To our former students. You have been our teachers and our source of inspiration. Thanks for all you do for critically ill patients and families.

To our husbands John and Barry. Thanks for your never ending support, love, and encouragement.

Preface

The practice of critical care nursing has changed dramatically since its inception in the 1960s. Critical care nurses, more than ever before, must possess an extensive body of knowledge in order to provide competent and holistic care to critically ill patients and their families. Critically ill patients are no longer found just in intensive care units. Instead, they are cared for in the emergency department, in progressive care units, in postanesthesia care units, and in the home. Today, critically ill patients are liable to be older and sicker than ever before, thus demanding extensive knowledge to meet their complex needs. Advances in nursing, medicine, and technology; the rapidly changing health care climate; and the shortage of nursing staff and faculty are other factors that have come together to effect great changes in the practice of critical care nursing.

Some of the requisite knowledge for the practice of critical care nursing can be attained through formal education and textbooks, like this one. The rest can only be gained through experience. It is our goal, with this 10th edition of *Critical Care Nursing: A Holistic Approach*, to assist readers on their journey by providing a comprehensive, up-to-date resource and reference.

As in past editions, this 10th edition promotes excellence in critical care nursing. Presenting theory and principles within the context of practical application helps the reader to gain competence and confidence in caring for critically ill patients and their families. As always, the patient as the center of the health care team's efforts is emphasized throughout. In the highly specialized and complicated technical environment of critical care, knowing how to deliver holistic care and demonstrating caring behaviors are just as important as knowing how to operate complex equipment and perform difficult procedures.

New to this 10th edition, the reader will find a special feature on genetics, more emphasis on evidence-based practice, and a more streamlined text that focuses on the most important knowledge and practices for the critical care nurse.

▲ An Overview

Critical Care Nursing: A Holistic Approach, 10th edition, consists of 13 parts. The following is a brief overview of those parts and the information they contain.

Part 1: The Concept of Holism Applied to Critical Care Nursing Practice

The six chapters that make up Part 1 introduce the student to the concept of holistic care, as it applies in critical care practice. In Chapter 1, the student is introduced to critical care nursing practice. Chapters 2 and 3 review the psychosocial effects of critical illness on the patient and the family, respectively. These chapters also describe the effect of the critical care environment on the patient and review actions the nurse can take to help reduce environment-induced stress and promote healing. Chapter 4 emphasizes the role of patient and family education in critical care. Chapter 5 focuses on strategies for relieving pain and promoting comfort. We conclude the part with Chapter 6, which concentrates on end-of-life and palliative care.

Part 2: Professional Practice Issues in Critical Care

This part consists of three chapters that are of concern to the nursing profession. In Chapters 7 and 8, ethical and legal issues are explored. Chapter 9 describes characteristics of critical care nurses, delineates aspects of nursing professionalism, and defines critical attributes of nursing excellence.

Part 3: Special Populations in Critical Care

The four chapters in this part focus on the special needs of certain groups of people who are critically ill. Chapters 10, 11, and 12 focus on the pediatric patient, the pregnant patient, and the elderly patient, respectively. Chapter 13 describes the role of the nurse in caring for the patient who is recovering from anesthesia.

Part 4: Special Situations in Critical Care

This section opens with a chapter that focuses on the care of the patient who is being transported within or between facilities as well as the role of the rapid response team. The second chapter in this section describes the role of the critical care nurse in disaster management.

Part 5: Cardiovascular System

This part, the first of eight organ system–based parts, focuses on the care of the patient with a cardiovascular disorder. Each organ system–based part begins with a chapter that reviews the anatomy and physiology of the organ system under discussion (e.g., Chapter 16). The part then continues with a chapter on patient assessment (e.g., Chapter 17), general patient management (e.g., Chapter 18), and common disorders (e.g., Chapter 19). In Part 5, heart failure and acute myocardial infarction are each given their own chapters (Chapters 20 and 21, respectively). The unit concludes with a discussion of the most recent developments in cardiac surgery (Chapter 22). Throughout the unit, the latest diagnostic

tests (such as cardiac serum markers), the newest medications for treating cardiovascular disorders, and updates on technologies (such as the left ventricular assist device, the implantable cardioverter defibrillator, and the cardiac pacemaker) are discussed.

Part 6: Respiratory System

In this part, current assessment technologies (such as end tidal carbon dioxide monitoring) and the newest modes of ventilation for patients in respiratory failure are discussed. Evidence-based treatment strategies for respiratory disorders such as pneumonia, pleural effusion, and chronic obstructive pulmonary disease are described. Chapter 27 is devoted to the latest developments in the assessment and management of the patient with acute respiratory distress syndrome (ARDS).

Part 7: Renal System

In this edition of the text, Part 7 includes a more in-depth discussion of the assessment and management of fluids, electrolytes, and acid–base balance. Updates on laboratory and diagnostic tests are included. The newest dialysis technologies and the latest drugs are discussed in Chapter 30. Chapter 31 focuses on common renal disorders, including recent developments in the care of the patient with renal failure.

Part 8: Nervous System

This part offers updates on neurological diagnostic studies and the newest approaches to treating the patient with increased intracranial pressure. The latest drugs for treating neurological disorders and the most recent developments in neurosurgery are addressed. Separate chapters are devoted to care of the patient with a head injury and spinal cord injury.

Part 9: Gastrointestinal System

In Part 9, the latest diagnostic tests for evaluating patients with gastrointestinal disorders are discussed. The management of patients with gastrointestinal disorders has been updated to include the newest drugs, the latest developments in the use of enteral and parenteral nutrition, and recent trends in the treatment of common disorders such as liver failure and hepatitis.

Part 10: Endocrine System

In this edition, Part 10 includes an assessment chapter covering multiple components of the endocrine system. The content is organized by the major gland, and for each gland addressed in the chapter, the reader is given information on the history, laboratory tests, and diagnostic tests. The most current information on the treatment of endocrine disorders, especially glycemic control and diabetic emergencies, is included in Chapter 44.

Part 11: Hematological and Immune Systems

This part continues to be a unique feature that is not included in many critical care texts. The numerous recent developments in organ and hematopoietic stem cell transplant are described in Chapter 47. Chapter 48 addresses up-to-date information on the assessment and management of critically ill patients with HIV/AIDS as well as those with oncological emergencies. The latest trends in the treatment of patients with hematological disorders such as disseminated intravascular coagulation are included in Chapter 49.

Part 12: Integumentary System

This part includes three chapters not covered in other critical care texts: the anatomy and physiology of the integumentary system, assessment of the integumentary system, and management of integumentary disorders, respectively. Evidence-based assessment and management of wounds are addressed. In addition, care of the critically ill burn patient is covered in Chapter 53.

Part 13: Multisystem Dysfunction

In Chapter 54, hypoperfusion states such as shock, systemic inflammatory response syndrome (SIRS), and multiple organ dysfunction syndrome (MODS) are discussed. The latest understanding of the pathophysiologic process is described, as well as how this knowledge guides the selection of the most recent interventions. Chapter 55 reviews care of the trauma patient, including the latest trends in the management of these complex patients. Chapter 56 reviews care of the patient with a drug overdose or poisoning, a problem that is becoming more common in the critical care setting.

Appendix

An appendix completes the textbook; it contains updated ACLS guidelines.

▲ Features

The features of the 10th edition of *Critical Care Nursing: A Holistic Approach* have been designed to assist readers with practice as well as learning.

Practice-Oriented Features

- **Considerations for the Older Patient boxes** highlight the special needs of this patient population and constitutes the largest numbers of critically ill patients.
- **Health History boxes** summarize key areas that should be covered and relevant information that may be revealed during the health history.

- **Nursing Diagnoses boxes** summarize common NANDA nursing diagnoses for particular conditions.
- **Collaborative Care Guides** describe how the health care team works together to manage a patient's illness and minimize complications. The information is presented in a tabular format, with outcomes in the first column and interventions in the second.
- **Teaching Guides** help the nurse to prepare patients and family members for procedures, assist patients and family members with understanding the illness they are dealing with, and explain postprocedure or postoperative activities.
- **Drug Therapy tables** summarize information related to the administration and monitoring of drug therapy.

Pedagogical Features

Learning Objectives, at the beginning of each chapter, help focus the reader's attention on important topics.

Clinical Applicability Challenges, at the conclusion of each chapter, consists of three to five **short-answer questions** or a **case study** followed by three to five short-answer questions.

▲ New to This Edition

- **New case study/short-answer questions** in every chapter guide the reader from knowledge to application. Discussion points for these questions are available on thePoint.
- **Evidence-Based Practice Highlights** help the reader to understand the importance of research-based practice and include excerpts from the latest AACN practice alerts as well as from recently published research and nationally published guidelines from the National Institutes of Health.
- **Spotlight on Genetics** appears in selected chapters and includes important genetic information and summaries of selected genetic disorders. These disorders may be the result of random genetic mutations, genetic mutations caused by environmental influences, or inherited mutated genes.
- **Patient Safety boxes** alert the reader to risk factors, signs and symptoms, side effects, and complications that the critical care nurse must anticipate and continuously monitor.

In order to streamline the text and to make important content readily available to users of the text, additional content to enhance learning and understanding of the chapters is available on thePoint. Visit the website to access:

- Chapter outlines
- Additional selected readings
- Chapter NCLEX-style review questions
- Answers to Chapter NCLEX-style review questions with accompanying rationales
- Internet resources

▲ Student and Instructor Resources

In addition to the chapter-specific content listed above, a wide variety of resources that support the student and instructor are also available online on thePoint.

Student Resources

Students who purchase this book have access to a wide variety of additional resources via thePoint website:

- Spanish-English audio glossary
- Concepts in Action animations
- Monographs of 100 commonly prescribed drugs
- Journal articles
- Learning objectives
- Nursing professional roles and responsibilities
- Heart and breath sounds
- Case study/short answer questions and discussion points
- Full text online

Additional study aids to help students review the basics are also available on thePoint:

- Practice and Learn video clips
- Watch and Learn video clips
- Clin Sims case study
- Clin Sim tutorial
- Dosage calculation quizzes

Instructor Resources

In addition to access to all of the student assets, instructors who adopt this text also have access to an Instructor's DVD-ROM, for those who prefer that format, as well as access to a special instructor's resource section on thePoint. The following are included on the DVD-ROM and the website:

- Test generator, featuring over a thousand questions
- Image bank, containing over 300 illustrations
- PowerPoint presentations and accompanying guided lecture notes for each chapter
- Syllabi
- Strategies for effective teaching

It is with great pleasure that we introduce these resources—the textbook and the accompanying interactive resource package—to you. One of our primary goals in creating these resources has been to promote excellence in critical care nursing practice so that nurses can help patients and families cope with the consequences of critical illness. It is our intent that these resources will provide aspiring and currently practicing critical care nurses the tools to make their optimal contribution to the care of critically ill patients and their families and to the nursing profession. We hope that we have succeeded in that goal, and we welcome feedback from our readers.

Patricia Gonce Morton, RN, PhD, ACNP-BC, FAAN
Dorrie K. Fontaine, RN, PhD, FAAN

Acknowledgments

This project required the help and cooperation of many people. First we want to thank our many colleagues who contributed to the text, either by authoring a chapter or by sharing their expertise as a reviewer. Our publisher, Lippincott Williams & Wilkins, through all editions of this book remains committed to producing the best text possible. We especially want to thank Helen Kogut, Senior Product Manager; Melanie Cann, former Senior Developmental Editor; and Elizabeth Nieginski, former Senior Executive Acquisitions Editor, for their support, commitment to excellence, and words of positive encouragement as they cheered us on to the finish line with this project. Special thanks are also due to Jacalyn Clay, former Editorial Assistant, for her assistance throughout the project.

We also wish to express our thanks to Regina Mabrey, who compiled and checked all the Internet resources that appear on thePoint website and to Lisa Vikell who assisted with all the references and additional selected readings. Their hours of work were an enormous help to us.

In addition, we wish to thank Dr. Dennis Cheek, a nationally known expert in genetics, for creating the new genetics feature, *Spotlight on Genetics*, that appears throughout the text.

And finally, we wish to express a word of thanks to our families and nursing colleagues who endured the time we took to complete this project.

Critical Care Nursing Practice: Promoting Excellence Through Caring, Collaboration, and Evidence

Roberta Kaplow, Kathleen Turner, and Michael V. Relf

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Describe the value of certification in critical care nursing.
2. Describe the value of evidence-based practice (EBP) in caring for critically ill patients.
3. Discuss the value of collaborative practice in critical care.
4. Provide examples of how the Synergy Model can promote positive patient outcomes.
5. Discuss future issues facing critical care nursing practice.

As the health care delivery system continues to evolve and transform, so too does the discipline of nursing and the specialty of critical care nursing. Today, the care of critically ill patients occurs not only in the traditional setting of the hospital intensive care unit (ICU) but also on the progressive care unit, medical and surgical clinical units, in the subacute facility, long-term care, community, and even the patient's home. As a consequence of recent health care reform legislation coupled with an aging population and application of genomics in personalized medicine, critical care nursing practice as we know it today will continue to evolve.

Since the first critical care unit opened in the late 1960s, significant technological, procedural, and pharmacological advances have occurred, accompanied by a knowledge explosion in critical care nursing and medicine. Consequently, critical care nurses, progressive care nurses, and home health nurses of the 21st century are routinely caring for the complex, critically ill patients who just a few decades ago would not have survived a critical illness. As a result, nurses are increasingly being challenged to integrate sophisticated technologies and interventions, implement care based on contemporary evidence while simultaneously caring for the whole person by addressing the psychosocial challenges and ethical conflicts associated with critical illness and delivering care not only to the patient but also to the patient's family, as defined by the patient—not in professional isolation but in collaboration with the interdisciplinary team.

In response to the ever-changing delivery system, critical care nurses are championing the needs of the patient and the family, integrating evidence to improve standards of care, striving to maintain patient safety, engaging in interdisciplinary collaboration, and developing healthy work environments (HWEs)—all in the pursuit of quality clinical outcomes. During the past several decades, critical care nurses have experienced firsthand what nurse scientists have consistently demonstrated—critical illness is not only a physiological alteration but also a psychosocial and spiritual process as well as a threat to individuals and their families. Through specialty certification by the American Association of Critical-Care Nurses (AACN), nurses voluntarily demonstrate their knowledge of critical care nursing. Furthermore, as health care becomes increasingly technical, the need for humanization is increasingly essential. Compatible with the need for "humanized" health care is the need to provide effective evidence-based interventions instead of those steeped in tradition or based on intuition.

This chapter describes select aspects of the critical care environment. These include the value of certification, evidence-based practice (EBP), quality and safety, healthy environments, and the AACN Synergy Model for Patient Care. Each of these, when implemented, helps promote optimal outcomes for acute and critically ill patients and their families.

▲ Value of Certification

"Certification is a process by which a nongovernmental agency validates, based on predetermined standards, an individual nurse's knowledge for practice in a defined functional or clinical area of nursing."[1] A white paper, *Safeguarding the Patient and the Profession*, published by the AACN, demonstrated the value of specialty certification.[2] Certification promotes continuing excellence in the critical care nursing profession helping nurses achieve and maintain an up-to-date knowledge base essential in the practice of critical care nursing.[2–4] In addition, it validates their knowledge to patients and families, employers, and themselves.

Value to the Patient and Family

As a consequence of medical errors, adverse outcomes, and complicated regulations governing reimbursement, many consumers are wary of today's health care delivery system. Certification provides patients and families with validation that the nurses caring for them have demonstrated experience and knowledge that exceeds that which is assessed in entry-level licensure examinations.[2] Nurses who have had their knowledge validated through a certification examination make decisions with greater confidence.[2,4,5] Although "failure to rescue" a patient in trouble cannot always be avoided, experienced and knowledgeable nurses are able to recognize signs and symptoms earlier and respond accordingly. In addition, certified nurses have demonstrated commitment to continual learning. This attribute is needed to care for patients with complex, multisystem problems requiring aggressive intervention and advanced technologies.

Value to Employers and Nurses

Certification allows the employer to know that the nurses working for them have the knowledge and expertise to promote optimal patient outcomes. Nurses who become certified have demonstrated their commitment to quality since they have taken the time to become certified in a specialty area of practice. Evidence across studies demonstrates that certified nurses have higher perceptions of workplace empowerment and do not intend to leave the profession.[4] In a review of the literature examining the perceived effects of specialty nurse certification, Wade[6] identified enhanced nurse communication and coordination of care with physicians and other health care team members, and nurse–physician collaboration was perceived to be more improved by certified nurses. Both communication and collaboration are essential to quality patient outcomes. Additionally, evidence also indicates that certified nurses intend to remain employed in an area where they can apply the knowledge.[4] It has been suggested that health care organizations that support and recognize the value of certification experience decreased turnover rates and higher nurse retention rates.[4]

As health care organizations apply to achieve Magnet designation by the American Nurses Credentialing Center (ANCC), certification is one of the many important factors considered.[7] Certification is also a means for hospitals to distinguish themselves from competitors.[2] In addition, hospital administrators must demonstrate to the Joint Commission that nurses are competent to provide care—certification is a clear demonstration of knowledge competency.[2]

Certification provides nurses with a sense of professional pride and achievement.[1] A survey by the American Board of Nursing Specialties revealed that most nurses who sat for certification examinations did so for personal fulfillment and commitment to excellence in practice.[8] Certified nurses demonstrate to their employers that they are taking responsibility for their own professional development, which may give them a competitive edge when seeking promotion or new career opportunities.

Research has identified that certified nurses perceive higher empowerment, recognize the intrinsic value of certification, experience enhanced collaboration with other members of the interdisciplinary team, and perceive knowledge being enhanced and validated through certification.[4–6]

▲ Evidence-Based Practice in Critical Care Nursing

Evidence-based practice (EBP) is "the process of shared decision making between practitioner, patient, and others significant to them based on research evidence, the patient's experiences and preferences, clinical expertise or know-how, and other available robust sources of information." (p. 57)[9] EBP is essential to help optimize patient outcomes in today's dynamic health care environment. In the United States, the Institute of Medicine (IOM), the ANCC, and the Joint Commission acknowledge EBP as a crucial step in improving healthcare quality.[10] Although knowledge regarding effective nursing interventions continues to increase, practice lags behind the available evidence. Practice based on intuition or information that does not have a scientific basis is not in the best interest of patients and families and should be discouraged when care decisions are being made.

EBP is often confused with conducting research. Research is conducted to generate new knowledge. Through translation of new knowledge, EBP takes what is known and uses it to guide patient care to achieve the best possible outcomes.[11] In the translation of knowledge into clinical practice, it is essential for the critical care nurse to consider the strength or level of the evidence. First, much of health care and nursing practice has little or no evidence or research to support it. Consequently, other sources of evidence must be considered. Second, different research designs have limitations that affect generalizability of findings to populations other than those studied.[12] Baumann[13] argues that nurses and other health care professionals must critically examine the evidence that they utilize in their clinical reasoning but should not restrict their definition to what constitutes evidence to only what can be measured in a randomized controlled trial (RCT). Therefore, it is essential for critical care nurses to familiarize themselves with the levels of evidence in order to evaluate the evidence or research and determine the applicability to their patients.

The AACN was one of the first nursing organizations to develop a rating system for evidence.[12] In 2008, a work group was charged by the AACN board of directors to review the evidence-leveling system and to align the AACN hierarchy with other health care organizations.

Levels of Evidence

In EBP, the lowest levels of evidence include the opinions of authorities or expert committees. This level of evidence would result from clinical practice committees and professional organizations that may convene to discuss guidelines when higher levels of evidence are not available. The next level of evidence is a single descriptive, qualitative, or physiologic study. Continuing up the evidence hierarchy is the systematic review of descriptive, qualitative, or physiologic studies. A systematic review refers to rigorous and systematic synthesis of findings from several studies in a focused area of inquiry. Proceeding in the hierarchy, a single correlational or observational study provides the next level of evidence. To guide clinical practice, these quantitative studies lend themselves to precise measurement allowing for examination of relationships. The next level is the systematic review of correlational or observational studies. Moving toward the stronger levels of evidence is a single RCT and nonrandomized control trial (quasi-experimental). The highest level of evidence is the systematic review of RCTs, also referred to as a meta-analysis. For studies utilizing qualitative methods, a meta-synthesis is analogous to a meta-analysis.[14]

Using ventilator-associated pneumonia (VAP), as an example, a critical care nurse would identify much literature on VAP yielding editorials from experts, descriptive studies, single RCTs, and meta-analyses. Since meta-analyses, the highest level of evidence, exist for VAP, critical care nurses can revise protocols and implement interventions based on evidence to prevent VAP. To improve quality of care and to protect patient safety during critical illness, critical care nurses must be able to systematically gather, review, synthesize, and evaluate the evidence to guide practice changes and promote quality clinical outcomes.

Barriers to Implementation

Despite the value of EBP, it unfortunately takes an average of 17 to 20 years to translate research findings into clinical practice.[15] Barriers to implementation include lack of knowledge of the research process, limited access to literature, lack of confidence in ability to critique research, limited interest in scientific inquiry, limited power to change practice, time factors, and lack of organizational support and commitment including resources and availability of mentors.[10,16]

An organization's culture, climate, or environment has significant impact on the nurses' autonomy to change nursing practice and the ability to adapt to change.[10] Critical care nurses are often adept and skillful in direct patient care but when care is not based on evidence, it is difficult to optimize outcomes, utilize resources efficiently, and protect patient safety. Thus, it is essential for critical care nurses to have the required knowledge, skills, and abilities for locating, evaluating relevant evidence, and translating the evidence into practice.

Strategies to Promote Implementation

Several strategies have been proposed to help enhance incorporating evidence into clinical practice including the use of protocols, clinical pathways, algorithms, and educational interventions. Increasing a critical care nurses' awareness of available resources and educating and mentoring them to implement EBP activities are essential. Similar to building a house, an organization committed to EBP must first establish EBP as a foundation of everyday practice and create a culture of clinical inquiry and commitment to lifelong learning. Accountability and role modeling, formal and informal, must be present for a successful foundation.[17,18]

Several resources are available for critical care nurses to facilitate adoption of an EBP culture. Superb databases include PubMed, CINAHL, and MEDLINE. The Cochrane Collaboration, a website containing high-quality, independent evidence to inform health care decision making and obtain evidence-based information is available via the worldwide web. In addition, professional nursing organizations have research-based practice recommendations frequently available via their websites. For example, AACN's Practice Alerts section is available to members as well as to the public. Other EBP resources include the websites and publications from the Agency for Healthcare Research and Quality (www.ahrq.gov), Centers for Disease Control and Prevention (www.cdc.gov), Institute for Healthcare Improvement (www.ihi.org), the IOM (www.iom.edu), National Guidelines Clearinghouse (www.guidelines.gov), National Institute for Health and Clinical Excellence in the United Kingdom (www.nice.org.uk), National Library of Medicine (www.nlm.nih.gov), and American Nurses Association (www.nursiingworld.org) as well as the Society of Critical Care Medicine (www.sccm.org). Table 1-1 summarizes evidence of perceived barriers regarding the implementation of EBP and aligns strategies for those perceived barriers.

▲ Healthy Work Environments

The current nursing shortage calls for major change in the workplace. A healthy work environment (HWE) can lead to positive patient outcomes. In addition, nurses gravitate to facilities that have optimal work conditions. Conversely, unhealthy work environments play a role in health care errors, result ineffective care, waste scarce resources leading to increased costs associated with health care, and contribute to moral distress and adverse outcomes.

AACN affirms that the best way to address the nursing shortage is to focus on HWEs. After conducting an extensive literature search, AACN developed the HWE initiative based on data indicating that harmful health care working environments exist nationwide and that these environments result in medical errors, poor health care delivery, and dissatisfaction among health care providers. The HWE initiative focuses on barriers to employee and patient safety and identifies six essential standards (Box 1-1). The six elements discussed encompass the aspects that are most important as nurses strive to provide optimal care.[19] Boxes 1-2 through 1-7 list the critical elements inherent in the respective standards.

Table 1-1 Barriers to and Recommended Strategies to Optimize Evidence-Based Practice (EBP) in Critical Care

Perceived Barriers to EBP	Strategies to Overcome Perceived Barriers
Time	
• No time to read and evaluate research or implement EBP	• Schedule time for review and discussion of evidence in the form of EBP committees • Nurses need time away from clinical bedside responsibilities for EBP activities
Knowledge	
• Unaware of research • Literature not compiled in one place • Not capable of evaluating quality of research	• Invest, as a student, in the process of searching and evaluating the evidence • Be a change agent in the facility, mentoring nurses who are less familiar with the process • Commit to lifelong learning
Resources and Mentoring	
• Lack of evidence • Isolated from knowledgeable colleagues • Lack of computers, computer skills, library access, search skills • Difficulty understanding research	• Administration must recognize and commit to EBP, putting systems in place to support the clinical nurses in their role with EBP • Managers need to recognize the ability of clinical nurses, provide the necessary resources, and document the effectiveness of initiatives • Implementation of an evidence-based champion • Designated work groups
Culture	
• No authority to change practice • Other staff and disciplines not supportive • Research not generalizable to setting • Lack of value of research in practice	• A research-based needs assessment to provide an evidence-based foundation for organizational strategic planning • Performance appraisals and clinical ladder reviews require examples of EBP • Educational activities that help clinicians critically review the literature • Clinical resources available 24 h a day • Streamlined processes for practice • Incorporating the doctor of nursing practice role as leader of this process • Progress reported to a central source and shared among clinical areas and facilities

J Perianesth Nurs 25(2): 64–70, 2010; and Schulman CS: Strategies for starting a successful evidence based practice program. Adv Crit Care 19(3):301–311, 2008.

Skilled Communication

As miscommunication is identified as a cause of many sentinel events in health care, skilled communication is essential to prevent these errors from occurring. A large majority of sentinel events reported to the Joint Commission from 2004 through the fourth quarter of 2010 were related to communication issues.[20]

AACN partnered with VitalSmarts, L.C., to conduct a study of conversations that do not occur in hospitals, to the detriment of patient safety and provider well-being. The "Silence Kills" study used focus groups, interviews, workplace observations, and surveys of nurses, physicians, and administrators in urban, rural, and suburban hospitals nationwide.[21] Overwhelming data indicated that poor communication and ineffective collaboration were prevalent among health care provider interactions.

In this report,[21] 53% of nurses reported concern about a peer nurse's competence but only 12% spoke with this peer about the concerns. Similarly, 34% of nurses were concerned about a physician's competence but only 12% spoke with this peer to discuss concerns. In both situations, failure to communicate skillfully and professionally can be linked to poor patient care and clinical outcomes.

A pharmacist reported letting incorrect orders "slide" if the physician was a "jerk" and the incorrect dose was not going to make the patient sicker. Another pharmacist reported filling an incorrect prescription without question because of the hostility experienced when confronting the physician in the past. Several physicians in this study stated that they worked

BOX 1-1 Essential Elements of a Healthy Work Environment (HWE)

- *Skilled Communication.* Nurses must be as proficient in communication skills as they are in clinical skills.
- *True Collaboration.* Nurses must be relentless in pursuing and fostering true collaboration.
- *Effective Decision Making.* Nurses must be valued and committed partners in making policy, directing and evaluating clinical care, and leading organizational operations.
- *Appropriate Staffing.* Staffing must ensure the effective match between patient needs and nurse competencies.
- *Meaningful Recognition.* Nurses must be recognized and must recognize others for the value each brings to the work of the organization.
- *Authentic Leadership.* Nurse leaders must fully embrace the imperative of a HWE, authentically live it, and engage others in its achievement.

From http://www.aacn.org/WD/HWE/Docs/HWEStandards.pdf.[21]

BOX 1-2 Standard 1: Critical Elements of Skilled Communication

Nurses must be as proficient in communication skills as they are in clinical skills.

- The health care organization provides team members with support for and access to education programs that develop critical communication skills including self-awareness, inquiry/dialogue, conflict management, negotiation, advocacy, and listening.
- Skilled communicators focus on finding solutions and achieving desirable outcomes.
- Skilled communicators seek to protect and advance collaborative relationships among colleagues.
- Skilled communicators invite and hear all relevant perspectives.
- Skilled communicators call on goodwill and mutual respect to build consensus and arrive at common understanding.
- Skilled communicators demonstrate congruence between words and actions, holding others accountable for doing the same.
- The health care organization establishes zero-tolerance policies and enforces them to address and eliminate abuse and disrespectful behavior in the workplace.
- The health care organization establishes formal structures and processes that ensure effective information sharing among patients, families, and the health care team.
- Skilled communicators have access to appropriate communication technologies and are proficient in their use.
- The health care organization establishes systems that require individuals and teams to formally evaluate the impact of communication on clinical, financial, and work environment outcomes.
- The health care organization includes communication as a criterion in its formal performance appraisal system, and team members demonstrate skilled communication to qualify for professional advancement.

From http://www.aacn.org/WD/HWE/Docs/HWEStandards.pdf.[21]

BOX 1-3 Standard 2: Critical Elements of True Collaboration

Nurses must be relentless in pursuing and fostering true collaboration.

- The health care organization provides team members with support for and access to education programs that develop collaboration skills.
- The health care organization creates, uses, and evaluates processes that define each team member's accountability for collaboration and how unwillingness to collaborate will be addressed.
- The health care organization creates, uses, and evaluates operational structures that ensure the decision-making authority of nurses is acknowledged and incorporated as the norm.
- The health care organization ensures unrestricted access to structured forums, such as ethics committees, and makes available the time needed to resolve disputes among all critical participants, including patients, families, and the health care team.
- Every team member embraces true collaboration as an ongoing process and invests in its development to ensure a sustained culture of collaboration.
- Every team member contributes to the achievement of common goals by giving power and respect to each person's voice, integrating individual differences, resolving competing interests, and safeguarding the essential contribution each must make in order to achieve optimal outcomes.
- Every team member acts with a high level of personal integrity.
- Team members master skilled communication, an essential element of true collaboration.
- Each team member demonstrates competence appropriate to his or her role and responsibilities.
- Nurse managers and medical directors are equal partners in modeling and fostering true collaboration.

From http://www.aacn.org/WD/HWE/Docs/HWEStandards.pdf.[21]

with peers who were incompetent, but they did not confront them. Rather, they avoided scheduling sicker patients when the incompetent physician was scheduled to work. The data further suggested that physicians were equally as unlikely to confront a peer as a nurse or other health care provider. This study also stated that 88% of physicians reported working with people with persistently poor clinical judgment, causing deleterious complications.[21]

Seventy-seven percent of nurses were concerned about the disrespect they experience in the health care environment. They reported being treated discourteously or abusively in at least 25% of their interactions. This study found a significant correlation between the frequency of being mistreated and the intent to resign from the job. The study concluded that health care providers repeatedly observe errors and dangerous levels of incompetence. Yet they do not speak up; rather, they consider leaving their respective units because of their concerns.[21]

True Collaboration

Collaboration has been defined as a "sharing of knowledge between stakeholders with joint responsibility for the outcome."[22] It permits people with varied expertise to combine efforts to accomplish the goal of helping a client, program, or organization.[23] The collaborative outcome is the integration of solutions contributed by more than one person.[24]

Many studies have been conducted regarding nurse–physician collaboration. The data suggest that a collaborative relationship was more important to nurses than physicians. However, physicians rated the quality of the collaborative relationship that existed higher than nurses did.[25–33] Ninety percent of all AACN members have reported that collaboration with physicians and administrators is among the most important elements in creating an HWE.[19]

A number of outcomes have been linked to positive nurse–physician collaborative relationships. Specifically reported are nurse and physician satisfaction,[34,35] nurse retention,[33] and attainment of optimal patient outcomes.[34–42] It has also been suggested that a positive nurse–physician relationship can result in a decrease in errors.[34] Data also suggest that a decrease in mortality and in length of stay in the ICU is linked to positive nurse–physician collaboration.[43] One researcher reported a direct relationship between nurse–physician collaboration and efficiency of health care workers.[44]

Despite the reported benefits of collaboration, it is not practiced often enough.[22] A number of barriers exist that preclude its existence in health care organizations. The lack of an agreed-upon definition and variation in how collaboration is conceptualized, the lack of time for communication, and the complexity of the skills required to ease the process are daunting.[22] Other barriers have historically included professional cultures, immaturity of nurses and physicians, coupling of unassertive nurse behavior and aggressive physician

BOX 1-4 Standard 3: Critical Elements of Effective Decision Making

Nurses must be valued and committed partners in making policy, directing and evaluating clinical care, and leading organizational operations.

- The health care organization provides team members with support for and access to ongoing education and development programs focusing on strategies that ensure collaborative decision making. Program content includes mutual goal setting, negotiation, facilitation, conflict management, systems thinking, and performance improvement.
- The health care organization clearly articulates organizational values, and team members incorporate these values when making decisions.
- The health care organization has operational structures in place that ensure the perspectives of patients, and their families are incorporated into every decision affecting patient care.
- Individual team members share accountability for effective decision making by acquiring necessary skills, mastering relevant content, assessing situations accurately, sharing fact-based information, communicating professional opinions clearly, and inquiring actively.
- The health care organization establishes systems, such as structured forums involving all departments and health care disciplines, to facilitate data-driven decisions.
- The health care organization establishes deliberate decision-making processes that ensure respect for the rights of every individual, incorporate all key perspectives, and designate clear accountability.
- The health care organization has fair and effective processes in place at all levels to objectively evaluate the results of decisions, including delayed decisions and indecision.

From http://www.aacn.org/WD/HWE/Docs/HWEStandards.pdf.[21]

BOX 1-5 Standard 4: Critical Elements of Appropriate Staffing

Staffing must ensure the effective match between patient needs and nurse competencies.

- The health care organization has staffing policies in place that are solidly grounded in ethical principles and support the professional obligation of nurses to provide high quality care.
- Nurses participate in all organizational phases of the staffing process from education and planning—including matching nurses' competencies with patients' assessed needs—through evaluation.
- The health care organization has formal processes in place to evaluate the effect of staffing decisions on patient and system outcomes. This evaluation includes analysis of when patient needs and nurse competencies are mismatched and how often contingency plans are implemented.
- The health care organization has a system in place that facilitates team members' use of staffing and outcomes data to develop more effective staffing models.
- The health care organization provides support services at every level of activity to ensure nurses can optimally focus on the priorities and requirements of patient and family care.
- The health care organization adopts technologies that increase the effectiveness of nursing care delivery. Nurses are engaged in the selection, adaptation, and evaluation of these technologies.

From http://www.aacn.org/WD/HWE/Docs/HWEStandards.pdf.[21]

BOX 1-6 Standard 5: Critical Elements of Meaningful Recognition

Nurses must be recognized and must recognize others for the value each brings to the work of the organization.

- The health care organization has a comprehensive system in place that includes formal processes and structured forums that ensure a sustainable focus on recognizing all team members for their contributions and the value they bring to the work of the organization.
- The health care organization establishes a systematic process for all team members to learn about the institution's recognition system and how to participate by recognizing the contributions of colleagues and the value they bring to the organization.
- The health care organization's recognition system reaches from the bedside to the board table, ensuring individuals receive recognition consistent with their personal definition of meaning, fulfillment, development, and advancement at every stage of their professional career.
- The health care organization's recognition system includes processes that validate that recognition is meaningful to those being acknowledged.
- Team members understand that everyone is responsible for playing an active role in the organization's recognition program and meaningfully recognizing contributions.
- The health care organization regularly and comprehensively evaluates its recognition system, ensuring effective programs that help to move the organization toward a sustainable culture of excellence that values meaningful recognition.

From http://www.aacn.org/WD/HWE/Docs/HWEStandards.pdf.[21]

behavior, challenges of human relationships and personalities, hierarchical barriers, power imbalances, decision-making processes in organizations, and role socialization.[45–51]

In the book *Internal Bleeding—The Truth Behind America's Terrifying Epidemic of Medical Mistakes*, the authors reported that despite the fact that nurses and physicians have worked closely together, "there is still little understanding and appreciation for each other's roles."[52] The question of "why is collaboration so hard to embrace when the evidence supports better outcomes when there is communication and collaboration?" still requires an answer.[52]

Effective Decision Making

Clinical decision making is an essential component of nursing responsibilities in an effort to promote quality patient outcomes. Researchers do not agree about the role of knowledge in decision making. Some have suggested that it entails application of knowledge learned in the classroom and through readings while others have proposed that clinical decision-making skills involve experiential knowledge and intuition.[53] In clinical practice, where true collaboration does not exist and the elements of a HWE are not embraced, it is difficult for nurses, who are accountable for a scope of practice, to fully participate in decisions that affect quality and safe, effective care. The HWE standards highlight that only a small percentage of physicians acknowledge nurses as part of the decision-making team.[19]

In one study, investigators found that the majority of nurses made clinical decisions related to direct patient care on a regular basis.[54] Nurses working in the ICU reported commonly making decisions in emergency situations and

BOX 1-7 Standard 6: Critical Elements of Authentic Leadership

Nurse leaders must fully embrace the imperative of a HWE, authentically live it, and engage others in its achievement.

- The health care organization provides support for and access to educational programs to ensure that nurse leaders develop and enhance knowledge and abilities in skilled communication, effective decision making, true collaboration, meaningful recognition, and ensuring resources to achieve appropriate staffing.
- Nurse leaders demonstrate an understanding of the requirements and dynamics at the point of care and within this context successfully translate the vision of a HWE.
- Nurse leaders excel at generating visible enthusiasm for achieving the standards that create and sustain HWEs.
- Nurse leaders lead the design of systems necessary to effectively implement and sustain standards for HWEs.
- The health care organization ensures that nurse leaders are appropriately positioned in their pivotal role in creating and sustaining HWEs. This includes participation in key decision-making forums, access to essential information, and the authority to make necessary decisions.
- The health care organization facilitates the efforts of nurse leaders to create and sustain a HWE by providing the necessary time and financial and human resources.
- The health care organization provides a formal comentoring program for all nurse leaders. Nurse leaders actively engage in the comentoring program.
- Nurse leaders role-model skilled communication, true collaboration, effective decision making, meaningful recognition, and authentic leadership.
- The health care organization includes the leadership contribution to creating and sustaining a HWE as a criterion in each nurse leader's performance appraisal. Nurse leaders must demonstrate sustained leadership in creating and sustaining a HWE to achieve professional advancement.
- Nurse leaders and team members mutually and objectively evaluate the impact of leadership processes and decisions on the organization's progress toward creating and sustaining a HWE.

From http://www.aacn.org/WD/HWE/Docs/HWEStandards.pdf.[21]

deciding to change patient medication. Medical and surgical nurses only made these types of decisions on an occasional basis.[54] In two review articles, the amount of clinical experience correlates with improved decision making.[55,56]

Effective clinical decision making is an essential factor that impacts delivery of quality care. Whether a nursing student or an experienced nurse, factors reported to impact nurses' clinical decision making include self-confidence, relationships with peer and other providers, organizational structure, access to supportive resources, nursing education, experience, knowledge, creative thinking ability, self-concept, work environment, and situational stressors.[55–58] It is important for nurses, organizations that employ nurses, and schools of nursing to identify barriers and augment factors that promote clinical decision making.[19,55–57,59]

To promote quality patient outcomes, nurses must utilize the nursing process, apply critical thinking, and utilize knowledge and experience to make salient clinical decisions promptly. The nurses' role is to effectively communicate with and be involved in decision making as members of the multidisciplinary team as they strive to identify and manage complex patient problems. Necessary skills include accepting the high degree of accountability and responsibility that is inherent with clinical decision making while also having the autonomy needed to guide one's own practice.

Appropriate Staffing

Appropriate staffing must consider the knowledge, skills, and abilities, collectively referred to as competencies, of staff assigned in relation to the individualized, holistic needs of the patient and family. When the needs of patients and families are matched with the competencies of the assigned nurse, optimal outcomes may be achieved.

In a landmark study, Aiken et al[60] documented an increased risk for patient mortality when the nurse/patient ratio increased in the medical–surgical setting. In this study, when the nurse/patient ratio was 1:8, the patient's risk for death was 31% higher than when the nurse/patient ratio was 1:4 or lower. After the fourth patient, each surgical patient added to a nurse's assignment resulted in a 7% increase in chance of patient death within 30 days of hospital admission and a 7% increase in failure to rescue.[59]

Researchers found significant relationships between lower nurse staffing and adverse patient outcomes. These outcomes include development of pneumonia, shock, cardiac arrest, upper gastrointestinal bleeding, and urinary tract infections. Longer hospital lengths of stay, failure to rescue, and higher 30-day mortality rates have been linked to lower nurse staffing as well. Two of the major factors that contributed to poorer staffing levels were higher patient acuity and a disparity between the number of available positions and available registered nurses (RNs) to fill them.[60–72]

In its report, the IOM acknowledged the relationship between nurse staffing and quality of care. Nurse staffing levels and knowledge and skill level have an impact on patient outcomes and safety. The Institute further acknowledged that the temporary fixes such as mandatory overtime or leaving units understaffed are ineffective and contribute to errors.[72]

Meaningful Recognition

HWEs as well as programs that effectively recognize nurses and nursing contribution to quality, safe patient care are important to retain high-performing nurses, to engage them actively in enhancing patient satisfaction, to use scarce nursing resources appropriately, and to enhance nursing accomplishment. Nurse recognition can have a significant effect on job satisfaction. Meaningful nurse recognition can be achieved in a variety of effective, inexpensive ways.[73] Because of generational, gender, and cultural differences in today's nursing workforce, nurses find workplace satisfaction through a variety of mechanisms and frequently desire more out of a job than just a big salary.[74] Staff recognition has been identified as one of the simplest, cost-effective approaches to retain experienced staff and is essential to maintain nurse morale.[75,76] Specifically, staff want to lead balanced lives, enjoy partnership with their employers, receive opportunities for personal and professional growth, be able to make a meaningful contribution through their work, and experience opportunities to socialize at work.[74–76]

There seems to be universal agreement that to retain nursing staff during a critical shortage, in addition to monetary rewards when possible, expression of recognition for excellent performance and appreciation are part of the strategy.[77–79] Nurses in one study rated recognition from patients, families, and other nurses of more value than recognition from nursing leadership and physicians. In a follow-up study, nurses continued to value recognition from patients and families most (48.9%). This was followed by recognition from other RNs (27%), administration (8.5%), immediate supervisor (7.7%), physicians (4.6%), and other coworkers (3.3%).[80]

Meaningful recognition has been found to be associated with several positive outcomes, such as job satisfaction, commitment to an organization and career, collaboration, and perceived organizational support.[81–88] Yet, nurses do not receive meaningful recognition in all situations.[89] Absence of meaningful recognition is associated with absenteeism, staff turnover, stress, burnout, and decreased quality of care. Therefore, in addition to appropriate staffing, effective decision making, and true collaboration, critical care nurses, like all nurses, value meaningful recognition which in turn improves job satisfaction and morale while reducing turnover and improving quality patient outcomes.[85–90]

Authentic Leadership

Nurses are attracted to health care systems that promote a HWE. Nursing leaders from unit manager to chief nurse executive as well as nursing peers are essential to creating and sustaining a healthy environment in today's dynamic health care climate.[19,72,90–92] It has been demonstrated that positive nursing leadership is linked to quality patient outcomes.[91] This has been corroborated by the Joint Commission, which asserts that leadership is essential to obtain high quality, safe health care and that ineffective leadership is a contributing factor when sentinel events occur.[20] Authentic leadership has been described as "the glue needed to hold together a HWE."[93] Attributes of an authentic leader include good communication skills, knowing what they stand for, inspiring others, working as part of the team, asking for and giving 100%, and establishing a vision.[94]

▲ The Synergy Model

The Synergy Model developed by the AACN has served as the foundation for certified practice since the late 1990s.[95,96] The model describes nursing practice on the basis of patients' characteristics. The underlying premises of the Synergy Model are: (1) patients' characteristics are of concern to nurses; (2) nurses' competencies are important to patients; (3) patients' characteristics drive nurses' competencies; and (4) when patients' characteristics and nurses' competencies match and synergize, outcomes for the patient are optimal.[95,97]

Eight patient characteristics and eight nurse competencies that constitute nursing practice form the basis of the model (Fig. 1-1; Boxes 1-8 and 1-9). The patient characteristics range in intensity and are expressed as level 1, 3, or 5. The level can change from 1 minute to the next. Like the patient characteristics, the nurse competencies exist on a continuum

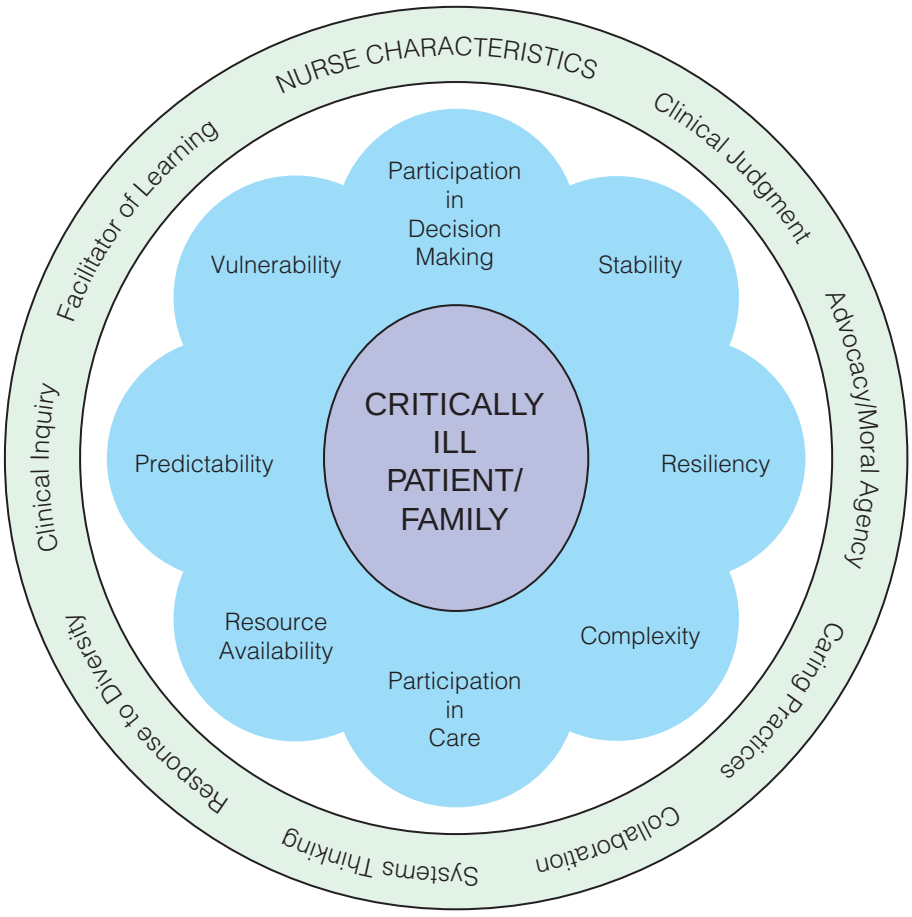

FIGURE 1-1 ▲ The relationship between the patient/family and the nurse in the Synergy Model.

