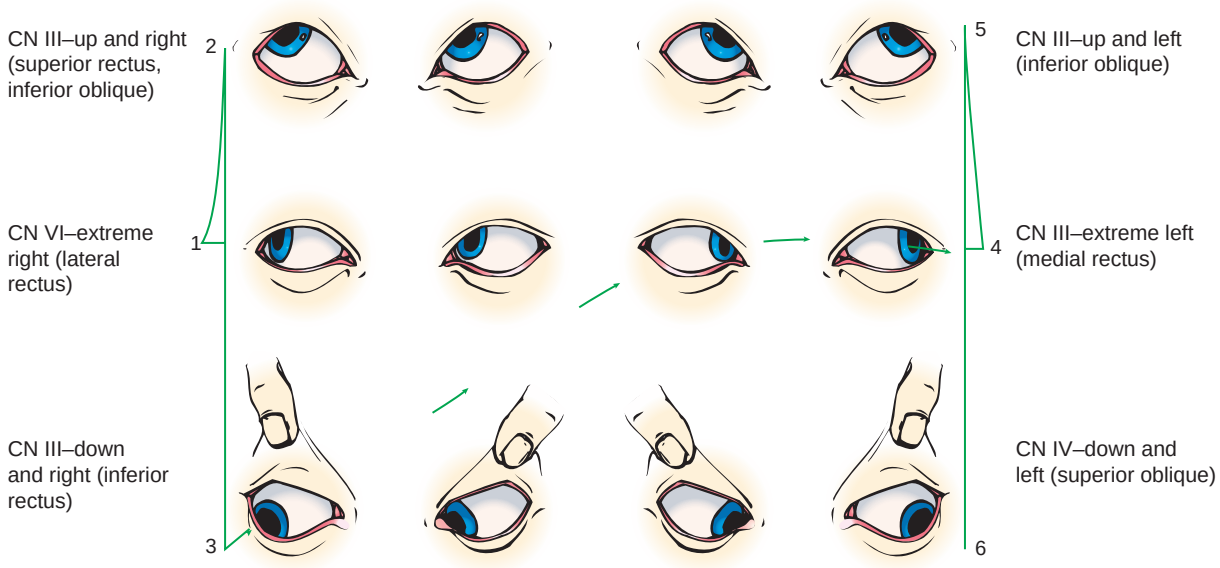

FIGURE 33-5 ▲ Muscles used in conjugate eye movements in the six cardinal directions of gaze. Lead the patient's gaze in the sequence numbered 1 through 6. CN III, oculomotor nerve; CN IV, trochlear nerve; CN VI, abducens nerve.

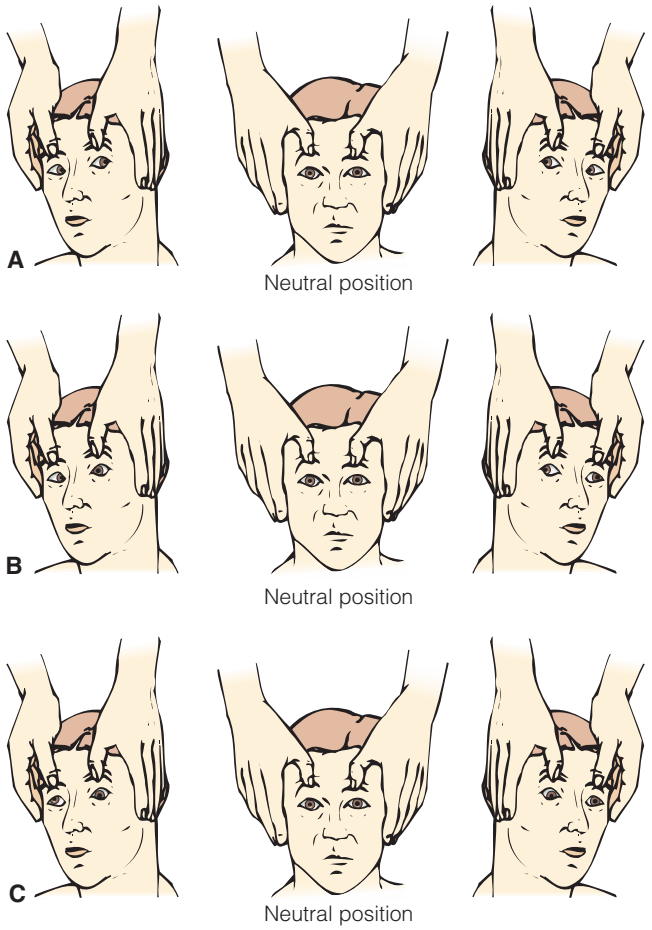

FIGURE 33-6 ▲ Test for oculocephalic reflex response (doll's eyes phenomenon). **A:** Normal response—when the head is rotated, the eyes turn together to the side opposite to the head movement. **B:** Abnormal response—when the head is rotated, the eyes do not turn in a conjugate manner. **C:** Absent response—as head position is changed, eyes do not move in the sockets.

The oculocephalic reflex can be assessed by quickly rotating the patient's head to one side and observing the position of the eyes (Fig. 33-6). This maneuver must never be performed in a person with possible cervical spine injury. A normal response consists of initial conjugate deviation of the eyes in the opposite direction, then, within a few seconds, smooth and simultaneous movement of both eyes back to midline position. This response indicates an intact brainstem. An abnormal reflex response occurs when one eye does not follow the normal response pattern. Absence of any ocular movement when the head is rotated briskly to either side or up and down indicates an absent reflex and portends severe brainstem dysfunction.

The examiner tests the oculovestibular reflex by elevating the patient's head 30 degrees and irrigating each ear separately with 30 to 50 mL of ice water (Fig. 33-7). This test should never be performed in a patient who does not have an intact eardrum or who has blood or fluid collected behind the eardrum. Also, the external ear canal should be unobstructed by cerumen or debris. In an unconscious patient with an intact brainstem, the eyes exhibit horizontal nystagmus with slow, conjugate movement toward the irrigated ear followed by rapid movement away from the stimulus. When the reflex is absent, both eyes remain fixed in midline position, indicating midbrain and pons dysfunction.

Cranial Nerve V (Trigeminal Nerve)

Cranial nerve V has three divisions: ophthalmic, maxillary, and mandibular. The sensory portion of this nerve controls sensation to the cornea and face. The motor portion controls the muscles of mastication. This nerve is partially tested by checking the corneal reflex; if it is intact, the patient blinks when the cornea is stroked with a wisp of cotton or when a drop of normal saline is placed in the eye. Care must be taken not to stroke the eyelash because this can cause the eye to blink regardless of a corneal reflex. Facial sensation can be tested by comparing light touch and pinprick on symmetrical sides of the face. The ability to chew or clench the jaw also is observed.

Cranial Nerve VII (Facial Nerve)

The sensory portion of cranial nerve VII is concerned with taste on the anterior two thirds of the tongue. The motor portion controls muscles of facial expression (Fig. 33-8). Testing is performed by asking the patient to raise the eyebrows, smile, or grimace. With a central (supranuclear) lesion, there is muscle paralysis of the lower half of the face on the side opposite the lesion. The muscles around the eyes and forehead are unaffected. With a peripheral (nuclear or infranuclear) lesion, there is complete paralysis of facial muscles on the same side as the lesion.

The most common type of peripheral facial paralysis is Bell's palsy, which consists of ipsilateral facial paralysis. There is drooping of the upper lid with the lower lid slightly everted. Facial lines on the same side are obliterated, with the mouth drawn toward the normal side.

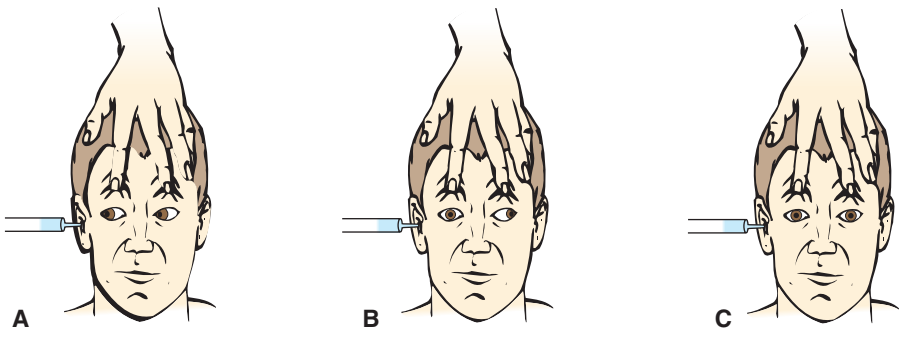

FIGURE 33-7 ▲ Test for oculovestibular reflex response (caloric ice-water test). **A:** Normal response—ice-water infusion in the ear produces conjugate eye movements. **B:** Abnormal response—infusion produces disconjugate or asymmetrical eye movements. **C:** Absent response—infusion produces no eye movements.

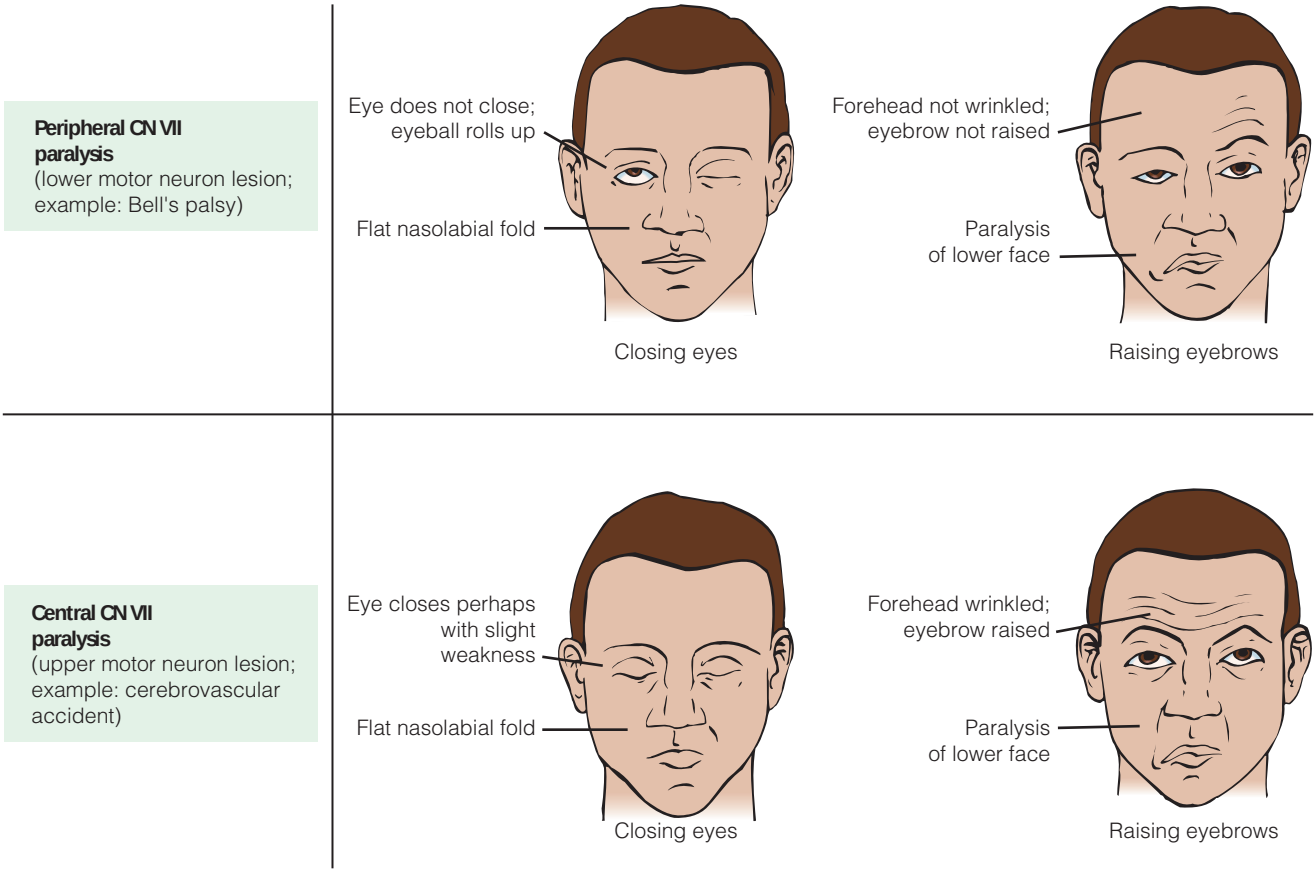

FIGURE 33-8 ▲ Facial movements with upper and lower motor neuron facial paralysis. CN VII, facial nerve.

In the comatose patient, motor function of the facial muscles and jaw can be ascertained by observing spontaneous muscle activity such as yawning, grimacing, or chewing. Symmetry of movement may be assessed, and facial droops may be observed.

Cranial Nerve VIII (Acoustic Nerve)

Cranial nerve VIII is divided into the cochlear and vestibular branches, which control hearing and equilibrium, respectively. The cochlear nerve is tested by air and bone conduction. There are two distinct auditory tests—the Weber and Rinne test. For the Rinne test, a vibrating tuning fork is placed on the mastoid process and the patient is asked to listen to the sound and to indicate when it disappears. The tuning fork is then placed in front of the ear and a normal test occurs when the patient can still hear sound transmitted through air. The Weber test involves placement of the tuning fork on the patient's forehead. A normal response would involve equal hearing of the sound in both ears. The patient may complain of tinnitus or decreased hearing if this nerve is damaged. The vestibular nerve may not be evaluated routinely. However, the nurse should be alert to complaints of dizziness or vertigo from the patient.

Cranial Nerves IX (Glossopharyngeal Nerve) and X (Vagus Nerve)

Cranial nerves IX and X usually are tested together. The glossopharyngeal nerve supplies sensory fibers to the posterior third of the tongue and the uvula and soft palate. The vagus nerve innervates the larynx, pharynx, and soft palate and conveys autonomic responses to the heart, stomach, lungs, and small intestine. These nerves can be tested by eliciting a gag reflex, observing the uvula for symmetrical movement when the patient says "ah," or observing midline elevation of the uvula when both sides are stroked. Inability to cough forcefully, difficulty with swallowing, and hoarseness may be signs of dysfunction. Autonomic vagal functions usually are not tested because they are checked during the general physical examination.

Cranial Nerve XI (Spinal Accessory Nerve)

Cranial nerve XI controls the trapezius and sternocleidomastoid muscles. The examiner tests this nerve by having the patient shrug the shoulders or turn the head from side to side against resistance.

Cranial Nerve XII (Hypoglossal Nerve)

Cranial nerve XII controls tongue movement. This nerve can be checked by having the patient protrude his or her tongue. The examiner checks for deviation from midline, tremor, and atrophy. If deviation is noted secondary to nerve damage, it will be to the side of the cerebral lesion.

Testing cranial nerve function completely is time consuming and exacting. A partial, quicker screening assessment may be performed, focusing on nerves in which

Table 33-5 A Quick Screening Test for Cranial Nerve Function

	Nerve	Reflex	Procedure
II III	Optic Oculomotor	Pupil constriction (protection of the retina)	Shine a light into each eye and note if the pupil on that side constricts (direct response). Next, shine a light into each eye and note if the opposite pupil constricts (consensual response).
V VII	Trigeminal Facial	Corneal reflex (protection of the cornea)	Approaching the eye from the side and avoiding the eyelashes, touch the cornea with a wisp of cotton. Alternatively, a drop of sterile water or normal saline may be used. A blink response should be present.
IX X	Glossopharyngeal Vagus	Airway protection	Touch the back of the throat with a tongue depressor. A gag or cough response should be present.

dysfunction may indicate serious problems or interfere with activities of daily living (Table 33-5). The cranial nerves of primary importance in a screening examination are the optic, oculomotor, trigeminal, facial, glossopharyngeal, and vagus nerves.

Reflexes

A reflex occurs when a sensory stimulus evokes a motor response. Cerebral control and consciousness are not required for a reflex to occur. Superficial and deep reflexes are tested on symmetrical sides of the body and compared by noting the strength of contraction elicited on each side.

Cutaneous, or superficial, reflexes occur when certain areas of skin are lightly stroked or tapped, causing contraction of the muscle groups beneath. Such reflexes are graded simply as normal, abnormal (pathological), or absent. An example is the plantar reflex. A sensory stimulus is applied by briskly stroking the outer edge of the sole and across the ball of the foot with a dull object, such as a tongue blade or key. The normal motor response is downward or plantar flexion of the toes. An abnormal response (Babinski's sign) is upward or dorsiflexion of the big toe, with or without fanning of the other toes. A positive Babinski's sign can indicate a lesion in the pyramidal tract. It should be noted however that a positive Babinski sign is normal in children under the age of 2.

Muscle stretch reflexes, also called deep tendon reflexes, are elicited by a brisk tap with a reflex hammer on the appropriate tendon insertion site. The target for this sensory stimulus is a stretched tendon of a muscle group. Deep tendon reflexes are tested on the biceps, brachioradial, triceps, patellar, and Achilles tendons. The desired motor response is contraction of the stimulated muscle group. Deep tendon reflexes are commonly graded on a scale of 0 to 4:

4+: A very brisk response; evidence of disease, electrolyte imbalance, or both; associated with clonic contractions
3+: A brisk response; possibly indicative of disease
2+: A normal response
1+: A response in the low-normal range
0: No response; possibly evidence of disease or electrolyte imbalance.

Hyperreflexia is associated with upper motor neuron disease, whereas areflexia (absence of reflexes) is associated with lower motor neuron dysfunction, such as spinal cord lesions. Reflexes can be tested on the comatose patient. It is anticipated that, depending on the severity and location of the neuronal damage, either hyperreflexia or areflexia will be present.

Sensation

The last component of the neurological examination involves a sensory assessment. Normal sensory findings depend on an intact spinal cord, sensory pathways, and peripheral nervous system. The primary forms of sensation are tested first. These include perception of touch (cotton wisp), pain (pinprick), temperature (hot, cold), proprioception (limb position), and vibration. With the patient's eyes closed, multiple and symmetrical areas of the body are tested, including the trunk and extremities.

The nurse assesses the perception of touch by asking the patient to close the eyes and identify when and where he or she feels a cotton wisp or cotton swab on the skin. Pain is assessed with the use of a pin or the sharp edge of a cotton swab, moving in a head-to-toe direction on both sides of the body. Temperature, if tested, uses glass tubes of hot and cold water and proceeds in the manner described previously. Two-point discrimination may also be tested and refers to the patient's ability to distinguish between two closely located points. Discrimination of sharp versus dull is also a commonly used test.

Proprioception is tested by asking the patient, again with the eyes closed, to identify the direction of movement (eg, moving a finger upward and then asking the patient if the finger is up or down). The same test is performed on the other hand, as well as both lower extremities. The nurse assesses vibration using a tuning fork placed over a bony prominence. The patient is asked to identify when vibration is felt.

The patient's ability to perceive the sensation is noted, with distal areas compared with proximal areas and right and left sides compared at corresponding points. The nurse also determines whether sensory change involves one entire side of the body. Abnormal results may indicate damage somewhere along the pathways of the receptors in the skin, muscles, joints and tendons, spinothalamic tracts, or sensory area of the cortex (Table 33-6).

Cortical forms of sensation also should be tested. When primary sensation is intact, but interpretation of the sensory input is altered, then damage to the parietal lobe may be anticipated. Problems with discriminative sensation include those involving stereognosis, graphesthesia, and point localization. The ability to recognize and identify objects by touch is called stereognosis and is a function of the parietal lobe. The inability to recognize objects by touch, sight, or sound is termed agnosia. This may be tested by placing an object in

Table 33-6 Testing Superficial and Deep Sensations

Sensation	Stimuli	Dysfunction
Spinothalamic Tracts Carry Impulses for		
Pain	Alternate sharp and dull ends of a pin, asking patient to discriminate between the two (superficial pain). Squeeze nail beds; apply pressure on the orbital rim; rub sternum (deep pain).	• Ipsilateral sensory loss implies a peripheral nerve lesion. • Contralateral sensory loss is seen with lesions of the spinothalamic tract or in the thalamus.
Light touch	Use a wisp of cotton on skin and ask patient to identify when it touches.	• Bilateral sensory loss may indicate a spinal cord lesion. • Paresthesia is an abnormal sensation, such as itching or tingling.
Temperature	Use test tubes filled with hot and cold water or use small metal plates of varying temperatures. (Test only if pain and light touch sensations are abnormal.)	• Causalgia is a burning sensation that can be caused by peripheral nerve irritation.
Posterior Columns Carry Impulses for		
Vibration	Apply a vibrating tuning fork on bony prominences, and note patient's ability to sense and locate vibrations bilaterally.	• Ipsilateral sensory loss may be due to spinal cord injury or to peripheral neuropathy.
Proprioception	Move the patient's finger or toe up and down and ask patient to identify final resting position.	• Contralateral loss may occur from lesions of the thalamus or of the parietal lobes.

a patient's hand and asking him or her, with the eyes closed, to identify the object solely based on touch. Identification of an object by the sense of sight is a function of the parieto-occipital junction. The temporal lobe is responsible for identification of objects by sound. Each of these senses should be tested separately. For example, a patient may not be able to identify a whistle by its sound but may recognize it immediately if he or she holds it or looks at it.

Graphesthesia is the ability to recognize numbers or letters traced lightly on the skin. Bilateral sides are compared. Point localization refers to the ability to locate the precise spot on the body touched by the examiner. One version of dysfunction in this area is called extinction phenomenon, the inability to recognize bilateral sensations when the examiner simultaneously touches two symmetrical areas on opposite sides of the body.

In a comatose patient, it is impossible to perform a complete test for sensation because patient cooperativeness is required. However, use of painful stimuli to elicit a response gives a gross indication that some degree of sensory function remains intact. More detailed data would be unavailable, though.

Vital Signs

Vital sign assessment is crucial to the neurological examination. Changes in temperature, heart rate, and blood pressure are considered late findings in neurological deterioration. Changes in respiratory rate, on the other hand, can indicate progression of neurological impairment and are frequently seen early in neurological deterioration.

Respirations

Variations in respiratory pattern are commonly associated with neurological injury. Shallow, rapid respirations can indicate a problem with maintenance of a patent airway or the need for suctioning. Snoring respirations or stridor can also indicate a partially obstructed airway. The inability to maintain an effective airway may be associated with a high cervical spinal cord lesion or progressive diaphragmatic paralysis (seen with neurodegenerative diseases), or it may be seen with a decreasing level of consciousness.

Changes in respiratory pattern can also be a direct indication of increasing intracranial pressure (ICP) (see Chapter 36, Fig. 36-6, p. 814). Cheyne-Stokes respirations (crescendo–decrescendo respirations alternating with periods of apnea) are frequently noted in neurological disease.

Hypoventilation after cerebral trauma can lead to respiratory acidosis. As the blood carbon dioxide increases and blood oxygen decreases, cerebral hypoxia and edema can result in secondary brain injury, thereby extending the degree of damage. Hyperventilation after cerebral trauma produces respiratory alkalosis with decreased blood carbon dioxide levels. This causes vasoconstriction of cerebral vessels, contributing to decreased cerebral blood flow.

Temperature

Normal regulation of temperature occurs in the hypothalamus. Diffuse cerebral damage can result in alterations in temperature. Central nervous system (CNS) fevers may be very high and differentiate themselves from other causes of fever by their resistance to antipyretic therapy. Hypothermia occurs with metabolic causes, pituitary damage, and spinal cord injuries.

Pulse

Variations in heart rate and rhythm may also be associated with neurological injury. An increase in ICP may lead to episodes of tachycardia and can predispose the patient to alterations in electrocardiogram pattern, such as ventricular or atrial dysrhythmias. As the ICP increases, bradycardia results, and the combination of the two is indicative of impending herniation.

Blood Pressure

Blood pressure is controlled at the level of the medulla. Therefore, specific damage to this area or encroaching edema secondary to injury in other areas results in alterations in blood pressure. Hypotension is not normally associated with neurological injury except in instances of impending cerebral herniation. On the other hand, hypotension must be avoided in the postinjury stage because it can lead to decreased cerebral perfusion, hypoxia, and extension of the initial injury.

Hypertension is much more commonly seen. In the intact brain, the mechanism of cerebral autoregulation maintains constant blood flow to the brain, despite wide variations in systemic pressure. However, after injury, autoregulatory mechanisms fail, and cerebral blood flow varies dramatically with variations in systemic pressure. As blood pressure increases, cerebral blood flow increases, resulting in an increase in ICP. Likewise, as blood pressure decreases, cerebral blood flow decreases, resulting in ischemia.

Signs of Trauma or Infection

Signs of trauma or infection may be evident on examination:

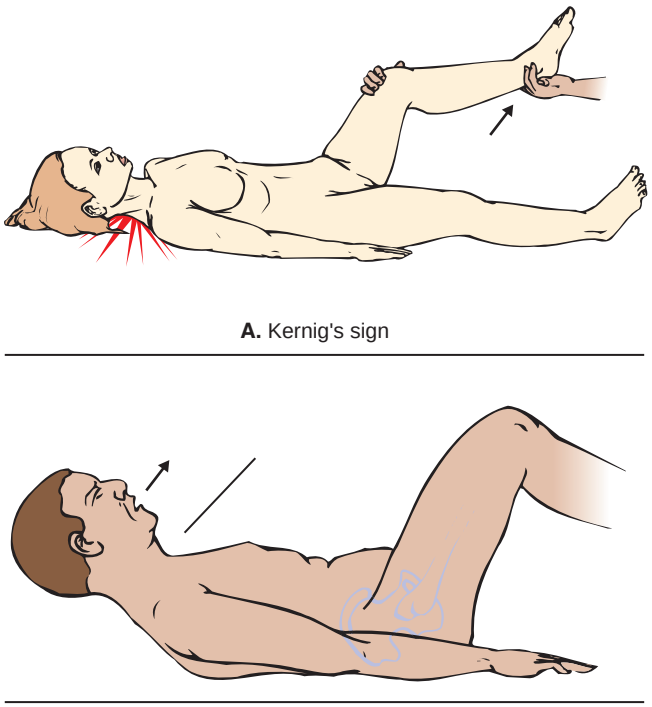
- **Battle's sign** (bruising over the mastoid areas) suggests a basilar skull fracture.
- **Raccoon's eye** (periorbital edema and bruising) suggests a frontobasilar fracture.
- **Rhinorrhea** (drainage of CSF from the nose) suggests fracture of the cribriform plate with herniation of a fragment of the dura and arachnoid through the fracture.
- **Otorrhea** (drainage of CSF from the ear) usually is associated with fracture of the petrous portion of the temporal bone.
- **Signs of meningeal irritation** include nuchal rigidity (ie, pain and resistance to neck flexion), fever, headache, and photophobia. A positive Kernig's sign (ie, pain in the neck when the thigh is flexed on the abdomen and the leg is extended at the knee) also may be present. Brudzinski's sign (involuntary flexion of the hips when the neck is flexed toward the chest) is another indication of meningeal inflammation. Kernig's sign and Brudzinski's sign are shown in Figure 33-9.

Signs of Increased Intracranial Pressure

The prevention of increased ICP, or intracranial hypertension, is of key importance to the nurse's role when caring for a patient with a neurological injury. It is first essential for the nurse to establish a baseline neurological assessment on the patient, on which further deterioration can be based. In general terms, increased ICP is manifested by deterioration in all aspects of neurological functioning.

Level of consciousness decreases as ICP rises. Initially, the patient may present with evidence of restlessness, confusion, and combativeness. This then decompensates into lower levels of consciousness, ranging from lethargy to obtundation to coma. Pupillary reactions begin to diminish, with sluggishly reactive pupils and eventually fixed, dilated pupils. Frequently, because of the potential for injury to be ipsilateral, one pupil dilates before the other one does, resulting in unequal pupils.

Motor function also declines, and the patient begins to show abnormal motor activity. For example, the patient who initially may have localized to painful stimuli now shows either abnormal flexion or extension. Changes in vital signs are considered a late finding. Variations in respiratory patterns occur, eventually resulting in complete apnea. Cushing's triad is considered a sign of impending herniation (see Chapter 36). This triad consists of an increased systolic pressure (resulting in an increased pulse pressure), bradycardia, and decreased irregular respirations.



A. Kernig's sign

B. Brudzinksi's sign

FIGURE 33-9 ▲ Two signs of meningeal irritation.

Evaluation of Dysfunction in the Patient's Living Patterns

Neurological nursing assessment would be incomplete if the process consisted solely of gathering data and identifying abnormal functions. Nursing expertise should expand the scope to include an evaluation of the impact of dysfunction on the patient's living patterns and ability to care for self. For example, diplopia (double vision) is an abnormal finding and may be an indicator of problems with the ocular muscles or with the nervous system; however, it also may be a clue suggesting difficulty in carrying out daily activities.

▲ Neurodiagnostic Studies

Many diagnostic tests are available to help diagnose neurological and neurosurgical problems. Such neurodiagnostic testing is performed in conjunction with a thorough neurological examination. The availability and diagnostic accuracy of current technology benefit the patient in an acute setting by shortening the time required to arrive at a diagnosis and institute therapy. The choice of which investigative test to perform should be based on the examiner's

ability to integrate the findings with neurological assessment and locate the cause of the abnormality.

The nurse's role in neurodiagnostic testing involves patient and family preparation and monitoring the critically ill patient for potential complications during and after the procedure. Although there has been a definite increase in the number of tests that can be performed at the bedside, many still require that the patient be transported to the imaging department or even out of the institution, further expanding the role of the critical care nurse. Table 33-7 summarizes some of the diagnostic tests and outlines nursing implications.

Neuroradiological Techniques

Conventional radiographs of the skull and spine are used to identify fractures, dislocations, and other bony anomalies, especially in the setting of acute trauma. In addition, radiographs may be diagnostic when displacement of the calcified pineal gland is visible, which is an immediate clue to the presence of a space-occupying lesion. Air inside the skull also suggests an open skull fracture, such as a frontal or basilar skull fracture, that may not be readily apparent externally. However, the use of plain films has decreased in recent years

Table 33-7 Neurodiagnostic Tests

Diagnostic Test	Description	Information Obtained	Nursing Considerations and Interventions
Computed tomography, or CT scan (invasive and noninvasive)	A scanner takes a series of radiographic images all around the same axial plane. A computer then creates a composite picture of various tissue densities visualized. The images may be enhanced with the use of IV contrast dye.	CT scans give detailed outlines of bone, tissue, and fluid structures of the body. They can indicate shift of structures due to tumors, hematomas, or hydrocephalus. A CT scan is limited in that it gives information only about structure of tissues, not about functional status.	Instruct the patient to lie flat on a table with the machine surrounding, but not touching, the area to be scanned. Patient also must remain as immobile as possible; sedation may be required. The scan may not be of the best quality if the patient moves during the test or if the x-ray beams were deflected by any metal object (ie, traction tongs, intracranial pressure (ICP) monitoring devices).
Magnetic resonance imaging (MRI)	A selected area of the patient's body is placed inside a powerful magnetic field. The hydrogen atoms inside the patient are temporarily "excited" and caused to oscillate by a sequence of radiofrequency pulsations. The sensitive scanner measures these minute oscillations, and a computer-enhanced image is created.	An MRI scan creates a graphic image of bone, fluid, and soft tissue structures. It gives a more defined image of anatomical details and may help one diagnose small tumors or early infarction syndromes.	Risk factors for this technique are not well identified. This test is contraindicated in patients with previous surgeries where hemostatic or aneurysm clips were implanted. The powerful magnetic field can cause such clips to move out of position, placing the patient at risk for bleeding or hemorrhage. Other contraindications include cardiac pacemakers, prosthetic valves, bullet fragments, and orthopedic pins. Inform patient that the procedure is very noisy. Use caution if patient is claustrophobic. The patient (and care givers) must remove all metal objects with magnetic characteristics (eg, scissors, stethoscope).
Positron emission tomography (PET); single-photon emission computed tomography (SPECT)	The patient either inhales or receives by injection radioactively tagged substances, such as oxygen or glucose. A gamma scanner measures the radioactive uptake of these substances, and a computer produces a composite image, indicating where the radioactive material is located, corresponding to areas of cellular metabolism.	These diagnostic tests are the only ones to measure physiological and biochemical processes in the nervous system. Specific areas can be identified as to functioning and nonfunctioning. Cerebral metabolism and cerebral blood flow can be measured regionally. PET and SPECT scans help diagnose abnormalities (tumors, vascular disease) and behavioral disturbances, such as dementia and schizophrenia, that may have a physiological basis.	The patient receives only minimal radiation exposure because the half-life of the radionuclides used is from a few minutes to 2 h. Testing may take a few hours. Procedure is very expensive. Inform the patient that remaining very still and immobile will produce best test results.

(continued on page 738)

Table 33-7 Neurodiagnostic Tests (continued)

Diagnostic Test	Description	Information Obtained	Nursing Considerations and Interventions
Cerebral angiography (invasive)	This is a radiographic contrast study in which radiopaque contrast medium is injected by a catheter into the patient's cerebral arterial circulation. The contrast medium is directed into each common carotid artery and each vertebral artery, and serial radiographs are then taken.	The contrast medium illuminates the structure of the cerebral circulation. The vessel pathways are examined for patency, narrowing, and occlusion, as well as structural abnormalities (aneurysms), vessel displacement (tumors, edema), and alterations in blood flow (tumors, arteriovenous malformations).	In preparation for this test, inform the patient as to the location of the catheter insertion (femoral artery is a common site) and that a local anesthetic will be used. Also warn that a warm, flushed feeling will occur when the contrast medium is injected. After this procedure, assess the puncture site for swelling, redness, and bleeding. Also check the skin color, temperature, and peripheral pulses of the extremity distal to the site for signs of arterial insufficiency due to vasospasm or clotting. A large amount of contrast medium may be needed during this test, with resulting increased osmotic diuresis and risk for dehydration and renal tubular occlusion. Other complications include temporary or permanent neurological deficit, anaphylaxis, bleeding or hematoma at insertion site, and impaired circulation to the extremity used for injection.
Digital subtraction angiography (invasive)	In this test, a plain radiograph is taken of the patient's cranium. Then, radiopaque contrast medium is injected into a large vein, and serial radiographs are taken. A computer converts the images into digital form and "subtracts" the plain radiograph from the ones with the contrast medium. The result is an enhanced radiographic image of contrast medium in the arterial vessels.	Extracranial circulation (arterial, capillary, and venous) can be examined. Vessel size, patency, narrowing, and degree of stenosis or displacement can be determined.	There is less risk to the patient for bleeding or vascular insufficiency because the injection of contrast medium is intravenous rather than intra-arterial. The patient must remain absolutely motionless during the examination (even swallowing will interfere with the results).
Radioisotope brain scan (noninvasive)	In this test, radioactive isotope is usually injected intravenously. The scanning device produces films of areas of concentration of the isotope within the patient's head.	Because damaged brain tissue absorbs more isotope, the presence of an intracranial lesion can be diagnosed as well as cerebral infarction or contusion. Lack of uptake of the isotope may indicate brain death.	Minimal patient preparation is required. The isotope may not be readily available within the institution. Movement will make the test difficult to interpret. This test is less commonly used than CT scan or MRI.
Myelography (invasive)	A myelogram is a radiographic study in which a contrast medium (either air or dye) is injected into the lumbar subarachnoid space. Fluoroscopy, conventional radiographs, or CT scans are used to visualize selected areas.	The spinal subarachnoid space is examined for partial or complete obstructions due to bone displacements, spinal cord compression, or herniated intervertebral disks.	Instruct the patient as for a lumbar puncture. In addition, advise that a special table will tilt up or down during the procedure. Postprocedure care is determined by the type of contrast medium used. Oil-based contrast dye: • Flat in bed for 24 h • Force fluids • Observe for headache, fever, back spasms, nausea, and vomiting Water-based contrast dye: • Head of bed elevated for 8 h • Keep patient quiet for first few hours • Do not administer phenothiazines • Observe for headache, fever, back spasms, nausea, vomiting, and seizures

(continued on page 739)

Table 33-7 Neurodiagnostic Tests (continued)

Diagnostic Test	Description	Information Obtained	Nursing Considerations and Interventions
Electroencephalogram, or EEG (noninvasive)	An EEG is a recording of electrical impulses generated by the brain cortex that are sensed by electrodes on the surface of the scalp.	Analysis of the resulting tracings helps detect and localize abnormal electrical activity occurring in the cerebral cortex. It aids in seizure focus detection, localization of a source of irritation such as a tumor or abscess, and diagnosis of metabolic disturbances and sleep disorders.	Reassure the patient that he or she will not feel an electrical shock or pain during this test. The nurse also may need to clarify for the patient that the machine cannot "read minds" or indicate the presence of mental illness. The patient's scalp and hair should be free of oil, dirt, creams, and sprays because they can cause electrical interference and thus an inaccurate recording. Inform the EEG technician of electrical devices around the patient that may cause interference during the procedure (eg, cardiac monitor, ventilator).
Cortical evoked potentials (noninvasive) Somatosensory evoked potentials Brainstem auditory evoked response Visual evoked potentials	In this test, a specialized device senses central or cortical cerebral electrical activity by skin electrodes in response to peripheral stimulation of specific sensory receptors. The sensory receptors stimulated can be those for vision, hearing, or tactile sensation. The signals are graphically displayed by a computer and characteristic peaks, and the intervals between them, are measured.	Cortical evoked potentials provide a detailed assessment of neuron transmission along particular pathways. It has value in determining the integrity of visual, auditory, and tactile pathways in patients with multiple sclerosis and spinal cord injury. This test also may be used in the assessment of a sensory pathway before, during, and after surgery.	This test may be used in conscious as well as unconscious patients and can be performed at the bedside. The patient must be as motionless as possible during some phases of this test to minimize musculoskeletal interference. Depending on the sensory pathway being tested, the patient may be instructed to watch a series of geometric designs or listen to a series of clicking noises.
Transcranial Doppler sonography	This is a test in which high-frequency ultrasonic waves are directed from a probe toward specific cerebral vessels. The ultrasonic energy is aimed through cranial "windows," areas in the skull where the bony table is thin (temporal zygoma) or where there are small gaps in the bone (orbit or foramen magnum). The reflected sound waves are analyzed for shifts in frequency, indicating flow velocity.	The speed or velocity at which blood travels through cerebral vessels is an indicator of the size of the vascular channel and the resistance to blood flow. An approximation of cerebral blood flow may be determined. Cerebral autoregulation can be monitored by observing the response of intracranial vessels to changes in arterial carbon dioxide and to the partial occlusion of the proximal vessels, as may occur in vasospasm.	The test is noninvasive and may be performed at the bedside by the physician or ultrasound technician in 30–60 min. There are no known adverse effects, and the procedure may be repeated as often as necessary. The testing is accomplished with the patient initially supine, and later on his or her side, with the head flexed forward.
Lumbar puncture (invasive)	A hollow needle is positioned in the subarachnoid space at L3–L4 or L4–L5 level, and cerebrospinal fluid (CSF) is sampled. The pressure of the CSF also is measured. Normal pressure varies with age from 45 mm H_2O in full-term newborns to 120 mm H_2O in adults.	The CSF is examined for blood and for alterations in appearance, cell count, protein, and glucose. The opening pressure is roughly equivalent to the ICP for most patients, if the patient is recumbent and no block is present.	This test is contraindicated in patients with suspected increased ICP because a sudden reduction in pressure from below may cause brain structures to herniate, leading to death. In preparation for this test, position the patient on side with knees and head flexed. Explain to the patient that some pressure may be felt as the needle is inserted and not to move suddenly or cough. After this procedure, keep the patient flat for 8–10 h to prevent headache. Encourage liberal fluid intake.

as computed tomography (CT) and magnetic resonance imaging (MRI) have proved to be better diagnostic tools.

Spinal films may still be used as an initial screening in suspected vertebral or spinal cord trauma; however, designated trauma centers rely increasingly on cervical spine CT scans. If plain films are to be taken, visualization of the cervical spine through C7 is indicated to rule out a cervical spine injury. Further, visualization of C1–C2 may require an odontoid or Waters' view. This film is taken through the open mouth of the patient and necessitates patient cooperation. The procedure for plain films of the skull and spine requires careful patient positioning and is relatively painless. The nurse's role involves monitoring the patient and attendant equipment during the procedure and being alert for complications related to patient position and the length of the procedure. In the spinal cord injured–patient, care should be taken to ensure stabilization of the neck by a hard cervical collar and logrolling during testing.

Computed Tomography

CT scans have been in use in the United States since 1973. CT scanning uses intersecting x-ray beams through the brain and skull to measure the density of tissues through which the x-ray beams pass. The denser the material (ie, skull), the whiter it appears on the film (Fig. 33-10). The less dense the material (ie, air), the darker it appears on the film. With mathematical reconstruction, multiple views or slices of the brain can be seen, which allows for a very precise, detailed picture of the brain and its contents.

The CT scan permits more refined measurement of the density of tissues, blood, and bone in the body compared with that afforded by conventional radiographs. For example, cerebral edema appears less dense and therefore is of a lighter color than normal tissue. The value of this technique is illustrated best in the trauma setting, where the ability to image rapidly and accurately the intracranial contents and position of vertebrae and spinal cord has dramatically changed the treatment of neurological patients. CT scans are recommended in the initial workup of seizures, headache, and loss of consciousness and for the diagnosis of suspected hemorrhage, tumors, and other lesions. CT scanning can reliably detect conditions such as skull fractures, tissue swelling, hematomas, tumors, and abscesses. However, it has been noted that some vascular lesions are not as reliably documented using CT scan as they are with MRI. Therefore, MRI is indicated if these lesions are suspected.

Use of a contrast medium can enhance a CT scan. Using radiographic contrast material allows better visualization of vascular areas and enhances lesions previously seen on noncontrast films. Serial CTs may allow the health care team to follow neurological progression and therefore to intervene in a rapid manner. Care should be taken in the patient with renal failure or renal insufficiency because contrast medium clearance by the kidneys may be impaired.

Sometimes two technologies are used in combination, such as myelography or angiography with CT scanning, to provide a more refined image of anatomical structures. With current technology, a routine scan now takes less than 5 minutes to survey the patient, analyze the data, and display a finished image.

Nursing management focuses on patient education to obviate any potential complications, such as poor patient tolerance. The patient should be aware that he or she must lie very still during the procedure and that he or she may experience feelings of claustrophobia. In addition, the nurse ascertains whether the patient has any preexisting allergies, particularly if contrast medium is to be used. The nurse may need to remain with the patient during the procedure to continue to monitor neurological status and vital signs.

Magnetic Resonance Imaging

MRI, known in the past as nuclear MRI, has become widely available in medium and large medical centers. This modality uses nonionizing forms of radiation to produce computerized cross-sectional images in much the same fashion as a CT scan. However, it provides more finely detailed images that look remarkably like anatomical slices of the body. MRI is superior to a CT scan in the early diagnosis of cerebral infarction and the detection of demyelinating disorders, such as multiple sclerosis. It is also helpful in diagnosing small lesions, such as tumors and hemorrhages, that might not

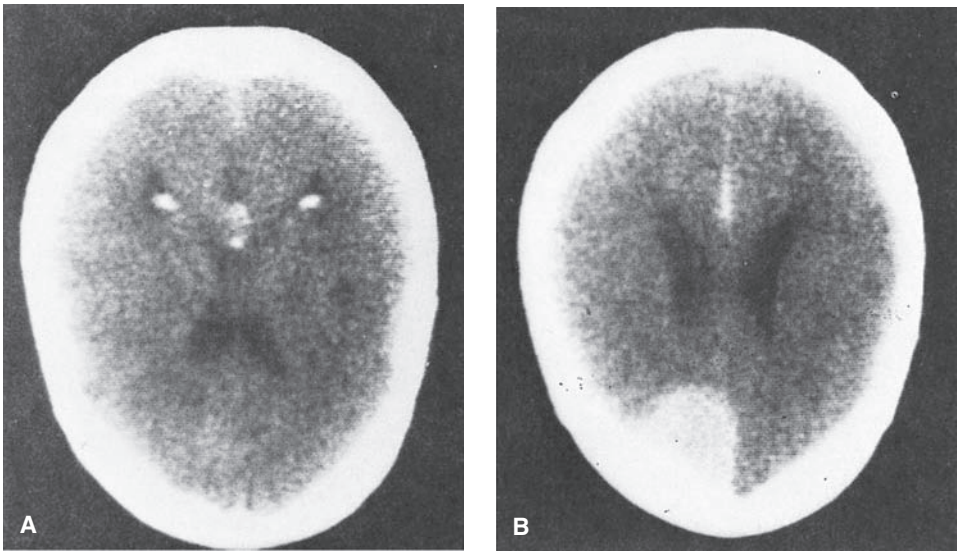


FIGURE 33-10 ▲ Computed tomography scan of the brain. **A:** Normal scan. **B:** Scan showing a large mass in the left frontal lobe. (Reprinted from Hickey J: The Clinical Practice of Neurological and Neuroscience Nursing, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 92, with permission.)

appear on a CT scan or in evaluation of ligamentous injury of the spinal cord. However, traditional CT scanning is superior for scanning for bony abnormalities, which are visualized poorly on MRI.

Although superior in many ways to CT scanning, MRI has its limitations. Its powerful magnetic fields interfere with the functioning of devices such as cardiac pacemakers. Patients with surgical clips and prosthetic implants made of ferrous metal cannot be scanned. It is also difficult to study patients on life-support equipment because most ventilators and monitors are constructed in part of ferrous metal. If emergency therapy is needed, the patient must be removed from the scanning chamber and the imaging suite before resuscitation can begin.

Positron Emission Tomography and Single-Photon Emission Computed Tomography

Positron emission tomography (PET) is a process in which molecules labeled with radioactive isotopes are located in the brain and recorded by radiation-sensitive detectors outside the head. PET has the capacity to measure cerebral blood flow and cerebral metabolism as the isotope-labeled glucose or oxygen is used in the body. It is superior to previous technologies that could image structure only, not function. It currently assists in diagnosing Alzheimer's disease, which shows a characteristic pattern of glucose consumption, as well as in Parkinson's disease, Huntington's disease, and Tourette's syndrome. However, the complexity of the testing, the comparatively high cost per scan, and the need to have a cyclotron nearby to produce the short-lived radioactive isotopes make this modality impractical and unwieldy in the clinical setting.

Single-photon emission computed tomography (SPECT) combines the imaging ability of conventional nuclear medicine scanners with the technology of transaxial CT scanning to overcome some limitations. Using more stable radioisotopes, SPECT scanning can detect diminished perfusion in an area of stroke before there is conventional CT evidence of infarction. SPECT can also detect alterations in regional blood flow in patients with Alzheimer's disease.

Angiography and Digital Subtraction Angiography

Cerebral angiography remains the study of choice for evaluating cerebrovascular problems (Fig. 33-11). It is the only test that can reveal large and small aneurysms and arteriovenous malformations and their relationship to adjacent structures and vessels. It involves the passage of a radiographic catheter through a large artery (usually femoral) to each of the arterial vessels bringing blood to the brain and spinal cord. Radiopaque contrast (a dye-like medium) is then injected into each vessel. A rapid sequence of images is taken after the contrast agent has passed through small arterial branches and capillaries and into the venous circulation. In this way, the vessel lumen and size and the presence of any occlusions can be visualized. Cerebral angiography has been used before surgery to help decide the appropriateness of medical versus surgical management. It has also been combined with balloon angioplasty in instances of vascular occlusion or coiling in the treatment of aneurysms.

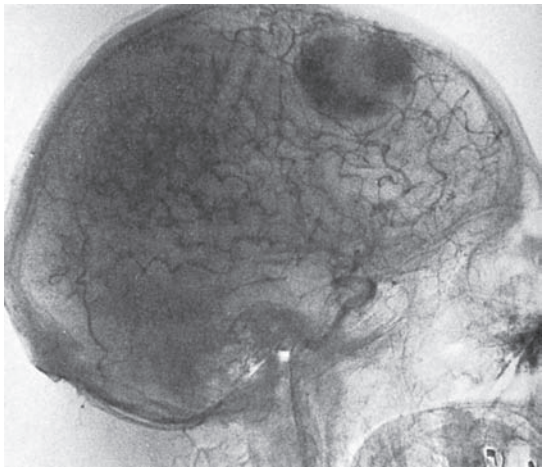

FIGURE 33-11 ▲ Cerebral angiogram showing an abnormal, large, space-occupying lesion at 1 o'clock. (Reprinted from Hickey J: The Clinical Practice of Neurological and Neuroscience Nursing, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 103, with permission.)

Digital subtraction angiography makes use of radiographic contrast to illuminate the cerebral circulation, but in considerably smaller quantities than required for conventional angiography. The contrast medium may be injected into the arterial or the venous systems. Films are taken before and after the injection and converted into digital information in the accompanying computer. The images are "subtracted" from each other, removing all images in common. The resultant image displays only the enhanced circulatory system, free of other anatomical distortion.

The major complications associated with angiography include stroke, vasospasm, or renal failure secondary to the contrast load. Contraindications to angiography include identified allergies to the contrast medium, anticoagulant therapy, and kidney and liver disease.

Cerebral Blood Flow Studies

In the diagnostic setting, cerebral blood flow is evaluated most commonly by a radioisotope brain scan. A radioactive isotope is injected intravenously. In unusual circumstances, the isotope can also be administered orally or intra-arterially. The brain is then scanned to determine which areas show an accumulation of the radioactive substance. If there is blood flow to the brain, damaged areas absorb more of the isotope than areas without damage. A newer technique, perfusion CT, involves scanning before, during, and after infusion of the contrast agent to obtain "real time" data with respect to blood flow. Cerebral blood flow studies are indicated in the detection of either increased or decreased blood flow during surgical procedures or to assess for vasospasm. They may also be used after carotid endarterectomy. The test may be used to determine brain death, which is evidenced if there is no flow to the cerebral hemispheres. In certain disorders, such as carbon monoxide poisoning, there may be increased blood flow to the brain, yet anoxic brain death may still occur. The measurement of cerebral flow assists in decision making regarding treatment and in the identification of complications.

Myelography

Myelography is a contrast study of the spinal cord and surrounding structures. It involves the introduction of water-soluble material into the CSF through a lumbar or cisternal puncture, performed under fluoroscopy, after about 10 mL of CSF has been removed. Myelography is indicated in evaluating herniated intervertebral disks, spinal cord tumors, and congenital problems and in assessing spinal cord trauma. It allows for better visualization of nerve roots and surrounding structures because it uses a contrast agent that is lighter than CSF. However, the agent disperses rapidly into the subarachnoid space, which means that the patient's position cannot be adjusted. The contrast agent does not require removal; therefore, the patient should be kept well hydrated to facilitate the agent's excretion. A heavier, oil-based contrast agent is sometimes used, and it must be removed at the end of the procedure.

The contrast agents are potentially toxic to cerebral tissue and may cause grand mal seizures. Thus, the patient must remain with the head up at least 30 to 45 degrees, and phenothiazine medications, which increase the toxic symptoms, must be avoided.

Ultrasonography and Noninvasive Cerebrovascular Studies

Transcranial Doppler ultrasonographic studies are a noninvasive means of monitoring intracranial hemodynamics at the bedside. The examination is performed through cranial "windows," areas in the skull where the bone is relatively thin, such as the temporal area, or where there are small spaces between bones, such as the orbit. The ultrasonic probe transmits sound waves at certain frequencies to a specified depth. The resultant reflected signal from blood traveling through cerebral vessels is interpreted for speed or velocity. As resistance or vascular size changes, it is reflected as a change in blood flow velocities. The data may be used to monitor therapy, aid in determining prognosis, and provide early recognition of cerebral vasospasm in patients after subarachnoid hemorrhage or severe head injury. Serial Doppler studies in patients with an aneurysm provide data regarding postoperative vasospasm and alleviate the need for repeat angiograms.

Carotid and vertebral artery duplex scans provide anatomical imaging of blood vessels combined with hemodynamic information. Doppler studies at the cranial window provide information about direction of flow, pulsatile rhythmicity, and resistance to flow of the cerebral vasculature. Carotid duplex scans are routinely used as a screening tool in patients at risk for atherosclerotic disease. The nurse should be aware of whether the patient has any history of dysrhythmias or cardiac disease because these may alter the hemodynamic profile and findings of the test.

Electrophysiological Studies

Electroencephalography

Using electroencephalography (EEG), a record is made of the brain's electrical activity. Small plate electrodes are placed in specific locations on the patient's scalp, and 16 to 21 channels transcribe the electrical potentials generated by the brain. Waveforms are classified in terms of voltage and amplitude. EEG is most valuable in the diagnosis and treatment of patients with seizures. In addition, it may help localize structural abnormalities, such as tumors and abscesses, and aid in the differentiation of structural and metabolic abnormalities. It also may provide confirmatory criteria in the diagnosis of brain death. In recent years, a modified form of EEG has been used at the bedside in critical care to monitor the effects of pharmacological agents that reduce cerebral blood flow and hence reduce electrical activity. This is termed continuous EEG monitoring and is rapidly becoming a standard of care in many facilities. It is intended to detect subclinical or nonconvulsive seizure activity in patients who are taking medications that suppress electrical activity.

A computerized technique that dramatically compresses standard EEG data and converts them into a more easily interpreted and colorized form is compressed spectral array. This technique is also seen at the bedside in neurological intensive care units to monitor patients with severe head injuries.

Evoked Potentials

An evoked potential is an electrical manifestation of the brain's response to an external stimulus: auditory, visual, somatic, or a combination of these. The measurement of such a response provides an assessment of the function of neuropathways from the periphery through the spinal cord and brainstem and finally to cortical structures. This technique has been most helpful in diagnosing multiple sclerosis and Guillain-Barré syndrome and in determining the prognosis for reversibility of coma in the brainstem-injured patient. It also may be used during surgery to monitor potential injury during manipulations of spinal nerves and structures.

The three most frequently used techniques in head trauma evaluation are somatosensory evoked potentials (SSEPs), which use electrical shock as a stimulus; brainstem auditory evoked response (BAERs), which uses click or sound stimulus; and visual evoked potentials (VERs), which use light stimulus. SSEPs assess neurological function in specific neural pathways postinjury and detect further CNS insults from secondary processes, such as hypoxia and hypertension.

Lumbar Puncture for Cerebrospinal Fluid Examination

A lumbar puncture for CSF analysis may be performed to help diagnose autoimmune disorders or infections. Occasionally, it is performed to verify subarachnoid hemorrhage, although a CT scan is the procedure of choice and is safer for such a patient. CSF is obtained by the insertion of an 18- to 22-gauge needle between the vertebrae at the L3–L4 or L4–L5 levels. The fluid is sent for content analysis and for culture, sensitivity, and other serological tests (Table 33-8). Pressure readings may also be obtained for diagnostic use.

If a lumbar puncture is performed in a patient with elevated ICP, herniation can be a life-threatening complication. Complications that can result from a CSF leak include a postprocedure headache, nuchal rigidity, fever, and difficulty voiding. Treatment involves the injection of blood into the dura, called a blood patch, to stop the leak.

Table 33-8 Normal and Abnormal Values for Cerebrospinal Fluid

Characteristic	Normal	Abnormal
Color	Clear, colorless	Cloudy often due to presence of WBC or bacteria Xanthochromic due to presence of RBC
White blood cell (WBC)	0–5/mm^3, all mononuclear	Elevated count accompanies many conditions (tumor, meningitis, subarachnoid hemorrhage, infarct, abscess)
Red blood cell (RBC)	None	Presence may be due to traumatic tap or subarachnoid hemorrhage
Chloride	120–130 mEq/L	Low concentration associated with meningeal infection and tuberculous meningitis Elevated level not neurologically significant
Glucose	50–75 mg/100 mL	Decreased level associated with presence of bacteria in CSF Elevated level not neurologically significant
Pressure	70–180 mm H_2O	Low pressure associated with inaccurate placement of needle, dehydration, or block along subarachnoid space or at foramen magnum Elevated pressure associated with benign intracranial hypertension; cerebral edema; central nervous system tumor, abscess, or cyst; hydrocephalus; muscle tension or abdominal compression; subdural hematoma
Protein	14–45 mg/100 mL	Decreased level not neurologically significant Increased level associated with demyelinating or degenerative disease, Guillain-Barré syndrome, hemorrhage, infection, spinal block, tumor

▲ Clinical Applicability Challenges

CASE STUDY

Mr. S. is a 25-year-old male involved in a motor vehicle accident. Witnesses upon the scene indicate that he had a 5-minute loss of consciousness. Upon arrival in the emergency department, it is noted that his GCS is 14 (E4/V4/M6). Pupils are 3 mm bilaterally and reactive. He demonstrates repetitive questioning. His blood pressure is 134/72, his pulse rate is 68, and his respiratory rate is 22. His cervical spine is immobilized, and intravenous fluids are infusing. Within moments of arrival, your assessment reveals decreasing responsivity. Upon reassessment, you note that his GCS is now 8 (E2/V2/M4), and his pupils are now unequal and sluggishly reactive.

1. What diagnostic tests are recommended?
2. If Mr. S.'s condition deteriorates, what neurological changes might you anticipate?
3. What nursing interventions would be appropriate at this time?

34 Patient Management: Nervous System

Mona N. Bahouth and Karen L. Yarbrough

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Define intracranial pressure (ICP) and intracranial hypertension.
2. Discuss several physiological principles affecting ICP, including the Monro-Kellie doctrine, compliance, autoregulation, and cerebral perfusion.
3. Discuss indications for ICP monitoring.
4. Describe currently available methods of monitoring ICP.
5. Explain three possible complications associated with ICP monitoring and discuss troubleshooting strategies.
6. Identify various strategies to manage increased ICP.
7. Discuss three general principles when selecting a sedating agent for use in the patient with neurological injury.

Caring for a critically ill patient with neurologic injury requires an understanding of three general themes: (1) the neurological examination as compared with baseline; (2) concepts of intracranial pressure (ICP) and factors that influence ICP; and (3) medications strategies in this population of patients.

ICP is defined as the pressure in the cranial vault relative to atmospheric pressure. Understanding general principles regarding the concepts of ICP provides the critical care nurse with a framework that he or she can then apply to multiple neurological conditions. In addition, a working knowledge of the pharmacological agents used in neurological emergencies, such as steroids, antihypertensive agents, diuretics, analgesics, sedatives, barbiturates, and anticonvulsants, better prepares the nurse to handle these situations.

▲ Physiological Principles

Intracranial Dynamics

Concepts of ICP management and intervention strategies are based on the principle that the skull is a rigid box, a nonexpansile, noncontractile space. Its contents are divided into three intracranial sections: blood maintained in the blood vessels, cerebrospinal fluid (CSF), and brain parenchyma. The brain's ability to self-regulate is based on the Monro-Kellie doctrine of fixed intracranial volume. This doctrine states that the volume of the intracranium is equal to the volume of the intravascular cerebral blood (3% to 10%); plus the volume of the CSF (8% to 12%); plus the volume of brain tissue, which consists of more than 80% water. As long as the total intracranial volume remains the same, ICP remains constant. To maintain equilibrium, there cannot be any increase in volume of one of these components without a compensatory decrease in the other two. Any alterations in the volume of any of these three components within the cranial vault, without a response from the other two components, may lead to a change in ICP. A normal ICP measurement ranges between 0 and 15 mm Hg. An ICP measurement greater than 15 mm Hg is considered intracranial hypertension or increased ICP. Basic physiological responses to illness in any of the three components in the intracranial vault can cause increased ICP (Table 34-1).

Cerebral Blood Flow

Autoregulation is defined as the ability of an organ to maintain consistent blood flow despite marked changes in arterial circulatory and perfusion pressures. The normal brain has the ability to autoregulate cerebral blood flow (CBF). Normally, autoregulation ensures a constant blood flow through the cerebral vessels over a range of perfusion pressures by changing the diameter of vessels in response to changes in arterial pressures. This mechanism is the brain's protective device against the constantly fluctuating changes of blood pressure. When autoregulation is impaired, the CBF fluctuates in direct correlation with the systemic blood pressure. In patients with impaired autoregulation, any activity that causes an increase in blood pressure, such as coughing, suctioning, or restlessness, can cause an increase in CBF that could also increase ICP.

The first of three components that may undergo changes as the body attempts to maintain a consistent intracranial

Table 34-1 Potential Causes of Increased Intracranial Pressure

Contributing Physiology	Intracranial Component Involved	Potential Cause	Potential Treatment
Overproduction of CSF	CSF space	Choroid plexus papilloma	Surgical removal, diuretics
Inadequate CSF reabsorption (communicating hydrocephalus)	CSF space	Subarachnoid hemorrhage, infection	Drainage of CSF from lumbar intrathecal site, shunt placement
Blockage of CSF circulation (obstructive hydrocephalus)	CSF space	Posterior fossa tumor, brain injury, birth defects (spina bifida)	Ventricular drainage, surgical removal of obstruction
Edema (vasogenic, cytotoxic)	Brain tissue	Tumor, infection, infarction, hypoxia, arteriovenous malformation	Drainage of CSF, removal of lesion, adequate oxygenation
Expansile mass	Brain tissue	Tumor, abscess, intracerebral hemorrhage	Surgical removal, steroids
Vasospasm	Intracranial circulation	Subarachnoid hemorrhage	Hypervolemia, hypertensive therapy, calcium channel antagonists
Vasodilation	Intracranial circulation	Elevated $PaCO_2$, systemic vasodilators (α-adrenergic agents)	Hyperventilation, removal of offending agent

volume is the CBF. Normal CBF is provided by a cerebral perfusion pressure (CPP) in the range of 60 to 100 mm Hg. The brain receives approximately 750 mL/min of arterial blood (15% to 20% of total cardiac output when at rest). For autoregulation to be functional, carbon dioxide levels must be in an acceptable range, and hemodynamic pressure targets must be within the following ranges: CPP greater than 60 mm Hg, mean arterial pressure (MAP) less than 160 mm Hg, systolic pressure between 60 and 140 mm Hg, and ICP less than 30 mm Hg.[1] Factors that alter the ability of the cerebral vessels to constrict or dilate, such as hypoxia, hypercapnia, and brain trauma, also interfere with autoregulation. Carbon dioxide is a potent vasodilator of cerebral vessels, causing increased CBF and increased volume, leading to increased ICP.

Cerebrospinal Fluid Circulation

Cerebrospinal fluid (CSF) also contributes to fluctuations in intracranial hemodynamics. CSF is a clear fluid produced predominantly in the choroid plexus in the lateral, third, and fourth ventricles. It fills the ventricles and subarachnoid space and protects the brain and spinal cord from injury. Circulation of CSF occurs in a closed system; it is predominantly reabsorbed by the arachnoid villi located in the subarachnoid space and dispersed into the venous system through the superior sagittal sinus (see Chapter 32, Fig. 32-6). Along the entire CSF cycle, potential disturbances in production, circulation, and absorption can contribute to changes in ICP. For instance, overproduction of CSF in the choroid plexus overwhelms the circulatory system. Obstruction of CSF circulation through the ventricles leads to dilation of the ventricular system (obstructive hydrocephalus). Marked slowing of absorption in the arachnoid villi caused by blood or infectious debris interferes with the reabsorption of CSF, thereby leading to systemic overload (communicating hydrocephalus).

Parenchyma

The third and most difficult intracranial component to manipulate without surgical intervention is the brain parenchyma. However, the brain tissue does respond to increased ICP and changes within the other two intracranial components. The brain can accommodate or compensate for minimal changes in volume by partial collapse of the cisterns, ventricles, and vascular systems, in turn decreasing production and increasing reabsorption of CSF. Compensatory mechanisms to maintain normal ICP include the following:

- Shunting of CSF into the spinal subarachnoid space
- Increased CSF absorption
- Decreased CSF production
- Shunting of venous blood out of the skull

During the compensatory period, ICP remains fairly constant. However, when these compensatory mechanisms have been exhausted, pressure increases rapidly until shifting of brain tissue toward open spaces in the skull occurs, and the blood supply to the medulla is cut off. The ability of the intracranial content to compensate depends on the location of the lesion, the rate of expansion, and cranial compliance.

Volume–Pressure Curve

The intracranial volume–pressure curve, also called a pressure–volume index (PVI), demonstrates the relationship between changes in intracranial volume and changes in ICP. An awareness of the patient's position on this curve is useful in monitoring and selecting appropriate interventions. The rate at which ICP increases in response to a change in intracranial volume depends on the compliance of the brain. *Compliance* is a change in volume resulting from a change in pressure. When compliance in the intracranial compartment is low, a small volume change causes a large increase in ICP. In Figure 34-1, the curve illustrates compliance, as the compensatory mechanisms maintain ICP in the normal range during increases in intracranial volume. Little change occurs in ICP during the initial increase in volume because the volume added to the cranium is compensated for by volume displacement. As the compensatory mechanisms become exhausted, the volume added becomes greater than the volume displaced, and there is a larger increase in ICP with any incremental

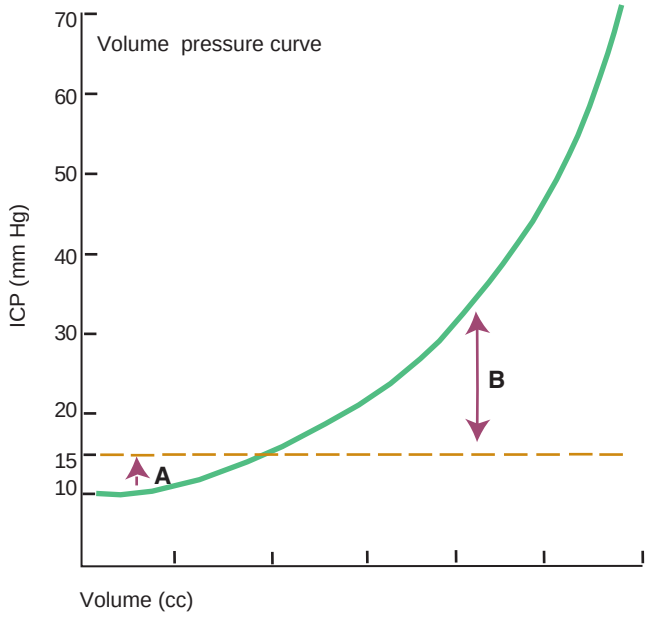

FIGURE 34-1 ▲ Volume–pressure curve. Volume–pressure response (VPR), also referred to as the pressure–volume index (PVI), provides a method of estimating the compensatory capacity of the intracranial cavity. Note that the intracranial pressure (ICP) remains within the normal limit of 0 to 15 mm Hg as long as compliance is normal and fluid can be displaced by the additional volume (**A**). Once the compensatory system is exhausted, a small additional volume causes a greater increase in pressure (**B**). Acute changes can cause serious and sometimes fatal neurological deterioration.

volume increase. Free communication of CSF between the lateral ventricles and infratentorium is lost as a result.

A major reason for controlling and decreasing ICP is the maintenance of cerebral oxygenation by adequate CBF, which is estimated clinically by the measurement of CPP. Many factors contribute to increased ICP along the volume–pressure curve. Drastic increases in ICP may result from hypercarbia, hypoxia, rapid eye movement sleep, pyrexia, or the administration of certain anesthetics. Additionally, ICP is affected by environmental stimulation and increased metabolic rates.[2]

Cerebral Perfusion Pressure

Cerebral perfusion pressure (CPP) is the blood pressure gradient across the brain. CPP is calculated by subtracting the mean ICP from the mean arterial pressure (MAP): CPP = MAP − ICP. When the CPP is greater than 100 mm Hg, there is a potential for hyperperfusion and increased ICP. When the CPP is less than 60 mm Hg, blood supply to the brain is inadequate, and neuronal hypoxia and cell death may occur. If MAPs and ICPs are equal, CPP is zero, indicating no CBF. CBF may also cease totally at pressures somewhat greater than zero. Patients with hypotension, such as postcardiac resuscitation or trauma patients, with normal ICPs (0 to 15 mm Hg), may have impaired CPP.

The autoregulation system for maintenance of constant blood flow does not function at pressures less than 40 mm Hg. Because an acutely injured brain requires a higher CPP than a normal brain, a minimum CPP of 70 mm Hg is required for maintenance of adequate cerebral perfusion and potentially improved outcomes in patients with brain injuries.[2] When CPP decreases, the cardiovascular system responds by increasing systemic pressure.

When brain damage is severe, as with widespread brain edema or when blood flow has been arrested in the brain, CBF may be reduced at relatively normal levels of CPP. The cause is impedance to the flow of blood across the cerebrovascular bed. If autoregulation is impaired, CBF may not increase despite increases in CPP. Increased ICP leads to ischemia, anoxic injury, decreased compliance, and possible herniation.[3]

▲ Increased Intracranial Pressure

Cushing's Triad

Cushing's triad is the classic syndrome of increased ICP and includes increased pulse pressure, decreased pulse, and change in respiratory pattern with pupillary changes. This syndrome usually occurs only in association with posterior fossa lesions and seldom with the more commonly observed supratentorial mass lesions, such as subdural hematomas. When these classic signs do accompany a supratentorial lesion, they are associated with a sudden pressure increase and usually herald a state of decompensation. Brain damage usually is irreversible if prolonged, and death is imminent without rapid intervention.

Cerebral Edema

Cerebral edema leading to increased ICP is a process common to multiple neurological illnesses including brain trauma, central nervous system (CNS) infections, brain tumors, stroke, etc. Its presence leads to secondary complications related to the expansion of brain tissue within the closed space of the cranium including impaired circulation leading to secondary hypoxia. Independently, cerebral edema can cause marked increases in ICP and must be treated aggressively. In general, once edema begins, its progression is rapid and difficult to control.

Treatment of cerebral edema may include using corticosteroids as well as osmotic diuretics directed at reducing ICP. These agents work by increasing plasma osmolarity, which draws fluid out of the brain tissue and into the circulating blood. The goal of therapy is to maintain plasma osmolarity up to 320 mOsm/L. See Chapter 36 for further information about cerebral edema.

Vasogenic Edema

The most common type of cerebral edema is vasogenic edema, which is characterized by a disruption in the blood–brain barrier and the inability of the cell walls to control movement of water in and out of the cells. Capillary permeability is affected, and fluid and protein are allowed to leak from the plasma into the extracellular space, resulting in increased extracellular fluid volume predominantly in the white matter. Common processes leading to vasogenic edema include brain tumors, cerebral abscess, and both ischemic and hemorrhagic stroke.

Cytotoxic Edema

Cytotoxic edema is characterized by swelling of the individual neurons and endothelial cells, which increases fluid

in the intracellular space and reduces available extracellular space, affecting the gray matter. Eventually, the cell membrane cannot maintain an effective barrier, and both water and sodium enter the cell, causing swelling and loss of function. Cytotoxic edema occurs after injuries such as anoxia or hypoxic injury.

Herniation

Herniation is defined as the displacement of tissue through structures within the skull and is the result of increased ICP. Transtentorial or uncal shifting of brain tissue through rigid openings in the skull or dura leads to displacement of midline brain structures and compression of structures in the CNS, causing traditional clinical herniation syndromes. See Chapter 36 for more information about herniation syndromes.

▲ Intracranial Pressure Monitoring

Monitoring ICP provides information that facilitates earlier interventions to prevent secondary cerebral ischemia and brainstem distortion. For ICP monitoring to be safe and effective, the indications for monitoring, methods of monitoring, and ethical considerations for patient care and nursing practice must be taken into account for each patient. Factors that affect patient selection include the potential benefit from invasive ICP monitoring and therapy, the patient's diagnosis and prognosis, and the availability of the appropriate level of critical care. ICP monitoring helps improve patient outcome by providing information about the likelihood of cerebral herniation and facilitating calculation of CPP. It is also helpful in guiding the use of potentially harmful treatments, such as hyperventilation, mannitol, and barbiturates.

Indications for Intracranial Pressure Monitoring

ICP monitoring is primarily used for guiding therapy. General guidelines exist to provide direction in therapy for patients at risk for and with increased ICP. Potential diagnostic indications for ICP measurement include brain injury, stroke, brain tumors, cardiac arrest, and surgery. The decision to use ICP monitoring should be based on clinical and radiographic evaluation as well as computed tomography (CT) diagnosis.

Currently, ICP monitoring is not indicated for patients with mild to moderate brain injury, defined as a Glasgow Coma Scale (GCS) score of 9 to 15. However, ICP monitoring may be appropriate for comatose patients or patients with severe brain injury with or without abnormalities on a CT scan of the head. Severe brain injury is defined as a GCS score of 3 to 8 with abnormal CT scan findings such as hematoma, contusion, edema, or compressed basal cisterns. ICP monitoring is also appropriate for patients who have brain injury with a normal CT scan and who have two or more of the following criteria: age greater than 40 years, any motor posturing, or systolic blood pressure less than 90 mm Hg.[4]

The upper limit of normal ICP is defined typically as 15 mm Hg. Although no prospective, randomized trial has been completed, a summary of the literature suggests that ICP monitors are beneficial in:

- Limiting indiscriminate use of therapies with potentially harmful consequences
- Reducing ICP through CSF drainage, thereby improving CPP
- Assisting in determining a prognosis
- Possibly improving outcomes[4]

Nontraumatic neurological disorders that may benefit from ICP monitoring are subarachnoid hemorrhage, intracerebral hemorrhage, large territory ischemic infarction, infection, hydrocephalus, and, rarely, brain tumors with associated edema or with significant lesion volume. Coagulopathy, systemic infection, CNS infection, and infection at the site of device insertion are relative contraindications to the placement of ICP monitors.

Intracranial Pressure Monitoring Devices

Various devices, such as intraventricular catheters, fiberoptic devices, and epidural monitors, are used to monitor ICP. A chosen ICP device should have pressure range capability of 0 to 100 mm Hg, accuracy within the ICP range of 0 to 20 ± 2 mm Hg, and a maximal error of 10% in the range of 20 to 100 mm Hg of ICP.[4] The type of monitor used depends on several clinical factors, the type of neurological process, and the patient's symptoms on presentation (Fig. 34-2). A variety of advantages and disadvantages exist with each of the devices; therefore, an awareness of potential complications is essential in the bedside management of the patient undergoing such monitoring (Table 34-2).

IVCs provide accurate, low-cost, and reliable ICP monitoring, and they are widely used. The catheter is a tubular instrument that is placed inside fluid-filled cavities in the ventricles. CSF is synthesized in these cavities and flows out to circulate over the surface of the brain. IVCs allow for simultaneous monitoring and treatment of ICP by intermittently draining CSF (Fig. 34-3). IVCs can be inserted

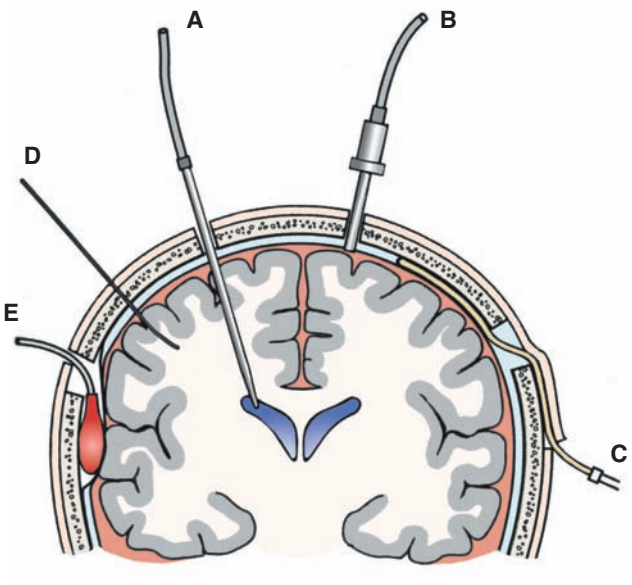

FIGURE 34-2 ▲ ICP monitoring systems: intraventricular (**A**); subarachnoid (**B**); subdural (**C**); parenchymal (**D**); and epidural (**E**).

Table 34-2 Advantages and Disadvantages of Intracranial Pressure Monitoring Devices

Monitoring Site	Advantages	Disadvantages
Intraventricular (ventriculostomy)	• Very accurate • True central direct measure of ICP • Can withdraw CSF to decrease ICP or measure compliance • Ease of CSF sampling	• Need transducer repositioned with every change in head position • High risk for serious infection • Difficult insertion in patients with small or displaced ventricles • Risk for intracerebral bleeding or edema along the cannula track
Intraventricular (fiberoptic catheter)	• Versatile; may be placed in ventricle or subarachnoid space • No adjustment of transducer with head movement	• Separate monitoring system required • Fragile catheter • Unable to recalibrate once device is placed
Intraparenchymal	• Ease of insertion • True brain pressures	• Infections rare, but serious
Lumbar/subarachnoid	• Simple-to-do single readings • No penetration of the brain parenchyma • Decreased risk for infection • Can sample CSF • Direct pressure management	• Contraindicated with evidence of increased ICP • Requires intact skull • Transducer repositioned with head movement
Subdural	• Ease of insertion	• Risk for serious infection
Epidural	• Low risk for infections • No transducer adjustment with head movement	• Imperfect correlation with intradural pressure (sensing through dura) • Operating room for placement • Unable to recalibrate once device is placed • Unable to drain CSF

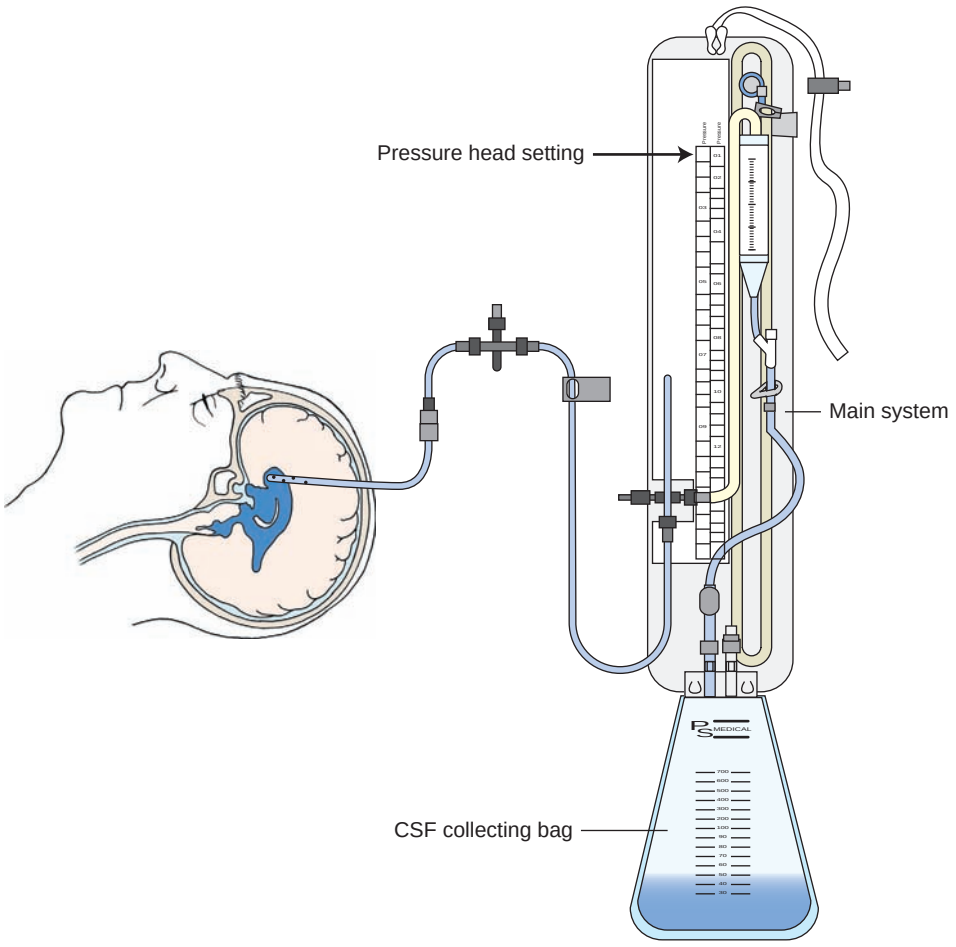

FIGURE 34-3 ▲ Intraventricular catheter system. (Courtesy of Medtronic Neurologic Technologies, Goleta, CA.)

under sterile conditions at the bedside in the intensive care unit (ICU) or in the operating room during surgery. Unlike parenchymal monitors, the IVC can be recalibrated *in situ*.

Fiberoptic monitors use fiberoptic technologies to measure ICP. The tip of the fiberoptic probe has a transducer, which is inserted into brain parenchyma, the ventricles it surrounds, or the subdural space. Fiberoptic monitors are easily inserted, and their use is increasing. Fiberoptic ventricular catheters provide benefits similar to those of IVCs, but at a higher cost. Of similar precision are parenchymal ICP monitors with fiberoptic or strain-gauge catheter-tip transduction; however, these devices are subject to potential measurement drift.

Subarachnoid, subdural, and epidural monitors are less accurate and less frequently used than the other types of monitors.[5] The subarachnoid bolt or screw is inserted through a twist drill hole to the level of the subarachnoid space and secured to a saline-filled pressure tubing transducer system. Epidural monitors are placed into the epidural space between the inner surface of the skull and the dura mater to monitor ICP.

Complications of Intracranial Pressure Monitoring Devices

Each type of monitoring system has potential complications. To ensure accurate measurements and reduce morbidity, the nurse must be alert to problems associated with ICP monitoring systems that could cause incorrect ICP measurements and complications. When the monitor indicates a change in ICP, the nurse must first determine whether the reading is accurate. If the reading is accurate, an attempt is then made to determine the reason for the pressure change. Table 34-3 provides a guide to troubleshooting ICP lines.

As with any invasive procedure, complications may occur. In critically ill patients with neurological problems, the risk/benefit ratio for any therapy must be considered before the implementation of that therapy. For instance, IVCs carry the potential risks for catheter misplacement, obstruction, infection, and hemorrhage. Use of antibiotic-impregnated IVCs is on the rise as a promising technology for reducing device-related infection rates. There are few published data about this practice to date; however, studies are ongoing.

Because drainage holes responsible for the collection of excessive CSF are very small, it is easy for the catheter to become obstructed; the nurse must monitor for this complication evidenced by either poor drainage of the system or change in the patient's neurological status. Malfunction or obstruction occurs at a rate of 6% to 10% in patients with an IVC and is significantly higher in patients with parenchymal or ventricular fiberoptic catheter-tip devices, at a rate of 9% to 40%.[6] Higher rates of obstruction have been correlated with malignant elevations of ICP greater than 50 mm Hg. A reduction in catheter infections has been reported with recent changes in insertion techniques, antibiotic prophylaxis, and improved CSF sampling methods.[6] Hemorrhage associated with IVC placement is poorly described in the literature, prompting the reporting of a 1.1% to 2.8% risk for hematoma formation. The hemorrhage rate is highly dependent on the choice of device.

Intracranial Pressure Waveforms

Waveforms of ICP provide an index of ICP dynamics, such as changes in intracerebral compliance. The appearance of ICP waveforms varies according to the measurement technique being used, the patient's pathological status and activities, interventions, or environmental changes. Hemodynamic and respiratory oscillations can be observed in ICP traces. Computerized systems are being developed to analyze waveforms and integrate ICP, CPP, and other relevant parameters.

Sometimes, the waveforms closely resemble arterial pressure waveforms; at other times, they resemble central venous pressure waveforms. To varying degrees, oscillations corresponding to intracranial arterial pulsations with retrograde venous pulsations are seen with each heartbeat (Fig. 34-4). In patients with ICP less than 20 mm Hg, a slower waveform, synchronous with respiration and caused by changes in intrathoracic pressure, can be seen (see Fig. 34-4, middle). Alterations in arterial driving force, disturbance of venous outflow, and cerebral vasodilation correlate with changes in waveform appearances. At times, a small "a" wave is superimposed on diastole, reflecting right arterial pressure.

Some patients exhibit waveform variation, most commonly A, B, and C waves. A waves, also known as plateau waves, are spontaneous, rapid increases of pressure ranging from 50 to 200 mm Hg, occurring at variable intervals (see Fig. 34-4, bottom). They tend to occur in patients with moderate elevations of ICP, last 5 to 20 minutes, and fall spontaneously. Plateau waves usually are accompanied by a temporary increase in neurological deficit.

Although the mechanism of A waves has not been established firmly, it is thought that they indicate decreased intracranial compliance; therefore, these waveforms should be identified and treated quickly. They may result from an increase in blood volume with a simultaneous decrease in blood flow. The sudden reversal of high pressure may be caused by increased CSF absorption. Falls in CPP with intact autoregulation and low intracranial compliance have been correlated with the initiation of plateau waves. Plateau waves may also be set off by a vasodilating stimulus or by nonspecific stimuli, such as hypoventilation or hyperventilation, pain, and aroused mental activities.

B waves are small, sharp, rhythmic waves with ICPs up to 50 mm Hg, occurring at a frequency of 0.5 to 2 per minute. They correspond to changes in respiration, providing clues to periodic respiration related to poor cerebral compliance or pulmonary dysfunction. B waves often are seen with Cheyne-Stokes respirations (see Chapter 36). They may precede A waves and increase as compliance decreases. At times, they occur in patients with normal ICP and no papilledema. They may be secondary to oscillations of cerebral blood volume.

C waves are small, rhythmic waves with ICPs up to 20 mm Hg, occurring at a rate of approximately six per minute. They are related to blood pressure. Like A waves, they indicate severe intracranial compression, with limited remaining volume residual in the intracranial space.

Intracranial Pressure Measurements

Normal measurements of ICP range between 0 and 10 mm Hg, with an upper limit of 15 mm Hg. During coughing or straining, a normal ICP may increase to 100 mm Hg. A patient's tolerance of a change in ICP varies with the acuteness of its onset. A patient with a slower buildup of ICP (eg, as the result of an expanding brain tumor) is typically more tolerant of elevations in ICP than a patient whose ICP increases rapidly (eg, as the result of an acute subdural

Table 34-3 Troubleshooting Intracranial Pressure Lines

Problem	Cause	Nursing Considerations and Interventions
No ICP waveform	Air between the transducer diaphragm and pressure source	Eliminate air bubbles with sterile saline solution.
	Occlusion of intracranial measurement device with blood or debris	Flush intracranial catheter or screw as directed by physician: 0.25 mL sterile saline solution is often used.
	Transducer connected incorrectly	Check connection, and be sure the appropriate connector for amplifier is in use.
	Fiberoptic catheter bent, broken	Replace fiberoptic catheter.
	Incorrect gain setting for pressure or patient having plateau waves	Adjust gain setting for higher pressure range.
	Trace turned off	Turn power on to trace.
False high-pressure reading	Transducer too low	Place the venting port of the transducer at the level of the foramen of Monro. For every 2.54 cm (1 inch) the transducer is below the pressure source, there is an error of ~2 mm Hg.
	Transducer incorrectly balanced	With transducer correctly positioned, rebalance. Transducer should be balanced every 2–4 h and before the initiation of treatment based on a pressure change.
	Monitoring system incorrectly calibrated	Repeat calibration procedures.
	Air in system: air may attenuate or amplify pressure signal	Remove air from monitoring line.
High-pressure reading	Airway not patent: an increase in intrathoracic pressure may increase $PaCO_2$	Suction patient. Position. Initiate chest physiotherapy.
	Ventilator setting incorrect	Check ventilator settings.
	PEEP	Draw arterial blood gases because hypoxia and hypercarbia cause increases in ICP.
	Posture	Head should be elevated 15–30 degrees unless contraindicated by other problems, such as fractures.
	Head and neck	The head should be positioned to facilitate venous drainage.
	Legs	Limit knee flexion. Avoid acute hip flexion.
	Excessive muscle activity during decerebrate posturing in patients with upper brainstem injury may increase ICP.	Muscle relaxants or paralyzing agents sometimes are indicated.
	Hyperthermia	Initiate measures to control muscle movement, infection, and pyrexia.
	Excessive muscle activity	
	Increased susceptibility to infection	
	Fluid and electrolyte imbalance secondary to fluid restrictions and diuretics	Draw blood for serum electrolytes, serum osmolality. Note pulmonary artery pressure. Evaluate input and output with specific gravity.
	Blood pressure: vasopressor responses occur in some patients with elevating ICP.	Use measures to maintain adequate continuous positive pressure.
	Low blood pressure associated with hypovolemia, shock, and barbiturate coma may increase cerebral ischemia.	
False low-pressure reading	Air bubbles between transducer and CSF	Eliminate air bubbles with sterile saline.
	Transducer level too high	Place the venting port of the transducer at the level of the foramen of Monro. For every 2.54 cm (1 inch) the transducer is above the level of the pressure source, there will be an error of approximately 2 mm Hg.
Low-pressure reading	Zero or calibration incorrect	Rezero and calibrate monitoring system.
	Collapse of ventricles around catheter	If ventriculostomy is being used, there may be inadequate positive pressure. Check to make sure a positive pressure of 15–20 mm Hg exists. Drain CSF slowly.
	Otorrhea or rhinorrhea	These conditions cause a false low-pressure reading secondary to decompression. Document the correlation between drainage and pressure changes.
	Leakage of fluid from connections	Eliminate all fluid leakage.
	Dislodgment of catheter from ventricle into brain	Contact physician regarding appropriate diagnostic studies and intervention. Use soft catheter designed for intraventricular measurement.
	Occlusion of the end of a subarachnoid screw by the necrotic brain	In most cases, remove screw.

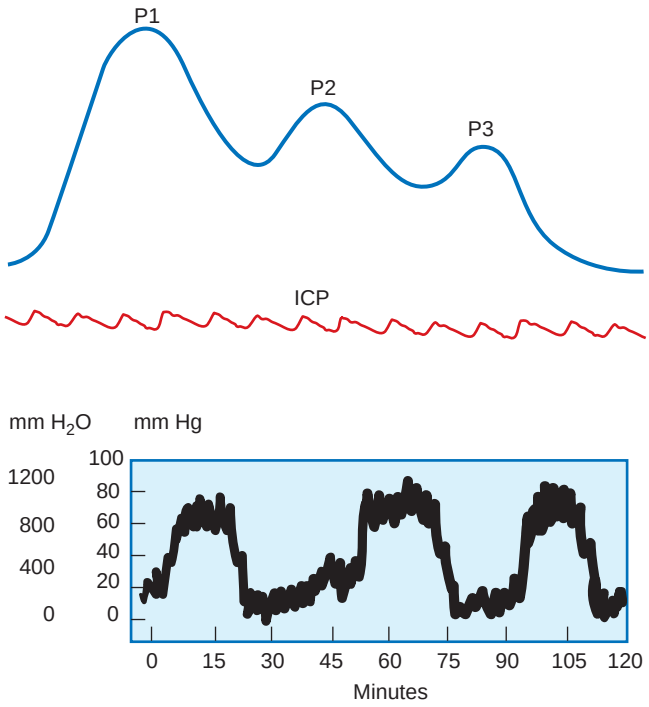

FIGURE 34-4 ▲ Intracranial pressure (ICP) waveforms. **Top:** A normal ICP pulse waveform may demonstrate three or more descending peaks. P1, the pressure wave, originates from choroid plexus pulsations. P2, the tidal wave, is more variable in shape and amplitude and ends on the dicrotic notch. P3, the dicrotic wave, follows the dicrotic notch and tapers down to the diastolic position unless retrograde venous pulsations cause a few more peaks. The P2 portion of the waveform most directly reflects the state of intracerebral compliance. As mean ICP rises, P2 progressively elevates, causing the pulse wave to appear more rounded. When a state of decreased compliance exists, the P2 component is equal to or higher than P1. **Middle:** An ICP waveform demonstrating hemodynamic and respiratory oscillations. Note the vascular pressure-type notches in the waveforms and the baseline variations that reflect respirations. **Bottom:** "A," or plateau, waves, associated with decreased intracranial compliance, may be secondary to an increase in blood volume with a simultaneous decrease in blood flow.

hematoma). Uncontrolled ICP between 20 and 25 mm Hg is considered extremely dangerous for the patient with brain injury. Sustained ICP greater than 60 mm Hg usually is fatal. ICP may rise to the level of the MAP. The greater the variations in the mean ICP, the more nearly exhausted are the compensatory mechanisms for intracranial volume increases.

CPP is the main indicator of the circulatory system's ability to infuse the brain. However, CPP has limitations; it measures only a single parameter that influences oxygen delivery and the neurons' ability to sustain injury. Neuronal demand for oxygen is governed by the cell's metabolic needs, which increase during neuronal activity or injury. Therefore, to understand the metabolic status of the neuron, both CBF and oxygen content in the blood must be measured. The equation CBF × OEF × SaO_2 is commonly used to calculate the cerebral metabolic rate for oxygen ($CMRO_2$). The oxygen extraction fraction (OEF), which is measured using both the arterial and venous oxygen content, describes how much oxygen is extracted. SaO_2 represents the oxygen saturation in the arterial blood. Necessary information can be obtained using multimodality monitoring, including blood flow studies, such as jugular venous bulb oximetry, as well as positron emission tomography and single-photon emission CT.

Jugular Venous Bulb Oximetry

Jugular venous bulb oximetry is an invasive technique that involves placing a sampling catheter in the internal jugular vein, with the tip of the jugular venous bulb at the base of the brain. Blood samples from this location measure the mixed venous oxygen saturation (SjO_2) of blood leaving the brain. This is normally 50% to 75%. The SjO_2 decreases when there is an imbalance between oxygen consumption and delivery. If the SjO_2 decreases to less than 50% (without a decrease in SaO_2), this implies either a decrease in CBF or an increase in oxygen utilization (higher $CMRO_2$). If CPP is maintained, a decrease in CBF is due to an increase in cerebrovascular resistance (CVR). Vascular spasm and an increase in CVR are very common after brain injury and are significantly worsened by hyperventilation; therefore, this technique is discouraged. An increase in SjO_2 greater than 85% implies either a hyperemia with an increase in CBF, shunting of blood away from neurons, or a decrease in $CMRO_2$ (impending cell death or brain death). It should be emphasized that SjO_2 is a measure of global cerebral oxygenation and is not sensitive to small areas of focal ischemia. However, SjO_2 may be of assistance in guiding some therapies for the patient with brain injury, including barbiturate-induced cerebral metabolic suppression and the rare use of induced hyperventilation.

Transcranial Doppler Ultrasound

Transcranial Doppler is a noninvasive method of assessing the state of the intracranial circulation. The velocity of flow can be measured in the middle, anterior, and posterior cerebral arteries, the ophthalmic artery, and internal carotid artery. Flow cannot be measured from velocity because the cross-sectional area of the arteries cannot be measured directly. However, the Doppler shift measured is inversely proportional to the diameter of the vessel, so that if all other factors remain constant, vascular narrowing leads to an increase in flow velocity. Doppler waveform analysis can provide further information about the state of blood flow, but the value and utility of these and other multimodality techniques are as yet unknown.

▲ Management of Increased Intracranial Pressure

In the stage between the onset of increased ICP and herniation, many treatments are available to reduce ICP and maintain adequate cerebral perfusion. No single management routine is appropriate for all patients. In addition to clinical pathways and nursing care protocols, algorithms for the incremental application and weaning of ICP management have been developed. First-tier therapy includes ventricular CSF drainage (as discussed previously), mannitol administration, respiratory support, and sedation and analgesia. Second-tier therapy includes hypothermia, barbiturate coma, optimized hyperventilation, hypertensive CPP therapy, and decompressive craniectomy.

Treatment goals for the patient with increased ICP are as follows: reduce ICP, optimize CPP, maintain adequate tissue

oxygenation, and avoid brain herniation. Most management techniques are oriented toward control of cerebral blood volume and CSF circulation, the two major mechanisms responsible for the regulation of ICP. Measures to reduce ICP are usually initiated when the patient's ICP increases to approximately 15 mm Hg.

Clinical Management

Hyperosmolar Therapy

Several options exist for the management of intracranial hypertension: hypertonic saline and mannitol administration.

HYPERTONIC AGENTS. Hypertonic saline is a mainstay for the treatment of patients with intracranial edema. Induced hypernatremia has been demonstrated to both increase cerebral perfusion pressures and decrease intracerebral pressure in the setting of multiple pathologies (stroke, subarachnoid hemorrhage, mass lesions). Timing of the initiation of such therapies continues to be debated and clear recommendations have yet to be provided. Therefore, treatment with hypertonic saline varies both in the concentration of the hypertonic solution and in the method of delivery. Induced hypernatremia can be achieved with solutions ranging from 2% to 23.4%. Additionally, agents can be administered via bolus dosing versus continuous infusion.

Peripheral intravenous access can be used if administering 2% hypertonic saline. However, giving a more hyperosmolar agent (>3%) requires central venous access to avoid infusion phlebitis or regional necrosis. A 250 mL bolus of 3% hypertonic saline can expected to raise serum sodium by nearly 5 mEq/L.[7] Central pontine myelinolysis remains a theoretical concern and has yet to be proven in the literature as a reality.

MANNITOL ADMINISTRATION. Mannitol, a hypertonic crystalloid solution that decreases cerebral edema, is also used as first-tier therapy for reducing ICP after brain injury. It is typically administered as a bolus intravenous (IV) infusion over 10 to 30 minutes in doses ranging from 0.25 to 2 g/kg body weight. Studies have demonstrated the effect of mannitol on ICP, CPP, CBF, and brain metabolism and have also shown a beneficial effect on long-term neurological outcome. The immediate plasma-expanding effect of mannitol, which reduces blood viscosity, increases CBF and cerebral oxygen metabolism, permitting cerebral arterioles to decrease in diameter. This lowers cerebral blood volume and ICP, while maintaining constant CBF. Use of hypertonic saline follows a similar pharmacodynamic effective in the treatment of elevated ICP and may provide an alternative therapy.[8–10]

Mannitol is excreted in the urine. If it is administered in large doses and serum osmolarity is greater than 320 mOsm, there is a significant risk for acute tubular necrosis and renal failure. Therefore, it is customary to measure serum osmolarity every 6 to 8 hours to a target of less than 320 mOsm.