BOX 1-8 Characteristics of Patients, Clinical Units, and Systems of Concern to Nurses

- **Resiliency**—the capacity to return to a restorative level of functioning using compensatory/coping mechanisms; the ability to bounce back quickly after an insult
  - *Level 1: Minimally resilient.* Unable to mount a response; failure of compensatory/coping mechanisms; minimal reserves; brittle
  - *Level 3: Moderately resilient.* Able to mount a moderate response; able to initiate some degree of compensation; moderate reserves
  - *Level 5: Highly resilient.* Able to mount and maintain a response; intact compensatory/coping mechanisms; strong reserves; endurance
- **Vulnerability**—susceptibility to actual or potential stressors that may adversely affect patient outcomes
  - *Level 1: Highly vulnerable.* Susceptible; unprotected, fragile
  - *Level 3: Moderately vulnerable.* Somewhat susceptible; somewhat protected
  - *Level 5: Minimally vulnerable.* Safe; out of the woods; protected, not fragile
- **Stability**—the ability to maintain a steady-state equilibrium
  - *Level 1: Minimally stable.* Labile; unstable; unresponsive to therapies; high risk of death
  - *Level 3: Moderately stable.* Able to maintain steady state for limited period of time; some responsiveness to therapies
  - *Level 5: Highly stable.* Constant; responsive to therapies; low risk of death
- **Complexity**—the intricate entanglement of two or more systems (eg, body, family, therapies)
  - *Level 1: Highly complex.* Intricate; complex patient/family dynamics; ambiguous/vague; atypical presentation
  - *Level 3: Moderately complex.* Moderately involved patient/family dynamics
  - *Level 5: Minimally complex.* Straightforward; routine patient/family dynamics; simple/clearcut; typical presentation
- **Resource Availability**—extent of resources (eg, technical, fiscal, personal, psychological, and social) the patient/family/community bring to the situation
  - *Level 1: Few resources.* Necessary knowledge and skills not available; necessary financial support not available; minimal personal/psychological supportive resources; few social systems resources
  - *Level 3: Moderate resources.* Limited knowledge and skills available; limited financial support available; limited personal/psychological supportive resources; limited social systems resources
  - *Level 5: Many resources.* Extensive knowledge and skills available and accessible; financial resources readily available; strong personal/psychological supportive resources; strong social systems resources
- **Participation in Care**—extent to which patient/family engages in aspects of care
  - *Level 1: No participation.* Patient and family unable or unwilling to participate in care
  - *Level 3: Moderate participation.* Patient and family need assistance in care
  - *Level 5: Full participation.* Patient and family fully able to participate in care
- **Participation in Decision Making**—extent to which patient/family engages in decision making
  - *Level 1: No participation.* Patient and family have no capacity for decision making; requires surrogacy
  - *Level 3: Moderate participation.* Patient and family have limited capacity; seek input/advice from others in decision making
  - *Level 5: Full participation.* Patient and family have capacity and make decisions
- **Predictability**—a characteristic that allows one to expect a certain course of events or course of illness
  - *Level 1: Not predictable.* Uncertain; uncommon patient population/illness; unusual or unexpected course; does not follow critical pathway, or no critical pathway developed
  - *Level 3: Moderately predictable.* Wavering; occasionally noted patient population/illness
  - *Level 5: Highly predictable.* Certain; common patient population/illness; usual and expected course; follows critical pathway

From the American Association of Critical-Care Nurses Certification Corporation.

BOX 1-9 Nurse Competencies of Concern to Patients, Clinical Units, and Systems

- **Clinical Judgment**—clinical reasoning, which includes clinical decision making, critical thinking, and a global grasp of the situation, coupled with nursing skills acquired through a process of integrating formal and informal experiential knowledge and evidence-based guidelines
  - *Level 1:* Collects basic-level data; follows algorithms, decision trees, and protocols with all populations and is uncomfortable deviating from them; matches formal knowledge with clinical events to make decisions; questions the limits of one's ability to make clinical decisions and delegates the decision making to other clinicians; includes extraneous detail
  - *Level 3:* Collects and interprets complex patient data; makes clinical judgments based on an immediate grasp of the whole picture for common or routine patient populations; recognizes patterns and trends that may predict the direction of illness; recognizes limits and seeks appropriate help; focuses on key elements of case, while sorting out extraneous details
  - *Level 5:* Synthesizes and interprets multiple, sometimes conflicting, sources of data; makes judgment based on an immediate grasp of the whole picture, unless working with new patient populations; uses past experiences to anticipate problems; helps patient and family see the "big picture"; recognizes the limits of clinical judgment and seeks multidisciplinary collaboration and consultation with comfort; recognizes and responds to the dynamic situation
- **Advocacy and Moral Agency**—working on another's behalf and representing the concerns of the patient/family and nursing staff; serving as a moral agent in identifying and helping to resolve ethical and clinical concerns within and outside the clinical setting.
  - *Level 1:* Works on behalf of patient; self-assesses personal values; aware of ethical conflicts/issues that may surface in clinical setting; makes ethical/moral decisions based on rules; represents patient when patient cannot represent self; aware of patients' rights
  - *Level 3:* Works on behalf of patient and family; considers patient values and incorporates in care, even when differing from personal values; supports colleagues in ethical and clinical issues; moral decision making can deviate from rules; demonstrates give and take with patient's family, allowing them to speak/represent themselves when possible; aware of patient and family rights
  - *Level 5:* Works on behalf of patient, family, and community; advocates from patient/family perspective, whether similar to or different from personal values; advocates ethical conflict and issues from patient/family perspective; suspends rules—patient and family drive moral decision making; empowers the patient and family to speak for/represent themselves; achieves mutuality within patient/professional relationships

(*continued on page 10*)

BOX 1-9 Nurse Competencies of Concern to Patients, Clinical Units, and Systems (continued)

- **Caring Practices**—nursing activities that create a compassionate, supportive, and therapeutic environment for patients and staff, with the aim of promoting comfort and healing and preventing unnecessary suffering. Includes, but is not limited to, vigilance, engagement, and responsiveness of caregivers, including family and health care personnel
  - *Level 1:* Focuses on the usual and customary needs of the patient; no anticipation of future needs; bases care on standards and protocols; maintains a safe physical environment; acknowledges death as a potential outcome
  - *Level 3:* Responds to subtle patient and family changes; engages with the patient as a unique patient in a compassionate manner; recognizes and tailors caring practices to the individuality of patient and family; domesticates the patient's and family's environment; recognizes that death may be an acceptable outcome
  - *Level 5:* Has astute awareness and anticipates patient and family changes and needs; is fully engaged with and sensing how to stand alongside the patient, family, and community; caring practices follow the patient and family lead; anticipates hazards and avoids them, and promotes safety throughout patient's and family's transitions along the health care continuum; orchestrates the process that ensures patient's/family's comfort and concerns surrounding issues of death and dying are met
- **Collaboration**—working with others (eg, patients, families, health care providers) in a way that promotes/encourages each person's contributions toward achieving optimal/realistic patient/family goals. Involves intradisciplinary and interdisciplinary work with colleagues and community
  - *Level 1:* Willing to be taught, coached, and/or mentored; participates in team meetings and discussions regarding patient care and/or practice issues; open to various team members' contributions
  - *Level 3:* Seeks opportunities to be taught, coached, and/or mentored; elicits others' advice and perspectives; initiates and participates in team meetings and discussions regarding patient care and/or practice issues; recognizes and suggests various team members' participation
  - *Level 5:* Seeks opportunities to teach, coach, and mentor and to be taught, coached, and mentored; facilitates active involvement and complementary contributions of others in team meetings and discussions regarding patient care and/or practice issues; involves/recruits diverse resources when appropriate to optimize patient outcomes
- **Systems Thinking**—body of knowledge and tools that allow the nurse to manage whatever environmental and system resources exist for the patient/family and staff, within or across health care and non–health care systems
  - *Level 1:* Uses a limited array of strategies; limited outlook—sees the pieces or components; does not recognize negotiation as an alternative; sees patient and family within the isolated environment of the unit; sees self as key resource
  - *Level 3:* Develops strategies based on needs and strengths of patient/family; able to make connections within components; sees opportunity to negotiate but may not have strategies; developing a view of the patient/family transition process; recognizes how to obtain resources beyond self
  - *Level 5:* Develops, integrates, and applies a variety of strategies that are driven by the needs and strengths of the patient/family; global or holistic outlook—sees the whole rather than the pieces; knows when and how to negotiate and navigate through the system on behalf of patients and families; anticipates needs of patients and families as they move through the health care system; utilizes untapped and alternative resources as necessary
- **Response to Diversity**—the sensitivity to recognize, appreciate, and incorporate differences into the provision of care. Differences may include, but are not limited to, cultural differences, spiritual beliefs, gender, race, ethnicity, lifestyle, socioeconomic status, age, and values.
  - *Level 1:* Assesses cultural diversity; provides care based on own belief system; learns the culture of the health care environment
  - *Level 3:* Inquires about cultural differences and considers their impact on care; accommodates personal and professional differences in the plan of care; helps patient/family understand the culture of the health care system
  - *Level 5:* Responds to, anticipates, and integrates cultural differences into patient/family care; appreciates and incorporates differences, including alternative therapies, into care; tailors health care culture, to the extent possible, to meet the diverse needs and strengths of the patient/family
- **Facilitation of Learning**—the ability to facilitate learning for patients/families, nursing staff, other members of the health care team, and community. Includes both formal and informal facilitation of learning
  - *Level 1:* Follows planned educational programs; sees patient/family education as a separate task from delivery of care; provides data without seeking to assess patient's readiness or understanding; has limited knowledge of the totality of the educational needs; focuses on a nurse's perspective; sees the patient as a passive recipient
  - *Level 3:* Adapts planned educational programs; begins to recognize and integrate different ways of teaching into delivery of care; incorporates patient's understanding into practice; sees the overlapping of educational plans from different health care providers' perspectives; begins to see the patient as having input into goals; begins to see individualism
  - *Level 5:* Creatively modifies or develops patient/family education programs; integrates patient/family education throughout delivery of care; evaluates patient's understanding by observing behavior changes related to learning; is able to collaborate and incorporate all health care providers' and educational plans into the patient/family educational program; sets patient-driven goals for education; sees patient/family as having choices and consequences that are negotiated in relation to education
- **Clinical Inquiry (Innovator/Evaluator)**—the ongoing process of questioning and evaluating practice and providing informed practice. Creating practice changes through research utilization and experiential learning
  - *Level 1:* Follows standards and guidelines; implements clinical changes and research-based practices developed by others; recognizes the need for further learning to improve patient care; recognizes obvious changing patient situation (eg, deterioration, crisis); needs and seeks help to identify patient problem
  - *Level 3:* Questions appropriateness of policies and guidelines; questions current practice; seeks advice, resources, or information to improve patient care; begins to compare and contrast possible alternatives
  - *Level 5:* Improves, deviates from, or individualizes standards and guidelines for particular patient situations or populations; questions and/or evaluates current practice based on patients' responses, review of the literature, research, and education/learning; acquires knowledge and skills needed to address questions arising in practice and improve patient care. (The domains of clinical judgment and clinical inquiry converge at the expert level; they cannot be separated.)

From http://www.certcorp.org/certcorp/certcorp.nsf/vwdoc/SynModel.

and are expressed as level 1, 3, or 5. The level can vary based on level of expertise in a given clinical situation.

The Synergy Model is also used to determine outcomes. Outcomes are evaluated based on those derived from the patient, nurse, and health care system. Patient-derived outcomes may include functional change, trust, satisfaction, comfort, and quality of life. Nurse-derived outcomes may include physiological changes, absence of complications, and extent to which treatment objectives are attained. Health care system–derived outcomes may include recidivism, costs, and resource utilization.

Since its development, the Synergy Model has been used in a variety of clinical settings as a basis for nursing clinical advancement, determining staffing ratios, preceptorship, and as a foundation for advanced practice nursing.[98–103] For example, the Clarian Health System in Indianapolis, Indiana, uses the model to facilitate organizational change.[104] Here, job descriptions are based on the eight nurse characteristics. At Baylor Hospital in Dallas, Texas, the model is the foundation for evaluation of nursing orientation and is the basis for the nursing advancement program. The model also has an effect in other areas, such as shift report, curriculum design, and nurse manager job analysis.

Case reports in the literature illustrate the use of the Synergy Model in promoting optimal patient outcomes.[105–108] Use of the Synergy Model has also been described as a framework that can be used as a basis for work to be done by facilities seeking Magnet designation.[109,110]

▲ Future Challenges in Critical Care Nursing

Because health care, nursing, and the world are dynamic, critical care nursing must continue to evolve. As the United States becomes increasingly diverse, nursing must increase its ability to deliver evidence-based care that is culturally congruent and relevant. The growing U.S. Hispanic population makes it increasingly essential for health care systems to have a multilingual, culturally diverse workforce. This requires not only the need to recruit and retain diverse professionals but also the need to expand the skill set of today's already experienced critical care nurses.

As new and emerging infectious diseases present, critical care nurses must be prepared to identify, manage, and treat unknown threats. Similarly, Hurricane Katrina clearly demonstrated the impact that natural disasters have on a nation, health outcomes, and the nursing workforce. Furthermore, in the era after September 11, critical care units must be prepared to handle any actual or potential bioterrorism threat.

Finally, as critical care continues to evolve and become increasingly technologically sophisticated, critical care nurses must continue to expand their repertoire of skills and evidence-based interventions to address not only the physiological needs but also the psychosocial, spiritual, ethical, and advocacy needs of patients and families. With implementation of advances in technology, the critical care unit will continue to require caring, competent, and knowledgeable nurses who can foster collaboration, navigate complex delivery and reimbursement systems, and facilitate patient/family learning while responding to diverse communities that are vulnerable with complex needs. These exciting challenges await critical care nurses—challenges that they will overcome with commitment, dedication, and grace!

▲ Clinical Applicability Challenges

SHORT ANSWER QUESTIONS

1. Describe a time in your workplace where you received meaningful recognition.
2. Describe some of the barriers in your workplace to implementing practice changes based on evidence.
3. Describe a clinical situation that exemplifies high levels of competence with the nurse competency response to diversity from the AACN Synergy Model for Patient Care.

2 The Patient's Experience with Critical Illness

Kathryn S. Bizek and Dorrie K. Fontaine

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Explore relationships among stress, response to illness, and anxiety.
2. Explore the role of the nurse in controlling environmental stressors to promote healing.
3. Compare and contrast techniques that the patient and family can learn in an effort to manage stress and anxiety.
4. Describe strategies to promote sleep in critically ill patients.
5. Develop nursing interventions that foster the ability of patients to draw strength from their personal spirituality.
6. Discuss alternatives to the use of physical restraint in the intensive care unit.

The patient's experience in an intensive care unit (ICU) has lasting meaning for the patient and his or her family members and significant others. Although actual painful memories are blurred by drugs and the mind's need to forget, attitudes that are highly charged with feelings about the nature of the experience survive. These attitudes shape the person's beliefs about nurses, physicians, health care, and the vulnerability of life itself.

This chapter describes specific measures that nurses use to support patients in managing the stressors associated with critical illness and injury. It is the caring and emotional support given by the nurse that will be remembered and valued.

▲ Perception of Critical Illness

Admission to an ICU may signal a threat to the life and well-being of the patient who is admitted. Critical care nurses perceive the unit as a place where fragile lives are vigilantly scrutinized, cared for, and preserved. However, patients and their families frequently perceive admission to critical care as a sign of impending death, based on their own past experiences or the experiences of others. Understanding what critical care means to patients may help nurses care for their patients. However, effective communication with critically ill patients is often challenging and frustrating.[1–3] Barriers to communication may relate to the patients' physiological status; the existence of endotracheal tubes, which inhibit verbal communication; medications; or other conditions that alter cognitive function.

About 30% to 100% of former ICU patients could recall part or all of their stay in the ICU. Although many of the patients recalled feelings that were negative, they also recalled neutral and positive experiences. Negative experiences were related to fear, anxiety, sleep disturbance, cognitive impairment, and pain or discomfort. Positive experiences were related to feelings of being safe and secure. Often, these positive feelings were attributed to the care provided by nurses. The need to feel safe and the need for information were predominant themes in other research studies.[2,4–6] Nurses' technical competence and effective interpersonal skills were cited by patients as promoting their sense of security and trust.

▲ Stress

Stress exists when an organism is faced with any stimulus that causes disequilibrium between psychological and physiological functioning. Patients admitted to the ICU are subject to multiple physical, psychological, and environmental stressors. Stimulation of the body's stress response involves activation of the hypothalamic–pituitary–adrenal axis. The resultant increase in catecholamine, glucocorticoid, and mineralocorticoid levels leads to a cascade of physiological responses.[7]

Acute Stress Response

Critical injury or illness can initiate the first phase of the stress response. This phase is characterized by the body's efforts to survive and involves the stimulation of the sympathetic nervous system and activation of multiple neuroendocrine responses. This "ebb phase" results in increased heart rate and contractility, vasoconstriction, and increase in blood pressure. Blood flow is redirected to vital organs. Pain sensations are temporarily attenuated. Body temperature and nutrient consumption fall.

Table 2-1 Major Stress-Related Hormones and Effects

Stress Hormones	Source	Major Effects
Adrenocorticotropic hormone	Anterior pituitary	Stimulates adrenal cortex to release cortisol
Catecholamines Epinephrine Norepinephrine	Adrenal medulla and the sympathetic nervous system	Increases overall strength, blood flow to vital organs, glyconeogenesis Increases myocardial contractility (inotropic effect), heart rate (chronotropic effect), venous return to the heart and cardiac output Constricts smooth muscle in all blood vessels, increases blood pressure, dilates pupils, inhibits gastrointestinal activity
Cortisol	Adrenal cortex (following stimulation by adrenocorticotropic hormone from the anterior pituitary)	Gluconeogenesis; hyperglycemia; decreases protein synthesis, immunoglobulin synthesis, number of lymphocytes, and leukocytes (at inflammatory site); promotes muscle and lymphoid tissue catabolism; delays healing; suppresses cell-mediated immune response
Antidiuretic hormone	Posterior pituitary	Increases water retention
Aldosterone	Adrenal cortex	Increases sodium and water retention
Growth hormone (somatotropin)	Anterior pituitary	Increases immune function; levels are increased during stress
Prolactin	Anterior pituitary	β-Cell activation and differentiation; levels are reduced during stress
Testosterone	Testis	Regulates male secondary characteristics; levels are decreased during chronic stress
Endorphins	Anterior pituitary	Endogenous opiates, elevated during stress, downregulate pathways to the stress response
Enkephalins	Adrenal medulla	Endogenous opiates, elevated during stress, downregulate pathways to the stress response

From Lusk B, Lash AA: The stress response, psychoneuroimmunology, and stress among ICU patients. Dimens Crit Care Nurs 24(1):25–31, 2003, with permission.

A sensation of thirst may be prominent. Other physiological effects include increase in minute ventilation and respiratory rate, hyperglycemia, insulin resistance, and coagulopathies. This initial phase is deeply catabolic as protein stores are mobilized to respond to the threat and begin to repair the injury. If this phase is prolonged, it can result in impaired oxygen and nutrients delivery to tissues secondary to alterations in microcirculatory blood flow. Table 2-1 summarizes the effects of hormones released in response to major stress.[8–18]

The second phase of the stress response, or the "flow phase," is a hyperdynamic state that results as the body compensates for the oxygen deprivation. This phase is also characterized by multiple hormonal influences. Pain and discomfort are now prominent. Movement is minimized to conserve metabolic costs. Prolonged activation of the stress response can lead to immunosuppression, hypoperfusion, tissue hypoxia, and eventual death. Treatment is directed at eliminating the stressors and providing supportive care in the form of nutrition, oxygenation, pain management, anxiety control, and specific measures related to the cause of illness or injury.[15,19–21]

Environmental Stressors in the Intensive Care Unit

The ICU is a stressful environment for patients and care givers. Walk into any ICU and you will find the following common physical features: blinking monitors, ventilators, intravenous (IV) pumps, noise from equipment and the many practitioners talking at the bedside, bright lights, and a hurried pace in a crowded space. Intra-aortic balloon pumps, extracorporeal membrane oxygenation machines, and multiple sophisticated technologies are commonplace. Critical care nursing was invented to flourish in this setting, where the most acutely ill and injured receive concentrated nursing care to enhance survival. In the early ICUs of the 1950s, nurses were confronted daily with pain, suffering, and death, while caring for patients in a confined though open space.[22] These ICUs were often a few beds carved out of existing wards in older hospitals that brought the sickest patients to one area. The most distinctive feature of the first ICUs was this concentration of nursing care, and the specialty of intensive care nursing was born. The design of ICUs has changed over the decades and provides a rationale for why care needs for the patient and family have also evolved. The concept of healing environments in hospitals emerged as one where the environment can make a difference in how quickly the patient recovers.[23]

Table 2-2 summarizes the key design features of ICUs from the 1950s to an envisioned future. Common to all these designs is the notion of close observation and rapid intervention. Meeting patient needs through continuous monitoring is the hallmark of all critical care. However, the close monitoring has led to patient complaints of

Table 2-2 Intensive Care Unit Designs

	First Generation (1950s)	Second Generation (1970s)	Third Generation (1980s–Present)	Fourth Generation—Future
Characteristics	Open unit/ward. No partitions except curtains or screens. Nurses' station/desk in center or at the foot of beds. Unit lighting control often on one switch.	Individual rooms or walled cubicles. Rooms often on either side of a hall containing an open nursing station or surrounding an open nursing station on three to four sides (square configuration). Central monitoring. Some units without external patient room windows (increased incidence of delirium). Patient room lighting with separate switch(es) from nursing station. Calendars and clock in patient rooms.	Individual rooms. Folding or sliding glass doors. Rooms often arranged on a semicircle or circle with the nursing station in the center. Some units configured with decentralized nursing stations. Patient room windows with external views/lighting. Increased control of patient room lighting levels.	Individual rooms. Folding or sliding glass doors with privacy curtains/blinds. Circular/pod-shaped floor plan. Increased noise reduction design. Patient windows with a view of outdoors (natural or contrived). Patient-controlled lighting—artificial and natural. Planned areas for family in patient rooms. Increased use of color and texture in wall, floor, and ceiling coverings.
Advantages	Increased nurses' proximity to patients	Increased patient privacy. Better control of lighting, noise, and infection.	Increased nursing access during high-intensity activities.	Nursing access and availability of high-tech care in a more homelike environment.
Disadvantages	Lack of privacy. Inability to control noise or light. Infection control issues.	Less direct patient access/ observation. Less than optimal control of noise and lighting.	Glass doors reduce patient privacy.	

From Fontaine DK, Prinkey Briggs L, Pope-Smith B: Designing humanistic critical care environments. Crit Care Nurs Q 24(3):21–34, 2001, with permission.

noise, lighting with no day–night distinction, and frequent interruptions of sleep and rest. Intensive care beds were often so close to each other that patients could hear everything happening to the critically ill patient in the next bed. Lack of privacy and fears related to overheard procedures and conversations in the unit created undue anxiety and the potential for physiological instability in vulnerable patients.

The evolution of ICUs has demonstrated increasing use of the precepts of family-focused care. Early units typically had no space for family to visit, and visits were not encouraged. Emphasis today is on how the design of the ICU can best meet the needs of patients and families as a unit, despite the important life-sustaining technology. The shift to family-focused care is a good example of how the structure and function of ICUs has changed. Signs that welcome family and visitors to the ICU often suggest the philosophy of the hospital and the culture of the unit. The more welcoming the ICU is to visitors, the more likely the environment is to offer a healing culture of care and support. Does the sign on the door read "Stop, Do Not Enter" or "Welcome to the ICU"?

Patients experience a positive outcome in an environment that incorporates natural light, elements of nature, soothing colors, meaningful and varied stimuli, peaceful sounds, and pleasant views.[24] In fact, research demonstrates less pain medication is needed and a faster recovery may occur when careful attention is given to providing a soothing environment. Hospitals that combine creative design elements with an emphasis on family-focused care are the leaders in creating healing spaces for recovery.

Noise

Despite third-generation unit design and architecture, the problems of noise and bright lighting have remained a challenge. Beds surrounded by noisy machines and equipment are intimidating to patients, family, and novice nurses in critical care. Noise is an environmental hazard that creates discomfort in a patient. Consequences of noisy environments include disrupted sleep, impaired wound healing, and activation of the sympathetic nervous system. Moderate noise levels may produce vasoconstriction. Hyperarousal related to noise can occur over many days to even weeks for patients with prolonged ICU stays.

Patient complaints include listening to banging noises, alarms going off at all times, water sounds (such as the bubbling of chest tubes), and doors opening and closing. Sources of noise include equipment, alarms, telephones, televisions, ventilators, and staff conversations. Health care providers are often unaware of the loudness of their conversations and the irritation they may create in the minds of patients. People differ in their perceptions of noise as irritating; therefore, nurses should perform an objective assessment of the environment.

Noise is measured in decibels using a logarithmic scale. An increase of 10 decibels makes a sound seem twice as loud. Sleep occurs best below 35 decibels. The Environmental Protection Agency recommends unit noise be less than

45 decibels during the day and 35 decibels at night. Numerous studies measuring noise levels in the ICU demonstrate consistent elevations as high as 80 to 90 decibels. Background noise can be above 50 decibels day and night.[25] New technology can be an additional source of noise, although several manufacturers attempt to provide equipment that lowers the total unit volume of sound.

Decades of studies consistently point to noise as a key aspect of the ICU environment. Noise was measured in two ICUs using a sound meter placed at the head of a patient's bed.[26] More than 50% of the noise in the environment was attributed to human behavior, with a mean sound level in the medical ICU of 84 decibels. Television and talking were some of the most frequent disruptive sounds for patients. Another study investigated the perceptions of 203 patients who filled out a questionnaire on discharge from the ICU and found that noise from talking and alarms was the most disruptive to sleep.[27] Sound peaks greater than 80 decibels are common in ICUs and are directly related to arousals from sleep.[28] Noise levels in ICUs have remained fairly unchanged despite the evolution of unit design. Newer thinking suggests that noise is not the only culprit in limiting sleep in the ICU, although it remains an important one.[29]

Lights and Color

Light is a powerful *zeitgeber*, or environmental synchronizer, that assists in entraining sleep by promoting the normal circadian cycle of sleep and wakefulness. Many critical care settings could benefit from more natural lighting and lights that are lowered during normal sleep times. In addition to natural lighting, providing a soothing view for the patient to look on instead of the ceiling or a hospital curtain may foster recovery. A classic study found that when a patient had a view of natural scenery and the outdoors, as opposed to viewing a brick wall, less pain medication was used and the hospital stay was shorter.[30] Other studies have demonstrated that impaired cognition occurs more often in windowless units than in those with windows.

In the hospital setting, artificial light is provided by fluorescent bulbs and tubes. If unshielded, this harsh light leads to visual fatigue and headaches. Glare reflected off environmental surfaces, such as glass, shiny metal, mirrors, and enameled or polished finishes, is troublesome to patients, especially elderly patients. Bright lights may be left on for many hours in ICUs, even when no direct patient care is being performed. Lack of control over artificial lighting is a source of frustration to critical care patients.

Interruptions in normal light–dark patterns can disrupt normal physiological processes. For example, artificial light exposure for as little as 20 minutes during a normal sleep cycle caused a drop in melatonin levels.[31] In addition, constant lighting and high-intensity light can lead to a complete disruption of the normal melatonin concentration rhythm. Melatonin secreted at night synchronizes the sleep–wake and dark–light cycles.[32] Patients with sepsis in an ICU are likely to have disrupted melatonin secretion not linked to the normal circadian pattern.[33] Therapy with melatonin can potentially increase sleep duration in critically ill patients.

The ideal ICU environment has windows with natural views, soothing artwork, and calm colors. The nurse and other health care providers have access to work and computer stations with glass soundproof partitions that permit proximity to the patient (for easy observation) while shielding the patient from noise. Equipment is selected for its low noise level. Stress created by unnecessary noise and light is diminished for the good of the patients, family, and staff. This vision may already be a reality in some institutions. For example, muted colors of beige, blue, and green were used to design a holistic nursing unit in a Minnesota Hospital.[34] Art on the walls depicts many different cultures and the peacefulness of nature. The goal of a more peaceful, healing ICU environment is possible to attain.

▲ Anxiety

For many, anxiety is an emotional state of apprehension in response to a real or perceived threat. Typically, the threat is associated with motor tension, increased sympathetic activity, and hypervigilance.

Causes of Anxiety

Any stressor that threatens a person's sense of wholeness, containment, security, and control can cause anxiety. Illness and injury are such stressors. Other common causes of anxiety include feelings of increased vulnerability and decreased security, which occurs when patients admitted to ICUs perceive a loss of control, a sense of isolation, and fear of death or loss of functionality. Anxiety, pain, and fear can all initiate or perpetuate the stress response. Left untreated or undertreated, anxiety can contribute to the morbidity and mortality of critically ill patients.

Anxiety occurs when people experience the following:

- Threat of helplessness
- Loss of control
- Sense of loss of function and self-esteem
- Failure of former defenses
- Sense of isolation
- Fear of dying

Assessment of Anxiety

Assessment of anxiety is challenging in the critical care population because of the severity of illness, barriers to communication, and altered cognitive states. However, most critical care nurses believe that assessment of anxiety is important. Multiple-item, self-report scales of anxiety may be used, but they have specific drawbacks in critical care areas, especially for patients receiving mechanical ventilation because of communication barriers.[1–3] According to many critical care nurses, the top five physiological and behavioral indicators of anxiety are agitated behavior, increased blood pressure, increased heart rate, verbalization of anxiety, and restlessness. Monitoring of these patient parameters is useful, but there is still a need for a reliable and comprehensive anxiety assessment tool.[10,16] Examples of nursing diagnoses associated with critical illness and injury can be seen in Box 2-1.

BOX 2-1 EXAMPLES OF NURSING DIAGNOSES

For the Patient With Critical Illness or Injury

- Grieving
- Anxiety
- Disturbed Body Image
- Impaired Verbal Communication
- Ineffective Coping
- Ineffective Denial
- Fear
- Hopelessness
- Risk for Loneliness
- Powerlessness
- Situational Low Self-Esteem
- Sleep Deprivation
- Spiritual Distress
- Readiness for Enhanced Spiritual Well-Being

▲ Nursing Interventions

In caring for the critically ill patient, the nurse helps the patient manage a multitude of stressors. Stress management includes not only physical and environmental stressors but also psychological stressors. This complex and labor-intensive process requires advanced assessment skills, adept manipulation of a variety of highly technological treatment strategies, and creativity in care and compassion.[35–38]

Creating a Healing Environment

Florence Nightingale, the founder of modern nursing, often wrote about the nurse's role in creating an environment to allow healing to occur. She emphasized holism in nursing—that is, caring for the whole person. In today's technological age, critical care nurses are challenged to create an environment of healing. These environments must allow critically ill patients to have their psychological needs as well as physical needs met. Manipulating the milieu may involve timing interventions to allow adequate sleep and rest, providing pain-relieving medication, playing music, or teaching deep-breathing exercises. As previously discussed, the physical environment of the ICU can be altered to create a more healing and restful environment.

Promoting Rest and Sleep

Sleep Assessment

Promotion of sleep and rest for critically ill patients begins with an understanding of sleep, the major environmental disruptions, and a sleep assessment. Sleep involves two very distinct types of brain activity: rapid eye movement (REM) sleep and non-REM sleep. These sleep stages are described in Box 2-2. Healthy adults progress through sleep stages in a specific order, from a light stage to a deeper stage, in 90-minute cycles. REM sleep increases later in the normal nighttime sleep patterns of most people, with morning naps containing primarily REM sleep. Specific sleep stages have a circadian rhythm and are controlled by brainstem mechanisms.[39]

BOX 2-2 Stages and Characteristics of Sleep

Stage 1	Transitional stage between wakefulness and sleep
	Relaxed state where person is somewhat aware of surroundings
	Involuntary muscle jerking that may waken the person
	Normally lasts only minutes
	Easily aroused
	Constitutes only about 5% of total sleep
Stage 2	Beginning of sleep
	Arousal occurs with relative ease
	Constitutes 50% to 55% of sleep
Stage 3	Depth of sleep increased and arousal increasingly difficult
	Constitutes about 10% of sleep
Stage 4	Greatest depth of sleep (*delta sleep*)
	Arousal from sleep difficult
	Physiological changes in the body—slow brain waves on electroencephalogram; decreased pulse and respiratory rates; decreased blood pressure; relaxed muscles; slow metabolism and low body temperature
	Constitutes about 10% of sleep
Stage REM	Sleep with vivid dreaming (rapid eye movement [REM])
	REM, fluctuating heart and respiratory rates, fluctuating blood pressure
	Skeletal muscle tone lost
	Most difficult to arouse
	Duration of REM sleep increased with each cycle and averages 20 minutes
	Constitutes about 20% to 25% of sleep

Adapted from Taylor C, Lillis C, LeMone P: Fundamentals of Nursing: The Art and Science of Nursing Care, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2008.

Although sleep patterns are very individual, most patients can tell when they feel rested and have had a "good night's sleep." Unfortunately, this is a rare occurrence in the hospital. Sleep, once thought to be a quiescent state, actually involves physiological activation while the brain and body rejuvenate themselves. Sleep is often appreciated only when it has been "lost" and is typically taken for granted by health care providers, who often do not make sleep a priority for patients. Often in the ICU, sleep is severely fragmented and nonconsolidated,[40] with those receiving mechanical ventilation experiencing some of the worst sleep disruption.[41]

Sleep deprivation in patients in ICUs can have cumulative effects and lead to altered cognition, confusion, impaired wound healing, and the inability to wean from the ventilator because of muscle fatigue and carbon dioxide retention. The clinical significance is not fully appreciated because the relationship between poor sleep and recovery is unknown. However, promotion of sleep for patients is not only a humanistic intervention but may also be a life-sustaining one.

Sleep in patients with critical illness is greatly disrupted.[42] Many drugs interrupt sleep in critically ill patients.[43] Over four decades, researchers have noted that patients in ICUs have frequent awakenings, little to no REM sleep, shorter total sleep time than at home, and perceived poor quality of sleep.[29,44,45] Care interventions, including unnecessary baths between the hours of 2:00 and 5:00 AM, have disturbed the sleep of critically ill patients on a routine

basis.[46] A poor sleep pattern is characteristic of all age groups, from elderly to pediatric patients.[47] The impact of sleep disruption on the clinical outcome of ICU patients is not fully known. However, patients often report that sleep disruption is one of the most unpleasant aspects of their illness.

The patient's own report of sleep quality is the best measure of sleep adequacy, although this is inherently difficult when the patient is receiving mechanical ventilation. Similar to pain assessment, only the person can make the assessment: "I slept well" or "I didn't sleep at all." Monitoring brain waves by polysomnography is the gold standard for measuring patient sleep but is not feasible as a standard measure in the ICU.[43] If self-report of sleep is unobtainable, systematic observation of patients by nurses has been somewhat valid and reliable.[48] In addition, a visual analog scale is recommended for select patients at high risk for sleep disruption owing to extended stay in the ICU.[49] Wrist actigraphy is used as a research tool to continuously monitor activity and rest but may overestimate sleep in sedentary and elderly people.[43]

Promoting Sleep

Despite four decades of research into reasons why patients do not sleep in the ICU, little is done to facilitate what patients often rate as their number one priority after pain relief: sleep. Box 2-3 outlines strategies that are most often recommended to promote sleep. The challenging environment dictates that the nurse first is sensitive to the patient's needs and attuned to the environment and then has the tools and resources to implement sleep promotion. An old idea is the 5-minute backrub. The concept of using back massage to ease patients to sleep seems intuitive; however, until recently, it has never been systematically studied. In a study of 69 patients in an ICU, a 5-minute slow back massage (or *effleurage*) promoted increased sleep by 1 hour, compared with a control group.[50] If back massage were a hypnotic medication, it would be routinely ordered for ICU patients. The effective backrub was not the cold application of lotion and a quick one-handed massage while holding the patient on his side with the other hand, but rather a soothing, slow-stroke massage, in which the nurse first became centered and truly present with the patient.

The role of the nurse as a gatekeeper to protect patient sleep time will be more difficult to fulfill as patient:nurse ratios escalate but must remain a priority. According to the 2012 clinical practice guidelines for sedatives and analgesics in the critically ill adult, developed by a multidisciplinary team of physicians, pharmacists, and nurses, sleep promotion should include optimization of the patient's environment through the use of strategies to control light and noise, to cluster patient care activities, and to decrease stimuli at night in order to protect the sleep cycle.[51] One intervention is to implement a sleep protocol that institutionalizes the importance of sleep,[52] blocks sleep times, and truly controls the environment. In several studies, having a "quiet time" helped improve the opportunity for sleep.[53,54] Earplugs and eyemasks can be considered[55] as well as staff behavior modification programs for limiting noise.[56]

Another innovation in sleep promotion, which decreased noise and promoted sleep, involved moving all routine chest radiographs from 3:00 AM to 10:00 PM.[57] Although this increased the workload of the radiology department on the evening shift, patient and nurse satisfaction rose dramatically. All health care providers need to be aware of the importance of restorative sleep and the impact on a patient's well-being and work toward a "sleep-friendly ICU."[58] Sleep of the health care provider is also an important aspect of the healing dyad in the ICU. Nurses who work nights are routinely sleep deprived and may have young children to care for at home or school to attend when the next day begins. The growing interest in patient safety makes the work patterns of nurses, including 12-hour shifts and overtime, a focus of study.[59] Nurses' vigilance to patient needs is threatened with longer work hours and increased risk for error. Antidotes for working at night include scheduling of shifts to phase-advance the sleep cycle (ie, going from days to evenings to nights), eating healthy snacks, using bright lights during a shift away from patient rooms, and obtaining regular exercise.[59] Compassionate caring includes the nurse caring for self to meet better the demands of patients, families, and colleagues.

BOX 2-3 NURSING INTERVENTIONS

For Promoting Sleep

- Provide large clocks and calendars.
- Block sleep times.
- Provide a quiet time.
- Have the patient use earplugs.
- Assess sleep time and quality of sleep by asking the patient when possible.
- Provide opportunity for music therapy.
- Provide a 5-minute backrub before sleep.
- Consider using white noise or ocean sounds.
- Eliminate pain.
- Position patient for comfort with pillows.
- Stop the practice of bathing patients in the middle of the night for the convenience of the nursing staff.
- Titrate environmental stimuli: turn down lights, turn down alarms, and decrease noise from television and talking.
- Evaluate the need for nursing care interruptions.
- At bedtime, provide information to lower anxiety. Do a review of the day and remind patient of progress made toward recovery, then add what to expect for the next day.
- Institute "PM Care" back to basics, brushing teeth, and washing face before "bedtime."
- Allow family to be with the patient.
- Use relaxation techniques and guided imagery.
- Ensure patient privacy: close door or pull curtains.
- Post sign at designated times: "Patient Sleeping."

Fostering Trust

Almost every nurse in critical care can relate stories of special bonds that formed with individual patients and families. They can describe special situations where a trusting relationship developed and they made a difference in the patient's recovery or even dignified death. In contrast, research has shown that when patients mistrust their care givers, they are more anxious and more vigilant of staff behaviors and lack the feeling of safety and security. The goals, then, are to display a confident, caring attitude, demonstrate technical competence, and develop effective communication techniques that will foster the development of a trusting relationship. Communication can be especially difficult with mechanically ventilated and intubated patients. Use of nonverbal

signals, writing pads, or commercial communication boards can help make communication of basic needs easier.[60]

Providing Information

Besides the need to feel safe, critically ill patients identify the need for information as having a high priority.[38,61,62] This need to know involves all aspects of care. Patients need to know what is happening at the moment. They also need to know what will happen to them, how they are doing, and what they can expect. Many patients also need frequent explanations of what happened to them. These explanations reorient them, sort out sequences of events, and help them distinguish real events from dreams or hallucinations. Anxiety can be greatly relieved with simple explanations. Consider the patient, for example, who was being weaned from the ventilator who just needed reassurance that if he did not breathe, the machine would do it for him. Families, too, have identified the need for information as a high priority. This is followed closely by the need to have hope. Most families identify physicians as the primary source for information. It is important for nurses to be mindful of patient confidentiality issues when speaking to family members. Nurses should have the patient's permission before giving confidential medical information to family members. If that is not possible because of the patient's condition, a family spokesperson should be identified as the person who may receive confidential information. This information should be recorded in the patient's medical record.

Allowing Control

Nursing measures that reinforce a sense of control help increase the patient's autonomy and reduce the overpowering sense of a loss of control. The nurse can help the patient exert more control over his or her environment in the following ways:

- Providing order and predictability in routines
- Using anticipatory guidance
- Allowing the patient to make choices whenever possible
- Involving the patient in decision making
- Providing information and explanation for procedures

Providing order and predictability allows the patient to anticipate and prepare for what is to follow. Perhaps it creates only a mirage of control, but anticipatory guidance keeps the patient from being caught off guard and allows the mustering of coping mechanisms. Allowing small choices when the patient is willing and ready increases the patient's feeling of control over the environment. Would the patient prefer to lie on his or her right or left side? In which arm should the IV line be placed? What height is preferred for the head of the bed? Does the patient want to cough now or in 20 minutes after pain medication? Any decisions that afford the patient a certain amount of control and predictability are important. These small choices may also help the patient accept lack of control during procedures that involve little choice.

Practicing Cultural Sensitivity

Interventions for individual patients must be contextually based and culturally sensitive. Transcultural nursing refers to a formal area of study and practice that focuses on providing care that is compatible with the cultural beliefs, values, and lifestyles of people. A cultural assessment includes the patient's usual response to illness as well as his or her cultural norms, beliefs, and world views. Because individual responses and values may vary within the same culture, the patient should be recognized as an individual person within the cultural context. Exploring the meaning of the critical event with the patient, family members, and significant others may give clues to the patient's perception of what is happening. In addition, the nurse may ask if there is a particular ethnic or religious group with which the patient identifies and if there is anything the nurses may do to provide care that is sensitive to individual values or norms while the patient is hospitalized. Awareness and acceptance are the heart of cultural competence. Incorporating complementary therapies that are culturally based may have a role in a person's treatment plan. Careful exploration of traditional or complementary therapies needs to be performed before implementation to avoid any harm from interaction of therapies. This is especially true with use of herbal therapies or nutritional supplements that may have multiple ingredients with unknown or undesired side effects or interactions.

Presencing and Reassurance

Presence, or just "being there," can in itself be a meaningful strategy for alleviating distress or anxiety in the critically ill patient. *Presencing* is the therapeutic use of self, adopting a caring attitude, and paying attention to a person's needs. However, this presence implies more than just physical presence. It means giving one's full attention to the person, focusing on the person, and practicing active listening. When a nurse uses presence, the focus is not on a task or outside thoughts. Energy and attention are directed at the patient and his or her needs or feelings. This means one makes a conscious effort to use all of one's capacity, including eyes, voice, energy, and touch, in a more intentionally healing way. Reassurance can be provided to the patient in the form of presencing and caring touch. Reassurance can also be verbal. Verbal reassurance can be effective for patients if it provides realistic encouragement or clarifies misconceptions. However, verbal reassurance is not valuable if it prevents a patient from expressing his or her emotions or stifles the need for further dialogue. Reassurance is intended to reduce fear and anxiety and evoke a calmer, more passive response. It is best directed at patients expressing unrealistic or exaggerated fears.

Cognitive Techniques

Techniques that have evolved from cognitive theories of learning may help anxious patients and their families. They can be initiated by the patient and do not depend on complex insight or understanding of one's own psychological makeup. They can also be used to reduce anxiety in a way that avoids probing into the patient's personal life. Furthermore, the patient's friends and family members can be taught these techniques to help them and the patient reduce tension.

Internal Dialogue

Highly anxious people are most likely giving themselves messages that increase or perpetuate their anxiety. These messages

are conveyed in one's continuously running "self-talk," or internal dialogue. The patient in the ICU may be silently saying things such as, "I can't stand it in here. I've got to get out." Another unexpressed thought might be, "I can't handle this pain." By asking the patient to share aloud what is going on in this internal dialogue, the nurse can bring to awareness the messages that are distracting the patient from rest and relaxation. Substitute messages should be suggested to the patient. It is important to ask the patient to substitute rather than delete messages because the internal dialogue is continuously operating and will not turn off, even if the patient wills it to do so. Therefore, asking the patient to substitute constructive, reassuring comments is more likely to help the patient significantly reduce his or her tension level. Comments such as, "I'll handle this pain just 1 minute at a time" or "I've been in tough spots before, and I am capable of making it through this one!" automatically reduce anxiety and help the patient shape coping behaviors accordingly. Any message that enhances the patient's confidence, sense of control, and hope and puts him or her in a positive, active role, rather than the passive role of victim, increases the patient's sense of coping and well-being.

The nurse helps the patient develop self-dialogue messages that increase:

- Confidence
- Sense of control
- Ability to cope
- Optimism
- Hope

External Dialogue

A similar method can be applied to the patient's external conversation with other people. By simply requiring patients to speak accurately about themselves to others, the same goals can be accomplished. For example, patients who exclaim, "I can't do anything for myself!" should be asked to identify the things that they are able to do, such as lifting their own bodies, turning to one side, making a nurse feel good with a rewarding smile, or helping the family understand what is happening. Even the smallest movement in the weakest of patients should be acknowledged and claimed by the patient. This technique is useful in helping patients correct their own misconceptions of themselves and the way others see them. This reduces patients' sense of helplessness and therefore their anxiety.