A Foley catheter must be inserted when mannitol is administered. When mannitol is used during the early resuscitation phase in hypovolemic patients with brain injuries, crystalloid solutions are infused simultaneously to correct hypovolemia. Adjunct crystalloid fluid administration facilitates rapid renal excretion of mannitol, preventing renal failure. In the early phases of acute brain injury, mannitol is recommended as monotherapy. When mannitol is combined with furosemide, there is a risk for excessive diuresis, causing depletion of intravascular volume and electrolytes.

Respiratory Support

There are several considerations when managing the respiratory status of a critically ill patient with neurological injury. Mean airway pressure is the leading factor affecting ICP in the patient who is receiving ventilation therapy. Positive airway pressure is transmitted to the intracranial cavity through the mediastinum by preventing jugular venous outflow. Therefore, any condition decreasing pulmonary compliance or use of positive end-expiratory pressure (PEEP) increases the mean airway pressure and decreases the MAP and CPP.

Normocapnia is essential for maintaining stable ICP because carbon dioxide directly affects the degree of vasodilation in the cerebral blood vessels. Hyperventilation remains controversial in the management of increased ICP. Hyperventilation decreases the arterial carbon dioxide tension ($PaCO_2$) and results in cerebral vasoconstriction. As a result, the CBF is reduced because of the strong vasoconstrictive effect of hypocarbia on the cerebral arteries. The $PaCO_2$ should be lowered gradually to avoid a rebound effect of vasodilation from overcorrection. When hyperventilation is discontinued, ventilation rates should be gradually returned to normal. In the absence of a malignant increase in ICP, hyperventilation therapy ($PaCO_2$ < 25 mm Hg) should be avoided after a traumatic brain injury. Also, the use of prophylactic hyperventilation therapy ($PaCO_2$ < 35 mm Hg) during the first 24 hours after a traumatic brain injury should be avoided because it can compromise cerebral perfusion during a time of critically reduced CBF.[4,11] Severe, prolonged hyperventilation has been conclusively shown to worsen the outcome of patients with a severe brain injury and should be reserved for those cases in which all other therapies have failed. Severe hyperventilation is defined as a $PaCO_2$ of less than 25 mm Hg by jugular venous oxygen saturation monitor. Extreme hyperventilation is believed to cause secondary ischemia by constricting cerebral vasculature.[4]

Increasing intrathoracic pressure directly increases ICP, and therefore suctioning should be approached thoughtfully. Limiting the duration of passes of the suction catheter to no more than 5 to 10 seconds avoids hypoxia. And limiting the number of passes to one or two avoids overstimulation of the cough reflex and decreases the incidence of increased intrathoracic pressure and ICP.

Pharmacological Therapy

Analgesics, Sedatives, and Paralytics

In patients with a severe brain injury (GCS score < 8), pain medications and sedatives are used to:

- Reduce agitation, discomfort, and pain
- Facilitate mechanical ventilation by suppressing coughing
- Limit responses to stimuli, such as suctioning, which may increase ICP

Before starting patients on analgesics or sedatives, every effort should be made to implement nonpharmacological management techniques for pain, agitation, anxiety, and confusion. When medication is required, the agent should be selected based on both desired mechanism of action as well as half-life of the medication because restoration of the neurological function is critical for the care of these patients (Table 34-4). The treatment of pain lowers energy expenditures and thereby facilitates healing. Further, analgesics and sedatives may potentiate each other, allowing patients to achieve comfort and sedation.[12]

Analgesics

Opioid narcotics primarily affect the CNS. Fentanyl and morphine are two of the most frequently used opiate narcotics for brain-injured patients (see Table 34-4). They:

- Limit pain caused by injuries and nursing interventions
- Facilitate mechanical ventilation
- Potentiate the effect of sedatives[12]

Potentially life-threatening adverse effects of narcotics include respiratory depression, depression of the cough reflex, mood changes, nausea, and vomiting. Vital signs and pulse oximetry values must be monitored diligently when a patient receives IV pain medication. When preparing for such complications, the critical care nurse should ensure that intubation equipment is readily available in case respiratory depression occurs. Naloxone, which reverses CNS depression that can occur with the administration of fentanyl and morphine, may be required. With proper dosing and diligent nursing observation, narcotic analgesics can be used effectively in the critically ill patient.

The basic principles of narcotic administration are adequate pain relief and safe administration. It is especially important to begin with the lowest possible dose when treating a patient with neurological illness because the injured brain's response to medication is unpredictable. When a patient with a brain injury also has severe pain caused by multiple traumatic injuries, a continuous infusion of fentanyl or morphine is indicated and can be titrated every 15 to 30 minutes until pain control is achieved. For a patient with moderate pain, a 24-hour regimen of opiate narcotic administration has proved to provide increased pain relief versus an "as-needed" schedule of opiate dosing.

For the patient who can communicate, a verbal pain scale is used to assess pain. Standardized rating scales, such as a 1 to 10 pain scale, should be used to quantify and evaluate pain status and response to therapy. In addition to location, quality, and duration of pain, the nurse must document the effectiveness of analgesics every hour for 4 hours with initial administration, then every 4 hours, and 15 minutes after each dose change.[12] All hospitals have a pain management protocol that identifies analgesics that should be used, dosing titration guidelines, and documentation requirements. In addition, most protocols address sedation recommendations.

For the patient who is unable to communicate, physiological parameters are used to determine the effectiveness of pain management. The nurse assesses heart rate, respiratory rate, use of accessory muscles for breathing, and blood pressure. Adequate pain management leads to less patient movement, such as thrashing, which increases metabolic activity. The following clues can be used to determine whether adequate pain relief has been obtained for the patient who cannot communicate:

- Ease of breathing
- Mechanically ventilated patient whose breathing is synchronous with the ventilator
- Possible decrease in heart rate
- Less agitation as indicated by restful sleep state
- Cooperation with nursing interventions without excessive physical activity

Also, narcotics decrease gastric motility and may cause constipation. Patients with neurological illness in the critical care setting are often immobilized or confined to bed and are especially prone to constipation. All patients on narcotic therapy should be on a bowel regimen to avoid this complication, and the quality and frequency of bowel movements should be monitored closely. Straining increases ICP and could possibly be avoided with strict bowel regimens. Patients may also be susceptible to nausea and vomiting with the administration of narcotics. Protection of the airway is especially important in the patient with a neurological diagnosis. Mechanically ventilated patients require the insertion of a nasogastric or orogastric tube to decompress the stomach and prevent vomiting.

Sedatives

The most commonly used sedatives in the ICU are benzodiazepines, which cause little change in CBF, ICP, and cerebral metabolic rate, and potentiate the effects of analgesic agents. Midazolam, diazepam, and lorazepam are used frequently for sedation before ICU procedures and as needed to treat anxiety (see Table 34-4). Lorazepam is frequently used for alcohol withdrawal and anticonvulsant therapy. Midazolam, in combination with fentanyl, is most often used for sedation before procedures to produce amnesia of immediate events. Side effects of sedatives include respiratory depression, hypotension, and somnolence. It is mandatory that resuscitation equipment be available at all times when IV benzodiazepines are used. Benzodiazepines should be administered at the lowest possible dose that produces effective sedation, without causing somnolence. As with analgesic agents, frequent vital signs must be obtained with the administration of sedatives. Recommended minimal documentation of vital signs should be every hour for 4 hours, then every 4 hours, and 15 minutes after every dosage change.[12]

Various scales may be used to document the patient's response to sedation. The target sedation level for a patient with a critical neurological illness is one that allows easy arousal of the patient with light touch or voice.[12] For the patient who cannot communicate (as discussed earlier with analgesic use), the assessment of physiological parameters can be used to determine the patient's response to sedation in order to achieve maximal comfort. Pharmacological management of sedation is only one strategy to treat anxiety. Nursing measures to provide comfort must be offered in addition to medications.

Anesthetics

Propofol is a fat-soluble anesthetic that is administered as a continuous infusion to decrease agitation in the critically ill patient. Studies have shown that propofol may decrease

Table 34-4 Major Classes of Pharmacological Medications Used to Treat Neurological Emergencies

Class	Medication	Mechanism of Action/Dosage	Comments
Direct vasodilators	Sodium nitroprusside Nitroglycerin Hydralazine	Directly dilate the peripheral vasculature and lower vascular resistance Sodium nitroprusside: start at 0.3 mcg/kg/min, maximal continuous IV infusion 10 mcg/kg/min Nitroglycerin: start at 5 mcg/min, then titrate as needed upward q5min (max 100 mcg/min) Hydralazine: 10–20 mg IV, may be repeated as needed	• Dilate the cerebral vasculature • Increase cerebral blood volume and ICP, decrease MAP and CPP • Sodium nitroprusside: at high doses may cause cyanide toxicity, check thiocyanate levels, protect infusion from light • Nitroglycerin: venous dilation, caution with high doses; may cause hypotension • Hydralazine: used in hypertensive emergency, may cause hypotension and headache
β-Adrenergic antagonists	Metoprolol Esmolol	β-Adrenergic receptor antagonist Metoprolol: 5 mg IV q3–5 min in three doses, followed by PO administration 25–50 mg PO twice daily and may increase to 50–100 mg PO twice daily Esmolol: for hypertensive emergency, bolus dose 500 mcg/kg over 1 min, then 50–200 mcg/kg/min	• Do not affect CBF • Use with caution with Cushing's response, can potentiate bradycardia
Mixed α- and β-adrenergic antagonists	Labetalol	Selective α- and nonselective β-adrenergic receptor antagonist Labetalol: for hypertensive emergency, start 20 mg IV over 3–5 min, followed by 40–80 mg IV every 10 min PRN up to 300 mg, or IV infusion 0.5–2 mg/min	• Reduce systemic vascular resistance (SVR) • Improve CPP and do not increase ICP • May slow heart rate
Calcium channel antagonists	Verapamil Diltiazem Nicardipine	Prevent transport of calcium ions in vascular smooth muscle, resulting in vasodilation, decreased myocardial contractility, decreased heart rate Verapamil: for supraventricular tachycardia, 5–10 mg IV over 2 min, followed by 40–80 mg three to four times a day Diltiazem: 20 mg over 2 min, continuous infusion 5–15 mg/h Nicardipine: Start 5 mg/h; increases 2.5 mg/h every 5–15 min; Max dose 15 mg/h	• Use with caution; may cause cerebral vasodilation with increased ICP • Contraindicated in patients with tumors and cerebral edema
Angiotensin-converting enzyme (ACE) inhibitors	Lisinopril	Shift the upper and lower limits of blood brain autoregulation by inhibiting angiotensin II–mediated vascular tone in large cerebral arteries, while small vessels vasoconstrict Lisinopril: start 10 mg/d, titrate to 80 mg/d PRN	• Preserve CBF after single dose • Increase CBF with chronic treatment • Have the potential to increase ICP in patients with intracranial hypertension by increasing CBF
Osmotic diuretic	Mannitol	Indicated for intracranial hypertension Mannitol: 0.25–2 g/kg IV over 30–60 min	• If infused too quickly, may contribute to renal insufficiency
Nondepolarizing muscle blockading agents	Pancuronium	Skeletal muscle paralysis Bolus 0.04–0.1 mg/kg Continuous infusion	• May cause tachycardia and dysrhythmias • Patient must be mechanically ventilated
	Atracurium	Skeletal muscle paralysis Bolus 0.4–0.5 mg/kg IV Continuous infusion 4–12 mcg/kg/min IV	• Rare occurrence of prolonged weakness after discontinuation of drug infusion • Patient must be mechanically ventilated • Use in patients with hepatic and renal impairment • Neuromuscular blockade should be preceded by adequate sedation and analgesia, which should be maintained during course of blockade
	Cisatracurium	Skeletal muscle paralysis Bolus 0.1–0.2 mg/kg Continuous infusion 2.5–3 mcg/kg/min IV	• Rare incidence of prolonged weakness after continuous IV infusion • Patient must be mechanically ventilated • Use in patients with hepatic and renal impairment

(continued on page 755)

Table 34-4 Major Classes of Pharmacological Medications Used to Treat Neurological Emergencies (continued)

Class	Medication	Mechanism of Action/Dosage	Comments
Sedatives	Diazepam Lorazepam Midazolam	Benzodiazepines are sedatives and hypnotics that induce anterograde amnesia Diazepam and lorazepam are also used to stop seizure activity Diazepam: 10–20 mg IV no faster than 2 mg/min, then repeat q4h Lorazepam: 0.05–0.2 mg/kg/dose, up to 8 mg, may repeat every 15 min, continuous infusion 1 mg/h and titrate to goal, not to exceed 8 mg/h Midazolam: 0.1–0.3 mg/kg bolus, no faster than 4 mg/min, continuous infusion 0.05 mg/kg/h up to 1.0 mg/kg/h	• May cause somnolence, hypotension, delirium, hallucinations, respiratory depression • Titrate to goal using sedation scale • Lorazepam/midazolam: use with caution in patients with hepatic/renal failure, contraindicated in patients with acute narrow-angle glaucoma or in shock, and in older patients
Anticonvulsants	Phenytoin Carbamazepine	Indicated for tonic-clonic seizures and partial seizures Phenytoin: loading dose 15–20 mg/kg for status epilepticus, no faster than 50 mg/kg; maintenance dose 200–500 mg daily or in divided doses three times a day Carbamazepine: 200 mg twice daily, maintenance 200–400 mg three times a day	• May cause ataxia, lethargy, movement disorders, rash, coarse facies, lymphadenopathy • May decrease theophylline, oral contraceptive, and warfarin levels • Phenytoin levels may increase with methsuximide and alcohol • Phenytoin levels may decrease when used with valproic acid and Tegretol • Contraindicated with alcohol ingestion, sinus bradycardia, heart block
Analgesics	Morphine Fentanyl Hydromorphone	Opiate analgesics blunt the pain response by interfering with central and peripheral pain pathways Morphine: bolus 1–4 mg, continuous infusion 0.07–0.5 mg/kg/h Fentanyl: bolus 50–100 mcg over 1–2 min, continuous infusion 0.7–10 mcg/kg/h Hydromorphone: continuous infusion 7–15 mcg/kg/h	• May cause respiratory depression; must have naloxone readily available • Have resuscitation equipment nearby at all times • Use the lowest dose that provides adequate pain relief • Use a 1–10 pain scale to assess effectiveness of pain relief • For severe pain, around-the-clock administration or a continuous infusion of pain medication provides more efficient pain relief than PRN dosing • Use lower doses in older patients • Use nonpharmacological approaches to pain management • Side effects: decreased gastric motility; nausea/vomiting, tremulousness
Sedation/Anesthetic	Propofol Precedex	Propofol is an IV general anesthetic agent that can be used to treat agitation in the ICU Propofol: bolus not necessary, continuous infusion 5–50 mcg/kg/min Precedex: 0.2–0.7 mcg/kg/h; start 1 mcg/kg then titrate to effect	• Patient must be mechanically ventilated (propofol) • Must have dedicated IV line • Must use aseptic technique • May cause hypotension • Must provide analgesics and sedation • Use for the shortest period possible • Can extubate patient while Precedex is still infusing • Watch for atrial fibrillation in patients prone to A fib
Barbiturates	Phenobarbital Pentobarbital	Used to produce CNS depression and reduce the spread of an epileptic focus Phenobarbital: loading dose 6–8 mg/kg IV; maintenance dose 1–3 mg/kg/24 h IV Pentobarbital: loading dose 3–10 mg/kg over 30 min; maintenance dose 0.5–3.0 mg/kg/h	• May cause respiratory depression and cardiac depression • Patient must be mechanically ventilated • Continuous EEG monitoring for barbiturate-induced coma

CBF, ICP, CPP, and cerebral metabolic function.[13] Propofol is easily titrated based on patient response. It also has a short half-life and can be discontinued for neurological assessments. Propofol can decrease the level of consciousness in 2 minutes. A common side effect is hypotension; therefore, frequent blood pressure monitoring must be performed, especially if the patient has increased ICP. Since this anesthetic agent causes loss of respiratory drive, diligent airway protection must be provided for the patient receiving propofol. To prevent respiratory depression, the patient must be intubated and mechanically ventilated when propofol is administered. For these reasons, the patient who receives a continuous infusion of propofol must be cared for in the ICU, with constant surveillance by the critical care nurse. In most states, an anesthesia provider may administer an IV bolus dose of propofol.

Propofol infusion syndrome is a rare but significant adverse drug event associated with prolonged propofol use (>48 hours) at high doses (>4 mg/kg/h). This syndrome is characterized by hypotension, severe metabolic acidosis, rhabdomyolysis, hyperkalemia, renal failure, hepatomegaly, and cardiovascular collapse. Therefore, duration of propofol therapy should be monitored and limited when possible.

Other considerations with propofol are related to the handling of the drug. Propofol is manufactured by using a fat emulsion, making it a powerful medium for bacterial growth. Propofol must be handled meticulously to prevent the risk for bacterial or fungal infection associated with its use. The fat calories provided by propofol should be included when calculating nutritional supplementation for the patient receiving this infusion. It may be necessary to monitor the triglyceride level for patients receiving propofol longer term.

Dexmedetomidine (Precedex) is an alpha-adrenergic receptor agonist that provides sedation, antianxiolysis, and analgesia without respiratory depression.[14] This IV medication may be a good alternative in the critical care setting since patients can be weaned from the ventilator and extubated while receiving this medication. The most common side effect is hypotension.

Neuromuscular Blockade

Neuromuscular blockading (NMB) agents (see Table 34-4, p. 754) are used to induce muscle paralysis and remain a "last resort" therapy. An NMB agent blocks the transmission of acetylcholine at the motor end plate, producing skeletal muscle paralysis. Reversal of NMB agents is provided by acetylcholinesterase inhibitors such as neostigmine, edrophonium, and pyridostigmine. The use of an NMB agent requires mechanical ventilation with full support. Resuscitation equipment must be present at all times when a patient is treated with an NMB agent. For a conscious patient, the inability to move and communicate is frightening; therefore, concurrent administration of analgesia and sedation is mandatory.[15] Analgesia and sedation provide the added benefit of producing amnesia.

Complications common with most NMB agents are tachycardia, hypotension, and dysrhythmias. Cardiac medications such as antidysrhythmics, diuretics, and calcium channel and β-blockers can potentiate the action of NMB drugs. Certain antibiotics, such as aminoglycosides and clindamycin, can potentiate the action of paralytic agents. Alterations in body temperature or acid–base balance and electrolyte disturbances also alter the action of NMB agents.[15]

A troubling complication of paralytic therapy is prolonged polymyopathy. A condition known as acute quadriplegic myopathy syndrome, or postparalytic quadriparesis, is one of the most devastating complications caused by prolonged use of an NMB agent.[15] This condition is manifested by prolonged weakness of the upper and lower extremities. The extraocular motor muscles are usually spared in this condition. A patient may also experience painful muscle fasciculations. To avoid these complications, the smallest dosage of an NMB agent should be used to obtain adequate respiratory support.

Peripheral nerve stimulation monitoring is mandatory with NMB therapy;[15] its use every 4 hours, with a dosage change as necessary, may help prevent complications associated with NMB therapy. A peripheral nerve stimulator is a small hand-held device used in the ICU to monitor the depth of NMB in the patient receiving prolonged paralytic therapy. This device delivers a small jolt of energy to the ulnar surface of the wrist, causing the thumb to twitch. The train-of-four method is used to measure the efficacy and depth of NMB. The peripheral nerve stimulator delivers four 2-Hz stimuli of 0.2 millisecond delivered at intervals of 0.5 second to the ulnar nerve at the wrist. Normally, the thumb twitches four times when the peripheral nerve stimulator is activated. The nurse observes thumb movements after peripheral nerve stimulation. If the thumb twitches two or three times, NMB dosing is usually sufficient. If four thumb twitches occur, paralysis is ineffective. If no twitches occur, paralysis is excessive, and the dose of the NMB agent must be reduced.

Excellent nursing care also can help prevent some of the complications caused by NMB agents. A rigid patient repositioning schedule must be maintained to prevent the development of pressure ulcers. Aspiration precautions and excellent pulmonary toilet must be maintained at all times to avoid pneumonia. Also, deep venous thrombosis prophylaxis must be implemented before induction of paralysis.

Barbiturate Coma

For the patient with severe and refractory elevated ICP, an induced barbiturate coma may be attempted to decrease systemic metabolic activity in an attempt to preserve brain function. It must be understood that induction of a barbiturate coma is a rare therapy and is used only as a last resort to save brain function. Criteria for inducing a barbiturate coma includes a GCS score of less than 7, ICP greater than 25 mm Hg at rest for 10 minutes, and failed maximal interventions, including drainage of CSF, mannitol, analgesia, and sedation. Barbiturate coma is typically used for less than 72 hours.

Barbiturates suppress seizure activity and reduce cerebral metabolic activity and cerebral oxygen demand (see Table 34-4, p. 754). Barbiturates affect CBF, metabolic demand, electroencephalographic (EEG) activity, and systemic hemodynamics. CBF may decrease by 50%. Barbiturate therapy appears to have a direct restrictive effect on cerebral vasculature by diverting small amounts of blood from well-perfused areas to ischemic areas, thereby improving cerebral pressure.

Before the administration of barbiturates, the following must be provided for the patient: a secure airway with mechanical ventilation; ICP, blood pressure, cardiac, and pulmonary artery monitoring; and continuous EEG monitoring. An EEG is obtained before administration of a barbiturate so that spontaneous electrocortical activity is documented.

The EEG pattern of burst suppression is the most common method to establish barbiturate dosing. The barbiturate dose is adjusted until EEG burst suppression is achieved. The initial dose may be supplemented by an IV bolus to achieve burst suppression. Barbiturate serum levels alone are poor measures of therapeutic efficacy and systemic toxicity.

Barbiturates should be discontinued with any of the following clinical findings:

- ICP less than 15 mm Hg for 24 to 72 hours
- Systolic blood pressure less than 90 mm Hg despite the use of vasopressors
- Progressive neurological impairment, as evidenced by deterioration of brainstem auditory evoked responses
- Cardiac arrest

At the time of discontinuation, the barbiturate dosage is gradually reduced over 24 to 72 hours. Arousal is gradual and prolonged, even after blood levels have been zero for several days. The patient must be weaned slowly and carefully from mechanical ventilation because residual muscle weakness may occur. Patients may experience facial weakness for several days after the barbiturate has been discontinued. Occasionally, the patient may experience dysarthria, related to weakness of the muscles of speech. During the first 24 hours of barbiturate withdrawal, slow, abnormal muscle movements may be observed.

Blood Pressure Management

The regulation of blood pressure is an important aspect of managing the patient with increased ICP. Blood pressure is directly related to cerebral blood volume, perfusion pressure, ischemia, and compliance. For patients with brain injuries, the preservation of CPP and maintenance of systemic oxygenation are two important goals. Also, patients with the most severe brain injuries are at risk for secondary injury caused by hypotension and hypoxia. Patients with brain injury may have increased metabolic oxygen consumption, mild hypertension, and increased cardiac indices. Invasive blood pressure monitoring is routinely used to provide continuous and accurate blood pressure measurement during the acute management phase of patients with brain injuries. MAP is the parameter used for evaluating CPP and the efficacy of antihypertensive or vasopressor therapies.

Patients with brain injuries must be monitored continuously for any adverse effect from drug therapies. In addition to the MAP, the cardiac output may be monitored in the acute management of patients with head injuries. See Chapter 17 for further description of hemodynamic monitoring. Drug therapies to manage blood pressure may cause a precipitous increase or decrease in cardiac output. When the cardiac output is low, patients with neurological injuries are in jeopardy of further ischemic injury since the protective mechanisms of autoregulation are disturbed. The cardiac index is usually maintained at 3 L/min/m^2 because patients with head injuries frequently have increased metabolic needs. The pulmonary artery capillary wedge pressure is usually maintained at 12 to 15 mm Hg in patients with head injuries. In addition, noninvasive continuous pulse oximetry and arterial blood gas measurement are used to determine arterial oxygen content.

Different classes of antihypertensive medications can be used to treat systemic hypertension in the critically ill patient.[16] To maintain CPP, avoidance of hypotension is critical for patients with neurological injury. Moreover, any dysrhythmias must be managed aggressively to avoid secondary hypotension. As with any medication, the patient must be assessed for the development of adverse effects associated with cardiovascular medications, including bradycardia, hypotension, myocardial ischemia, tachycardia, and decreased cardiac output.

For patients with acute ischemic stroke, acute hypertension is defined as a systolic blood pressure greater than 185 mm Hg and a diastolic blood pressure greater than 110 mm Hg. These patients are especially dependent on systemic blood pressure to maintain perfusion through a partially occluded intracranial vessel. IV hydralazine or labetalol are frequently used for elevated blood pressure and should be titrated slowly to avoid sudden episodes of hypotension. If the patient remains hypertensive after hydralazine or labetalol administration, nicardipine or nitroprusside may be used (see Table 34-4, p. 754). Both nicardipine and nitroprusside are potent vasodilators and can lower the blood pressure quickly. They are administered as continuous infusions, are easily titrated, and have relatively short half-lives. These medications must be used in the ICU or emergency department where continuous blood pressure monitoring can be provided. Hypotension may occur if the infusion is increased too quickly.

For patients with hemorrhagic brain injury, a more rigorous blood pressure range is maintained. An MAP greater than 110 mm Hg is avoided in these patients.[17] Angiotensin-converting enzyme (ACE) inhibitors and β-blockers are often used to treat hypertension in the head-injured patient with systemic hypertension. β-Blockers are most often used because of their safe side effect profile, although they may cause bradycardia. Calcium channel blockers are usually avoided in head-injured patients because of their potential to exacerbate cerebral edema. See Table 34-4 for additional information.

Seizure Prophylaxis

Often, patients with neurological injury are prone to seizure activity. Seizure activity markedly elevates the cerebral metabolic rate and CBF and may lead to hypoxia. In patients with traumatic brain injury, use of antiepileptic agents for 7 days has been shown to decrease the incidence of early seizure activity but does not prevent development of later seizures. Anticonvulsant therapy may be used to prevent early posttraumatic seizure, especially in patients with a reduced seizure threshold (eg, brain tumor; temporal lobe pathologies). Phenytoin, levetiracetam, and carbamazepine are considered treatment agents for preventing early (<7 days) posttraumatic seizure activity. Levetiracetam may be more convenient to administer as no blood drug levels need to be followed.

The treatment of choice for acute-onset seizures (such as tonic–clonic seizures) in the critically ill patient remains diazepam. The patient should be positioned on his or her side and an oxygen mask applied. Attempting to restrain a seizing patient may lead to joint dislocation or fracture and this should be avoided. When seizure activity has subsided, the nurse should obtain a serum glucose analysis to determine whether hypoglycemia is a contributing cause. An EEG may also be ordered to determine whether the patient is continuing to experience subclinical seizures and to determine seizure focus.

Table 34-5 Nursing Considerations for Patients at Risk for Increased Intracranial Pressure

Problem	Nursing Action	Rationale
Adequate ventilation	• Assess respiratory patterns and rate	• Indicates neurological changes, pain status, and patency of airway
	• Suctioning: Preoxygenate with 100% O_2, one or two catheter passes, no more than 10 s per catheter insertion	• Prevents increased CO_2 (vasodilator that increases ICP); decreases coughing stimulation and increased intrathoracic pressure
	• Monitor continuous pulse oximetry and blood gases	• Alerts nurse to airway problems; good indicator of hemodynamics of respiration
Neurological assessment	• Evaluate patient baseline neurological status at beginning of shift (preferably with previous shift RN)—mental status; pupil shape, size, and response; motor function	• Subtle changes from baseline indicate deterioration and the need for early intervention
	• Assess vital signs—note trends (review ordered parameters for notification of physician)	• MAP directly correlates with ICP in patient with loss of autoregulation
	• Review nursing actions and emergency algorithm for neurologic deterioration (available medications—mannitol, hyperventilation, etc.)	• Ensures optimal benefit to patient and decreases secondary injury from prolonged ICP
Positioning	• Place head of bed flat or at 30 degrees elevation per orders	• Promotes cerebral perfusion or facilitates venous drainage; orders based on physiological process
	• Maintain head in neutral position	• Promotes jugular outflow
	• Avoid hip flexion	• Decreases intrathoracic pressure
	• Assess agitation in restrained patients	• Increases ICP
	• Turn patient every 2h, instructing patient to exhale with turn	• Prevents skin breakdown and avoids Valsalva maneuver during repositioning
	• Carry out passive range-of-motion exercises	• Prevents contractures while avoiding Valsalva-inducing isometric contractions
	• Avoid clustering of patient activities (eg, turning, bathing, suctioning)	• Produces prolonged ICP spikes
	• Use therapeutic interventions for emotional upset—speak with soft voice, use caution with unpleasant conversations, decrease noxious stimuli (noise), use therapeutic touch	• Causes elevations in ICP; comatose patients still respond to unpleasant environmental stimuli
Transport of patient with invasive ICP monitor	• Confirm time of test or possibility of completing as portable study	• Avoids excessive delays in uncontrolled and potentially overstimulating environment
	• Prepare respiratory therapy and other assistants during transport	• Adequate oxygenation remains a priority; multiple lines necessitate additional manpower
	• Gather transport supplies (sedation if ordered, transport monitor, antihypertensives)	• Prepare for intervention with any adverse patient response during travel specific to contributors of increased ICP
	• Assist with transfer of patient to diagnostic table with RN at head of bed monitoring device	• Ensures patient protection and provides for monitor equipment recalibration for accuracy of monitoring
	• Monitor and record hemodynamics and ICP dynamics during study	• Monitors patient response to procedure
Temperature control	• Frequent temperature checks (oral or rectal preferred if no contraindications)	• Cerebral metabolic rate increases with elevated body temperature
	• Confirm orders for early treatment of fever and aggressively treat	• Increased CBF increases ICP
	• Provide gradual cooling with cooling blanket, closely monitored	• Shivering increases ICP
Glycemic control	• Monitor serum glucose and fingersticks as ordered (every 4–6h)—adhere closely to sliding scale protocols in nondiabetic patients	• Alterations in glucose can produce neurological changes (ie, changes in metabolic rate)
	• Maintain euvolemia with normal saline	• Hypotonic glucose IV solutions should be avoided
Bowel and bladder regimens	• Administer daily stool softeners as ordered	• Reduces risk for straining and increased intra-abdominal pressure, which increases ICP
	• Avoid enemas	• Prevents Valsalva maneuver
	• Assess patency of Foley catheters	• Important to monitor amount of diuresis, especially in patients treated with osmotic diuretics
	• Document strict intake and output	• Important to maintain euvolemia
Seizure precautions	• Seizure precautions per hospital protocol (padding, etc.)	• Prevents injury in high-risk patients
	• Monitor serum anticonvulsant drug levels	• Maintains therapeutic levels

Other Management Methods

Hypothermia

Hypothermia continues to be explored as a means for reducing the brain's metabolic demands during peak times of cerebral edema and brain injury. One difficulty is cooling the patient adequately to achieve optimal neuroprotection. To date, the degree of coolness has not been established, although it continues to be investigated in multicenter clinical trials. However, control of fever is essential and is being more aggressively addressed using different types of cooling devices (both surface cooling and intravascular cooling devices).[18]

Decompressive Craniectomy

Another strategy used for managing refractory intracranial hypertension is decompressive craniotomy. This surgery is based on the theory that ICP can be reduced through surgical release of the rigid skull. Although surgical decompression remains an option for patients with uncontrollable ICPs, studies of patients suffering massive cerebral edema and refractory intracranial hypertension after ischemic stroke have shown varying results when comparing postdecompression outcomes and outcomes after best medical management.[19–28] However, the procedure remains widely used for patients with malignant cerebral edema after traumatic brain injury. Further studies are in progress to evaluate the risks and benefits of craniectomy for patients with traumatic brain injury. Evaluation of long-term morbidity and mortality as well as the best timing for this procedure continues.[19–27]

Patient Care Considerations

Nursing care activity can compound primary and secondary intracranial insults, contributing to rapid deterioration in the unstable patient who has lost intracranial compliance, autoregulation, and vasomotor tone.[24] Patient positioning, agitation, pain, hemodynamic and respiratory status, and seizures can all contribute to a patient's elevated ICP. The following sections describe a few patient management strategies for reducing ICP (Table 34-5).

Positioning

Primary positioning strategies for the patient with impending or active increased ICP include placement of the head and neck in a neutral position. Extreme neck flexion, extension, or rotation restrict venous drainage from the head through the internal jugular venous system and the vertebral venous plexus, increasing the total intracranial content. Decerebrate or decorticate posturing may also increase ICP. In addition, head-of-bed elevation has been shown to promote venous drainage and decrease ICP. The head is elevated 15 to 30 degrees, unless contraindicated by spine or limb fractures.

Tracheostomy ties and cervical collars are frequently checked for proper fit. Flexion of the hips greater than 90 degrees is avoided because it contributes to intra-abdominal and thoracic pressures and also impairs venous outflow.

Environmental Stimuli

Environmental stimuli contributing to pain, stress, or anxiety can increase cerebral metabolic rates and blood flow, confounding the management of increased ICP. Pain control and sedation are essential to reduce environmental overload, with consideration for the need for serial neurological assessments in the critically ill patient. Anxiety and discomfort in the ICU cannot be underestimated and should be considered in the patient who is neurologically impaired. Periods of uninterrupted sleep and rest should be provided between activities. Only essential interventions are performed during times of poor intracranial compliance, and activities are spaced to avoid a cumulative effect. Also, avoiding unnecessary painful procedures, such as frequent blood draws, is helpful.

▲ Clinical Applicability Challenges

CASE STUDY

Mr. H., a 56-year-old retired man, is brought by ambulance to the emergency department after having fallen down. At that time, he had speech problems and right arm and leg weakness. His neurological baseline examination and following workup suggests a large middle cerebral artery (MCA) territory ischemic infarction.

Past medical/surgical history: Hypertension and hyperlipidemia

- Allergies: none
- Social history: retired military computer analyst, married with supportive wife, three biological children, ages 28, 26, and 25, and all healthy; social ingestion of alcohol; smoking history 1 pack per day for 35 years
- Medications: lisinopril (Zestril), 20 mg/d; atorvastatin (Lipitor), 10 mg/d

Mr. H. is admitted to the neuroscience ICU for acute stroke management, monitoring, and treatment of potential complications. Because of his large left MCA stroke, he is at risk for cerebral edema, seizure, and worsening of his stroke. During the first 24 hours, neurological checks are completed hourly, and findings remain unchanged compared with baseline examination findings.

(continued on page 760)

CASE STUDY *(Continued)*

On day 2, neurological examination shows a decrease in level of consciousness, a decrease in heart rate to 55 beats/min, and an increase in blood pressure to 200/110 mm Hg. He requires immediate intubation for airway protection. The nurse suspects that Mr. H. is experiencing increased intracranial pressure (ICP) resulting from either cerebral edema or hemorrhagic conversion of the ischemic stroke territory. Blood samples are sent to the laboratory for analysis; computed tomography (CT) scan is obtained. The neurology specialist and neurosurgeon are notified of the rapid change in Mr. H.'s status.

The CT scan confirms massive cerebral edema with midline shift (no hemorrhage noted). Foley catheter is placed and Mr. H. is given his first dose of mannitol. The neurosurgeon places an intraventricular drainage device under sterile conditions at the bedside with initial ICP recorded at 32 mm Hg. Mr H's nurse activates strict interventions to avoid increased ICP including: maintaining a quiet environment, limiting nursing activities, and avoiding flexion and extension of the neck. The patient's blood pressure decreases, and he does not require antihypertensive medications.

On day 3, Mr. H.'s nurse observes a 30-second tonic–clonic seizure, which is treated with diazepam and a phenytoin load, with daily phenytoin ordered. Again, CT scan is negative for hemorrhage. On day 4, neurological examination findings and vital signs are stable for 24 hours and the intraventricular catheter is removed.

On day 5, Mr. H. is extubated. He is alert enough to understand what is being said to him and begins aggressive physical, occupational, and speech therapy.

Mr. H. is at risk for complications of immobility related to this stroke and therefore receives prophylaxis for stress ulcers and deep venous thrombosis, as well as aspirin for stroke prevention. He remains on lisinopril for hypertension. Diagnostic studies to determine the stroke etiology include a transthoracic echocardiogram, which reveals a normal ejection fraction, no right-to-left shunting, and no valvular abnormalities or vegetation. A carotid duplex scan does not reveal significant carotid stenosis.

Until discharge, Mr. H.'s vital signs and clinical status remain stable. Mr. H. is transferred to a stroke rehabilitation facility for aggressive treatment of persistent hemiparesis and dysarthria.

1. Describe other noninvasive approaches that the nurse might incorporate into Mr. H.'s care in order to reduce ICP.

2. Describe the potential complications that Mr. H. might experience while the intraventricular catheter for ICP monitoring is in place.

3. Does the neurological worsening that Mr. H. experiences on day 2 occur at a "typical" time point for patients with neurological injury? Explain your answer.

35 Common Neurosurgical and Neurological Disorders

Richard Arbour

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Discuss the surgical management of the patient with a brain tumor.
2. Explain the care for the patient with a cerebral aneurysm or arteriovenous malformation.
3. Compare and contrast the classifications of stroke.
4. Discuss the nursing management of a patient who has experienced a stroke.
5. Differentiate between partial and generalized seizures.
6. Review the current antiepileptic drugs used to manage epilepsy.
7. Describe the clinical manifestations and management of the patient with Guillain-Barré syndrome.
8. Describe the clinical manifestations and management of the patient with myasthenia gravis.

During the course of illness, many patients with neurological diseases require critical care management. Routine neurosurgical procedures may involve a short intensive care unit (ICU) admission for monitoring in the immediate postoperative period. Complications of tumor or related treatments may necessitate readmission. ICU admission may follow use of thrombolytic therapy for stroke and may be required to treat the patient with stroke complicated by increased intracranial pressure (ICP). Patients with myasthenia gravis or Guillain-Barré syndrome may require ICU level of care for cardiorespiratory consequences of their disease. The critical care nurse is better prepared to manage the acute and chronic needs of this patient population when armed with understanding of the course of the disease, as well as available medical and surgical tools. This chapter provides an overview of the etiology, clinical manifestations, diagnostic tests, and current management of the neurosurgical and neurological disorders most often encountered in the ICU environment.

▲ Neurological Surgery

Surgery is indicated for several neurological disorders. Neurological surgery is a common and integral part of the management of patients with intracranial tumors, arteriovenous malformations (AVMs), and aneurysms. Craniotomy is the most common procedure performed for these problems. The following section reviews the etiology and pathophysiology of these conditions and describes surgical approaches used for the management of these patients.

Brain Tumors

A brain tumor is broadly described as any neoplasm arising within the intracranial space. Tumors may originate in the brain (primary) or seed in the brain from other organs (metastatic).[1,2] Pathological examination of a tumor is used to classify the tumor by cell type. Tumors are further graded based on the degree of malignancy. Classification and grade are used to predict patient outcome.[1,2] Table 35-1 outlines the most common brain tumors designated by the World Health Organization (WHO) system.[3] Other predictors of outcome include patient age and general health, early detection, and tumor location.[2,4]

Although many brain tumors are low grade or "benign," their location may impede surgical removal and cause brain edema as well as shifting of the surrounding structures. This causes increased ICP. Untreated ICP can lead to brain herniation and can be fatal. Early diagnosis, symptom management, and histological diagnosis are important prognostic factors.[1,2,4]

Etiology

The cause of most brain tumors is still unknown. As research advances in the area of genetics, there is increased interest in identifying chromosomal abnormalities in many types of cancer, including brain tumors. Cytogenetic studies of glioblastoma multiforme, the most common primary brain tumor, have shown multiple chromosomal changes, with both gain and loss of certain chromosomes.[3,4] It is hypothesized that this information will, at the very least, aid in the development

Table 35-1 Classification and Grading of Brain Tumors (Most Common Intracranial Tumors)*

Classification/Grade	Description	Symptoms	Treatment/Prognosis
Neuroepithelial (approximately 50% of primary tumors)			
Gliomas			
Astrocytic			
WHO grade I—pilocytic astrocytoma	Pediatric; 85% cerebellar; slow growing; well circumscribed; cystic; benign	Increased ICP; focal neurologic signs	Curable with surgery (craniotomy for tumor removal)
WHO grade II—astrocytoma	Infiltrative; slow growing	Seizures; acute or subtle onset of symptoms	Radiation therapy (RT) for residual tumor; may withhold RT after gross total resection; young age is good prognostic factor
WHO grade III—anaplastic astrocytoma	Hypercellular; anaplasia	May have acute onset of symptoms	RT with or without chemotherapy; high recurrence rate; age and overall health affect prognosis
WHO grade IV—glioblastoma multiforme	Poorly differentiated, with high mitotic rate; highly malignant; most common glioma in adults	Rapid onset of symptoms; increased ICP or focal signs	Infiltrative nature: complete removal of all cells not possible; RT with chemotherapy; experimental protocols; recurrence in virtually all cases; median survival: 12–18 mo
Oligodendroglioma	Well differentiated; calcified; infiltrative; slow growing; some tumors are malignant (anaplastic)	Seizures; headaches; subtle onset of symptoms	RT with residual tumor; may withhold after gross total resection; RT with or without chemotherapy for anaplastic oligodendroglioma
Mixed glioma (oligoastrocytoma)	May behave more or less aggressively, depending on features	Dependent on location and degree of malignancy	Variable outcome
Ependymoma	Pediatric and young adult patients; originates from lining of the ventricles; frequently in posterior fossa; usually benign	May present with hydrocephalus; symptoms related to location	RT for residual or recurrent disease; craniospinal RT for evidence of spinal disease only; good prognosis
Embryonal (primitive neuroectodermal tumor) medulloblastoma, most common	Primarily pediatric; malignant; occurs mainly in posterior fossa; CSF metastasis in 33% of patients	Symptoms by location; hydrocephalus common	Craniospinal RT; poor prognosis, particularly with CSF dissemination
Peripheral Nerve Tumors (approximately 8% of primary brain tumors)			
Vestibular schwannoma (acoustic neuroma)	Cerebellopontine angle; benign; encapsulated; seen in association with neurofibromatosis, type 2	Decreased hearing; tinnitus; balance problems; may have other cranial nerve deficits	Curable with surgery; excellent prognosis; cranial nerve deficits may be permanent or temporary; affect quality of life
Meningeal Tumors (approximately 30% of primary brain tumors)			
Meningioma	Composed of arachnoid cells; attached to dura; usually benign; well circumscribed; may be vascular; common locations: falx convexity; olfactory groove; sphenoid ridge; parasellar region; optic nerve	Headaches may occur from dural stretching; seizures and focal neurologic signs	Degree of resection (and recurrence) associated with location; excellent prognosis with gross total resection; atypical and malignant meningiomas have more aggressive features and less favorable outcomes

(continued on page 764)

Table 35-1 Classification and Grading of Brain Tumors (Most Common Intracranial Tumors)* (continued)

Classification/Grade	Description	Symptoms	Treatment/Prognosis
Lymphomas and Hematopoietic Tumors (approximately 3% of primary brain tumors)			
Malignant CNS lymphoma	Arise in CNS without systemic lymphoma; commonly suprasellar; diffuse brain infiltration; may be periventricular and may involve leptomeninges; solitary or multiple	Neurologic or neuropsychiatric symptoms	Diagnosis commonly via stereotactic biopsy or CSF cytology; steroids may decrease or temporarily obliterate lesion on CT or MRI; RT with or without chemotherapy; high-dose methotrexate used as single medication; some studies defer RT; increasing incidence in immunocompetent persons; decreasing in patients with AIDS; possible improved survival with newer treatments
Germ Cell Tumors (approximately 1% of primary brain tumors)			
	Developmental tumors—from gonads and extragonadal sites; germinoma (solid, enhancing on MRI) and teratoma (cystic, with fat and calcification) most common	Symptoms are location dependent; germinomas are often suprasellar—diabetes insipidus	RT for germinomas; curable; teratoma has less favorable prognosis; gross total resection means improved survival; chemotherapy in some cases
Sellar Tumors (approximately 7% of primary brain tumors)			
Pituitary adenoma	6.3% of sellar tumors; benign; originate from adenohypophysis; classification by hormonal content; microadenoma 1 cm or less; macroadenoma 1 cm or more	Hypersecretion • Prolactin: amenorrhea, galactorrhea • Growth hormone: acromegaly • Adrenocorticotropic hormone: Cushing's syndrome • Thyroid-stimulating hormone: hyperthyroidism (rare) Hyposecretion caused by compression of the pituitary gland Visual field deficits (bitemporal hemianopia); headache; pituitary apoplexy: acute hemorrhage or infarct of gland—emergency treatment indicated	*Surgical:* transsphenoidal for approximately 95% of surgical cases; *medical:* appropriate in some cases of prolactin-secreting and growth hormone–secreting tumors; RT for recurrence or for hypersecretory tumors, when medical management has failed
Craniopharyngioma	Benign, calcified, cystic tumors	Endocrine abnormalities; visual impairment; cognitive and/or personality changes; may have increased ICP	Gross total resection affects prognosis; RT for residual tumor
Metastatic Tumors (approximately 150,000 new cases yearly; occur in 20%–40% of cancer patients)			
	Originate from primary systemic tumors; discrete, round, ring-enhancing; 50% are solitary; lung and breast are most common primary sites	Symptoms are location dependent	Prognosis dependent on number of tumors, tumor location, systemic disease, and patient age; improved prognosis with gross total resection and RT

*For all tumors, biopsy or craniotomy for tumor removal is necessary to establish a definitive diagnosis.

of individualized therapies for patients with primary brain tumors. Some hereditary diseases, such as neurofibromatosis and polyposis, are associated with the development of certain types of brain tumors.

Environmental factors currently being studied for their association with intracranial tumors include electric and magnetic fields, foods (particularly those that are broken down in the stomach or bladder to form *N*-nitroso compounds), occupational exposure, and chemical exposure.[2–4]

Ionizing radiation has been shown to increase the occurrence of some brain tumors (nerve sheath tumors, meningiomas, and gliomas) when given in high doses.[2–4] Low-dose radiation exposure is a topic of discussion and controversy.

Epidemiology

Recent statistics indicate that there are approximately 14 cases per 100,000 person-years of newly diagnosed primary brain tumors in the United States each year.[2] The prevalence of primary high-grade or malignant brain tumors is 29.5 per 100,000 persons.[2] There is a significantly higher incidence of metastatic brain tumors diagnosed in the United States each year.

Epidemiological studies have confirmed certain patterns of brain tumor incidence. There has been a significant increase in the incidence of brain tumors in developed countries over the past several decades. Some of this increase can be attributed to improved diagnostic techniques, access to medical care, and an increasing elderly population. However, it is suspected that some of these increases are also attributable to environmental and lifestyle factors, as previously discussed.

Other patterns of incidence have been documented by age, ethnicity, and sex.[2,4] For example, the average age of onset for glioblastomas and meningiomas is approximately 60 years. Gliomas are diagnosed more often in the white population and in men. African Americans and women have higher rates of meningiomas.

Pathophysiology

The brain has its own distinct protective mechanism in the form of the blood–brain barrier. Studies undertaken in the mid-19th century showed that dyes injected intravenously were not observed in brain tissue as they were in other body organs.[1] However, when injected directly into the cerebrospinal fluid (CSF), they were absorbed into the brain but not disseminated through the brain's vascular system to the rest of the body. These studies confirmed the restricted permeability between the blood and the brain and between the blood and the CSF, but not between the brain and CSF.[1] Tumors are able to disrupt this blood–brain barrier, as evidenced by computed tomography (CT) and magnetic resonance imaging (MRI) scans, which show contrast uptake at the site of many tumors.[1,4] Disruption of the blood–brain barrier may relate to increasing permeability of the tumor blood supply at the capillary level with higher levels of malignancy.

Vasogenic edema, caused by increased capillary permeability and commonly seen in association with brain tumors and other brain lesions, is the direct result of blood–brain barrier disruption.[1,4,5] As outlined in the Monro-Kellie doctrine, the contents of the cranial vault—brain, CSF, and blood—have a fixed volume. Any addition to this volume must be balanced by reduction in one of the other components. When

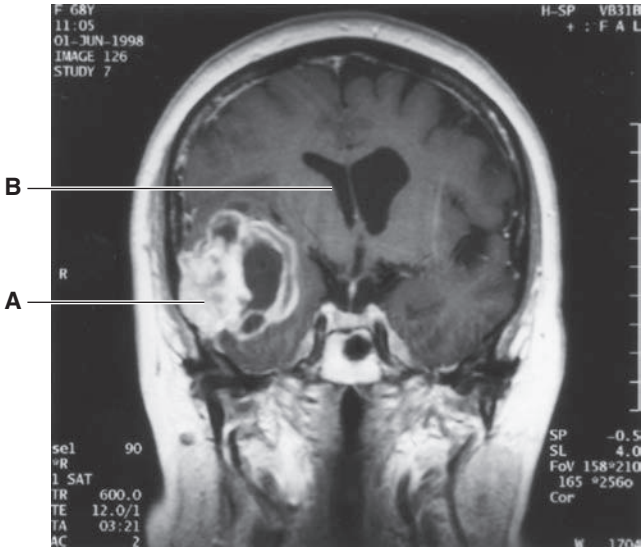

FIGURE 35-1 ▲ Coronal MRI view of ring-enhancing glioblastoma multiforme (**A**) with evidence of mass effect (**B**). (Courtesy of Henry Brem, MD, Johns Hopkins University, Baltimore, MD.)

this compensatory mechanism can no longer function, edema develops and ICP increases.[1,5] In Figure 35-1, an MRI scan shows brain edema and mass effect (shifting of brain structures) caused by a glioblastoma multiforme. Some slow-growing tumors (eg, meningiomas) can become quite large as a result of this compensatory mechanism and the brain's plasticity. This plasticity allows the brain to accommodate to slow tumor growth over a long period of time.

Clinical Manifestations

The patient with a brain neoplasm may present with one or more signs of tumor growth. The signs may be general or focal. The most common general signs of brain tumors are headaches, seizures, or mental status changes. These are related to increasing ICP.[1,2,4,5]

The triad of symptoms associated with increased ICP includes headache, nausea with or without vomiting, and papilledema (swelling of the optic disks). Symptoms are typically treated with corticosteroids, which are discussed later in this chapter.[1,2,5] Clinical evidence of herniation (shifting of brain tissue by masses, increased ICP, or both) often requires critical care management using fluid restriction, hyperventilation, osmotic drugs, and diuretics. Some situations necessitate the use of CSF drainage through an intraventricular catheter (see Chapter 34).

The frequency of seizures depends on tumor location as well as tumor histology. More than 60% of patients experience seizures over the course of their disease.[1,4] Seizure activity is more common in patients with low-grade tumors. Tumors in the cerebral hemispheres are much more likely to cause seizure activity than posterior fossa tumors. Seizures may be focal or generalized, as discussed later in this chapter.

Mental status changes occur as the result of mass effect on the brain caused by increased ICP or hydrocephalus. Patients may become drowsy and mentally slower as ICP increases. Cognitive changes occur in the form of problems concentrating, memory difficulties, personality changes, confusion, or disorientation. Although mental status changes are

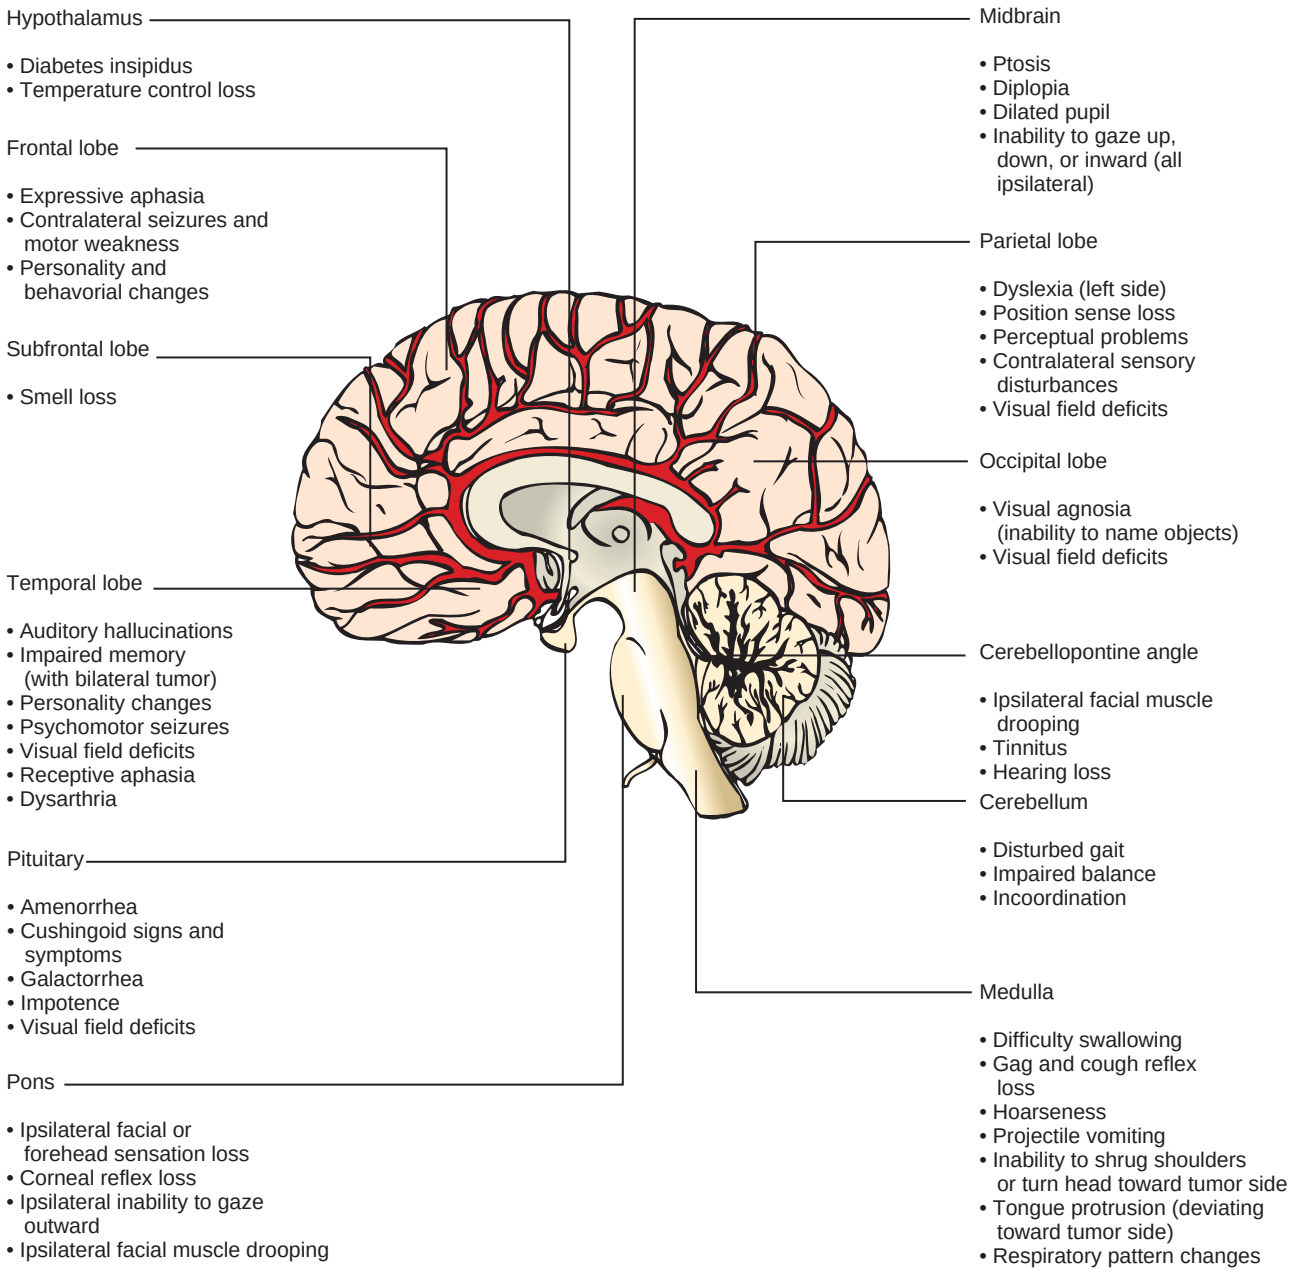

FIGURE 35-2 ▲ Site-specific signs and symptoms of brain tumors.

associated with frontal lobe tumors, they are also the result of increased ICP.[1]

Focal neurological deficits may be the temporary result of tumor compression, or may be permanent, as a result of tumor destruction. These deficits are directly related to tumor location. Figure 35-2 outlines site-specific signs and symptoms of brain tumors.

Diagnosis

History taking is a key element in the process of diagnosing a brain neoplasm. The duration, frequency, and severity of symptoms are ascertained. It is important to assess whether there is a particular time of day or series of activities that initiate symptoms. Are symptoms intermittent or continuous? Do they resolve with pharmacological management? Morning headaches and headaches that increase with Valsalva maneuver or are associated with nausea and vomiting are seen in patients with tumor-induced increased ICP.[1,2,4] The physical examination aids in further localizing the lesion. Patients may minimize or are often unaware of subtle neurological deficits. Family involvement in this discussion is useful.

Imaging studies, such as CT scans and MRI, are typically ordered to localize the lesion and assess the amount of edema and mass effect on surrounding structures. CT scans are often performed to establish a differential diagnosis when a patient is seen in the emergency department.[1,4] Because MRI shows tumors in three dimensions (axial, coronal, and sagittal), it is the preferred diagnostic tool. An electroencephalogram (EEG) is used to confirm the presence of seizure discharges, which may be useful in determining whether anticonvulsants

are needed. Magnetic resonance angiography (MRA) images the vascular anatomy and vessels that feed certain tumors. It can be a noninvasive alternative to the angiogram, which is an invasive study that may be needed to identify and perform embolization of feeding vessels to the tumor with the use of glue preparations. In some cases, angiography and embolization are performed within 24 to 48 hours of surgery for large tumors such as meningiomas.

Functional MRI (fMRI) is a type of imaging used for tumors in the dominant hemisphere or motor strip. It is believed that increased cerebral blood flow (CBF) is recognized as an increased signal on the fMRI. The patient performs a particular task, and the fMRI indicates which part of the brain is activated. This noninvasive procedure is currently used in some centers as part of the preoperative assessment of language, motor, and sensory function in relation to tumor location. Positron emission tomography (PET) uses radionuclides to measure CBF and brain metabolism. It is used to differentiate low-grade from high-grade (and more metabolically active) tumors. PET is also used to differentiate radiation necrosis from high-grade tumors in previously treated patients. Magnetic resonance spectroscopy (MRS) is a noninvasive radiographic technique that measures metabolite levels in brain tumors. Biological compounds, such as choline, can be quantitated in brain tumors. Because MRS is obtained at the same time as MRI, the anatomic and metabolic characteristics of the tumor are obtained with little additional inconvenience to the patient.

Clinical Management

Once the differential diagnosis of brain tumor is obtained through history, physical examination, and imaging studies, decisions are made regarding appropriate treatment modalities. A medical and surgical plan of care is discussed with the patient and family members.

Pharmacological Management

Tumors and tumor treatments are known to cause increased ICP, which is treated with corticosteroids.[4,5] Corticosteroids such as dexamethasone reduce brain edema by reducing the permeability of tumor capillaries and possibly by shifting some of the fluid into the ventricular system. A dose of 16 mg daily is standard in the perioperative period. It is usually given in two to four divided doses, spaced over the course of the day. Resolution of symptoms can be quite rapid. Steroids also increase the safety of the surgical procedure. They are, however, associated with significant side effects, as outlined in Table 35-2.[4,5]

Type 2 histamine receptor (H_2) blockers are often prescribed for the patient taking steroids. They are used to prevent gastrointestinal (GI) symptoms that can be associated with prolonged steroid use. Steroids used alone have a low risk for causing peptic ulcers and GI bleeding, but the risk increases in patients taking nonsteroidal anti-inflammatory drugs (NSAIDs).[1,3–5]

Anticonvulsant therapy is initiated when the patient presents with a seizure. Many surgeons also use prophylactic antiepileptic drugs (AEDs) during the perioperative period. Because studies have shown little difference in the occurrence of postoperative seizures in patients receiving AEDs compared with control groups without such drugs, some physicians are limiting the use of postoperative and prophylactic AED therapy. However, 70% of members of the American Association of Neurological Surgeons who responded to a survey stated that they continue to prescribe prophylactic AEDs for their patients with brain tumors. Seizures are extensively discussed later in this chapter.

Surgical Management

Clinical and radiographic evaluations are useful in obtaining a differential diagnosis. However, pathologic examination of tumor tissue produces the definitive diagnosis. There are two

Table 35-2 Complications of Corticosteroid Therapy

System	Complications
Neurological	*Common:* Behavior changes, insomnia, myopathy, hallucinations, hiccups, tremor, cerebral atrophy *Uncommon:* Psychosis, dementia, seizures, dependence, paraparesis (epidural lipomatosis)
General	Weight gain, cushingoid features (moon facies, buffalo hump, centripetal obesity), opportunistic infections (eg, candidiasis, *Pneumocystis carinii* pneumonitis), night sweats, hypersensitivity reactions, peripheral edema *Note:* Steroid taper may cause recurrence of preexisting conditions (eg, arthritis, allergic reaction)
Cardiovascular	Hypertension, atherosclerosis, increased cardiovascular and cerebrovascular disease
Dermatological	Thin skin, ecchymoses, purpura, acne, striae, inhibited wound healing, hirsutism
Endocrinological	Hyperglycemia, hypokalemia, hyperlipidemia, fluid retention
Gastrointestinal	Increased appetite, abdominal bloating, GI bleeding, peptic ulcers, pancreatitis, liver hypertrophy
Genitourinary	Polyuria, menstrual irregularities, infertility
Hematological	Neutrophilia, lymphopenia
Ophthalmological	Visual blurring, cataracts, glaucoma, uveitis
Rheumatological	Osteoporosis, avascular necrosis

Modified from Hickey JV: The Clinical Practice of Neurological and Neurosurgical Nursing. Philadelphia, PA: Wolters Kluwer/Lippincott Williams & Wilkins, 2009; and Stummer W: Mechanisms of tumor-related brain edema. Neurosurg Focus 2007. Accessed June 9, 2010 from http://www.medscape.com/viewarticle/559000.

distinct surgical approaches to diagnosing and treating brain tumors. Stereotactic biopsy is used to obtain small samples of tumor tissue under CT or MRI guidance. Craniotomy is performed when tumor removal is feasible and provides both a pathological diagnosis and surgical resection of the lesion.[2–4] These approaches are discussed in the "Surgical Approaches" section of this chapter (see pages 778–779).

During the past several decades, improvements in anesthesia, microsurgical equipment, intraoperative monitoring techniques, and pharmacological management have significantly improved intraoperative mortality rates. Postoperative morbidity has also significantly decreased. The perioperative management of the patient with a brain tumor involves a multidisciplinary team approach, as outlined in Table 35-3.

Despite substantial improvements in the management of the patient with a brain tumor, surgical complications may be severe and require critical care monitoring and management. The most common complications include brain edema, infection, hyponatremia or other electrolyte imbalances, hemorrhage, venous thromboembolism (including deep venous thrombosis [DVT] and pulmonary embolism [PE]), and seizures (Table 35-4).[2]

Radiation Therapy

Many brain tumors are treated with adjuvant therapies, either because they cannot be surgically resected or because of their aggressive nature. For most brain tumors, radiation therapy (RT) is the first-line treatment after biopsy or craniotomy. The energy produced by radiation damages tumor DNA at the time of cell division.[3,4,6] Three-dimensional conformal radiation is generally used to treat those tumor cells that are not surgically resectable. This form of RT treats the shape and the volume of tumor while normal brain tissue is protected. A standard dose of up to 6,000 centigray (cGy; also referred to as radiation absorbed dose, or rad) is administered to primary brain tumors 5 days a week over a period of 6 weeks. Multiple metastatic tumors receive a dose of approximately 3,000 cGy divided over 10 treatments. Some metastases may be treated with higher radiation doses with or without a boost of focused radiation.[4,6,7]

There are other approaches to applying RT. Intensity-modulated radiation therapy (IMRT) modifies the radiation beam so that a more focused dose can be given, without exposing surrounding brain tissue. Stereotactic radiosurgery (SRS) (eg, gamma knife and linear accelerator) is applied under MRI guidance. A three-dimensional image is obtained, and radiation is given in one large dose to residual tumor, sparing normal brain tissue.[4,7–9] Brachytherapy uses radioactive isotopes in seeds or liquid-filled balloons inserted into residual tumor.[4] Radiosensitizers are agents given in addition to RT. It is postulated that some substances increase oxygen delivery to hypoxic tumors. The oxygen enhances the effects of radiation. Hyperthermia is also being applied with the same goal of increasing oxygen to tumors to maximize the effects of radiation.[3]

Chemotherapy

Malignant brain tumors require multiple treatment modalities. Chemotherapy is given in conjunction with radiation or at the time of tumor recurrence. Drugs may be administered orally or intravenously but can cause systemic toxicities and have difficulty crossing the blood–brain barrier in sufficient amounts to provide benefit. An approach using RT in conjunction with temozolomide chemotherapy has shown survival benefit in the most malignant primary brain tumor, glioblastoma multiforme.[1,4]

Chemotherapy can also be placed in the tumor resection cavity at the time of craniotomy. A biodegradable polymer wafer that delivers a continuous infusion of carmustine (BCNU) chemotherapy over a period of 2 to 3 weeks is being used for primary malignant and metastatic brain tumors. The wafer is surgically implanted at the time of initial diagnosis or when the tumor recurs.[4]

Research Initiatives

Radiation and chemotherapy are targeted at damaging cell DNA, thereby killing the cell or preventing it from dividing. Other approaches have been used in an effort to address different aspects of tumor growth:

- Glioma cells are deficient in a protein that suppresses tumor growth (−p53). Gene therapy is being explored using adenoviruses, for example, which are engineered to replicate in and inactivate these cells. They are designed not to replicate in normal (+p53) cells.[4]
- Antiangiogenic factors are used to prevent tumors from forming their own blood supply, crucial to tumor growth.[3,4,10]
- Immunotherapy is designed to stimulate the immune system to eliminate tumors. Targeted toxins are injected into and infiltrate tumor cells. Cytokines, such as interferon and interleukin, are proteins produced by the body to stimulate an immune response. They are being combined with inactivated tumor cells as the basis for tumor vaccines.[4]
- Cancer cells have enzymes that resist chemotherapy. Certain drugs called resistance modifiers are being used to inhibit these enzymes and to increase the effectiveness of chemotherapy.[4]
  - Surgical techniques, such as neuroendoscopic approaches and fluorescence-guided resection, are increasingly being used in managing malignant gliomas.[10]
  - Genetic research has refined glioblastoma classification into four distinct molecular entities and may lead to new treatments as may use of cancer stem-like cells.[10]

Nursing Management

ASSESSMENT. Some tumors are cured with surgery, whereas others have a protracted course involving adjuvant therapies and treatment for recurrent disease. As part of the multidisciplinary team, the nurse plays a central role in patient care and family support throughout the course of the patient's illness. The nurse participates in the diagnosis, treatment, and follow-up care of the patient with a brain tumor.[1,2] One additional significant factor to consider in patient assessment is the potential for mental status changes, however subtle, that may compromise decision-making capacity in the patient with a brain tumor. This patient population must frequently make medical and surgical care decisions. As such, ongoing assessment of medical decision-making capacity is an appropriate part of care.[11]

PLAN. Careful history taking and symptom evaluation contribute to the accurate diagnosis of a brain tumor. Once

Table 35-3 Multidisciplinary Management Guide for the Patient With a Brain Tumor

Stage	Management Team	Interventions	Nursing Considerations
Preoperative			
• History and physical	• Neurosurgeon, nurse practitioner, RN	• Baseline history and physical examination; neurological evaluation: mental status, cranial nerves, motor and sensory function, coordination, reflexes	• Preoperative teaching to begin • Involve family as much as possible
• Medications	• Physician, pharmacist, nurse practitioner, RN	• Steroids; histamine type 2 receptor (H_2) blockers, as needed; anticonvulsants for supratentorial lesions • Prescribe new medications; medication review; discuss interactions or contraindications	• Anticoagulants, NSAIDs to be discontinued (with consent of prescribing physician)
• Diagnostic testing	• Neuroradiologist	• Baseline MRI or CT scan • ECG, chest x-ray • Other diagnostic studies as indicated	• Most preoperative testing performed within 1 wk of surgery
• Preoperative teaching	• By specialty: RN, neurosurgeon, neuroanesthesiologist	• Informed consent • Obtain all test results before admission day	• A written teaching pamphlet is recommended for patient and family use
• Hospital admission	• Admitting office, OR staff	• Obtain/confirm demographics	• Most patients are admitted the day of surgery
Intraoperative			
• Stereotactic biopsy	• OR team, surgeon, anesthesiologist, radiologist, pathologist	• Stereotactic frame placed; samples taken through catheter inserted under MRI/CT guidance • Histological evaluation	• May be performed in radiology suite or OR • Teaching regarding stereotactic frame • May also be done as a frameless procedure
• Craniotomy	• OR team, surgeon, anesthesiologist, pathologist	• Tumor tissue obtained for biopsy; tumor resected • Histological evaluation	• Teaching regarding general anesthesia
Postoperative			
• Critical care unit	• Critical care staff, neurosurgeon	• Hemodynamic monitoring; frequent neurological evaluations	• If possible, it is useful for patient and family to see the unit before surgery
• Nursing unit	• Floor nurses, surgeon, consulting physicians, rehabilitation medicine, pharmacist, clergy, nutritionist	• Postoperative care to include vital signs, neurological exam, wound care, cough, and deep breathing; increase activity as tolerated; advance diet as tolerated • Rehabilitation medicine consult • Evaluate for deficits and complications and provide consultations, as indicated	• More family participation in care when possible • Patients are usually out of bed within 24 h of surgery • Recently, short hospital stays cause increased family involvement and responsibility; begin teaching while patient is on the nursing unit
Discharge Planning	• Social worker, nursing staff, consulting physicians, radiation oncologist, medical oncologist (when indicated)	• Inpatient/outpatient rehabilitation as needed (occupational therapy, physical therapy, speech, cognitive) • Outpatient therapies as needed (eg, radiation, chemotherapy) • Hospice care (inpatient or home hospice) may be indicated, particularly in cases of recurrent malignant gliomas, refractory to conventional treatments	• Ideally, planning begins as soon as the patient arrives on the nursing unit • Family takes on greater role because patient is often discharged from the hospital 2–3 d postoperatively, particularly in cases of highly malignant tumors where home hospice is indicated

Table 35-4 Critical Care Management of the Patient With Brain Tumor Complications

Diagnosis	Management
Increased ICP	• Corticosteroids and antacids or histamine type 2 receptor (H_2) blockers • IV fluids: Avoid hypotonic solutions • Elevate head of bed and maintain adequate body alignment • Avoid hypotension and control hypertension; arterial line useful; if ICP monitor is available, titrate fluid therapy and vasoactive/inotropic drugs as ordered and clinically appropriate to maintain MAP between 70 and 80 mm Hg to maintain CPP. Elevated ICP may require higher MAP to maintain CPP 60–70 mm Hg. • Keep well oxygenated; may need to intubate • Judicious use of osmotic therapy: mannitol to expand plasma volume and draw fluid out of the brain; may be used in conjunction with furosemide • Sedation to reduce activity and decrease hypertension • Intraventricular catheter may be necessary to monitor ICP and drain CSF • Cautious use of hyperventilation for short periods only to reduce arterial carbon dioxide pressure (PCO_2) (6–24 h) • May require surgical intervention for hematoma
Wound infection, intracranial abscess, or bone flap infection	• Blood work, including complete blood count and blood cultures • CT scan, MRI, and in some cases MRS to identify abscess • Surgical removal of abscess or bone flap, when feasible • Appropriate wound cultures, when possible • Antibiotic therapy • Infectious disease consultation for appropriate drug, dose, and duration
Hyponatremia or hypernatremia	• Possible diabetes insipidus, salt-wasting syndrome, or syndrome of inappropriate antidiuretic hormone secretion • For hyponatremia: fluid restriction, hypertonic saline • For hypernatremia: fluids, vasopressin
Intracranial hemorrhage	• Immediate CT scan to evaluate for early signs of a bleed • Monitor BP • Check laboratory values: prothrombin time, partial thromboplastin time, platelets • Management of increased ICP, as described above • May need to intubate and ventilate • Surgery may be necessary to remove blood clot
Thromboembolism: DVT and pulmonary embolus (PE)	• Diagnosed through TCD study or ventilation-perfusion scan • Heparinization *only after* CT scan has ruled out intracranial blood • Alternatively, vena cava filter (Greenfield filter) may be used • Large PEs require ICU care for further medical treatment
Seizures	• Potential for status epilepticus • Protect patient from injury • Titrate antiepileptics to therapeutic levels

medications are prescribed, patient education includes discussion of dose, side effects, and contraindications. The results of tests leading to a differential diagnosis are reviewed with the patient and family. When a decision has been made to proceed with surgery, extensive teaching is required in the perioperative period. Table 35-3 outlines the nurse's role in the plan of care for this patient population. Patient teaching is better retained if it is both verbal and written. Teaching sheets are useful and can be referred to at different times during the treatment period.

Although surgery and follow-up therapies are disruptive to patient and family activities, it is important to encourage a return to normalcy as soon as possible. Continuing with activities of daily living that encourage a positive and motivated attitude contributes to recovery.

Hospice

Multiple surgical procedures and adjuvant therapies are often successful in containing malignant brain tumors for a period of time. Inevitably, these tumors recur and become resistant to all treatment modalities. In addition, patient quality of life may be so compromised that further therapy is not feasible. Palliative care services are now available in many hospitals. Home and inpatient hospice are available in most communities and provide dedicated and supportive end-of-life care.

Aneurysms

An aneurysm is a weakening in the arterial wall that causes either a ballooning effect or overall distention of the affected vessel. Aneurysms may be congenital or degenerative arterial lesions. Concern arises if the outpouching of the vessel wall ruptures or becomes large enough to exert pressure on surrounding brain structures.[12–14]

Approximately 10% to 30% of patients die from the initial bleeding of their aneurysm before reaching medical care.[14] An additional 50% die within 1 month from the

initial hemorrhage.[12] Rebleeding is the leading cause of death in patients with a history of ruptured aneurysm. Of those who survive the initial bleeding, 25% die within 24 hours, and 40% to 49% die within 3 months.[13] Some recent data suggest that the overall mortality rate from aneurysmal subarachnoid hemorrhage (SAH) is as high as 65%.[13] Rebleeding most often occurs around the seventh day after the original bleed. Predictors of good recovery by 1 month after the bleed include a high score on the admission Glasgow Coma Scale (GCS) and an absence of blood on the first CT scan.[12–14]

Etiology

The etiology of aneurysms is unclear but is probably a combination of congenital and degenerative factors. Carmichael described the combination hypothesis of aneurysm formation. Of the three layers of an artery—tunica intima (innermost), tunica media (middle), and tunica adventitia (outer layer)—he found that congenital focal defects of the tunica media are common. However, degenerative changes are also necessary for the formation of aneurysms. Histological investigation of the normal vessel wall into the aneurysmal sac shows that the tunica media usually ends at the neck of the aneurysm and the internal elastic lamina becomes fragmented as it enters the sac. Consistent with this hypothesis, aneurysms are rare in childhood but are common into late adulthood.[12–14]

Although the exact cause of intracranial aneurysms is not understood, there is evidence to support that acquired and genetic factors contribute to their development. Genetic factors include heredity and genetically transmitted diseases. Acquired factors include traumatic brain injury, sepsis, cigarette smoking, and hypertension.[12–14] Multiple concurrent clinical conditions including Marfan syndrome, coarctation of the aorta, polycystic kidney disease, and systemic lupus erythematosus are associated with cerebral aneurysms, supporting a genetic component to aneurysm development.[12–14]

Epidemiology

Intracranial aneurysms are common lesions, with autopsy reports indicating a prevalence of 1% to 6% of the adult population. Most of these aneurysms are small and do not rupture during the patient's lifetime, and some people have more than one aneurysm.[12] In the United States, approximately 30,000 new cases of SAH each year are attributed to aneurysmal rupture.[14] The incidence of SAH is 8 to 10 cases per 100,000 persons.[14] The annual risk for rupture is about 1.34% per year.

Aneurysm may also be associated with other pathological processes, such as polycystic kidney disease.[12–14] Screening with MRI is warranted for patients with two immediate relatives with a history of intracranial aneurysm and for all patients with autosomal dominant polycystic kidney disease. The incidence of aneurysms increases with age, with peak incidence occurring between 55 and 60 years.[12–14] They occur more often in women than in men and, as noted earlier, can be linked to cigarette smoking. Seasonal variability is another epidemiological feature. Clinicians observed that there may be a seasonal variability, with increases occurring in spring and fall.

The Cooperative Study of Intracranial Aneurysms and Subarachnoid Hemorrhage reported that in 32% of cases, the hemorrhage occurred during physical activity. The study also reported that a similar proportion occurred during sleep. In summary, the incidence of SAH can be roughly divided into thirds: sleeping, active, and at rest.

Pathophysiology

Arterial vessels are composed of three layers: endothelial lining, smooth muscle, and connective tissue. A defect in the smooth muscle layer, or tunica media, allows the endothelial lining to bulge through, creating an aneurysm. Most aneurysms arise from larger arteries around the anterior section of the circle of Willis. The most frequent sites of occurrence in the anterior circulation are the anterior communicating artery, the posterior communicating artery (PCA), the middle cerebral artery (MCA) bifurcation, and the internal carotid artery bifurcation.[12–14] In the posterior circulation, the most common locations are the basilar artery apex and the posterior inferior cerebellar artery.[12–14]

As the intimal layers of the vessel weaken, high-velocity blood begins to flow to create a whirlpool effect, thus stretching the wall of the vessel. This creates an abnormal pocket or sac of blood. As the wall of the vessel expands, it begins to weaken and may eventually rupture. Compression by the sac on surrounding brain structures may result in focal neurologic deficits. Rupture of the aneurysm may result in subarachnoid, intracerebral, or intraventricular hemorrhage.[12–14]

Aneurysms may be classified according to shape. *Saccular* aneurysms are also known as "berry" because of a well-defined stem and berry-like outpouching of the medial layer of the arterial wall. Berry aneurysms are usually located on major cerebral arteries at the apex of branch points, which is where maximal hemodynamic stress occurs in the vessel (Fig. 35-3). *Fusiform* aneurysms are another type of aneurysm that occur more commonly in the vertebrobasilar system. Fusiform aneurysms are dilated circumferentially and usually occur secondary to atherosclerosis. A third type of aneurysm is known as *mycotic*, which is due to infection.[12–14]

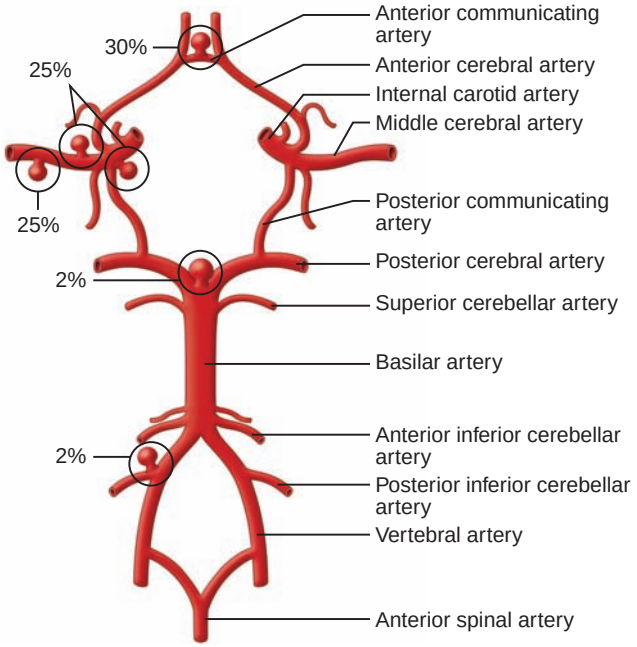

FIGURE 35-3 ▲ Circle of Willis with common aneurysm sites.

Aneurysms may also be categorized according to size. A small aneurysm is smaller than 10 mm, a large one is 10 to 20 mm, and a giant one is larger than 25 mm. Giant aneurysms are a cause for great concern because they may compress surrounding brain tissue or compromise the existing circulation to that area. Controversy exists about size and relationship to rupture. Seven millimeters is the average size of a ruptured aneurysm, but smaller lesions routinely hemorrhage.[12–14] Hemorrhage from an aneurysm usually occurs in the subarachnoid space because aneurysm-forming vessels usually lie in the space between the arachnoid layer of the meninges and the brain. The force of the rupturing vessel can be so great that it can push blood through the pia mater and into the brain substance, causing an intracerebral hemorrhage. It can also push through the arachnoid into the subdural space, causing a subdural hemorrhage.[12,13]

Clinical Manifestations

Many aneurysms are silent and never cause a problem but may be discovered on postmortem examination. An aneurysm that does cause problems typically does so in patients between ages 35 and 60 years. Use of a grading scale can enhance the ability to determine clinical outcome. Aneurysmal SAHs are graded according to their severity on the Hunt and Hess scale. In this grading system, grade 0 is the unruptured aneurysm, and grade V is a hemorrhage with severe neurological sequelae (Table 35-5). However, the Hunt and Hess scale is not the only grading system that has been developed for SAH. The World Federation of Neurological Surgeons grading scale is also used for SAH. The Fisher scale is another grading scale that is used to estimate the density of subarachnoid blood on CT scan at the time of a patient's admission to the hospital (Table 35-6).[12–14] A score of 3 or 4 on the Fisher scale has been found to increase the likelihood of poor clinical outcomes. A score of 1 to 2 has not been shown to increase mortality rates.

Table 35-5 Hunt and Hess Grading Scale for Aneurysms

Grade 0	Unruptured aneurysm
Grade I	Asymptomatic Minimal headache Slight nuchal rigidity (neck stiffness)
Grade II	Moderate to severe headache Nuchal rigidity Cranial nerve deficits
Grade III	Lethargy Mental confusion Mild focal neurological deficit
Grade IV	Stupor Moderate to severe motor deficit Possible posturing
Grade V	Deep coma Posturing Declining appearance

Am Assoc Neurosci Nurses 2007.

Approximately half of patients have some warning signs before an aneurysm ruptures. These signs may include headache, lethargy, neck pain, a "noise in the head," and optic, oculomotor, or trigeminal cranial nerve dysfunction.[12–14]

After an aneurysm has bled or ruptured, the patient usually complains of a horrific headache. The classic description is "the worst headache of my life," which is often abbreviated as WHOL in the medical record. Other symptoms that may accompany SAH or aneurysms that present with mass effect are nausea, vomiting, focal neurologic deficits, or coma. Aneurysms presenting with mass effect typically show symptoms associated with increased ICP. With an SAH, there are also signs of meningeal irritation, such as a stiff and painful neck, photophobia, blurred vision, irritability, fever, positive Kernig's sign, and positive Brudzinski's sign. Exactly which deficits are present depends on the location of the aneurysm, the subsequent hemorrhage, and the severity of the bleeding.[12–14]

Bleeding stops because ICP in the subarachnoid space reaches mean arterial pressure (MAP) quickly, resulting in a tamponade effect that stops the bleeding long enough for the rupture to seal. If this does not occur, the patient dies.[12–14]

When there is blood in the subarachnoid space, it irritates the brainstem, causing abnormal activity in the autonomic nervous system, often with cardiac dysrhythmias and hypertension. Hypertension can also result from elevated ICP. Another complication of blood in the subarachnoid space is hydrocephalus. Blood in the subarachnoid space impedes reabsorption of CSF by the arachnoid villi. Hydrocephalus results in enlargement of the lateral and third ventricles.[12–14]

Diagnosis

The diagnosis of a cerebral aneurysm usually is made on the basis of history, physical examination, CT scan, lumbar puncture, and cerebral angiogram. When the nurse takes the patient's history, he or she identifies risk factors such as genetic predisposition, hypertension, and cigarette

smoking. Patients with an SAH may present with a headache, neck discomfort, or both without any neurological signs. The headache may range in severity from mild to severe. A CT scan reveals hemorrhage in most cases when it is obtained within 24 hours of the hemorrhage. It has the most sensitivity when obtained within 24 hours of onset.[12–14] There is a steady decline over ensuing days, with approximately 50% of CTs being positive 5 days after an SAH occurs.

If the results of a CT scan are negative and there are signs and symptoms indicating that a patient has experienced an SAH, a lumbar puncture is typically performed to confirm the diagnosis. After a positive lumbar puncture, a cerebral angiogram is obtained to determine the source of the SAH. Different types of angiography may be used for this purpose, including CT angiography, MRA, or digital subtraction angiography (DSA). Although all of these studies can determine vascular anatomy, DSA is the gold standard if surgery is planned. Transcranial Doppler (TCD) ultrasonography can also be used to diagnose and treat vasospasm, a common complication of an SAH.[12–14] Examples of nursing diagnoses for the patient with a cerebral aneurysm or AVMs nursing (discussed later) are presented in Box 35-1.

Clinical Management

Before repair, the management of a patient with a ruptured or leaking aneurysm focuses on minimal stimulation of the patient. Some institutions initiate "aneurysm precautions" as precautionary measures to prevent rebleeding. These measures include providing a quiet environment, establishing a bowel regimen to prevent straining (Valsalva maneuver), and limiting visitors.[14]

Pharmacological Management

Antihypertensive medications may be used to manage blood pressure (BP) before procedures or surgery. Plasma volume should not be allowed to fall. Frequently, abnormalities of electrolytes, notably hyponatremia, exist. Hyponatremia, usually associated with cerebral salt wasting rather than syndrome of inappropriate antidiuretic hormone, must be managed with sodium replacement and euvolemia.[12–15]

Stool softeners are used in managing patients with an aneurysm to prevent straining. Mild analgesics can be used to relieve headaches. An antipyretic, usually acetaminophen, and hypothermia blankets can be used to manage fever typically caused by blood in the subarachnoid space. Acetaminophen can be used without masking neurological signs. Judicious use of narcotics is appropriate in these patients.[12–14]

BOX 35-1 EXAMPLES OF NURSING DIAGNOSES

For the Patient With Cerebral Aneurysm or Arteriovenous Malformations

- Risk for Ineffective Cerebral Tissue Perfusion related to interruption in CBF or intracranial hypertension
- Acute Pain related to meningeal irritation
- Excess Fluid Volume related to hypervolemia used to treat vasospasm
- Deficient Fluid Volume Risk for fluid volume deficit related to fluid restriction and use of osmotics to control intracranial hypertension

Surgical Management

CLIPPING. Surgical clipping may be considered if the aneurysm is in an accessible area. The goal of surgery is complete obliteration of the aneurysm. Aneurysms of the vertebrobasilar system often present the problem of surgical inaccessibility. The accepted surgical treatment is the placement of a clip across the neck of the aneurysm. These clips, which are made of titanium, come in a variety of shapes and sizes. For larger or wider aneurysms, more than one clip can be used to ensure complete occlusion of the neck of the aneurysm. Once clipped, the aneurysm may be punctured to allow it to collapse and relieve mass effect if present.[12–14]

Some aneurysms may be wrapped in a gauze-like material or coated with an acrylic substance that gives the aneurysm support. Although wrapping or coating should not be the goal of surgery, there may be conditions, as with a fusiform aneurysm, in which there is no other option.

In the past several years, controversy continued about when surgical intervention should occur. The current thinking is that surgery should occur sooner rather than later. Thus, surgery may generally be performed 24 to 48 hours after the rupture and initial bleed occur.[12–15] (Fig. 35-4).

After aneurysm clipping, the patient is managed in a critical care environment. Maintenance of an adequate airway is vital. If the patient is intubated and suctioning is needed, it is important that the suction catheter be passed and removed quickly to prevent oxygen desaturation as well as surges in ICP consequent to increased intrathoracic pressure resulting from stimulation of the cough reflex.

Signs of vasospasm, such as hemiparesis, visual disturbance, seizures, or a decreasing level of consciousness (LOC), should be noted and reported so that medical interventions can be rapidly implemented. Control of ICP is a collaborative effort. Nurses should keep the head of the patient's bed elevated and ensure that there is no neck flexion or severe rotation. Nursing care activities should be spaced to avoid causing a sharp rise in ICP.[12–14]

COILING. One of the most valuable recent developments in aneurysm management has been the technique of endovascular thrombosis of aneurysms with Guglielmi detachable coils (GDCs). These are thrombogenic platinum alloy microcoils. They are soft to allow the coil to conform to the shape of the aneurysm. Coils are available in various shapes, dimensions, lengths, and diameters to provide maximal occlusion.[12,13,16]

The procedure used to introduce the coil into the aneurysm is similar to that used for a cerebral angiogram, using the femoral artery and fluoroscopic equipment. In this procedure, a microcatheter is passed through the aorta, around the aortic arch, and then into the vessel specific to the aneurysm. Once the catheter is in position, the coil system is advanced through the catheter into the aneurysm sac. The coil is then in position, and if placement is satisfactory, a low-voltage current is applied. The current causes the coil to detach. If the coil is successfully placed, it occludes the aneurysm and separates it from the cerebral circulation. The number of coils placed is individualized to the patient. Through this

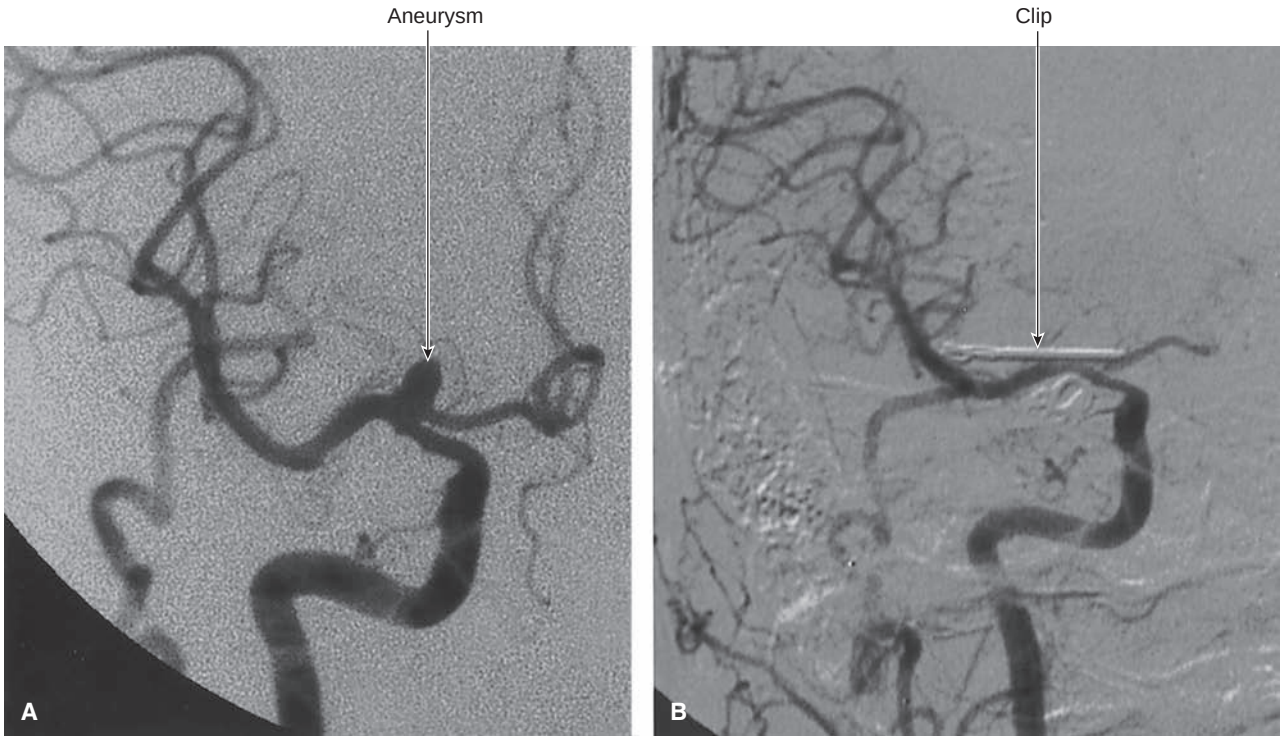

FIGURE 35-4 ▲ Preoperative (**A**) and postoperative (**B**) angiography: clipping of right internal carotid artery termination aneurysm. (Courtesy of Rafael Tamargo, MD, and Richard Clatterbuck, MD, Johns Hopkins University, Baltimore, MD.)

coiling procedure, the risk for hemorrhage or rehemorrhage is reduced.[12,13,16]

Complications of this treatment are embolic stroke, coil migration, failure to obliterate the aneurysm, and aneurysm rupture. Stroke may occur because the parent artery feeding the aneurysm becomes occluded or because of the introduction of air or particles into the catheter system. Coil migration occurs because of reintroduction of blood into the sac. The coils become repositioned outside the fundus of the sac and can then migrate to other anatomic areas of the brain, creating complications such as brain ischemia in areas supplied by the affected blood vessel. Failure to obliterate the aneurysm is also a possibility. If the coils fail to obliterate the aneurysm, the sac may grow larger, cause more symptoms, and may even rupture. Further intervention with another endovascular procedure or surgery is then warranted.[12,13]

Although clipping is the preferred treatment or gold standard for most aneurysms, GDC coiling is an option for patients who are considered to be surgically high risk because of medical instability, or those who would otherwise be treated conservatively. With the rapidly evolving technology, endovascular embolization of cerebral aneurysms is a safe alternative to surgical clipping in treating ruptured and unruptured cerebral aneurysms.[12,13,16] Long-term outcomes require further study. Some experts currently consider coiling to be the preferred treatment, although this is still a matter of controversy.

Medical Management of Complications

As previously noted, vasospasm can occur after, as well as before, surgery in the patient with an aneurysm. Angiographic vasospasm is seen early. Vasospasm may be recognized clinically through frequent neurological assessment. The patient's signs and symptoms can fluctuate but may include changes in LOC, headache, language impairment, hemiparesis, and seizures.[12–15]

Vasospasm usually occurs 3 to 12 days after an SAH. The peak incidence is between postbleed days 7 and 10. Although the aneurysm may have been clipped successfully, vasospasm can cause the development of a large area of ischemia or infarcted brain, with severe deficits. Vasospasm is of clinical significance because it decreases CBF, depriving brain tissue of oxygen and promoting accumulation of metabolic waste products, such as lactic acid. The reduced size of the vessel lumen restricts blood flow to the brain tissue, causing brain ischemia and possible permanent neurologic consequences.[12–15]

TCD imaging is a valuable noninvasive technique used to diagnose vasospasm. This technique, which can be performed at the bedside, measures the velocity of blood flow through segments of the arterial vessels. Monitoring trends in flow velocity allows prompt identification of early indications of vasospasm and patients at risk for developing vasospasm. The results of the neurological examination can be correlated with TCD findings for prompt diagnosis and treatment of vasospasm. This technique is highly reliable in predicting vasospasm of the middle cerebral and internal carotid arteries.[12–14]

The exact etiology of vasospasm is not clear. Apparently, there is a positive correlation between the size of the hemorrhage seen on CT scan and the subsequent development of spasm. Vasospasm is likely caused by inflammatory processes. There has been some success in using nimodipine

(Sular), a calcium antagonist, after an SAH to improve patient outcomes. It is recommended that nimodipine be used from onset through day 21. Nimodipine reduces the contraction of smooth and cardiac muscles without affecting skeletal muscles. The dose is 60 mg every 4 hours. The theory is that nimodipine improves outcomes by limiting collateral cerebral damage that is mediated by calcium.[12–15]

"Triple H" therapy is the standard for preventing and treating vasospasm. It consists of hypervolemic expansion, hemodilution, and induced hypertension in postoperative patients. Nimodipine is used with this therapy. These measures reduce smooth muscle spasm and maximize perfusion when spasm does occur.[12–15]

Hypervolemia is accomplished by volume expansion, using both intravenous (IV) colloid and crystalloid solutions. They are given to increase intravascular volume and decrease blood viscosity. Through hypervolemia, the cerebral vessels dilate and the MAP increases, thereby improving cerebral perfusion pressure (CPP). During this therapy, the patient should be monitored for pulmonary edema and heart failure. A pulmonary artery catheter helps monitor the patient's hemodynamic status.[12–15]

Hemodilution through the administration of IV fluids decreases blood viscosity, increases regional CBF, and may decrease infarction size and increase oxygen transport. The goal of hemodilution is to reduce the hematocrit by 15%. The patient's hematocrit level should be maintained between 30% and 33%, which helps improve CBF without causing hypoxia.[12–15]

Vasopressors are used to induce hypertension. The objective is to maintain systolic BP at greater than 20 mm Hg over normal. Vasopressors raise the patient's BP and brain perfusion to the point where neurological deficit improves.[12–15]

When conventional medical therapy is not effective, acute arterial vasospasm secondary to an SAH can be managed by balloon angioplasty in centers where this technology is available. Recent advances in microballoon technology now allow access to the cerebral vasculature with soft, flexible angioplasty balloons, which mechanically dilate and improve CBF through the major arterial segments affected by vasospasm. Balloon angioplasty allows direct widening of the stenotic segment.[12,13,15] Intra-arterial administration of nicardipine to selectively treat cerebral vasospasm is an additional technique to utilize. Increasing vasopressor dosing may be required to maintain systemic arterial pressure but was noted to be well-tolerated.[17] IV administration of magnesium sulfate in high doses has been shown effective in attenuating cerebral vasospasm and reducing cerebral ischemic events.[18]

Another complication after aneurysmal rupture is hydrocephalus. Hydrocephalus indicates an imbalance between the production and absorption of CSF. It may occur in patients who have experienced an SAH. When there is blood in the subarachnoid space, the red blood cell clots and possible brain edema can occlude the very small channels leading from one ventricle to another. If this occurs, an obstructive hydrocephalus develops and obstructs the normal flow of CSF, often between the third and fourth ventricles, or at the exits from the fourth ventricle. There is also the potential for a reabsorption problem, whereby red blood cells and their breakdown products occlude the arachnoid villi, impeding reabsorption and resulting in a communicating hydrocephalus. The patient may require a shunt. With a ventriculoperitoneal shunt, the proximal tip of the catheter is placed in a lateral ventricle, and the distal tip is placed in the peritoneum. The shunt drains CSF into the peritoneal cavity to treat the hydrocephalus and prevent dangerous ICP elevations.[12–14]

Seizures may occur from blood in the subarachnoid space acting as an irritant to neurons. Typically, patients receive an anticonvulsant to minimize seizure risk.[12–14]

Rebleeding is another complication in patients with an SAH if the aneurysm is not repaired. There is a 2% to 4% risk of aneurysmal rebleeding within the first 24 hours of initial hemorrhage. This increases to 15% to 20% risk of rebleeding within the next 2 weeks after the initial bleeding. The immediate mortality rate of rebleeding may be high—between 50% and 80%.[14]

Nursing Management

ASSESSMENT. One of the nurse's primary responsibilities is to obtain a baseline neurological assessment and perform subsequent assessments to monitor for changes. After surgery, the nurse must be alert to the development of new deficits or a worsening of preoperative deficits. The severity and duration of any postoperative disability depend largely on the location and extent of the vascular lesion and resultant ischemia. The patient must also be carefully monitored for the development of cerebral edema.[14]

PLAN. Before surgery, the nurse implements aneurysm precautions by providing a quiet environment with limited stimulation. The nurse does a bowel assessment and implements individualized interventions.