Cognitive Reappraisal

This technique asks the patient to identify a particular stressor and then modify his or her response to that stressor. In other words, the patient reframes his or her perception of the stressor in a more positive light so that the stimulus is no longer viewed as threatening. The patient is given permission to take personal control of responses to the stimulus. This technique may be combined with guided imagery and relaxation training.

Guided Imagery and Relaxation Training

Guided imagery and relaxation training are two useful techniques that can be taught to the patient to help reduce tension. The nurse can encourage the patient to imagine either being in a very pleasant place or taking part in a very pleasant experience. The patient should be instructed to focus and linger on the sensations that are experienced. For example, asking the patient questions such as, "What colors do you see?", "What sounds are present?", "How does the air smell?", "How does your skin feel?", or "Is there a breeze in the air?" helps increase the intensity of the fantasy and thereby promotes relaxation through mental escape.

Guided imagery also can be used to help reduce unpleasant feelings of depression, anxiety, and hostility. Patients who must relearn life-sustaining tasks, such as walking and feeding themselves, can use imagery to prepare mentally to meet the challenge successfully. In these instances, patients should be taught to visualize themselves moving through the task and successfully completing it. If this method seems trivial or silly to the patients, they can be reminded that this method demands concentration and skill and is commonly used by athletes to improve their performance and to prepare themselves mentally before an important event. Guided imagery is a way of purposefully diverting or focusing the patients' thoughts and has been shown to empower patients, improving their satisfaction and well-being.[63,64] The nurse can also use techniques that induce deep muscle relaxation to help the patient decrease anxiety. Deep muscle relaxation may reduce or eliminate the use of tranquilizing and sedating drugs. In progressive relaxation, the patient is first directed to find as comfortable a position as possible and then to take several deep breaths and let them out slowly. Next, the patient is asked to clench a fist or curl toes as tightly as possible, to hold the position for a few seconds, and then to let go while focusing on the sensations of the releasing muscles. The patient should practice this technique, beginning with the toes and moving upward through other parts of the body—the feet, calves, thighs, abdomen, chest, and so on. This procedure is done slowly while the patient gives nonverbal signals (eg, lifting a finger) to indicate when each new muscle mass has reached a state of relaxation. Extra time and attention should be given to the back, shoulders, neck, scalp, and forehead because many people experience physical tension in these areas.

Once a state of relaxation is achieved, the nurse can suggest that the patient fantasize or sleep as deeply as the patient chooses. The patient must be allowed to select and control the depth of relaxation and sleep, especially if the fear of death is prominent in the patient's mind. A moderately dark room and a soft voice facilitate relaxation. Asking the patient to relax is frequently nonproductive compared with directing the patient to release a muscle mass actively, let go of tension, or imagine tension draining through the body and sinking deeply into the mattress. Again, the patient is assisted to take an active rather than passive role by the nurse's careful use of language. In addition, a number of commercially available recordings can be used to assist in guided imagery and relaxation

Deep Breathing

When acutely anxious, the patient's breathing patterns may change, and the patient may hold his or her breath. This could be physically and psychologically detrimental. Teaching

diaphragmatic breathing, also called abdominal breathing, to the patient may be useful as both a distraction and a coping mechanism. Diaphragmatic breathing can be taught easily and quickly to the preoperative patient or to a patient experiencing acute fear or anxiety. The patient may be asked to place a hand on the abdomen, inhale deeply through the nose, hold briefly, and exhale through pursed lips. The goal is to have the patient push out his own hand to demonstrate the deep breath. The nurse may demonstrate the technique and perform it along with the patient until the patient is comfortable with the technique and is in control. The mechanically ventilated patient may be able to modify this technique by concentrating on breathing and on pushing out the hand. However, a mechanically ventilated patient experiencing severe agitation may not be able to respond to this technique.

Music Therapy

Music therapy has been used in the critical care environment as a strategy to reduce anxiety, provide distraction, and promote relaxation, rest, and sleep.[65–68] The patient receives a choice of specially recorded audiotapes and a set of headphones. Usually, music sessions are 20 to 90 minutes long, once or twice daily. Music selections may vary by individual taste, but the most commonly used selections have a tempo of 60 to 70 beats; a simple, direct musical rhythm; and a low-pitched sound with primarily a string composition. Most patients prefer music that is familiar to them. Many ICUs maintain a CD library with a variety of genres to satisfy patient choices. Patients or family members are also encouraged to bring in their own MP3 players with the patient's favorite music selections already programmed. This intervention has proved effective for relaxing mechanically ventilated patients. Some hospitals have used loudspeakers to play music overhead in their ICUs, emergency rooms, and postanesthesia units to promote a healing environment.

Humor

A good belly laugh produces positive physiological and psychological effects. Laughter can increase the level of endorphins, the body's natural pain relievers, which are released into the bloodstream. Laughter can relieve tension and anxiety and relax muscles. Humor is a universal emotion that can help patients cope with stressful experiences. The use of humor by nurses in critical care, which can be spontaneous or planned, can help reduce procedural anxiety or provide distraction. Once again, the humor must be compatible with the context in which it is offered and with the person's cultural perspective. Many nurses report using humor cautiously after they have established a rapport with the individual. Nurses also report that they are able to take cues from the patient and visitors regarding the appropriate use of humor. Patients have reported that nurses who have a good sense of humor are more approachable and easier to talk with. Humor that is lighthearted, witty, and, of course, timed just right, is the most well received by adults.

Humor therapy has been used successfully in a variety of treatment settings, including pediatrics, surgery, oncology, and palliative care. In an effort to incorporate the positive effects of humor into health care settings, some institutions have developed humor resource rooms or mobile humor carts. These provide patients with a variety of lighthearted reading materials, videotapes, and audiotapes. Also included on the cart may be games, puzzles, and magic tricks. Some nurses have created their own portable therapeutic humor kits, comic strips, jokes, or humorous stories to which their patients can relate.

Use of humor by patients may help them reframe their anxiety and channel their energy toward feeling better. Some patients link humor with spirituality, noting that humor helped them cope better with serious illness and develop a closer relationship with God. In addition, appropriate use of humor can relieve stress among critical care nurses who work in complex, challenging environments with significant economic pressures.

Massage, Aromatherapy, and Therapeutic Touch

Massage is the purposeful stroking and kneading of muscles with the goal of providing comfort and promoting relaxation.[69–72] Nurses have traditionally used effleurage for backrubs for patient comfort. Effleurage uses slow, rhythmic strokes from distal to proximal areas of long muscles such as the back or extremities. Consistent, firm, yet flexible hand pressure is applied with all parts of the hand to conform to body contours. Lotion may be used to decrease friction and add moisture. Massage has been effective at reducing anxiety and promoting relaxation. Patient selection is an important consideration when electing massage as a therapeutic intervention. Patients who are hemodynamically unstable, for example, would not be appropriate candidates. In addition, nurses require additional training in massage therapy to effectively incorporate more advanced massage techniques such as pétrissage or pressure points into plans of care for critically ill patients.

Massage can be combined with aromatherapy, in which massage is carried out with scented oils or lotions. Some scents have been associated with specific beneficial effects. For example, lavender oil and other floral scents are said to be relaxing, citrus oils to be positive mood enhancers, and peppermint oils to be promoters of mental stimulation. Aromatherapy can also be accomplished with use of scented bath water or unlit scented candles placed in the room.

Therapeutic touch is a set of techniques in which the practitioner's hands move over a patient in a systematic way to rebalance the patient's energy fields. An important component of therapeutic touch is compassionate intent on the part of the healer. Therapeutic touch as a complementary therapy has been used successfully in acute care settings to decrease anxiety and promote a sense of well-being. It is a foundational technique of healing touch. Healing touch involves a number of full-body and localized techniques to balance energy fields and promote healing. Implementation of healing touch therapy involves a formal educational program for healers, and its potential benefits are under active investigation.

Meridian Therapy

Complementary and alternative medicine describes an array of nontraditional healing approaches. Meridian therapy refers to therapies that involve an acupoint, such

as acupuncture, acupressure, and the activation of specific sites with electrical stimulation and low-intensity laser.[73–76] Meridian therapy originates from traditional Chinese medicine. Meridians are complex energy pathways that integrate into intricate patterns. These pathways contain sensitive energy points that are amenable to stimulation to relieve blockages that affect various physiological functions. Research has demonstrated the effectiveness of meridian therapy for pain relief, postoperative nausea, and other functions. Currently, research is underway to validate acupoint sites. Meridian therapy should be performed only by professionals with specialized training.

Animal-Assisted Therapy

The human–animal bond has been well documented. Pet ownership has been linked to higher levels of self-esteem and physical health. Pet therapy (or, more broadly, animal-assisted therapy) has had measurable benefits for schoolchildren and residents of nursing homes. More recently, this concept has been introduced to the acute and critical care settings with positive results. Some hospitals have developed guidelines for pet visitation; a patient's leashed pet may be brought to the hospital to visit with the patient. This type of program has been well received by patients and staff. However, it does require coordination between staff and family members. Pets must in good health, have up-to-date vaccinations, and be well-behaved in unfamiliar environments. The handler must be familiar with the pet and agree to follow hospital guidelines regarding time limits (generally 20 to 30 minutes per visit). A private patient room or visiting room is required. It is recommended that pets be leashed and wear a "shirt," which reduces shedding and identifies the pet. In some hospitals, a formal program exists in which volunteer owner–dog teams visit patients in the hospital on a variety of units. In addition, one hospital reported patients' delight in having fish aquariums placed in their rooms while they were awaiting heart transplantation.

Fostering Spirituality and Healing

Caring in nursing includes recognition and support of the spiritual nature of human beings. Spirituality refers to the realm of invisible and intangible factors that influence our thoughts and behaviors. This includes religious beliefs and extends beyond them. When people sense power and influence outside of time and physical existence, they are said to be experiencing the metaphysical aspects of spirituality.

Spirituality, which includes one's system of beliefs and values, can be defined as the *means or* manner by which persons seek meaning in their lives and experience transcendence-connectedness to that which is beyond the self.[77–79] Intuition and knowledge from unknown sources and origins of unconditional love and belonging typically are viewed as spiritual power. A sense of universal connection, personal empowerment, and reverence for life also pertains to the existence of spirituality. These elements also may be viewed as benefits of spirituality. Spirituality includes the following:

- Religion
- Beliefs and values
- Intuition
- Knowledge from the unknown
- Unconditional love
- A sense of belonging
- A sense of connection with the universe
- Reverence for life
- Personal empowerment

Critical care patients and their families frequently find strength in prayer, which is used by people of many faiths. Research on prayer and health has demonstrated prayer to be a powerful tool to help patients cope with difficult situations, chronic illnesses, and impending death.

Nursing goals related to spirituality include the recognition and promotion of patients' spiritual sources of strength. By allowing and supporting patients to share their beliefs about the universe without disagreement, nurses help patients recognize and draw on their own sources of spiritual courage. Recognition of the unique spiritual nature of each patient is thought to assist personal empowerment and healing.

Nurses who find their own spiritual values in religion must acknowledge and respect that nonreligious people may also be spiritual and experience spirituality as a life force. Regardless of personal views, the nurse is obligated to assess patients' spiritual belief systems and assist them to recognize and draw on the values and beliefs already in existence for them.

Furthermore, critical illness may deepen or challenge existing spirituality. Patients have reported deeper faith after coping with critical illness. During these times, it may be useful for the nurse or family to call on a spiritual or religious leader, hospital chaplain, or pastoral care representative to help the patient make meaningful use of the critical illness experience. Patients may also gain support from members of their congregation or family. It is important for nurses to assess and recognize the spiritual nature of their patients, to allow time for spiritual and religious practices, and to make referrals when needed. Referrals may be made to the hospital chaplain or to a clergy person of the patient's choice.

▲ Restraints in Critical Care

Restraints in critical care include any drug or device that is used to restrict the patient's mobility and normal access to his or her body. Physical restraints may include limb restraints, mittens with ties, vests or waist restraints, geriatric chairs, and side rails. Side rails are considered a restraint if used to limit the ability of the patient to get out of bed rather than to help him or her sit or stand up.

Chemical Restraint

Chemical restraints refer to pharmacological agents that are given to patients as discipline or to limit disruptive behavior. Medications that have been used for behavior control include, but are not limited to, psychotropic drugs such as haloperidol, sedative agents such as benzodiazepines (eg, lorazepam, midazolam), or the anticholinergic antihistamine, diphenhydramine. This definition does not apply to medications that are given to treat a medical condition. The use of sedative, analgesic, and anxiolytic medications is an important adjunct in the care of the critically ill patient.

BOX 2-4 Summary of Care Standards Regarding Physical Restraints

Initiating Restraints

- Restraints require the order of a licensed independent practitioner who must personally see and evaluate the patient within specified time periods.
- Restraints are used only as an emergency measure or after treatment alternatives have failed. (Treatment alternatives and patient responses are documented.)
- Restraints are instituted by staff members who are trained and competent to use restraints safely. (A comprehensive training and monitoring program must be in place.)
- Restraint orders must be time limited. (A patient must not be placed in a restraint for longer than 24 hours, with reassessment and documentation of continued need for restraint at more frequent intervals.)
- Patients and families are informed about the reason/rationale for the use of the restraint.

Monitoring Patients in Restraints

- The patient's rights, dignity, and well-being are to be protected.
- The patient will be assessed every 15 minutes by trained and competent staff.
- The assessment and documentation must include evaluation of adequate nutrition, hydration, hygiene, elimination, vital signs, circulation, range of motion, injury due to the restraint, physical and psychological comfort, and readiness for discontinuance of the restraint.

Care must be taken to provide adequate comfort for patients experiencing life-threatening illnesses and a variety of noxious interventions. It is desirable to use the least amount of medication as feasible to achieve the goals of patient care because all medications have potential side effects and adverse reactions. Patients must be continually assessed for adequacy of comfort. Behaviors that seem to indicate pain may actually indicate a change in the patient's physiological status. Agitation, for example, may be a sign of hypoxemia. Caution must be exercised when using as-needed (PRN) medications to reduce pain and promote comfort. Without consistency in assessment, goal setting, and administration, PRN dosing may inadvertently lead to overmedication or undermedication in the critically ill patient. In addition, these medications can have rebound effects if abruptly withdrawn. Weaning a patient from analgesic or sedative medication may be as important as weaning a patient from a mechanical ventilator. Many ICUs incorporate assessment tools for patient comfort on their daily flow sheets.

Physical Restraints

Historically, physical restraints have been used for patients in critical care to prevent potentially serious disruptions in patient care through accidental dislodgment of endotracheal tubes or lifesaving IV lines and other invasive therapies. Other reasons that have been cited for use of restraints include fall prevention, behavior management, and avoidance of liability suits resulting from patient injury. However, research related to restraint use, especially in elderly patients, has demonstrated that these reasons, although well intentioned, are seldom valid.[80–84] Patients who are restrained have been shown to have more serious injuries secondary to falls as they "fight" the device that limits their freedom. In addition, there are reportedly a greater number of lawsuits related to improper restraint use than to injuries sustained when restraints were not used. Critically ill, intubated patients have been known to self-extubate despite the use of soft wrist restraints.

The forced immobilization that results from restraining a patient can prolong a patient's hospitalization by contributing to skin alterations, loss of muscle tone, impaired circulation, nerve damage, and pneumonia. Restraints have been implicated in accelerating patients' levels of agitation, resulting in injuries, such as fractures or strangulation.

Standards on physical restraint use are published and monitored by the Joint Commission and the Centers for Medicare and Medicaid Services. A summary of these standards is given in Box 2-4. These standards may be viewed on the websites of the respective agencies. Many hospitals have revised their policies, procedures, and documentation of the use of restraints to comply with the most recent revision of these standards. Clinical practice guidelines have been published by the Society of Critical Care Medicine.

BOX 2-5 Alternatives to Physical Restraints

Modifications to Patient Environment

- Keep the bed in the lowest position.
- Minimize the use of side rails to what is needed for positioning.
- Optimize room lighting.
- Activate bed and chair exit alarms where available.
- Remove unnecessary furniture or equipment.
- Ensure that the bed wheels are locked.
- Position the call light within easy reach.

Modifications to Therapy

- Frequently assess the need for treatments and discontinue lines and catheters at earliest opportunity.
- Toilet patients frequently.
- Disguise treatments, if possible (eg, keep intravenous [IV] solution bags behind patient's field of vision, apply loose stockinette or long-sleeved gown over IV sites).
- Meet physical and comfort needs (eg, skin care, pain management, positioning wedges, hypoxemia management).
- When possible, guide the patient's hand through exploration of the device or tube, and explain the purpose, route, and alarms of the device or tube.
- Mobilize the patient as much as possible (eg, consider physical therapy consult, need for cane or walker, reclining chairs, or bedside commode).

Involvement of the Patient and Family in Care

- Allow patient choices and control when possible.
- Family members or volunteers can provide company and diversionary activities.
- Consider solitary diversionary activities (eg, music, videos or television, books on tape).
- Ensure that the patient has needed glasses and hearing aids.

Therapeutic Use of Self

- Use calm, reassuring tones.
- Introduce yourself and let the patient know he or she is safe.
- Find acceptable means of communicating with intubated or nonverbal patients.
- Reorient patients frequently by explaining treatments, devices, care plans, activities, and unfamiliar sounds, noises, or alarms.

Alternatives to Restraints

What, then, is the well-meaning nurse to do when a patient is experiencing confusion or delirium and is pulling at his or her lifesaving devices and tubes? Remember that physical restraint is the last resort, to be used only when the patient is a danger to himself or others and when other methods have failed. Restraints may actually potentiate the dangerous behavior. Rather, the nurse should attempt to identify what the patient is feeling or experiencing. What is the meaning behind the behavior? Is the patient cold? Does the patient itch? Is the patient in pain? Does the patient know where he or she is and why he or she is there? Sometimes addressing the patient's needs or concerns and reorienting the patient is all that is needed to calm him or her. Other interventions may include modifying the patient's environment, providing diversionary activities, allowing the patient more control or choices, and promoting adequate sleep and rest (Box 2-5, p. 25). Some hospitals have instituted restraint protocols and decision trees to help nurses with assessment and care of patients in restraints.

▲ Clinical Applicability Challenges

SHORT ANSWER QUESTIONS

1. Anxiolytic medication has been used to assist the intubated patient cope with the stressor of being on a mechanical ventilator. Please describe a nonpharmacological intervention that may be employed in this situation.
2. An elderly Arab-American female recovering from emergency bowel surgery has indicated that she only wants female nurses to care for her. How should this request be handled?

3 The Family's Experience with Critical Illness

Colleen Krebs Norton

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Describe the impact of a critical illness and the critical care environment on the family.
2. Describe methods to assess the needs of individual family members.
3. Describe nursing behaviors that help families cope with crisis.
4. Discuss palliative care issues in the critical care environment that have an impact on the family.
5. Define the components and application of the Critical Care Family Assistance Program.
6. List items to include in a plan of care that reflect the needs of the family.

Nurses who strive to deliver consistent quality holistic critical care need to recognize the importance of assessing and caring for patients and their families. The interaction between the family/support system, the nurse, and the patient in the critical care environment, and the needs that result from this interaction, remain a challenge and responsibility of the contemporary critical care nurse.

The *Oxford English Dictionary* defines family as "a group of persons consisting of the parents and their children whether actually living together or not; in a wider sense, the unity formed by those who are nearly connected by blood and affinity." For the purpose of this chapter, *family* is defined as any people who share intimate and routine day-to-day living with the critically ill patient. Anyone who is a significant part of the patient's normal lifestyle is considered a family member. The term family describes the people whose social homeostasis and well-being are altered by the patient's entrance into the arena of critical illness or injury. To provide family centered care, a philosophy that acknowledges that patients are part of a larger "whole" or family is essential to provide the best possible care to the patient and family.[1]

This chapter addresses the family in crisis, stressors in the critical care environment, family assessment, coping mechanisms, and the nursing process. The evolution of the Critical Care Family Assistance Program (CCFAP), family presence during resuscitation in the intensive care unit, and palliative care are also discussed.

▲ Stress, Critical Illness, and the Impact on the Family

A critical illness is a sudden, unexpected, and often life-threatening occurrence for both the patient and the family that threatens the steady state of internal equilibrium usually maintained in the family unit. It can be an acute illness or trauma, an acute exacerbation of a chronic illness, or an acute episode of a previously unknown problem. A family member's entrance as a participant in the life–death sick role of a loved one threatens the well-being of the family and can trigger a stress response in both the patient and the family. Family members of patients in the critical care unit (CCU) may experience stress, disorganization, and helplessness, which may ultimately result in difficulty in mobilizing appropriate coping resources, thus leading to anxiety.[2] The family enters this unplanned situation with its unexpected outcomes and often is forced into the role of decision maker. The balance of strengths and limitations within the family, including the degree of cohesion within the family and conflict resolution strategies, often determines how much stress can be confronted.[3] The astute critical care nurse recognizes that the fear and anxiety demonstrated by the patient and family is an expected consequence of activation of the stress response, a somewhat protective, adaptive mechanism initiated by the neuroendocrine system in response to stressors. The stress response of family members varies.

Stress Syndrome

Studied initially by Hans Selye in 1956,[4] *stress* has been defined as a specific syndrome that was nonspecifically induced. Selye also discussed the role of stressors, the stimuli that produced tension and could contribute to disequilibrium. Stressors can be physiological (trauma, biochemical, or environmental) and psychological (emotional, vocational, social, or cultural). The critical care environment is rich in both physiological and psychosocial stressors that threaten the state of well-being of the patient and family.

In response to a stressor, the fight-or-flight mechanism is activated, releasing the catecholamines norepinephrine and epinephrine through the sympathetic nervous system. These hormones are responsible for the increased heart rate, increased blood pressure, and vasoconstriction that make up the physiological response to the *alarm stage*, the initial stage of the general adaptation syndrome to stress described by Selye. The alarm stage is followed by the *stage of resistance*, which attempts to maintain the body's resistance to stress. According to Selye's theory, all people move through the first two stages many times and become adapted to the stressors encountered during ordinary life. If the person is unsuccessful at adaptation, or if the stressor is too great or prolonged, alarm and resistance are followed by the *stage of exhaustion*, which can lead to death, the result of a wearing down of the human body. It is a challenge to the critical care nurse to assist both the patient and family through this stress response, resulting in an adaptation to the critical care environment. Helping the patient's family resolve the crisis response and facilitate successful coping by creating a safe passage is an identified competency of the contemporary critical care nurse.[5] Family members expect nurses to intervene and meet their needs, and they have high expectations for family centered care.[6]

After the initial fear and anxiety over the critical illness and possible death of the family member, other considerations affect the family, including a shift in responsibilities and role performance, unfamiliarity with the routines of the CCU, and a lack of knowledge concerning the course and outcome of the disease. These issues can develop and persist over the duration of the patient's stay in the CCU.

Contributions to the family unit previously attributed to the patient are added to the responsibilities of others. Financial concerns are usually major, and daily activities that were of little consequence before become important and difficult to manage. Chores, such as balancing a checkbook, contributing to car pools, and shopping for groceries, can become critically significant if left undone. This consequence of the critical illness requires adding the responsibilities of the patient to the responsibilities of others.

The social role that the patient plays in the family is absent during the critical illness. Comforter, organizer, mediator, lover, friend, and disciplinarian are examples of important roles in family functioning that may be, under normal circumstances, fulfilled by the patient. When that role function is unfulfilled, havoc and grief may ensue.

The circumstances surrounding the nature of the patient's illness can also be a stressor for the family. In a sudden, unexpected event, such as a blunt trauma or an acute myocardial infarction, the life of the family can be brought to a halt in a matter of minutes. Having little or no time to prepare for such an event, the family is overwhelmed with a massive amount of unmanageable stress and can be thrown into crisis. The hospital CCU, in most instances an unknown entity, becomes the center of the life of the family. When allowed to visit in the CCU, the family observes sophisticated, intimidating equipment that causes additional fear. Such stress often can manifest itself as anger toward the care giver. The care giver, absorbed with the physical care of the patient, frequently has limited or inadequate time to respond to family members' emotional needs, unrealistic goals, and expectations of the health care staff.[7]

In other instances, the critical event is an acute exacerbation of a chronic but life-threatening illness. Such an episode brings with it a different set of stressors, reminding the family of difficult and painful times in the past when they have faced similar circumstances. Prolonged critical illness can present emotional difficulties for the family, which may increase the likelihood of crisis.

Coping Mechanisms

Coping mechanisms can be defined as a person's response to a change in the environment; they can be healthy or unhealthy. The critical care nurse, as care giver to both the patient and family, should be aware of the use of coping mechanisms by the family as a means of maintaining equilibrium. A sense of fear, panic, shock, or disbelief is sometimes followed by irrational acts, demanding behavior, withdrawal, perseveration, or fainting. The family attempts to obtain some sense of control over the situation, often demonstrated by refusing to leave the bedside or, alternatively, by minimizing the severity of the illness through denial. Reactions to crisis are difficult to categorize because they depend on the different coping styles, personalities, and stress management techniques of the family. The nurse must be able to interpret the feeling that a person in crisis is experiencing, particularly when that person cannot identify the problem or the feeling to himself or herself or to others. The following are four generalizations about crisis:

- Whether people emerge stronger or weaker as a result of a crisis is based not so much on their character as on the quality of help they receive during a crisis state.
- People are more open to suggestions and help during an actual crisis.
- With the onset of a crisis, old memories of past crises may be evoked. If maladaptive behavior was used to deal with previous situations, the same type of behavior may be repeated in the face of a new crisis. If adaptive behavior was used, the impact of the crisis may be lessened.
- The primary way to survive a crisis is to be aware of it.

▲ The Family and the Nursing Process

Nursing Assessment

In 2010, the Institute of Medicine recommended that health care delivery systems become patient centered rather than disease or clinician centered and that an assessment be made of the patient's preferences and beliefs.[8] In the CCU, this translates into an increase in family involvement. Nursing assessment by the critical care nurse involves primarily, but not exclusively, an appraisal of the patient. It also includes an assessment of the members of the family. The family remains the most important social component to consider. Family centered care is described as an expansion of total patient care and includes the family in the planning and implementation phases of the nursing process.[9] Family centered care is advocated by both the Joint Commission and Nursing Practice Standards.[10]

The nursing assessment serves as a database and an identification of strengths and concerns on which care of the patient and family can be supported. It includes not only physiological data but also psychological, social, environmental, cultural, economic, and spiritual reactions. It involves an assessment and validation of verbal and nonverbal behavior and requires clinical expertise. A thorough nursing assessment guides the formulation of nursing diagnoses. The standards of the American Association of Critical-Care Nurses (AACN) emphasize and support the importance of an assessment of the family and the continual involvement of the family in implementing the plan of care and participating, to the extent they are able, in decision making about the nursing care.[11]

An important part of the family assessment is a history of the family. Who does the patient include in the description of his or her family? Although all patients belong to a family, the family might not include or be restricted to blood relatives. Who are the people most upset about the patient's illness? Is there a formal or informal leader identified by the group? This becomes important when communicating with the family in decision making, as well as in legal matters, such as obtaining consent and withdrawing life support. What is the coping style of the family? Does the family have a history of dealing with a critical illness? What are the relationships between the members of the family? How close is the family? Do the family members identify any unresolved issues? The family history can aid the nurse in interpreting how the family is coping with stress, how their coping mechanisms will affect the patient, and how they are adapting to the patient's illness.

Four intrinsic elements of an assessment of the family are:[12]

1. Providing a human, caring presence
2. Acknowledging multiple perceptions
3. Respecting diversity
4. Valuing each person in the context of the family

Numerous assessment tools are available to aid the nurse in determining the needs and problems the family faces. One of the initial assessment tools was developed by Molter in 1979.[13] This method includes a 45-item needs assessment tool, which became an instrument to describe the needs of critical care family members. Leske modified the tool used by Molter by adding an open-ended item and calling it the Critical Care Family Needs Inventory (CCFNI).[14] The CCFNI has been used widely during the past two decades to identify the needs of family members in the CCU. The CCFNI, after analysis, was found to contain five distinct subscales: support, comfort, information, proximity, and assurance.[15] Mendonca and Warren[2] used the CCFNI to assess the needs of family members and the importance of these needs in the first 18 to 24 hours after admission of the adult patient to the CCU. The family remains the most important social context to assess and consider when determining interventions to influence patient outcomes in a positive way.[14]

Nursing research using these tools reveals consistency in which areas are important and should be addressed with family members. These areas include but are not limited to:

1. Family satisfaction with care given
2. Explanations that the family can understand
3. The need for close proximity to the patient
4. Honest information about the patient's condition
5. An understanding of why things are done
6. Delivery of care by staff members who are courteous and show interest in how the family is doing
7. Assurance that someone will notify the family of any changes

The tools also suggest assessing how comfortable the family is in the waiting room and inquiring about what things could be made better for them. Identified needs included physical needs (eg, having comfortable furniture, having the waiting room near the patient, and having a bathroom nearby) as well as emotional needs, such as a place to be alone in the hospital and the opportunity to discuss negative feelings. In addition, families of critically ill patients have other needs, which should be addressed frequently. These needs include:[15]

- To feel that there is hope
- To feel that hospital personnel care about the patient
- To know the prognosis
- To receive information about the patient at least once a day
- To see the patient frequently

In summary, recent research has shown that the top needs of families of critically ill patients are the need for information, the need for support from hospital staff, and the need for hope.[16]

Although the needs perceived by the family may differ from those perceived by the nurse, strong communication skills, as well as an atmosphere of concern and caring, help the nurse gather the subjective and objective assessment data and formulate the appropriate nursing diagnoses for the family. Examples of nursing diagnoses appropriate to the family members of a critically ill patient are given in Box 3-1. The nursing diagnosis guides both the nurse and the family in establishing mutual goals.

BOX 3-1 EXAMPLES OF NURSING DIAGNOSES

For the Family With Critical Illness or Injury

- Acute Confusion
- Anxiety
- Risk for Caregiver Role Strain
- Readiness for Enhanced Communication
- Decisional Conflict
- Defensive Coping
- Deficient Knowledge
- Disturbed Sleep Pattern
- Dysfunctional Family Process
- Fatigue
- Fear
- Grieving
- Hopelessness
- Ineffective Health Maintenance
- Ineffective Denial
- Ineffective Role Performance
- Interrupted Family Processes
- Impaired Memory
- Impaired Parenting
- Risk for Loneliness
- Powerlessness
- Spiritual Distress
- Risk for Spiritual Distress

Nursing Interventions

The time spent by the critical care nurse with the family is often limited because of the crucial physiological and psychosocial needs of the patient. Therefore, it is important to make every interaction with the family as useful and therapeutic as possible. Categories of nurse caring behaviors as perceived by the families of critical care patients include informing, enhancing, touching, and spiriting. Interaction between the nurse and family has the potential to develop a bond as a result of these caring behaviors.[17] Nursing interventions should address cognitive, affective, and behavioral domains[18] and should be designed to:

- Help the family learn from the crisis experience and move toward adaptation
- Regain a state of equilibrium
- Experience the normal (but painful) feelings associated with the crisis, to avoid delayed depression, and allow for future emotional growth

A novel idea in the practice of family centered care is to consider inviting a family member on daily rounds with the team in the CCU. An advantage of having a family member on rounds includes reduced stress in families because members have current information and a representative who can ask questions. A disadvantage could be that care is complex; a family member may not be well prepared to handle the information cognitively or emotionally. However, a recent study demonstrated widespread family member satisfaction with the invitation to join patient care rounds in a trauma patient population.[19] This example of including family members on rounds is just one of several ideas to improve the family's experience in critical care. Asking family members to assist in providing some aspects of basic care has also been studied, but not all family members are willing participants, and thus the requests must be considered on an individual basis.[20,21] The use of family visiting kits has also been explored, which includes activities that could be performed at the bedside (hand massage), directions on personal care activities (applying lip balm around an endotracheal tube), cognitive recovery tools, (such as dominoes and plating cards), and personal care items for the families themselves (toiletries and a log for questions).[10]

Suggestions for nursing interventions with the family in crisis are outlined in Box 3-2. Considerations for the older patient are presented in Box 3-3.

BOX 3-2 NURSING INTERVENTIONS

For Care of the Family in Crisis

- Guide the family in defining the current problem.
- Help the family identify its strengths and sources of support.
- Prepare the family for the critical care environment, especially regarding equipment and purposes of the equipment.
- Speak openly to the patient and the family about the critical illness.
- Demonstrate a concern about the current crisis and an ability to help with the initial relationship.
- Be realistic and honest about the situation, taking care not to give false reassurance.
- Convey feelings of hope and confidence in the family's ability to deal with the situation.
- Try to perceive the feelings that the crisis evokes in the family.
- Help the family identify and focus on feelings.
- Assist the family to determine the goals and steps to take in facing the crisis.
- Provide opportunities for the patient and the family to make choices and avoid powerlessness and hopelessness.
- Assist the family in finding ways to communicate with the patient.
- Encourage the family to help with the care of the patient.
- Discuss all issues as they relate to the patient's uniqueness; avoid generalizations.
- Help the family to set short-term goals so that progress and positive changes can be seen.
- Ensure that the family receives information about all significant changes in the patient's condition.
- Advocate the adjustment of visiting hours to accommodate the needs of the family as permitted by the situation in the unit.
- Determine whether there is space available in the hospital near the unit where the family can be alone and have privacy.
- Recognize the patient's and family's spirituality, and suggest the assistance of a spiritual advisor if there is a need.

Visitation Advocacy

The concept of open visiting hours is seen as another method of enhancing family centered care. Policies regarding the use and provision of visiting hours should be evaluated periodically. Research demonstrates that novel approaches to visitation, such as allowing children who are accompanied by an adult to visit a relative in the CCU and the use of animal-assisted therapy in the CCU, can have positive effects on the patient, including increased feelings of happiness and calmness and reduced feelings of loneliness.[22]

Visiting hours in CCUs have been restricted for many years, with the rationale that rest, quiet, and an undisturbed environment were all therapeutic nursing interventions. Families often interpreted these restrictions as denying access to their loved ones. As early as 1978, Dracup and Breu reported that satisfying the needs of the families of patients was improved by relaxing a policy of restricted visiting hours and initiating set communication with patients' spouses.[23]

BOX 3-3 CONSIDERATIONS FOR THE OLDER PATIENT

Providing Care for the Critically Ill Older Patient

- Respect the dignity, intelligence, privacy, and maturity of the patient at all times.
- Maintain the patient's right to make decisions as long as possible.
- Avoid the use of paternalism in patient care.
- Integrate the physiological and cognitive changes of aging with the assessment and care of the patient.
- Allow the family to share in the care of their family member.
- Provide active participation and a sense of control for the patient and family.
- Make sure that the patient remains the focus of care and that interventions are performed for the good of the patient.
- Assess the impact that medical and nursing interventions have on quality of life and sense of well-being.
- Determine family burdens resulting from the critical illness.

Increased visiting time was seen as a strategy to improve coping skills and strengthen the relationship between nurses and the family members of patients.[24] Over time, many units began the policy of unrestricted visiting hours. Such interventions were designed to strengthen the relationship between the family and health care provider as well as foster adaptation to the crisis on the part of the family. Research demonstrates that patients have increased satisfaction and decreased anxiety with family around, that families are satisfied with the experience, that nurse/patient/family communication is enhanced, and that patients receive increased support, which improves their well-being.[25] Unrestricted visiting policies in CCUs have been linked to a decrease in septic complications; a decrease in the amount of cardiovascular complications, specifically shock and pulmonary edema; and an improvement in the physiological presentation of blood pressure, heart rate, and intracranial pressure.[26] See Evidence-Based Practice Highlight 3-1.

Critical care nurses must take the responsibility for revising visiting hours to meet the needs of patients and families. When choosing a less-restrictive policy, the physical layout of the unit must be considered. Smaller units may be less appropriate for unrestricted visiting hours with unlimited visitors. The focus should be on what proves to be best for the patient, not for the nurse. The effectiveness of changes in visiting hours must also be evaluated. Additional nursing research is needed to determine the effect of changes in visiting hours on the needs of patients and families.

The nurse must prepare family members for the initial visit to the CCU because it can be an overwhelming environment. The functions of monitors, intravenous drips, ventilators, and other technologies, as well as the meaning of alarms, should always be explained before and during the family visits to avoid causing anxiety and the potential of becoming a barrier between nurse/patient/family.

The names, roles, and responsibilities of all members of the interdisciplinary health care team should be identified to both the patient and family. The nurse, by example, can demonstrate the value of communication and touch to the family. Encouraging family members to provide direct care to the

EVIDENCE-BASED PRACTICE HIGHLIGHT 3-1
Family Visitation in the Adult ICU

△ Expected Practice

- Facilitate unrestricted access of hospitalized patients to a chosen support person (eg, family member, friend, or trusted individual) who is integral to the provision of emotional and social support 24 hours a day, according to patient preference, unless the support person infringes on the rights of others and their safety, or it is medically or therapeutically contraindicated.[1] (Level D)
- Ensure that the facility/unit has an approved written practice document (ie, policy, procedure, or standard of care) for allowing the patient's designated support person—who may or may not be the patient's surrogate decision maker or legally authorized representative—to be at the bedside during the course of the patient's stay, according to the patient's wishes.[1–6] (Level D)
- Evaluate policies to ensure that they prohibit discrimination based on age, race, ethnicity, religion, culture, language, physical or mental disability, socioeconomic status, sex, sexual orientation, and/or gender identity or expression.[1–6] (Level D)
- Ensure that there is an approved written practice document (ie, policy, procedure, or standard of care) for limiting visitors whose presence infringes on the rights of others and their safety or are medically or therapeutically contraindicated to support staff in negotiating visiting privileges.[6] (Level D)

△ Supporting Evidence

- In practice, 78% of ICU nurses in adult critical care units prefer unrestricted policies[7–13]; yet, studies show that 70% of hospital ICU policies restrict family visitation.[3,7–9,13,14] This variability creates conflict between nurses and confusion in families.[10,15]
- Some ICU nurses believe that family visitation increases physiologic stress in the patient and interferes with the provision of care,[16] is mentally exhausting to patients and families,[11,15–19] and contributes to increased infection[8,19]; however, the evidence does not support these beliefs.[8,9,20–29]
- Evidence does suggest that for patients, flexible visitation decreases anxiety,[17,20,21] confusion, and agitation,[22] reduces cardiovascular complications,[20] decreases length of ICU stay,[31] makes the patient feel more secure,[32] increases patient satisfaction,[14,20,29,32–34] and increases quality and safety.[20,24–26,30,35,36]
- For family members, evidence suggests that unrestricted visitation increases family satisfaction,[7,11,17,20,29,36–38] decreases family member anxiety,[7,17,29,36,39,40] promotes better communication,[11,14,17,24,29,41] contributes to better understanding of the patient,[11,32,36] allows more opportunities for patient/family teaching as the family becomes more involved in care,[11] and is not associated with longer family visits.[36]
- Finally, evidence suggests that some nurses in adult ICUs restrict children's visits based on the intuition that children will be harmed by what they see or based on a concern that they would be uncontrollable. These biases are not grounded in evidence or based on the patient's or the child's actual needs.[8,42–44] Yet, when allowed to visit relatives in the ICU, properly prepared children have less negative behavior and fewer emotional changes than those who did not visit.[45–48] It is recommended that they be allowed to visit unless they carry contagious illnesses.[49]

AACN Levels of Evidence

Level A Meta-analysis of quantitative studies or metasynthesis of qualitative studies with results that consistently support a specific action, intervention, or treatment
Level B Well-designed, controlled studies with results that consistently support a specific action, intervention, or treatment
Level C Qualitative studies, descriptive or correlational studies, integrative reviews, systematic reviews, or randomized controlled trials with inconsistent results
Level D Peer-reviewed professional and organizational standards with the support of clinical study recommendations
Level E Multiple case reports, theory-based evidence from expert opinions, or peer-reviewed professional organizational standards without clinical studies to support recommendations
Level M Manufacturer's recommendations only

Excerpted from American Association of Critical-Care Nurses Practice Alert. Available online at http://aacn.org. All references cited in this alert are available with the associated resources related to this chapter. Visit: http://thepoint.lww.com

patient, if they are interested, can help decrease anxiety and provide the family with some control. Direct care activities for the family to perform may include brushing teeth, combing hair, helping with a meal, providing skin care, or giving a bath.

Allowing children to visit a CCU may require special arrangements on the part of the staff. Visits should include short, simple explanations to the child concerning the patient's condition. Answering the child's questions in developmental terms that he or she can understand helps reduce possible fears. The person who is escorting the child into the CCU should be aware that invasive monitoring and other equipment might upset a youngster. If a visit from the child is not possible, arrangements can be made for a telephone visit.

In addition to unrestricted visiting hours, family presence during invasive procedures and resuscitation should be addressed. Positive and compelling evidence has emerged in the research on family presence and the emergency department (ED), necessitating that family presence in adult CCUs be investigated. Although differences exist between the CCU and the ED in terms of appropriateness, terminal weaning, organ donation, and planned invasive procedures seem suitable for the family to witness. When studied, a significant positive relationship was found between spirituality and support for family presence among physicians, physician assistants, and nurses.[27,28] Families believe it is their right to be present, but nurse perceptions continue to vary widely. A common theme that emerges is the need for individuality and uniqueness in each situation.

Use of the Nurse–Family Relationship

Initiating nursing interventions and establishing a meaningful relationship with the family tends to be easier during crisis than at other times. People in crisis are highly receptive to an interested, caring, and empathetic helper. When first meeting the patient's family, the nurse must demonstrate the desire and ability to help. Help that is specific to the family's needs at that time demonstrates the nurse's interest in their comfort and well-being. Deciding on a family representative who is to be notified of the patient's status and validating that contact person's telephone number can be an overwhelming family decision. Assisting the family to determine immediate priorities is essential in the early phase of crisis intervention. The existence of advanced directives, a living will, and power of attorney should be determined. In the absence of these documents, support and methods to obtain them should be given to the family.

With this type of timely involvement, the family will begin to trust and depend on the nurse's judgment. This process then allows family members to believe the nurse when the nurse conveys feelings of hope and confidence in the family's ability to cope with whatever is ahead. It is important to avoid giving false reassurance; rather, the reality of the situation should be expressed in a kind, supportive fashion.

Problem Solving With the Family

As the relationship between the nurse and the family develops, the nurse begins to understand the dynamics of the problem facing the family. Problem solving with the family takes into consideration items such as:

- The meaning the family has attached to the event
- Other crises with which the family may be coping
- The adaptive and maladaptive coping behaviors previously used in time of stress
- The normal support systems of the family, which might include friends, neighbors, clergy, and colleagues

Using the information collected and recorded in the assessment base enables the nurse to help the family deal with the stress. Areas to include in interventions are defining the problem, identifying support, focusing on feelings, and identifying steps.

Defining the Problem

A vital part of the problem-solving process is to help the family clearly state the immediate problem. Often people are overwhelmed and immobilized by the anxiety or panic caused by acute stress. Being able to state the problem and acknowledge the difficulty or threat it poses reduces the family's anxiety by helping family members realize that they have achieved some sort of an understanding of what is happening. Defining the problem is a way of delimiting its parameters. Simply asking the family members their understanding of the problem and the greatest concern for them at this time helps in problem definition. In addition, the family's response helps the nurse to clarify his or her understanding of what the family needs.

Defining and redefining problems can and should occur many times before the problem is solved. Stating the problem clearly helps the family assign priorities and direct needed actions. Goal-directed activities help decrease anxiety.

Identifying Support

Under high levels of stress, some people expect themselves to react differently. Rather than turning to the resources they use daily, they become reluctant to involve them. Asking people to identify the person to whom they usually turn when they are upset, and encouraging them to seek assistance from that person now, helps direct the family back to the normal mechanisms for handling stressful issues. Few families are truly without resources; rather, they only have failed to recognize and call on them.

Defining and redefining the problem may also help put the problem in a different light. It is possible in time to view tragedy as a challenge and the unknown as an adventure. The process of helping the family view a problem from a different perspective is called reframing.

The nurse can also help the family call on its own inherent strengths. What is it as a family that they do best? How have they handled stress before? Encouraging the family members to capitalize on their strengths as a family unit is well worth the effort.

Focusing on Feelings

A problem-solving technique emphasizing choices and alternatives helps the family achieve a sense of control over part of their lives. It also reminds them, and clarifies for them, that they are ultimately responsible for dealing with the event and that they will live with the consequences of their decisions.

Helping the family focus on feelings is extremely important to avoid delayed grief and protracted depression in the future. The reflection of feelings or active listening is necessary

throughout the duration of the crisis. Valuing the expression of feelings might help the family avoid the use of unhealthy coping mechanisms, such as alcohol or excessive sleep. In difficult and sad times, the critical care nurse can promise the family, with some certainty, that things will become easier with the passage of time. Adaptation takes time. Providing valid assurance (eg, that a patient will eventually be weaned from a ventilator, or that tube feeding is a temporary measure) can give the family a sense of trust in the care giver.

During the difficult days of the critical illness, the family may become dependent on the judgment of professionals. The family may have some difficulty identifying the appropriate areas in which to accept the judgments of others. It is important that the nurse acknowledges the family's feelings and recognizes the complexity of the problem, while emphasizing the responsibility each member of the family has for his or her feelings, actions, and decisions. Encouraging family members to focus on things they can change helps to give them a sense of control. For example, if the patient is experiencing pain, the family can be encouraged to advocate for the patient by requesting that the physician evaluate the patient's pain control.

Identifying Steps

Once the problem has been defined and the family begins goal-directed activities, the nurse may help further by asking the family members to identify the steps that they must take. Such anticipatory guidance may help reduce the family's anxiety. However, the nurse must recognize moments when direction is vital to health and safety. It is often necessary to direct families, for example, to return home to rest. This can be explained by stating that by maintaining their own health, family members will, at a later date, be as helpful to the patient as possible. To make each interaction more meaningful and therapeutic, the nurse should focus on the crisis situation and avoid involvement in long-term chronic problems.