A patent airway is required. Management of the patient's fluid and electrolytes includes careful monitoring for hyponatremia, which can cause an increase in cerebral edema. Accurate intake and output measurements are imperative.[14]

The nurse also monitors vital signs to rapidly identify any changes in BP and initiate corrective action to maintain BP within the target range. Hypotension must be treated immediately to prevent a drop in cerebral perfusion. Cardiac dysrhythmias may be present, especially if there was bleeding into the subarachnoid space. Dysrhythmias require prompt management because they may precipitate a drop in cardiac output and a consequent drop in cerebral perfusion.[12–14]

A patent IV site is maintained for hydration. Maintaining two IV accesses may be appropriate as a matter of clinical judgment. Continuous fluids are a part of the management of vasospasm. The IV site is monitored frequently, and fluids are not interrupted for any reason. In the event of an infiltrate, the nurse restarts the line immediately.[14] Measures also need to be taken to manage increased ICP elevation if it develops. It would be noted initially as a decline in LOC. In the event the ICP elevation is severe enough to markedly reduce the LOC, endotracheal intubation and controlled ventilation should be initiated. Hyperventilation may be done as an initial emergent measure to lower dangerous ICP elevations pending initiation of additional therapies, such as osmotic diuretics and ventricular drainage, which are valuable tools in managing ICP elevations.

Emotional support is also a crucial part of the overall nursing care of the patient with a ruptured aneurysm. Because of an aneurysm's abrupt onset, the hospital admission cannot be planned. Often the rupture suddenly interrupts the patient's daily life and may leave the patient with neurological

impairment. The patient's support system needs to be organized to tend to daily activities and responsibilities in his or her absence. Families require assistance when confronting the financial, physical, and emotional burden of caring for a patient after an SAH. A social worker can be instrumental in helping to organize the support of friends and family.[14]

Patient Education and Discharge Planning

Smoking and hypertension are both preventable risk factors associated with intracranial aneurysm and SAH. Patients can be instructed that cessation of smoking and control of hypertension can reduce the incidence of aneurysm formation and rupture.

Patients who have undergone clipping of cerebral aneurysms should be carefully screened before MRI. Although titanium clips used after 1996 are "MRI friendly," it is necessary to determine the composition of the clip before the patient undergoes MRI.

If a patient has experienced a seizure and is being maintained on anticonvulsant therapy, instructions should be given about medication monitoring and the need for compliance. In addition, the patient should be instructed about seizure safety.

Patients who have experienced SAH face a lengthy recovery. Rehabilitation for specific deficits should begin early.[14] Also, family participation in the rehabilitation plan is encouraged. Members of the health care team, such as physical, occupational, and speech therapists, can help towards restoring the patient's independence, and such services can be coordinated either for inpatient or outpatient settings, depending on the extent of impairment and financial circumstances.

Arteriovenous Malformations

Arteriovenous malformations (AVMs) are lesions consisting of dilated arteries and veins without a capillary system. Arterial blood flows directly into the venous system. AVMs are usually described as a "tangle" of blood vessels with a well-defined nidus that does not involve brain parenchyma.[19–21] Presumably, AVMs are congenital, and they typically enlarge with age.[19] Although they are found throughout the central nervous system (CNS), approximately 90% of AVMs are located in the cerebrum. Of these, the most common locations are the frontal and temporal lobes, most often supplied by the MCA.

Epidemiology

AVMs are relatively uncommon brain lesions. Population-based studies have estimated an prevalence of approximately 0.01% of the general population.[19] There is no statistically significant predisposition by sex. AVMs are diagnosed most often in young adults, with the majority being diagnosed in patients younger than age 40.[19] In cases in which the patient has both an AVM and an aneurysm (7%), the symptomatic lesion is treated initially. In some instances, both can be surgically treated at the same time. Of the two, aneurysms are more likely to be the cause of hemorrhage.

Pathophysiology

AVMs develop as an atypical preservation of embryonic connections between arteries and veins, most likely between 4 and 8 weeks of embryo development. This is the period in which cells begin to differentiate and capillary components to the brain develop. AVMs are most likely to arise at this time because of the failure of the primitive vasculature to develop an adequate capillary system. Because blood is shunted directly from the arterial to the venous circulation without benefit of a capillary bed, there is less resistance, and AVMs receive significant blood flow. Arteries and veins enlarge to carry this increased flow, and their walls are characteristically quite thin. Arteries providing blood to the malformation and draining veins also become enlarged with increased flow volume in the lesion.[19–21]

Clinical Manifestations

Hemorrhage, the most common presenting sign of AVMs, occurs in 38% to 70% of affected patients according to population-based studies.[20] These hemorrhages may be intracerebral, subdural, or subarachnoid. Opinions differ regarding whether the size of the lesion affects the likelihood of bleeding. Small size may be associated with an increased risk for hemorrhage, which may be caused by higher flow and pressure from the feeding vessels. In addition, increased risk of hemorrhage is seen in AVMs located in the basal ganglia, posterior fossa, and lesions with deep venous drainage, having fewer or single draining veins as well as high pressures within the arterial vessels feeding the AVM.[20]

There is an approximate 10% mortality rate after a hemorrhage with a higher percentage of patients having significant morbidity following initial bleeding.[21] The risk for rebleeding is higher in the first year after the initial hemorrhage and declines over subsequent years.[19] Cerebral AVMs cause about 4% to 5% of SAHs. An SAH caused by an AVM is less lethal than one caused by an aneurysm rupture but is associated with significant neurological morbidity.

Seizures are another common presenting sign (15% to 40%) of an AVM.[20] The risk for a seizure increases with the size of the lesion. Patients are treated with AEDs after presentation with a seizure, but AEDs are not routinely used prophylactically for AVMs. Seizures are more likely to occur in patients who have large and more superficial AVMs.[20,21]

Other presenting signs include headache, increased ICP, neurological deficits (5% to 7%) referable to the location of the lesion, bruit, and visual symptoms.[19–21] Cognitive decline is seen particularly in older patients with large AVMs. This may be related to cerebral steal, which can cause ischemic changes by diverting arterial blood away from normal brain tissue to the AVM.[20]

AVMs are graded based on features, location, and venous drainage. The Spetzler-Martin grading system assigns 1 point for lesions less than 3 cm, 2 points for 3- to 6-cm lesions, and 3 points for lesions greater than 6 cm. If the AVM is located in an eloquent area of the brain (sensory, motor, speech, visual, brainstem), it is given 1 point. No points are given for noneloquent areas. Deep venous drainage associated with the malformation is allotted 1 point, with no points for superficial venous drainage. A low score is associated with better outcomes and a higher score with increased morbidity from surgery.[21]

Diagnosis

CT and MRI are used to evaluate the presence of an AVM. The lesion is differentiated from tumors and other brain

lesions by the presence of a hemosiderin ring around the lesion. Three-dimensional imaging is useful in establishing the malformation in relation to the surrounding anatomy. MRA is a noninvasive method of evaluating feeding and draining vessels in relation to the nidus of the AVM. Although MRA does provide useful information, it cannot consistently replace the more invasive angiography that is also used to evaluate feeding arteries and draining veins. Rarely, the AVM is not angiographically evident. This may be true of lesions that have bled, have small feeding and draining vessels, or have low flow. TCD, single-photon emission computed tomography (SPECT), and PET are also used to image blood flow changes. To identify the AVM in relation to eloquent areas of the brain, fMRI is useful.[19–21]

Clinical Management

AVMs can be managed in a number of ways based on the patient's age and medical condition, flow associated with the malformation, history of hemorrhage, other symptoms, and the location of the lesion. Table 35-7 outlines procedures, indications, outcomes, and possible complications.

Interventional, Surgical, and Radiosurgical Management

Endovascular embolization of feeding arteries is used for small, low-grade malformations. The cure rate is low (10% to 15%), and one or more procedures may be needed to occlude the abnormal vessels. Embolization is used as an adjunct to surgery and radiosurgery. In this procedure, particles, liquids (such as acrylic glue), balloons, or coils are inserted into the AVM nidus before surgery or radiosurgery.[19–22] Endovascular treatment of intracranial micro-AVMs can be accomplished immediately, with good patient selection, and may be an alternative to open operative resection of the lesion.[23]

SRS provides good outcomes for relatively small lesions. This can be accomplished by gamma knife, linear accelerator, or heavy ion radiation. When radiosurgery is used for lesions less than 3 cm in diameter, the cure rate is estimated at 65% to 85%. However, complete obliteration of the malformation takes 2 to 3 years, and there is a risk for hemorrhage during this time.[20] Very large cerebral AVMs may be successfully treated by staged radiosurgical procedures. Given the time required to achieve obliteration of the lesion, long-term follow-up remains necessary.[24]

Surgery is the preferred treatment for most AVMs. Surgery can reduce the risk for both hemorrhage and seizure. Brain mapping, fMRI, and intraoperative evoked potentials may be used in surgical planning for lesions in eloquent areas of the brain. Outcomes are positive, particularly in the case of Spetzler-Martin grade I and II lesions. Moreover, neurological complications are low; surgery also provides an immediate cure. Intraoperative angiography is recommended.[20,21]

Treatment approaches vary between surgery and radiosurgery for Spetzler-Martin grade III lesions. For large AVMs or lesions in eloquent areas of the brain, multimodality therapy with embolization, radiosurgery, or microsurgery is preferred. The most appropriate treatment approach for Spetzler-Martin

Table 35-7 Management of the Patient With Arteriovenous Malformation

Procedure	Indication	Outcome	Complications and Comments
Surgery	Surgically accessible AVM	Removal of lesion Decreased risk for bleeding Improved seizure control Preoperative propranolol believed to minimize postoperative bleeding and edema Labetalol used to keep MAP 70–80 mm Hg perioperatively	Inability to remove lesion Risks for surgery: cerebral edema; hemorrhage; neurological deficits Inpatient hospital stay Excellent results in Spetzler-Martin grade I–III lesions
Radiation: Stereotactic radiosurgery (SRS) (external beam radiation effective in only a small percentage of cases; gamma knife, proton beam, or linear accelerator used)	3 cm or smaller AVM Surgery not indicated	Reduction in size of lesion Noninvasive Outpatient, no recovery period	Lesion not removed May take years for complete obliteration May require multiple treatments Continued risk for bleeding for 2–3 y Used for small AVMs or as part of multimodality treatment
Embolization	Injection of substance to occlude the feeder vessels	Facilitates other therapies (surgery; radiation) by reducing AVM Useful for larger AVMs Short hospital stay	Does not typically cure AVM May need more than one procedure Need to wait days or weeks before surgery or SRS Risk for stroke or hemorrhage

grade IV and V lesions is a matter of controversy. Some practitioners recommend the multimodality approach, and others opt for no treatment. In addition to intracranial hemorrhage as a presenting event of AVM, hydrocephalus may also occur. Hydrocephalus may be consequent to the AVM acting as a space-occupying lesion, interfering with CSF flow. Cerebral hydrodynamics may also be affected by mechanical obstruction by a draining vein associated with the lesion. In the event this causes acute hydrocephalus and ICP elevation, ventricular drainage may be necessary; if chronic, ventriculoperitoneal shunt may be necessary for long-term management. Definitive management should be prioritized at management of the AVM.[25]

Nursing Management

ASSESSMENT. The nursing management of the patient with an AVM is similar to that described for a patient with a cerebral aneurysm. Baseline and follow-up neurological assessments are necessary to monitor for subtle changes or evidence of hemorrhage.

PLAN. Careful evaluation of focal neurological signs or evidence of cerebral edema minimizes significant postoperative morbidity.

Patient Education and Discharge Planning

Patients who have experienced a hemorrhage or seizures secondary to an AVM are managed in much the same way as patients with aneurysms. Safeguards and family teaching include a discussion of signs of increased ICP, seizure control and safety, anticonvulsant therapy, postoperative complications, and side effects of radiation, when appropriate.

Surgical Approaches

Neurological surgery may be performed in a number of situations as follows:

1. To obtain tissue for pathological diagnosis
2. To remove an abnormal mass or space-occupying lesion (eg, tumor, cyst, hemorrhage) and, consequently, to reduce mass effect
3. To repair an abnormality (eg, aneurysm)
4. To place a device (eg, shunt, reservoir)

A number of factors are considered when making the appropriate surgical decision. Diagnostic studies are first performed to establish a differential diagnosis. Patient age, neurological status, and concurrent medical conditions are factors in the decision to proceed with surgery and the decision regarding the appropriate approach. The most commonly used surgical procedures are briefly described in the following sections.

Stereotactic Biopsy

A stereotactic biopsy is used to obtain tissue for definitive pathological diagnosis. It is often used when a tumor is suspected but the lesion is too small or deep for surgical removal. It is used for tumors in eloquent areas of the brain, lesions crossing the corpus callosum, and multiple lesions that are not resectable.[2,26,27] A stereotactic biopsy is also used to confirm the diagnosis of previously treated tumors—for example, when a malignant glioma has been treated with multiple therapies, tissue is obtained and analyzed to differentiate active tumor from treatment effect (ie, necrosis). In addition, some patients may have multiple medical problems and be too ill to proceed with a craniotomy. Others may opt to have the less invasive biopsy.[2]

The goal of stereotactic surgery is to locate a target using a trajectory. Stereotactic biopsies with a frame require placement of a rigid head frame to establish the appropriate coordinates. Next, a contrast-enhanced CT scan or MRI is obtained in the radiology suite by using the localizing frame. An axial image of the tumor is displayed, with a number of coordinates to indicate entry points. After the imaging is completed, the patient is usually transferred from the radiology suite to the operating room for completion of the procedure.[2] The biopsy can be performed under general or local anesthesia.[2] After the skin is shaved and prepared, a small hole (twist drill or burr hole) is made, a needle is passed to the lesion, and one or more biopsies are obtained and immediately evaluated by a pathologist. Once sufficient tissue or cyst fluid is obtained for diagnostic purposes, the procedure is complete. Because of the possibility of sampling error, it is not unusual for the neurosurgeon to take multiple specimens from various areas of the tumor or other abnormal area defined on neuroimaging, when feasible.[2,27]

A stereotactic biopsy may also be performed without a frame. Frameless stereotaxy is a navigational system used to generate a three-dimensional tumor image. A CT or MRI scan is taken before the procedure, and markers (fiducials) are placed on the scalp. The markers are evident on the scan and are used to determine the actual target. A computer image is then generated from the imaging data.[2,26]

Craniotomy

A craniotomy is performed to remove a space-occupying abnormality such as a tumor, cyst, or vascular malformation. This procedure may also be needed on an emergency basis to evacuate a hematoma or reverse a herniation syndrome. When appropriate, a craniotomy is used to clip an aneurysm.[1,2]

In this procedure, the surgeon makes a skin incision, elevates the bone flap, opens the dura, and obtains tissue from the lesion for biopsy or performs resection. The neurosurgical patient has quite distinct intraoperative pharmacological needs. The neuroanesthesiologist administers drugs that provide the needed anesthetic effect while minimizing risks for increasing ICP or lowering seizure threshold. Rapid reversibility is also particularly important in patients receiving a craniotomy because their postoperative neurological status needs to be assessed quickly.[1,2]

In addition to the equipment used during surgery to maximize safety and efficiency, specific tools for intraoperative monitoring may enhance the outcome for these patients. During the past 10 to 15 years, significant advances have taken place. Ultrasonography has been a standard of neurosurgical monitoring for some years because it can distinguish abnormal lesions from normal brain tissue and edema. Residual abnormal tissue may be identified before closing the surgical site. Frameless stereotaxy, as described previously, is also used during craniotomy. It is thought that this procedure enhances surgical safety and effectiveness by reducing craniotomy size, minimizing brain manipulation, and maximizing tumor resection.[2,26,27] Cortical mapping is used for masses in

eloquent areas of the brain. Somatosensory evoked potentials are recorded during surgery under general anesthesia to assess the relationship between the motor strip and the lesion to be resected. Direct cortical stimulation provides for localization of the sensorimotor cortex and is also used to minimize neurological deficits and maximize tumor removal. In some cases, greater seizure control is accomplished with these procedures. Direct cortical stimulation requires local anesthesia and the patient to be conscious during much of the procedure.[28]

Craniotomies have been enhanced by the use of microscopes, operating loupes, self-retaining retractors, high-speed drills, ultrasonic aspirators (using sound waves/high-frequency vibration and immediate aspiration of tissue from the lesion), and laser (using light beams). Bipolar coagulation is used to minimize bleeding.[2]

Postoperative management of the patient who has undergone a craniotomy or stereotactic biopsy for a brain tumor focuses on assessment of and intervention for a number of potential complications. In the immediate postoperative period, patients may be slow to respond because of the effects of general anesthesia. Temporary changes in mental status or new focal neurological signs should resolve rather quickly in this situation.[1,2] If there is a significant change from the baseline examination, radiographic documentation of hemorrhage or cerebral edema is performed. A CT scan or MRI is obtained to rule out postoperative complications. Edema is expected and can often be treated with corticosteroids. If significantly increased ICP occurs, the patient is medically managed in an intensive care environment under close observation. Occasionally, surgical intervention is required for acute postoperative hemorrhage.

Other postoperative monitoring includes ongoing evaluation of vital signs and neurological status; early ambulation to avoid pulmonary and cardiovascular complications; physical and occupational therapy evaluations; speech and cognitive assessment when indicated; DVT and PE prophylaxis; and wound evaluation and care.

Transsphenoidal and Transnasal Surgeries

Transsphenoidal and transnasal surgeries are being used in many centers to remove pituitary tumors and cysts. The transnasal and transsphenoidal approaches replace transcranial surgery, when appropriate. An estimated 75% to 95% of cases are treated in this way. The patient is positioned on the operating table under general anesthesia. The sphenoid sinus is opened, the sella is opened, and the tumor is removed using the surgical microscope. If there is evidence of a CSF leak at the time of surgery, the sellar cavity is packed with fat tissue, typically taken from the patient's abdomen. The mucosal incision is closed with reabsorbable sutures. Nasal septal splints are applied.[1,2]

This procedure is usually well tolerated. Postoperative care is aimed at increasing mobility, monitoring respiration, evaluating fluid and electrolyte balance, and observing for evidence of CSF leak. The major risks of intracranial surgery—cerebral edema and intracerebral hemorrhage—are avoided. Nasal splints are removed 2 to 4 days after surgery.[1,2]

Neuroendoscopy as a Surgical Tool

Endoscopic microsurgical techniques are being used with increasing frequency. This surgical tool improves visualization of normal anatomy and of abnormal lesions. It is most often used for smaller, avascular lesions of soft consistency. Colloid and choroid plexus cysts, ependymomas, some skull base tumors, and certain gliomas are amenable to this approach. The technique involves the use of an angled, flexible endoscope, thus enhancing the approach to tumor removal and aneurysm clipping.[2,29] Additionally, it allows for improved inspection during transsphenoidal surgery, providing closer evaluation of the pituitary tumor versus the normal gland.[2,29] Risks of neuroendoscopy approaches to pituitary tumor resection include persistent CSF leakage. Detailed surgical repair using autologous materials such as fat, bone, and fascia may be successfully done at the time of surgery.[29]

In selected endoscopic cases, frameless stereotaxy is used to increase accuracy and minimize brain trauma. It should be noted that the surgeon's experience and expertise are crucial to minimizing morbidity and maximizing the effectiveness of this approach.[2,26]

▲ Neurological Disorders

Common neurological disorders requiring critical care management are discussed in the following section. Spotlight on Genetics 35-1 contains information about Huntington's Disease, a neurodegenerative genetic disorder that affects muscle coordination and leads to cognitive decline and dementia.

Stroke

Cerebrovascular disease includes any pathological process that involves the blood vessels of the brain. It is the most frequent

SPOTLIGHT ON GENETICS 35-1

Huntington's Disease

- Huntington's disease affects an estimated 3 to 7 per 100,000 people of European ancestry and causes uncontrolled movements, emotional problems, and loss of thinking ability.
- Mutations in the HTT gene cause Huntington's disease. The HTT gene provides instructions for making a protein called huntingtin, which appears to play an important role of neuron coordination in the brain.
- The HTT mutation that causes Huntington's disease involves a DNA segment known as a CAG trinucleotide repeat. This segment is made up of a series of three DNA building blocks (cytosine, adenine, and guanine) that appear multiple times in a row. The CAG segment is repeated 10 to 35 times within the gene. In people with Huntington's disease, the CAG segment is repeated 36 to more than 120 times. People with 36 to 40 CAG repeats may or may not develop the signs and symptoms of Huntington's disease, while people with more than 40 repeats almost always develop the disorder.
- Genetic testing, such as targeted mutation analysis, is available.

Genetic Home Reference-http://ghr.nlm.nih.gov, accessed July 14, 2011.

neurological disorder that affects adults. Most cerebrovascular disease is caused by thrombosis, embolism, or hemorrhage. The mechanism of each of these etiologies is different, but the ultimate result is damage to a focal area of the brain.[30–32]

A stroke may be defined as a neurological deficit that has a sudden onset, results in permanent damage to the brain, and is caused by cerebrovascular disease. A stroke occurs when there is a disruption of blood flow to a region of the brain. Blood flow is disrupted because of an obstruction of a vessel, a thrombus or embolus, or the rupture of a vessel. The apparent clinical features depend on the location of the event and region of the brain perfused by the vessel.[30–32]

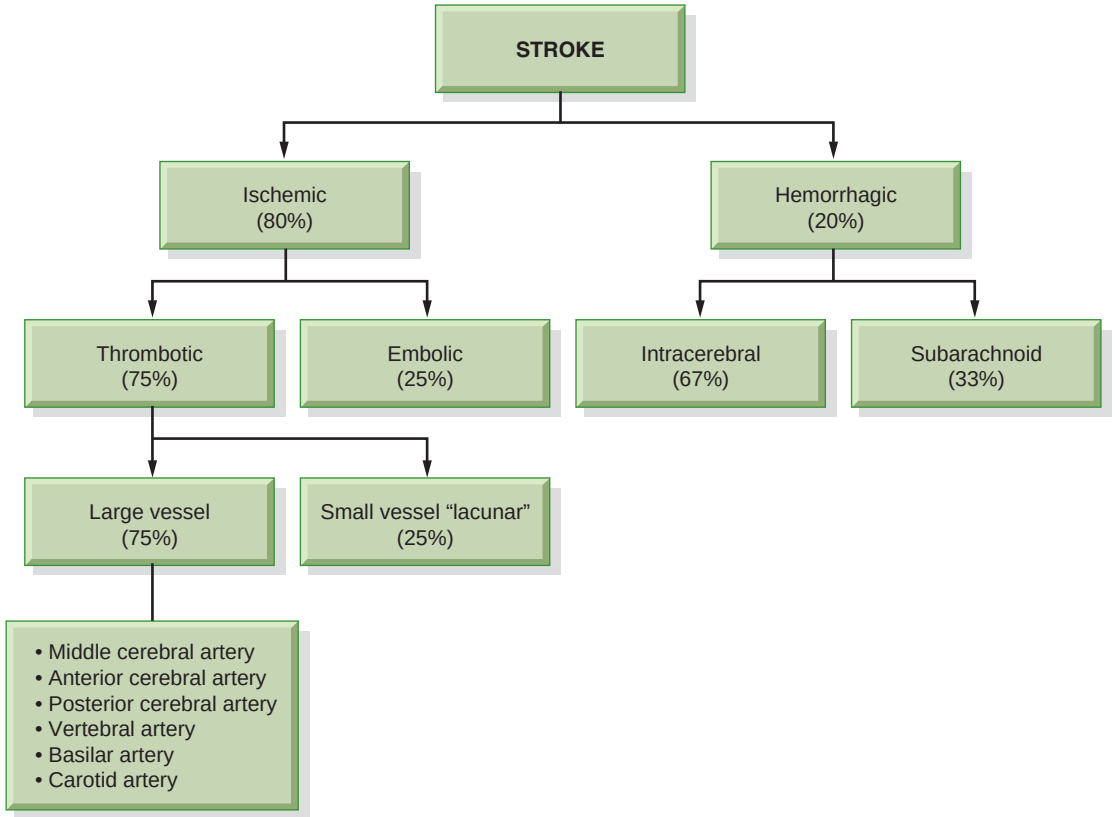
A stroke is now referred to as a "brain attack" to encourage health care professionals and the public to think about stroke with the same urgency as a "heart attack." A "brain attack" must be viewed as a medical emergency. To reverse cerebral ischemia, patients must be evaluated promptly. Ischemic brain injury occurs when arterial occlusion lasts longer than 2 to 3 hours. Delay in seeking medical care may eliminate the potential for tissue-saving therapy with thrombolytic drugs. Stroke is the fourth leading cause of death in the United States.[33] Even when stroke is not fatal, it can result in serious long-term disability.[30,34]

During the past several years, advances have been made in the treatment of stroke. Early recognition and prompt entry into the emergency medical system (EMS) are essential to reduce death and disability from stroke. Media campaigns have been launched to increase public awareness about the signs and symptoms of stroke so that care may be sought promptly.

A recent innovation in the way stroke care is delivered involves the establishment of the Joint Commission's certified stroke centers. The Joint Commission implemented a Disease-Specific Care Certification program in 2002, and stroke was one of the disease-specific categories in which program certification could be achieved. In this voluntary program, organizations have disease management programs reviewed by the Joint Commission. Criteria for the program include compliance with consensus-based national standards, effective use of established clinical practice guidelines to manage and optimize care, and an organized approach to monitor performance improvement activities. Achievement of Primary Stroke Center certification denotes clinical excellence in the management of stroke provided by a multidisciplinary team from several departments. This designation is attractive to many institutions that aspire to be recognized for their care of stroke patients.[34,35]

Etiology

Approximately three fourths of strokes in the United States are due to vascular obstruction (thrombi or emboli), resulting in ischemia and infarction. About one fourth of strokes in the United States are hemorrhagic, resulting from hypertensive vascular disease (which causes an intracerebral hemorrhage), a ruptured aneurysm, or an AVM.[30,32,34,35] Figure 35-5 outlines stroke classification.



Note: Generated/simplified data

FIGURE 35-5 ▲ Classification of stroke. (Courtesy of Eric Aldrich, MD, PhD, The Johns Hopkins University, Baltimore, MD.)

Epidemiology

Approximately 780,000 people have a new or recurrent stroke each year, with a mortality rate of 35%.[35] Even though the average age of stroke is 70 years, 40% of all strokes occur in people younger than 60 years. Women have overtaken men in stroke incidence, with about 60,000 more women than men experiencing strokes annually. With longer life expectancies for women, more women actually die of stroke, accounting for 61% of stroke deaths. It is estimated that there are 3 million stroke survivors and that stroke is a leading cause of disability and a leading diagnosis for long-term care.[35] Risk factors for stroke include smoking, hypertension, obesity, cardiac disease, hypercholesterolemia, diabetes, cancer, use of birth control pills, and patent foramen ovale with atrial septal aneurysm. Prevention efforts focus on lifestyle changes that can modify risk factors. In addition, the appropriate use of warfarin (Coumadin) in patients at risk for cardiac sources of emboli (eg, atrial fibrillation) and use of aspirin in patients at risk for thrombotic stroke constitute primary prevention.[30,32,34,35]

Pathophysiology

When blood flow to any part of the brain is impeded as a result of a thrombus or embolus, oxygen and substrate deprivation of the cerebral tissue begins. Deprivation for 1 minute can lead to reversible symptoms, such as loss of consciousness. Oxygen deprivation for longer periods can produce microscopic necrosis of the neurons. The necrotic area is then said to be infarcted.[30,32,34,35]

The initial oxygen deprivation may be caused by general ischemia (from cardiac arrest or hypotension) or hypoxia (from an anemic process or high altitude). If the neurons are ischemic only and have not yet necrosed, they may be saved. This situation is analogous to the focal injury caused by a myocardial infarction. An occluded coronary artery can produce an area of infarcted (dead) tissue. Surrounding the infarcted zone is an area of ischemic tissue, which has been marginally deprived of oxygen. This ischemic tissue, as in the brain, may be either salvaged with appropriate treatment or killed by secondary events.[30,32,34]

Cerebral ischemia is a complex process that depends on the severity and duration of the decline in CBF. The ischemic cascade begins within seconds to minutes after perfusion failure, creating a zone of irreversible infarction and a surrounding area of potentially salvageable "ischemic penumbra." The goal of acute stroke management is to salvage the ischemic penumbra, or the territory at risk. Without prompt intervention, the entire ischemic penumbra can eventually become an infarcted region.[32,34,35]

A stroke caused by an embolus may be a result of blood clots, fragments of atheromatous plaques, lipids, or air. Emboli to the brain most often have a cardiac source, secondary to myocardial infarction or atrial fibrillation. If hemorrhage is the etiology of a stroke, hypertension often is a precipitating factor. Vascular abnormalities, such as AVMs and cerebral aneurysms, are more prone to rupture and cause hemorrhage in the presence of hypertension.[35]

The most frequent neurovascular syndrome seen in thrombotic and embolic strokes is due to involvement of the MCA. This artery supplies mainly the lateral aspects of the cerebral hemisphere. Infarction to that area of the brain can cause contralateral motor and sensory deficits. If the infarcted hemisphere is dominant, dysphasia may be present. It is difficult to predict the amount of brain ischemia and infarction resulting from a thrombotic or embolic stroke. There is a possibility that the stroke will extend after the initial insult. There can be massive cerebral edema and an increase in ICP to the point of herniation and death after a huge thrombotic stroke. The area of the brain involved and the extent of the insult influence the prognosis. Because thrombotic strokes often are caused by atherosclerosis, there is risk for a future stroke in a patient who already has had one.[32,34,35] With embolic strokes, patients also may have subsequent episodes of stroke if the underlying cause is not treated. If the extent of brain tissue destroyed from a hemorrhagic stroke is not excessive and is in a nonvital area, the patient may recover with minimal deficits. If the hemorrhage is large or in a vital area of the brain, the patient may not recover; however, if the intracerebral hemorrhage is less massive, survival is possible. For the purposes of this discussion, the focus is on the diagnosis and management of ischemic stroke.

Clinical Manifestations

A stroke is usually characterized by the sudden onset of focal neurological impairment. The patient may experience signs such as weakness, numbness, visual changes, dysarthria, dysphagia, or aphasia. The manifestations of a stroke depend on the anatomical location of the lesion; an infarct in a certain portion of the brain results in loss of function of the body part that it controlled or skill for which it was responsible.[32,34,35] Table 35-8 presents the correlation of blood supply to symptomatology in a brain attack.

If symptoms resolve in less than 24 hours, the event is classified as a transient ischemic attack (TIA), which is defined as a "neurological deficit lasting less than 24 hours that is attributed to focal cerebral or retinal ischemia." Most TIAs last for only minutes to less than an hour, which further clouds recognition and prompt treatment. A significant proportion of people who experience a TIA will have a stroke within 5 years.[35] An aggressive workup following TIA is encouraged.

Diagnosis

Rapid diagnosis of a stroke is essential so that appropriate patients can receive thrombolytic therapy, the goal of which is to save damaged brain tissue and minimize permanent deficits. The patient should be taken to an emergency department where a neurologist can perform an initial screening and obtain appropriate neuroimaging studies.[30–32,34,35] The time of symptom onset to administration of thrombolytic therapy (or "time to needle") should be as quickly as possible. Formerly, the time limit for administration of thrombolytic therapy was to be within a 3-hour window from symptom onset. Recent evidence supports a time window of 4.5 hours from symptom onset for administration of thrombolytic therapy.[30,31,36] Emergency departments need to have services streamlined so that testing may be performed and treatment initiated promptly.

The patient's history helps determine what has happened to the person. It is important to obtain a description of the neurological event; how long it lasted; and whether the symptoms are resolving, completely gone, or the same as at the time of onset. The differential diagnosis of stroke includes ruling out intracerebral hemorrhage, SAH, subdural

Table 35-8 Anterior and Posterior Blood Supply

Artery	Brain Structure	Signs/Symptoms of Occlusion
Anterior Blood Supply		
Anterior choroidal	Globus pallidus, lateral geniculate body, posterior limb of internal capsule, medial temporal lobe	Contralateral hemiplegia Hemihypesthesia Homonymous hemianopia
Ophthalmic	Orbit and optic nerve	Transient mononuclear blindness or complete unilateral blindness
Anterior cerebral	Anterior three fourths of medial surface of cerebral hemispheres, caudate nucleus, globus pallidus, and the internal capsule	Contralateral sensory and motor deficits greater in leg than arm Incontinence Deviation of the eyes and head toward the lesion Contralateral grasp reflex Abulic symptoms Arm apraxia Expressive aphasia (in dominant hemisphere occlusion) Motor or sensory aphasia (distal occlusion)
Middle cerebral	Cortical surfaces of the parietal, temporal, and frontal lobes Basal ganglia and internal capsule	Complete: Spatial neglect and homonymous hemianopia Global aphasia (left lesion) Superior trunk: Contralateral hemiplegia and hemianesthesia in face and arm Ipsilateral deviation of eyes and head Broca's aphasia (usually left sided) Inferior trunk: Contralateral hemianopia or upper quadrantanopia Wernicke's aphasia (left lesion) Left visual neglect (right lesion)
Posterior Blood Supply		
Vertebral	Anterolateral parts of the medulla	Contralateral impairment of pain and temperature sensation
Posterior cerebral	Occipital lobe, medial and inferior surface of temporal lobe, the midbrain, third and lateral ventricles	Contralateral hemiplegia, sensory loss, and ipsilateral visual field deficits
Posterior inferior cerebellar	Medulla and cerebellum	Medial branch: Vertigo, nystagmus, ataxia, persistent dizziness Lateral branch: Unilateral clumsiness with gait and limb ataxia Inability to stand Sudden falling Vertigo, dysarthria, oculomotor signs
Anterior inferior cerebellar	Cerebellum and pons	Horner's syndrome and contralateral loss of pain and temperature sense of the arm, trunk, and leg
Superior cerebellar	Upper part of cerebellum, midbrain	Slurred speech and contralateral loss of pain and thermal sensation
Basilar	Pons and midbrain	Limb paralysis, bulbar or pseudobulbar paralysis of cranial nerve motor nuclei, nystagmus, coma, or locked-in syndrome

From Testani-Dufour L, Morrison CAM: Brain attack: Correlative anatomy. J Neurosci Nurs 29(1):213–224, 1997.

or epidural hematoma, neoplasm, seizure, or migraine headache.[30,32,34,35] Identifying the type of symptoms can help determine the diagnosis and locate a possible vascular distribution. Determination of risk factors for stroke, such as hypertension, chronic atrial fibrillation, elevated serum cholesterol, smoking, oral contraceptive use, or a familial history of stroke, also aids in diagnosis.

In the emergency department, some of the tests that are frequently used to evaluate the patient with acute ischemic stroke are a CT scan of the brain without contrast media, blood studies, neurological examination, and screening using the National Institutes of Health Stroke Scale (NIHSS).[30,32,34,35] This tool allows a score to be given for the severity of the stroke. Table 35-9 summarizes the NIHSS.

There is no definitive laboratory study currently available that determines whether a patient has experienced a stroke. Rather, the results are viewed in conjunction with the history, neurological examination, and neuroimaging studies. Laboratory tests, including complete blood cell count, electrolytes, glucose, and coagulation parameters, are obtained.

Table 35-9 National Institutes of Health Stroke Scale

1.a.	Level of consciousness (LOC)	Alert	0
		Drowsy	1
		Stuporous	2
		Comatose	3
1.b.	LOC questions: The patient is asked the month and/or his or her age. There is no partial credit for being "close" with an answer. Aphasic and stuporous patients who do not comprehend the question would score a "2."	Answers both correctly	0
		Answers one correctly	1
		Answers neither correctly	2
1.c.	LOC commands	Performs both correctly	0
		Performs one correctly	1
		Performs neither correctly	2
2.	Best gaze	Normal	0
		Partial gaze palsy	1

An urgent CT scan should be performed to rule out intracerebral hemorrhage. Ideally, the CT scan is obtained within 60 minutes of arrival in the emergency department so that treatment decisions can be made. A CT scan can be useful in differentiating between cerebrovascular and nonvascular lesions. For example, a subdural hemorrhage, brain abscess, tumor, SAH, or intracerebral hemorrhage is visible on the CT scan.[30,32,34,35] However, an area of infarction may not show on the CT scan for 24 to 48 hours.

Newer neuroimaging techniques also provide valuable information. MRI, including T1- and T2-weighted, fluid-attenuated inversion recovery (FLAIR), and diffusion-weighted techniques, has become widely available and is better at detecting infarction than a CT scan.[32,34] The earliest changes normally appear within the first 24 hours.

Other studies that may be performed, based on availability of the technology, are MRI diffusion-weighted imaging (DWI) and perfusion-weighted imaging (PWI). These techniques help identify the infarct core and penumbra, which is important because the presence of viable tissue directs interventions such as reperfusion. The ischemic penumbra surrounds the infarcted tissue. It is the marginally perfused area of the brain that has been damaged by the insult but is potentially salvageable. DWI detects acute infarction as early as a few hours after the onset of symptoms. It can reveal changes associated with infarcted tissue hours before

a CT scan or conventional MRI can detect any abnormality. It also differentiates acute from chronic ischemic changes. PWI shows the regional abnormalities of CBF. The difference between the diffusion defect and the perfusion defect represents the ischemic penumbra, or the "territory at risk."[32] DWI-PWI identifies patients who are ideal candidates for thrombolytic therapy.

Cerebral angiography has been the gold standard for evaluating cerebral vasculature. There is an estimated 1.5% to 2% associated risk for morbidity or mortality with this procedure. However, it can demonstrate an arterial occlusion or embolus. Because of the time that it takes to perform cerebral angiography, the window of opportunity to treat a patient with IV thrombolytics may be missed. However, angiography is necessary for intra-arterial thrombolysis in which tissue plasminogen activator (t-PA) or another thrombolytic is administered at the site of the clot by catheter into the artery.[31,34] The time window may be as long as 6 hours from symptom onset for intra-arterial thrombolysis, 8 hours from symptom onset for mechanical thrombolysis, and 24 hours for intravascular intervention for basilar artery stroke. The vasculature can be evaluated noninvasively by the use of TCD, ultrasonography, MRA, or CT angiography.

An electrocardiogram (ECG) should be obtained to assess for evidence of dysrhythmia or cardiac ischemia. The ECG helps determine whether a dysrhythmia is present, which may have caused the stroke. Atrial fibrillation is a dysrhythmia in which clots form in the heart and may travel to the brain (hence a cardioembolic etiology). Other changes that might be found on an ECG are an inverted T wave, ST elevation or depression, and QT prolongation. Transesophageal echocardiography and Holter monitoring may also be performed.[35]

In summary, prompt performance of a CT scan and subsequent interpretation are crucial to acute stroke management. Head CT provides vital information to allow the physician to make the decision to use thrombolytic therapy. An alternate approach is urgent MRI with PWI and DWI.

Clinical Management

The management of an ischemic stroke has four primary goals: restoration of CBF (reperfusion), prevention of recurrent thrombosis, neuroprotection, and supportive care. The timing of each element of clinical management should be implemented in a decisive manner.

Optimally, patients are initially evaluated at a center that has a stroke program, perhaps even a Joint Commission Primary Stroke Center. Decisions in the emergency department determine the patient's treatment plan. Emergency departments may have standardized orders, clinical pathways, or protocols that have been developed by a multidisciplinary team to guide care.[30,34,35]

The focus of initial treatment is to save as much of the ischemic area as possible. Three ingredients necessary to this area are oxygen, glucose, and adequate blood flow. The oxygen level can be monitored through arterial blood gas analyses or pulse oximetry, and oxygen can be given to the patient if indicated. Hypo/hyperglycemia can be evaluated with serial checks of blood glucose levels. Reperfusion may be accomplished by the use of IV t-PA.[30,34,35]

CPP is a reflection of the systemic BP and ICP. Regional perfusion is influenced by autoregulation in the brain, and MAP is influenced by cardiac output and heart rate (CPP = MAP − ICP). The parameters most easily controlled externally are the BP and cardiac rate and rhythm.[1] Dysrhythmias can reduce cardiac output and BP but usually can be corrected. There is a loss of autoregulation in the ischemic penumbra, so that reducing BP can further reduce blood flow in the penumbra and can lead to infarction.[32,34]

If the patient is a candidate for IV thrombolytic therapy, treatment with t-PA begins in the emergency department, and he or she is then moved to the ICU or other specialized monitored setting such as a neuroscience step-down or dedicated stroke unit for further monitoring. If the patient is not a candidate for thrombolytic therapy, the complexity of the patient's problems determines his or her placement in the ICU, medical unit, or stroke specialty unit.

Currently, two emergency treatments are available for stroke management: IV t-PA and the mechanical embolus removal for cerebral ischemia (MERCI) retriever. IV t-PA is an approved U.S. Food and Drug Administration (FDA) treatment. The MERCI retriever was approved by the FDA in 2004 for other uses and is currently being used in trials to determine its efficacy, but it is not approved as a treatment for stroke management.

Thrombolytic Drugs

Thrombolytic medications are exogenous drugs that dissolve clots. IV t-PA dissolves the clot and permits reperfusion of the brain tissue. IV thrombolytic therapy should be initiated as quickly as possible from symptom onset. The maximal time window is now expanded to 4.5 hours or less from the onset of neurological symptoms.[30,31,35,36] The clock begins for the patient from the time he or she was last seen well. For example, a patient retires to bed at 11:00 PM and awakens at 5:00 AM to go to the bathroom. As he attempts to rise from the bed, he feels weak and has difficulty standing up. As he calls out for his wife's help, his speech is garbled. The last time he was awake and functioning normally was 11:00 PM. Even if his symptoms started only a few minutes ago, the time he was last seen well was 6 hours ago. Therefore, he is already outside of the treatment window for IV t-PA.

Candidate selection for IV t-PA must be done carefully. The neurological examination, NIHSS score, and results of neuroimaging studies assist the physician with the decision to offer thrombolytic therapy. Box 35-2 outlines eligibility criteria for this treatment. The standards for the administration of IV t-PA to treat stroke are a result of the National Institute of Neurologic Disorders and Stroke t-PA Stroke Study. A dose of IV t-PA, 0.9 mg/kg (maximal dose, 90 mg), is administered as 10% of the total dose as a bolus over 1 to 2 minutes, with the remainder infused over 60 minutes. The t-PA activates plasminogen, a naturally occurring enzyme present in the intravascular endothelium that protects against excessive clotting. Activating plasminogen initiates the process of dissolving the clot through fibrinolysis. No other antithrombotic therapy should be given for the next 24 hours. A major risk of this therapy is intracerebral hemorrhage.[31,32,36] However, it is encouraging that this agent may prove effective in reversing a neurological deficit and improving quality of life after a stroke.

The direct administration of a thrombolytic into an artery is an alternative to IV t-PA. Such administration is effec-

BOX 35-2 Eligibility Criteria for Thrombolytic Therapy

Inclusion Criteria

1. Symptom onset of less than 4.5 hours
2. Clinical diagnosis of ischemic stroke with measurable deficit on the NIHSS
3. Older than 38 years
4. CT criteria: absence of high-density lesion consistent with intracerebral hemorrhage; absence of significant mass effect or midline shift; absence of parenchymal hypodensity; or effacement of cerebral sulci in more than 33% of the MCA territory

Exclusion Criteria

1. Stroke or serious head trauma within past 3 months
2. Systolic BP more than 185 mm Hg or diastolic BP more than 110 mm Hg refractory to aggressive pharmacological treatment, or BP readings that require aggressive treatment and yield only marginal BP control.
3. Conditions that could precipitate or suggest parenchymal bleeding (subarachnoid and intracerebral hemorrhage; recent-onset myocardial infarction; seizures at onset; major surgery within past 14 days; GI or urinary tract hemorrhage within previous 21 days; and arterial puncture of a noncompressible site or lumbar puncture within previous 7 days)
4. Glucose less than 50 mg/dL or greater than 400 mg/dL; INR greater than 1.7; platelet count less than 100,000/mm^3
5. Rapidly improving or deteriorating neurological signs or minor symptoms
6. Recent myocardial infarction
7. Recent treatment with IV or subcutaneous heparin within past 48 hours and elevated partial thromboplastin time
8. Women of childbearing age who have a positive pregnancy test result

Data from Saver JL, Kalafut M: Thrombolytic therapy in stroke. Updated April 15, 2010; accessed June 5, 2010 from http://emedicine.medscape.com/article/1160840-print; Becker JU, Wira CR, Arnold JL: Stroke, ischemic. Updated May 12, 2010, accessed June 15, 2010 from http://emedicine.medscape.com/article/793904-print; Pugh S, Mathiesen C, Meighan D, et al: Care of the Patient With Ischemic Stroke: AANN Reference Series for Clinical Practice. Stroke 40:2911–2944, 2009.

tive in acute ischemic stroke and can be given up to 6 hours after the onset of symptoms. A limiting factor is that the patient must be admitted to a specialty center in which localized intra-arterial infusion of thrombolytic drugs is possible. Through this approach, an occluded cerebral artery can be reopened. For intra-arterial therapy, a femoral arterial sheath is usually inserted, through which a microcatheter can be threaded, under fluoroscopy. The catheter tip is positioned into the clot and advanced as the clot dissolves. The femoral sheath usually remains in place for 24 hours in case of recurrent vessel occlusion. The advantage of this approach is that the medication can be delivered directly to its target.[30,32,34]

MERCI Retriever

The MERCI system (a mechanical clot retriever) can be used for up to 8 hours after stroke onset to remove blood clots from vessels. If a patient arrives at the hospital too late to receive IV t-PA, the MERCI device presents another treatment option if the patient meets strict criteria. Inclusion criteria include diagnosis of acute ischemic stroke; NIHSS greater than 8; and occlusion of internal carotid artery, basilar artery, or vertebral artery on cerebral angiography.[37] Some exclusion criteria include blood glucose level less than 50 mg/dL, excessive vessel tortuosity, hemorrhagic tendency, elevated international normalized ratio (INR), decreased platelets, sustained hypertension, CT revealing large areas of hypodensity, and arterial stenosis on angiography proximal to the embolus.[37]

The MERCI retriever works like a corkscrew to retrieve the clot. During cerebral angiography, an interventional radiologist passes the microcatheter into the femoral artery. It is advanced into the carotid until it reaches the clot. A wire is then pushed through the catheter, causing it to return to a corkscrew shape. It then snares the embolus.[37]

Potential hazards from use of the MERCI retriever include bleeding and vascular dissection or perforation. The patient needs to be closely monitored for the first 24 hours to detect adverse effects. The nurse, who plays a key role in postprocedure monitoring, performs neurological assessments and carefully monitors the patient for signs of intracranial hemorrhage, new stroke, or myocardial infarction.[37]

Anticoagulation

Aside from thrombolytic therapy and mechanical clot retrieval, secondary treatment options for stroke include anticoagulation with antithrombotic and antiplatelet drugs. If a patient experiences atrial fibrillation, anticoagulation with warfarin may be warranted. The patient will need instruction about bleeding precautions. Education also includes the purpose of the medication, information about moderate consumption of leafy green vegetables containing vitamin K, and the importance of having blood drawn regularly to monitor prothrombin time and the INR. In addition, for safety, patients should be instructed to obtain medical identification cards and bracelets so that they can be identified as taking an anticoagulant in the event of a medical emergency.[34,35]

Antiplatelet drugs include dipyridamole-ER, ticlopidine, clopidogrel, and aspirin. These drugs deter platelets from adhering to the wall of an injured blood vessel or other platelets and are given to prevent a future thrombotic or embolic event. The modified-release formula of dipyridamole increases the effect of specific factors that act as antiaggregates to reduce platelet aggregation. Ticlopidine inhibits platelet function by suppressing adenosine diphosphate–induced platelet aggregation and aggregation due to other factors. The recommended dose of ticlopidine is 250 mg twice a day. Neutropenia and thrombocytopenia are known serious adverse effects, so it is now rarely used. Clopidogrel also inhibits the activity of adenosine diphosphate but is not associated with an increased risk for neutropenia. Aspirin limits platelet adhesion and aggregation. The suggested dose of aspirin is 81 to 325 mg/d. The administration of these drugs plays a role in stroke prevention by decreasing the risk for future strokes.[30,34,35]

Control of Hypertension and Increased Intracranial Pressure

The control of hypertension, increased ICP, and CPP takes the efforts of the nurse and the physician. The nurse must assess for these problems, recognize them and their significance, and advocate for the patient, ensuring that medical interventions are initiated.