Interdisciplinary Management

The health care providers who most often meet the needs of family members are generally thought to be nurses and physicians. Additional help comes in the form of written materials, other family members, the patient, and other hospital sources. In some cases, nurse-coached hospital volunteer programs have proved effective.[29] These programs consist of an in-service program taught by nurses and followed by the assignment of a nurse mentor to the volunteer. Some families benefit by a referral to a mental health clinical specialist, a social worker, a psychologist, or a chaplain. Other interdisciplinary teams can include pharmacists, family care specialists, and therapists.[9] A nurse can best encourage the family to accept help from others by acknowledging the difficulty and complexity of the problem and providing several names and phone numbers. It may be appropriate for the nurse to set up the first meeting, with follow-up meetings coordinated between the family and the consultant. Many CCUs have such resources on a 24-hour on-call basis to ensure prompt interventions. An objective professional with experience in critical illness and its impact on the family can be an excellent resource. Family members of former patients are also being used as a method of sharing experiences and providing information to assist with the critical care experience.[29]

A new concept for improving family centered care in critical care is the Patient-Family Advisory Council.[30] An advisory council composed not just of nurses and other health care providers but also of past patients and family members represents the needs of family members. Driven by the consumer movement, the concept of the advisory council has the potential to provide new insights leading to improved family care. In one institution, clinical nurse specialists served as the facilitators, and the council worked on assessing how well the unit was doing in several categories with plans for improvement.[31]

▲ Palliative Care Issues in Critical Care

According to the World Health Organization, palliative care is an "approach that improves the quality of life of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial, and spiritual."[32] Important components of palliative care are the inclusion of the family in decision making and the provision of patient care. Families are faced with complex palliative care decisions that must be made in the unfamiliar environment of the CCU. These decisions can be made easier with the involvement of the nurse in facilitating and guiding the decision-making process. The focus of palliative nursing care should be the entire family. This is often difficult in acute care units with time and space constraints. Nurses' personal issues, such as previous experiences with the death of their own family members, have the potential to either enhance or threaten assessment and intervention. Family meetings with the critical care nurse and the palliative care team help to ensure that the wishes and concerns of the family are heard.[33]

Caring for a patient's family at any point during the dying process encompasses three major areas: access, information and support, and involvement in care giving activities. Family members of dying loved ones should be allowed more liberal access in both visiting hours and number of visitors allowed. Ensuring that a family can be with their critically ill loved one will be a source of comfort. Information has been identified as a crucial component in the family's coping, and support in the form of the nurse's caring behaviors is influential in shaping the critical care experience for both the patient and family. Honesty and truth telling are important skills in this emotionally charged time. Finally, family involvement in care giving, in tasks as simple as being physically present to those as complex as assisting with postmortem care, may help families work through their grief. Facilitation of family involvement is a practical nursing intervention. See Chapter 6 for further discussion of end-of-life and palliative care issues in the critical care setting.

▲ The Critical Care Family Assistance Program

Several hundred research studies during the past 20 years have focused on the environmental and social issues of anxious families awaiting the outcome of a family member's stay in the CCU, demonstrating that attending to the needs of

these family members cannot be ignored.[33] Additionally, a crucial initiative of the AACN, established in 1969, focuses on establishing respectful, healing, and humane nursing care environments. As a result of collaboration between the Chest Foundation and Eli Lilly and Company Foundation, the Critical Care Family Assistance Program (CCFAP) was developed as an example of a renewed awakening to the concepts of family centered care.[1] The objectives of the CCFAP are:[34]

- To better prepare a multidisciplinary team to meet the needs of families
- To increase families' satisfaction with the care and treatment of critically ill patients
- To improve families' comprehension of, and satisfaction with, the information provided by care givers
- To identify common formats for providing information and financial resources
- To improve a hospital's ability to respond to family needs within a structured feedback model
- To increase the medical team's knowledge and understanding of the CCFAP model
- To increase knowledge about the CCFAP and foster dissemination of the information within the medical and lay community
- To compare and contrast specific levels of family needs across various models of care

Needs assessments completed at the original CCFAP sites validate the findings of decades of research. Commonly noted gaps in supporting the families of patients included:

- Discrepancies in the viewpoint with regard to the sharing of information
- The need of the family to involve more family members in decision making
- A lack of resources and services offered during this time of crisis

Because of shortened lengths of stay and nursing shortages, family members are increasingly more active participants in the care of their loved ones. Family centered care focuses on better integration of the family into the care planning process. Engaging family members early and encouraging them to work in partnership with the nursing staff can make a difference. Box 3-4 lists the components of the CCFAP model. It is hoped that with expanded use of this model, quality of critical care delivered will increase, whereas cost of critical care delivery will decrease.

BOX 3-4 Components of the Critical Care Family Assistance Program (CCFAP)

Communication
Example: "ICU Navigators," weekly group family sessions that provide information about equipment, medical procedures, and assertiveness skills

Environmental Changes
Examples: Expanding the waiting area, brightening the look of the room, new and more comfortable furniture

Educational Materials
Example: Publications that are up-to-date and written in nontechnical language

Information Kiosk
Examples: Electronic messaging system, Internet access, CCFAP family satisfaction surveys

Hospitality Programs
Examples: Hotel discounts, meals for families

Other Services
Examples: Music therapy, pet therapy

▲ Cultural Issues Related to Critical Illness

Nursing interventions for the critically ill patient include recognition and appreciation of the cultural uniqueness of each person. In today's diverse society, culture affects the nursing care of patients in many ways—from pain control and visitation expectations to care of the body after death. Critical care nurses must recognize the uniqueness of each person and the ways in which that uniqueness affects the care of the patient and the needs of the family.

Health care providers in Western medicine often address a critical illness as a disease process and focus on the physical symptoms, the pathology of organ function, or injury to a body part. The patient and family, having a different cultural perspective, may view the illness in a more psychophysiological manner, focusing on the physical, psychological, personal, and cultural ramifications of the illness. In other cultures, the patient's critical illness may be viewed as a curse or disharmony in the universe. Culture serves as an important influence in the patient's attitudes about approach to suffering, beliefs about life-prolonging treatments, palliative care, and advanced directives and health care proxies.[35]

Cultural competence is a reflection of one's attitudes, knowledge base, acquired skills, and behavior. Although it is unrealistic to expect that the nurse should know the customs and beliefs of all critically ill patients he or she cares for, it is not unreasonable to expect some degree of cultural competence. Glass et al[36] make the following suggestions:

- Be aware of one's own ethnocentrism.
- Assess the family's beliefs about illness and treatment.
- Consistently convey respect.
- Request that the family and patient act as guides for cultural preferences.
- Ask for the patient's personal preference.
- Respect cultural differences regarding personal space and touch.
- Note appropriate complementary and alternative medical practices, and allow their use if possible.
- Incorporate the patient's cultural healing practices into the plan of care.
- Be sensitive to the need for a translator.

Cultural characteristics, such as language, values, behavioral norms, diet, and attitudes toward disease prevention, death and dying, and management of illness, vary from culture to culture. Critical illness may be viewed by the family from a religious or spiritual perspective. Astuteness and sensitivity on the part of the critical care nurse ensure that the beliefs of the highly technologic, illness-focused health care system will not clash with cultural beliefs in folk medicine, rituals, religious healing, and medicine men.

▲ Clinical Applicability Challenges

SHORT ANSWER QUESTIONS

1. Mrs. J. is a critically ill patient with multiple trauma who has been admitted to your unit. She is not expected to survive her injuries. Mrs. J.'s husband, her two children ages 6 and 10, and her parents have just arrived on your unit. Formulate a plan of care that reflects sensitivity to the issues that will assist the patient's family in dealing with the probable death of their loved one.

2. Mr. E. is a 73-year-old man admitted to your unit after resuscitation. He has a long-standing history of cardiac disease and collapsed at home after what has been interpreted as a life-threatening rhythm disturbance. Although he received cardiopulmonary resuscitation, he was unconscious for 10 minutes before the rescue team arrived. His older daughters are fighting over the maintenance of ventilatory support. Discuss how you would help his daughters at this difficult time.

3. Mr. and Mrs. P. are the parents of a critically ill child on your unit. They are Indian and speak very little English. Describe the criteria you would use to assess their degree of stress and anxiety. How could you be certain that the cultural needs of the family are met while the child is a patient in your unit?

4 Patient and Family Education in Critical Care

Mary O. Palazzo

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Describe the barriers to learning that are unique to the critical care setting.
2. Describe and differentiate between the concepts of education and learning.
3. Identify the three domains of learning.
4. Identify the six principles of adult learning.
5. Describe the assessment of learning in the critical care environment.

In the critical care setting, it is always a challenge to meet the educational needs of patients and families because of the life-threatening nature of critical illness. Patient and family education is a vital component of nursing care. The nurse must deal with the anxiety and fear that is associated with a diagnosis of critical illness, while trying to teach difficult concepts in an environment that is poorly suited to learning.

Health care is no longer solely defined in terms of sound clinical decision making; now, it also encompasses prudent use of resources and financial accountability. In March of 2010, the American people witnessed the passage of "The Affordable Care Act," deemed by many to be the broadest health care reform legislation in U.S. history. A key element of this reform shifts the payment structure for hospitals and health care providers from a traditional fee-for-service model to an incentive model. Reimbursement for care will be based on hospital performance against several clinical outcome measures. Quality outcomes related to myocardial infarction, congestive heart failure, pneumonia, surgical care, health care–associated infections, and patient satisfaction will be required. Many of the quality indicators include patient and family education components. Reforms to the health care infrastructure necessitate clear evidence of nursing involvement in patient and family instruction and quantification of nursing care.

Hospital admissions and length of stay have also decreased with patients being discharged home, sometimes before they are ready to learn. Today, it is not unusual for a patient to be discharged home from an intensive care unit (ICU), placing even greater responsibility on the patient and family to provide for high-intensity care at home. The critical care nurse not only manages the hemodynamic instability that often accompanies critical illness but also prepares the patient and family for the likelihood of early discharge from the hospital.

At the same time, hospitals are facing an ongoing shortage of experienced critical care nurses. ICUs that were once reserved for the most experienced nurses are now training grounds for the newly graduated nurse. The novice nurse must focus on learning how to manage the myriad of technological devices used to support the critically ill patient while understanding the pathophysiology of multisystem illness. For the new nurse, it may be very difficult to move beyond the essential nursing tasks that are an integral part of patient care to address the educational needs of the patient and family. In addition, the 12-hour nursing work schedule creates a highly variable pattern; often, nurses work only 2 or 3 days per week. The resulting staff inconstancy provides limited opportunity for care continuity, relationship building, or follow-up related to patient and family learning needs.

These are just a few examples of the realities of health care. The fragmentation of patient care across the health care system presents many obstacles and barriers to patient education. The purpose of this chapter is to assist students and nurses in developing the skills and tools needed to meet the challenge of patient and family education in the presence of critical illness. Nurses who understand the learning barriers that are unique to the critical care setting are better prepared to address the learning needs of patients and families.

▲ Barriers to Learning

Critical Illness and Stress

Typically, the patient and family enter an ICU quite unexpectedly because of a life-threatening event. The onset of illness signals the beginning of a physical and emotional crisis for all involved. Altered metabolic responses, sepsis, exposure to general anesthesia, organ failure, use of cardiopulmonary bypass, episodes of hypoxia, and marked sleep deprivation are common conditions of the critically ill. Each of these factors

can compromise mental acuity and decrease a person's learning capacity and recall. In addition, combating a severe illness consumes most of the patient's energy, leaving him or her with a limited ability to learn.

The patient experiences not only the physical effects related to the disease process but also emotional and spiritual distress. When facing serious illness, patients express feelings of powerlessness, profound terror, and fear of death. In a qualitative study by Lof,[1] ICU patients recounted unpleasant emotions, horrifying unreal experiences, and feelings of imminent death as they lost consciousness from anesthetics. The vigilant critical care nurse who recognizes a patient's fear and anxiety and offers the patient guidance through the unfamiliar course of illness, treatment, and recovery can support the patient's need for safety. For example, patients frequently report that the process of ventilator weaning is difficult to endure. Many experience feelings of "air hunger" and heightened anxiety when the ventilator support is reduced and the patient assumes more of the work of breathing. The nurse who provides clear explanations and reassurances during this period can greatly enhance the patient's probability for successful extubation. Other examples of nursing interventions with patient education include the preparation of the patient for an invasive procedure or treatment, or through discussions regarding an impending transfer to another level of care.

However, in the critical care setting, it is not unusual for the focus of education to quickly shift away from the patient and be redirected to meet the learning needs of the family members. An emotional and physical toll is exacted on the family members of critically ill patients, with stress levels peaking within 72 hours of admission to the unit.[2] The descriptive study by Halm et al[2] demonstrates changes in the sleeping and eating patterns of family members, as well as an increased use of cigarettes, over-the-counter medications, alcohol, and prescription drugs, while coping with the crisis of a critically ill patient. Stress can also manifest in hypervigilant behaviors such as repetitive questions, frequent telephone calls, and numerous visits. Early research by Molter using the Critical Care Family Needs Inventory (CCFNI) identified that the family of the critically ill patient has needs for support, comfort, information, proximity to the patient, and assurance.[3] Subsequent research by Burr using the CCFNI tool validated the same results and identified another family need: the need to maintain vigil or watch over the patient in the event that something happens.[4] Critical care nurses often witness this "hovering" behavior of family members, especially during the admission phase of care. Research studies such as these have provided evidence of family needs of the critically ill patient and have provoked substantive changes to hospital visitation policies. Many critical care units now offer "open visitation," or unrestricted visiting hours. This paradigm shift creates greater opportunity for the critical care nurse to educate the family members and helps them to feel more comfortable in this stress-filled circumstance. The critical care nurse can encourage the family to participate in the basic care of a loved one. Simply getting ice chips, providing mouth care, or combing hair may assist the families in feeling that they are doing something to help the patient in an otherwise "helpless" situation.[4] The following case study demonstrates how the interventions of the critical care nurse are used to support the educational and emotional needs of a family in crisis.

CASE STUDY

A Patient and Family in Crisis

The electronic doors to the cardiovascular intensive care unit (CVICU) swing open, and Vernon and Barbara enter their 43-year-old daughter's room. Sherrill has just returned to the CVICU after a mitral valve replacement and a tricuspid valve repair. Unfortunately, the valve replacement was complicated, and she had a prolonged course on cardiopulmonary bypass. Her heart was quite weak before the surgery, and now she requires an intra-aortic balloon pump and multiple medications to support her cardiac output. She has also developed a coagulopathy related to the extended time on cardiopulmonary bypass and continues to bleed. Her vital signs are stable, but she requires a continuous infusion of blood products to keep up with the blood loss from her chest tubes.

Vernon and Barbara are shocked by their daughter's appearance. Her pale, edematous face and lifeless expression are certainly not what they expected to see. There is little about their daughter that resembles the person they know and love. Equipment surrounds her bed and supports nearly every bodily function. Visibly shaken, they look at each other with tears in their eyes, wondering how a seemingly routine valve operation could turn out this way.

Kate, the critical care nurse caring for Sherrill, greets Vernon and Barbara and begins to talk about their daughter's appearance. She carefully explains the purpose of all the bedside equipment as she cares for their daughter. Kate tells the worried parents what she is doing and why she is performing each procedure. It is the nurse's calm and caring approach that engenders a sense of hope for their daughter's eventual recovery. The parents begin to relax a little and start to ask questions about what to expect in the next few hours.

This brief example illustrates the unpredictability of illness and just how quickly a crisis can develop. In this scenario, the bedside nurse initiates family education through an informal discussion of the patient's status. The initial interaction with family members is fundamental for the care delivery team and the family to establish frequent and open communication about the patient.[5] In the course of talking with the parents, the nurse is continually assessing their learning needs and developing an understanding of their coping mechanisms. By allowing the family to spend time with the patient at the bedside, the nurse enables them to meet their need to keep watch over the patient. Moreover, consistent and accurate information about their loved one is enabling the family to deal with the crisis phase of illness. Research has demonstrated that up-to-date information is the highest priority for family members who are coping with critical illness.[6] The critical care nurse teaches families about the pathophysiology of the illness, the diagnostic studies that are performed, the equipment that is used to support the patient, and the treatment plan that is under way. The primary education goal for most families is to learn all that they can about their loved one.

Prolonged Illness and Stress

Frequently, the period of illness extends well beyond the initial crisis phase and creates additional burdens for the patient and the family. The critically ill patient may experience a slow and unpredictable course with periods of organ system compromise or failure over time. Recovery is tedious and is

measured in small changes that occur over days and weeks. Families are forced to balance their home and work schedules with time spent at the hospital, often evoking feelings of guilt and anxiety. Over time, it may become increasingly difficult for the family to obtain information and patient status reports from the health care team. Often, physician schedules are unpredictable and do not mesh with family visits. This further underscores the vital role that the critical care nurse plays as a link to the family. With protracted critical illness, many families struggle to keep the lines of communication open to the extended family, creating opportunities for conflict and misinformation.

As a patient and family advocate, the nurse provides accurate information and shares the plan of care with the family. Additional interventions such as a patient care or ethics conference may be arranged by the critical care nurse to give the family an opportunity to discuss the case with the entire health care team. Inviting key family members to participate in the patient care conference can be an effective strategy for the health care team. Once everyone is assembled, the conference should begin with open-ended questions to allow the family members to express in their own words their understanding of the patient situation and the current plan of care. It allows the health care team to clarify misunderstandings and to provide additional opportunity for consensus decision making.[7] Patient conferences offer a therapeutic method of shared decision making between the health care team and the patient's family.

As the patient's condition improves and plans for transfer to progressive care or medical–surgical floor status are discussed with the health care team, the critical care nurse must prepare the patient and family for the eventual discharge from the unit. This milestone in recovery is typically viewed by the patient and family in one of two ways. If the patient and family believe that the patient's condition has improved sufficiently and that the intensity of critical care is no longer necessary, then this step is viewed in a positive light. However, should they believe that the depth of nursing support and level of monitoring on the accepting unit are inadequate to meet the needs of the patient, there may be resistance to the transfer process. When the critical care nurse spends time educating the patient and family about the unit routine, staffing patterns, and visiting hours before making the transfer, it helps mitigate some of the negative feelings and anxiety associated with the change.[8]

Once the transfer has been made, it is important that the receiving nurse further assist the patient and family with "settling" into the new routine. The nurse should begin by acknowledging the normal anxiety that accompanies the transfer process. He or she should establish trust and allay fears by explaining the changeover in care in transitioning from ICU to progressive care status, emphasizing that the transition is a positive stage in the recovery process. The nurse should also reassure the patient and family that even though the intensity of treatment has changed, the staff are trained to anticipate each patient's recovery needs and will respond appropriately to changes in the patient's status. Once the patient and family's initial anxiety diminishes, the nurse can begin to set new self-care goals and expectations based on his or her assessment. Clearly, nursing plays a vital role in helping the patient and family cope with the crisis of critical illness and the transitions in care by providing education from admission to discharge.

Environmental Stress

Ringing telephones, chiming call lights and pagers, overhead announcements, equipment alarms, staff conversations, banging automatic doors, and pneumatic tubes are just a few examples of the sounds that fill the air of a typical ICU. It is easy for nurses to become desensitized to these familiar noises because they are an integral part of the work environment. However, taking a quick moment to listen to the background sounds from a patient's bedside reminds a person how stressful noise can be. Patients and families are not accustomed to the normal sounds of an ICU. Yet, as difficult as it may be, nurses ask patients and families to learn in this setting.

A typical ICU setting is hardly an optimal learning environment. Ideally, a quiet moment is spent with the patient and family using comfortable chairs arranged to optimize discussion and with audiovisual aids, if possible. However, common measures can help reduce the environmental stress and enhance the success of learning. The simple act of closing the door to the patient's room or placing a comfortable chair at the bedside can reduce the background noise sufficiently and enhance the learner's attention span. Reducing the alarm volumes on bedside equipment while the nurse is talking with the patient or family helps minimize the number of interruptions and may improve the learner's ability to focus on the topic of a teaching session.

Ensuring privacy while sensitive or confidential information is being exchanged can markedly reduce the anxiety of a patient or family member. Often, strangers witness the emotional outbursts and intimate interactions of families who are agonizing over the illness of a loved one. Health care providers are not always mindful of their surroundings when discussing confidential details of a patient's case. Critical care nurses can direct health care team members and families to a quiet room away from the general waiting area to afford privacy when discussing specific patient information.

This regard for the patient also applies to teaching rounds or patient care rounds that are held in the halls of an ICU. Patients should be treated with respect, and they often wish to be included in bedside presentations. Open visitation in the ICU requires that the health care team be mindful of visitors who may be at the patient's bedside and to make sure that the patient has given permission for health care issues to be discussed in the presence of visitors before proceeding with rounds. A concerted effort to ensure patient privacy is a responsibility of all health care team members, but often it is the nurse who knows the patient's wishes and the family dynamics and is in the best position to direct the team. At the beginning of rounds, health care team members should make appropriate introductions and give clear explanations of the medical jargon used in the course of conversation.

Cultural and Language Barriers

As the U.S. population changes, the patients and families whom nurses care for in hospitals and critical care settings are becoming increasingly diverse. Currently, Asians and Hispanics are the two largest immigrant groups in our country.

The U.S. Census Bureau projections for 2050 estimate that the Hispanic population will double and the Asian population will increase by 79%.[9] Beliefs about health and illness are deeply rooted in culture. How a patient or family member responds to the diagnosis or a proposed treatment and education may be strongly influenced by his or her values and culture.[10] Although the nursing literature readily acknowledges the importance of providing culturally sensitive patient care, in practice there is little evidence of cultural awareness in the nurse's daily assessments and interactions with patients and families. Culturally competent nursing care is patient centered and focuses on asking the right questions to understand the patient's point of view.[11] Galanti describes an effective method of questioning patients to ascertain information that is culturally sensitive. She uses the mnemonic, the*4 C's of Culture*, with the first C standing for *Call*. This question attempts to identify what the problem is by asking, "What do you call your problem?" The second C is for *Cause*. The latter is intended to understand what the patient believes to be the source of the problem. The third C is for *Cope*. In this instance, the focus of the health care provider shifts to how the patient is managing the problem, or what other treatments have been prescribed to date. The final C is for *Concern*, such as, "What concerns do you have about your condition or the recommended treatment?"[11] This open-ended method of seeking information can also be used when speaking with family members, as culturally competent nursing considers the family structure and gender role as it relates to the patient. For example, in the Asian culture, important health care decisions should be discussed with the family. In many other cultures, the oldest male makes all the important decisions and this would include health care treatment decisions.

Successful education of culturally diverse patients and families requires more than just basic knowledge regarding ethnic groups. Critical care nurses must recognize their own individual biases and examine their personal values and beliefs about health and nursing care. Many of our health beliefs are based on commonly held Euro-American values such as belief in individualism, autonomy, independence, clock time, physical fitness, and beauty.[11] The imposition of these Euro-American values on other cultures may impede communication between the nurse and patient and hinder the education process. Although critical care nurses do not have the time to complete a thorough cultural assessment, several key pieces of information should be obtained. This information is outlined in Box 4-1.

BOX 4-1 Key Pieces of Information to Obtain as Part of the Cultural Assessment

- Does the patient live in an ethnic community?
- When medical decisions are made, who should be consulted before making the decision?
- Primary and secondary languages (speaking and reading ability)
- Religious practices
- Health and illness beliefs and practices
- Family expectations to remain with a hospitalized family member
- Communication practices (verbal and nonverbal)
- How decisions are made in the context of the patient and family.

Adapted from Galanti GA: Caring for Patients from Different Cultures, 4th ed. Philadelphia, PA: University of Pennsylvania Press, 2008, pp 93–108.

Language barriers also pose a major obstacle to patient and family education, especially in the stressful critical care environment. Every effort should be made to provide an interpreter to translate information for the non–English-speaking patient and family. Although it is convenient for health care providers to rely solely on a family member or friend to translate complex medical information and terminology that is likely to be unfamiliar, it may be difficult for the family member or friend to keep personal bias from entering the context of the conversation. In many cultures, decision making is assumed by the eldest member of the family, and asking a child to interpret medical information disrupts the social order of the family.[11] In addition, the information that is exchanged between the health care provider and the patient may be personal or embarrassing to either the patient or the family member who is pressed into service. Box 4-2 offers some suggestions for communicating with a patient and his or her family through a trained interpreter. Written instructions should also be translated and reviewed in the presence of an interpreter so that any questions can be addressed immediately. Printed instructions in several languages should be readily available for use in the ICU.

BOX 4–2 TEACHING GUIDE *Guidelines for Communication Using a Trained Interpreter*

- Before the session, meet with the interpreter to give background information and explain the purpose of the session.
- If possible, have the interpreter meet with the patient or family to determine their educational level, health care beliefs, and health care attitudes to plan the depth of information needed.
- Speak in short units of speech and avoid long explanations and use of medical jargon, abbreviations, and colloquialisms.
- Pause at regular intervals so that the interpreter has time to interpret and convey the information.
- Some concepts have no linguistic or conceptual equivalent in other languages and may require the interpreter to paint a picture, and this takes additional time and effort.
- When communicating to the patient or family, look directly toward the person and not at the interpreter. Watch the patient's and family members' body language and nonverbal communication response.
- Have the interpreter ask questions to alert about potential cultural misunderstandings that may arise.
- Be patient. Interpreted interviews take a long time to complete and may become tiresome for the patient.
- Have the patient and family members validate the information given to them through the interpreter, to make sure that they understand the instructions or message that has been given.
- Debrief with the interpreter after the session is complete.

Sensory Barriers

Effective education for deaf and hearing-impaired patients and families necessitates planning and additional resources. The Americans with Disabilities Act prohibits discrimination against people with disabilities, including those who are deaf or hearing impaired.[12] Under the law, these disabled people must be able to communicate with hospital staff, and the medical facility must be ready to meet that requirement. Deaf or hearing-impaired patients or family members should indicate their preferred mode of communication such as sign language, written notes, lip reading, oral interpreters, or other assistive devices.[12] To ensure that deaf or hearing-impaired patients or family members can communicate effectively, an oral interpreter should be used in the critical care setting for the discussion of treatment options; informed consent for procedures, blood administration, or surgery; and discharge instructions. These types of decisions typically require extended discussions and free-flowing communication that is best supported with an interpreter.

▲ Education and Learning

Many times the terms *education* and *learning* are used interchangeably, but there is a difference between these two concepts. *Education* is an activity, initiated by one or more persons, that is designed to effect changes in the knowledge, skill, and attitudes of people, groups, or communities.[13] Education places more emphasis on the person facilitating the learning, whereas *learning* is a phenomenon of internal change. The learner experiences a flash of insight that results in behavioral changes.[13] The focus shifts from the role of the educator to that of the person who experiences the change.

Three Domains of Learning

Three domains of human behavior or learning to consider when developing an education plan are the cognitive domain, the affective domain, and the psychomotor domain. Keeping these domains in mind while assessing and developing a teaching plan can assist the nurse in selecting suitable teaching methods.

The *cognitive domain* of learning involves the development of insight or understanding that provides a basis or guideline for behavior.[14] In this domain, knowledge expands, and teaching–learning material is organized from simple to complex. Learning is enhanced when information builds on previous knowledge. Therefore, the basic ideas should be well introduced before attempting to teach the hard-to-remember facts. As an example, cognitive learning occurs when a family member learns to assess wound healing. The critical care nurse provides basic information about the normal healing process and the appearance of a healthy incision. Once the family member understands how a healed incision should look, the nurse can explain the signs and symptoms of infection and when to call the physician. Once prepared, the family member should then be able to apply the learned principles to provide appropriate home care for the patient.

The *affective domain* pervades all spheres of learning because it encompasses the patient's values, attitudes, and feelings.[14] Attempting to modify an attitude or emotional response requires a safe and trusting relationship between the patient and the nurse. When formulating a teaching plan, the nurse should take a nonthreatening approach to assessing what the patient considers important enough to learn. A helpful teaching strategy may be the interactive group learning that is typical of a smoking cessation class. In this situation, the teacher demonstrates behaviors that the learner wants to imitate and provides positive feedback to the participants to encourage them to stop smoking cigarettes. If the learning experiences are satisfying and the patient associates positive feelings with the experience, it may help influence the change in behavior.

The *psychomotor domain* involves motor skills that are composed of an ordered sequence of movement that must be learned.[14] To learn a particular skill, the patient must have a neuromuscular system that is able to perform the skill and the capacity to form a mental image of the act.[14] A mental image is created when the learner watches a demonstration while the teacher points out the relevant steps that are required to successfully complete the task. The nurse may use a written, step-by-step guide as a reference while demonstrating the skill and allowing the patient to ask questions. Learning to inject insulin is an example of psychomotor learning. It takes practice for the patient or family member to become proficient at performing the task. The thought of learning a new skill is intimidating to many adults; therefore, it is important that the nurse provide praise and encouragement with each teaching session.

Teaching methods that are based on the three domains of learning are displayed in Figure 4-1.

Adult Learning Principles

The principles of adult learning are based on multiple learning theories that originate in many different disciplines, such as developmental psychology, sociology, philosophy, and education. Adult learning is a relatively new field (about 50 years old), with the fundamental principles grounded in childhood learning and education. A new conceptual framework known as the andragogical model emerged from research studies that identified some of the unique characteristics of adult learners.[13] The core principles of the andragogical model of adult learning are as follows:

1. *The need to know.* Adults need to understand why they need to learn something before they are willing to commit the energy and time to learn it. It is important for the learner to understand and be aware of the "need to know." To raise the learner's level of awareness, the facilitator may need to use real or simulated experiences to help the learner discover the lack of knowledge.
2. *The learner's self-concept.* Adults are self-directed and responsible for their own decision making. In general, adults resent the feeling that others are making choices for them. Adult educators need to create learning situations that are more self-directed and independent.

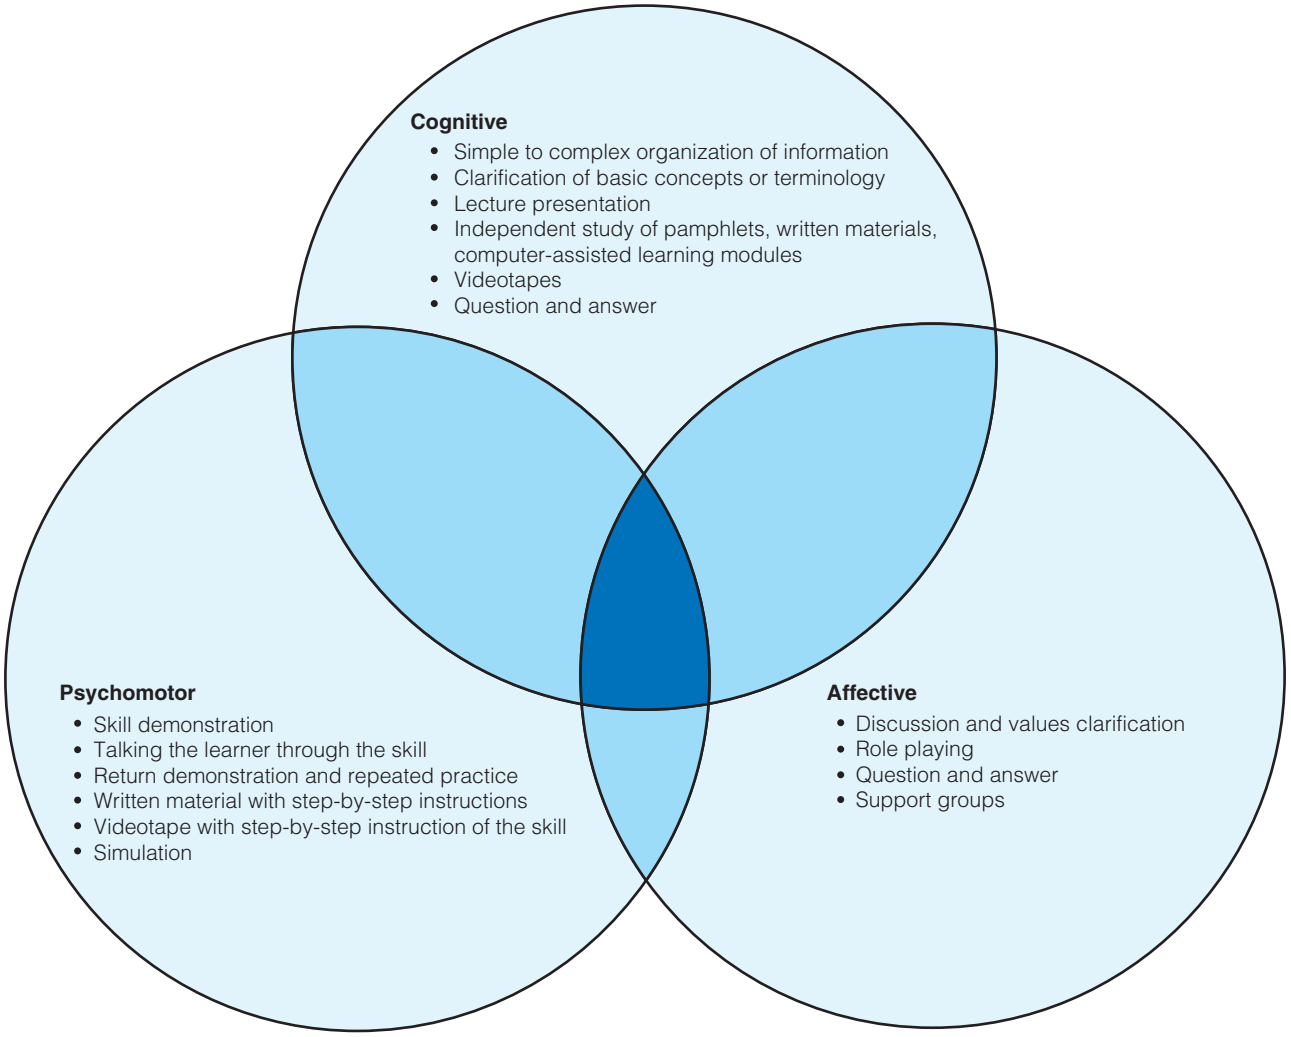

FIGURE 4-1 ▲ Teaching methods based on the domains of learning.

3. *The learner's life experience.* Adults have lived longer and accumulated more life experiences than children. Life experience defines and shapes adult beliefs, values, and attitudes. Adult education methods emphasize experiential techniques such as case method, simulation, and problem-solving exercises. In addition, adults learn well from their peers, making group learning an effective teaching method.
4. *Readiness to learn.* Adults are ready to learn the things they need to know. The information should be applicable to real-life situations.
5. *Orientation to learning.* Adults are motivated to learn if the information will help them to perform useful tasks or to deal with problems in their life.
6. *Motivation to learn.* Adults are more motivated by internal forces such as improved quality of life, increased job satisfaction, and improved self-esteem. External factors such as job promotion or increased salary are less likely to sustain learning.[13]

An example of how the critical care nurse might use adult learning principles in the practice setting is presented in the following scenario.

CASE STUDY

A Patient Who Is Motivated to Learn

Mr. Murray underwent a coronary artery bypass graft procedure 2 days ago. He questions the nurse about a breakfast tray that contains scrambled eggs and ham, while explaining that the eggs contain too much cholesterol and that he has been told to avoid all high-cholesterol foods. The nurse replies that the scrambled egg is an egg-substitute product that is actually part of a heart-healthy diet. Mr. Murray is demonstrating his readiness to learn and is attempting to apply the new knowledge to alter his eating habits. His learning motivation stems from an intrinsic desire to change that is now focused on his overall quality of life and improving his health. His question affords the nurse an opening to discuss other heart-healthy activities and lifestyle changes that will help the patient achieve wellness in his recovery.

The critically ill patient and family are highly motivated to learn because a life-threatening event has triggered an intense need for information. Successful teaching plans should incorporate adult learning principles and relevant information that readily apply to real life and assist with recovery from critical illness.

▲ The Process of Adult Education

The process of patient and family education entails more than just providing an educational brochure or turning on an instructional videotape; it is an interactive process based on a therapeutic relationship. The fundamentals used in patient and family education include assessment, diagnosis, goals, intervention, and evaluation.[14] Frequently, the nursing process is used informally by critical care nurses because teaching is so highly integrated into routine nursing care and family interactions. Just as the bedside nurse uses clinical judgment to recognize and treat the hemodynamic instability that often accompanies critical illness, he or she also diagnoses and intervenes to meet the learning needs of the patient and family. As nurses advance in practice, learning assessment becomes more refined and focuses on meeting the educational goals. Each learning session enhances the knowledge of the patient and family and offers the nurse a chance to evaluate the success or failure of what he or she has taught.

Assessing Learning Needs in a Time of Crisis

The critical care nurse must be very sensitive to the heightened anxiety that accompanies an admission to the ICU. Anxiety markedly reduces the ability of the patient and family to concentrate. Therefore, the nurse should avoid long explanations or tedious questions. The first step in the assessment process is to get to know the patient and family. This often begins with a simple introduction. Taking a few minutes to learn the family names and their relationship to the patient signifies respect and begins to build a therapeutic and trusting relationship. It gives the nurse a chance to orient the patient and family to the ICU as well as to teach them about some of the equipment used in the care of the patient.

Assessment of the learning needs can be a formal or informal process. In the critical care setting, it is preferable to use an informal and open-ended dialogue between the nurse and the family to establish the "need to know." Use of open-ended questions such as "What is your understanding of your mother's condition?" or "What did the physician tell you about the surgery?" gives the nurse a starting point for teaching the family. It also validates whether the patient or family member clearly understands previous explanations given by other members of the health care team.

Informal assessment often provides the nurse with a baseline evaluation of literacy and the person's level of education. Literacy assessment can be very difficult and requires sensitivity because most adults with a reading difficulty spend a lifetime hiding it.[14] Nonthreatening questions such as, "Do you prefer to learn new information by reading or watching a program on television?" may give the nurse a clue about a patient or family member's level of literacy. With about 20% of the U.S. population considered to be functionally illiterate, it is very likely that the educational brochures or the operative consent forms that are given to patients or families are beyond their reading level.[14] Every day, critical care nurses assume that the consent forms are clearly understood when they are returned signed and unquestioned. Written educational material should always be in the active voice and targeted for a 7th- to 8th-grade reading level.[15] In addition, the nurse should verbally review any written material with the patient or family in case they are unable to read the document and are too embarrassed to admit it.

Further assessment may reveal that a patient or family has a low level of health literacy. This term describes "the degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions."[16] Within the context of critical care, patients and families with low health literacy often struggle with the urgency and the abstract concepts that health care decisions demand.[17] For example, a physician explains the risks and benefits of a tracheostomy for a patient who has been intubated for 3 weeks and cannot be weaned from mechanical ventilation. To fully comprehend the assignment of risk, it is necessary to have a basic understanding of the concept of percentages as applied to the probability of complications. In this situation, a family member may have difficulty making an informed decision because the risks and benefits are not meaningful, and they are fearful of "cutting a hole into a loved one's neck." Such an emotional reaction should signal to the critical care nurse the need to bridge the knowledge gap between the physician's explanation and the family's negative perception of the procedure. To accomplish this, it helps to use more concrete methods such as the phrase "most people experience few complications following this procedure" to illustrate the risk for complications instead of using percentages to quantify the risk. In addition, using familiar words, showing a picture of a tracheostomy, and giving family members time to talk about the procedure may dispel further misconceptions and reduce their anxiety, thus enabling them to reach a decision about the surgery.

Assessment is a dynamic and ongoing process, providing the critical care nurse with many opportunities to assist patients and families to cope with the stress and anxiety associated with critical illness while meeting their learning needs. It also entails knowing when the patient or family is unable to learn. For example, patients who are experiencing pain are not able to focus on learning a new skill such as insulin administration without first having adequate pain control. A family member who has just learned that a loved one has suffered a cardiac arrest is not likely to be able to assimilate the intricate details of myocardial ischemia. Setting unrealistic educational goals hinders learning and frustrates both the nurse and the learner. The teaching plan must be continually evaluated. If the plan is ineffective, poorly timed, or not meeting the learner's needs, it should be altered.

Intervention: Effective Teaching Strategies in Critical Care

Learning Opportunities

Life-threatening illness often stimulates changes in unhealthy behavior patterns, only then igniting a patient's interest in learning. Much of the learning required of a patient who is recovering from critical illness involves behavior changes that require alterations in lifestyle. Smoking cessation, dietary restrictions, and activity limitations are the types of

lifestyle changes that patients frequently struggle to achieve and maintain. Learning opportunities often present in the course of routine patient care. Therefore, the nurse should be ready to incorporate teaching while providing care. For example, the nurse can review postoperative incision care in a brief teaching session while performing skin assessment. The review can include the signs and symptoms of infection, proper wound cleansing, and a description of a healthy healing incision. Teaching pertinent information about the indications or side effects of medications, while giving them to the patient, is another way to reinforce learning. Both of these examples highlight the importance of focusing on a single concept, especially considering the limited attention span that is typical of a patient who is recovering from a critical illness. Learning is best accomplished when the message is consistent and the knowledge progresses from simple to more complex concepts.

The Family Connection

Often the critical care nurse recognizes the limitations of the patient's ability to comprehend information and then turns to the family to provide instruction. Most patients forget 80% of the information they receive, and nearly half of what they remember is incorrect.[18] It is likely that retention of information by critically ill patients is much worse. Therefore, family participation in teaching sessions helps ensure the success of the teaching plan. In addition, providing written materials that patients can review after discharge from the hospital helps bridge the retention gap. Guidelines for developing printed materials that are appropriate for use with older patients are presented in Box 4-3.

Another effective teaching strategy for the adult learner is group learning. For example, postoperative cardiac surgical patients can benefit from a class on posthospital care. A group teaching session allows patients the chance to share common experiences and concerns about recovery with each other. Including families in the group may stimulate questions and allow them to express concerns about potential complications and fears about taking care of a loved one at home. Many times, families are fearful of caring for a loved one who has recovered from a life-threatening illness. They are afraid that they will miss an important symptom or that something will go wrong and their loved one will become ill again or even die. The critical care nurse should acknowledge these feelings and provide the family with emotional support while giving the tools and information to ensure safe care at home. The family interaction also provides the nurse with an assessment of potential home health care needs. A newly learned skill such as a complex dressing change or administration of an IV medication requires both the patient and a family member to learn and demonstrate the basic steps of the procedure to ensure that adequate learning has occurred before the patient leaves the hospital. It may become apparent that a home health care consultation is indicated for further teaching, and reinforcement of newly learned skills may be needed to facilitate a safe transition from the hospital to home.

Hospitals have expanded education tools to include computer-based educational libraries and other audiovisual systems that can be used to supplement individual instruction. The content can be especially helpful for patients and families who are learning a new skill, such as intermittent urinary catheterization. Some education systems are quite sophisticated, linking the health care provider to the patient by "prescribing" specific education content. The computer software can be interactive with the learner through a series of questions and answers that can assist the nurse with validating the learning success of the patient or family member. In addition, electronic interfaces to the education system can provide basic documentation of the teaching session in the medical record. This deliberate and interactive process between the health care provider, the nurse, and the patient and family helps to facilitate education. Such checks and balances are designed to ensure that the patient and family are exposed to basic information before they are discharged from the hospital. Electronic patient education libraries also provide consistent information and are less dependent on the teaching skills of a particular nurse to get the information across to the patient and family. Moreover, these patient education libraries are often available in multiple languages and can reduce the need for an interpreter for each learning session. Regardless of the level of sophistication of electronic learning tools, an interpreted session remains an important tool to ensure that the patient and family have learned the required information and that questions are answered thoroughly.

BOX 4-3 CONSIDERATIONS FOR THE OLDER PATIENT

Guidelines for Printed Educational Materials

- Font should be 12 points or greater.
- Serif type is preferred over sans-serif type.
- Avoid script or stylized types.
- Use boldface headings.
- Avoid using all uppercase letters for body type.
- Use specific language and avoid generalizations.
- Use "calls to action" to highlight important points.
- Use four to five lines of text broken up with white space.
- Avoid paper with a glossy finish because the glare makes reading difficult. Use matte-finish paper instead.
- Enhance legibility by using black ink printed on white or off-white paper.
- Avoid printing over a designed or customized background.

Evaluating the Learning Process

Evaluation is a measurement of the critical learning elements established in the teaching plan. It provides evidence about patient accomplishments or skills that may need further development.[19] Evaluation also reinforces correct behavior on the part of learners and helps teachers determine the adequacy of their instruction.[19] Questions provide the teacher and learner with immediate feedback and validate the learner's grasp of the information presented. The nurse should avoid using leading questions to achieve a desired answer. True evaluation is based on the learner's responses, which indicate whether additional reinforcement of the key concepts is needed. Direct observation of newly learned skills or procedures should also be part of the evaluation. Because adults do not want to appear awkward or clumsy when performing a task, it is important to have a relaxed, positive learning environment where the teacher and student have a good rapport before asking a patient or family member to

demonstrate a new task or skill. The learner should be able to successfully answer or perform 94% of all the critical elements outlined in the teaching plan.[19] Often the success or failure of patient and family education influences the discharge plans. Patients who are unable reliably to perform new tasks need supervision and further practice to learn the new skill. Therefore, adequate evaluation of the learning process is an essential component of the health care continuum.

There are many ways to develop a patient and family teaching plan. Given a homogeneous population, standardized patient teaching plans and records can be used. Plans should include information that is essential for most patients but can also be flexible enough to accommodate individual needs. Teaching plans include nursing diagnoses, outcome criteria, and interventions. Box 4-4 provides a sample teaching plan for a patient who has experienced a myocardial infarction.

BOX 4–4 *COLLABORATIVE CARE GUIDE for Educating a Patient About Myocardial Infarction*

Mr. Mitchell is a 54-year-old married African-American man who was admitted to the hospital after experiencing chest pain while at work. He had mild elevation in his cardiac enzyme levels and was taken to the cardiac catheterization laboratory within a few hours of the onset of the chest pain. The interventional cardiologist found two arteries 80% occluded. He was able to perform an angioplasty, place a stent in the arteries, and successfully restore the blood flow to the affected myocardium. The morning after his procedure, Mr. Mitchell spoke with the cardiac rehabilitation nurse, who reviewed his cardiac risk factors. He is 30-pound overweight with mild hypertension, his cholesterol level is 250 mg/dL, and he smokes 2 packs of cigarettes per day. After this procedure, Mr. Mitchell is anxious to learn ways to reduce his risk for myocardial infarction.

Nursing Diagnoses	Outcomes	Interventions
Deficient Knowledge	Patient will be able to state content presented.	• Plan teaching sessions for a period of time with minimal interruptions. • Include patient's wife and family in teaching sessions. • Provide written information to reinforce the verbal information. • Review the diagnosis of myocardial infarction and the therapies used to prevent further damage to the heart muscle. • Review cardiac risk factors for this patient and identify those risk factors that he can control. • Consult the dietitian for weight reduction and meal planning. • Discuss the sodium content of foods related in order to control his hypertension. • Discuss the target cholesterol level for this patient and the medications and dietary changes needed to reduce the risk for myocardial infarction. • Discuss tobacco use related to myocardial oxygen demand and the vasoactive effects of nicotine. • Offer information about smoking cessation programs and medical options available to assist him with stopping smoking. • Refer the patient to a formal cardiac rehabilitation program after discharge from the hospital.
Readiness for Enhanced Knowledge	Patient will participate in goal setting for weight loss, tobacco cessation, and achievement of cholesterol and blood pressure targets. The patient will participate in an exercise program, lose weight, stop smoking, and decrease cholesterol according to his personal goals.	• Plan and set goals with the patient for weight loss, cessation of tobacco use, and target cholesterol levels. • Have the patient identify appropriate menu selections and portion control to achieve weight loss. • Have the patient identify the triggers for tobacco use and steps that he might find useful to reduce or stop smoking. • Refer the patient to a weight-loss and a smoking-cessation support group. • Have the patient identify appropriate exercises after myocardial infarction.
Ineffective Coping	Patient will begin to demonstrate effective coping mechanisms.	• Discuss the patient's feelings about multiple lifestyle changes and the diagnosis of myocardial infarction. • Discuss the patient's feelings about participating in both a weight-loss and smoking-cessation program. • Mobilize the patient's resources for support. • Help the patient to design a chart to map his progress with weight loss, smoking cessation, and blood pressure and cholesterol target goals. • Acknowledge all questions and concerns that the patient expresses as meaningful.

The nursing diagnosis assists the nurse to identify the appropriate content to teach. It also helps formulate the outcomes that are used to evaluate the progress of the patient and family and the effectiveness of the teaching plan. The outcomes should be stated in measurable terms, and the teaching should be outlined in a logical sequence. Each nursing intervention should include the content, method, and media used for teaching. In addition, the patient's barriers to learning should be addressed, and the nursing interventions are aimed at meeting those personal needs. In critical care, families are often included in the teaching plans because of the limited learning ability of the patient.

▲ The Standards of Patient and Family Education

There is great emphasis on patient and family education that stems from the Joint Commission patient care standards. These standards serve to promote overall patient care quality in health care organizations. Hospitals voluntarily participate in Joint Commission surveys to ensure that the patient care provided meets or exceeds the criteria set forth in the standards. Some examples of Joint Commission standards related to patient and family education include the following:

- "The hospital provides, coordinates, and evaluates patient education and training based on each patient's needs and abilities."
- "The hospital performs a learning needs assessment which includes cultural and religious beliefs, emotional barriers, desire and motivation to learn, physical or cognitive limitations, and barriers to communication."[20]

The goal of these educational standards is to guide hospitals to create an environment in which both the patient and the health care team members are responsible for teaching and learning. The medical record should reflect an interdisciplinary approach toward patient education throughout the hospital stay. The initial nursing history should include an assessment of the patient's understanding of the current health issues, preferred learning methods, family support, and any social or cultural beliefs that will impact learning. The Joint Commission recommended educational topics are detailed in Box 4-5. Teaching documentation should indicate the learning topic and how it relates to the patient's health issues. In addition, if home health care or community resources are necessary to support the safe transition of the patient from the hospital to home, the medical record should reflect coordination of these services prior to discharge.

Finally, the teaching record should also reflect an evaluation of how well the patient and family absorbed the information. The details of teaching documentation are outlined in Box 4-6. A sample patient education record is shown in Figure 4-2.

How do these standards affect patient education in the critical care setting? It may be difficult for critical care nurses to think in terms of teaching plans and interdisciplinary learning because critically ill patients have so much instability and require great vigilance just to maintain physiological function. However, remember that much of the patient teaching is informal and may not be clearly visible at first glance. Nurses are taught to explain each procedure, medication, intervention, or diagnostic test to the patient beforehand. This is patient education. For example, the nurse who explains that the bag of liquid medication she is hanging is an antibiotic that is given through the intravenous line to fight the patient's abdominal wound infection is teaching. Yet, many nurses would not recognize this action as patient education, and they would not document it in the teaching record. Nonetheless, this type of informal instruction meets the Joint Commission standard for patient education. Critical care nurses teach patients and families routinely, but often the patient education record is left blank because "there isn't enough time to teach." If critical care nurses would only remember to note each informal teaching session, the patient's educational records would be filled with entries after just 1 day in the unit.

BOX 4-5 The Joint Commission–Recommended Topics for Patient and Family Education

- Explanation of the plan of care
- Basic health practices and safety
- Safe and effective use of medications
- Nutrition interventions
- Pain management
- Safe and effective use of medical equipment
- Techniques that help the patient reach maximum independence
- Fall reduction strategies

BOX 4-6 Components of Teaching Documentation

- Participants (Who was taught?)
- Content (What was taught?)
- Date and time (When was it taught?)
- Patient status (What was the patient's condition at the time?)
- Evaluation of learning (How well was the information absorbed?)
- Teaching methods (How was the patient taught?)
- Follow-up and learning evaluation (If teaching was incomplete, what was the reason? What additional education needs does the patient have?)

KEY

Barriers to Learning	**Learners**	**Tools/Method**	**Level of Learning (LOL)**
1. No barrier 2. Language/Communication/Literacy 3. Cultural/Religious Practices 4. Cognitive/Sensory Impairment 5. Severity of illness/pain 6. Motivation 7. Physical limitation	P = patient F = family/significant other O = other	C = Class/group D = Demonstration A = Audiovisual L = Literature T = Translator TV = Video/ed channel M = Model 1:1 One to one	8. Needs further reinforcement 9. Demonstrates partial skill or knowledge 10. Demonstrates skill with minimal assistance 11. Demonstrates competent skill and knowledge

EDUCATION	Content	Date	Barrier	Learner	Tool	LOL	Initials
Outcome Criteria **Discharge Plan of Care** • Identifies disease process • Cause • Signs and symptoms • Risk factors • Prevention							
Medications/ Food and Drug Interactions • Identifies purpose of medications • States side effects of medications • Demonstrates administration of medications • Reviews food–drug interactions							
Activity • Verbalizes activity restrictions after discharge • Identifies need for assistive apparatus as needed • Identifies safety precautions							
Equipment • States purpose • Demonstrates correct use of equipment • Identifies safety measures							
Treatments • States the purpose of the treatment • Demonstrates correct technique • Identifies findings that should be reported to health care provider							
Follow-up Care and Community Resources

▲ Clinical Applicability Challenges

SHORT ANSWER QUESTIONS

1. From the *Case Study: A Patient and Family in Crisis* on page 40, discuss the strategies used by the nurse to effectively manage the admission phase for the patient's family.
2. Discuss nursing interventions that have effectively reduced patient and family anxiety in a clinical situation that you have encountered.
3. Discuss when patient and family anxiety would preclude all learning.

5 Relieving Pain and Providing Comfort

Cynthia L. Renn and Tara Leslie

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Differentiate between acute and chronic pain
2. Identify factors that exacerbate the experience of pain in the critically ill
3. Prepare patients for the common sources of procedural pain in intensive care
4. Compare and contrast tolerance, physical dependence, and addiction
5. Discuss national guidelines and standards for pain management
6. Identify appropriate analgesics for high-risk critically ill patients
7. Describe nonpharmacological interventions for alleviating pain and anxiety

Pain is one of the greatest stressors and most common symptoms for critically ill patients.[1,2] In addition to being a coexisting symptom of critical illness, patients experience increased levels of pain during many critical care interventions and routine procedures.[3,4] Even though pain management has become a national priority in recent years, pain continues to be misunderstood, poorly assessed, and undertreated in intensive care units (ICUs) and many other health care settings.[4,5] Uncontrolled pain triggers physical and emotional stress responses, inhibits healing, increases the risk of other complications, and increases the length of ICU stay. Critical care nurses need a clear understanding of concepts related to pain assessment and management to achieve effective pain control. For an overview of the physiological processing of pain, refer to Chapter 32. Chapter 5 provides an overview of key concepts related to managing acute pain and comfort in the critically ill adult patient.

▲ Pain Defined

Pain is a complex, subjective phenomenon. It is a protective mechanism, causing one either to withdraw from or to avoid the source of pain and seek assistance or treatment. The International Association for the Study of Pain defined pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage."[6] McCaffery provides an operational definition of pain that considers the subjectiveness and individuality of the pain experience. This definition is based on the premise that the individual experiencing the pain is the true authority: "Pain is whatever the experiencing person says it is, existing whenever he or she says it does."[7]

Not all pain is the same. The various types of pain are categorized based on the duration (acute or chronic) and source (somatic, visceral, or nerve) of the pain. It is essential that the type(s) of pain a patient is experiencing be properly identified so that the most efficacious management strategies can be implemented. The type of pain that most ICU patients experience is classified as *acute*. Acute pain is a physiological response to an identifiable cause, is generally time-limited, and typically responds well to opioid and nonopioid therapies. For example, the pain experienced during endotracheal suctioning or a dressing change is expected to end when the treatment is completed. Similarly, pain at an incision or area of injury is expected to cease once healing has occurred. Often, patients in the critical care setting will experience pain from more than one source. For example, a postoperative patient will likely have somatic pain stemming from the site of the incision, visceral pain from organs that were manipulated, and possibly, nerve pain from nerves that were cut or damaged during the surgical procedure.

In contrast, *chronic* pain is caused by physiological mechanisms that are less well understood. Chronic pain differs from acute pain in terms of etiology and expected duration. Chronic pain extends past the usual course of an acute illness or injury for an indefinite period of time, usually exceeding 3 to 6 months. It is difficult to treat, responds poorly to routine pain management strategies, and adversely affects the quality of life for the individual.[8] It is essential for the critical care nurse to be aware that, in addition to acute pain associated with the illness or injury leading to hospitalization, ICU patients will frequently have a concomitant chronic pain condition that must be properly managed as well.

▲ Pain in the Critically Ill

Acute critical illness, regardless of the etiology, is painful. Consider the most common illnesses or injuries treated in the ICU: myocardial infarction, thoracic surgery and neurosurgery, multiple trauma, and extensive burns. All of these conditions are associated with severe pain. Therefore, nearly all ICU patients will experience moderate to severe acute pain.[9] Moreover, ICU patients with chronic critical illnesses are likely to experience a combination of both acute pain (due to a new illness, injury or procedure) and the chronic pain stemming from the chronic illness. Further, chronic pain in a critically ill patient is often associated with additional symptoms, such as respiratory distress, fatigue, and cognitive impairment, that must be managed.[10] Previously, it was thought that critically ill patients were unable to remember their painful experiences because of the acute nature of the illness or injury. More recent research, however, demonstrates that ICU patients do remember painful experiences, and they frequently describe their pain as being moderate to severe in intensity.[4]

In addition to the patient's illness-, injury- or procedure-induced pain, the critical care nurse must also be cognizant of the many factors inherent to an ICU admission and the ICU environment that will increase the patient's pain experience (see Box 5-1). Each of these factors alone will exert a significant negative effect on the patient's pain and, when they are experienced in combination, they act synergistically to further increase pain. For example, pain and anxiety act in a cyclical fashion to exacerbate each other.

BOX 5-1 Factors Contributing to Pain and Discomfort in the Critically Ill

Physical
Symptoms of critical illness (eg, angina, ischemia, dyspnea)
Wounds—posttrauma, postoperative, postprocedural, or penetrating tubes and catheters
Sleep disturbance and deprivation
Immobility, inability to move to a comfortable position due to tubes, monitors, restraints
Temperature extremes associated with critical illness and the environment—fever, hypothermia

Psychosocial
Anxiety and depression
Impaired communication, inability to report and describe pain
Fear of pain, disability, or death
Separation from family and significant others
Boredom or lack of pleasant distractions
Sleep deprivation, delirium, or altered sensorium

Intensive Care Unit (ICU) Environment or Routine
Continuous noise from equipment and staff
Continuous or unnatural patterns of light
Awakening and physical manipulation every 1 to 2 hours for vital signs or positioning
Continuous or frequent invasive, painful procedures
Competing priorities in care—unstable vital signs, bleeding, dysrhythmias, poor ventilation—may take precedence over pain management

▲ Procedural Pain

Efforts to provide pain relief and comfort measures are complicated by the fact that critical care nurses must continuously perform procedures and treatments that cause pain to the patient. Procedures like chest tube insertion and removal, endotracheal suctioning, and wound débridement are obviously painful. Less obvious are the simple procedures, such as turning and positioning, that can also cause considerable pain for critically ill patients.

Several studies have investigated which routine nursing procedures were reported to be painful or not painful by conscious oriented patients.[4,11] The investigators documented the patients' responses to six procedures that are frequently performed on critically ill patients: position changes, tracheal suctioning, deep line removal, deep breathing and coughing exercises, dressing changes, and drain removal. The findings of this study are summarized as the least painful to the most painful procedures in Table 5-1.[4] Studies also found that procedural pain is often described by patients as different from other types of pain; descriptors included "intense," "episodic," "severe," and "tiring."[12,13] It was also found that 50% of patients undergoing drain removal, 38.5% of patients doing deep breath and coughing exercises, and 32.6% of patients undergoing position changes received preemptive analgesia with morphine within an hour prior to their procedure, while only 12.5% of the patients undergoing tracheal suctioning, reported by patients to be one of the more painful procedures, received prophylactic morphine.[4] Approximately 79% of patients undergoing a painful procedure reported inadequate pain management with only 22.1% receiving preemptive analgesia prior to the procedure, 84.1% receiving an analgesic medication during the procedure, and only 7.3% receiving analgesic pain medication postprocedure.[14] Critical care nurses must be attuned to the pain the patient is experiencing before the procedure and anticipate the pain that occurs as a result of the procedure in order to provide the best interventions to help the patient during the procedure.

Before performing procedures known to be associated with pain, patients should be premedicated (preemptive analgesia), and the procedure should be performed only after the medication has taken effect. During procedures, intravenous (IV) opioids, such as morphine or fentanyl, are

Table 5-1 Patients' Self-Report of Painful Procedures*

Procedure	Level of Pain
Simple dressing change	Least painful
Central line removal	Painful
Position changes/turning	Painful
Tracheal suctioning	More painful
Deep breathing and coughing exercises	More painful
Drain removal	Most painful

*Ranked from least to most popular.

From Siffleet J, Young J, Nikoletti S, et al: Patients' self-report of procedural pain in the intensive care unit. J Clin Nurs 16(11):2142–2148, 2007.

usually used for analgesia. The IV bolus dose of morphine is individualized and depends on the age, weight, pain intensity, and type of procedure. The patient's response must be monitored during the procedure with additional doses given as needed for breakthrough pain. Anxiolytic medications, such as midazolam or propofol, can be given to relieve anxiety during the procedure; however, these agents should *only* be used as *adjuncts*, because they simply provide sedation and no analgesia to relieve the pain associated with the procedure. In addition to providing preemptive analgesia and anxiolytic medications before the procedure, the nurse should educate patients about the procedure to help them prepare for anticipated pain and discomfort. Further, the nurse can use interventions, such as imagery, distraction, and family support during procedures, to supplement the effect of the analgesic and anxiolytic medications.

▲ Consequences of Pain

Pain produces many harmful effects that impact negatively on the function of all body systems, inhibit wound healing, and slow recovery from critical illness. The autonomic nervous system responds to pain by causing vasoconstriction and increased heart rate and contractility. Additionally, pulse, blood pressure, and cardiac output all increase, leading to concomitant increases in myocardial workload and oxygen use, both of which can cause or exacerbate myocardial ischemia in an already compromised critically ill person. Patients in pain are also hesitant to move, cough, or breathe deeply because the associated movements increase pain. This decrease in movement manifests as pain-induced respiratory alterations that include splinting, decreased respiratory effort, and reduced pulmonary volume and flow. These pain-induced respiratory alterations can then lead to pulmonary complications, such as atelectasis and pneumonia. In the gastrointestinal system, undertreated pain can cause decreased gastric emptying and intestinal motility, which can result in impaired function and ileus.

Unrelieved pain also negatively affects the musculoskeletal system by causing muscle contractions, spasms, and rigidity and by suppressing immune function, which predisposes the patient to pneumonia, wound infections, and sepsis. The negative effects of uncontrolled pain on the course of a critical illness are clear. It is vital for the critical care nurse to understand that the impact of uncontrolled pain during a critical illness can extend beyond the time of recovery from the critical illness. Evidence shows that patients who have a high level of uncontrolled pain during an acute hospitalization are at increased risk for delayed recovery and the development of chronic pain syndromes after discharge.[15]

Patients who are pain free have better outcomes than those stressed by unrelieved pain. In a classic study, patients whose pain was controlled with epidural anesthesia and epidural analgesia had shorter ICU stays, shorter hospital stays, and half as many complications as patients receiving standard anesthesia and analgesia.[16] The benefits of effective pain relief are summarized in Table 5-2.

Table 5-2 Benefits of Effective Pain Relief

System	Benefit
Cardiovascular	Decreased pulse rate, blood pressure, and myocardial workload
Respiratory	Enhanced respiration, oxygenation, ability to perform deep breathing and coughing exercises, and decreased incidence of pulmonary complications
Neurological	Decreased anxiety and mental confusion, enhanced sleep
Gastrointestinal/ Nutritional	Enhanced gastric emptying, promotion of positive nitrogen balance, increased appetite
Musculoskeletal	Earlier ambulation, reducing complications of immobility
Economic	Decreased length of stay, decreased costs, enhanced patient satisfaction with care

▲ Barriers to Effective Pain Control

Pain continues to be undertreated in many settings, even though the negative consequences of uncontrolled pain and the benefits of pain relief have been well documented. Often pain relief is relegated to a low priority due to the life-threatening nature of the patient's illness and the other life-saving interventions that are required. Critical care nurses are often concerned that analgesic administration may create problems, such as hemodynamic and respiratory compromise, oversedation, or drug addiction.[17]

The fear of addiction is one of the greatest concerns and impediments associated with analgesia and pain control. This fear causes anxiety for patients and their families as well as health care providers. Critical care nurses must have a clear understanding of the differences between, and implications of, addiction, tolerance, and dependence. Patients who require long-term analgesic medication for pain control can develop tolerance or physical dependence. However, these scenarios should not be confused with addiction, which is characterized by behaviors, such as impaired control, compulsive use, and continued use despite serious negative physical and/or social consequences.[18] See Table 5-3 for clarification of these concepts.

Patients with a history of opioid addiction and tolerance provide a unique challenge to nurses trying to manage pain when these patients present with a critical illness. This particular patient population may require much larger doses of pain medication to produce an adequate level of pain control than a patient not addicted to opioids. Research shows that patients with opioid addiction often require 30% to 50% more opioid pain medication than they were taking preoperatively. Continuous epidural delivery and patient-controlled analgesia (PCA) are often beneficial in these patients due to the continuous infusion of opioid medication. Opioid withdrawal is another significant concern when caring for an opioid-addicted patient. The onset of withdrawal can occur between 6 and 48 hours after the last use, depending on the drug.[19] Symptoms of withdrawal may include flu-like symptoms

Table 5-3 Tolerance, Physical Dependence, and Addiction

Condition	Definition	Implication
Tolerance	A state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the drug's effects over time.	Increase dose by 50% and assess effect. Tolerance to side effects, such as respiratory depression, will increase as the dose requirement increases.
Physical dependence	A state of adaptation that is manifested by a drug class–specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist.	Gradually taper opioid dosage to discontinuation to avoid withdrawal symptoms.
Addiction	A primary, chronic, neurobiological disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving.	Rarely seen in critical care patients, unless patient is admitted for drug overdose or other sequelae of illicit drug use

Definitions from American Pain Society: Definitions related to the use of opioids for the treatment of pain. Available at: http://www.ampainsoc.org/advocacy/opioids2.htm. Accessed April 1, 2010

(nausea, vomiting, diarrhea, headaches, muscle/joint/joint pain, fever), tachycardia, dilated pupils, runny nose, lacrimation, piloerection (hair standing on end), yawning, restlessness, sweating, irritability, anxiety, and hypertension. Although opioid withdrawal does not tend to be fatal, underlying medical conditions (hypertension or recent myocardial infarction) may increase the patient's risk for death.[20] Important to note is that withdrawal can also occur in patients who do not have a history of opioid drug abuse, but who have been treated for an extended period of time with opioids to control pain. In this patient population, it is vital to taper (incrementally decrease) the use of the opioid and avoid an abrupt stoppage of the drug.

Pain treatment should not be restricted in patients with a history of opioid abuse; rather, it should be more aggressive. The period of critical illness in these patients is not the appropriate time for drug rehabilitation attempts, and the symptoms associated with opioid withdrawal can exacerbate conditions related to the critical illness. The critical care nurse must focus on providing all necessary measures to allow a full recovery from the illness, which can then be followed by a proper referral for drug-dependence rehabilitation. However, though the incidence is fairly small, the nurse should be alert to the possibility of a patient feigning symptoms to seek more than required opioid pain medication. In all cases, the nursing care for substance-abusing patients should be focused on forming a nonjudgmental, trusting relationship between the nurse and the patient.[19]

▲ Resources to Promote Effective Pain Control

In recent decades, government agencies, professional organizations, health care institutions, and pain management experts have focused attention on improving pain management across the United States. These efforts have produced abundant resources to support nurses in their efforts to provide effective pain management.

Clinical Practice Guidelines

Early in the 1990s, the Agency for Health Care Policy and Research (AHCPR), now known as the Agency for Healthcare Research and Quality (AHRQ), introduced the concept of clinical practice guidelines. These guidelines were intended to serve as nationwide standards of care for specific clinical problems. This concept arose from the recognition that in the midst of a rapidly expanding body of health care research and literature, there were still wide variations in opinions and practice patterns regarding the best interventions for common clinical problems. The AHCPR convened multidisciplinary panels of national experts to review the research, provide expert opinions, summarize the current knowledge, and make recommendations for practice for each targeted clinical problem. Acute pain management was the topic of the first guideline that was published and disseminated by this agency.[21]

Over the next few years, several national agencies, including the American Association of Critical-Care Nurses, the American College of Cardiology, and the Society of Critical Care Medicine (SCCM), assembled their own panels of experts to develop clinical practice guidelines for their target populations. In 1996, the AHRQ discontinued its support for producing clinical practice guideline documents and instead entered into a collaborative relationship with the American Medical Association and the American Association of Health Plans to sponsor the web-based National Guideline Clearinghouse.[21] This Web site currently contains more than 2,500 practice guidelines developed by a variety of organizations. Via these various mechanisms, pain management guidelines have been disseminated throughout the United States and have served as a catalyst for several improvements in pain management. These guidelines are also used as legal documents representing the national standard of care for pain management in medical liability cases.

One practice guideline that is particularly useful to critical care nurses and physicians is the guideline published jointly

Table 5-4 National Standards and Guidelines Related to Pain Management

Agency or Source and Standard or Guideline	Content Highlights
Society of Critical Care Medicine and the American Society of Health-System Pharmacists Clinical Practice Guidelines for the Sustained Use of Sedatives and Analgesics in the Critically Ill Adult[22]	Developed by a national panel of experts in critical care medicine, nursing, and pharmacy. Includes summaries and recommendations of recent research related to analgesia and sedation specifically in the critically ill population. Contains 28 explicit recommendations targeted to the critically ill, including the following: • Patient report is the most reliable standard for pain assessment. • Scheduled doses or continuous infusions of opioids are preferred over PRN or "as needed" regimens. • Fentanyl, hydromorphone, and morphine are the drugs of choice for intravenous (IV) doses of opioid analgesia. • Fentanyl is preferred for rapid onset of analgesia in acutely distressed patients. • Sedation of agitated patients should be provided only after providing adequate analgesia. • Lorazepam is recommended for sedation of most patients via intermittent IV or continuous infusion • Midazolam or diazepam should be used for rapid sedation of acutely agitated patients • Haloperidol (Haldol) is the preferred agent for treatment of delirium (pp 140–141)[22]
American Geriatric Society The Management of Persistent Pain in Older Adults[23] Pharmacological Management of Persistent Pain in Older Persons[24]	This guideline, originally published in 1998, was revised in 2002 and 2009 by an interdisciplinary panel of geriatric experts. Major recommendations include the following: • All older persons should be screened for persistent pain on admission to any health care facility. • The verbal 0 to 10 scale is a good first choice for assessment of pain intensity; however, other scales such as word descriptor scales or pain thermometers may be more appropriate for some older patients. • For patients with cognitive impairment, assessment of behaviors and family observations are essential. • Opioid analgesic drugs are effective, with a low potential for addiction, and may have fewer long-term risks than other analgesic drugs.[23] • Acetaminophen should be the first drug to consider in the treatment of mild to moderate musculoskeletal pain. • Patients with neuropathic pain and other types of refractory persistent pain may be candidates for adjuvant analgesics. • Patients with moderate to severe pain, or continuous pain on a daily basis, that diminishes quality of life or causes functional impairment should be considered for opioid therapy.[24]
American College of Cardiology/American Heart Association Task Force on Practice Guidelines[21]	This joint task force has published multiple practice guidelines that are relevant to painful conditions experienced by critically ill patients, including: • Management of patients with chronic stable angina • Management of patients with unstable angina • Management of patients with peripheral arterial disease • Management of patients with ST-elevation myocardial infarction • Guideline update for coronary artery bypass graft surgery These guidelines are available from the National Guideline Clearinghouse at http://www.guideline.gov/[21]

by the SCCM and the American Society of Health-System Pharmacists on *Sustained Use of Sedatives and Analgesics in the Critically Ill Adult*.[22] Table 5-4 includes information about this and other important guidelines and standards for pain management.[21–24]

Internet Resources

The Internet is one of the most important sources of information and resources for pain management. Table 5-5 lists websites containing pain management information that may be useful to critical care nurses, patients, and families.

▲ Pain Assessment

The failure of staff to routinely assess pain and pain relief is one of the most common reasons for unrelieved pain in hospitalized patients.[25] Assessment of pain is as important as any method of treatment and is the only way to determine the presence and severity of pain. The patient's pain must be assessed at regular intervals to determine the effectiveness of therapy, the presence of side effects, the need for dose adjustment or the need for supplemental doses to offset procedural pain. Pain should be reassessed at an appropriate interval after pain medications or other interventions have

been administered, for example, 30 minutes after an IV dose of morphine. However, in the critical care setting, a number of conditions may exist that can make assessment of the patient's pain and subsequent treatments difficult. These conditions include the following:

- Acuity of the patient's condition
- Altered levels of consciousness
- Inability to communicate pain
- Restricted or limited movement
- Endotracheal intubation

When any of the above-mentioned conditions are present, a common misconception among health care professionals is that they are the most qualified to determine the presence and severity of the patient's pain, and unfortunately, the absence of physical signs or behaviors is often incorrectly interpreted as the absence of pain. Thus, the patient may suffer unnecessarily. The critical care nurse must make every effort to elicit a self-report from the patient to perform an effective pain assessment. Behavioral observation and changes in physiological parameters can be helpful but should be considered along with the patient's self-report. In those instances when the patient cannot self-report due to sedation or cognitive impairment, an objective tool for assessing the noncommunicative patient should be used.

Pain assessment is an ongoing process. In addition to the initial pain assessment, assessment after pain management interventions and prior to procedures is essential. After pharmacological therapy, pain reassessment should correspond to the time of onset or peak effect of the drug administered and the time the analgesic effect is expected to dissipate.

BOX 5-2 EXAMPLES OF NURSING DIAGNOSES

For the Patient in Pain
- Acute Pain
- Anxiety
- Chronic Pain
- Fear
- Powerlessness
- Ineffective Coping
- Impaired Physical Mobility

Response to therapy is best measured as a change from the patient's baseline pain level. Occasionally, there may be discrepancies between the patient's self-report and behavioral and physiological manifestations. For example, one patient may report pain as 2 out of 10, while being tachycardic, diaphoretic, and splinting with respirations. Another patient may give a self-report of 8 out of 10 while smiling. These discrepancies can be due to the use of diversionary activities, coping skills, beliefs about pain, cultural background, fears of becoming addicted, or fears of being bothersome to the nursing staff. When these situations occur, they should be discussed with the patient. Any misconceptions or knowledge deficits should be addressed and the pain treated according to the patient's self-report. Box 5-2 lists common nursing diagnoses for the patient in pain.

Patient Self-Report

Because pain is a subjective experience, the patient's self-report is considered to be the gold standard and forms the foundation of the pain assessment (remember McCaffery's operational definition). However, family members and care givers can be used as proxies for the patient self-report in situations, such as critical illness, where significant communication barriers can be present.[26] A self-report and/or proxy assessment of pain should be obtained not only when the patient is resting, but also during routine activities and procedures such as coughing, deep breathing, and turning. Critical care nurses are frequently more attuned to objective indicators of pain than to the patient's self-report. If the patient can communicate, the ICU nurse must accept the patient's description of pain as valid. In the conscious and coherent patient, behavioral cues or physiological indicators should *never* take precedence over the patient's self-report of pain. Behavioral and physiological manifestations of pain are extremely variable and may be minimal or absent, despite the presence of significant pain.

During the pain assessment, the nurse should elicit a specific verbal description of the quality of the patient's pain, such as burning, crushing, stabbing, dull, or sharp whenever possible. The location, duration, and exacerbating/alleviating measures should also be established in the assessment process. Often, this descriptive information helps to determine the cause of the pain and the best treatment strategies to employ. All of the information gathered during the pain assessment must be clearly documented in the patient record with a quotation from the patient's self-reported description included.

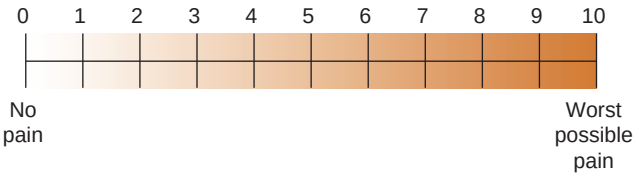

FIGURE 5-1 ▲ Numeric rating scale for pain assessment.

Pain scales and rating instruments based on the patient's self-report provide a simple, but consistent, measure of pain trends over time. It is vital that the same pain scale is used for every pain assessment to produce a valid comparison with previous and subsequent measurements. Numeric rating scales and visual analog scales are used to measure pain intensity. With these scales, the patient chooses a number, word, or a point on a line that best describes the amount of pain he or she is experiencing. The SCCM clinical practice guideline suggests that the numeric rating scale is the preferred type of scale for use in critical care units.[22] With this type of scale, the patient is asked to rate the pain with 0 being no pain and 10 being the worst possible pain imaginable. See Figure 5-1 for an example.

Pictures or word boards can also facilitate communication about the patient's pain. The board should include questions, such as "Do you have pain?" "Where is the pain located?" "How bad is your pain?" and "What helps your pain?" Developing a simple system of eye movements ("blink once for yes and twice for no") or finger movements can be effective for the patient who cannot speak or move his hands.[26]

If the patient is unable to use any of the above methods to verbalize or indicate that he or she is in pain, this can lead to a dilemma when attempting the pain assessment and planning the subsequent treatment. In this situation, it is appropriate to observe for the behavioral cues or physiological indicators discussed in the next section. However, the absence of physiological indicators or behavioral cues should *never* be interpreted as absence of pain. If the procedure, surgery, or condition is believed to be associated with pain, the presence of pain should be assumed and treated appropriately.

Observation

Recent research has demonstrated that ICU nurses can rely on behavioral and physiological indicators of pain in critically ill patients who cannot provide a verbal self-report.[5,26] Nonverbal behaviors, such as guarding, withdrawal, and avoidance of movement, protect the patient from painful stimuli. Attempts by the patient to seek relief, such as touching or rubbing the affected area and changing positions, are palliative behaviors. Crying, moaning, or screaming are affective behaviors and reflect an emotional response to pain. Facial expressions, such as frowning, grimacing, clenching of the teeth, tight closure of the eyes, and tears, can indicate pain. If one or more of these behaviors are present in the nonverbal/noncommunicative patient, it should be assumed that the patient has pain and the proper treatment should be administered.

Patients who are alert and oriented but who are unable to speak may use eye or facial expressions or movement of hands or legs to communicate their pain. Restlessness, agitation, and muscular bracing may be indicators of pain in the nonverbal patient. Since nonverbal cues can be difficult to interpret as indicators of pain, input from family members or other care givers is often helpful in interpreting specific behavioral manifestations of pain based on their knowledge of the patient's behavior before hospitalization.

Physiological Parameters

Critical care nurses are skilled in assessing the patient's physical status in terms of changes in blood pressure, heart rate, or respirations. Therefore, the observation of the physiological effects of pain will assist in pain assessment. Unfortunately, the physiological response to pain is highly individualized. Vital signs, such as heart rate, blood pressure, and respirations, may increase or decrease in the presence of pain.[5] The potential for physiological changes can also be masked by medications that are administered to manage the critical illness, for example, medications that slow the heart rate or decrease blood pressure. When physiological changes do occur in critically ill patients, it can be difficult to attribute these physiological changes specifically to pain rather than other causes. Further, a sudden unexpected increase in the severity and intensity of a patient's pain, with or without associated physiological signs, may be an indication that a life-threatening complication has developed and must be evaluated immediately.

▲ Pain Intervention

The nurse plays a key role in providing pain relief. While pharmacological intervention is the most commonly used strategy, nursing management of pain also includes physical, cognitive, and behavioral measures. Further, in addition to administering medications or providing alternative therapies, the nurse's role involves measuring the patient's response to those therapies. Because pain may diminish or the pain pattern may change, therapy adjustments may be needed before improvements are seen. General guidelines for nursing interventions are listed in Box 5-3.

BOX 5-3 NURSING INTERVENTION GUIDELINES

For Pain Management

- Perform systematic pain assessments in all critically ill patients.
- Reassess hourly the need for rescue doses of analgesic.
- If the patient is experiencing a condition or procedure that is thought to be painful, provide preemptive analgesic medication.
- Remember that critically ill patients who are unconscious, sedated, or receiving neuromuscular blockade are at high risk for undertreatment of pain.
- Prevent pain by treating it in advance.
- If the patient has frequent or continuous pain, give analgesics by continuous intravenous infusion or around the clock, rather than PRN.

From Puntillo K: Part 1: Managing pain in the ICU patient. Critical Care Nurse 27(1):8–10, 2007.

Pharmacological Interventions

In general, the ideal method of analgesia should allow adequate serum drug levels to be achieved and maintained. Therefore, analgesic medications should always be administered on a regular schedule around the clock and not on an "as needed" (PRN) basis.[22] The efficacy of analgesia depends on the presence of an adequate and consistent serum drug level. Regardless of the method being used, scheduled opioid doses or a continuous infusion are preferred over "as needed" (PRN) administration.[22] The traditional PRN analgesic order is a major barrier to effective pain control in all patient populations. The PRN order suggests that the nurse should administer a dose of analgesic only when the patient requests it and only after a certain time interval has elapsed since the previous dose. Invariably, a delay occurs between the time of the request and the time the medication is actually administered. In some cases, this delay can be up to an hour. The PRN order poses another problem when the patient is asleep. As serum drug levels decrease, the patient is suddenly awakened by severe pain, and a greater amount of the drug is needed to achieve adequate serum levels. PRN analgesic medication doses should be reserved for breakthrough pain or when the patient has recovered from the critical illness, is predominantly pain free, and continuous analgesia is no longer required.

Analgesic medications should be titrated based on the patient's response, and the drug should be eliminated when analgesia is no longer needed. Most clinicians agree that when using a numerical scale for assessment, pain medications should be titrated according to the following goals:

- The patient's reported pain score is less than his or her own predetermined pain management goal (eg, 3 on a scale of 1 to 10).
- Adequate respiration is maintained.

Nonopioid Analgesics

Ideally, analgesic regimens should include a nonopioid drug, even if the pain is severe enough to also require an opioid.[2] In many patient populations, nonsteroidal anti-inflammatory drugs (NSAIDS) are the preferred choice for the nonopioid component of analgesic therapy. NSAIDS decrease pain by inhibiting the synthesis of inflammatory mediators (prostaglandin, histamine, and bradykinin) at the site of injury and effectively relieve pain without causing sedation, respiratory depression, or problems with bowel or bladder function. When NSAIDs are used in combination with opioids, the opioid dose can often be reduced and still produce effective analgesia. This decreases the incidence of opioid-related side effects.

Many NSAIDS are supplied only in oral forms, which is not sufficient for critically ill patients whose oral intake is restricted. Ketorolac (Toradol) is available in parenteral form, but it can cause renal impairment if administration exceeds 5 days; therefore, it must be used with caution in patients with renal insufficiency or those receiving dialysis. Indomethacin (Indocin) is available in suppository form and can be combined with opioids to provide effective pain relief.[25]

NSAIDS have been widely used in the non-ICU settings, but the potential benefits of NSAIDS compared to their potential risks have not been studied in critically ill patients. When administering NSAIDS as a complement to opioid analgesic medications, it is important to consider the possible side effects as potentially harmful in the ICU patient population. Prostaglandins help protect the gastric mucosa, are active in the aggregation of platelets, and are involved in the autoregulatory response of the vasculature in the kidneys. The inhibition of prostaglandins by NSAIDS can lead to impaired platelet aggregation, renal dysfunction, and gastric irritation resulting in increased bleeding risk, sodium and water retention, increased creatinine, and gastric ulceration. NSAIDS can also put a patient at higher risks for bronchospasms. Due to these potential risks, NSAIDS should be used with extreme caution in any critically ill patient with renal dysfunction, cardiac failure, coagulation problems, or respiratory failure.[27] Second-generation NSAIDS, such as celecoxib (Celebrex) and rofecoxib (Vioxx), are more selective in their site of action and therefore do not cause these harmful adverse effects, but their slow onset of action may decrease their utility in critically ill patients. Long-term use of these agents can increase the risk of developing cardiovascular disease.[22]

Acetaminophen is commonly used in critical care. When it is combined with opioids, it produces a greater effect than opioids alone. In addition to mild analgesia, acetaminophen is an effective antipyretic; however, it does have the potential to cause hepatic damage. Dosages should be limited to a maximum of 2,400 mg/d if patients have a history of, or high potential for, liver impairment. Nonopioid analgesics that are commonly used in critical care and their recommended doses are listed in Table 5-6.

Opioid Analgesics

Opioids are the pharmacological cornerstone of postoperative pain management. They provide pain relief by binding to various receptor sites in the central and peripheral nervous systems, thus changing the perception of pain. Opioids are selected based on individual patient needs and the potential for adverse effects. Commonly used opioids are compared in Table 5-7. According to the SCCM, morphine sulfate, fentanyl (Duragesic), and hydromorphone (Dilaudid) are the preferred agents when IV opioids are needed.[22] Other opioids used in critical care include codeine, oxycodone (OxyContin), and methadone.

Meperidine (Demerol) is the least potent opioid and is administered in the largest doses. For example, to produce a level of analgesia comparable to 10 mg of morphine every 4 hours, 100 to 150 mg of meperidine every 3 hours would be needed. Meperidine is commonly underdosed and given at intervals too infrequent to be effective. Meperidine also produces a toxic metabolite that can cause significant negative physiological effects when used long term. Therefore, even though meperidine continues to be widely used in some settings, national experts and national practice guidelines do not recommend it for most patients.[22,28] Rationale for avoiding this drug is summarized in Box 5-4.[28]

DOSING GUIDELINES. Equianalgesia means approximately equal analgesia. This term is used when changing a patients' regimen from one analgesic to another. Morphine, 10 mg IM, is generally considered the gold standard dose for comparison. Dosing guidelines for opioid analgesics are presented in Table 5-7. Opioid dosage varies depending on the individual patient, the method of administration, and

Table 5-6 Nonopioid Analgesic Drugs

Drug	Adult Dose	Usual Pediatric Dose	Comments
Acetaminophen	325–650 mg every 4–6 h	10–15 mg/kg every 4–6 h	Available in liquid form, lacks anti-inflammatory action. Doses exceeding 4,000 mg/d increase the risk of hepatic toxicity.
Aspirin	325–650 mg every 4–6 h	10–15 mg/kg every 4–6 h	Can cause gastrointestinal or postoperative bleeding
Celecoxib (Celebrex)	100–400 mg twice a day		Less adverse effects than other nonsteroidal anti-inflammatory drugs, considerably more expensive
Ibuprofen (Motrin)	200–400 mg every 4–6 h	4–10 mg/kg every 6–8 h	Available in liquid form
Indomethacin (Indocin)	25–50 mg every 8–12 h		Available in rectal and IV forms, but high incidence of side effects
Ketorolac (Toradol)	30–60 mg IM initially, then: 30 mg IV every 6 h or 30 mg IM every 6 h 10 mg PO every 4–6 h		Available in parenteral form, limit use to 5 d, contraindicated with renal insufficiency
Naproxen (Naprosyn)	500 mg initially then 250 mg every 6–8 h	5 mg/kg every 12 h	Available in liquid form

All doses are oral, unless noted otherwise.

the pharmacokinetics of the drug. Adequate pain relief will occur once a minimum serum level of the opioid has been achieved. Each patient's optimal serum level will be different, and this level can change as pain intensity changes. Therefore, the dosing and titration of opioids must be individualized, and the patient's response and any undesirable effects, such as respiratory depression or oversedation, must be closely assessed. If the patient has previously received an opioid (eg, before surgery), doses should be adjusted above the previous required dose to achieve an optimal effect. Factors such as age, individual pain tolerance, coexisting disease(s), type of surgical procedure, and the concomitant use of sedatives warrant consideration as well. Older patients are often more sensitive to the effects of opioids; therefore, decreasing the initial opioid dose and slow titration are recommended for older patients.

METHODS OF ADMINISTRATION.

Oral Administration. Oral administration is simple, noninvasive, and inexpensive and provides effective analgesia. Oral is the preferred route for patients with cancer and chronic nonmalignant pain. The oral route is used infrequently in the ICU setting, however, because many patients are unable to take anything by mouth. Serum drug levels obtained after oral administration of opioids are variable and difficult to titrate. In addition, the transformation of oral opioids by the liver causes a significant decrease in serum levels.

Rectal Administration. Morphine and hydromorphone are available in a rectal form. This provides an alternative for patients who cannot take anything by mouth. Unfortunately, this mechanism has many of the same disadvantages as oral administration, including variability in dosing requirements, delays to peak effect, and unstable serum drug levels.

Transdermal Administration. Fentanyl is available in a transdermal patch format. This form is used primarily to control chronic cancer pain because it takes 12 to 16 hours to see substantial therapeutic effects and up to 48 hours to achieve stable serum concentrations. If used for acute pain, such as postoperative pain, high serum concentrations may remain after the pain has subsided, putting the patient at risk for respiratory depression.[29] The nurse must exercise caution when administering fentanyl by a transdermal patch. Gloves should be worn when handling the patch to avoid accidental exposure to the drug. The site where the patch will be applied should be chosen carefully. The skin must be intact. Any open areas in the skin (abrasions, rashes, wounds, etc.) could cause the drug to be absorbed more rapidly than anticipated, leading to increased serum concentrations and a possible overdose. Avoid using lotion in the area where the patch will be applied. The lotion can act as a barrier and reduce or prevent the absorption of the drug, thus decreasing the serum concentration and the analgesic effect. When the fentanyl patch is changed, the old patch must be disposed of properly to avoid accidental exposure to the drug or illicit use of the discarded patch.

Intramuscular Injection. Intramuscular (IM) injections should not be used to provide acute pain relief for the critically ill patient for several reasons:

- IM injections are painful.
- IM drug absorption is extremely variable in critically ill patients because of alterations in cardiac output and tissue perfusion.
- Anticipated discomfort associated with the injection increases the patient's anxiety.
- Repeated IM injections can cause muscle and soft-tissue fibrosis.

Table 5-7 Opioid Analgesic Drugs

Drug	Equianalgesic Dose (mg)		Comments	Precautions
	Oral	IM/IV		
Morphine	10–30 every 4 h	5–10 IM or 1–4 IV every 4 h	Considered the gold standard of comparison for opioids. Oral sustained-release, once-a-day, and rectal forms available	Use caution with impaired ventilation. Not recommended with hemodynamic instability or renal insufficiency.
Fentanyl		0.25–0.5 IV every 1–2 h	Drug of choice for rapid onset of analgesia in acutely distressed patients. Rectal and transdermal forms available	With transdermal form—12–24 h delay to peak effect, and fever increases dose and absorption rate.
Hydromorphone (Dilaudid)	2–8 every 3–4 h	0.7–2 every 1–2 h	More potent and slightly shorter duration than morphine. Rectal form available	
Meperidine (Demerol)	50–150 every 2–4 h	50–75 IM every 3–4 h	Not recommended (See Box 5-4.) Slightly shorter acting than morphine	Toxic metabolite accumulates, causing central nervous system excitation Limit use to <48 h
Methadone (Dolophine)	2.5–10 every 8–12 h	2.5–10 IV/IM every 8–12 h	Good oral potency, long half-life (24–36 h)	Accumulates with repetitive dosing, causing excessive sedation
Oxycodone (OxyContin)	2.5–30 every 4–6 h		Used for moderate pain when combined with a nonopioid (eg, Percocet). As a single entity—useful for severe pain	Dosing must be individualized due to high variability in pharmacokinetics.

Intravenous Injection. Intravenous (IV) administration is usually the preferred route for opioid therapy, especially when the patient requires short-term acute pain relief, for example, during procedures such as chest tube removal, diagnostic tests, suctioning, or wound care. IV opioids have the most rapid onset and are easy to administer. With morphine, the time to peak effect is 15 to 30 minutes; for fentanyl, peak effect is achieved within 1 to 5 minutes. However, the duration of analgesia is shorter with intermittent IV injections, and this can cause serum drug levels to fluctuate.