Patients with moderate hypertension usually are not treated acutely. If their BP decreases after the brain becomes accustomed to the hypertension needed for adequate perfusion, the brain's perfusion pressure falls along with the BP. If the diastolic BP is above approximately 105 mm Hg, it needs to be lowered gradually. This can be accomplished effectively with labetalol as well as calcium channel blockers.[32,34,35]

If ICP is elevated in a patient who has had a stroke, it usually occurs after the first day. Although this is a natural response of the brain to some cerebrovascular lesions, it is destructive to the brain. The usual methods of controlling increased ICP can be instituted: hyperventilation (in a patient receiving controlled ventilation in the short term only to control critical ICP elevations pending institution of additional therapies); fluid restriction; head elevation; avoidance of neck flexion or severe head rotation that would impede venous outflow from the head; and the use of osmotic diuretics (mannitol) to decrease cerebral edema (see Chapter 34 for more information).

Surgical Management

In patients with carotid stenosis, carotid endarterectomy may be performed to prevent a stroke. Carotid endarterectomy is a surgical procedure in which atherosclerotic plaque that has accumulated inside the carotid artery is surgically removed. Once the plaque is removed, blood flow is restored. The North American Symptomatic Carotid Endarterectomy Trial and the European Carotid Surgery Trial were designed to examine the benefit of surgery for patients with symptomatic carotid stenosis. These studies determined that carotid endarterectomy is justifiable in patients with high-grade stenosis (>70%) if the operation is performed by a skilled surgeon. The benefit of surgery increases for male patients with a prior history of stroke. Patients with less than 50% stenosis do not benefit from surgery.[35] During aggressive clinical management for stroke, brain edema and ICP elevation may become refractory to measures such as controlled/short-term hyperventilation and osmotic diuresis. A subset of patients may benefit from hemicraniectomy, allowing additional space for edematous brain to expand and relieving ICP elevations pending resolution of brain edema. Additionally, extracranial–intracranial bypass surgery, with careful patient selection in limited case series, has been effective in arresting stroke progression and has resulted in rapid improvement in neurological assessment findings.[38]

Nonsurgical Management

Although the gold standard for managing carotid artery stenosis has been carotid endarterectomy, another management option, carotid stenting, is available. This newer, minimally invasive procedure is attractive for patients in whom traditional surgery is contraindicated, such as those with severe cardiac or pulmonary disease. Carotid artery stenting opens vessels that have been narrowed by plaque accumulation. An interventional radiologist passes a catheter along the femoral artery to the narrowed artery. Once the catheter crosses the area of stenosis, a small filter may be deployed to catch any pieces of plaque that may be dislodged during the procedure. Angioplasty, in which plaque is pressed against the artery wall, may be performed, and a stent is placed in the artery. Recent research showed that relative risk of stroke, myocardial infarction, or death did not differ significantly between patients who underwent carotid artery stenting versus carotid endarterectomy.[39]

Following carotid stenting, there is a risk for stroke and hyperperfusion syndrome. Postprocedure, the nurse monitors the patient's neurological status and assesses the groin site for bleeding and hematoma formation.

Additional options under study and potentially on the treatment horizon for stroke patients include therapeutic hypothermia. Hyperthermia after a stroke has a direct correlation with additional neuronal death and further neurological deficits. Aggressive control of fever (aggressive normothermia) in the stroke patient may be accomplished using acetaminophen as well as convective and conductive cooling devices. Therapeutic hypothermia has been studied after cardiac arrest and is under study poststroke for neuroprotection. Pharmacological neuroprotective agents are being studied with no clear benefit obtained at this stage.[32,34]

Intracerebral Hemorrhagic Stroke

Intracerebral hemorrhagic (ICH) stroke is a potentially devastating consequence of cerebrovascular disease. It may occur, as noted earlier, consequent to cerebral aneurysm or AVM rupture. It may also occur consequent to prolonged hemodynamic stress within arterial vessels in the brain parenchyma. With vessel rupture, blood, under arterial pressure, flows from a high-pressure arterial system into the low-pressure system of the intracranial space and brain parenchyma. Expanding hematoma formation acts as a space-occupying lesion, displacing internal structures and promoting brain edema as an additional mechanism of injury. Additionally, if hemorrhage extends to the ventricles or causes obstruction of CSF pathways, obstructive or communicating hydrocephalus may result. Figure 35-6, a CT scan of the brain, shows a severe ICH stroke with resulting hematoma formation and progressive displacement of intracranial structures.

FIGURE 35-6 ▲ Large hypertensive hemorrhagic stroke. CT of head illustrating expanding hematoma with mass effect, brain edema, displacement of brain structures with midline shift and hemorrhage extending into the ventricular system. (Courtesy of Richard Arbour, MSN, RN, FAAN, Albert Einstein Healthcare Network, Philadelphia, PA.)

Intracerebral hemorrhage accounts for 10% to 15% of all strokes. The 30-day mortality rate for hemorrhagic stroke is 40% to 80% with approximately 50% of all deaths occurring within the first 48 hours. In addition to aneurysmal and AVM hemorrhage, ICH may be caused by coagulopathies, vasculitis, and abuse of cocaine or other sympathomimetic drugs.[40] Clinical assessment findings are determined by location of hemorrhage and affected vessel watershed within the brain as well as degree and rate of ICP elevation.[40] Diagnostics include clinical neurological examination and CT of the brain. Based on clinical state and LOC, airway control and ICU admission may be necessary for aggressive, mechanism-based care.[40]

Aggressive, mechanism-based care for managing ICH may include airway control and mechanical ventilation to prevent hypercarbia. Controlled ventilation may also be utilized for short-term hyperventilation ($PaCO_2$ 25 to 30 mm Hg) to modulate CBF in the short term only while other therapies for ICP control are being maximized. Osmotic diuresis with agents, such as mannitol or hypertonic saline solution, may be utilized to draw water from edematous brain tissue. Ventricular drainage may be utilized to remove CSF and decrease ICP as well as provide an ICP monitoring device. Metabolic suppression using drugs such as sedatives/analgesics, propofol or barbiturates decreases brain metabolism, blood flow and ICP in a dose-related manner.[40] Surgical intervention, as clinically appropriate, for clot removal as well as aggressive BP control may be utilized.[41,42] Aggressive BP control may slow hematoma expansion and preserve neurological function.[42]

Nursing Management

ASSESSMENT. A thorough neurological assessment is essential to identify deficits the patient is experiencing. As previously discussed, the NIHSS is a valuable tool that can be used in the emergency department to rate severity of the stroke and determine whether the patient is a candidate for t-PA (see Table 35-9). The brevity and reliability of the tool make it ideal for use in the emergency department. The NIHSS is also helpful for making subsequent assessments and should be performed in conjunction with the neurological examination.

As a member of a large multidisciplinary team, the nurse must be prepared to assume a critical role to assist with the administration of thrombolytic therapy, optimize acute patient care, and move the patient to rehabilitation quickly to maximize the patient's opportunity for an improved outcome. The nurse is in the unique position to identify problems and collaborate with the physician to initiate appropriate referrals to rehabilitation medicine specialists, social workers, speech-language pathologists, and dietitians. Because of the nature of the patient's problems, the multidisciplinary approach provides comprehensive care by addressing all needs.

In addition, the nurse must carefully monitor the patient for infection, changes in temperature, and changes in glucose level, all of which have potentially deleterious effects in people who have had a stroke. Hyperglycemia in acute stroke patients increases cerebral infarction size and worsens neurologic outcomes with and without preexisting diabetes mellitus. In a critical care unit, the upper limit of glycemic control should be 110 mg/dL. Strict glycemic control in the intensive care setting may be achieved with a continuous insulin infusion or sliding-scale regimen. Sliding-scale insulin regimens typically measure point-of-care blood glucose levels at intervals between 4 and 6 hours. Depending on the blood glucose level obtained, a specific insulin dose is ordered. For example, blood glucose between 150 and 200 mg/dL may be treated with 8 units of regular insulin. Correspondingly, a blood glucose level between 200 and 250 mg/dL may be treated with 14 units of regular insulin. The insulin dosing is increased or decreased based on patient response.

PLAN. The nurse plays a significant role in preventing complications associated with immobility, hemiparesis, or any neurological deficit produced by a stroke. Preventive measures are particularly important in the areas of urinary tract infections, aspiration, pressure ulcers, contractures, and thrombophlebitis. Patients in critical care units are at risk for DVT and its resultant complications. Mechanical prophylactic measures for DVT prevention include range-of-motion exercises, antiembolism stockings, and pneumatic compression devices. Additionally, pharmacological measures such as unfractionated heparin, low-molecular-weight heparin, or warfarin may be ordered to prevent blood coagulability. Effective interventions for treating acute stroke help lower the mortality rate and reduce the morbidity of patients who have had a stroke. The Collaborative Care Guide (Box 35-3)

BOX 35–3 *COLLABORATIVE CARE GUIDE for the Patient Who Has Experienced a Stroke*

Outcomes	Interventions
Oxygenation/Ventilation	
Adequate airway is maintained. Oxygen saturation (SpO_2) is maintained within normal limits. Atelectasis is prevented.	• Monitor breath sounds every shift. • Check oxygen saturation every shift. • Instruct to cough and deep-breathe and use incentive spirometry every 2 h while awake. • Assist with removal of airway secretions as needed.
Circulation/Perfusion	
Patient is free of dysrhythmias.	• Monitor vital signs closely. • Manage BP carefully; avoid sharp drops in BP that could result in hypotension and cause an ischemic event secondary to hypotension. • During cardiac monitoring, identify dysrhythmias. • Treat dysrhythmias to maintain adequate perfusion pressure and reduce chance of neurological impairment.

(*continued on page 788*)

BOX 35-3 COLLABORATIVE CARE GUIDE for the Patient Who Has Experienced a Stroke (continued)

Neurological	
Adequate perfusion pressure is maintained.	• Obtain vital signs and perform a neurological assessment to establish a baseline and to monitor for the development of additional deficits. • Use the NIHSS for detection of early changes suggesting cerebral edema or extension of stroke. • Position head of bed at 30 degrees to promote venous drainage.
Effective communication is established.	• Assess ability to speak and to follow simple commands. • Arrange for consultation with speech-language pathologist to differentiate language disturbances. • Use communication aids such as picture cards, pantomime, erase board, or computer to enhance communication. • Provide a calm, unrushed environment. Listen attentively to the patient. Speak in a normal tone.
Fluids/Electrolytes	
Electrolytes are within normal limits.	• Monitor laboratory results, especially glucose. • Monitor intake and output.
Mobility/Safety	
Safety is maintained. Complications of immobility are avoided.	• Initiate DVT precautions to include TED hose, sequential compressive devices, and subcutaneous heparin, as ordered. • Perform fall risk assessment. • Consult with physical therapy. • Provide active or passive range-of-motion exercises to all extremities every shift. • Establish splinting routine for affected limbs. • Instruct in use of mobility aids and fall prevention strategies. • For visual field cuts, teach scanning techniques.
Skin Integrity	
Skin is intact.	• Perform skin assessment using the Braden scale. • Provide pressure relief mattress as indicated by Braden scale. • Turn and reposition patient every 2 h. • Consult with wound nurse specialist for skin issues and concerns.
Nutrition	
Patient has adequate caloric intake and does not experience decrease in weight from baseline. Patient is free from aspiration.	• Obtain admission weight. • Perform cranial nerve assessment (including ability to swallow) to identify deficits. • Obtain consultation from speech-language pathologist to determine whether patient is safe to eat orally. • Provide proper diet and assist with feeding as needed. • Monitor calorie intake; implement calorie count, if necessary. • Obtain dietary consultation to obtain recommendation for nutritional supplements.
Psychosocial	
Support network is established.	• Use picture boards or aids to facilitate communication. • Assess for family support systems. • Screen for poststroke depression.
Teaching/Discharge Planning	
Risk factors are modified. Secondary preventive measures have been taken.	• Provide education about BP management. • Provide dietary instructions.

delineates the specific outcomes and interventions for the patient who has had a stroke.

EMOTIONAL AND BEHAVIORAL MODIFICATION. Patients who have experienced a stroke may display emotional problems, and their behavior may be different from baseline. Emotions may be labile; for example, the patient may cry one moment and laugh the next, without explanation or control. Tolerance to stress may also be reduced. A minor stressor in the prestroke state may be perceived as a major problem after the stroke. Families may not understand the behavior. Patients may show frustration or agitation with the nursing staff or their family members.

It is the nurse's role to help the family understand these behavioral changes. The nurse can help modify the patient's behavior by controlling stimuli in the environment, providing rest periods throughout the day to prevent fatigue, giving positive feedback, and providing repetition when the patient is trying to relearn a skill.

COMMUNICATION. Patients can demonstrate much frustration with their deficits. Probably no deficit produces more frustration for the patient and those trying to communicate with him or her than the one involving the production and understanding of language. Dysphasia can involve motor abilities, sensory function, or both. If the area of brain injury is in or near the left Broca's area, the memory of motor patterns of speech is affected. This results in an expressive or nonfluent dysphasia, in which the patient understands language but is unable to use it appropriately.

Receptive or fluent dysphasia usually is a result of injury to the left Wernicke's area, which is the control center for recognition of spoken language. The patient therefore is unable to understand the meaning of the spoken word (and usually the written word). Having both expressive and receptive dysphasia is referred to as global dysphasia. Box 35-4 summarizes differences between expressive and receptive problems.

It is important for the nursing staff to inform families that having dysphasia does not mean that a person is intellectually impaired. Communication at some level should be attempted, whether it is by writing, using picture boards, or gesturing.

Patient Education and Discharge Planning

Education provides information to patients about modifying risk factors and teaches people to recognize the signs and symptoms of a stroke. Information can be presented regarding medication and other lifestyle modifications to manage BP. Patients can be referred to smoking cessation programs. Teaching about glucose control, weight management, and exercise programs is also valuable. Compliance with medication regimens should be stressed as well.

Hospitals need to organize community outreach programs regarding stroke prevention, the recognition of signs and symptoms of a stroke, its emergent nature, and the need to contact 911 at the onset of symptoms. There must be public awareness about the signs and symptoms, such as sudden onset of numbness or weakness of the face, arm, or leg; confusion; trouble speaking or understanding; vision problems; dizziness; loss of balance; or severe headache. The urgency of immediate attention must be stressed. Emergency medical personnel must be able to identify the symptoms of a stroke and mobilize the patient to the nearest hospital with a full complement of stroke services from diagnosis to discharge.

In addition, a stroke is often a life-altering experience for the patient and family. Depending on the outcome, family members may require education about how to provide care for the patient at home. Instruction about mobility, nutrition, safety, sleep, and eliminative care must occur, along with referrals for home care, if appropriate. With support, the patient will be able to achieve maximal quality of life and reintegrate into the community.

Seizures

A seizure is an episode of abnormal and excessive discharge of cerebral neurons. It can result in altered sensory, motor, or behavioral activities and can be associated with changes in the LOC. Specific symptoms depend on the location of the discharge in the brain. The most common sites of seizure origin are the frontal and temporal lobes, particularly the hippocampus in the medial temporal lobe.[43] Some

BOX 35-4 Comparison of Expressive and Receptive Dysphasia

Expressive Dysphasia	Receptive Dysphasia
Hemiparesis is present because motor cortex is near Broca's area.	Hemiparesis is mild or absent because lesion is not near motor cortex.
	Hemianopsia or quadrantanopsia may be present.
Speech is slow, nonfluent; articulation is poor; speaking requires much effort. Total speech is reduced in quantity. Patient may use telegraphic speech, omitting small words.	Speech is fluent; articulation and rhythm are normal. Content of speech is impaired; wrong words are used.
Patient understands written and verbal speech.	Patient does not understand written and verbal speech.
Patient writes dysphasically.	Content of writing is abnormal. Penmanship may be good.
Patient may be able to repeat single words with effort. Phrase repetition is poor.	Repetition is poor.
Object naming is often poor, but it may be better than attempts to use spontaneous speech.	Object naming is poor.
Patient is aware of deficit, often experiencing frustration and depression.	Patient is often unaware of deficit.
Curses or other ejaculatory speech may be well articulated and automatic. Patient may be able to hum normally.	Patient may use wrong words and sounds.

seizures are so mild that only the patient is aware of them. Others are quite severe. The actual period of the seizure (the ictal period) may be followed by a postictal phase of lethargy and disorientation, which varies with the severity of the seizure.

Epilepsy is a condition in which seizures are spontaneous and recurrent. Status epilepticus is defined as a condition of either continued seizure activity or repetitive seizures without interictal recovery, over a period exceeding 30 minutes. Status epilepticus can be associated with tonic-clonic, complex–partial, or absence seizures. It is a neurological emergency and requires immediate treatment.[43–45]

Psychogenic nonepileptic seizures, which emulate epileptic seizures, are events that involve either motor activity or physical collapse.[44] Pseudoseizures can often be clinically differentiated from epilepsy because they may involve asymmetrical motor activity, side-to-side head movements, and purposeful activity. They also may be gradual in onset. The motor activity can last for many minutes, unlike epilepsy. There is usually a brief or no "postictal" phase. Patients, who are likely to have either emotional or psychological disorders, may require antidepressants, counseling, and psychiatric intervention. In about 20% of cases, patients also suffer from true epilepsy. Childhood abuse is not uncommon in these patients, although the episodes are usually signs of abnormal coping and can have many causes.

Etiology

Many generalized seizures may have a genetic basis and are termed "idiopathic" or primary seizures. They have no specific underlying cause. Symptomatic or secondary seizures have a known cause.[43–45]

Idiopathic seizures account for about 50% of all epileptic seizures. They occur most often in children younger than 10 years. Congenital and genetic causes of epilepsy are seen in approximately 10% of the population. Although inherited epilepsy is more often idiopathic, it is also associated with other conditions.[45]

Symptomatic seizures have numerous causes, including vascular disease, alcohol, cerebral tumors, trauma, infection or fever, metabolic disturbances, anoxia, and degenerative diseases. Developmental abnormalities, such as cortical dysgenesis (abnormal development of the cerebral cortex), are common causes of childhood-onset epilepsy.[43–45]

A number of other variables affect seizure frequency and intensity. Fatigue and sleep deprivation may lower the seizure threshold.[46] Emotional and physical stresses correlate with seizure onset but are difficult to quantify. Many women who keep records of seizure activity discover that they are cyclic, occurring more frequently or increasing in severity during menstruation, pregnancy, or menopause. Alcohol and drug abuse as well as electrolyte disturbances cause seizures and may provoke epileptic seizures.[43,45] Many medications have the effect of lowering seizure threshold, although most patients with controlled epilepsy on medications are not affected. Patients keeping a diary of seizure activity, warning signs, and any precipitating factors, such as sleep deprivation or emotional upset, may potentially lead to effective preventive treatment.[46]

Common causes of new-onset status epilepticus are cerebrovascular disease, brain tumors, intracranial infections, fevers, head trauma, and metabolic disorders. Status epilepticus is also associated with drug withdrawal, metabolic disturbances, or concurrent illness in patients with known epilepsy.[43,45]

Epidemiology

Approximately 1% to 3% of the population has a diagnosis of epilepsy.[45] Infants and young children are most likely to experience seizures, followed by elderly people.[43,45] Populations in developing countries are at greater risk for seizures or epilepsy, probably because of compromised hygiene, poor nutrition, increased risk for infection, and the high percentage of children. Single seizures are much less common than epileptic seizures (epilepsy or seizure disorder) (20 per 100,000 versus 50 per 100,000, respectively). Five percent of patients who develop epilepsy present with status epilepticus. Of epileptic seizures, partial seizures account for approximately 57%, and generalized seizures account for 40%. Medical treatment completely controls seizures in approximately 70% of patients.

Pathophysiology

Nerve cells (neurons) in the brain possess an electrical charge that reflects a balance between intracellular and extracellular charged ions. The electrical activity of the neuronal membrane is determined by the flow of ions between these spaces. Ions, such as sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), and chloride (Cl^-), are regulated by receptor channels and flow across the membrane when receptors are activated by voltage changes and neurotransmitter modulation. If the permeability of the cells is altered, their excitability can change, making the neuron more likely to discharge. Hyperexcitability can result in increased random neuronal firing. When this is combined with a certain pattern of neuronal firing (synchronization), epileptogenic properties in the neuron exist.[43,44]

Although it is not known exactly how the mechanisms of abnormal neuronal excitation and synchronization lead to epileptiform activity, continued exploration of cell membrane activity, environmental variables, and pharmacological responses has led to increased understanding and management of epilepsy.

Clinical Manifestations

Clinical features of epilepsy are based on the location of the epileptiform discharge and the type of event.[43–45] Box 35-5 describes specific seizures and resulting clinical characteristics.

Diagnosis

The patient who presents with a seizure is initially evaluated to ascertain the cause of the seizure and establish a diagnosis of epilepsy.[43–45] History taking begins with a description of the event by the patient or witnesses. This description should include the following:

1. What the patient was doing at the time of the seizure
2. Duration of the episode
3. Unusual symptoms or behaviors before the seizure

BOX 35-5 Classification of Seizure Types

1. **Generalized:** involves both hemispheres; loss of consciousness; no local onset in the cerebrum
   a. *Tonic-clonic* (grand-mal)—loss of consciousness; stiffening; forced expiration (cry); rhythmic jerking
   b. *Clonic*—symmetrical, bilateral semirhythmic jerking
   c. *Tonic*—sudden increased tone and forced expiration
   d. *Myoclonic*—sudden, brief body jerks
   e. *Atonic* ("drop attacks")—sudden loss of tone; falls
   f. *Absence* (petit mal)—brief staring, usually without motor involvement
2. **Partial:** involves one hemisphere
   a. *Simple partial seizure*—no change in LOC, jacksonian
      i. Motor—frontal lobe
      ii. Somatosensory—parietal lobe
      iii. Visual—occipital lobe
      iv. May involve: autonomic (eg, respiratory changes, tachycardia, flushing); psychic (eg, déjà vu); cognitive (without change in LOC)
   b. *Complex partial seizures*—altered LOC; with or without automatisms: lip smacking, swallowing, aimless walking, verbalizations
      i. Simple partial followed by change in LOC
      ii. Starts with change in consciousness
      iii. Typically of temporal lobe origin
   c. *Partial with secondary generalization*
      i. Simple partial→ generalization
      ii. Complex partial → generalization
      iii. Simple partial → complex partial → generalization
      iv. Continuous EEG monitoring may be necessary to differentiate from generalized seizures
3. **Unclassified**

4. Specific features, including movements, sensations, sounds, tastes, smells, and incontinence
5. LOC during and after the event
6. Duration and description of symptoms after the seizure
7. Reporting of any similar previous episodes and age of onset

Inquiry should be made about the following:

1. Sleep patterns
2. Alcohol or drug abuse
3. History of illnesses or injuries
4. Family seizure history
5. Other possible variables: menstrual cycle, stress, fevers, metabolic disorders
6. If other seizures have occurred, similarities in symptoms, duration, frequency, and time of day

After the first seizure occurrence, a CT scan or MRI is obtained to assess for a structural lesion. An EEG is obtained to screen for interictal seizure discharges (electrical abnormalities present in between seizures) and to measure cerebral excitability. These techniques can help determine whether the seizures have focal origins or are more generalized. During the EEG, scalp electrodes are placed to measure neuronal membrane activity in the underlying cerebral cortex. Rhythms may be obtained when the patient is both awake and asleep. The EEG localizes the region from which the patient's seizure arises at one time point.[43–45]

If additional information regarding seizure patterns and characteristics is needed, an inpatient hospital stay may be recommended in an epilepsy monitoring unit, as discussed in the following section. Also, continuous EEG monitoring is now being used in the ICU, where it has helped identify subtle seizures in critically ill patients. Because it is not uncommon for these patients (eg, brain injured or comatose patients) to suffer nonconvulsive seizures, use of EEG is becoming more widespread in the ICU.[45,47]

Other diagnostic studies that may be obtained include PET to identify abnormal hypometabolic cortical areas that correlate with the epileptogenic area; SPECT to identify CBF and perfusion differences during and after a seizure; bilateral carotid amobarbital (Amytal) testing to assess speech dominance and memory; fMRI to localize seizure focus and identify its relationship to a structural lesion; and neurocognitive testing to obtain a baseline evaluation.[43,45]

Epilepsy Monitoring Unit

Patients who require more detailed seizure characterization or localization are admitted for video EEG monitoring to an appropriate unit, where scalp electrodes are placed. Video EEG monitoring is continuous and involves audiovisual observations. Monitoring occurs while the patient is awake and asleep. Medication dosages may be slowly reduced or withdrawn during these observations. Because video EEG monitoring captures ictal, postictal, and interictal data, seizures are documented and localized, and the patient's clinical symptoms are observed. Video EEG can often localize seizures for possible epilepsy surgery. It is also very helpful for identifying pseudoseizures and other disorders that are mistaken for epileptic disorders. Neuropsychological and psychiatric evaluations may be part of the assessment, particularly if surgery is being anticipated.[45]

In situations in which localization is not obtained or is questionable, a more invasive approach using surgical electrodes to localize seizure activity may be necessary. Three different types of electrodes can be implanted for intracranial recording.

Depth electrodes are typically placed bilaterally, targeting the hippocampus and other common seizure sites in the amygdala and frontal lobes. Multiple electrodes are placed under local or general anesthesia through twist drill or burr holes for simultaneous recording. The electrode cables exit the skull, and patients have continuous video monitoring over several days in the epilepsy monitoring unit. Hemorrhage, headache, and infection are possible complications. This procedure is most often used to show which regions are involved at seizure onset.[45]

Subdural and epidural electrodes are typically placed unilaterally, under general anesthesia. Strips are placed through burr holes. Grids require a craniotomy and allow for a larger region to be monitored (Fig. 35-7). They are secured to the dura, and the electrode leads exit through an incision for continuous monitoring. Infection, hemorrhage, and mass effect from cerebral edema are possible risks. The bone flap can be replaced at the end of the procedure or after the strips or grids are removed. Intracranial monitoring may be initiated before seizure surgery.[45]

Clinical and Pharmacological Management

In most cases, the patient with epilepsy can be medically treated. Some AEDs are known to be more appropriate for specific classes of seizures. Certain drugs are found most useful in the pediatric patient population. Some AEDs are preferred as monotherapy, and others are more appropriate as adjunctive therapy with

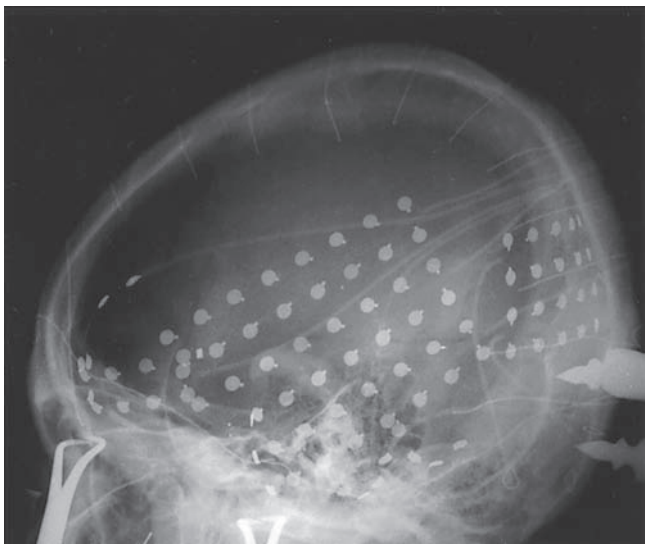

FIGURE 35-7 ▲ Radiograph of a grid for seizure monitoring. (Courtesy of Frederick Lenz, MD, and Ira Garonzik, MD, The Johns Hopkins University, Baltimore, MD.)

other drugs.[43,45] Table 35-10 describes current AEDs with general indications, doses, side effects, and nursing considerations.

Status epilepticus is an emergency situation and requires rapid pharmacological management. Parenteral drugs are given to provide fast absorption. Drugs are given intravenously or intramuscularly. In emergent circumstances benzodiazepines such as diazepam (Valium) may be administered rectally in an emergency in the absence of intravenous access.[48] Many fast-acting drugs are lipid soluble and have a tendency to redistribute from the plasma to the fat and muscle, thereby leading to an initial drop in blood and brain concentrations. This may lead to seizure recurrences. Repeat boluses or a continuous infusion must be administered judiciously because the drugs saturate fat, and muscle and plasma levels will increase. This may result in prolonged decreased mental status, obtundation, and even death. In-hospital mortality of status epilepticus overall is low but may increase significantly in patients with controlled ventilation and other comorbidities such as increased age and hypoxic/ischemic brain injury.[49] Emergency management of status epilepticus is summarized in Box 35-6.

Surgical Management

There are situations in which AEDs are unable to control epilepsy. Attempts at monotherapy and adjunctive therapy have been exhausted and multiple drug regimens have failed; seizure activity has compromised a patient's quality of life. In these cases, seizures are intractable, and surgery is considered to obtain seizure control. It may also be considered in situations in which the side effects of therapy are so debilitating that the patient is unable to function at an acceptable capacity.[43,45]

In many cases, the patient is monitored before surgery in an epilepsy monitoring unit using a video EEG. Surgery for grid or strip placement to localize seizure focus and identify functional areas is often performed. After surgery, the nurse

Table 35-10 Drug Therapy: Antiepileptic Drugs

Drug Name (Brand)	Indications	Daily Adult Dose	Side Effects	Nursing Considerations
Carbamazepine (Tegretol, Tegretol XR, Carbatrol)	Mono/adjunctive therapy Partial and generalized seizures	400–2,000 mg; serum levels of 4–12 mcg/mL	Drowsiness, fatigue, dizziness, blurred vision, rash, hyponatremia, bone marrow dyscrasia	Interactions with other AEDs; rare aplastic anemia, hepatic failure; obtain blood levels
Gabapentin (Neurontin)	Adjunctive Partial and secondary generalized seizures	900–4,800 mg	Sedation, dizziness, weight gain	No significant drug interactions; minimal side effects
Levetiracetam (Keppra)	Adjunctive therapy for partial seizures	1,000–3,000 mg	Somnolence, asthenia, irritability, dizziness, infection	Can be administered IV
Phenobarbital	Mono/adjunctive therapy Partial or generalized (myoclonus/absence)	90–180 mg	Sedation, depression, ataxia, rash, impotence, hyperactivity	Potential CNS toxicity, especially in children; taper slowly
Phenytoin (Dilantin)	Mono/adjunctive therapy Partial and generalized (not absence/myoclonus)	300–600 mg; serum levels of 10–20 mg/L	Ataxia, dizziness, sedation, rash, gingival hyperplasia	Interactions with multiple other drugs; dose guided by blood levels; less expensive
Fosphenytoin	Replacing IV phenytoin	Loading dose 15–20 mg IV or IM; administered 100–150 mg/min		
Valproate (Depakote)	Mono/adjunctive therapy Generalized seizures; childhood epilepsy; febrile convulsions	1,000–3,000 mg	Nausea, weight gain, endocrine, thrombocytopenia, hair loss	Interactions with other AEDs; can be administered IV

BOX 35-6 Emergency Treatment of Status Epilepticus

- **Goals:** maintain airway, breathing, circulation; stop seizures; stabilize patient; identify and treat cause
- **Treatment:** airway; O_2; intubation, if necessary; EEG monitoring; monitor ECG and BP; catheter for incontinence; CT scan; lumbar puncture if CNS infection is suspected; CPR if needed
- **Blood work:** electrolytes; magnesium; calcium; anticonvulsant levels; blood gases; complete blood count; renal and liver function studies; coagulation studies; toxicology studies may be needed
- **Medications:**
  - Benzodiazepines (lorazepam, 1 to 2 mg/min as a starting dose over 8 minutes or diazepam to total of 20 mg). These are short-acting drugs, and simultaneous loading with phenytoin at 50 mg/min or fosphenytoin at equivalent of 150 mg phenytoin/min is necessary; may total 20 mg/kg
  - For persistent seizures, add 5 to 10 mg/kg phenytoin *or* phenobarbital at 50 to 100 mg/min to total of 20 mg/kg
  - If ineffective, barbiturate anesthesia: pentobarbital and intubation. Benzodiazepines (eg, midazolam) may be attempted prior to barbiturate anesthesia. Continuous EEG monitoring in ICU environment.

performs regular, intermittent neurological examinations and has the patient attempt to perform certain tasks. Language deficits and motor weakness are observed. The goals of this procedure are to localize epileptiform discharges in relation to speech, memory, and sensory or motor function. It is also useful in identifying the relationship between seizure discharges and a focal lesion, such as a tumor, when present. This enhances the safety and accuracy of tumor surgery.[45]

The decision to proceed with surgery depends on a thorough discussion among the multidisciplinary team members. The neurologist, neurosurgeon, patient, and family review the medical treatment used to date and establish that therapy has been maximized. They evaluate the likelihood of seizure control with surgery. Preoperative neuropsychological testing is obtained, and other appropriate testing is established and discussed. Some or all of the diagnostic studies previously outlined may be indicated.

The goal of seizure surgery is to remove or disrupt the seizure focus. Patients are often maintained on AEDs for 2 years postoperatively because seizure recurrence is most likely during this period. Table 35-11 summarizes the most commonly performed surgical procedures, along with expected outcomes, possible complications, and nursing considerations.

Nursing Management

ASSESSMENT. Careful history taking is a central component of the accurate diagnosis and management of epilepsy. Family history, age at onset, frequency, and a description of symptoms and their duration all aid in the development of a plan of care tailored to the patient's particular situation. AEDs are prescribed based on all these data. Changes in severity or frequency of symptoms require modification of the treatment regimen. Drug therapy may last indefinitely; therefore, treatment should address both efficacy and tolerability. Side effects can compromise quality of life, necessitating the use of different, and possibly less effective, medications or multiple AEDs.[45]

PLAN. Inpatient nursing care includes monitoring the patient during the seizure (the patient is never left alone) and providing support and protection without attempting to restrain the individual. Turning the patient to his or her side during a generalized seizure, if possible, helps maintain a patent airway.

Patient Education and Discharge Planning

Patient education should provide instructions for independent functioning. The following patient education points are critical parts of discharge planning:

1. Make the home environment safe, particularly in the case of tonic-clonic epilepsy.
2. Assess for injury after each seizure.
3. Keep a log to record a description of the seizure and postictal period, duration, time of day, severity, and any new characteristics.
4. Know the specifics of a ketogenic (high-fat, low-carbohydrate) diet, when appropriate, for children with intractable seizures.
5. Be aware of state laws on driving restrictions related to epilepsy.
6. Wear a medical identification bracelet.
7. Monitor serum AED levels when appropriate.
8. Be aware of circumstances when emergency treatment is required.
9. Consult seizure experts for intractable epilepsy.

Guillain-Barré Syndrome

Guillain-Barré syndrome, also known as acute inflammatory demyelinating polyneuropathy, is a rapidly evolving illness that commonly presents as symmetrical weakness, sensory loss, and areflexia. This condition is an inflammatory peripheral neuropathy in which lymphocytes and macrophages strip myelin from axons. The diffuse inflammatory reaction may be seen in the peripheral nervous system, cranial nerves, and spinal nerve roots. It is referred to as a syndrome, as opposed to a disease, because of the combination of signs and symptoms seen in the patient.[50,51]

Etiology

Guillain-Barré syndrome is an immune-mediated neuropathy that is associated with a broad range of symptoms, severity, and length of progression. This disorder follows an antecedent infection in some patients.[50–53] Approximately half of the people in whom Guillain-Barré syndrome develops have a mild febrile illness 2 to 3 weeks before the onset of symptoms. The febrile infection is usually respiratory or GI. *Campylobacter jejuni* and cytomegalovirus are causes of the most frequent antecedent infections, which usually occur 1 to 4 weeks before the onset of symptoms of Guillain-Barré syndrome.[50–53] Some studies show a potential association between vaccinations and increased risk of Guillain-Barré syndrome.[51,52] Although previously administered vaccinations, including H1N1 and rabies vaccines, have been linked to the development of Guillain-Barré syndrome,[51,52] a strong causal relationship has not been demonstrated. Currently, no recent vaccine has been conclusively demonstrated to induce the disease.

The attack on the immune system is extensive and occurs proximally at the nerve roots and distally at the motor axon terminal. Both cellular and humoral immune mechanisms appear to be implicated. Lymphocytes and macrophages are the effector

Table 35-11 Clinical Applications of Seizure Surgery

Procedure	Indications	Expected Outcomes	Possible Complications	Nursing Considerations
Temporal lobectomy: removal of 6 cm of temporal lobe in the nondominant hemisphere and 4–5 cm in the dominant hemisphere	Intractable anterior temporal lobe seizures >5 y' duration Significant quality-of-life compromise	60%–70% seizure free 20% greatly improved seizure control	Visual (superior quadrantanopsia) field defects Dysphasia (usually temporary) Mild memory problems Depression Transient psychiatric disturbance Infection and/or bleeding	At 1 y postoperatively, it is expected that seizure status will not change Medication management continues for 2–3 y postoperatively
Hemispherectomy: surgical removal (or disconnection) of a hemisphere in children and adolescents	Severe seizures Often multiple seizure types and daily seizures	90%–95% improvement in seizure activity 70%–85% resolution of seizures	Contralateral neurological deficits Late hydrocephalus Chronic bleeding into surgical cavity would produce increased morbidity re: hematoma formation, infection risk, ICP elevation. → neurological disability and death	Careful patient selection required May see improved behavior and social development
Corpus callosectomy: transection of the corpus callosum (or anterior two thirds)	Cases of severe secondarily generalized epilepsy; drop attacks	Reduces number of generalized seizures Seizure-free periods usually temporary and occur in only 5%–10% of patients	Hemiparesis Transient syndrome of mutism, urinary incontinence, and bilateral leg weakness	Used when other options have failed Many patients have learning disabilities Wada test recommended for left-handed patients
Vagal nerve stimulator: implanted programmable signal generator in the chest with stimulating electrodes to the left vagus nerve	Refractory to medication Often partial seizures	Reduction in seizure frequency: high stimulation 25%; low stimulation 15%	Changes in voice Dyspnea Tingling in neck during stimulation Rare cases of bradycardia or asystole	Does not generally resolve seizures Used when resective surgery is not an option
Deep brain stimulator: Electrodes placed in deep brain structures (thalamus, hippocampus, internal capsule) and programmed to activate when seizure activity is recorded	Uncontrolled epilepsy	Reduction in seizures	Bleeding Infection Neurological deficits	Has been used for tremor in Parkinson's disease Relatively new use in refractory seizures with unknown long-term outcomes

cells that result in damage to myelin and adjacent axons. Motor, sensory, and autonomic nerves are involved. Weakness and sensory disturbances result from blockage of nerve fiber action potentials (secondary to demyelination or axon damage).[50–53]

In affected patients, the immune system most likely is first primed as it responds to a virus or bacteria. Then, the immune system inappropriately attacks host tissue that shares an epitope (surface portion of an antigen capable of triggering an immune response). This process is referred to as molecular mimicry.[51,52]

Epidemiology

Guillain-Barré syndrome occurs with equal frequency in both sexes and all races. It can develop at any age. The annual incidence is approximately 1 to 3 cases per 100,000 population in the United States.[50]

Pathophysiology

In Guillain-Barré syndrome, the myelin sheath surrounding the axon is lost. The myelin sheath is quite susceptible to injury by many agents and conditions, including physical trauma, hypoxemia, toxic chemicals, vascular insufficiency, and immunological reactions. Demyelination is a common response of neural tissue to any of these adverse conditions.[50–53]

Myelinated axons conduct nerve impulses more rapidly than nonmyelinated axons. Along the course of a myelinated fiber are interruptions in the sheath (nodes of Ranvier), where there is direct contact between the cell membrane of the axon and the extracellular fluid. The membrane is highly permeable at these nodes, resulting in especially good conduction. The movement of ions into and out of the axon

can occur rapidly only at the nodes of Ranvier; therefore, a nerve impulse along a myelinated fiber may jump from node to node (known as saltatory conduction) quite rapidly. Loss of the myelin sheath makes saltatory conduction impossible, and nerve impulse transmission is aborted.[51–53]

A current theory regarding the disease process of Guillain-Barré syndrome speculates that a primary lymphocytic T-cell mechanism is the cause of the inflammation. Cells migrate through the vessel walls to the peripheral nerve. The result is edema and perivascular inflammation. Macrophages then break down the myelin.[51] A potential secondary process is that demyelination is initiated by an antibody attack on the myelin early in the course of the disease. Demyelination causes axon atrophy, which results in slowed or blocked nerve conduction.[52]

Clinical Manifestations

Guillain-Barré syndrome may develop rapidly over the course of hours or days, or it may take up to 3 to 4 weeks to develop. Most patients demonstrate the greatest weakness in the first weeks of the disorder and are weakest by the third week of the illness.[50–53]

In the beginning, a flaccid, ascending paralysis develops quickly. The patient is most commonly affected in a symmetrical pattern. The patient may first notice weakness in the lower extremities that may quickly extend to include weakness and abnormal sensations in the arms. Deep tendon reflexes are usually lost, even in the earliest stages. The trunk and cranial nerves may become involved. Respiratory muscles can become affected, resulting in respiratory compromise.[50–53] Autonomic disturbances such as urinary retention and orthostatic hypotension may also occur. Some patients experience tenderness and pain on deep pressure or movement of some muscles.[50–53]

Sensory symptoms of paresthesias, including numbness and tingling, may occur. Pain is a complaint in many patients. It is aching in nature and often compared with the feeling of muscles that have been overexerted. If there is cranial nerve involvement, cranial nerve VII, the facial nerve, is most often affected. Guillain-Barré syndrome does not affect LOC, pupillary function, or cognitive functioning.[50–53]

Symptoms may progress for several weeks. The level of paralysis may stop at any point. Progression usually occurs in three stages: acute, plateau, and recovery. The acute stage starts at the onset of symptoms and rapidly progresses until no additional deterioration occurs. The plateau stage, during which patients are symptomatic, lasts for a few days up to a few weeks. The recovery phase can take up to 2 years. It is thought that the recovery phase coincides with remyelination and axonal regeneration. Although demyelination occurs rapidly, the rate of remyelination is approximately 1 to 2 mm/d. Motor function returns in a descending fashion.[50–53]

Diagnosis

The diagnosis of Guillain-Barré syndrome depends greatly on the patient's history and clinical progression of symptoms. As noted, onset is usually sudden, and the history often reveals an upper respiratory or GI disorder occurring 1 to 4 weeks before onset of the neurological manifestations. The history of the onset of symptoms can be revealing because symptoms of Guillain-Barré syndrome usually begin with weakness or paresthesias of the lower extremities and ascend in a symmetrical pattern.[50–53]

A lumbar puncture may be performed and reveals increased protein. However, negative results from this test should be interpreted cautiously because only 50% of patients in the first week of illness have increased protein. By 3 weeks, this percentage increases to greater than 90%. Also, nerve conduction studies record impulse transmission along the nerve fiber. In the patient with Guillain-Barré syndrome, the velocity of conduction is reduced.[50–53]

Pulmonary function tests are performed when Guillain-Barré syndrome is suspected to establish a baseline for comparison as the disease progresses. Declining pulmonary function capacity may indicate the need for mechanical ventilation and management in an ICU.[50–53] Severe respiratory failure consequent to Guillian-Barré syndrome requiring mechanical ventilation is a predictor of mortality in the hospitalized patient. Additional predictors of mortality include comorbid states, cardiovascular complications, sepsis, and advanced age.[54]

Clinical Management

Because of the risks associated with respiratory failure, bulbar symptoms, and autonomic dysfunction, all patients with Guillain-Barré syndrome, except those with mild disease, should be admitted to a hospital that has specialized ICUs. Progression to mechanical ventilation is expected in patients with rapid disease progression, bulbar involvement, bilateral facial weakness, or dysautonomia. ICU admission is recommended for patients with vital capacity below 20 mL/kg, vital capacity checks that are required more than every 4 hours, aspiration, autonomic instability, or rapid progression or weakness.[50–53] Patients who are older, have rapid progression or prior GI infection, or are ventilator dependent, tend to have a poor prognosis and need to be monitored closely.[54]

Certain strategies can lessen the severity of the illness and hasten recovery. A useful clinical sign of respiratory compromise is the strength of the neck flexor muscles. When the head cannot be lifted against gravity, the phrenic nerves are also affected, causing diaphragm paralysis and reduction of the forced vital capacity (FVC)—the amount of air a patient can forcefully exhale after maximal inhalation. Under these circumstances, the airway cannot be successfully managed without intubation.

Preventive measures need to be established so that DVT and subsequent PE do not develop. DVT prophylaxis includes subcutaneous heparin, 5,000 units twice daily, along with antiembolism stockings and sequential compression devices. Also, autonomic nervous system fluctuations need to be evaluated by checking BP and monitoring for cardiac dysrhythmias.[51–53]

Plasmapheresis was the first therapy proved to benefit patients with Guillain-Barré syndrome. It is the only therapy that has been proved superior to supportive treatment alone. This procedure mechanically removes humoral factors. Currently, it is recommended that patients with Guillain-Barré syndrome receive plasmapheresis. A dual-lumen central vascular access device and a specially skilled team are needed to perform the plasmapheresis treatments. The physician may order plasmapheresis when the patient's

condition is worsening in an attempt to reduce the severity of the disease.[50–53] Of note, two prominent risks associated with plasmapheresis are catheter-related infections and hemorrhage during catheter placement.

Intravenous immunoglobulin (IVIG) is also useful in managing Guillain-Barré syndrome. A blood product that has been derived from large pools of plasma donors, IVIG has the potential to bind many common pathogens and modulate a wide range of effectors in autoimmune disease, such as Guillain-Barré syndrome. The major component is immunoglobulin G, with a trace amount of immunoglobulin A. Immunoglobulins can be infused easily, even in the home setting, without expensive equipment. The optimal dosages and frequency of administration are individualized. Immunoglobulin, which binds to receptors on T cells or receptors on nerves, induces only a temporary improvement because of the turnover of T cells or the loss of antibodies from the receptors. Daily treatments with IVIG may be helpful in acute Guillain-Barré syndrome when the patient is rapidly deteriorating.[51–53]

The dose of IVIG is set at 2 g/kg, and usually the total dose is divided into five daily infusions of 400 mg/kg each. Neurologists who use IVIG for Guillain-Barré syndrome are familiar with the side effects, which include low-grade fever, chills, myalgia, diaphoresis, fluid overload, hypertension, nausea, vomiting, rash, headaches, aseptic meningitis, and neutropenia.[52,53] The most serious adverse effect is acute tubular necrosis, which occurs with any concomitant disease that compromises renal glomerular filtration.

Currently, there are no efficacy data that favor IVIG rather than plasmapheresis in managing Guillain-Barré syndrome. IVIG and plasma exchange have a similar ability to speed a patient's recovery. The individual patient's circumstances, such as availability of resources to perform plasmapheresis and underlying medical conditions, dictate the specific treatment for each patient. IVIG is an attractive treatment because it can be easily administered in the critical care setting.[52,53]

Nursing Management

ASSESSMENT. For the patient with Guillain-Barré syndrome, careful assessment and the resultant plan help minimize the complications of immobility and move the patient toward rehabilitation without deficits. Although patients are critically ill, their chances of returning to a productive life are good if they survive the acute stages and avoid the complications of immobility. Most deaths are due to preventable respiratory complications or autonomic dysfunction.