Continuous IV administration has many benefits for critically ill patients, especially those who have difficulty communicating their pain because of an altered level of consciousness or an endotracheal tube. Continuous IV infusions are easily initiated and maintain consistent serum drug levels. For continuous IV opioid infusions, fentanyl and morphine are commonly used because of their short elimination half-life (compared with other available opioids). Before starting a continuous IV infusion, an initial IV loading dose(s) is given to achieve an optimal serum level. Appropriate dosing and titration must be individualized, and this can be difficult because many critically ill patients have hepatic or renal dysfunctions that result in decreased metabolism of the opioid. A disadvantage of continuous IV infusions is that pain occurring during painful procedures may not be managed unless additional IV bolus injections are given.

PCA is an effective method of pain relief for the critically ill patient who is conscious and able to participate in the pain management therapy. The PCA method of opioid administration produces good quality analgesia, stable drug concentrations, less sedation, less opioid consumption, and fewer adverse effects.[22] Effective use of PCA is based on the assumption that the patient is the best person to evaluate and manage his or her pain. PCA individualizes pain control therapy and offers the patient greater feelings of control and well-being.

BOX 5-4 PATIENT SAFETY

Precautions and Concerns Associated with Meperidine Use

Meperidine (Demerol) is a dangerous analgesic that continues to be used in some settings. For safety's sake, it is not recommended for the following reasons:

- Low potency—requires unusually high doses
- Produces toxic metabolite—normeperidine
- May cause central nervous system excitation, anxiety, tremors, seizures
- Intramuscular administration produces fibrosis
- Contraindicated in patients with compromised renal function
- Contraindicated in elderly patients
- Should not be used for more than 48 hours
- Dose should not exceed 600 mg/24 h
- Should not be used for chronic pain treatment
- Use in sickle cell disease creates high risk for seizures
- Coadministration with monoamine oxidase (MAO) inhibitors can be lethal

Raymo LL, Camejo M, Fundin J: Eradicating analgesic use of meperidine in a hospital. Am J Health Syst Pharm 64(11):1148–1153, 2007

With PCA, the patient self-administers small, frequent IV analgesic doses using a programmable infusion device. Most often, morphine sulfate or fentanyl is used. The PCA device limits the opioid dose within a specific time period; thus preventing oversedation and respiratory depression. If the patient is physically or cognitively unable to use "conventional" PCA, other adaptations can be made. For example, the PCA pump can be activated by a designated family member. This family member will need thorough education in terms of how to assess for the presence of pain, how to administer the medication, and how to assess for oversedation and respiratory depression. The PCA pump can be also be activated by the patient's nurse.

Subcutaneous Administration. In some situations, venous access may be limited or impossible to obtain. When this occurs, continuous subcutaneous infusion and subcutaneous PCA may be used.

Spinal Administration. Spinal opioids can provide superior pain management for many patients. Spinal opioids selectively block opioid receptors, while leaving sensation, motor, and sympathetic nervous system function intact. This results in fewer opioid-related side effects than oral, IM, or IV routes of administration. Analgesia from spinal opioids has a longer duration than other routes, and significantly less opioid is needed to achieve effective pain relief. Opioids, such as fentanyl or morphine, can be given as a single injection in the epidural or intrathecal space, as intermittent injections, or continuous infusions through an epidural catheter, or epidural PCA.

Epidural analgesia is noted for providing effective pain relief and improved postoperative pulmonary function. This method is especially beneficial for critically ill patients after thoracic, upper abdominal or peripheral vascular surgery, rib fractures, orthopedic trauma, or postoperative patients with a history of obesity or pulmonary disease. With epidural analgesia, opioids are administered through a catheter inserted in the spinal canal between the dura mater and vertebral arch. Opioids diffuse across the dura and subarachnoid space and bind with opioid receptor sites.

Intermittent injections may be given before, during, or after surgical procedures. For more sustained pain relief, continuous epidural infusions are recommended. For patient-controlled epidural analgesia, the same parameters are used as with IV PCA, except that smaller opioid doses are used. Contraindications to epidural analgesia include systemic infection/sepsis, bleeding disorders, and increased intracranial pressure.

Preservative-free morphine and fentanyl are most commonly used for epidural analgesia because preservatives can be neurotoxic and may cause severe spinal cord injury. Morphine is more water soluble than fentanyl and thus is more likely to accumulate in the cerebrospinal fluid and systemic circulation. With increased accumulation, side effects are more likely. Fentanyl diffuses more quickly to the opioid receptors and causes fewer opioid-related side effects. The most serious adverse effect of epidural analgesia is respiratory depression. Although the incidence of serious respiratory depression is extremely low with epidural analgesia, respiratory assessments should be performed hourly during the first 24 hours of therapy and every 4 hours thereafter.

Because epidural analgesia is more invasive than the other drug delivery methods discussed, the patient must be closely monitored for signs of local or systemic infections. The insertion site is covered with a sterile dressing, and the catheter is taped securely. To avoid accidental injection of preservative-containing medications, the epidural catheter, infusion tubing, and pump should be clearly marked.

With intrathecal analgesia, the opioid is injected into the subarachnoid space, located between the spinal cord and dura mater. Intrathecal opioids are significantly more potent than those given epidurally; therefore, less medication is needed to provide effective analgesia. The intrathecal method is usually used to deliver a one-time dose of analgesic, such as before surgery, and is infrequently used as a continuous infusion due to the risk of central nervous system infection.

With epidural or intrathecal analgesia, a local anesthetic, such as bupivacaine (Marcaine), can be added to the continuous opioid infusion. Local anesthetics block pain by preventing nerve cell depolarization. They act synergistically with intraspinal opioid and have a dose-sparing effect. Less opioid is needed to provide effective analgesia, and the incidence of opioid-related side effects is decreased. This combination is more commonly administered via the epidural route.

OPIOID EFFECTS. Opioids cause undesirable side effects, such as constipation, urinary retention, sedation, respiratory depression, and nausea. These side effects represent a major drawback to their use. Opioid-related side effects are best managed in the following ways:

- *Decreasing the opioid dose:* This is the most effective strategy because it is directed at the *cause* of the side effect. Side effects are usually seen with excessively high serum levels of the drug. Decreasing the opioid dose can alleviate the side effect while still providing effective pain relief.
- *Avoiding PRN dosing:* When opioids are administered on a PRN basis, fluctuating serum drug levels occur, causing a greater tendency toward sedation and respiratory depression. Around-the-clock administration of analgesics, including opioids, is recommended.
- *Adding an NSAID to the pain management plan*: Using an NSAID in addition to an opioid can decrease the amount of opioid needed, still provide effective pain relief, and decrease opioid-related side effects.

Medications can be given to minimize or alleviate some side effects (eg, stool softeners for constipation, antihistamines for pruritus, and antiemetics for nausea). However, medications commonly prescribed to treat the opioid-related adverse effects can actually cause other adverse effects. For example, promethazine, a commonly prescribed antiemetic, can cause hypotension, restlessness, tremors, and extrapyramidal effects in the older patient.

Respiratory depression, a life-threatening complication of opioid administration, is often a concern for nurses and physicians. The incidence of true opioid-induced respiratory depression is low in most patients. In some cases, a respiratory rate as low as 10 may not be significant if the patient is still breathing deeply. Patients most at risk for respiratory

depression are infants, elderly people who have not recently used opioids, and patients with coexisting pulmonary, renal, or hepatic disease.

Opioid Antagonists

If serious respiratory depression does occur, naloxone (Narcan), a pure opioid antagonist that reverses the effects of opioids, can be administered. The dose of naloxone is titrated to effect—which means reversing the oversedation and respiratory depression, not reversing analgesia. This usually occurs within 1 to 2 minutes. After giving naloxone, the nurse needs to continue observing the patient closely for oversedation and respiratory depression because the half-life of naloxone (1.5 to 2 hours) is shorter than most opioids.

Naloxone should be diluted (0.4 mg in 10 mL of saline solution) and given IV, very slowly. Giving the drug too quickly or giving too much can precipitate severe pain, withdrawal symptoms, tachycardia, dysrhythmias, and cardiac arrest. Patients who have been receiving opioids for more than a week are particularly at risk.

Sedatives and Anxiolytics

Acute pain is frequently accompanied by anxiety, and anxiety can increase the patient's perception of pain. When treating acute pain, anxiolytics can be used to complement analgesia and improve the patient's overall comfort. This is an important consideration, especially prior to and during painful procedures.

Benzodiazepines

Benzodiazepines, such as midazolam (Versed), diazepam (Valium), and lorazepam (Ativan), can control anxiety and muscle spasms, and produce amnesia for uncomfortable procedures. In the ICU, benzodiazepines may be given IV as an intermittent bolus or by continuous infusion and titrated according to the patient's response. Because these medications have no analgesic effect (except for controlling pain caused by muscle spasm), an analgesic must be administered concomitantly to relieve pain. If an opioid and benzodiazepine are used together, the doses of both medications should usually be reduced because of their synergistic effects. The patient should also be closely monitored for oversedation and respiratory depression.

Midazolam is recommended for conscious sedation and short-term relief of anxiety because of its rapid onset (1 to 5 minutes with IV administration) and its short half-life (1 to 12 hours). Another advantage is its retrograde amnesia effect, which is particularly beneficial during procedures. The duration of effect of midazolam can be longer in older or obese patients and those with liver disease.[22]

A major advantage of benzodiazepines is that they are reversible agents. If respiratory depression occurs from benzodiazepine administration, flumazenil (Romazicon) can be administered IV. Flumazenil is a benzodiazepine-specific reversal agent that reverses the sedative and respiratory depressant effects without reversing opioid analgesics. The dosing of flumazenil should be individualized and titrated so that only the smallest effective amount is used. After prolonged benzodiazepine therapy, flumazenil should be used with caution due to the potential for stimulating withdrawal symptoms, increasing intracranial pressure, causing hypertension, and lowering the seizure threshold.[29]

Critically ill patients who are receiving repeated doses or continuous infusions of sedatives are given a break from sedation at least once a day. Administration should be interrupted until the patient is fully awake. This helps to prevent oversedation, which can inhibit weaning from mechanical ventilation.

Propofol

Propofol (Diprivan) is a rapid-acting sedative/hypnotic agent that has no analgesic properties and minimal amnesic effects. With appropriate airway and ventilatory management, propofol can be an ideal agent for patients requiring sedation during painful procedures. Because of its ultrashort half-life and high rate of elimination, it is reversible simply by discontinuing the infusion and patients will awaken within a few minutes. Propofol can also be used as a continuous infusion for mechanically ventilated patients who require deep, prolonged sedation.

Because propofol is only slightly water soluble, it is formulated in a white, oil-based emulsion containing soybean oil, egg lecithin, and glycerol. It is contraindicated, therefore, in patients allergic to eggs or soy products. Propofol contains no preservatives. Each ampule or vial must be used as a "single-dose" product vial and should be discarded within 6 to 12 hours after breaking the sterile seal to minimize the risk of systemic infections. Adverse effects commonly associated with propofol include respiratory depression, hypotension, elevated triglycerides, and pain and stinging at the injection site. Table 5-8 provides a comparison of sedatives commonly used in critical care.[35]

Nonpharmacological Comfort Measures

The combination of nonpharmacological and pharmacological interventions provide better pain control, with less use of opioid analgesics, decreased incidence of anxiety, and increased patient satisfaction.[27,28] These nonpharmacological approaches, which include interventions, such as distraction, relaxation, music, therapeutic touch, and massage, can be challenging to provide in the critical setting.

Environmental Modification

In critical care, the most basic and logical nonpharmacological intervention is environmental modification. The excessive noise and light in ICUs can disrupt sleep and increase anxiety and agitation, in turn contributing to pain and discomfort. Sources of noise may include alarms, equipment, telephones, ventilators, and staff conversations. The severity of illness has also been shown to be associated with sleep disturbances. Care should be preplanned to minimize noise and disruptions during normal sleeping hours and to create a pattern of light that mimics normal day–night patterns. Earphones, with music of the patient's choice, and earplugs have also been recommended for use in the ICU.[30,31]

Table 5-8 Comparison of Sedatives Commonly Used in Critical Care

Drug	Recommended Use	Onset (IV)	Unique Adverse Effects
Diazepam (Valium)	For rapid sedation of acutely agitated patients.	2–5 min	Phlebitis
Lorazepam (Ativan)	For long-term sedation of most patients via intermittent or continuous infusion	5–20 min	Acidosis/renal failure with high doses
Midazolam (Versed)	For conscious sedation and rapid sedation of acutely agitated patients. For short-term use only.	2–5 min	Prolonged wakening and delayed weaning from ventilator, if used long term
Propofol	Preferred sedative when rapid awakening is important.	1–2 min	Pain on injection and elevated triglycerides

Honiden S, Siegel MD: Analytic reviews: Managing the agitated patient in the ICU: Sedation, analgesia and neuromuscular blockade. J Intensive Care Med 25(4):187–204, 2010

Distraction

Distraction helps patients direct their attention away from the source of pain or discomfort toward something more pleasant. Patients, families, and nurses often use distraction routinely without giving it much consideration. Initiating a conversation with the patient during an uncomfortable procedure, watching television, and visiting with family are all excellent sources of distraction.

Relaxation Techniques

Relaxation can be described as a state of calmness or peacefulness. It is a state that is free from anxiety and skeletal muscle tension.[9] Relaxation exercises involve repetitive focus on a word, phrase, prayer, or muscular activity and a conscious effort to reject other intruding thoughts. Relaxation can give the patient a sense of control over a particular body part. Most relaxation methods require a quiet environment, a comfortable position, a passive attitude, and concentration. Each of these can be challenging to achieve in an ICU.

Breathing exercises have been used with much success in childbirth. They can also be used successfully in the critically ill patient. The quieting reflex is a breathing and relaxation technique that reduces stress and can easily be taught to the conscious and coherent patient. Instructions regarding the quieting reflex are given in Box 5-5. The nurse encourages the patient to perform the quieting reflex frequently during the day. This relaxation technique can be done in only 6 seconds, and it calms the sympathetic nervous system and gives the patient a sense of control over stress and anxiety.

BOX 5–5 TEACHING GUIDE *Instructions for the Quieting Reflex*

1. Inhale using an easy, natural breath.
2. Think "alert mind, calm body."
3. Smile inwardly (with your internal facial muscles).
4. As you exhale, allow your jaw, tongue, and shoulders to go loose.
5. Allow a feeling of warmth and looseness to go down through your body and out through your toes.

Touch

Historically, one of the greatest contributions nurses have made is the comfort and caring of presence and touch. These contributions still have an important place in today's highly technical ICUs. Nurses may feel that touching is too simple to be effective. However, few medical advances can replace the benefits of warm and caring touch. The need for touch is thought to intensify during times of high stress and cannot be totally met by other forms of communication. Nurses, when using touch, are usually trying to convey understanding, support, warmth, concern, and closeness to the patient. Touching not only contributes to the patient's sense of well-being but also promotes physical recovery from disease. It has a positive effect on perceptual and cognitive abilities and can influence physiological parameters, such as respiration and blood flow. Touch represents a positive therapeutic element of human interaction.

The effects of touch in the clinical environment are far-reaching. Touch has played a major part in promoting and maintaining reality orientation in patients prone to confusion about time, place, and personal identification. Nursing touch may be most helpful in situations in which people are experiencing fear, anxiety, depression, or isolation. It may also be beneficial for patients who have a need for encouragement or nurturing, who have difficulty verbalizing needs, or who are disoriented, unresponsive, or terminally ill. Patients often feel that the desire for touch increases with the seriousness of the illness.

Massage

Superficial massage initiates the relaxation response and has been shown to increase the amount of sleep in ICU patients, decrease fatigue, improve the immune system, and help relieve pain, anxiety, and nausea.[32] While the back is the most common location used for massage, backs are often difficult to access in ICU patients. Hands, feet, and shoulders are also good sites for massage. Massage is an excellent intervention for family members to use in their attempts to provide comfort to the critically ill.

Patient Education

To educate the patient about pain and pain relief, the critical care nurse must be familiar with the patient's pain

management plan and therapy being used. Communication between the nurse and patient is essential. Any information given should be reinforced periodically during the course of therapy, and the patient should be encouraged to verbalize any questions or concerns. Family members should be included whenever possible. Plans for pain management should be discussed with patients when they are most able to understand, for example, prior to surgery rather than during the recovery period. Emphasis is on prevention of pain because it is easier to prevent pain than to treat it once it becomes severe.

Patients need to know that most pain can be relieved and that unrelieved pain may have serious consequences on physical and psychological well-being and may interfere with recovery. The nurse helps patients and families understand that pain management is an important part of their care and that the health care team will respond quickly to reports of pain. Patients should also be given instructions about nonpharmacological interventions and traditional methods to minimize pain. Splinting the incisional area with a pillow while coughing or ambulating is a traditional pain-relief measure.

The potential for drug addiction or overdosage is often a major concern for the patient and family. These issues should be addressed and clarified because they create a barrier to effective pain relief. The patient also needs a clear understanding of any specialized pain management technology, such as PCA to alleviate the fear of overdosage.

BOX 5-6 CONSIDERATIONS FOR THE OLDER PATIENT

In Pain

- Painful chronic diseases often compound the acute pain of critical illness in older patients.
- Arthritis, the most common cause of chronic pain in older patients, often affects the back, hips, knees, and shoulders, increasing the patient's pain when being turned, particularly in the ICU.
- Some older patients can experience acutely painful conditions, such as myocardial infarction or appendicitis, without feeling pain.
- Older patients often use words such as "aches" or "tenderness" rather than "pain."
- Family care givers can help assess pain in older patients who have cognitive or language impairments.
- Older patients are particularly sensitive to opioids; higher peak concentrations and longer duration of actions are achieved in older adults.
- Meperidine (Demerol), pentazocine (Talwin), propoxyphene (Darvon), and methadone should not be used to treat pain in older adults.[29]
- Some older patients often have an increased need for meaningful touch during episodes of crisis.

▲ Pain Management in Specific Populations

Some critically ill populations create unique pain management challenges. Special considerations for the elderly patient are noted in Box 5-6.[29] Another population that is particularly challenging is patients who are known to be dying. Pain is a primary concern for patients and their families at the end of life. Initiatives to promote high-quality palliative and end-of-life care have contributed to the diligence of health care providers in their efforts to understand and control pain in dying patients.[33,34]

Progression toward death is often marked by decreased cardiac output, decreased perfusion, and failure of major organ systems. This can create problems with excessive accumulation of analgesics and their metabolites resulting from limited hepatic and renal function. In such cases, hydromorphone, oxycodone, and fentanyl are preferred agents because of their short half-lives. If pain or dyspnea becomes uncontrollable despite aggressive analgesic administration, high doses of sedatives may also be employed. In such cases, the goal of sedation is comfort and relief of suffering, and the common by-product is end-stage unconsciousness.[35]

Critical illness is painful. The subjective nature of pain, coupled with communication impairments and the interactions of acute and chronic disease processes, makes pain assessment and treatment particularly challenging in the ICU. Misconceptions and knowledge deficits on the part of health care providers, patients, and family members must be recognized and corrected. When providing pain management, all available modes of therapy—opioids, adjuvants, and nonpharmacological therapies—should be integrated into the plan of care. Critical care nurses must stay abreast of current pain management research and resources to provide the highest quality of pain and comfort management.

▲ Clinical Applicability Challenges

CASE STUDY

Mr. B., a 31-year-old construction worker who fell three stories onto concrete, was just admitted to the trauma intensive care unit from the Emergency Department's trauma resuscitation room. Mr. B. is alert, oriented, and reporting that he is in severe pain despite receiving several IV morphine injections. His injuries include fractures of the seventh and eighth ribs on the right with a hemopneumothorax, a fracture of the right radius and ulna, and a compound fracture of the right tibia and fibula. Blood in his urine and bruising in the right flank area also indicate a probable injury to the right kidney. While Mr. B. was being evaluated in the trauma room, a

(continued on page 65)

CASE STUDY *(Continued)*

chest tube was inserted to correct the hemopneumothorax; the fractures of his radius and ulna were reduced and a cast was applied; a Foley catheter was inserted to monitor his urinary output; and the compound fractures of his tibia and fibula were reduced and a splint was applied. Mr. B. will be taken to the operating room later in the day for débridement of the wound on his lower leg and external fixation of his fractures.

1. Often an NSAID is prescribed in conjunction with opioid drugs for optimal pain control. This patient is in extreme pain. Should he be receiving an NSAID in addition to his morphine and why?

2. Mr. B. is prescribed morphine 4 mg/IV every 2 hours for pain, yet he is still rating his pain at 10/10. The chief surgical resident has been contacted to write new orders for a higher or more frequent morphine dose; however, he is hesitant to increase the morphine due to the impending surgery to repair Mr. B.'s leg fractures. How could uncontrolled pain negatively affect Mr. B.'s condition?

3. Mr. B.'s pain remains 10/10, and the nurse contacts the attending trauma surgeon, explaining the situation and the reluctance of the surgical resident to increase the morphine dose. The attending surgeon decides to take an alternate approach that will increase the effectiveness of the morphine without increasing the dose. What alternative method of pain management would achieve these goals?

6 Palliative Care and End-of-Life Issues in Critical Care

Garrett K. Chan

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. List at least three end-of-life issues related to critical care nursing.
2. List at least three components of palliative care.
3. Describe how palliative care can be integrated into curative or disease-modifying care.
4. Identify at least three symptoms commonly experienced at the end of life.
5. Recognize the importance of flexible visiting hours for a patient at the end of life.
6. Describe activities by the nurse in preparing for and coordinating a family conference.
7. Identify strategies for self-care of the nurse.

About 2 million people die in the United States every year. Although some people die in peace and comfort, others die in severe distress and suffering. Over the past decade, nurses in the acute care setting have been increasingly concerned about how people die. Thoughts about critical care have slowly shifted; clinicians now recognize that death may be inevitable and that the use of technology to prevent death is limited. Critical care nurses are well positioned to help patients and families during this difficult transitional period. "Being with" patients and families in addition to "doing things to" them enables critical care nurses to provide the holistic care that is central to nursing.[1]

▲ Need for Quality End-of-Life Care in the Critical Care Setting

In the early 20th century, the average life expectancy was 50 years. Common causes of death included infection, accidents, and childhood mortality.[2] Few life-extending measures were available, and death occurred after hardly any interventions. The focus was on caring for the dying person by family members, who witnessed the death.

However, in the mid to late 20th century, medical interventions such as antibiotics, cardiopulmonary resuscitation (CPR), mechanical ventilation, dialysis, intra-aortic balloon pumps, and pulmonary artery catheters were discovered and routinely used to combat morbidity and mortality. These technologies, combined with other public health initiatives such as improved sanitation, carried the promise of treating the causes of death and therefore extending life. By the year 2000, the average life expectancy had been extended to 77 years.

Critical care nurses became focused on these life-extending procedures, and critical care units were developed to house seriously ill patients in one area of a hospital and closely monitor their response to curative, lifesaving, and aggressive treatments.[3] Increasingly, people died in the hospital setting surrounded by health care practitioners rather than their families. Over the course of the years of technological advancement, nurses increasingly viewed patients in terms of disease processes or technologies. The concept that the patient lying in the bed was a person who experienced physical, emotional, psychological, social, and spiritual suffering was lost.[4]

Over the past decade, evidence shows that skillful communication, family centered care, and shared decision making among the patient, family, and the interdisciplinary team can lead to healthy work environments, decreased moral distress, and mitigation of traumatic stress experienced by all persons involved in the care of the patient.[5–7] It is important to recognize that people approach death in a variety of ways. Therefore, instituting these caring practices from the moment the patient reaches the critical care environment is vital to providing good care. While palliative and end-of-life care education is important, there has been a paucity of prelicensure and continuing education programs addressing these topics.[8,9] The End-of-Life Nursing Education Consortium-Critical Care (ELNEC-CC) project was designed specifically to educate nurses about palliative and end-of-life care in critical care settings.[10]

Understanding Human Death

Over the past decade, there has been an increase in understanding the human experience of dying in the acute care setting. In 1995, a major study titled the *Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment* (SUPPORT) was published.[11] This study, conducted in five major academic medical centers across the United States, involved more than 9,000 seriously ill patients. The goal was to improve end-of-life decision making and reduce the frequency of mechanically supported, painful, and prolonged death. Despite use of an intervention designed to communicate preferences among providers, patients, and families, such wishes were often unknown, and aggressive treatment was common. Physicians were not aware that their patients preferred to avoid CPR. In addition, nearly 40% of patients who died spent at least 10 days in an intensive care unit (ICU), and 50% of family members of conscious patients reported that the patients were in moderate to severe pain at least half the time.

After publication of the SUPPORT study, the Institute of Medicine (IOM) released a report titled *Approaching Death: Improving Care at the End of Life*.[12] The IOM group of experts listed seven recommendations to improve end-of-life care (Box 6-1). These recommendations are important for critical care nurses because it is estimated that about 20% of deaths in the United States occur while patients are using ICU services.[13] Critical care nurses play an important role in recognizing opportunities for interventions that support patients, families, and other staff members during this difficult transition in life. Although technology, urgency, uncertainty, and conflict are common in critical care practice, these characteristics may inhibit or fragment a coordinated effort that aims to provide good end-of-life care.[1]

BOX 6-1 Recommendations to Improve End-of-Life Care

1. People with advanced, potentially fatal illnesses and those close to them should be able to expect and receive reliable, skillful, and supportive care.
2. Physicians, nurses, social workers, and other health professionals must commit themselves to improving care for dying patients and to using existing knowledge effectively to prevent and relieve pain and other symptoms.
3. Because many deficiencies in care reflect system problems, policy makers, consumer groups, and purchasers of health care should work with health care providers and researchers to:
   a. Strengthen methods for measuring the quality of life and other outcomes of care for dying patients and those close to them
   b. Develop better tools and strategies for improving the quality of care and holding health care organizations accountable for care at the end of life
   c. Revise mechanisms for financing care so that they encourage rather than impede good end-of-life care and sustain, rather than frustrate, coordinated systems of excellent care
   d. Reform drug prescription laws, burdensome regulations, and state medical board policies and practices that impede effective use of opioids to relieve pain and suffering
4. Educators and other health professionals should initiate changes in undergraduate, graduate, and continuing education to ensure that practitioners have the relevant attitudes, knowledge, and skills to care well for dying patients.
5. Palliative care should become, if not a medical specialty, at least a defined area of expertise, education, and research.
6. The nation's research establishment should define and implement priorities for strengthening the knowledge base for end-of-life care.
7. A continuing public discussion is essential to develop a better understanding of the modern experience of dying, the options available to dying patients and families, and the obligations of communities to those approaching death.

Adapted from Field MJ, Cassel CK: Approaching Death: Improving Care at the End of Life. Washington, DC: Institute of Medicine, 1997

Palliative Care

The introduction of palliative care principles into critical care can provide a framework to address these end-of-life issues. Palliative care originated from hospice care, which was designed to improve the quality of death and dying for patients and their families by addressing aspects of care that are unrelated to disease-specific treatments, cure, or rehabilitation.[14] According to the World Health Organization[15] and the IOM,[12] palliative care from an interdisciplinary perspective includes the following core principles: symptom management; advanced care planning; family centered care; emotional, psychological, social, and spiritual care; facilitating communication; awareness of ethical issues, and caring for the care giver. These principles should be addressed and incorporated into the total care of the patient, even when disease-modifying or curative therapies are used. In critical care nursing, it is vital that these core palliative care principles are incorporated in the daily plan of care of patients using an interdisciplinary approach.[16–18] Figure 6-1 illustrates how palliative care can be incorporated throughout the patient's illness.

Palliative care services in critical care have demonstrated an improvement in symptom management, family support, reduction in length of hospital stay, increased discharges to home with hospice referrals, and reduced costs.[16,19,20] The American Association of Critical-Care Nurses (AACN) has developed protocols for critical care practice in palliative and end-of-life care.[21] These protocols provide a good overview of core issues and clinical recommendations for critical care nurses. Resources to assist nurses in addressing issues surrounding the end-of-life phase are given in Table 6-1.

A particular therapeutic intervention may be either curative or palliative depending on its intent. For example, a packed red blood cell transfusion may be curative in a patient with an acute hemorrhage or palliative in a patient with chronic anemia and severe fatigue following chemotherapy. Whether an intervention attempts to cure or to palliate determines whether it is curative or palliative. Additional examples of treatments that can be either curative or palliative are surgeries that resect the bowel to remove a tumor that is causing an intestinal obstruction or administering furosemide in a patient who has severe pulmonary edema. If the treatment relieves the patient's suffering, then it is considered palliative.

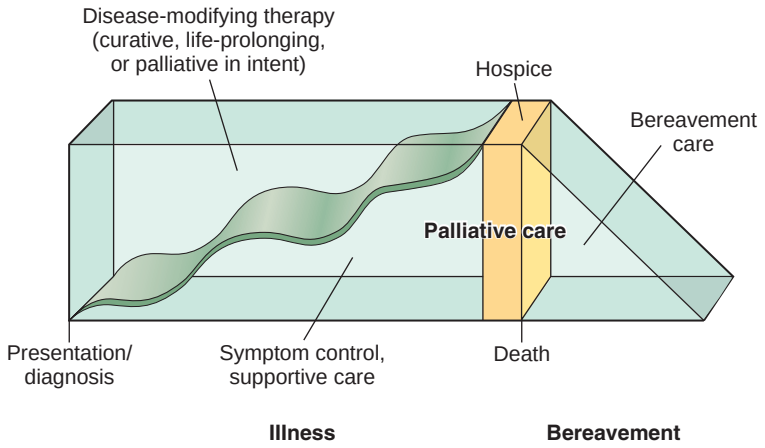

FIGURE 6-1 ▲ The continuum of care. (Adapted from Emanuel L, von Gunten C, Ferris F, et al (eds): The Education in Palliative and End-of-Life Care [EPEC] Curriculum: The EPEC Project. Chicago, IL: Author, 2003.)

▲ Symptom Management

In critical care, patients experience a wide range of symptoms from their diseases as well as from the therapies that are used to treat those diseases. Common symptoms at the end of life include pain, dyspnea, anxiety and agitation, depression, delirium, and nausea and vomiting. The nurse assesses for the presence and severity of each of these symptoms. Interventions appropriate for the symptoms and an evaluation of those interventions are crucial in providing good end-of-life care.

Pain

Pain is the most prevalent symptom in critical care units and is distressing to patients and families.[11] Diseases, procedures, and interventions such as turning, suctioning, and wound care can be sources of painful stimuli.[22,23] Assessing for the presence of pain and intervening to prevent or treat it using pharmacological and nonpharmacological interventions should be incorporated into every patient's care plan. Dose escalation to treat severe pain is an appropriate treatment modality provided there are accurate pain assessments and in the hands of skilled clinicians.[22] Including a bowel regimen to prevent constipation is crucial in the management of pain. Chapter 5 describes, in detail, the assessment of pain and nursing interventions that can be used to treat it.

Dyspnea

It is estimated that dyspnea is present in 21% to 90% of all patients with a life-threatening illness.[24] Causes of dyspnea can include the underlying disease pathology (eg, chronic obstructive pulmonary disease, pulmonary embolism, pleural effusion); anxiety; or family, spiritual, or social issues. Investigation for the source of the dyspnea directs the nurse to the appropriate intervention. Accurate and frequent assessment of dyspnea will also alert the nurse to the presence and severity of this distressing symptom.[25] Instruments that can accurately assess dyspnea include the Modified Borg Scale[26] for patients who can verbally respond and the Respiratory Distress Observation Scale (RDOS)[27] for patients who cannot verbally respond. Common interventions used for dyspnea include oxygen, opioids, and anxiolytics.[25] Nonpharmacological interventions such as pursed-lip breathing, relaxation strategies, reducing the room temperature (but not chilling the patient), reducing the number of people in the room at one time, keeping an unobstructed line of sight between the patient and the outside environment, and using a fan to blow gently across the face (not

directly into mucous membranes) have all been found to be effective in decreasing dyspnea.[25,28]

Anxiety and Agitation

Patients and families who face life-threatening illnesses commonly experience anxiety.[28] Anxiety can be related to any number of physical, emotional, psychological, social, practical, and spiritual issues. Assessment of anxiety can be complex, and an interdisciplinary approach, including nursing, social services, psychology, and chaplaincy, may be needed to evaluate the patient accurately and treat the anxiety properly. Nonpharmacological interventions may include counseling, taking care of practical matters (eg, arranging for the care of a pet), and arranging for spiritual concerns to be addressed (eg, arranging for a visit from a clergy member). If medication is needed, short- or long-acting benzodiazepines and atypical antidepressants may be helpful. Additional interventions for anxiety are discussed in Chapter 2.

Depression

When confronted with a serious illness, many patients experience intense sadness and anxiety accompanied by depressive symptoms such as anhedonia (loss of pleasure); loss of self-esteem; pervasive despair; thoughts of suicide; or feelings of helplessness, hopelessness, or worthlessness.[28] These are natural feelings and are usually present for only a short time. It is a myth that depression is "normal" at the end of life. If these feelings of depression persist, appropriate treatment needs to be initiated using a multidimensional approach, such as supportive psychotherapy, cognitive–behavioral therapy, and antidepressants.

Delirium

Delirium is an acute change in awareness or cognitive status that may manifest as agitation, withdrawal, or confusion. "Confusion" is an all-inclusive term that refers to inappropriate behavior, disorientation, or hallucinations. Terminal delirium is common in patients near death and may manifest as day–night reversal.[28] Management of delirium during the end-of-life phase is focused more on symptom control and relief of the distress of the patient and family than on the diagnosis and treatment of the underlying cause of the delirium. Benzodiazepines or neuroleptics (eg, haloperidol) are helpful in managing this symptom.

Nausea and Vomiting

Nausea is very common in patients with advanced disease. Nausea can be acute, delayed, or anticipatory. It can be exhausting, debilitating, and frustrating for the patient and the family. The pathophysiology of nausea and vomiting is complex and can vary based on the underlying etiology. Causes of nausea and vomiting may include physiological factors such as gastrointestinal causes (eg, intestinal obstruction, constipation, pancreatitis); metabolic causes (eg, hypercalcemia, uremia); central nervous system causes (eg, increased intracranial pressure); emotional factors; treatment-related factors (eg, chemotherapy); and vestibular disturbances.

A careful assessment and investigation of the source of nausea and vomiting is important in determining the appropriate treatment course. Drug classes that are commonly used to treat nausea and vomiting are serotonin (5-HT) receptor agonists (eg, ondansetron), anticholinergics (eg, hyoscine hydrobromide), antihistamines (eg, dimenhydrinate), phenothiazines (eg, prochlorperazine), steroids (eg, dexamethasone), prokinetic agents (eg, metoclopramide), butyrophenones (eg, haloperidol), and benzodiazepines (eg, lorazepam). A nasogastric tube may be used, but it may cause discomfort. To relieve persistent nausea and vomiting, surgery to resect an intestinal obstruction may be appropriate. If a patient has an unresectable intestinal obstruction, a draining percutaneous endoscopic gastrostomy tube may also be placed. Lastly, patients should be positioned to avoid any aspiration of emesis.

Palliative or End-of-Life Sedation

Palliative sedation, also known as end-of-life or terminal sedation, may be considered when all interventions have failed to control the symptoms. Palliative sedation is used when the patient (1) is experiencing unbearable and unmanageable pain or other symptoms, and (2) is approaching the last hours or days of his or her life.[28] The goal of end-of-life sedation is to produce a level of obtundation sufficient to relieve suffering without hastening death.[28] Before palliative sedation is considered, specialists in pain or palliative care are consulted, and it is verified that all therapies have been attempted without success. In addition, other disciplines such as social services, chaplaincy services, and psychology, should be consulted to investigate other potential causes of suffering before resorting to palliative sedation.

▲ Advanced Care Planning

Advanced care planning involves deciding how a patient would like to be treated in the event that he or she becomes unable to make decisions or communicate his or her wishes regarding care.[6] Advanced care planning involves more than just advance directives—it also involves issues such as determining health care proxies as well as trying to discover from the patient or the health care proxy the preferences for the goals of care during the end-of-life phase.

The critical care nurse communicates with the patient's primary care provider, who may have a long-standing relationship with the patient and know the patient's preferences regarding end-of-life treatment. The primary care provider may have had conversations with the patient on this subject. It is important to note that some patients want aggressive treatment despite a poor prognosis, whereas other patients want to forego any aggressive treatment despite the treatment's probable success. Patients are allowed, by federal law, to refuse treatment.

Advance Directives

Advance directives are written or oral instructions about future medical care that are to be followed in the event that the person loses the capacity to make decisions.[29] Types of advance directives include living wills and health care proxies (durable powers of attorney for health care). Each state regulates the use of advance directives differently. Advance directives are not "set in stone." They can be revised, orally or in writing, at any time.

A health care proxy is a person who has been designated to make decisions in the event that the patient cannot make decisions for himself or herself. The designation of a person as a health care proxy must be in written form and should always be up to date. The proxy should know the preferences of the patient and be able to communicate and adhere to those preferences. He or she should not confuse his or her own wishes and desires with those of the patient. Health care proxies are also known as "surrogate decision makers" or "health care agents."

Do Not Resuscitate and Do Not Attempt Resuscitation Orders

The standard of care for patients who suffer a cardiac or respiratory arrest is to initiate CPR. Do not resuscitate (DNR) or do not attempt resuscitation (DNAR) orders are orders placed by a physician, most often with the consent of the patient or the health care proxy, to alert other care givers that if the patient has a cardiac or pulmonary arrest, no attempts to restore cardiac or pulmonary function should occur.[12,30]

Although resuscitation efforts should not be initiated for a patient with a DNR or DNAR order, the patient should continue to receive appropriate care. In one study of critically ill cancer patients in a surgical ICU, researchers noted that the patients with a DNR or DNAR order received less medical care than other patients.[31] However, supportive nursing care remained unchanged. It is important to recognize that DNR and DNAR are not intended to give the impression that nurses should give inappropriate care.[32]

▲ Family Centered Care

Family centered care is a cornerstone of critical and palliative care. In palliative care, the patient is recognized as being part of a larger social network. Serious illness and death affect not only the patient but also the family. The Society of Critical Care Medicine published clinical practice guidelines[7] delineating recommendations to support families during critical illness. These recommendations include endorsement of a shared decision-making model, early and repeated care conferencing to reduce family stress and improve consistency in communication, honoring culturally appropriate requests for truth-telling and informed refusal, spiritual support, staff education and debriefing to minimize the impact of family interactions on staff health, family presence at both rounds and resuscitation, open flexible visitation, way-finding and family friendly signage, and family support before, during, and after a death.

When the patient can communicate, according to Stannard,[33] the ideal definition of family is whomever the patient defines as his or her family. When a patient is unable to communicate, the practical definition of family is anyone who shares a history and a future with the patient. The legal definition of family is based on blood relations and is purposefully narrow and limiting to clearly distinguish who may have authority over the patient should the patient lose decision-making capacity.

Family Presence During Resuscitation

In a critical review of the literature, Halm[34] noted that research has found that families have a right to be present during resuscitation; in addition, families report that being present during resuscitation was helpful during the bereavement process. Family members who have been present during resuscitations have not experienced more anxiety, depression, grief, intrusive imagery, or avoidance behavior compared with family members who did not witness resuscitations. In addition, there is no evidence to substantiate that the presence of family members invites litigation.

However, research studies do report that many health care providers are uncomfortable with family presence. Nurses who have less experience with resuscitation report more discomfort with family presence than nurses who have more such experience. In addition, the staff surveyed expressed concern that family members may take time and attention away from the patient. The AACN recommends that hospitals should have policies and procedures about how family presence during resuscitation is to be handled in their institutions.[35] It has been suggested that a successful family presence program depends on having a dedicated staff member attend to the family witnessing the resuscitative efforts. See Evidence-Based Practice Highlight 6-1.

Visitation

To the greatest extent possible, families should be free to visit a patient who is near death, to allow for coping during this period. Family members may communicate with and touch the patient, which may reassure both the patient and family. During this period of closure, cultural or spiritual ceremonies may also take place. Staff who have developed a relationship with the family should continue to work with the patient and family to the greatest extent possible. The extended visiting hours provide a continuity of care that is invaluable to families and helps cultivate a trusting relationship to reassure families that the nurses are working for the benefit of the patient.

It is important to be aware of the dynamics of each individual family. For example, if there is tension among certain family members, a visiting schedule may need to be established to allow family members to see the patient without crossing paths. In addition, the nurse should be alert to any signs from the patient that a particular family member is unwelcome. The patient may exhibit signs of agitation when that person is in the room. The nurse acts as an advocate to uphold the patient's wishes. Visitation advocacy as it relates to families and the critical care environment is discussed in more detail in Chapter 3.

EVIDENCE-BASED PRACTICE HIGHLIGHT 6-1

Family Presence During Resuscitation and Invasive Procedures

△ Expected Practice

- Family members* of all patients undergoing resuscitation and invasive procedures should be given the option of presence at the bedside. (Level B)
- All patient care units should have an approved written practice document (ie, policy, procedure, or standard of care) for presenting the option of family presence during resuscitation and bedside invasive procedures. (Level D)

△ Supporting Evidence

- Research [1–11] and public opinion polls [12–14] have found that 50% to 96% of consumers believe family members should be offered the opportunity to be present during emergency procedures and at the time of their loved one's death.
- Despite support by professional organizations and critical care experts, [15–24] only 5% of critical care units in the United States have written policies allowing family presence.[25] Surveys of nurses' practice find that most critical care nurses have been requested by family members to be present during resuscitation and invasive procedures and have brought families to the bedside, despite the lack of formal hospital policies.[25–27]
- Studies find the following benefits of family presence:
  - For patients: Almost all children want their parents present during medical procedures;[28–30] and adult patients report that having family members at the bedside comforted and helped them.[3,31–32]
  - For family members: Their presence at the bedside helped in removing doubt about the patient's condition by witnessing that everything possible was being done.[8,9,32–35] It decreased their anxiety and fear about what was happening to their loved one.[7,10,29,32,36–37] It facilitated their need to be together[8,10] and the need to help and support their loved one. [8–11, 33,34,36] They experienced a sense of closure,[3,8,11,34] and their presence facilitated the grief process should death occur.[3,5,11,32–36]
- Studies show that 94% to 100% of families involved in family presence events would do so again.[3,7–9,33,36]
- Studies also find that there are no patient care disruptions, no negative outcomes during family presence events,[8,9,29,32–34,38–39] and no adverse psychological effects among family members who participated at the bedside.[8–10,32,40]

AACN Evidence Leveling System

Level A Meta-analysis of quantitative studies or metasynthesis of qualitative studies with results that consistently support a specific action, intervention, or treatment.
Level B Well-designed, controlled studies with results that consistently support a specific action, intervention, or treatment.
Level C Qualitative studies, descriptive or correlational studies, integrative review, systematic reviews, or randomized controlled trials with inconsistent results.
Level D Peer-reviewed professional organizational standards with clinical studies to support recommendations.
Level E Multiple case reports, theory-based evidence from expert opinions, or peer-reviewed professional organizational standards without clinical studies to support recommendations.
Level M Manufacturer's recommendations only.

*Family members are those individuals who are relatives or significant others with whom the patient shares an established relationship.

Family Conferences

The family conference is a mechanism for sharing information in an organized way among clinicians and family members. During the family conference, the health care team (1) provides information about the condition of the patient and the patient's prognosis and (2) reviews recommendations from the primary and consult services. Family conferences also serve as a forum for exploring future care preferences with the family—how family members may wish to participate in determining the goals of care for the patient.[36] Cultural or religious beliefs may influence how these conversations develop and how the family reacts to the information.

Careful planning should occur before the family conference as family conferences can be very stressful to all participants. Curtis et al[36] describe the nurse's role before and after the family conference (Box 6-2). Box 6-3 describes how to facilitate a family conference. Encouraging the family to be active participants during the family conference increases their level of satisfaction and improves the quality of communication among providers and families.[37] Early and proactive multidisciplinary meetings help reduce confusing or conflicting messages and improve emotional and spiritual support to the family.[38]

Bereavement Care

The death of a patient can affect the family members and the staff in different ways. Previous coping skills, cultural and spiritual beliefs, and the circumstances surrounding the death influence the grief experience. A multidisciplinary team consisting of other nurses, social workers, chaplains, physicians, and volunteers can assist family members and staff with managing their grief. Critical care nurses should be familiar with the bereavement information and support services available within their institutions for both family members and themselves. Bereavement support includes providing family members with information regarding what to do after the death and who can be contacted at the hospital if questions arise.

Critical care staff should do everything possible to allow the family sufficient time to go through their leave-taking rituals. Bed shortages can make this difficult. However, not allowing family members the chance to say goodbye can complicate the grieving process. Survivors have reported

BOX 6-2 The Nurse's Role Before and After the Family Conference

Before the Conference

- Explain to the family about the patient's medical equipment and therapies.
- Tell the family what to expect during their conference with the health care team members.
- Talk with the family about their spiritual or religious needs, and take actions to address the unmet spiritual or religious needs.
- Talk with the family about specific cultural needs and take actions to address unmet cultural needs.
- Talk with the family about what the patient valued in life.
- Talk with the family about the patient's illness and treatment.
- Talk with the family about their feelings.
- Reminisce with the family about the patient.
- Tell the family it is all right to talk to and touch their loved one.
- Discuss with the family what the patient might have wanted if he/she were able to participate in the treatment decision-making process.
- Locate a private place or room for the family to talk among themselves.

After the Conference

- Talk with the family about how the conference went.
- Talk with any other health care team members who were present at the conference about how the conference went.
- Ask the family if they had any questions following the conference.
- Talk with the family about their feelings.
- Talk with the family about any disagreement among the family concerning the plan of care.
- Talk with the family about changes in the patient's plan of care as a result of the conference.
- Support the decisions the family made during the conference.
- Assure the family that the patient will be kept comfortable.
- Tell the family it is all right to talk to and touch their loved one.
- Locate a private place or room for the family to talk among themselves.

From Curtis JR, Patrick DL, Shannon SE, et al: The family conference as a focus to improve communication about end-of-life care in the intensive care unit: Opportunities for improvement. Crit Care Med 29(2 Suppl): N26–N33, 2001

that they remember unsatisfactory interactions with staff for a very long time. Sensitivity must be exercised during this potentially traumatic period.

▲ Emotional, Psychological, Social, and Spiritual Care

Patients nearing the end of their lives may experience emotional, psychological, social, and spiritual crises. Critical care nurses play a vital role in helping patients identify these concerns. An interdisciplinary team can attend to these potential feelings of loss, isolation, fear, and existential distress. At times, these crises can manifest as physical symptoms, such as pain, dyspnea, and fatigue. To assist patients at the end of life, assessment and interventions by social services, chaplaincy, psychologists, and volunteers are encouraged. One way to conduct a spiritual assessment is by using the FICA tool (see Box 6-4).[39]

BOX 6-3 Facilitating a Family Conference

Preparing for an ICU Family Conference About End-of-Life Care

- Review previous knowledge of the patient and/or family.
- Review previous knowledge of the family's attitudes and reactions.
- Review your knowledge of the disease—prognosis, treatment options.
- Examine your own personal feelings, attitudes, biases, and grieving.
- Plan the specifics of location and setting: a quiet, private place.
- Discuss with the family in advance about who will be present.

Holding an ICU Family Conference About End-of-Life Care

- Introduce everyone present.
- If appropriate, set the tone in a nonthreatening way: "This is a conversation we have with all families…."
- Discuss the goals of the specific conference.
- Find out what the family understands.
- Review what has happened and what is happening to the patient.
- Discuss prognosis frankly in a way that is meaningful to the family.
- Acknowledge uncertainty in the prognosis.
- Review the principle of substituted judgment: "What would the patient want?"
- Support the family's decision.
- Do not discourage all hope; consider redirecting hope toward a comfortable death with dignity if appropriate.
- Avoid temptation to give too much medical detail.
- Make it clear that withholding life-sustaining treatment is not withholding caring.
- Make explicit what care will be provided including symptom management, where the care will be delivered, and the family's access to the patient.
- If life-sustaining treatments will be withheld or withdrawn, discuss what the patient's death might be like.
- Use repetition to show that you understand what the patient or family is saying.
- Acknowledge strong emotions and use reflection to encourage patients or families to talk about these emotions.
- Tolerate silence.

Finishing an ICU Family Conference About End-of-Life Care

- Achieve common understanding of the disease and treatment issues
- Make a recommendation about treatment.
- Ask if there are any questions.
- Ensure basic follow-up plan, and make sure the family knows how to reach you for questions.

From Curtis JR, Patrick DL, Shannon SE, et al: The family conference as a focus to improve communication about end-of-life care in the intensive care unit: Opportunities for improvement. Crit Care Med 29(2 Suppl): N26–N33, 2001

▲ Facilitating Communication

Communication among the health care team, the patient, and family is the most important aspect of care giving in critical care, especially at the end of life. Through good communication, all people involved in the patient's care have a better understanding of how to care for the patient and family through this hospitalization. In addition, good

BOX 6-4 Spiritual Assessment

F	Faith, Belief, Meaning "Do you consider yourself spiritual or religious?" or "Do you have spiritual beliefs that help you cope with stress?" If the patient responds "no," the nurse might ask "What gives your life meaning?"
I	Importance and Influence "What importance does your faith or belief have in your life? Have your beliefs influenced you in how you handle stress? Do you have specific beliefs that might influence your health care decisions?"
C	Community "Are you a part of a spiritual or religious community? Is this of support to you and how? Is there a core group of people you really love or who are important to you?" Communities such as churches, temples, and mosques can serve as strong support systems for some patients.
A	Address/Action in Care "How should the health care provider address these issues in your health care?" Referral to chaplains, clergy, and other spiritual care providers.

Puchalski CM. Spirituality and the care of patients at the end-of-life: An essential component of care. Omega (Westport) 56(1):33–46, 2007

communication facilitates a healing environment that supports the physical and psychosocial needs of the patient, family, and providers. Three significant communication issues that surface frequently in end-of-life care include establishing treatment goals and priorities, ensuring interdisciplinary communication, and delivering bad news.

Establishing Treatment Goals and Priorities

Establishing goals and treatment priorities is essential to facilitating decision making with regard to care. The way in which options are presented can influence the decisions the patient and family make. For example, if a nurse asks the family, "Do you want the health care team to do everything for your loved one," it sets the family up for a "yes" answer. In the family's mind, the opposite of "everything" is "nothing." So, if the family answers "no" to the question, they may feel as if they are abandoning their loved one. In addition, it is important that nurses avoid ambiguous language and clearly define terms to ensure a shared knowledge. For example, the critical care nurse's understanding of "everything" commonly means intubation, CPR, defibrillation, and other aggressive procedures, whereas the family's understanding of "everything" may include only those interventions that might be helpful and calling a spiritual leader.

Emanuel et al[28] suggest a seven-step approach to help negotiate goals for care for patients.

1. Create the proper setting. Sit down, ensure privacy, and allow adequate time.
2. Determine what the patient and family know. Clarify the current situation and the context in which decisions about goals of care should be made. For example, if the family thinks that the renal failure is transient, yet the nurses believe the kidneys are beyond recovery, the determination of goals of care must be delayed until everyone has agreed about the clinical situation.
3. Explore what the patient and family are expecting or hoping for, such as asking the family what they hope will happen during this last hospitalization, or asking the family what outcomes they think will be attained while in the ICU. Understanding these hopes and expectations will assist the nurse in tailoring communication and reorienting families to what is or might be possible. Focus on what you will do to achieve those expectations and hopes. As appropriate, identify those things that you cannot do, perhaps because they will not help achieve the goals or because they are not possible.
4. Suggest realistic goals. To assist with decision making, share your knowledge about the patient's illness, its natural course, the experience of patients in similar circumstances, and the effects that contemporary health care may have. After sharing this information, suggest realistic goals (eg, comfort, peace, closure, loving care, withdrawal of interventions) and how they can be achieved. Work through unreasonable or unrealistic expectations.
5. Respond empathically to the emotions that may arise.
6. Make a plan and follow through with it.
7. Review and revise the goals and treatments as appropriate.

Ensuring Interdisciplinary Communication

A clear and a unified communication process is important to minimize confusion and distress among patients, families, and the health care team.[40] Critical care nurses should explore their understandings and beliefs about prognosis, goals, and plans of care and share these understandings with other health care providers to develop a unified message before discussing these issues with the families. An interdisciplinary approach in which all nurses are giving the same information consistently is ideal. Consensus among providers is an important step in deciding how treatment choices are presented.[40] Providing conflicting information creates confusion for everyone involved and may lead families to request nonbeneficial interventions. Being asked to provide care that is not helpful for the patient can create moral distress in nurses. Other disciplines such as social services, chaplaincy, and the bioethics committee can assist in clarifying issues and values among patients, families, and providers.

Delivering Bad or Serious News

Despite the best efforts of the health care team, patients may not respond positively to interventions. Keeping an honest and open line of communication is essential to preserve the trust of the patient and family. For this reason, it is important that critical care nurses practice strategies for delivering bad news. Such news can range from reporting that an antibiotic is not reducing an infection or a vasopressor medication is not maintaining an acceptable blood pressure to telling a family member that a patient has died. Because nurses are at the bedside 24 hours a day, communicating with families early that a patient is not doing well may help avoid a "surprise" announcement that the patient has died. Critical care nurses must remember

that family members are not health care professionals. The health care system requires that patients and their proxy decision makers be active in making decisions about health care treatment. However, at times, the health care team tries to place the responsibility of making a crucial decision, such as withdrawing mechanical ventilation, on the family because clinicians may fear a threat of legal retaliation and may try to abdicate responsibility for the decision. A better approach would be to help the family understand the benefits and drawbacks of continuing mechanical ventilation and making the decision jointly. Even if family members are health care professionals, they are family members first and health care professionals second, and they may make decisions based more on their relationship with their loved one than on sound medical or nursing decisions.

Simple strategies for communicating bad news may include phrases such as the following:

- "The blood pressure is worrisome given the amount of medication that we are giving your sister. We have reached the limit of how much we can safely give, and her blood pressure is not responding."
- "The ventilator alarm keeps ringing. It is letting me know that your father's lungs are becoming more resistant to mechanical ventilation. This is not a good sign."
- "I have noticed that your mother's kidneys have not been working well for the past couple of days. We have been trying to reverse her disease. However, now it seems that her heart and lungs are having difficulty as well."

Phrasing bad news in this way clearly indicates that the patient is not doing well but that the health care team is doing its best to help the patient. If discussions regarding withholding or withdrawing life-sustaining measures become necessary, the family may be more receptive because they see what the nurses are seeing.

Notifying the family members that the patient has died is a special case of delivering bad news. The manner that the nurse uses to deliver the bad news has a significant impact on how the family members remember the last moments of the patient's life. An excellent resource to help nurses learn more about how to communicate bad news to families is the book by Dr. Kenneth Iserson, *Grave Words: Notifying Survivors About Sudden, Unexpected Deaths*.[41] This book recommends that nurses divide death notification into four stages: prepare, inform, support, and afterwards.

1. In the preparation stage, the nurse gathers all the facts surrounding the death of the patient in order to answer any questions that might come up. Family members try and make sense of the death and request information.
2. In the inform stage, the nurse uses the person's name instead of "the patient" or "the deceased."
3. In the support stage, the nurse is available to the family members to answer any questions.
4. In the afterwards stage, the nurse provides information for the family, such as the names of funeral homes, medical examiner/coroner's office information, and who to contact at the hospital if the family has any questions.

Many more interventions and how to discuss these issues with the family are found in Dr. Iserson's book. Using clear, unambiguous language is important when delivering the bad news. Supporting the family members after the notification is essential. Becoming comfortable with the wording of the message (eg, by practicing phrases before they are needed) allows the nurse to focus on the family and their reaction to the message, instead of the message itself and how that message is delivered.

▲ Ethical Issues

Ethical issues affect how nurses work and provide care in the critical care environment. Ethical and legal issues are discussed in general terms in this chapter and in Chapter 8. Four ethical issues with special significance when talking about end-of-life care are the principle of double effect, moral distress, the withdrawal of life-sustaining technology, and organ and tissue donation.

Principle of Double Effect

The principle of double effect is an ethical principle that distinguishes between consequences a person intends and consequences that are unintended but foreseen and may be applicable in various situations where an action has two effects, one good and one bad.[42] The principle of double effect is most commonly applied to the administration of pain medications to patients who are dying. Opioids are used to relieve pain and other symptoms of suffering (ie, the good effect). However, opioids also may cause respiratory and cardiovascular depression that may, if left untreated, lead to death (ie, the bad effect). If the primary intention is to relieve pain and suffering with the recognition that the patient may die, it is morally and legally permissible to administer the opioid. If the primary intention is to cause death, it is not morally or legally permissible to administer the opioid.

The End-of-Life/Palliative Education Resource Center (EPERC) has created Fast Facts, which are quick step-by-step instructions about how to deal with a variety of end-of-life issues (see Table 6-1, p. 69).

Moral Distress

Moral distress occurs when nurses cannot turn moral choices into moral action.[43,44] This distress occurs when the nurse knows the proper course of action to take, but institutional or interpersonal constraints make it nearly impossible to pursue it.[43] For example, nurses tend to recognize when therapies are no longer beneficial or helpful to a patient sooner than family members. For families, it is difficult to realize that therapies may no longer be helpful. Moral distress can arise when the family's understanding about the utility of therapy differs from that of the nurse.

The AACN has identified moral distress as a key issue affecting the work environment. To produce a more healthy occupational environment, the AACN has developed a resource for nurses to use to address this issue.[45] This resource, *The Four A's to Moral Distress*, provides a framework for nurses to address their moral distress and find avenues for its

resolution. The four A's are ask, affirm, assess, and act, which facilitates change, thus creating a healthier nursing environment. Copies of this resource are available to AACN members or by contacting the AACN office (see Table 6-1, p. 69). In addition, hospital bioethics or ethics committees are available to staff to help work through situations in which moral distress is a factor.

Withholding or Withdrawing Life-Sustaining Measures

When it becomes clear to both the nurse and family that additional treatment will not be beneficial, the decision may be made to withdraw life-support methods. Mechanical ventilation is one intervention that is often withdrawn in such circumstances. Other life-sustaining measures that may be stopped include implantable cardiac defibrillators or pacemakers and hemodialysis.

When the decision is made to withdraw a therapy, special considerations are taken to reduce the suffering of the patient and to minimize the exhibition of distress to the family members. In the case of withdrawing mechanical ventilation, the decision is first made jointly with the family. In the case of extubation, opioids and sedatives are administered to the patient to reduce the pain and discomfort. In addition, the alarms to both the ventilator and the cardiac monitor are silenced to focus the family on the patient rather than the technology. Campbell[46] has published recommendations to successfully withdraw a mechanical ventilator. Additionally, many of the Fast Facts on the EPERC website relate to withdrawal of therapies, including mechanical ventilation and tube feeding (see Table 6-1, p. 69).

Organ and Tissue Donation

Organs and tissues can be procured after cardiac death or brain death. Federal law (Public Law 99-5-9; section 9318), Medicare, and the Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations) all require that (1) hospitals have written protocols regarding organ and tissue donation and (2) these institutions give the surviving family members the chance to authorize donation of their family member's tissues and organs.[47] When organ or tissue procurement is an issue, it is important that all family members are given the information they need to make a decision with which they are comfortable and that their grief is respected. In some cases, family members have initiated the conversation with their health care providers independently.

The local organ procurement organization (OPO) can provide additional resources. To find the OPO in your area, see Table 6-1 on page 69.

▲ Caring for the Nurse

Some deaths affect some people significantly. The death of a child, the death of a friend or colleague, mass casualties, or a particularly horrific, traumatic death can have a profound effect on the nurse. Colleagues must be supportive, exploring ways to support each other rather than dismissing the impact the death has on a colleague. According to Badger,[48] some self-care strategies to cope with the event include asking to be relieved from care responsibilities and to take a break; discussing the experience with a colleague, friend, or a nurse leader; taking a moment to reflect on one's feelings after the event; focusing on what was done right; and following basic health principles such as physical exercise, meditation, humor, music, eating properly, and obtaining adequate rest.

Working in a critical care unit is demanding physically, intellectually, and emotionally. Dealing with death on a consistent basis can take its toll on the nurse's well-being.[48] In the critical care setting, nurses caring for the patient may delay attending to their own grief because the demands of the unit and the needs of the family members may take precedence. It is important to be vigilant in recognizing signs and symptoms of unexpressed grief, burnout, and posttraumatic stress. Symptoms may include an increase in the number of sick days; indecision; difficulty with problem solving; isolation or withdrawal; behavioral outbursts; denial and shock; fixation on a single detail; immobilization; a feeling of extreme serenity; emotionally numbing responses, such as withdrawal, pessimism, or a diminished capacity for experiencing pleasure; and intrusive responses, such as unwanted or unpleasant recollections or flashbacks.[48] To maintain emotional health, it is important to seek assistance in dealing with these issues. Nurse leaders and human resources representatives can provide resources to assist with the stresses of working in critical care.

▲ Clinical Applicability Challenges

CASE STUDY

You are caring for Mr. J., a 42-year-old man who suffered a massive myocardial infarction. From the emergency department, he was admitted to the cardiac catheterization laboratory (CCL). He had occlusions in the left anterior descending artery and the left circumflex coronary artery that were opened via angioplasty and stent. However, in the CCL, the patient had persistent hypotension of systolic blood pressures in the 70s, cardiac index of 1.2, and pulmonary edema suggestive of cardiogenic shock. Dobutamine and an intra-aortic balloon pump were initiated in the CCL, and the patient was transferred to the ICU.

1. When the cardiologist arrives to discuss the events and prognosis with Mr. J.'s family, the cardiologist asks, "Do you want us to do everything if his heart stops beating?" The family looks puzzled at the question. As the nurse, what should you do?
2. On hospital day 7, the patient's blood pressure, cardiac index, and mentation have not improved, and the interdisciplinary team has scheduled a family conference. As the nurse, how will you prepare the family for the conference and how will you debrief with them after the conference?
3. The patient continues to decline, and on hospital day 10 the family decides to withdraw the intra-aortic balloon pump and dobutamine. It is 6:30 PM, and Mr. J.'s wife wants to go home to take a shower and eat dinner and come back at 9:00 PM, which is past the posted visiting hours. In addition, the change of shift will occur at 7:00 PM, and you will transfer care to the oncoming nurse. As the nurse, how will you handle her request?

PART 2

Professional Practice Issues in Critical Care

7

Ethical Issues in Critical Care Nursing

Connie M. Ulrich and Christine Grady

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Explain the way ethics assists nurses and other clinicians in resolving moral problems.
2. Name and describe ethical principles applicable to clinical ethics.
3. Describe steps in the process of ethical decision making.
4. Identify resources available to nurses to help resolve ethical dilemmas.
5. Discuss an example of an ethical issue confronted by critical care nurses in practice and how applying ethical principles may help to resolve it.

Critical care nurses face some of the most daunting ethical challenges in clinical practice. Nurses who work in intensive care and step-down units, operating rooms, emergency rooms, and other fast-paced, highly specialized settings must be able to recognize ethical issues they face in the daily care of patients and be prepared to address them in collaboration with patients, families, colleagues, administrators, and relevant others. Because of the precarious condition of critically ill patients, difficult ethical issues often consist of conflicts among members of the health care team surrounding the benefits and burdens of treatment. Some issues may include the following: How to alleviate suffering when the patient and/or family want to continue aggressive measures? How do nurses and other members of the health care team openly discuss end-of-life issues when often these discussions are perceived as giving up hope? How do nurses provide beneficent care in the context of finite resources? And, how can nurses feel good about the choices that are made in critical practice environments, reflecting their professional goals for optimal care? This chapter provides a foundational overview of nursing ethics, the application of ethical principles, and ethical reasoning skills in critical care to enable nurses to confidently advocate for the best interests of their patients.

▲ Differentiating Between Ethics and Morals

Ethics is the study of morality or standards of conduct[1] and a critical reflection or evaluation of moral choices that are made.[1,2] *Morals*, on the other hand, are commonly shared beliefs by members within a society about the "rightness" or "wrongness" of actions and behaviors that include the "shoulds," "should nots," "oughts," and "ought nots" and are usually learned through family systems as well as religious and cultural traditions.[1,2]

Nurses often struggle with ethical issues because they are strong patient advocates and develop intimate human relationships when caring for critically ill patients. These are especially challenging when there is limited consensus about what the *ethically right or wrong* approach may be in any given situation. For example, what "ought" the nurse do if a family member asks that the patient with a poor prognosis not be told about a cancer diagnosis? Should the truth always be told in these kinds of situations? Ulrich et al[3] noted that an *ethical problem* can occur in any clinical or research situation when there are salient questions about the *rightness* or *wrongness*

of particular aspects of the care and treatment of patients. Applying ethical principles and considerations helps nurses to articulate sound reasons for ethical positions, clarify the ethical principles that might be in conflict, and address the issues they encounter.

▲ Ethical Principles

Ethical principles serve as general guidelines in health care decision making. Principles, such as autonomy, beneficence, nonmaleficence, veracity, fidelity, and justice, can guide conduct and provide a basis for ethical reasoning. These principles are not, however, absolute and can conflict with one another. Because critical care nurses address ethically laden patient care problems daily, understanding and applying these principles can assist them in determining an appropriate course of care for their patients.

Autonomy

Autonomy is the right to self-determination or the right to make independent decisions about one's own body or actions free from interference or coercion from others.[1] It is a central value in the Western world and reflects personal values, goals, and convictions for self-governance.

Critical care nurses are often recognized for their advocacy roles and their willingness to speak up for their patients. In fact, the patient care population that they care for seems to demand it. These patients range from those who are ventilator dependent for long periods of time to patients whose families must make immediate decisions pertaining to end-of-life care. It is not unusual for nurses to be "caught in the middle"[4] as they struggle to promote autonomous decision making of their patients, including ensuring that patients have given their informed consent and have opportunities to plan advance directives. In a study investigating the everyday ethical issues that nurses face, the authors found that nurses (including those in acute care settings) reported frequently encountering issues associated with protecting patients' rights and informed consent to treatment procedures.[3]

Informed consent respects autonomy by providing patients and families with the pertinent information they need to make an ethically sound decision. In essence, "respect for autonomy obligates professionals in health care and research involving human subjects to disclose information, to probe for and ensure understanding and voluntariness, and to foster adequate decision making."[1] Conflict can occur when health care professionals have views about care in the patient's best interests that do not match the patient's autonomous wishes. Critical care nurses can use the "Nursing Interventions Classification" (NIC)[5] system for guidance when developing activities to facilitate autonomous decision making in the critical care setting (Box 7-1).

BOX 7-1 NURSING INTERVENTIONS CLASSIFICATION

Supporting Autonomous Decision Making

Definition

Providing information and support for a patient who is making a decision regarding health care.

Activities

- Determine whether there are differences between the patient's view of his or her own condition and the view of health care providers.
- Assist patient to clarify values and expectations that may assist in making critical life choices.
- Inform patient of alternative views or solutions in a clear and supportive manner.
- Help patient identify the advantages and disadvantages of each alternative.
- Establish communication with patient early in admission.
- Facilitate patient's articulation of goals for care.
- Obtain informed consent, when appropriate.
- Facilitate collaborative decision making.
- Be familiar with institution's policies and procedures.
- Respect patient's right to receive or not to receive information.
- Provide information requested by patient.
- Help patient explain decision to others, as needed.
- Serve as a liaison between patient and family.
- Serve as a liaison between patient and other health care providers.
- Use interactive computer software or Web-based decision aides as an adjunct to professional support.
- Refer to legal aid, as appropriate.
- Refer to support groups, as appropriate.

From Bulechek GM, et al: Nursing Interventions Classification (NIC), 5th ed. St. Louis, MO: Mosby, 2008, p 247, with permission.

Beneficence

Nurses are ethically, legally, and professionally obligated to avoid harm and promote benefit for their patients; the American Nurses Association (ANA)[6] notes that nurses' primary commitment is to the "health, welfare, and safety of the client." This includes acts of caring and compassion as well as protection from harm. The ethical principle of beneficence is the *sine qua non* for the nursing profession, guiding all nurses in their daily interactions and activities with patients. The principle of beneficence presupposes that any harm patients are exposed to is justified by the potential benefits. Beauchamp and Childress outline three obligations of beneficence, including preventing harm to others, promoting and acting for the good of others, and eliminating untoward or harmful circumstances.[1]

In the critical care setting, the ethical principle of beneficence often conflicts with other ethical principles, including that of autonomy. Patients and their families in some cases may be more comfortable deferring treatment decisions to their health care provider, especially since the crisis and chaotic nature of intensive care may make it difficult to make decisions. The critical care nurse and physician often speak and act on behalf of a patient who, for example, is neurologically or cognitively impaired. Without knowledge of the patient's autonomous wishes, the nurse acts to promote the patient's best medical interests. Intentionally acting on behalf of another without the other's explicit consent may be considered paternalistic. "Paternalism is commonly framed in terms of the conflict between the primary obligation of physicians, nurses, and other provider–practitioners to abide by the principle of beneficence in their practice and the

assertion of the rights of persons who are receiving services to make autonomous decisions about their lives."[7] Paternalism can be acceptable for patients in the critical care setting when there are benefits to the patient that clearly outweigh the paternalistic action. A common example is helping the patient turn, breathe deeply, cough, and ambulate following an extensive surgical procedure when the patient is in pain, is sleep deprived, or wants to be left alone.

Nonmaleficence

The ethical principle of nonmaleficence obligates us to avoid causing undue pain and suffering or harm to another. This principle is often discussed along with the principle of beneficence because the two are intricately linked. Nonmaleficence is a *prima facie* duty for the nurse, meaning that it is morally binding unless there are other conflicting moral obligations that outweigh its primacy.[1,2,8] Nonmaleficence obligates nurses to avoid harm of not only a physical or bodily nature but also psychological or emotional distress; in some cases, harm can be caused by a breach of professional standards of care. Nurses are constantly balancing the benefits and harms of decisions, treatments, and procedures associated with critically ill patients. Indeed, administration of medications meant to improve a patient's condition, including steroids, morphine, amphotericin B, heparin, and other pharmacological agents, may also have serious adverse effects. Nurses must constantly apply the principle of nonmaleficence in critical care where the quality of life of patients is an important consideration.

Veracity

Nurses remain one of the most trusted professional groups in the United States,[9] and therefore, veracity or truth-telling is foundational to the nurse–patient relationship. The American Nurses Association Code for Nurses states: "Truth-telling and the process of reaching informed choice underlie the exercise of self-determination, which is basic to respect for persons…. Clients have the moral right to determine what will be done with their own person; to be given accurate information, and all the information necessary for making informed judgments."[6]

Much current research suggests that patients want to be told the truth about their diagnosis and need full disclosure of the potential risks and benefits of specific treatments and alternatives to make an informed decision related to their care.[10–12] Sometimes, information can be presented in ways that are misleading or biased even though accurate; this can create conflict and uneasiness. Truth-telling in the clinical setting preserves autonomy and trust and maintains sound communication patterns with patients.

Fidelity

Fidelity is the duty to be faithful to one's patients by keeping promises and fulfilling contracts and commitments. It is the moral covenant between individuals in a relationship.[1] Nurses are involved in many aspects of a patient's immediate care: physical, emotional, spiritual, and psychological. For this reason, they often develop close relationships with patients and their families and are called upon to be forthright and to keep their promises to inform, update, and communicate unforeseen circumstances that might occur in the nurse–patient–family relationship. However, there are times when keeping promises can be problematic, for example, in the following case of a husband asking the nurse to keep a secret from his ill wife. The husband of a 50-year-old woman who is suffering from sudden onset bacterial pneumonia with severe hypoxia, respiratory distress, and receiving mechanical ventilation in the intensive care unit (ICU) tells the primary nurse that he is HIV positive and has known his status for the past year. He has been afraid to tell his wife and now wonders if she also has the disease. Should the nurse agree to keep his secret and withhold the information from the patient until her husband can work through his emotions and the best way to discuss the issue as he is terrified that it will destroy their relationship? Does the nurse have obligations based on an implicit promise to the patient to make sure that her current illness is not HIV related? How should the nurse handle it after the patient is weaned from the ventilator and asks what is wrong with her and why she went into respiratory distress?

Confidentiality is an aspect of fidelity that is an essential component of trusting relationships. Patients have the right to know who has access to their personal health care information and that it will be kept confidential and that there are safeguards in place for privacy, security, and authorized access.[13] A commitment to maintain confidentiality in patient–provider relationships is part of every professional health care code of ethics, but it is not absolute. In certain circumstances, confidentiality can be broken. This can occur if there is imminent danger to the patient or other third party. Additionally, disclosure is required for public health reporting purposes related to certain infectious diseases or abusive situations.[14]

Justice

Justice is an important ethical principle in critical care settings and is usually defined in terms of fairness or that which is due to others. In health care, it is often discussed in terms of distributive justice or how one allocates scarce or finite resources. The most recent national health care debate has brought to light many ethical concerns associated with the escalating costs of U.S. health care as well as the quality of care that is provided to the public and the cost-effectiveness and cost-benefit analysis of current standard therapies. Questions of distributive justice often arise in intensive and emergency settings because of the need to prioritize care; this happens on a daily basis. ICU care is expensive and unfortunately, about one of five Americans die in ICUs each year with the elderly accounting for up to half of all ICU admissions.[15] Not only does distributive justice concern the appropriate allocation of technology and aggressive measures but also the unit and nursing-based resources needed to provide that care.

Hospital understaffing has emerged as a major factor in the care of critically ill patients. Aiken et al[16] at the University of Pennsylvania reported an association between nurse staffing levels and patient mortality and failure to rescue (mortality following complications) in adult surgical patients cared for in Pennsylvania hospitals. In this research, nurses were found

to be important surveillance and safety measures within hospitals because higher patient-to-nurse ratios negatively impacted outcomes of care. Staffing is an ethical concern and an indicator of distributive justice because it directly affects the beneficent care of patients. Staffing inadequacies have been found to be a major source of ethics-related stress that ultimately impacts job satisfaction and retention of nurses.[3] Critical care nurse managers and staff nurses are constantly allocating resources as they weigh the patient care needs required on their units, the number of admissions and available beds, and the ability of staff to meet those needs. Staffing shortages sometimes require utilizing personnel who are not readily familiar with a particular unit or hospital, and this could include novice nurses or those designated as float staff. Critical care unit-based orientation and other special training sessions are imperative to address standards of practice, policies, procedures, and additional technological aspects of caring for critically injured patients.

Withholding and Withdrawing Treatment

Determining when to withhold or withdraw treatment for critically ill or injured patients is stressful for all of those involved. This is true not only for the families who surrender their hope for continued survival but also for those health care providers who have been caring for a patient for an extended period of time. Withholding care may be at the request of the patient or family and is sometimes a consideration for those patients deemed critically or irreversibly ill and for whom there is no foreseeable recovery regardless of the treatment offered. Withdrawing life supportive treatments (eg, ventilator and respiratory support, nutrition, and hydration) once they have been started is also sometimes ethically appropriate, but generally creates more controversy and distress for physicians and nurses. Ethical and legal advice is often sought, and professional guidelines (eg, Society of Critical Care Medicine) and in-house hospital and ethics committees' policies and procedures can assist both physicians and nurses when making these determinations. Brock notes that "any set of circumstances that would morally justify not starting life-sustaining treatment would justify stopping it as well."[17]

Open communication is imperative in critical care as "the majority of deaths in the intensive care setting involve withholding or withdrawing multiple life-sustaining therapies."[18] Families are often confronted with the difficult task of deciphering medical information about the prognosis of their loved one. Some patients and their families prefer a shared decision-making model or one in which decisions are made with clinicians; others prefer recommendations by the physician.[19] Critical care nurses can help prepare families for difficult discussions about withdrawing or withholding life supportive treatments by facilitating care conferences to address cultural, spiritual, and value-based needs of the patient. When a patient cannot speak for himself, it is important to talk with families about the wishes of their loved one and to present information about the patient's plan of care in a timely fashion with up-to-date, clear, and honest expectations about the situation at hand.

Medical Futility

Medical futility has been defined in various ways and is frequently discussed in critical care situations. When the health care team believes that an intervention has no prospect of helping the patient, they may describe the intervention as futile. This can create much conflict and turmoil if family members hold out hope of recovery and seek to pursue all aggressive measures. Medical futility includes both a qualitative (ie, value judgment) and a quantitative aspect.[20] Schneiderman et al[20] note that "when physicians conclude (either through personal experience, experiences shared with colleagues, or consideration of reported empirical data) that in the last 100 cases, a medical treatment has been useless, they should regard that treatment as futile. Furthermore, the Hastings Center notes that physicians have no obligation to comply with a patient or surrogate's request for treatment if that treatment is deemed to provide no physiological benefit.[21]

▲ Ethics as a Foundation for Nursing Practice

Nursing is guided by historical precepts and ethical norms that form the basis of nursing's contract with society. This fiduciary relationship is based on trust. In fact, in public polls about health care professionals, nurses consistently rank highly on issues of trust and ethical standards. Nursing's primary commitment is to the patient and to ensure the delivery of safe, quality care; however, there is also a collective moral responsibility to serve the good of society. All professional groups define themselves by their body of scholarly knowledge, degree of self-regulation, and the professional code of ethics that underlie their beliefs, practices, and norms.[22,23]

Ethics is important in understanding how the philosophy of the profession of nursing as well as its values, duties, and obligations to patient care remain constant within a society with a changing demography (ie, chronically ill and aging society) and rising health care costs. Ongoing evaluations of the professional standards of nursing and specifically, critical care nursing, are necessary as the profession continues to evolve and develop new knowledge that will address advancing technology and its use in the care of the critically ill.

▲ Nursing Code of Ethics

The American Nurses Association (ANA) *Code of Ethics for Nurses* was first adopted in 1950 but has gone through several revisions to reflect the ethical, professional, and societal concerns of the day.[24] The most recent *Code of Ethics for Nurses with Interpretive Statements*[6] (2001) is a document that embodies the moral values of the profession. It represents not only the expectations for ethical conduct in clinical practice but also the duty of the nurse to protect his or her own integrity within the health care environment. The Code symbolizes a collective agreement among its members for societal good and serves as a guideline for nurses to follow in ethical decision making related to patient, family, and community care. There may be times when the law and ethics conflict; however, every discipline, including nursing, is bound to a code of ethics that represents the moral basis for its professional standards of practice and helps to ensure the public's trust with their care. The nine provisions of the code are outlined in Box 7-2.

BOX 7-2 ANA Code of Ethics for Nurses

1. The nurse, in all professional relationships, practices with compassion and respect for the inherent dignity, worth, and uniqueness of every individual, unrestricted by considerations of social or economic status, personal attributes, or the nature of health problems.
2. The nurse's primary commitment is to the patient, whether an individual, family, group, or community.
3. The nurse promotes, advocates for, and strives to protect the health safety, and rights of the patient.
4. The nurse is responsible and accountable for individual nursing practice and determines the appropriate delegation of tasks consistent with the nurse's obligation to provide optimum patient care.
5. The nurse owes the same duties to self as to others, including the responsibility to preserve integrity and safety, to maintain competence, and to continue personal and professional growth.
6. The nurse participates in establishing, maintaining, and improving health care environments and conditions of employment conducive to the provision of quality health care and consistent with the values of the profession through individual and collective action.
7. The nurse participates in the advancement of the profession through contributions to practice, education, administration, and knowledge development.
8. The nurse collaborates with other health professionals and the public in promoting community, national, and international efforts to meet health needs.
9. The profession of nursing, as represented by associations and other members, is responsible for articulating nursing values, for maintaining the integrity of the profession and its practice, and for shaping social policy.

▲ Ethical Issues

An ethical issue or problem can occur in any clinical situation where there are concerns about what might be "morally right or wrong" in the care of the critically ill patient and his or her family. There are many ethical issues in critical care. These can include but are not limited to end-of-life treatment decisions, truth-telling, transplantation, do not resuscitate (DNR), informed consent, clinical research with critically ill patients, assisted suicide, the use of aggressive measures, conflict among colleagues, and resource allocation. Ulrich et al[3] reported that these everyday ethical issues occur frequently and often reflect providers' concerns about protecting the rights of their patients and informed consent to treatment procedures as well as issues of advance care planning and surrogate decision-making.

Although nurses interact daily with patients and their families, some evidence suggests that they are hesitant to speak about the ethical issues they encounter for fear of retaliation.[25] Sulmasy et al[26] stress that nurses can be included in sensitive conversations (eg, DNR) because they are both confident and capable. They are in a key position to listen, explain, and comfort patients and address unmet needs. Health care organizations should develop policies and procedures that provide support to nurses to seek consultation for ethical concerns. Ethics education, in professional training and continuing education, is also essential. Interdisciplinary team work is also needed as the complex needs of intensive care patients require all members of the health care team, including nurses to be part of the discussion.

Moral Distress

Moral distress has become a frequent topic of discussion in the literature and remains a common concern among health care providers, including nurses and physicians. This phenomenon was originally defined by Andrew Jameton[27] more than 20 years ago as the distress that one feels when one knows the ethically correct action to take but is precluded from doing so. Constraints can include those at the individual, societal, or organizational level and consist of patient demands, limited resources, or circumstances within the workplace where one feels powerless because of authoritative structures. Bell and Breslin[28] further add that acting against one's personal and professional values creates moral distress. Physical and emotional symptoms, such as anger, anxiety, frustration, powerlessness and fatigue, are common outcomes associated with moral distress. Additionally, studies have shown that moral distress is linked to nurses' intent to leave their positions.[29,30]

Strategies to minimize moral distress and to create a healthy workplace have been outlined by the American Association of Critical Care Nurses (AACN) and include the four As: Ask, Affirm, Assess, and Act[31] (see Fig. 7-1). Ulrich and Hamric[32] also urge nurses to foster an open communication plan with other health care team members, seek ethics consultation services as needed, uphold a zero tolerance policy for retaliation if members speak out, and continually assess and dialogue about the needs of complex patients.

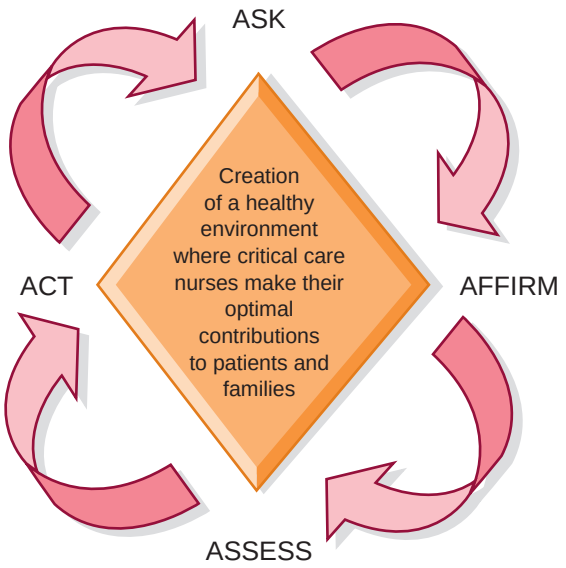

FIGURE 7-1 ▲ Framework to address moral distress. (From American Association of Critical-Care Nurses: Position statement: Moral distress. Aliso Viejo, California, July 8, 2004, AACN).

▲ Ethical Decision Making

Several models exist to assist clinicians in the ethical decision-making process. A pragmatic case method approach is useful because it allows all members of the health care team to focus on a specific clinical case, address the ethical issues that may be morally problematic, and develop a plan of action.

The Case Method Approach

Steps in the case method of ethical decision making are listed in Box 7-3. These steps are similar to the nursing process.

Step One

Assessment is an initial task of any medical or nursing clinician and applies to the ethical decision-making process as well. Determining or identifying the ethical problem is the most critical part of the assessment. One needs to understand the patient's medical condition/problem, as well as the prognosis, potential sequelae, and treatment goals, and any additional contextual factors that may influence the ethical decision making process, including family and organizational systems. It is always important to gather sociodemographic information, such as age, gender, education, setting of care, and other factors (eg, religion, culture, language), that might influence decisions or communication. For example, assessment questions that might be helpful include the following: Is the patient legally competent and capable of making a decision associated with his or her care? What are the preferences of the patient and family? Are there advance directives that outline the patient's wishes for treatment? Are there competing interests that need further discussion such as conflict amongst family members, and/or conflict between the patient, family members, and clinicians? Finally, are institutional factors contributing to the ethical problems presented by the clinical case? The usual goals in the critical care setting, for example, trend toward aggressive treatment rather than palliation or support.

Step Two

Explicating and ranking the relevant ethical issues or moral considerations associated with a particular case of interest is the second step in the ethical decision-making process. Clinicians can use relevant literature, institutional policies, professional groups, commissions, their past clinical experiences, or other resources to seek out information on cases that pose similar ethical challenges. This can help illuminate how to resolve the specific problem or if there are different morally acceptable options that are available to the clinician.

BOX 7-3 Steps in Ethical Decision Making

1. Assessment of the problem
2. Define the ethical issues
3. Delineate the goals; decision making and implement plan of action
4. Evaluation of the process and modify action as needed.

Adapted from Spencer E: A case method for consideration of moral problems. In: Fletcher JC, Spencer EM, Lombardo PA (eds): Fletcher's Introduction to Clinical Ethics, 3rd ed. Hagerstown, MD: University Publishing Group, 2005.

Step Three

Step three focuses on goal setting, decision making, and implementation. During this step, all personnel involved in the decision-making process are encouraged to clarify their own values and moral convictions so that the needs of the patient can be discussed forthrightly. Spencer notes that "moral problem-solving and planning for the care of the patient go hand in hand."[33] Weighing the benefits and burdens of each option as well as examining the ethical principles and underlying theories in regard to the case at hand can assist clinicians in making a decision. For instance, in the case study presented in the Clinical Applicability Challenges at the end of this chapter about Ms. X., is the autonomy of the patient being promoted by allowing her to die? How do we reconcile the moral distress it creates for the staff and the perception that it violates the norms of professional behavior by the resident in the case? Sometimes, ethics consultation, referral to an ethics committee, or other types of assistance are needed to provide an objective outside voice and to facilitate open dialogue among clinicians or family members when discussions appear to be at an impasse.

Step Four

Evaluation of an ethical decision allows all parties to reflect on the decision at hand and address any missed opportunities. Some questions to consider during this step include: Was the ethical problem adequately addressed? Were the goals of treatment met? If not, why? Were all parties satisfied with the outcome? Is there an alternative option that could be used if there is a need to rethink the plan of care? What factors contributed to a positive resolution of the case? What factors led to a less than desirable outcome? What have I/we learned from this process? Finally, what, if any, educational changes can be made in the clinical environment to resolve similar ethical challenges in the future?

▲ Strategies for Promoting Ethical Decision Making

The highly charged environment in which critical care nurses work calls for strategies to assist them with the increasing demands they encounter. Two strategies for developing an environment that is supportive of ethical concerns are briefly discussed here: institutional ethics committees and ethics rounds and conferences.

Institutional Ethics Committees

Many health care facilities have institutional ethics committees (IEC) to help resolve ethical conflicts in patient care as well as address ethics-related questions that might arise in clinical practice.[34–36] Ethics committees usually involve a diverse group of individuals, including physicians, nurses, social workers, pastoral care counselors, legal counsel, administrators, and community members. IECs provide ethics consultation and can assist practitioners by providing an external voice on contentious ethical issues that may seem irresolvable and facilitate education for all members of the health care team. Recommendations by the IEC can be either binding

or nonbinding, depending on the individual committee. However, an IEC can offer support to practitioners, patients, and families and improve their satisfaction with the delivery of care. Some institutions provide an ethics consultation service by a subset of the IEC or an independent consultant.

Ethics Rounds and Conferences

Ethics rounds may be an important and useful aspect of patient care, as they provide an opportunity to discuss a particular patient's health care needs in-depth and identify clinical, social, or ethical problems early in the course of care. Importantly, ethics rounds allow providers to express their views on issues of concern as well as clarify the most salient values and preferences at stake. This can include questions on DNR status, palliative care versus curative care, advance directives, conflicts associated with family systems, disagreements among health care providers about future goals of care, organ donation, cultural and religious differences, and many others. Nurses can make ethics rounds a regular part of their unit's activities by establishing a set time to focus on a specific case that raised ethical concerns or was particularly distressing for the staff. Interdisciplinary ethics rounds also provides an opportunity to build trusting work relationships with multidisciplinary care providers and develop a team approach to addressing value conflicts that arise in the unit. An individual patient ethics conference can be useful in resolving complex cases and opening a dialogue with patients, families, and the nursing staff or a multidisciplinary group.

▲ Clinical Applicability Challenges

CASE STUDY

Ms. X. is a 72-year-old female who has been on dialysis for the past 4 years and has a history of hyperlipidemia and chronic obstructive pulmonary disease. Ms. X. presents with an aortic aneurysm and seeks surgical repair for her condition. The patient survives the surgery and receives standard postoperative nursing care interventions for an aortic aneurysm repair. This includes neurological checks and a 10-minute neurological assessment every hour, mechanical ventilator support measures, hypovolemic shock and hemodynamic prevention activities, and monitoring mean arterial pressure. She also remains on continuous dialysis, and her postoperative course is relatively stable.

On postoperative day 5, Ms. X. remains in serious condition but is doing remarkably well considering her diagnosis and surgical repair. However, she writes a note to the nurse that reads: "I want to die." The nurse reassures the patient that she is doing very well for her postoperative course, and no further action was taken at that point regarding the patient's note. On postoperative day 6, the patient is extubated and on oxygen via nasal cannula as well as some vasoactive medications. Within an hour, Ms. X. begins to belly breathe and is having some respiratory distress. She is given 40% oxygen via face mask. Oxygen saturation levels remain at 94% and greater and she stabilizes with oxygen by nasal cannula at 6 L/min. Regarding long-standing back pain, the patient indicates, however, that "the pain is unbearable," and again states that "I want to go." She was offered an epidural at the bedside for the back pain, but refused the epidural and simply stated that she was "done and does not want to fight anymore." Her family agreed with her request that she should be allowed to die and to stop all interventions/treatments. The attending physician does not agree and wants postoperative care to continue. An ethics, legal, and psychological consult is called by the nurse. Ms. X., however, refuses to see the psychologist and asks that he not come into her room as she is completely lucid and "wants to die." The resident argues, "This is homicide" and wants no part of Ms. X.'s care. The nurse thinks that the patient's wishes should be taken seriously, consistent with respect for her autonomy, but that careful steps should be taken to assess the basis for her words and what she understands and means by them.

1. How should we evaluate a patient's request that reverses her previous preferences for treatment?
2. What factors might have a bearing on the patient's plan of care?
3. What possible learning needs would you anticipate for all those involved in this case?
4. What interventions should be initiated to address the concerns of the patient?
5. How would you determine the best course of action for this patient's plan of care?

Acknowledgment

8 Legal Issues in Critical Care Nursing

Nayna C. Philipsen and Patricia C. McMullen

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Describe major areas of the law that affect critical care nursing practice.
2. Define the four elements of malpractice (professional negligence).
3. Delineate allegations commonly made against critical care nurses.
4. Explain types of vicarious liability.
5. Apply knowledge of informed consent and advance directives to critical care patient situations.

Because society in the United States seems to be more litigious than ever, legal issues involving critical care are of increasing concern. The number of malpractice suits that name or involve nurses is increasing. Issues from refusal and termination of treatment to the spiraling costs of the malpractice system are widely discussed. Legislators have become involved by introducing and/or enacting living will statutes and bills designed to address the malpractice crisis in their jurisdictions.

This chapter begins with an overview of the major areas of law of governmental organizations and major areas of law that impact the practice of nursing. Next, the legal principles of negligence, vicarious liability, and patient autonomy are reviewed, with pertinent critical care case examples. The chapter then proceeds to identify and address selected current legal issues that are most applicable to the practice of critical care nursing.

▲ An Overview of Governmental Organization and Major Areas of the Law

The United States Constitution provides the basic principles and guiding policy for all law in the land. Three branches of government were established to create a "balance of powers" to minimize the risk of abuse of the law by those in power. The structure of each state government is similar to the federal structure. The *Legislative Branch*, composed of representatives of the people, creates and modifies *statutes*. The *Executive Branch* is headed by the president or a state governor and consists of federal and state agencies that write and enforce *regulations* that give the people *notice* of what they need to do to comply with the statutes. The *Judicial Branch* consists of the federal and state court systems, which interpret statutes and regulations and examine constitutionality when disputes arise. The courts generate *case law*, which becomes *precedent or common law*, providing guidance for future interpretation of the law.