Once Guillain-Barré syndrome is suspected, the patient is hospitalized so that frequent assessments can be performed to monitor the patient for deterioration. Because of the progressive nature of the disease, assessment should focus on the neurological examination (ie, cranial nerve involvement, motor weakness, and sensory changes). Cranial nerve deficits identify if the patient is at risk for aspiration. The patient's level of numbness, tingling, and pain should be assessed.[50]

Cardiovascular assessment is done to monitor BP and heart rate. The autonomic nervous system is frequently involved in Guillain-Barré syndrome. Dysautonomia manifests itself as sinus tachycardia but may result in other cardiac dysrhythmias or labile BPs that require close monitoring because they may be life threatening. The patient's respiratory status should be monitored, and FVC should be assessed at least once every shift. GI and urinary function should come under surveillance as well. The patient is at risk for constipation and urinary tract infections resulting from urinary retention. Other complications of immobility are the potential for pressure ulcers and DVT.[50–53]

PLAN. When caring for a patient with Guillain-Barré syndrome, the major goals are to prevent infections and complications of immobility, provide functional maintenance of the body systems, treat life-threatening crises promptly, and provide psychological support for the patient and family. In terms of the patient's neurological status, weakness results in impaired mobility. Range-of-motion exercises should be performed at least once per shift to minimize the patient's risk for contractures.[50] Families are encouraged to help with this beside therapy.

Also, steps are taken to maintain proper body alignment. Measures such as splint placement are implemented to prevent wrist hyperflexion and footdrop.[50,53] Physical therapy is initiated early in the course of hospitalization and continued throughout the recovery period.

Cranial nerve involvement places the patient at risk for aspiration, and adequate nutrition must be maintained. If the patient is unable to take oral feedings, enteral tube feedings are initiated. A nutritional consultation with a registered dietitian should occur to provide adequate calories for remyelination as well as rehabilitation activities. Enteral nutritional support that supplies at least 1,500 to 2,000 kcal/d should be instituted if the patient is unable to receive food by mouth.[50–53]

Additionally, because of intubation or impaired verbal communication, alternate methods to facilitate communication are important. Alternate ways to communicate are established using communication boards as well as nonverbal means such as gestures and eye blinking. Inability to communicate can be frustrating for the patient and cause undue anxiety.

Respiratory failure is the most severe complication of Guillain-Barré syndrome. Weakened respiratory muscles put the patient at great risk for hypoventilation and repeated pulmonary infections. Fifty percent of patients with Guillain-Barré syndrome have some respiratory compromise, resulting in reduced tidal volume and vital capacity or perhaps complete respiratory arrest. A tracheostomy may be indicated if the patient requires long-term mechanical ventilation.[50]

If there is autonomic nervous system involvement, drastic changes in BP (hypotension or hypertension), heart rate, or both can occur. Labile hypertension and dysrhythmias occur frequently, prompting admission and management in the ICU. Cardiac monitoring allows quick identification and treatment of dysrhythmias. Because Valsalva maneuver, coughing, and suctioning may trigger an autonomic nervous system disturbance, the patient needs to be monitored closely.[50–53]

Comfort measures, such as frequent position changes, may be helpful. When remyelination occurs, it is often uncomfortable, and the patient may complain of numbness and pain. This can be an encouraging sign to the patient because the disease process is reversing.

Although the patient is incapacitated physically, he or she is fully aware of the surroundings. The patient may experience

a sense of fear, loss of control, as well as helplessness and hopelessness. Frequent explanations of the interventions and of progress are useful.[50] The patient should be allowed to participate in care as much as functionally possible. It is essential that the nurse in the critical care setting provide empathy, compassion, sensitivity, and active listening to the patient with Guillain-Barré syndrome so that his or her emotional concerns can be addressed. In addition, the nurse can provide positive reinforcement for achievement of physical gains.[50]

Patient Education and Discharge Planning

Education of the patient and family about all issues of care is important. Knowledge is power and is helpful in a situation in which the patient is powerless. The nurse can provide information about the disease process, course, and recovery.[50] Patients need to know that the disease may progress to the point at which mechanical ventilation is required. In addition, they should understand that they may be discharged to a rehabilitation facility where recovery can continue. Many months of rehabilitation may be required for them to regain strength and previous level of functioning. Patients may continue to show improvement for up to 2 years. The nurse can tell patients and their families about the Guillain-Barré Syndrome International Foundation, which provides information and resources. Before discharge to home, the patient can be referred to a support group so that he or she can interact with other people who have had Guillain-Barré syndrome.[50]

Myasthenia Gravis

Myasthenia gravis is an autoimmune disorder of the neuromuscular junction transmission that presents with fatigue and muscle weakness in the ocular, bulbar, diaphragm, or limb muscles. Myasthenia is derived from the Greek words for "muscle" and "weakness," whereas gravis means "grave" in Latin. Because of the high mortality related to diaphragmatic muscle weakness, the disorder was called "grave muscle weakness."[1] However, myasthenia gravis is not a grave disease today because of advancements with immunomodulatory treatments and the ability to manage respiratory failure.

Etiology

Myasthenia gravis is an autoimmune disorder characterized by weakness and fatigability of skeletal muscles. The disease involves a reduction in the number of acetylcholine receptors (AChRs) at the neuromuscular junction caused by antibodies against the AChR.[55–57] The factors that trigger the autoimmune process are not known, but the thymus gland plays an important role. The thymus gland lies behind the sternum and may extend down to the diaphragm and up to the neck. This gland plays a role in the responsiveness of T cells to foreign antigens. The thymus gland is large in children and small in adults. By adulthood, the gland has shrunken and has nearly been replaced by fat. Abnormalities in the thymus gland occur in approximately 75% of patients with myasthenia gravis. Eighty-five percent of patients with myasthenia gravis have thymic hyperplasia, and approximately 15% have tumor (thymoma) of the thymus gland.[55]

Epidemiology

Myasthenia gravis is seen more often in women than in men at a ratio of 3:2. It is primarily a disease of young women and older men. Symptoms most commonly appear in the third decade of life, although any age group may be affected.[55] Myasthenia gravis is uncommon with an estimated annual incidence of 2 cases per 100,000 population.[56] During the past 40 years, prevalence has increased because of improved recognition of the disorder, medical management, and survival. Myasthenia gravis is not hereditary in the Mendelian sense; however, there may be a history of autoimmune disorders in the family, including thyroid disorders or lupus. It should be remembered that approximately 10% of women with myasthenia gravis may transmit a transient type of neonatal myasthenia to the infant that resolves within days after birth.

Pathophysiology

Myasthenia gravis is a result of circulating antibodies directed toward the AChRs in the skeletal muscle.[55–57] The AChR is a protein composed of five subunits situated in a specialized surface of the muscle membrane termed the end plate. When acetylcholine is released from the nerve after depolarization, it binds to the AChR and causes the ion channel to open. This passage of ions moving through the channel leads to depolarization of the end plate, action potential generation, and subsequent muscle fiber contraction. With this process, the depolarization of the end plate is three to four times greater than what is required for action potential generation. Therefore, fluctuations in end plate depolarization do not affect action potential generation or the overall strength of muscle contraction.[56]

The AChR antibodies in myasthenia gravis lead to the loss of AChRs by increased internalization of the receptor and complement-based lysis of the muscle membrane. Compromise of ion flow through AChR occurs, leading to a decrease in end plate depolarization, which may be insufficient to generate an action potential. This results in a failure of the muscle to contract. Often, at rest, the compromise of neuromuscular transmission is mild, and action potentials are still generated. However, with exercise or with repetitive nerve stimulation, the end plate potential is further reduced, the action potential is not generated, and muscle weakness occurs. In summary, antibodies attack the AChRs of the neuromuscular junction, thereby blocking the transmission of nerve impulses to muscle.[55–57]

Clinical Manifestations

Myasthenia gravis can be characterized as ocular myasthenia or generalized myasthenia, depending on whether the symptoms are limited to the eye muscles or are spread elsewhere. In ocular myasthenia, patients may present with problems such as droopy eyelids or double vision. More than 90% of patients have ocular symptoms. In only 16% of the patients, the symptoms remain confined to the eye muscles. In the rest, the symptoms spread to other

muscles (bulbar, limb, diaphragm) within a year of the onset of eye symptoms.[55,56]

In generalized myasthenia gravis, patients may demonstrate ocular manifestations as well as bulbar symptoms, presenting as difficulty with chewing, swallowing, talking, and handling secretions, and neck weakness. The voice may have a nasal quality. Prolonged talking brings on slurred speech. Weakness of jaw closure (masseter muscle) may lead to the jaw hanging open. Muscle weakness in the limbs is also apparent and can vary among patients. Patients often demonstrate more proximal than distal weakness. They often report increased weakness with sustained activity and improvement with rest. Patients may also demonstrate respiratory compromise due to weakness of the respiratory muscles. The most serious potential complication of myasthenia gravis is respiratory failure (myasthenic crisis) secondary to intercostal and diaphragmatic muscle weakness.[55,56] Respiratory failure may result in death. With earlier diagnosis and intervention for patients with myasthenia gravis, in-hospital mortality is low. Respiratory failure consequent to myasthenia gravis as well as advanced age are predictors of increased mortality.[58]

Diagnosis

Similar to other neurological disorders, the patient's history along with other diagnostic tests aids in an accurate diagnosis. Patients may present with complaints of double vision or drooping eyelids. Also, myasthenia gravis causes weakness of the shoulder girdle muscles. Therefore, the patient may complain of the inability to perform a variety of self-care activities, such as drying the hair with a blow dryer.

The neurological examination is also valuable in making the diagnosis. The cranial nerve examination may reveal ptosis and diplopia as well as other cranial nerve involvement. Motor weakness may be exhibited.[55,56] In addition, laboratory studies are obtained. Blood is drawn for AChR antibodies, which are present in 74% of patients.[56]

Repetitive nerve conduction study during electromyography (EMG) is helpful in the diagnosis of myasthenia gravis. In EMG, a needle electrode is inserted into a skeletal muscle, and a recording of the electrical activity at rest, during voluntary activity, and with electrical stimulation is displayed on an oscilloscope. The patient should be informed that the needle causes some discomfort. In myasthenia gravis, the loss of functional AChRs results in a decrease in action potential size with repeated stimulation. Repetitive muscle stimulation produces a rapid decline in muscle action potential because of the deficient numbers of AChRs. Single-fiber EMG is a very sensitive test to assess the functioning of neuromuscular junction transmission.[55,56,59]

The Tensilon, or edrophonium, test is a classic diagnostic tool for confirming a diagnosis of myasthenia gravis. A positive test result lends strong support for the diagnosis of myasthenia gravis. In this test, 10 mg of IV Tensilon, a short-acting anticholinesterase agent, is given over approximately 1 minute. When injected, it transiently inhibits the breakdown of acetylcholine at the neuromuscular junction. A response is anticipated within 2 to 3 minutes. The test is most useful if there is improvement of ptosis or strength of the extraocular muscles. Limb strength or improved bulbar function may be difficult to interpret. When Tensilon is administered, atropine should be readily available in the event that the patient develops bradycardia. Because there have been reports of ventricular tachycardia and death as well, Tensilon should be administered in a monitored setting.[55,56]

A CT scan or MRI of the chest may also be performed to rule out thymoma or thymal hyperplasia. As noted earlier, patients with myasthenia gravis may have thymic tumors and should be screened. Thyroid function tests and vitamin B_{12} levels should also be checked, along with antinuclear antibodies, parietal cell antibodies, and antimicrosomal antibodies.[55,56]

Clinical Management

The clinical management of myasthenia gravis includes the following strategies: use of medications to enhance neuromuscular transmission; long-term immunosuppression with corticosteroids, mycophenolate mofetil (CellCept), azathioprine (Imuran), or cyclosporine; cyclophosphamide (Cytoxan); short-term immunomodulation with plasmapheresis or IVIG; or thymectomy.[55,56,60]

Pharmacological Management

Pharmacological management includes the use of anticholinesterases, steroids, or other immunosuppressive drugs. Pyridostigmine (Mestinon) is available in three formulations: liquid, a 60-mg tablet, or a 180-mg time-span formula. If the patient is unable to swallow the tablet or has a nasogastric tube or percutaneous endoscopic gastrostomy, the 60-mg tablet may be crushed, or the liquid form of pyridostigmine may be used. This drug inhibits the enzymatic elimination of acetylcholine, thus prolonging its action at the postsynaptic membrane and enhancing neuromuscular transmission. As a result of this action, more acetylcholine is available at the neuromuscular junction, and the patient has improved muscle strength. Medication onset of action is 30 minutes after administration, peaks in 1 hour, and lasts for 3 to 4 hours.[55,56]

Pyridostigmine should always be administered promptly as prescribed. It should be given every 3 to 4 hours when the patient is awake. If there is difficulty with chewing and swallowing, timing the medication 30 minutes before meals is helpful. The 180-mg time-span tablet is administered at bedtime and should never be crushed. Because the medication is given at night, the patient will have the benefit of sleep. Muscarinic side effects include diarrhea, abdominal cramping, increased salivation, blurred vision, bradycardia, and increased perspiration. Nicotinic side effects include muscle twitching, weakness, and fatigue.[55,56]

If the patient cannot take oral pyridostigmine because of fasting, or NPO status, or intubation, a comparable approach is to use IV neostigmine. IV neostigmine bromide 1 mg is equivalent to pyridostigmine 60 mg. Neostigmine can be infused as a continuous infusion, and care should be taken to ensure the patency of the IV access. Cardiac monitoring is essential.[55,56]

Steroids and other immunosuppressive medications may be used with pyridostigmine in managing myasthenia gravis.[55,56] A summary of the mechanism of action, onset of immunosuppression, usual dosage, and nursing considerations can be found in Table 35-12.

The patient should not receive some medications. For example, D-penicillamine is contraindicated in patients with myasthenia gravis. Other drugs, including some antibiotics, can cause an increase in myasthenic weakness (Box 35-7).[56] Both patients and health care professionals need to be

Table 35-12 Immunosuppressive Drugs for the Treatment of Myasthenia Gravis

Drug Mechanism of Action	Onset of Immunosuppression	Dose	Adverse Effects	Considerations and Patient Teaching
Corticosteroid (Prednisone):reduces amount of antibodies produced, blocks immune mechanism, and restores chemical reaction at neuromuscular junction	3 wk	60 mg daily	Steroid-induced diabetes Osteoporosis Weight gain Fluid retention Hirsutism Moon facies Insomnia Mood changes Gastric ulcers Susceptibility to infection	Starting with high dose may increase motor weakness temporarily
Azathioprine (Imuran):reduces the level of circulating acetylcholine receptor (AChR) antibodies	3–6 mo Maximal improvement in 36 mo	2–3 mg/kg/d	Bone marrow depression Increased risk for carcinoma Hepatotoxicity	Should be taken with food Pregnancy precautions Nurse to follow safe handling of hazardous drugs
Mycophenolate mofetil (CellCept):inhibition of purine synthesis by the *de novo* pathway	3–6 mo	1 g twice daily	Neutropenia; anemia; thrombocytopenia; leukopenia GI hemorrhage/perforation	Cautious use in digestive system disorders
Cyclosporine: suppresses T-cell function that decreases circulating AChR antibodies	4 wk	2–3 mg/kg/d; after morning and evening meals	Hypertension Nephrotoxicity	Traditionally used to provide immunosuppression after organ transplantation More costly than azathioprine
Cyclophosphamide (Cytoxan):chemotherapeutic agent; potent immunosuppressant	4 wk	2–3 mg/kg/d	Hair loss Hemorrhagic cystitis Bone marrow suppression Jaundice Kidney failure	Chemotherapy administration protocol to be followed Nurses to follow safe handling principles Education about reproductive risks

cognizant of these medications. Although physicians and nurses working in the neuroscience arena are often familiar with these drugs, patients may face potential difficulties in settings, such as the emergency department or surgery, where health care professionals do not encounter patients with myasthenia gravis on a regular basis and may not be familiar with these medications.[56]

Plasmapheresis

Plasmapheresis may be indicated for patients in crisis or who are otherwise refractory to treatment. Plasmapheresis is initiated to remove circulating anti-AChR antibodies from the plasma, which results in clinical improvement. This procedure is performed through a dual-lumen central vascular access device, which is similar to a dialysis catheter. A specialized team of nurses, trained in plasmapheresis, performs the treatment, usually three times a week, while the patient is an inpatient.[55,56] Treatments may continue on an outpatient basis. The patient's circulating blood volume is removed through one of the lumens, filtered, and then returned through the second lumen. The patient's plasma is removed and albumin is returned, along with the solid components of the patient's blood. The procedure takes several hours, and

BOX 35.7 PATIENT SAFETY

Medications to Avoid in Myasthenia Gravis

Antibiotics
Aminoglycosides, "mycins," tetracycline, polymyxin B and E, colistin

Antiepileptic Drugs
Phenytoin, mephenytoin, trimethadione

Cardiovascular Medications
Quinidine, procainamide, beta-blockers

Psychotropic Drugs
Lithium carbonate, phenothiazines

Muscle Relaxants
Curare, succinylcholine

Others
Magnesium preparations, quinine, D-penicillamine, chloroquine

Data from Shah AK: Myasthenia gravis. Updated January 15, 2009; accessed June 15, 2010 from: http://emedicine.medscape.com/article/1171206-print; Arbour, R. Mastering neuromuscular blockade. Dimens Crit Care Nurs 19(5):4–18, 2000.

the patient is monitored for hypotension. Electrolytes and clotting factors are evaluated after each treatment.

The catheters must be managed appropriately because they are a potential source of infection. They can pose a special challenge because the patient with myasthenia gravis may be receiving steroids or other immunosuppressive therapy. The nurse must also be aware that plasmapheresis removes medications, including pyridostigmine, which the patient has taken. The nurse must obtain an order from the physician to withhold the medication.

Intravenous Immunoglobulin

Another treatment in place of plasma exchange is IVIG. It is used either for acute disease management or as a long-term treatment for patients with myasthenia gravis who do not respond to other types of treatments. It is often used before thymectomy to stabilize the patient. The patient's dose is individualized. Patients may exhibit clinical improvement in 2 to 4 days, and it may last for varying intervals. The mechanism of action of IVIG is unknown. The patient needs to be monitored for fever and chills, leukopenia, headache, fluid overload, and renal failure.[55,56]

Thymectomy

Thymectomy is a standard treatment for patients younger than 52 years with generalized myasthenia gravis. This surgical procedure promotes sustained remission and improvement, although no controlled studies have been performed. However, the fall in antibody titers after surgery supports the use of thymectomy. Patients must be aware that this procedure is performed for its long-term benefit so that they do not expect a dramatic improvement immediately after surgery. Clinical improvement may not be realized for 6 to 12 months after thymectomy. In some cases, benefit may not be seen for several years.[55,56] Patients may demonstrate enough improvement so that their medications may be reduced, thereby reducing adverse effects.

Postthymectomy care involves a short stay in the ICU. Epidural analgesia is used to manage pain after the procedure. The patient is usually extubated immediately after the surgery. Intermittent positive-pressure breathing may be used to minimize postoperative respiratory complications. After the critical care stay, patients are transferred to an inpatient setting, where they are monitored for complications. Over the long term, thymectomy is considered more effective than conservative management as measured by rates of remission, overall survival, and clinical improvement.[60]

Management of Myasthenic Versus Cholinergic Crisis

Factors such as stress, respiratory infection, too rapid a steroid taper, or medication affecting the neuromuscular junction may predispose the patient to a crisis. A myasthenic crisis needs to be differentiated from a cholinergic crisis because the management of each is different.[55]

A myasthenic crisis is characterized by respiratory failure along with sudden exacerbation of weakness in other muscle groups. It is usually caused by lack of medication or lack of responsiveness at the neuromuscular junction to cholinergic treatment, as well as a worsening of the disease process. The patient is unresponsive to an increase in anticholinesterase medications and can experience severe weakness, dysphagia, and respiratory compromise. Frequent FVC checks should be performed, and when FVC falls below 15 mL/kg, the patient should be intubated. Any patient with myasthenia gravis with uncertain respiratory status should be admitted to an ICU to permit close monitoring of FVC, negative inspiratory force, and anxiety, as well as to facilitate a physical examination.[55,56]

The hallmarks of cholinergic crisis are muscarinic or nicotinic side effects, namely, increased perspiration, abdominal cramping, and diarrhea. Cholinergic crisis results from too much medication that causes neuromuscular blockage (which prevents muscle depolarization because of excess acetylcholine). The patient may also experience respiratory failure. Indeed, respiratory failure may be seen in both types of crises.[55]

Patients should be managed intensively. Admission to the ICU includes DVT prophylaxis and ulcer prevention. Providers need to be aware that patients in myasthenic crisis are not intubated due to lung or systemic problems, but rather to difficulties with muscle strength.[55,56,58] Given the hazards of intubation and controlled ventilation, including airway injury as well as lung injury and ventilator-associated pneumonia, measures to avoid intubation should be considered as clinically appropriate. One option is noninvasive positive pressure ventilation (NIPPV). Vigilant assessment and early recognition of impending respiratory failure may identify appropriate candidates for NIPPV. Using NIPPV in patients with myasthenic crisis before hypercapnia develops may prevent intubation and prolonged mechanical ventilation as well as decrease hospital length of stay and reduce risk of pulmonary complications.[61]

In the past, the Tensilon test was used to determine whether the patient was in a myasthenic or cholinergic crisis. If there was an improvement in muscle strength when Tensilon was administered, it indicated a myasthenic crisis.[53,54] If there was no improvement or further deterioration of muscle strength, the patient was most likely experiencing a cholinergic crisis. This test is no longer required because the withdrawal of cholinesterase drugs is necessary for improvement in both crises. Respiratory and nutritional support is provided in both situations.

Nursing Management

ASSESSMENT. The nurse must focus the neurological assessment on cranial nerve involvement, motor strength, and the extent of respiratory involvement. The patient should be monitored for ptosis and double vision. The patient's motor strength should be evaluated by the use of arm abduction times up to 5 minutes. One valuable tool for monitoring respiratory function a handheld spirometer to measure FVC. The nurse must be vigilant in monitoring the patient's respiratory status because the patient's diaphragm and intercostal muscles may become weak. If the patient's FVC falls below 1 liter, it usually indicates respiratory failure, and intubation and mechanical ventilation are necessary. An easy bedside test involves counting out numbers in one breath. Most patients should be able to count out up to 50 in

one breath. In summary, useful clinical assessment involves arm abduction times, FVC, range of eye movements, and time to the development of ptosis on upward gaze. Muscle strength testing is also valuable.

PLAN. The patient with myasthenia gravis may need assistance with activities of daily living. Adaptive equipment can help him or her perform self-care activities. Short rest periods are planned throughout the day, to help reduce patient fatigue and conserve energy.

Nutrition also needs to be addressed. Meals should be planned when pyridostigmine is at its peak. Aspiration precautions should be established. Thin liquids should be given only if the patient can tolerate them well. If the patient chokes when swallowing water, oral intake should cease. If the patient has a wet, gurgling voice or respiratory sounds or develops stridor, intubation may be necessary for airway protection, and nutrition may need to be offered through the enteral route. Caloric intake must be sustained to prevent a negative energy balance that interferes with weaning from the ventilator.

Skin care also needs to be incorporated into the care routine, and measures should be taken to avoid pressure ulcers. Pressure relief devices can be used in bed or on chairs.

An effective method of communication should also be developed, particularly if it becomes difficult to understand the patient because of the nasal quality of the voice. A communication board may be helpful as an alternate communication device.

Patient Education and Discharge Planning

Support and education about myasthenia gravis are crucial for the successful management of the disease. The patient needs to learn about the purpose of medications, medication schedules, and side effects. Patients should be instructed to adhere to their medication schedules and to contact the physician for modification if needed. Doses of medication should be kept at home and work so that they are readily available. During travel, the patient should always carry his or her medication (eg, in a purse or camera case) so that it does not become lost with luggage.

It is also helpful for the patient to obtain a medical identification bracelet and card so that rapid identification can occur in the event of a medical emergency. If the patient is unable to communicate, successful management may hinge on health care professionals recognizing that the person has myasthenia gravis.

The patient and family are taught to recognize signs and symptoms of a crisis. In addition, the importance of avoiding potential triggers for a crisis, such as respiratory infection or undue stress, is emphasized. During the winter months, when colds and flu are prevalent, the patient should be instructed to stay away from places where large groups of people gather, such as movies or concerts.

The patient should also be educated about community support groups. The Myasthenia Gravis Foundation can provide valuable resources. Box 35-8 lists patient teaching guidelines for myasthenia gravis. Long-term outcomes in myasthenia gravis have improved markedly because of the availability of immune-modulating therapies, and patients need to be educated on how to live with their disease.

BOX 35-8 TEACHING GUIDE *Living With Myasthenia Gravis*

Safety
- Obtain a medical identification (MedicAlert) bracelet and wear it at all times. Always carry personal identification in your wallet or purse.
- Avoid respiratory infections. Stay away from concert halls and movie theaters in the winter months or flu season.
- Avoid stress and stressful situations.
- Consider grinding or pureeing foods to make them easier to eat. Choose calorie-rich, nutritious snacks. Request a consultation with a dietitian if you have difficulty maintaining your weight.

Activity
- Plan frequent rest periods during the day.
- Conserve energy as much as possible.
- Avoid shopping at peak times or substitute "online" shopping so items can be delivered directly to your door.

Medications
- Mestinon (pyridostigmine) should be taken as directed by your physician. Adjustments should be made only under the direction of your physician. Remember not to crush Mestinon Timespan product.
- Mestinon should be stored at home and at work. Do not store medication in your car where it could be exposed to extreme heat and cold. When traveling, keep medication with you; do not store it in your luggage.
- Avoid medications (certain antibiotics, such as aminoglycosides, anticonvulsants, and muscle relaxants) that could exacerbate myasthenia gravis.
- Do not take any over-the-counter preparations or complementary medications without first contacting your physician.
- If you are taking Imuran (azathioprine) or cyclophosphamide, you need to follow precautions about hazardous drugs. Be certain to discuss family planning issues with your physician.

When to Call the Physician
- Call your physician if you are experiencing increased weakness, swallowing problems, or respiratory difficulties.
- Contact your physician immediately if you are hospitalized for any reason.

The Myasthenia Gravis Foundation of America is a valuable resource. Contact the Foundation for additional information and to find local support groups.

▲ Clinical Applicability Challenges

CASE STUDY

Ms. E.B. a 44-year-old marketing executive, was working in her office when she experienced severe dizziness and what she described as the "worst headache of her life." She called for help, and within moments, a colleague entered her office. E.B. was unable to stand or open her eyes. She was experiencing severe headache as described. Acting quickly, E.B.'s colleague activated the EMS, and E.B. was transported to the emergency department of a nearby tertiary care facility. Upon arrival, she had a neurological assessment performed revealing severe headache, nuchal rigidity, and deficit in the oculomotor nerve. The patient reported diplopia; dysconjugate gaze was noted on examination, and ptosis was evident. IV accesses were initiated, and the family was notified. Given the physical assessment findings of hard neurological signs, E.B. was taken immediately for CT of the brain. Head CT revealed slight effacement of the sulci and concurrent layering of blood in the subarachnoid space of 1 mm. Based on radiological and neurological assessment findings, the diagnosis of SAH was made. E.B. remained responsive, able to communicate and answer questions as well as maintain her own airway and lung ventilation. As such, she was transferred to an available monitored bed in the medical intensive care unit (MICU). While in the MICU, E.B.'s neurological status was monitored and documented hourly, stimulation was minimized, and she received analgesics for pain. Appropriate care was taken to balance effective analgesia with avoiding the side effect of sedation as a side effect of opioid analgesia. The plan of care for the next day included four-vessel cerebral angiography to identify location and distribution of vascular lesions such as cerebral aneurysms.

At 9:00 AM on day 2 of hospital admission, E.B. was transported to the angiography suite for urgent four-vessel cerebral angiography. The procedure was performed using a right femoral artery approach with a procedural duration of 94 minutes. E.B. tolerated the procedure well with no additional neurological deficits. Effective hemostasis was obtained following removal of the femoral arterial sheath. Upon return to the MICU, E.B. experienced diuresis consequent to crystalloid administration during the procedure as well as the osmotic diuretic effect of contrast media. Cerebral angiography showed aneurysms in the MCA, tip of the basilar artery, and the PCA, for a total of three.

The next step was deciding on a plan of treatment. Given location of the lesions and higher risk of morbidity from open craniotomy for clipping or wrapping the aneurysms, E.B. and her family elected a neurointerventional embolization procedure to treat the aneurysms. The procedure was planned in stages, with one aneurysm embolized at a time. The MCA aneurysm was identified as the lesion that had bled. As such, it was to be embolized first. Stage 1 of the embolization procedure was scheduled for hospital day 5. During the intervening time, E.B. was to remain in the monitored setting. Due to blood within the subarachnoid space, cerebral vasospasm was a risk. To maintain vigilance, neurological assessments were frequent and included arousal, consciousness, sensory and motor function, as well as communication.

During the night of ICU day 3, E.B. became lethargic and her pupils became dilated and sluggish. Her trachea was intubated orally, and she was placed on controlled ventilation. After stabilization, she was transported to the radiology department for emergent CT of the head. Head CT showed dilation of the ventricles as compared with the CT study on admission. She was transported immediately back to the MICU. An emergent ventriculostomy was performed. Opening CSF pressures were 25 to 30 mm Hg, and 25 mL of slightly blood-tinged CSF were drained, decreasing her ICP to 13 to 17 mm Hg. Monitoring parameters included placing the catheter to monitor continuously, with orders to drain 5 mL CSF for ICP readings sustained over 20 mm Hg. Within 7 hours following ventricular catheter placement, E.B.'s neurological assessment returned to baseline. She followed commands and was more responsive and interactive with care givers and family members. The embolization procedure was delayed pending stabilization of these clinical issues. Multiple IV accesses were maintained for administration of fluids and medications. E.B. was at risk for seizure activity from altered neuronal physiology, which can decrease electrical stability in the brain and increase the risk of seizure activity consequent to neurological injury. Administration of anticonvulsant drugs was potentially necessary.

Over the ensuing 5 ICU days, E.B.'s ICP remained stable, requiring CSF drainage on only two occasions. On ICU day 9, the ventricular catheter was clamped. ICP measurements remained stable (15 mm Hg or less), and neurological assessment remained stable as well, reflecting an interactive patient, able to protect her own airway. Lung ventilation and pulmonary status remained stable on continuous positive airway pressure and pressure support settings, giving her control over rate, depth, and pattern of her respiratory cycle. Follow-up head CT revealed resolution of ventricular dilation and no effacement of the sulci. The ventricular catheter was removed, and E.B. was extubated and received supplemental oxygen delivered by nasal cannula at 4 L/min.

Following stabilization, the embolization procedure for the MCA aneurysm was rescheduled for the following week. E.B. was transported to the interventional radiology suite and monitored for oxygenation and cardiovascular status by the anesthesiology provider. EEG monitoring was initiated to closely monitor neurologic status intraprocedure while anesthesia was being administered. The neurointerventional radiologist successfully placed detachable coils within the aneurysm, effectively eliminating it from the circulation. Extreme care was taken to avoid coil placement outside of the aneurysm, which may

(continued on page 803)

▲ Clinical Applicability Challenges

CASE STUDY *(Continued)*

cause ischemic stroke. Following coil placement within the aneurysm, follow-up angiography was done, demonstrating coil placement within the aneurysm and absence of any blood flow within the aneurysm. No EEG findings of neurologic injury were evident intraprocedure, and E.B. recovered from anesthesia in stable condition.

Neurologic assessment findings were intact, were interactive, and demonstrated no neurologic sequelae from the aneurysm and subsequent hydrocephalus. Long-term follow-up was planned and reviewed with E.B. and her family for two reasons. First, two additional aneurysms needed coil embolization. Second, coils may become compressed with long-term exposure to hemodynamic stress within the native blood vessel, increasing the risk for rebleeding and possibly requiring subsequent coil embolization. E.B. was discharged ultimately to home with anticipated embolization of the remaining aneurysms in a staged procedure. She ultimately returned to work following hospital discharge.

1. Increased ICP is one means by which a patient with ischemic stroke, hemorrhagic stroke, or SAH may experience increased mortality or morbidity. What are the mechanisms by which ICP elevations occur in these populations?

2. For a patient with a long-standing seizure disorder or a patient experiencing seizures in an acute-care setting, what are the means by which emergent administration of anticonvulsant medications is accomplished?

3. Pain may be managed with opioid analgesics and anxiety managed with sedative-hypnotic drugs, such as benzodiazepines. What are the significant nursing considerations in administering these drugs to a patient with a neurological disorder?

36 Traumatic Brain Injury

Elizabeth Zink and Elizabeth Kozub

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Explain the significance of the mechanism of injury when assessing the patient with traumatic brain injury.
2. Compare and contrast various types of head injuries and typical patient presentation.
3. Differentiate between primary and secondary brain injury.
4. Explain the importance of and technique for serial neurological assessment in the patient with traumatic brain injury.
5. Discuss the rationale for medical and nursing management in the care of the patient with a traumatic brain injury.
6. Describe the roles of multidisciplinary health care team members in caring for the patient with traumatic brain injury.

Traumatic brain injury (TBI) affects as many as 1.7 million Americans each year and has devastating effects on patients and their families. About 1.4 million people, or 80% of those with TBI, are evaluated and discharged from emergency departments (EDs) each year; 275,000 are admitted to hospitals and 52,000 die. It is suspected that a large number of people who sustain TBI do not seek health care. Falls are the leading cause of TBI, constituting 35% of all cases, followed by unknown causes (21%) and motor vehicle crashes, which account for 17% of all TBI.[1] The incidence of TBI is greater in males than females, and TBI occurs most frequently in children younger than age 4 years and in adolescents between ages 15 and 19 years.[1] TBI in adults older than age 65 most often result from falls (61%) (Box 36-1). Critical care nurses play an important role in reducing the incidence of head injury through patient and family teaching as well as participation in primary prevention efforts (eg, helmet safety, violence prevention, fall prevention, and drug and alcohol awareness).

TBI can have a profound and lasting effect on the patient and family. Neurologic deficits may affect the patient's ability to resume his or her chosen career or to return to work at all. Emotional and behavioral changes may affect interpersonal relationships and family roles. A thorough understanding of the pathophysiology of TBI enables the critical care nurse to individualize nursing care and positively affect patient and family outcomes. Critical care nurses play a key role in planning and implementing the multidisciplinary care of these complex patients and their families.

▲ Mechanisms of Traumatic Brain Injury

Typical mechanisms of injury include acceleration, acceleration–deceleration, coup–contrecoup, rotational injury, and penetrating injury (Fig. 36-1):

- Acceleration injuries occur when a moving object strikes the stationary head (eg, a bat striking the head or a missile fired into the head).
- Acceleration–deceleration injuries occur when the head in motion strikes a stationary object. For example, a motor vehicle crash in which the head strikes the windshield produces an acceleration–deceleration injury. Acceleration–deceleration injuries can also occur with falls or physical assaults.
- Coup–contrecoup injuries occur when the brain "bounces" back and forth within the skull, striking both poles of the brain (ie, front and back or right side and left side). Coup refers to the area of brain tissue initially making forceful contact with the inside of the skull, and contrecoup refers to the second impact of brain tissue with the inside of the skull, usually on the opposite side. When assessing a patient struck in the back of the head, the clinician evaluates for injury to posterior structures (ie, the occipital lobes and cerebellum) as well as anterior brain structures (ie, the frontal lobes).
- Rotational forces cause the brain to twist within the meninges and the skull, resulting in stretching and tearing of blood vessels and shearing of neurons. Physical assaults

BOX 36-1 CONSIDERATIONS FOR THE OLDER PATIENT

Preventing Falls in the Older Adult

Screen patients 75 years old and older for history of falling or at age 70 if they are deemed to be at a higher risk for falling

Consider the following factors, which may need to be evaluated and/or modified in patients found to be at a greater risk for future falls:

- Impaired vision
- Medications
- Blood pressure (postural hypotension)
- Balance and gait
- Hazards in living environment

Tinchi ME: Preventing falls in elderly persons. N Engl J Med 384(1):42–49, 2003.

and motor vehicle crashes are examples of situations in which rotation and torsion may be a mechanism of injury.

- Penetration injuries may be caused by a bullet, shrapnel, or another sharp object traveling at a velocity substantial enough to disrupt the integrity of the skull. Depending on the speed and trajectory of the object, underlying brain structures may or may not be injured.

Cervical spine injury must be automatically assumed and systematically excluded with all types of TBI before immobilization devices are removed. TBI is categorized by severity based on radiographic injury and the Glasgow Coma Scale (GCS) (Table 36-1).

▲ Primary and Secondary Brain Injury

The term *primary brain injury* describes injury occurring at the time of trauma. Injury occurring after the traumatic event is referred to as *secondary brain injury*. The initial injury causes immediate disruption of the skull, brain structures (ie, meninges, blood vessels, brain tissues, neurons), and functions (blood flow, oxygenation, cellular metabolism). Secondary injury describes the physiological response to brain injury, including cerebral edema, cerebral ischemia, and biochemical changes. Current research and existing therapies are aimed at preventing and mitigating secondary brain injury to maximize chances for positive functional outcomes.

Primary Brain Injury

Scalp Laceration

A scalp laceration frequently causes significant bleeding because of the vascularity of the scalp and may be associated with other underlying injuries to the skull and brain. The scalp should be carefully palpated assessing for deformation. Skull fractures may be present even if deformities are not palpable; therefore, care must be exercised in applying pressure to scalp wounds. Scalp lacerations can be sutured at the bedside or may require surgical repair, depending on the size and extent of injury. Avulsion of areas of the scalp may require surgical reimplantation to address injured vascular structures.

Skull Fracture

The skull protects the brain by distributing forces outward, lessening direct impact to the brain. Skull fractures are categorized by location; the fractured bones may be located in the anterior, middle, or posterior fossae, or the base of the skull. Skull fractures may be compound (ie, occurring with an open wound), displaced (closed wound in which the edges of the fracture no longer meet), or linear. Depressed skull fractures are fractures in which bone fragments are driven into the underlying meninges or brain tissue; this often presents as a depression or dip on palpation. Patients with depressed skull fractures may require surgical management to débride bone fragments, repair the skull or dura, evacuate a hematoma, or repair other adjacent structures, such as sinuses or blood vessels.[2] Blood vessels travel along bony grooves on the inside surface of the skull; as a result, they are vulnerable to injury during a direct blow to the skull. Injury to the dura places the patient at risk for meningitis; therefore, careful monitoring for signs and symptoms of infection is important.

Basilar skull fractures occur at the base or floor, of the skull, typically in the areas of the anterior and middle fossae. Basilar skull fractures are linear or displaced. Assessment of extraocular movements is important in detecting impingement of cranial nerves. Nasogastric and nasotracheal intubation are avoided to reduce the risk for passing the tube through fractured areas into the brain.

Drainage of cerebrospinal fluid (CSF) from the ear or nose indicates injury to the dura. Drainage from the ear, otorrhea, typically signifies a fracture in the middle fossa. Ecchymosis (bruising) behind the ear (Battle's sign) is a delayed sign of a basilar skull fracture in the middle fossa. Rhinorrhea, CSF drainage from the nose, occurs with a fracture in the anterior fossa. "Raccoon eyes," a ring-like pattern of bruising around the eyes, is a late sign of this type of fracture.

Drainage from the ear or nose may be mixed with blood, making identification of CSF difficult. A layering of fluids, with blood on the inside and CSF in a yellowish ring on the outside (the "halo sign"), will appear when the area is wiped with gauze. Patients may also report a sweet or salty taste if CSF is draining into the pharynx. Clear fluid may be tested for a substance called beta-2 transferrin to distinguish between CSF and other body fluids.

CSF leaks typically heal on their own with rest; however, when a CSF leak persists, diversion of CSF into an external drainage device may be necessary to reduce pressure on the dural tear and allow time for healing. In some cases, surgical repair of the damaged region of dura must be performed. A loose gauze dressing can be applied to the ear or nose to quantify the amount and character of drainage while allowing unobstructed drainage of the fluid. The skin around the site of drainage is kept clean, and the patient is instructed not to blow his or her nose.

Concussion

A concussion is defined as any alteration in mental status resulting from trauma. The patient may or may not lose consciousness. Often patients are unable to recall events leading up to the traumatic event, and occasionally short-term memory is affected. Concussions are not associated with structural abnormalities on radiographic imaging, however, a growing body of research suggests that neuronal injury does

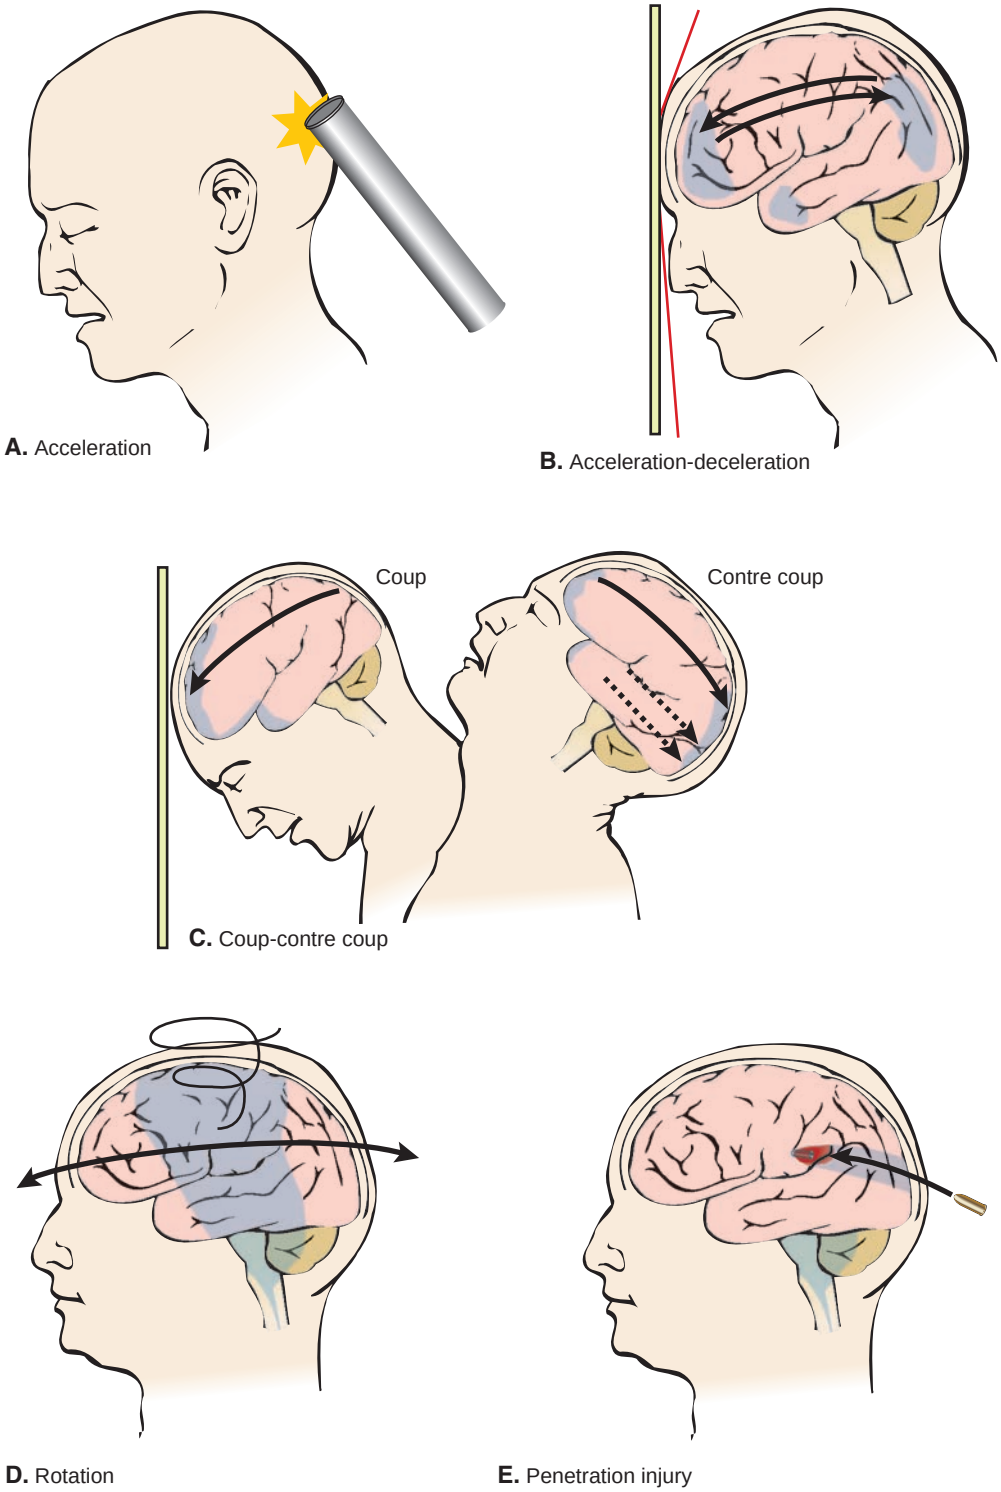

FIGURE 36-1 ▲ Typical mechanisms of head injury. **A:** Acceleration. **B:** Acceleration–deceleration. **C:** Coup-contrecoup. **D:** Rotation. **E:** Penetration.

occur with concussions and is associated with a metabolic crisis at the cellular level. This cellular metabolic crisis may cause the symptoms attributed to post-concussive syndrome.[3] Recovery after a concussion is usually quick and complete; however, some patients exhibit symptoms of postconcussive syndrome, which include headaches, decreased attention span, short-term memory impairment, dizziness, irritability, emotional lability, fatigue, visual disturbances, noise and light sensitivity, and difficulties with executive functions.[4] These symptoms may last for months to 1 year and can be alarming to the patient and the family. Discharge teaching must include a review of these signs and symptoms as well as criteria for obtaining medical follow-up.

Contusion

Contusions in the brain are the result of laceration of the microvasculature. They are focal and superficial, occasionally

Table 36-1 Defining the Severity of Head Injury

Severity	Description
Mild	GCS score 13–15 Loss of consciousness or amnesia for 5–60 min No abnormality on CT scan and length of hospital stay <48 h
Moderate	GCS score 9–12 Loss of consciousness or amnesia for 1–24 h May have abnormality on CT scan
Severe	GCS score 3–8 Loss of consciousness or amnesia for >24 h May have a cerebral contusion, laceration, or intracranial hematoma

GCS, Glasgow Coma Scale.

spreading to deeper layers of the brain. Cerebral contusions can range from mild to severe depending on the location, size, and extent of brain tissue injury. The diagnosis of cerebral contusion is made using computed tomography (CT). Small lesions may result in focal neurological deficits, whereas multiple or large contusions may result in a depressed level of consciousness and coma. Complications of a cerebral contusion include development of a hematoma and cerebral edema. Cerebral edema peaks 24 to 72 hours after injury, causing increased intracranial pressure (ICP). The patient's clinical condition may progressively deteriorate over the first 72 hours; therefore, the patient requires intensive anticipatory monitoring (serial neurological assessments) to identify signs and symptoms of increased ICP quickly and prevent further brain injury.

Epidural Hematoma

An epidural hematoma is a collection of blood between the dura and inside surface of the skull, often caused by laceration of the middle meningeal artery (Fig. 36-2). Although this type of hemorrhage is often associated with injury to an artery, injury to an extradural vein or venous sinus may also produce an epidural hematoma. Prompt recognition and expeditious surgical intervention to evacuate the hematoma result in improved outcomes. Patients may present in a coma or fully conscious.

Subdural Hematoma

A subdural hematoma is an accumulation of blood below the dura and above the arachnoid layer covering the brain (see Fig. 36-2). Tearing of the surface veins or disruption of venous sinuses can cause a subdural hematoma. The risk for subdural hematoma is increased in the elderly and in people with alcoholism. Cortical atrophy in these two populations causes tension on bridging veins leading from the surface of the brain to the inner surface of the dura. An increased incidence of falls also compounds the risk for subdural hematomas in these populations. Subdural hematomas can be separated into three categories based on the time from injury to the onset of symptoms: acute, subacute, and chronic.

Patients with acute subdural hematomas manifest symptoms within 24 to 48 hours after injury depending on the rate and amount of blood accumulation. Symptoms include headache, focal neurological deficit, unilateral pupillary abnormalities, and a decreasing level of consciousness. Size and location of the hematoma and the degree of neurological dysfunction are considered in making the decision to surgically evacuate the hematoma.

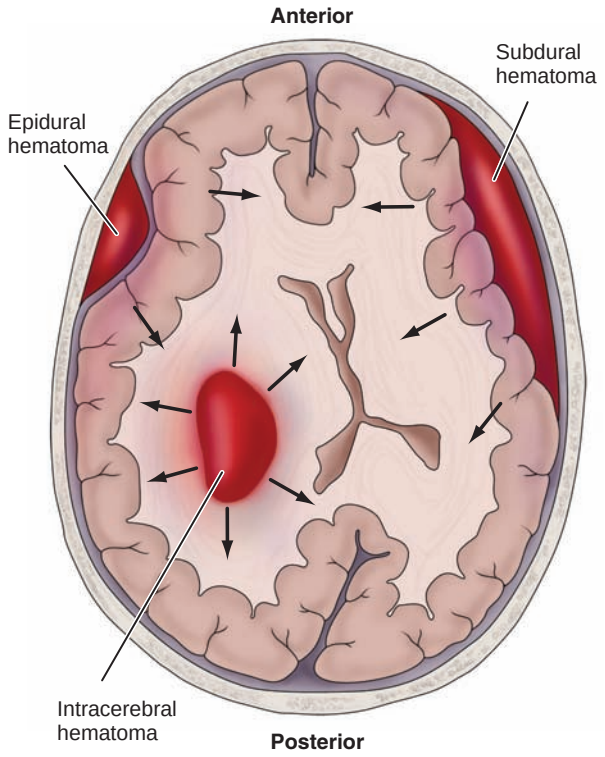

FIGURE 36-2 ▲ Cerebral hematomas. **A:** An epidural hematoma. **B:** A subdural hematoma. **C:** An intracerebral hematoma. (From Smeltzer: Brunner & Suddarth's Textbook of Medical-Surgical Nursing, 12th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 1922.)

Patients with subacute subdural hematomas have a delayed onset of symptoms, 2 days to 2 weeks after injury. The delay in symptom onset may be explained by a slower accumulation of blood caused by disruption of smaller blood vessels. In some cases, cerebral atrophy may allow for a greater amount of fluid to collect before symptoms of increased ICP manifest. Surgical evacuation of the clot may be performed on an elective basis depending on the degree of neurologic dysfunction.

Patients with chronic subdural hematomas may initially experience a small bleed that does not cause symptoms. Over time, slow capillary leaking of proteinaceous fluid causes expansion of the mass and produces symptoms of increased ICP. Chronic subdural hematomas are often seen in elderly patients with a history of falling. The slow accumulation of fluid accounts for delayed presentation of signs and symptoms of increased ICP.[5] Common symptoms include headache, lethargy, confusion, and seizures. Surgical intervention may include drilling burr holes into the skull or craniotomy to remove the hematoma. A drain may be placed intraoperatively to prevent reaccumulation of fluid. It is necessary to keep the head of the patient's bed flat to decrease tension placed on bridging veins. When the head is elevated, the brain settles downward. Therefore, the head of the patient's bed must be raised slowly to prevent rebleeding.

Intracerebral Hematoma

An intracerebral hematoma is a collection of blood within brain tissue caused by disruption of blood vessels (see Fig. 36-2). Traumatic causes of intracerebral hematoma include depressed skull fractures and penetrating injuries. Surgical management of intraparenchymal hematomas is indicated in patients with deteriorating neurological status referable to the injured region of brain tissue or patients with increased ICP that is uncontrolled with maximal medical therapies (eg, osmotic therapy, hyperventilation, and sedation). Medical therapy aims to manage cerebral edema and promote adequate cerebral perfusion.

Traumatic Subarachnoid Hemorrhage

Traumatic subarachnoid hemorrhage occurs with tearing or shearing of microvessels in the arachnoid layer where CSF flows around the brain. A traumatic subarachnoid hemorrhage often accompanies other severe brain injuries and appears to be associated with poor neurologic outcome and increased mortality.[6] Additional complications, such as hydrocephalus and cerebral vasospasm, add to the complexity of the injury.

Diffuse Axonal Injury

Diffuse axonal injury (DAI) is characterized by direct tearing or shearing of axons, and during the first 12 to 24 hours edema develops. DAI prolongs or disables signal conduction from the white matter to gray matter in the brain and is thought to occur with rotational and acceleration–deceleration forces. DAI can be classified as mild, moderate, or severe based on length of coma and degree of neurological dysfunction. Mild DAI is associated with a coma lasting no longer than 24 hours. Moderate DAI is characterized by a coma lasting longer than 24 hours with transient flexor or extensor posturing. Severe DAI is characterized by prolonged coma, fever, diaphoresis, and severe extensor posturing. DAI is not easily identified through radiographic imaging in the first 24 hours; however, small punctate hemorrhages may be visualized deep in the white matter, a finding that increases suspicion that DAI has occurred. Magnetic resonance imaging (MRI) may be helpful in identifying neuronal damage after 24 hours.

Cerebrovascular Injury

Carotid or vertebral artery dissection must be considered in situations in which a patient presents with neurologic deficits unexplained by other brain injuries. Arterial dissection is caused by shearing of the innermost or middle vessel layers, the intima and media. Damage to the intima can result in clot formation or an intimal flap, either of which can occlude the vessel, resulting in stroke. The key to preventing stroke in these patients is early identification of the injury, exclusion of concomitant hemorrhage, and possibly initiation of anticoagulation therapy. To detect this type of injury, cerebral angiography may be performed in patients who have sustained injury to the neck or have unexplained focal neurological deficits. Damage to the intima or media allows blood to leak between the blood vessel layers, resulting in a ballooning of the outermost vessel layers and creating an aneurysm. This type of aneurysm is referred to as a traumatic intracerebral aneurysm and may also be called a pseudoaneurysm.

Secondary Brain Injury

Secondary brain injury events occur after the initiating traumatic event and cause additional brain injury. Examples of conditions causing or exacerbating secondary brain injury are uncontrolled ICP, cerebral ischemia, hypotension, hypoxemia, and local or systemic infection. Secondary brain injury occurs as a function of the inflammatory response, reduced cerebral blood flow, and dysfunctional cerebral autoregulation causing damage to neurons. These secondary processes can result in cerebral infarction, coma, and increased cerebral edema. Prevention of hypotension, hypercarbia, hypoxemia, and seizures is extremely important in attempting to prevent further injury.[7]

Understanding intracranial dynamics and the nature of cerebral blood flow is essential to preventing and treating secondary brain injury (see Chapter 34 for a complete discussion of intracranial dynamics and the Monro-Kellie doctrine).

Compensation for increased volume in the cranium occurs when CSF is channeled through the foramen magnum into the spinal canal, CSF production is decreased, and venous blood is channeled out of the cranium into the jugular veins. The compliance curve (Fig. 36-3) illustrates the body's ability to compensate for the addition of water, CSF, or blood into the cranial vault and the point at which intracranial compliance is maximized. Decreased intracranial compliance results in a small addition of volume causing disproportionate increases in ICP. Examples of conditions causing decreased intracranial compliance are cerebral edema (an increase in brain water), expansion of a hematoma (an increase in blood), and hydrocephalus (an increase in CSF). An understanding of pressure–volume relationships allows the nurse to anticipate deterioration of the patient's clinical condition, tailor nursing interventions, and anticipate potential medical or surgical treatments.

Cerebral autoregulation is a protective mechanism that enables the brain to receive a constant blood flow over a range of systemic blood pressures (see Chapter 34 for a complete discussion). Several studies have suggested that cerebral blood flow may decrease up to 50% during the first 24 to 48 hours after TBI.[8]

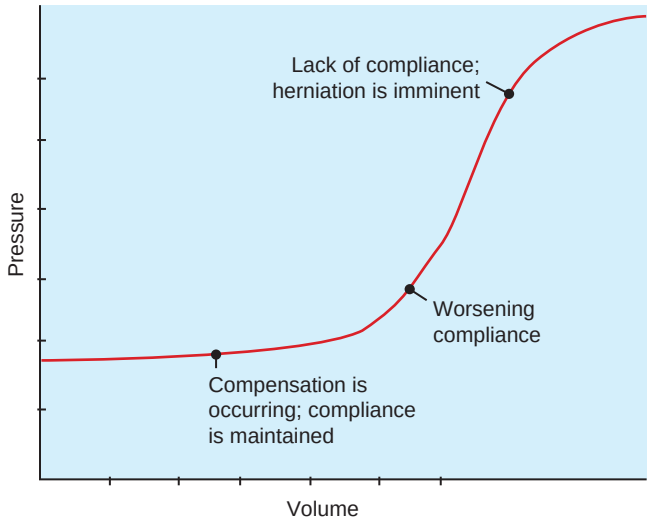

FIGURE 36-3 ▲ The compliance curve. The body is able to compensate for the addition of water, blood, or CSF to the cranial vault until a critical point is reached where compensation has been maximized. At this point, the addition of a small amount of volume will cause a disproportionate increase in ICP.

Biochemical mechanisms also play a significant role in causing secondary brain injury. The inflammatory response has been implicated as a potential cause or exacerbating factor in secondary brain injury.

Cerebral Edema

Cerebral edema commonly occurs in patients with TBI 24 to 48 hours after the primary insult and typically peaks at 72 hours.[9] Patients require increased observation during this period because of the increased risk for neurological deterioration. If cerebral edema is not quickly and aggressively treated, herniation syndrome may ensue. The treatment of cerebral edema is discussed in Chapter 34.

The two most common types of edema occurring after TBI are cytotoxic and vasogenic edema. Cytotoxic edema occurs as a result of intracellular sodium–potassium pump failure, allowing an influx of sodium and water into the cell. Vasogenic edema occurs as a result of a disruption to the blood–brain barrier.[9]

Ischemia

Cerebral ischemia, a major cause of morbidity and mortality, may be a result of direct vascular injury or cerebral edema that causes compression or occlusion of blood vessels within the brain. Ischemia in the brain may occur at the time of injury or during the period subsequent to the injury. Cerebral ischemia occurs whenever blood flow is inadequate to meet metabolic demands of the brain. If the cause of cerebral ischemia is not controlled, cerebral infarction (stroke) may result (see Chapter 35 for further information on cerebral ischemia and stroke).

Herniation Syndrome

Herniation syndrome occurs when pressure builds within the cranium, exceeding the brain's ability to compensate for the increase in pressure and causing brain tissue to be displaced. Cushing's triad refers to the three late signs of herniation: increased pulse pressure, decreased heart rate, and an irregular respiratory pattern. It is of critical importance to identify early signs of increased ICP (such as change in level of consciousness) in order to prevent herniation syndrome. The examination findings of a patient with increased ICP differ significantly from those of a patient with herniation syndrome (Table 36-2).

Cerebral herniation syndrome is classified according to the brain structures involved. The most common syndromes in the setting of critical care and trauma are uncal and central herniation (Table 36-3). Herniation of the medial temporal lobe (uncus) through the tentorium and into the brainstem is called uncal herniation. Herniation of the uncus through the tentorium results in pressure on the midbrain where the third cranial nerve exits, producing ipsilateral pupillary dilation. Contralateral hemiparesis occurs during uncal herniation. Central or tonsillar herniation describes the downward displacement of the cerebellar tonsils through the foramen magnum, causing compression of the brainstem. Clinical signs of central herniation syndrome include loss of consciousness, bilateral pupillary dilation, respiratory pattern changes or respiratory arrest, and flaccid paralysis. Central herniation may be caused by bilateral expanding lesions or a centrally located mass lesion causing downward displacement of the cerebral hemispheres and midline structures (ie, the basal ganglia, diencephalon, and the midbrain) through the tentorium (Fig. 36-4).

Critical care nurses have the opportunity to make a significant contribution to patient outcome by performing thorough serial neurological examinations, taking into account subtle changes. Once thought to be immediately fatal, herniation syndrome may be reversible in certain circumstances if it is identified early and aggressive therapies are administered.

Coma

Coma is an alteration in consciousness caused by damage to both hemispheres of the brain or the brainstem. Coma results from disruption of the reticular activating system (RAS), which is a physiologic region encompassing nuclei from the medulla to the cerebral cortex. The RAS is responsible for wakefulness, heightened arousal, and alertness. Consciousness spans a continuum from full consciousness to coma (see Chapter 33, Box 33-3). The states of coma can be subdivided into light coma, coma, and deep coma.

Persistent Vegetative State

Several terms describe a persistent vegetative state, such as irreversible coma or coma vigil. A persistent vegetative state is characterized by a period of sleep-like coma followed by a return to the awake state with an inability to respond to the environment. In a persistent vegetative state, higher cortical functions of the cerebral hemispheres have been damaged permanently, but the lower functions of the brainstem remain intact. The patient's eyes open spontaneously and may appear as if they are opening in response to verbal stimuli. Sleep–wake cycles exist, and the patient maintains normal cardiovascular and respiratory control. Also seen are involuntary lip smacking, chewing, and roving eye movements. A diagnosis of persistent vegetative state cannot be made for at least 4 weeks after onset of TBI and coma.[10]

The critical care nurse organizes resources for family and patient support such as pastoral care and social services. Support groups and assistance programs are often available for families of patients with TBI. Supporting the family in

Table 36-2 Increased Intracranial Pressure Versus Herniation Syndrome

	Increased Intracranial Pressure	Herniation Syndrome
Level of arousal	Increased stimulus required	Unarousable
Motor function	Subtle motor weakness or pronator drift	Dense motor weakness, posturing or absent response
Pupillary response	Sluggish pupillary response	Unilateral dilated and fixed pupil ("blown pupil")
Vital signs	May be stable or labile	Cushing's triad (increased systolic blood pressure, decreased heart rate, irregular respiration)

Used with permission from an unpublished lecture, Lower J, 1997.

Table 36-3 Herniation Syndromes

Name	Tissue Displaced	Common Causes	Clinical Signs
Central (transtentorial) herniation	Supratentorial	Compression and impaired blood flow to the brainstem Chronic increases in ICP Tumor in frontal, parietal, occipital lobes	Early altered alertness Respiratory sighs, yawns, pauses Roving eyes, small pupils Late sign: decorticate or decerebrate posturing
Uncal herniation	Supratentorial	Rapidly expanding lesions—hematoma	Early unilateral dilating pupil Once brainstem signs begin, deterioration is rapid
Upward cerebellar herniation	Infratentorial	Posterior fossa mass	Coma Cerebellar infarct if superior cerebellar arteries occluded Hydrocephalus with involvement of sylvian aqueduct
Tonsillar herniation	Infratentorial	Elevated ICP Expanding mass	Cranial nerve abnormalities Respiratory changes (apneustic/cluster breathing) Change in level of consciousness (rapid)

the process of gathering information and making decisions is an essential role of the multidisciplinary critical care team.

▲ Assessment

Physical Examination

Two essential tenets of neurological assessment are (1) level of consciousness is the most sensitive indicator of increased ICP and (2) maximal stimulus must be applied to achieve the maximal patient response.

Performing serial neurological examinations that include evaluation of level of consciousness and motor and cranial nerve function is necessary to identify increased ICP and prevent herniation syndrome. The GCS (see Chapter 33, Box 33-4) is useful for assessing trends of neurological function over time; however, focal motor deficits are not taken into consideration. The advantages of the GCS are ease of use and proven consistency across evaluators.

Assessment of Cognitive Function

Cognitive function is usually assessed by asking three orientation questions regarding person, place, and time. However,

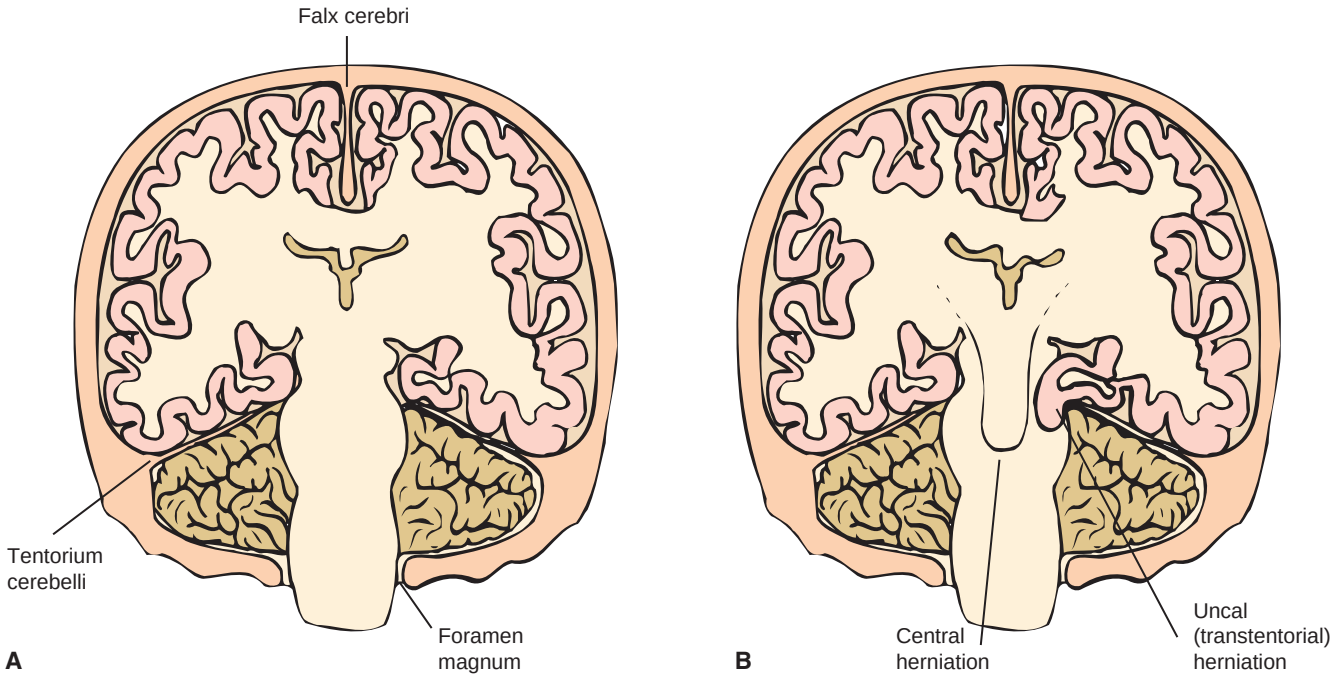

FIGURE 36-4 ▲ **A:** Normal brain. **B:** Herniated brain. Herniation associated with brainstem compression is called *central herniation*, whereas herniation associated with the supratentorial structures is called *uncal* (*transtentorial*) *herniation*.

it is necessary to elicit an "embroidered" or specific history from the patient to facilitate the detection of subtle changes over time. Patients may learn to answer the same questions correctly because of repetition but may continue to be confused when questioned further. Instead of asking the patient to state his or her location, the nurse may ask the patient to recall what type of place he or she is in or ask the name of the hospital, the city, and the state. Asking the patient to name his or her children, spouse, or close family members may also be helpful.

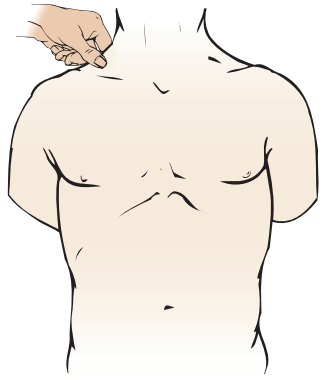
Assessment of Level of Arousal

Assessment of arousal determines a patient's capacity for wakefulness. A maximum stimulus must be applied in a systematic and escalating fashion to effectively elicit the patient's best, or maximal, response. A patient should be stimulated first by calling his or her name (in the same manner as you would try to wake a person who is sleeping), then by shouting the name (as you would to wake a "sound sleeper"), next by shaking, and finally by applying central pain. This staged approach affords the patient the opportunity to demonstrate increasing wakefulness or his or her best response. If the patient awakens readily, the ability to follow simple commands is assessed by asking the patient to move his or her extremities or "show two fingers." When asking a patient to grip or squeeze the evaluator's hand, it is important to make sure that the person can squeeze and release the grip. Patients with injury to the frontal lobe may have damaged the area of grasp inhibition, which develops in infancy. In this instance, the patient would grasp because of a reflex instead of a voluntary action.

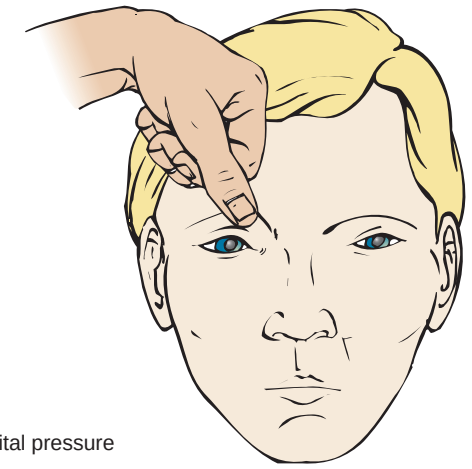
If a painful stimulus must be applied, the following techniques are useful: Squeeze the belly of the trapezius muscle with the thumb and first finger where the neck and shoulder meet, apply pressure over the supraorbital notch, or perform a sternal rub (Fig. 36-5). If a response is not elicited with these maneuvers, pressure may be applied to the nail beds of the patient's fingers or toes by placing a pencil on the nail and rolling it back and forth while applying pressure. Movement elicited by nail bed pressure is a result of activation of a spinal cord reflex. A painful stimulus should be applied for 15 to 30 seconds before the patient is considered not to have a motor response. Patients with brain injury may exhibit delayed responses to stimuli.

Assessment of the Eyes

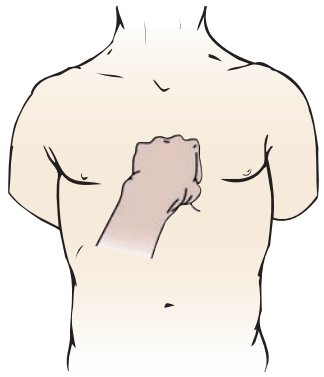
Assessment of the eyes includes evaluation of the pupils and extraocular movements, which assists in localizing cranial nerve dysfunction. Testing of cranial nerve II (the optic nerve) involves detection of gross visual field defects and visual acuity. Visual fields can be adequately assessed by the patient's ability to detect movement of the evaluator's finger in each field of vision (see Chapter 33 for technique). Visual



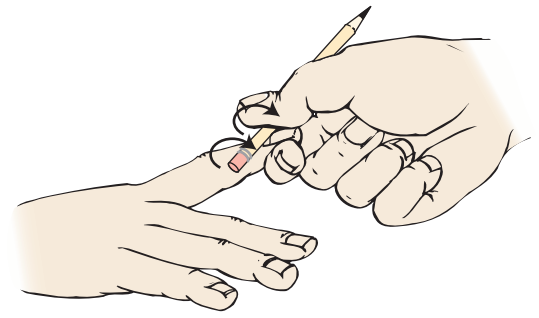
A. Trapezius squeeze



B. Supraorbital pressure



C. Sternal rub



D. Nailbed pressure

FIGURE 36-5 ▲ Methods of applying a painful stimulus. **A:** Trapezius squeeze. **B:** Application of supraorbital pressure. **C:** Sternal rub. **D:** Application of pressure to the nail bed.

acuity can be grossly assessed by asking the patient to read printed words on a page or by using a Snellen eye chart. If there is concern about optic nerve impairment, a full evaluation by an ophthalmologist is recommended.

Evaluation of cranial nerve III (the oculomotor nerve) involves inspection of the pupil, including size, shape, equality, and reaction to light. Increased ICP can cause irregularities in shape, pupillary inequality (anisocoria), and sluggish or absent reaction to light. Cranial nerves III, IV, and VI (the oculomotor, trochlear, and abducens nerves) enable movement of the eyes. Cranial nerves III and IV exit at the level of the midbrain, and cranial nerve VI exits at the level of the pons. Assessment of these nerves is accomplished by asking the patient to follow the evaluator's finger while it is moved in an "H" pattern. Double vision (diplopia) is a sign of eye muscle weakness and cranial nerve impairment.

In the comatose patient, the following tests are performed to evaluate cranial nerves III, VI, and VIII (the oculomotor and abducens nerves, and the vestibular portion of the acoustic nerve). The oculocephalic reflex (ie, the "doll's eyes" phenomenon; see Chapter 33, Fig. 33-6) is tested by moving the head from side to side in a horizontal plane (after confirming the absence of cervical spinal fracture). If the oculocephalic response is present, the eyes move together in the opposite direction of the head as it is turned from side to side. Absence of eye movement on head turning reflects brainstem dysfunction. The oculovestibular reflex (see Chapter 33, Fig. 33-7) is tested by instilling cold water into each ear and observing the eyes for movement. A normal oculovestibular response is characterized by movement of the eyes toward the stimulus with nystagmus. The absence of movement signals loss of function of the vestibular portion of the eighth cranial nerve as well as the brainstem.

Assessment of Brainstem Responses

The brainstem can be further assessed in the unconscious patient by testing corneal, cough, and gag reflexes. The corneal reflex reflects function of cranial nerves V and VII (the trigeminal and facial nerves), which exit the brain at the level of the pons. This reflex is tested by passing a wisp of cotton over the lower conjunctiva of each eye. Movement of the lower eyelid indicates the presence of the reflex. Sensation of the irritating stimulus represents gross function of one branch of the trigeminal nerve, and movement of the lower eyelid represents motor function of the facial nerve. Care must be taken in testing the corneal reflex to avoid corneal abrasions.

Cranial nerves IX and X (the glossopharyngeal and vagus nerves) exit at the level of the medulla and are responsible for the cough and gag reflexes and protection of the airway from aspiration. The cough and gag reflexes should be evaluated in the awake and unconscious patient.

Assessment of Motor Function

Motor function is evaluated by using the staged approach described earlier. Further detailed assessment of motor function is tested in the awake and cooperative patient by having the patient move his or her extremities against gravity and with passive resistance, grading the movement on a scale of 1 to 5 (see Chapter 33).

The unresponsive patient may exhibit localization, withdrawal, flexor posturing, or extensor posturing in response to noxious stimuli. Localization of a painful stimulus is observed as a purposeful response in which the patient is able to locate the source of pain and move toward it with one or both extremities crossing the midline of the body. A patient may try to remove the evaluator's hand when he or she performs a trapezius squeeze, or the patient may attempt to grab medical equipment (eg, catheters or endotracheal tubes). A withdrawal response is characterized by movement away from a painful stimulus. Flexor (decorticate) posturing is indicative of diffuse cortical injury and is characterized by the bending or flexing of the upper extremities and extension of the lower extremities and feet. Extensor (decerebrate) posturing indicates injury to the brainstem and is observed as extension and internal rotation of the upper extremities and extension of the lower extremities and feet (see Chapter 33, Fig. 33-1). It is possible that a patient may exhibit one type of movement in one extremity and another type of movement in another extremity. Presence of the Babinski reflex may also be observed in the patient with severe TBI.

Assessment of Respiratory Function

Assessment of respiratory patterns is important in detecting worsening neurologic injury and the need for airway management and mechanical ventilation. Numerous locations in both cerebral hemispheres regulate voluntary control over the muscles used in breathing. The cerebellum synchronizes and coordinates the muscles involved in respiration. The cerebrum controls the rate and rhythm of respiration. Nuclei in the pons and midbrain regulate the automaticity of respiration.

Abnormal respiratory patterns may be correlated with injured regions of the brain (Fig. 36-6). Cheyne-Stokes breathing is periodic breathing in which the depth of each breath increases to a peak and then decreases to apnea. The hyperpneic phase usually lasts longer than the apneic phase. This breathing pattern may be seen in patients with bilateral lesions located deep in the cerebral hemispheres. Compression of the midbrain can cause central neurogenic hyperventilation. Hyperventilation is sustained, regular, rapid, and deep. It is usually caused by a lesion above the midbrain. Apneustic breathing is characterized by respiration with a long pause at full inspiration or full expiration. The etiology of this pattern is loss of all cerebral and cerebellar control of breathing, with respiratory function at the brainstem level only. Cluster breathing may be seen in a patient when the lesion is high in the medulla or low in the pons. This pattern of respiration is seen as gasping breaths with irregular pauses.

The critical centers of inspiration and expiration are located in the medulla oblongata. Rapidly expanding intracranial lesions, such as cerebellar hemorrhage, can compress the medulla, resulting in ataxic breathing. This irregular breathing consists of both deep and shallow breaths with irregular pauses. This pattern of respiration signals the need for definitive airway control (ie, endotracheal intubation).

Assessment of Other Body Systems

In addition to thorough assessment of the central nervous system, comprehensive assessment of all other body systems is crucial in the early identification of complications in patients with TBI. Organ dysfunction, particularly respiratory failure, is common in patients with severe TBI.[11]

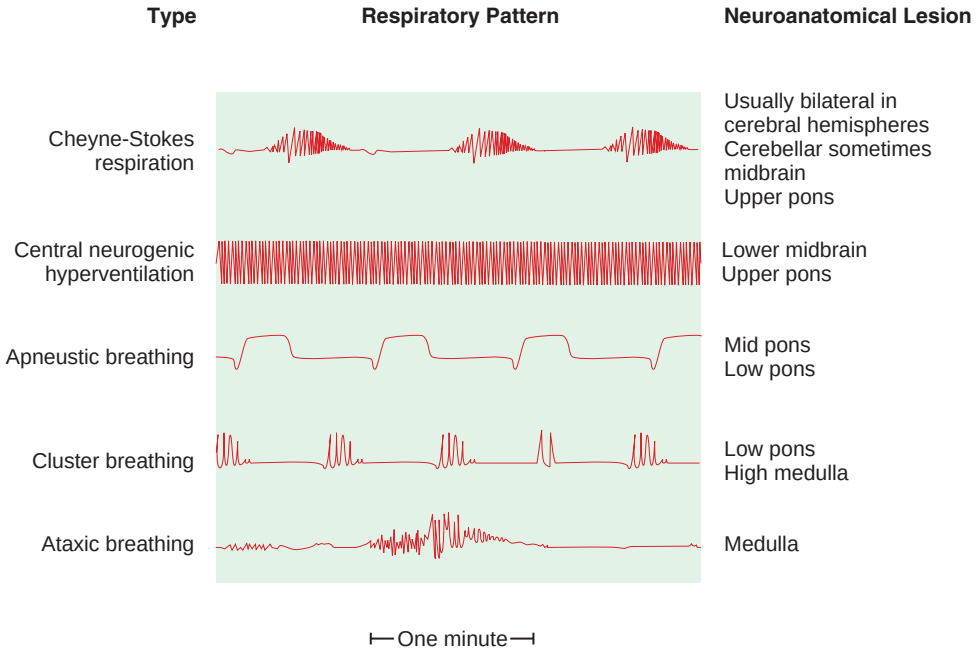


FIGURE 36-6 ▲ Injury to the brainstem can result in various abnormal respiratory patterns.

Diagnostic Testing

CT is performed as an initial diagnostic test to identify structural injuries in the brain and intracranial bleeding. A CT scan can be obtained quickly. One disadvantage of the CT scan is that it does not provide adequate views of the cerebelli and brainstem. An initial CT scan is performed without contrast. CT scans performed with intravenous contrast are used to investigate suspected masses (ie, tumors or abscesses). MRI is useful to assess structures in the posterior fossa and spinal cord. Magnetic resonance angiography may be used to evaluate cerebral vascular injuries such as carotid or vertebral dissection.

Cerebral angiography is the gold standard diagnostic test to investigate injuries to cerebral blood vessels. A cerebral angiogram may also be obtained to confirm the absence of cerebral blood flow in brain death.

Transcranial Doppler (TCD) ultrasonography indirectly evaluates cerebral blood flow and autoregulatory mechanisms by measuring the velocity at which blood travels through blood vessels. TCD may also be used to document cessation of blood flow to the brain.

Other diagnostic tests are used to assess electrical impulse transmission in the brain. These tests are often obtained to provide information for patient prognosis. Neurophysiological tests include the electroencephalogram (EEG), brainstem auditory evoked responses (BAERs), and somatosensory evoked potentials (SSEPs). The EEG measures electrical activity in all regions of the cortex and is useful in identifying seizures and correlating the abnormal neurological examination with abnormal cortical function. The EEG is necessary in ruling out subclinical or nonconvulsive seizures in the comatose patient. It may also be used as a confirmatory test in brain death to demonstrate cessation of electrical conduction to the cerebral cortex. A common finding in a patient with TBI is slowing of electrical activity in the area of injury. BAER and SSEP are useful prognostic tests in a patient with TBI. Abnormal results of either of these tests may help confirm a diagnosis of severe brainstem or cortical dysfunction.

Global cerebral oxygenation can be measured using jugular venous oxygen saturation (SjO_2), which is determined by inserting an intravenous catheter into the internal jugular vein and directing it upward toward the brain. The SjO_2 is indicative of oxygen extraction in the brain; in the healthy brain, SjO_2 is 55% to 70%.[12] If SjO_2 is less than 55%, cells are not extracting oxygen from the hemoglobin molecule efficiently (see Chapter 17 for discussion of oxygen consumption). If SjO_2 is greater than 70%, the rate of oxygen extraction is increased. An increase in cerebral oxygen extraction often occurs as a result of cerebral ischemia.

Measurement of oxygen delivery and extraction in brain tissue using an oxygen sensor placed in the deep white matter may be used as an adjunct to ICP and cerebral perfusion pressure (CPP) monitoring. Therapies aimed at keeping the partial pressure of brain tissue oxygen ($PbtO_2$) greater than 15 to 20 mm Hg in conjunction with ICP and CPP management may optimize the patient's chances for maximal functional recovery.[13,14]

In addition, microdialysis is used to measure cellular metabolites, such as glutamate, as markers of cellular dysfunction and injury. A small microdialysis catheter is inserted into the brain tissue through a hole made in the skull. Small amounts of CSF-like fluid are infused at very slow rates by a specialized infusion pump, and extracellular fluid is pumped out into a collection chamber. Currently, this monitoring modality primarily is used in the context of research.

▲ Management

Guidelines for the management of severe TBI have been developed by the Brain Trauma Foundation and the American Association of Neurological Surgeons to disseminate evidence-based recommendations.[14] The goal of these guidelines is to create a consistent standard for the care and treatment of patients with severe TBI. Several studies have suggested the benefit of evidence-based standardization of

care in improving functional outcomes after TBI.[15] Specific guidelines for managing severe TBI in infants, children, and adolescents are available, outlining the unique needs of the pediatric population.[16] The focus of the discussion in this chapter is the management of severe TBI in adults.

Initial Management

Initial assessment and treatment of the patient with TBI begins immediately after the insult, often with prehospital care providers. Specific guidelines for prehospital management of TBI were revised and published by the Brain Trauma Foundation in 2007. Prehospital treatment of the patient with a head injury focuses on rapid neurological assessment, definitive airway management, and treatment of hypotension.[17] These guidelines emphasize early correction of hypoxia and hypercarbia, which have been shown to affect morbidity and mortality in patients with TBI (Fig. 36-7).[7]

Airway management is a crucial initial step to prevent hypoxia and hypercarbia, which exacerbate secondary brain injury. Initial mechanical ventilation strategies aim to maintain normal ventilation or a partial pressure of carbon dioxide ($PaCO_2$) within normal limits (35 to 45 mm Hg). Signs

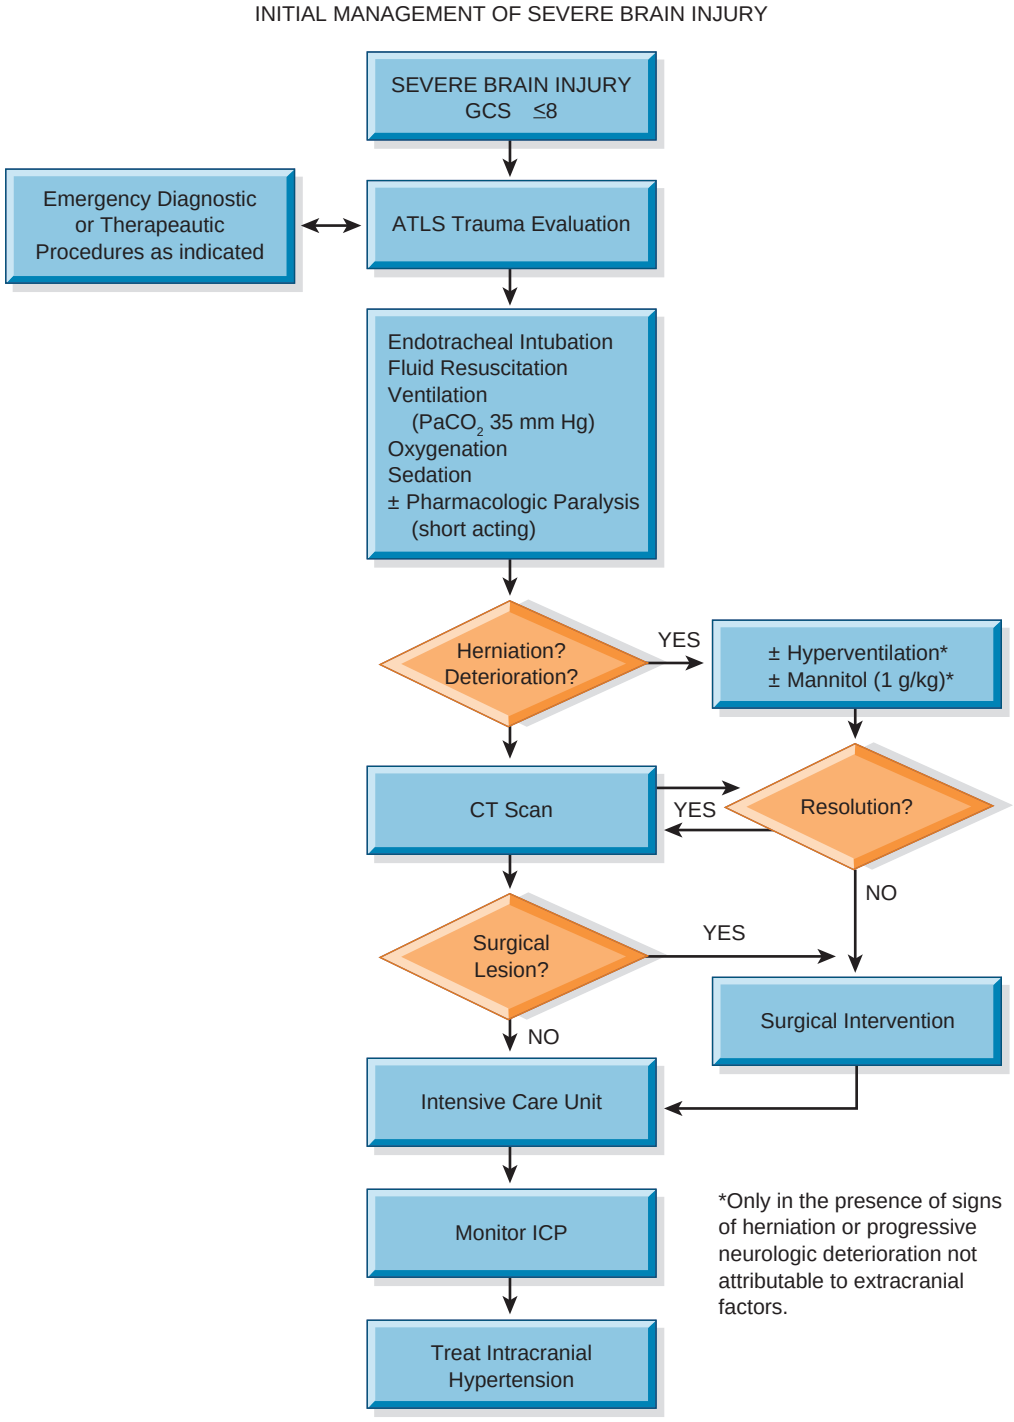

FIGURE 36-7 ▲ Flowchart for resuscitation of the patient with a severe head injury before ICP monitoring. (© 2000 Brain Trauma Foundation, Inc. Used with permission.)

of cerebral herniation may necessitate hyperventilation therapy ($PaCO_2$, 30 to 35 mm Hg). The goal of hyperventilation in TBI is to decrease $PaCO_2$, causing constriction of cerebral blood vessels and decreased cerebral blood volume. Decreased blood volume in the brain results in decreased ICP. Global cerebral vasoconstriction places healthy regions of brain tissue at risk for developing ischemia and should not be used prophylactically.[14] Continuous surveillance of end tidal carbon dioxide ($EtCO_2$) or frequent assessment of $PaCO_2$ is essential to prevent cerebral ischemia. Monitoring cerebral oxygenation (ie, SjO_2 or $PbtO_2$) is an option for identifying cerebral ischemia. Research suggests that the brain experiences decreased blood flow in the first 24 hours after injury; therefore, hyperventilation should be avoided during this period.[14]

Diagnostic testing is performed subsequent to the initial resuscitation to evaluate the need for immediate surgical intervention. Typical tests include radiographs of the cervical spine and a CT scan of the brain, which is useful in diagnosing intracranial bleeding that may require surgical intervention. Additional imaging and blood tests may be obtained to rule out systemic injuries and assist in treating complications. The mechanism of injury helps determine appropriate diagnostic testing.

Continuing management seeks to control ICP, promote cerebral perfusion, and correct the primary pathological process. Examples of nursing diagnoses for the patient with TBI are given in Box 36-2. General management of the patient with TBI requires a holistic, multisystem, multidisciplinary approach, taking into consideration the unique physiological and psychosocial characteristics of the patient (Box 36-3).

Monitoring and Controlling Intracranial Pressure

ICP monitoring, which is discussed in depth in Chapter 34, allows the health care team to make rapid treatment decisions based on pressure displays and ICP waveform analysis. ICP monitors are typically inserted by neurosurgeons at the bedside or in the operating room. ICP monitoring is recommended for patients with severe head injury (GCS score < 8) and CT scan abnormalities on admission. ICP monitoring may also be considered when the CT scan is normal but the patient meets two or more of the following criteria: older than 40 years, posturing, or a systolic blood pressure less than 90 mm Hg.[14]

Nursing interventions to manage increased ICP include maintaining body alignment as well as avoiding sharp turning of the head to one side and sharp hip flexion. Turning the head to one side causes compression of the jugular vein, preventing drainage of venous blood from the head, increasing ICP. Sharp hip flexion increases intra-abdominal pressure, decreasing venous outflow and causing an increase in ICP.

BOX 36-2 EXAMPLES OF NURSING DIAGNOSES

For the Patient With a Head Injury

- Risk for Ineffective Cerebral Tissue Perfusion
- Ineffective Airway Clearance related to diminished airway protective reflexes
- Risk for Infection related to multiple indwelling monitoring devices
- Impaired Skin Integrity related to physical immobilization
- Imbalanced Nutrition: Less Than Body Requirements related to increased energy expenditure
- Acute Pain related to injury
- Disturbed Sleep Pattern related to ICU routine care and environment
- Interrupted Family Processes related to acute crisis
- Anticipatory Grieving related to uncertain prognosis and critical illness

Maintaining Cerebral Perfusion

Management of cerebral perfusion involves control of ICP and maintenance of mean arterial pressure (MAP). Cerebral perfusion pressure (CPP) is calculated by subtracting ICP from MAP: CPP = MAP − ICP. Maintenance of CPP within the range of 50 to 70 mm Hg prevents cerebral ischemia at the lower end and mitigates the risk for acute respiratory distress syndrome (ARDS), which has been shown to occur more frequently when CPP is pushed over the upper limit of 70 mm Hg.[14]

Preventing and Treating Seizures

Seizures during the early stages of TBI can have severe negative effects on ICP and cerebral metabolic demands. Evidence-based guidelines support the use of antiseizure medication in the first 7 days after TBI.[14] Seizures that occur after this initial period are called late posttraumatic seizures and are not prevented by prophylactic administration of antiseizure medications.[14,18]

Phenytoin is one of the most common drugs used in the acute period. Phenytoin is usually given as a bolus dose intravenously, followed by a maintenance dosing schedule. The patient is monitored closely for hypotension, bradycardia, rashes, and IV infiltration during and after administration. Hypotension can be mitigated by administering the drug slowly (no greater than 50 mg/min). Truncal rashes with varying severity, including Stevens-Johnson syndrome, can occur with administration of phenytoin. The drug should be discontinued at the appearance of rash. The drug, fosphenytoin, is administered IV or IM and is metabolized in the body to phenytoin. Fosphenytoin can be administered rapidly without the infusion site reactions associated with phenytoin.

Maintaining a Normal Body Temperature

Hyperthermia (body temperature >37.5°C) in a patient with severe TBI increases cerebrometabolic demands and may compound secondary brain injury. Frequent monitoring of body temperature is necessary to maintain normothermia (35°C to 37.5°C). Infection must be ruled out as the cause of fever, and cooling methods are used as needed to maintain a normal body temperature. Inducing hypothermia in patients with TBI may be beneficial in improving functional

BOX 36-3 *COLLABORATIVE CARE GUIDE for the Patient With a Head Injury*

Outcomes	Interventions
Oxygenation/Ventilation	
Patient will maintain a patent airway. Lungs will be clear to auscultation. Arterial pH, PaO_2, and SaO_2 will be maintained within normal limits. $ETCO_2$ or PCO_2 will be maintained within prescribed range. There will be no evidence of atelectasis or pneumonia on chest x-ray.	• Auscultate breath sounds every 2–4 h and as needed. • Hyperoxygenate before and after each suction pass. • Avoid suction passes >10 s. • Monitor ICP and CPP during suctioning and chest physiotherapy. • Provide meticulous oral hygiene. • Monitor for signs of aspiration. • Encourage nonintubated patients to use incentive spirometer, cough, and deep breathe every 4 h and as needed. • Turn side-to-side every 2 h. • Move patient out of bed to chair one to two times daily when ICP has been controlled.
Circulation/Perfusion	
Patient will exhibit normal sinus rhythm without ectopy or ischemic changes. Patient will not experience thromboembolic complications.	• Monitor for myocardial ischemia and dysrhythmias due to sympathetic activation and catecholamine surges. • Prevent DVT with the use of pneumatic compression devices, antiembolism stockings, and subcutaneous heparin. • Implement early mobilization. Facilitate moving to a chair one to two times daily. • Monitor blood pressure continuously by arterial line or frequently by noninvasive cuff. • Monitor oxygen delivery (hemoglobin, SaO_2, cardiac output). • Administer red blood cells, inotropes, intravenous fluids as indicated.
Cerebral Perfusion/Intracranial Pressure	
CPP will be >60 mm Hg. ICP will be <20 mm Hg. Patient will not experience seizure activity.	• Monitor ICP and CPP every hour. • Perform neurological checks every 1–2 h. • Elevate the head of bed to 30 degrees unless contraindicated. • Maintain proper body alignment, keeping the head in a neutral position, and avoiding sharp hip flexion. • Maintain normothermia. • Maintain a quiet environment, cluster care, and provide rest periods. • Provide sedation as necessary and as prescribed. • Administer prophylactic antiepileptic agents as prescribed to prevent seizure activity.
Fluids/Electrolytes	
Serum electrolytes will be within normal limits. Serum osmolality will remain within prescribed range.	• Strict documentation of input/output; consider insensible losses from intubation, fever, and the like. • Monitor serum electrolytes, glucose, and osmolality as ordered. • Consider need for electrolyte replacement therapy and administer per physician order or protocol.
Mobility/Safety	
There will be minimal and transient changes in ICP/CPP during treatments or patient care activities. ICP/CPP will return to baseline within 5 min. Patient will not experience complications related to prolonged immobilization (eg, DVT, pneumonia, ankylosis). Patient will not harm self by dislodging medical equipment or falling.	• Provide range of motion and functional splinting for paralyzed limbs or patients in a coma. • Position patient off of pressure points at least every 2 h. • Consider use of specialty mattresses based on skin and risk factor assessments. • Keep bed rails in the upright position. • Provide restraints if necessary to prevent dislodgment of medical devices as policies permit.

outcome, although further research is required before this practice is recognized as a standard.[14]

Identifying and Managing Sympathetic Storming

Patients with severe TBI may experience a condition known as sympathetic storming. This condition is characterized by diaphoresis; agitation, restlessness, or posturing; hyperventilation; tachycardia; and fever. Sympathetic storming occurs as a result of an imbalance of the sympathetic and parasympathetic nervous systems. The precise cause of this imbalance is poorly understood; however, theories have suggested that TBI causes disruption in autonomic relay pathways and injury to the cerebral cortex, which limits control of autonomic function.[19] Triggers of a storming episode may include any stressful event, such as endotracheal suctioning, turning, development of fever, or alarm sounds in the patient's room.[19] The diagnosis of sympathetic storming is typically based on the appearance of suggestive signs and symptoms. Treatment focuses on finding a medication regimen that suppresses the sympathetic nervous system while avoiding adverse effects such as hypotension and bradycardia. Medication regimens may include one or more of the following drug classes: alpha-adrenergic blockers, beta blockers, opiates, sedatives, gamma-aminobutyric acid agonists, and dopamine agonists. Nursing management of the patient with sympathetic storming includes monitoring and assessing the patient to determine the effectiveness of the medication regimen, reducing environmental stimuli to reduce triggers of storming episodes, and preventing complications such as skin breakdown or injury from restlessness or agitation. Patients experiencing sympathetic storming may appear uncomfortable and evoke concern in family members; therefore, family education is important.

Monitoring Fluid and Electrolyte Status