A legal dispute is first heard by a *trial court*, which examines the evidence and makes a decision based on the facts of the case. Some disputes then go on up to higher courts, called *appeals courts*. These courts make decisions about alleged legal and procedural mistakes by the judges or lawyers in the trial courts. They do not retry the initial dispute.

Three types of law affect the practice of critical care nurses. These are administrative law, criminal law, and civil law.

Administrative Law

Administrative law includes state and federal statutes, their accompanying regulations, and the regulatory agencies that enforce those laws. Nurses deal with state agencies and state laws and regulations when they apply for a nursing license to enter the profession. Every state legislature has enacted a Nurse Practice Act (NPA). The NPA defines the practice of nursing, requires nursing licensure, establishes standards for nursing schools, and delegates enforcement powers to a state agency, usually the State Board of Nursing. This agency develops regulations that give notice to the public and to nurses of how the NPA will be interpreted and implemented in that state. The Boards of Nursing work together to develop common standards and address common challenges through the National Council of State Boards of Nursing, Inc. (NCSBN), where their representatives conduct research, pool resources, and publish model practice acts and position statements. The NCSBN is also responsible for the development and integrity of the national licensure examination known as the NCLEX.

Practicing nurses are expected to know the provisions of the NPA and any regulations dealing with the practice of nursing in every state where they practice. If a nurse is unfamiliar with the NPA, it is important that he or she contact

the State Board of Nursing to obtain access to and review this act. State boards of nursing increasingly place their NPA and regulations on a Web site. The NCSBN Web site provides links to the Web sites of all of the boards of nursing, as well as other useful information related to legal aspects of nursing licensure and practice.[1]

Why do state governments regulate nursing practice? The United States Constitution charges the states with protecting the health, safety, and well-being of their citizens. For nurses, this begins with nursing licensure, a process in which the new nurse applicant must show that he or she can enter practice as a safe practitioner by completing an approved nursing education program, passing a national examination (the NCLEX), and demonstrating good moral character. While public protection during initial licensure is proactive, assurance of continuing competency after licensure is often reactive. As long as they continue to pay their renewal fees, nurses may be required to practice a certain number of hours per year or attend approved continuing education seminars, but they typically do not have to return to nursing school or face reexamination to renew a license. Instead, the boards identify loss of competency by responding to complaints.

Complaints, whether to the Board of Nursing or to the courts in the form of a lawsuit, are a special concern of critical care nurses. Because their patients are not as stable as patients in most other areas of health care, they are at high risk for an undesired outcome. These complaints can come from many sources, such as patients, their families, other health care workers, or the nurse's employer. Even a revengeful ex-spouse of a nurse can allege any of the violations listed in the NPA.

For example, if a patient feels that he or she has received incompetent or unethical nursing care, he or she may contact the State Board of Nursing and file a complaint against the nurse or nurses involved in the care. The state board then determines whether the complaint, if true, would violate the NPA and possibly result in limits on or loss of the nurse's license to practice. If so, the board conducts an investigation to determine whether the claim has merit.

Under the Fifth Amendment of the U.S. Constitution, all citizens are afforded the right to *due process* before the state or federal government can take any property. Case law indicates that a nurse's license is a form of property because it helps a person earn a living. Therefore, due process rights are attached to a nursing license. This means that the State Board of Nursing must meet certain procedural requirements before it can discipline by taking away or placing conditions or limitations on a nursing license. First, the nurse is entitled to *notice* that someone has filed a claim against his or her license. The nurse is also entitled to a hearing that follows the procedures outlined in the NPA, in order to answer and defend alleged violations.

In most states, the final defense against charges on a nurse's license takes the form of a hearing before the State Board of Nursing, whose members typically include nurses. To be sure that the hearing is fair, the nurse should attend the hearing and should arrange to have representation at the hearing by an attorney whose practice includes nursing licensure. The American Association of Nurse Attorneys (TAANA) is an excellent source of attorneys with this special expertise. At a hearing, the board members listen to the case against the nurse's license, which is presented by an attorney or other representative for the state. Witnesses who have knowledge of facts surrounding the complaint will testify and introduce evidence. These witnesses may include board staff members who investigated the complaint or who acquired the related medical records and other documents, the person who filed the complaint, any witnesses to the incident, and people who supervised the nurse. Then the nurse, either directly or through legal counsel, can question the board's witnesses and can introduce evidence or testimony to refute the allegations in the complaint. Based on the presentations by the state and by the nurse, the State Board of Nursing makes a determination as to whether the nurse violated the NPA and what, if any, discipline is warranted to protect the public. Typically, the decision of the State Board of Nursing is final, and unless there were violations of the nurse's due process rights, a court upholds the state board's findings if either side appeals.

Although the nurse's right of due process cannot be abridged, state boards of nursing have the right to *immediately* suspend a nurse's license for acts that the Board deems so dangerous to the public welfare that the complaint, if true, would constitute an emergency. When the state immediately suspends a license, the nurse must stop any nursing practice immediately. The NPA provides the nurse with the right to an accelerated hearing, within a short period of time from the date of the suspension.

HIPAA

A federal agency that has a major impact on nursing practice is the U.S. Department of Health and Human Services (HHS), which generates regulations and enforces federal statutes such as the Health Insurance Portability and Accountability Act (HIPAA), Medicare, and Medicaid, including the rules for reimbursement to providers and health care institutions. Critical care nurses are familiar with HIPAA, a statute enacted by Congress in response to concerns about the security of electronic health records. The Title II HIPAA Privacy Rule in particular has raised the awareness of critical care nurses about their need to verify who can have access to patient information before sharing it. HIPAA made it clear that patients have a great deal of control over their health information, and in many circumstances the right to decide with whom the nurse can share that information. HIPAA also provides guidelines for communicating this right to the patient. The exceptions include sharing information in the record needed for care with other care givers, information needed for billing with payers, information that is de-identified (personal and all possibly identifying information are removed), and information needed for the general welfare, such as public health data and the regulation of health care facilities and professionals, including HIPAA enforcement. HIPAA's security rules also impact nursing practice. As the use of electronic health records increases, nurses must comply with regulations designed to protect electronic information, including the use of passwords and biometric identification and the location of computer screens to protect them from unauthorized eyes. Violation of relevant federal regulations and standards can have serious consequences, including the loss of federal reimbursement for care.

▲ Employment Law

Workplace statutes and their supporting regulations form another area of administrative law that clearly impacts nursing practice. A full discussion of these is beyond the scope of this chapter, but critical care nurses should be aware that a number of statutes affect their practice, their conditions of employment, their right to a safe workplace, and the responsibilities of health care supervisors and employers. Each statute is enforced by the federal or state government agency that is also responsible for drafting and revising such regulations. For example, the Fair Labor Standards Act, the Occupational Health and Safety Act, and the Family Medical Leave Act are enforced by the U.S. Department of Labor. The U.S. Equal Employment Opportunity Commission enforces Title VII of the Civil Rights Act of 1964 with Amendments, including the Lilly Ledbetter Fair Pay Act of 2009. The National Labor Relations Board is a federal agency formed to enforce the National Labor Relations Act. A number of federal agencies share responsibility for enforcing the Americans with Disabilities Act, including the Office of Civil Rights of HHS and the U.S. Department of Justice.

Criminal Law

Criminal law is public law. It encompasses cases in which the local, state, or federal government has filed a lawsuit against an individual alleging that he or she has committed a wrongful and illegal act against society. In criminal cases, the victim has the role of witness for the state. If the nurse is the victim of the charged crime, he or she is a witness. If the state files charges against the nurse for committing a crime, the nurse is the defendant. If the defendant nurse is convicted of a crime, the penalty can include loss of liberty. Criminal cases in nursing have included intentional assault and battery, fraud, theft, negligent homicide, and murder. If a nurse intended harm to a patient through substandard treatment, the nurse may be charged by the state under criminal law, in addition to any civil case for malpractice damages filed by the patient. There is a growing body of law around workplace violence involving nurses. In general, however, criminal cases are unusual in nursing situations. Nurses caring for trauma patients whose injuries may have resulted from criminal acts sometimes find themselves involved in a criminal case as a witness to the injury. In some states, they may be required to report certain injuries to criminal law enforcement authorities. An example of a criminal case is presented with the case studies later in this chapter.

Civil Law

Civil law is private law, and deals with conflicts among individuals. Civil law includes tort law, contract law, and the concepts of vicarious liability and product liability. Torts include trespass, assault, battery, and negligence.

▲ Nursing Negligence in Critical Care

The fundamental legal responsibility of the registered nurse in critical care settings does not differ from that of the registered nurse in any work setting. The registered nurse adheres to five principles for the protection of the patient and the practitioner (Box 8-1). The most common lawsuits against nurses and their employers are based on *negligence by a professional*, which is called *malpractice*.

BOX 8-1 Five Legal Responsibilities of the Registered Nurse

- Performs only those functions for which he or she has been prepared by education and experience
- Performs those functions competently
- Delegates responsibility only to personnel whose competence has been evaluated and found acceptable
- Takes appropriate measures as indicated by observations of the patient
- Is familiar with policies of the employing agency

A nursing malpractice case can begin when a patient experiences bad bedside manner or an undesired outcome related to nursing care. If a significant financial loss can be attributed to that outcome, the distressed patient might file a lawsuit against the nurse in a civil court, alleging nursing malpractice. The nurse then becomes the defendant in a civil malpractice case. This experience is a great burden for any nurse, even in the best of times. First, the nurse should contact his or her malpractice insurance carrier and obtain legal counsel who has expertise in nursing malpractice. The nurse may soon be involved with the next step of the civil lawsuit, called *discovery*. This can involve requests for documents, preparing written answers to written questions called "interrogatories," and, most stressful of all, a deposition, which is oral testimony given under oath and recorded by a court reporter, but out of court. In the best case, the plaintiff patient's attorney will advise dropping the case after hearing the nurse's testimony, but in the worst case this testimony will be used later to challenge the nurse's credibility during the next major phase of the lawsuit, the *trial*. During trial, witnesses will testify for both sides and introduce evidence for cross-examination in the courtroom. As in all cases, the person filing the lawsuit (complainant) must prove his or her case before a defense is necessary. To prove a malpractice case, the complaining patient must prove all of the required "elements" of malpractice: duty, breach of duty, damages, and causation.

Duty

A duty is a legal relationship between two or more parties. In most nursing cases, duty arises out of a contractual relationship between the patient and the health care facility. That is, when a patient receives health care, an implied contract arises. The patient, the insurer, or both agree to pay for any health care services the patient receives. In return, the health care facility agrees to supply "reasonable care." One way the duty of an individual nurse to the patient may be confirmed is by the appearance of the nurse's name in the patient's record. A nurse has a legal duty to provide reasonable care to all of his or her patients. This means that the nurse must provide care that complies with the established *standard of care* for a reasonable nurse under the circumstances present at the time of the incident.

Arguing the standard of care is the core of many malpractice cases. In a typical malpractice lawsuit, this is done by both sides hiring expert witnesses, sometimes called "dueling experts," to introduce evidence arguing for their different versions of the standard of care. The following factors can be used to determine the standard of care for a critical care nurse:

- Testimony from experts in critical care, which may include a critical care nurse who is working as an expert witness
- The employing institution's procedure and protocol manuals
- Nursing job descriptions
- Nursing research, textbooks, professional journals, medication books
- Professional organization standards and guidelines (eg, Advanced Cardiac Life Support [ACLS] and Certified Critical Care Registered Nurse [CCRN] standards)
- Laws and regulations governing professionals and institutions
- Standards of private accrediting bodies
- Equipment manufacturers' instructions

Breach of Duty

What was the standard of care? What would a reasonable critical care nurse have done under the circumstances? After the plaintiff patient establishes duty, the patient must show that the nurse breached (violated) that duty, that is, the nurse was negligent. Professional negligence is determined by comparing the nurse's conduct with the standard of care. The critical care nurse who fails to meet the standard of care has breached (violated) his or her duty to the patient.

Negligence may be either "ordinary" or "gross." Ordinary negligence implies professional carelessness. Gross negligence suggests that the nurse willfully and consciously ignored a known risk for harm to the patient. Most cases involve ordinary negligence, but gross negligence can be found if, for example, the nurse ignored sound nursing advice or harmed a patient while under the influence of drugs or alcohol.

Causation

Malpractice law requires a causal relationship between the critical care nurse's breach of the standard of care and the injury to the patient. To prove malpractice, the plaintiff patient has to show that injury or harm occurred as a result of the nurse's action or inaction; that is, the injury would not have occurred without the conduct in question. The plaintiff must also show that the injury was reasonably anticipated. For example, if a critical care nurse administered digoxin to a cardiac patient who had a pulse of 30 beats/min and the patient suffered a cardiac arrest, the court would likely find that the critical care nurse caused the patient's arrest; that is, the wrongful administration of the digoxin was the "proximate cause" of the arrest. However, if the patient had a pulse of 70 beats/min when the digoxin was administered, and the patient suffered a totally unanticipated seizure, it is probable that the nurse's action would not be found to be careless such as to be the cause of the seizure. In this case, the nurse would normally be exonerated, because seizures are not an expected complication of digoxin administration.

Damages

The intent of malpractice negligence law is to make the injured party "whole." The law attempts to return the plaintiff as close as possible to a position that he or she would have been in had the nurse's conduct not caused this injury. Unfortunately, injuries sustained usually cannot be undone. Therefore, most court awards attempt to give the injured plaintiff an award of monetary "damages" that will compensate the plaintiff for his or her injuries. Monetary damages are grouped under the broad headings of economic and noneconomic damages.

Economic damages relate to those damages that can be calculated within a degree of certainty. Medical costs and lost wages are the two major types of economic damages. Noneconomic damages are more difficult to calculate. These damages include pain and suffering and loss of consortium (relations) that occurred as a result of the malpractice. Many state and federal governments place monetary limits on the amount a patient can recover for pain and suffering, regardless of the amount that may be awarded by a jury. "Loss of consortium" damages include the patient's inability to perform household tasks and the loss of marital relations.

The spouse and minor children of a patient may also be able to recover economic and noneconomic damages that they suffer as a consequence of injuries to the patient. When a minor child is the plaintiff, it is not unusual for the parents to file for noneconomic losses due to the loss of society and affection of their child. On the economic side, a parent can sue for his or her own lost wages due to a need to care for the child.

Many types of malpractice complaints are lodged against critical care nurses. The following cases illustrate reasons nurses are often named in malpractice suits.

CASE STUDY

Failure to Comply With Reasonable Standards of Care

"T" was 7 years old when his parents took him to the emergency department complaining of nausea, vomiting, and a fever. The child was examined and a complete blood count (CBC) ordered. The physician diagnosed a viral upper respiratory infection and discharged the boy. The next morning his parents brought T back to the hospital. His complaints now included abdominal and chest pains. T was classified as Emergent Level 2 and placed in an examination room. An hour later he was examined, and lab tests and chest x-ray were ordered. As a result, T was diagnosed with pneumonia a little over 2 hours after arrival. The doctor ordered transfer to a pediatric intensive care unit (PICU) at another hospital, as well as antibiotics and fluids, which were administered. The receiving hospital informed the doctor that they had to prepare a bed for T in the PICU, and wanted him transferred with a pediatric transfer team, after it completed its current run to another city. T's condition worsened. He was intubated and developed malignant hyperthermia. Nine hours after his arrival, doctors arranged for his transfer by helicopter. T was in the second hospital for several weeks, diagnosed with septic shock, which caused

(*continued on page 91*)

organ damage. His parents sued the first hospital and doctor on T's behalf, for negligence and for violation of the Emergency Medical Treatment and Active Labor Act. The evidence showed that two nurses and a doctor examined T and physically assessed him. The court found that this was reasonable care, ruled against T and his parents, and dismissed the case.[2]

In 1999 the Institute of Medicine (IOM) released a study, *To Err is Human: Building a Safer Health System*,[3] which raised awareness of medical errors, including serious medication errors, which occur in 5% to 10% of patients admitted to hospitals. Experts agreed that the most common cause of error is the system itself, not the individual practitioners in the system. This report triggered the formation of the National Patient Safety Foundation by the American Medical Association, and the creation of a nonpunitive sentinel events reporting system by the Joint Commission for the Accreditation of Healthcare Organizations (JCAHO), now known as the Joint Commission. Remaining controversies include what type of errors should be reported, and whether individual practitioners should be disciplined for this type of error. In the case of gross negligence, the nurse is likely to be found liable for a medication error, regardless of the answers to these questions.

CASE STUDY

Improper Medication Administration

Baby A was admitted to the pediatric intensive care unit (PICU) of a local hospital to determine why she developed respiratory dysfunction. A pulmonologist, a critical care specialist, neurologists, and geneticists examined her to rule out various disorders. During a right femoral central line placement, a doctor inadvertently cannulated the artery and immediately removed the line. Thereafter, inadequate perfusion of blood through her leg was noted. A vascular surgeon performed an emergent thrombectomy and administered 162 mg of papaverine. Shortly after that, Baby A went into cardiac arrest and died. Baby A's parents sued the doctor for administering an incorrect dosage of papaverine. The patient's expert witness stated that administering papaverine to the infant caused her death, and that the doctor's failure to ascertain the correct dose was a substantial factor in her death. The doctor argued that it was the responsibility of the operating room staff, specifically the circulating nurse, to prepare medications for administration, and the standard of care permitted the doctor to rely on that. In this case, an effort to transfer the responsibility for a medication error from the doctor to the nurse was unsuccessful. A trial was ordered on the malpractice claim against the doctor.[4]

CASE STUDY

Criminal Liability in Critical Care

Mr. D., an 86-year-old man, was admitted to the hospital with abdominal pain. He was diagnosed with a perforation in the proximal duodenum, causing diffuse peritonitis. The day after his surgery, he was found to have a serum potassium level of 3.2 mEq/L, below the normal level of 3.3 to 5.5 mEq/L. The intensive care unit (ICU) nurse administered an ordered dose of potassium chloride elixir through his nasogastric tube. However, subsequent laboratory tests showed this had not been well absorbed.

Mr. D.'s physician ordered the ICU nurse to administer 40 mEq of potassium chloride in 100 mL of saline solution in a bag of intravenous fluid. After the nurse informed the physician that the potassium chloride would need to be infused over the course of 1 hour, the physician ordered the nurse to draw up a syringe of 40 mEq of potassium chloride in 30 to 50 mL of saline solution. The nurse prepared the syringe but refused to administer it, knowing that this was dangerous. Another ICU nurse was also present and informed the physician that it was hospital policy to administer a maximum dosage of 40 mEq of potassium chloride over 1 hour. The physician then took the syringe from the nurse and administered the potassium chloride directly. During the injection, Mr. D. stopped breathing, and efforts at cardiopulmonary resuscitation were unsuccessful.

The physician's failure to use reasonable standards of medical care and total disregard of the cautions given by the ICU nursing staff resulted in criminal liability. A court convicted the physician of involuntary manslaughter, "the unlawful killing of a human being without malice in the commission, without due caution and circumspection, of a lawful act which might produce death." The sentence was 5 months' imprisonment, 36 months' supervised parole, a $100 assessment, and a $25,000 fine. The U.S. Court of Appeals for the 10th Circuit upheld the criminal conviction.[5]

Vicarious Liability

Vicarious liability means to hold someone (a person or institution) responsible for the actions of another. Critical care nurses sometimes find themselves in situations where various types of vicarious liability apply, including respondeat superior, corporate liability, negligent supervision, and the rule of personal liability.

Respondeat Superior

The doctrine of respondeat superior is translated as "let the master answer for the sins of the servant." Under this legal theory, hospitals are held liable for the negligence of their employees. Respondeat superior is a legal doctrine based on public policy that notes that because a hospital profits from the patients seeking care, the hospital should pay for some of the damages caused by hospital personnel if negligence occurs. This doctrine applies only when hospital employees act within the scope of their employment.

Respondeat superior does not apply in situations involving temporary agency personnel because they are usually employees of the agency, not of the hospital. Nor does it typically apply to physicians, because they usually are not employed by the hospital. This doctrine would not apply to nurses who are employed by a hospital but who are accused of malpractice for work outside of their hospital employment.

Because hospitals may be held liable for nursing activities conducted by their employees, they carry professional liability insurance for the activities of their employees, intended to cover the cost of defending individuals named in a malpractice case. However, many nurses also carry their own malpractice insurance, to cover off-the-job nursing activities and to cover the cost of choosing their own independent counsel to protect their rights in a case where multiple parties from their institution are sued, because they are likely to have conflicting interests.

Corporate Liability

Corporate liability is vicarious liability that occurs when a hospital is found liable for its own unreasonable conduct. For example, if it is found that a unit is chronically understaffed and a patient suffers an injury as a result of short staffing, the hospital can be held accountable. It is reasonable to expect any hospital that has an ICU or an emergency department to take precautionary measures to ensure that it is adequately staffed or that beds or admissions are reduced. Failure to ensure adequate staffing can lead to payment of monetary damages under the theory of corporate liability.

Corporate liability may also occur within "floating" situations. A nurse working in a critical care setting must be competent to make immediate nursing judgments and to act on those decisions. If the nurse does not possess the knowledge and skills required of a critical care nurse, he or she should not be attempting to render critical care. A nurse who is not well versed in critical care should notify the charge nurse or nursing supervisor of this fact. The nurse needs to clearly state which nursing care activities he or she can and cannot implement. The supervisor and charge nurse must then delegate the remaining nursing duties to staff members with adequate education, training, and experience. Box 8-2 addresses issues of concern to the floating nurse.

BOX 8-2 Commonly Asked Questions When Rotating to an Unfamiliar Unit

1. *If I am asked to go to another unit, must I go?*
   Usually, you will be required to go to the other unit. If you refuse, you can be disciplined under the theory that you are breaching your employment contract or that you are failing to abide by the policies and procedures of the hospital. Some nursing units negotiate with hospitals to ensure that only specially trained nurses rotate to specialty units.
2. *If I rotate to an unfamiliar unit, what types of nursing responsibilities must I assume?*
   You will be expected to carry out only those nursing activities that you are competent to perform. In some instances, this will be the performance of basic nursing care activities, such as blood pressures, and uncomplicated treatments. If you are unfamiliar with the types of medications used on the unit, you should not be administering them until you are thoroughly familiar with them. Consider the medication cards the student completes in nursing school. They were assigned because a reasonable, prudent nurse does not give medications without knowledge of their pharmacology, dosage, method of administration, side effects, and interactions with other medications. The same reasoning applies for any other type of critical care monitoring.
3. *What should I do if I feel unprepared when I get to the unit?*
   Suggest that you assist the unit with basic nursing care requirements and that specialized activities (eg, invasive monitoring, cardiac monitoring, or the administration of unfamiliar drugs) be performed by staff members who are adequately prepared. Do not feel incompetent because you are not familiar with all aspects of nursing care. After all, when is the last time you saw the neurologist go to labor and delivery and perform a cesarean birth?
4. *What if the charge nurse orders me to do something I am not able to do safely*?
   You are obligated to say you are unqualified and request that another nurse carry out the task. The charge nurse also needs to remember that she could be held liable for negligent supervision if she orders you to do an unsafe activity and a patient injury results.

Negligent Supervision

Negligent supervision is vicarious liability claimed when a supervisor fails to reasonably supervise people under his or her direction. For example, if a nurse rotates to an unfamiliar unit and informs the charge nurse that he or she has never worked in critical care, it would be unreasonable for the charge nurse to ask the floating nurse to perform invasive monitoring. If the charge nurse did assign such responsibilities to the floater and a patient injury resulted, the charge nurse could be held accountable to the patient for negligent supervision.

Captain of the Ship Doctrine

At one time, the physician was viewed as the "captain of the ship" in relation to the nurse. Therefore, the nurse was expected to follow any order from the physician. This doctrine has largely been replaced by a legal concept known as the *rule of personal liability*. As a result, nurses are responsible for making sound decisions by virtue of their own specialized education, training, and experience. A critical care nurse today who is unsure about whether a physician's order is safe or appropriate for a patient should not follow it as a matter of course, but should seek clarification from the physician or, if needed, from the nursing supervisor.

CASE STUDY

Rule of Personal Liability and Independent Nursing Judgment

Mr. S., a 46-year-old man with a history of ventricular tachycardia, was prescribed flecainide acetate (Tambocor) for his heart condition. One evening he reported his heart "started feeling funny" and had a friend take him to the emergency department. An electrocardiogram on admission to the emergency department revealed he was experiencing ventricular tachycardia.

Mr. S. told a nurse and a physician in the emergency department that he did not want cardioversion. The emergency department physician, in telephone consultation with a cardiologist, ordered 5 mg of verapamil. Within 2 minutes, Mr. S.'s blood pressure crashed, he had a seizure, and he went into cardiac arrest. As a result, Mr. S. suffered brain damage and was forced to reside in a nursing home because he lacked independent motor function and was unable to speak.

The emergency department nurse, physician, and hospital were sued for several reasons, including malpractice. During deposition, the nurse testified that she was ACLS certified and admitted to knowing that verapamil was contraindicated in patients with ventricular tachycardia. She related that she had serious questions about administering the verapamil but acceded to the physician's orders.

The court found that the standard of reasonable nursing care required the nurse to intervene to prevent complications and that failure to intervene was a violation of the nursing standard of care. In addition, the court determined that the standard of nursing care requires a nurse to exercise independent nursing judgment if he or she believes that an order may have adverse consequences for the patient.[6]

The Questionable Medical Order

The above case describes a difficult situation for nurses, who frequently feel that their employment may be threatened if they do not follow the order of a physician. However, an order that is patently wrong can harm the patient if it is followed. A secondary consequence can be liability for the physician, the nurse, and the hospital (as the employer) if the patient suffers harm as a direct result of the order. Both ethics and professional preservation (where can a critical care nurse work without a license?) argue the wisdom of refusing to obey orders in some situations.

A policy statement should exist in procedures or by directive that indicates the manner of resolving the issue of the "questionable" medical order. This is important for all medical orders, but particularly for those given for critically ill patients where unusual doses of medication are frequently ordered. The nurse who questions an order should express his or her specific reasons for concern to the physician who wrote the order. This initial approach frequently results either in an explanation of the order and a medical justification for the order in the patient's medical record, or in an alteration of the order based on additional information from the nurse. If this approach is unsuccessful, many hospitals require that the attending physician or the nursing supervisor be notified. Others have a policy that the chief of the service must be consulted about questionable orders. If these options are unavailable or are unsuccessful, a critical care nurse or any other nurse can refuse to give a medication, and should if patient harm is the expected result.

Establishment of Protocols

If the critical care nurse is required to perform medical acts and is not under the direct and immediate supervision of the delegating physician, the activities must be based on established protocols. These protocols should be created by the medical and nursing departments and should be reviewed for compliance with the state's NPA. Protocols must be reviewed frequently so health care professionals can make sure that they reflect current medical and nursing regulations and standards of care. In the event of a malpractice suit, the critical care protocols and procedures can be introduced as evidence to help establish the applicable standard of care. Although it is important that protocols provide direction, excessive detail restricts the critical care nurse's flexibility when selecting a proper course of action and is more likely to be different from actual practice, increasing the liability risk of the nurses and the institution.

Liability for Defective Medical Equipment

A medical device, defined as virtually anything used in patient care that is not a drug, includes intricate pieces of equipment (eg, intra-aortic balloon pumps, endotracheal tubes, pacemakers, defibrillators), along with less complicated ones, such as bedpans, suture materials, patient restraints, and tampons. Before 1976, medical devices were unregulated; since 1976, the U.S. Food and Drug Administration (FDA) within HHS has regulated medical devices sold in the United States. Before November 1991, hospitals, their employees, and staffs were permitted, but not required, to report device malfunctions to the device manufacturer or to the FDA. The Safe Medical Devices Act of 1990 requires user facilities (which include hospitals and ambulatory surgery facilities, but not physician offices) to report to the manufacturer medical device malfunctions that result in serious illness, injury, or death to a patient. They are also required to report to the FDA those that result in a patient's death. A serious illness or injury includes not only a life-threatening injury or illness but also an injury that requires "immediate medical or surgical intervention to preclude permanent impairment of a body function or permanent damage to a body structure."[7] Therefore, the rupture of an intra-aortic balloon pump that requires that the balloon-dependent patient immediately be transported to the operating room for removal and replacement of the device is a reportable event. Nursing and other staff must now participate in reporting device malfunctions, including those associated with user error, to a designated hospital department. Personnel in that area are usually responsible for determining which malfunctions engender an obligation to report and to whom they should be reported.

In 2009 the Secretary of HHS directed the FDA commissioner to issue regulations for class III devices, those with the greatest risk to harm patients, to ensure that they are approved through the most stringent premarket review process.[8] There is a duty not to use equipment that is patently defective. If the equipment suddenly ceases to do what it was intended to do, makes unusual noises, or has a history of malfunction and has not been repaired, the hospital could be liable for damage caused by it. Likewise, the nurses could be liable if they know or should know of these problems and use the equipment anyway. The following cases involved liability for defective equipment.

CASE STUDY

Defective Equipment and Negligence

Mrs. V was admitted to a hospital in stable condition for an elective ambulatory cardiac catheterization. Doctors determined that she needed an angioplasty and stent procedure, performed the next day. Complications arose, and Mrs. V was transferred to ICU, where she suffered a cardiorespiratory arrest, entered into a comatose state, and died of abdominopelvic hemorrhage 2 days after her initial admission. Her children sued the hospital for the malpractice of its employee nurses under the vicarious liability doctrine, alleging that the nurses failed to notify the doctors immediately of the emergency. They also sued the hospital for negligence citing its failure to have a CT scan machine on its premises, characterizing it as "adequate and necessary" medical equipment. The court denied the hospital's motions to dismiss this case.[9]

Patient Decision-Making Autonomy

Laws protecting patient autonomy require that patients receive enough information to make an informed, intelligent decision to accept or reject a proposed treatment. This is called *informed consent*. It can be especially challenging

for nurses caring for patients who are critically ill. Obtaining informed consent from the patient, or from the family or designated proxy in the case of a patient who is not competent, is the responsibility of the care giver who is ordering the care, usually a physician. The nurse is frequently asked to witness the signing of the consent form. In these cases, the nurse is merely attesting that the signature on the consent form is that of the patient or the patient's surrogate decision maker. When the nurse actually witnesses a physician's explanation concerning the nature of the proposed treatment, the risks and benefits of the treatment, alternative treatments, and potential consequences if the patient decides to do nothing, the nurse may place a note in the nurse's notes or designated part of the patient's record stating, "consent procedure witnessed." This information may be vital in the rare case in which the patient or family alleges that the care giver failed to provide informed consent.

▲ Advance Directives: Living Wills and Powers of Attorney

Advance directives are legal documents that preserve the patient's right to determine his or her care by permitting a patient to make decisions about health care ahead of time, in case the patient becomes incompetent to make decisions later. Incompetence can occur due to illness, age, trauma, or court determination. If a patient is deemed incompetent, the nurse must identify the patient's surrogate decision maker and contact the surrogate to make health care decisions on the patient's behalf.

If the patient's surrogate is not designated in writing, state law identifies the appropriate family members to make decisions. The surrogate should refer to the patient's advance directives and any other known wishes for guidance. This situation can become complex, especially when the surrogate decision maker disagrees with the advice of the physician or other care giver, with the wishes stated by the patient in an advance directive or otherwise, or with another surrogate, which can occur in a situation where the patient's children, parents, or siblings share this responsibility. While the nurse should not implement procedures that he or she identifies as unethical, neither nurses nor physicians can substitute their judgment for the patient's right to make the decision about accepting or rejecting available procedures.

A *living will* is a written directive from a competent patient to family and health care team members concerning the patient's wishes in the event the patient is unable to express these wishes in the future. A living will only applies to the limited situations that it describes, which may not include the particular decision that must be made. A living will becomes effective only if the patient is both terminally ill and incompetent to communicate his wishes, or is permanently comatose. Consequently, when the patient is critically ill or temporarily unable to make health care decisions, the living will may not be operative.

To provide broader coverage, patients must prepare a *durable power of attorney for health care*. This is the legal document that allows the patient to appoint a surrogate decision maker while he or she is still competent. The surrogate, also known as a health care agent or proxy, has authority to make treatment and health care decisions in the event that the patient is not able to do so. This type of document allows a trusted friend or relative to "stand in the shoes of the patient" to make health care decisions when the patient is not able to make them.

Savvy patients will prepare both a living will and the durable power of attorney for health care. This ensures that the decision maker's decisions will be as close as possible to what the patient wants. Many advance directives give the health care agent specific instructions concerning health matters. For example, the advance directive may provide instructions concerning artificial nutrition and hydration, or it may outline specific treatments, such as a "no code" status under specified circumstances.

In response to a federal statute referred to as the Patient Self-Determination Act of 1991,[10] all 50 states have statutes that allow patients to execute living wills, durable powers of attorney for health care, and advance directives. However, each state may place unique requirements on the drafting of these documents. Some states require that the directive be notarized. Other states mandate that a state-appointed ombudsman who outlines the pros and cons associated with the advance directive counsel the patient. Witness requirements also vary from state to state. Consequently, it is important to know the laws concerning advance directives that apply in your state. An excellent starting point is the web page of the National Hospice and Palliative Care Organization (caringinfo.org), where you can download advance directives and instructions from each state. The Web site of the American Association of Retired Persons (aarp.org) provides lay people and health care providers with up-to-date information about advance planning for health care.

In most states, it is likely that a recent living will would be taken as evidence of what the patient would have wanted had he or she been competent when the decision was presented. Although there have not been any cases concerning a written living will, there have been several involving patients who had expressed wishes orally about life-sustaining measures.

▲ Issues That Involve Life-Support Measures

Several basic issues regarding refusal and termination of treatment can involve the critical care nurse. Do not resuscitate (DNR) orders, refusal of treatment for religious reasons, advance directives, and withdrawal of life support all fall into this category.

Do Not Resuscitate (DNR) Orders

Cardiopulmonsry resuscitation (CPR) success rates for those receiving in-hospital care are variable and are affected by patient environment and resuscitative factors.[11] However, CPR is not appropriate for all patients who experience a cardiac arrest, because it is highly invasive and may constitute a "positive violation of an individual's right to die with dignity." Furthermore, CPR may not be indicated when the

illness is terminal and irreversible and when the patient can gain no benefit.

Prestigious authorities (eg, the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research; hereafter "the President's Commission") have recommended that hospitals have an explicit policy on the practice of writing and implementing DNR orders.[12] Most hospitals and medical societies, and some states, have published DNR policies.[13]

Whether to resuscitate any patient is a decision that is made with the attending physician, the patient, and the family, although critical care nurses and other nurses often have substantial input into the decision. However, in general, the consent of a competent patient or the patient surrogate is required when a DNR decision is made and the order is written.

Once the DNR decision has been made, the order should be written, signed, and dated by the responsible physician. It should be reviewed periodically; hospital policies may require review every 24 to 72 hours. The more informal methods of designating patients with whom CPR is not to be undertaken can lead to uncertainty and inappropriate responses if an arrest occurs. If an arrest occurs in an emergency department or in another situation in which a formal DNR decision has not been made and written, the presumption of the medical and nursing staffs should be in favor of intervention, and a code should be called. A "slow code" (in which the nurse takes excessive time to call or the health care team takes its time responding) is never permissible. Either CPR is indicated, or it is not.

Courts sometimes become involved in DNR decisions and provide legal guidance through case law. In 2004, a California court ruled that a physician may lawfully write a DNR order for a minor patient for whom there is no lifesaving or life-prolonging treatment. This case involved a DNR order for Christian, an 11-year-old boy with cystic fibrosis who developed the flu and then pneumonia after his parents had rejected the flu shot for him. A nurse testified that she was present during the discussion between the doctor and the parents, and that both parents agreed to the DNR order "in view of (Christian's) chronic irreversible condition."[14]

CASE STUDY

Discontinuation of Ventilator Support

Dr. B. was a 79-year-old nuclear engineer in the end stages of Alzheimer's disease who was admitted to the hospital in a vegetative state with aspiration pneumonia. Mr. B. had no advance health care directive. A family dispute evolved among his sons over his care. After hearings, the court appointed one son as Dr. B's guardian and surrogate decision maker. In 2009, the court denied the request of another son for a hearing on the issue of whether his brother may authorize the removal of hydration, nutrition, and respiratory care.[15]

Unfortunately, it is estimated that as few as 4% to 24% of Americans have an advance directive.[16–18] An advance directive can help with troublesome decisions, such as those that were faced by both the family and the health care team in this case. It is also important for patients to speak with their families and their attending physician concerning end-of-life decisions.

Right to Refuse Treatment for Religious Reasons

CASE STUDY

Lifesaving Transfusion for a Jehovah's Witness

Petitioner was a 17-year-old Jehovah's Witness diagnosed with lymphoblastic leukemia when his doctors wrote a letter to the court requesting an order authorizing them to be able to transfuse him to prevent death or serious harm. A juvenile court issued an order authorizing the administration of transfusions using whole blood products despite his religious beliefs and the wishes of his parents. Petitioner filed an appeal, asking the court to establish a common-law "mature minor" exception to the statute that allowed a judge in the juvenile court to authorize emergency medical care. The exception would have allowed the mature minor to make these decisions. The court did not rule in this case, because Petitioner turned 18 and was now legally able to make his own health care decisions, including refusal of transfusions to treat his leukemia.[19]

Some courts are unwilling to rule against the religious-based decisions of a patient to refuse treatment, but they are most likely to do so if the welfare of a dependent child is at stake. For example, in one case, the Connecticut Supreme Court found that a hospital could not "thrust unwanted medical care on a patient who… competently and clearly denied that care." Critical care nurses need to consult the hospital's risk management department or legal counsel in such situations to ensure proper handling of these types of legal issues.[20] There are exceptions to the informed consent requirements. For example, an emergency situation in which time and circumstances create critical barriers does not require informed consent before initial procedures are implemented. A patient can also waive the right to informed consent by stating that he or she does not want information about a proposed treatment or procedure.

Landmark Legal Cases on Withdrawal of Treatment

What constitutes life support, when these measures must be used, and when they may be terminated are issues that have been raised in many court cases. However, the law in these areas is still developing and will continue to do so as each state creates its own guidelines and as technology continues to introduce new possibilities.

In the matter of *Schiavo v. Schiavo*,[21] the United States was drawn into a legal and emotional battle over the issue of the right to die and, barring advance directives, who may speak for an unconscious patient. Theresa (Terri) Schiavo was in a vegetative state for 13 years. In 2003, Ms. Schiavo's husband, Michael, petitioned to cease his wife's feeding and hydration over the objections of her parents and brother.

In response, Terri's parents, Robert and Mary Schindler, led a battle before the Florida State Courts, the U.S. Courts of Appeal, the Florida State Legislature and Executive Branch, the U.S. Congress, the White House, and, eventually, the U.S. Supreme Court.[22] Aside from the legal activities, the parties to the action also tried Terri's circumstances and future before the court of public opinion.

Although it is unusual for this type of case to be heard in the U.S. Supreme Court, lower court involvement in this type of situation is not unusual. When a disabled person is unable to understand and coherently speak on his or her own behalf, the law requires that health care providers first obtain the patient's personal advance directives. Courts have repeatedly struggled over who should make decisions about the disabled patient's care when there is no advance directive and relatives cannot agree on the appropriate plan of care for the patient, such as occurred in the Schiavo case.

Initially the Schiavo case was representative of a typical guardianship action. The petitioner (eg, husband Michael Schiavo) petitioned the court to act on behalf of the alleged disabled patient (eg, his wife, Terri). Notice of the proposed order to name Mr. Schiavo as Terri's guardian was given to all interested persons, including her parents Mr. and Mrs. Schindler.[21] In addition, courts may appoint a temporary *guardian ad litem*, charged with the duty to represent the interests of the alleged disabled. The temporary guardian ad litem, usually an attorney, is an independent, disinterested party whose responsibilities are to review the medical records, interview all medical providers, interview the petitioner (ie, Mr. Schiavo) and any interested persons, and most importantly, interview the alleged disabled as to his or her mental and physical capacity. The temporary guardian ad litem reports independently to the court on his or her findings of the status of the alleged disabled.

In the Schiavo case, a custodial hearing was held allowing the petitioner, witnesses, and any other interested persons to testify as to (1) the competency of the alleged disabled, (2) whether the alleged disabled would be best served with a guardianship, and (3) who would be best to act as *permanent* guardian ad litem. In deciding these issues, the courts place great weight on the findings of the temporary guardian ad litem.

Michael Schiavo prevailed in maintaining his position as permanent guardian ad litem of Terri,[22] and her tube feeding was discontinued. As a result of this and other cases, families throughout the nation became more aware that they might be faced with the awful possibility of being pitted emotionally, legally, and monetarily against each other when advance directives are not executed.

Nurses, particularly those working in critical care areas, are frequently confronted with patients who are incompetent to understand the nature of their care. Nurses are instrumental in educating patients, families, friends, and society about the importance of understanding and executing advance directives. From an attorney's perspective, the consensus is, "Pay me a little now to prepare a valid advance directive, or pay me dearly when we need to litigate guardianship and end-of-life issues."

Given the regularity with which life-support decisions must be made in health care facilities, it is remarkable that it was not until 1976 that the first case, *In re Quinlan*, focused national attention on the "right to die" controversy. The cases concern competent minors and adults who have a disease or condition that would eventually be terminal. States have not been consistent in their decisions, even when the situations are arguably similar. For example, the New Jersey court in the case of Karen Ann Quinlan, a 21-year-old woman in a persistent vegetative state, held that the decision about treatment is in the hands of the patient's guardian in consultation with the hospital ethics committee.[23] The President's Commission stated (p 6) that judicial review of these decisions should be reserved for occasions when "adjudication is clearly required by state law or when concerned parties have disagreements that they cannot resolve over matters of substantial import."[12]

CASE STUDY

Right to Restrict Food and Fluids

Nancy Cruzan, a young woman who suffered anoxic brain damage in an automobile accident, remained in a persistent vegetative state in Missouri and was fed by gastrostomy. After rehabilitation was unsuccessful, Ms. Cruzan's parents (as co-guardians) requested withdrawal of the feeding tube. After the employees of the residential rehabilitation center where Ms. Cruzan was receiving care refused to withdraw the feedings, her parents sought judicial review of their request. After testimony, the trial court approved the parents' request.

On appeal, the Missouri Supreme Court reversed the lower court. First, it held that Missouri law does not permit surrogate decision making in decisions of this importance. For a person to exercise the right to terminate artificial feeding in Missouri, that person must have previously expressed his or her wishes, either orally or in writing. Evidence of those wishes had to meet a relatively high evidentiary standard, a standard that the court held had been met in the lower court proceeding.

This case was appealed to the U.S. Supreme Court, and in 1990, it was affirmed on constitutional grounds.[24] After the decision was issued, the Cruzans returned to the Missouri lower court and presented further evidence (through additional witnesses) about what their daughter had expressed while competent. The lower court found that they had presented clear and convincing evidence and affirmed the rights of the co-guardians to authorize withdrawal of the feeding tube.

It is important to note that although the Cruzan case is still applicable law, the way in which this landmark case has been interpreted and implemented has been extremely variable at state court levels. This case received much publicity, but it did not change the law in any state except Missouri. Most states continue to permit surrogate decision making by relatives and require a lower evidentiary standard than that required in Missouri. Also note that, unlike the Schiavo case described previously, family members were all in agreement that Ms. Cruzan's artificial nutrition and hydration should be discontinued.

The right to consent to treatment is meaningless without the right to refuse treatment before or after it is initiated. In recent years, as health care providers have become more comfortable recommending rejection or termination of treatment in selected cases, they have met resistance from some families who wish to continue treatment no matter what the chance of success. Although no law or legal principle requires that extraordinary, but clearly futile, treatment be provided, it is probably also true that health care providers have little legal recourse against families who refuse to withdraw life support, that is, unless the patient has left written indications of his or her wishes before incompetence. This may change as society reexamines the allocation of limited resources in health care.

In most states, problems of terminating treatment need not be resolved in court. This is not an easy decision, but decisions regarding treatment or nontreatment that meet accepted medical standards and with which the patient concurs are made virtually every day in health care settings such as critical care. Hospital ethics committees typically play a crucial role in such circumstances.

A distinction should be made between termination of treatment and termination of care. Ending treatment is not the same as giving up. Patients who are not being "treated" for their terminal condition require competent and sensitive nursing and medical care. Palliative care provides pain relief and symptom management, and a better quality of life for those nearing the end of life and their families. The duty to provide good nursing care does not end with the decision to move from treatment for cure to providing comfort care and (ideally) timely referral to hospice.

Brain Death

In 1968, an ad hoc committee at Harvard Medical School established the Harvard criteria for determining brain death, or irreversible coma. In 1981, the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research published *Defining Death*. The Commission recommended a uniform statute defining death, to address "general physiological standards rather than medical criteria and tests, which will change with advances in biomedical knowledge and refinements in technique."[25] All states have laws addressing the definition of death in the state. Some states adopted the Harvard criteria by statute, whereas other states enacted legislation that defines brain death in broader, less restrictive terms. Some states use brain death as the sole criterion; other states rely on a number of factors, such as response to pain and cessation of cardiac function. It is important that the nurse know the legal definition of death in any state where he or she is practicing, although such a determination typically rests with the patient's attending physician and may require the concurrence of other consulting physicians.

A patient who is brain-dead is legally dead, and there is no legal duty to continue to treat him or her. It is not necessary to obtain court approval to discontinue life support on a patient who is brain-dead. Furthermore, although it can be desirable to obtain family permission to discontinue treatment of a brain-dead patient, it is not a legal requirement. Before terminating life support, physicians and nurses should determine whether the patient is an organ donor.

Organ Donation

Every state in the United States has a law based on the Uniform Anatomical Gift Act. The statutes establish the legality of organ donation by people and their families, and set procedures for making and accepting the gift of an organ. Every state also has some provision to enable people to consent to organ donation using a designated place on a driver's license. More recently, many states have enacted "required request" laws. These laws attempt to increase the supply of organs for transplantation by requiring hospital personnel to ask patients' families about an organ gift at the time of the patient's death.

▲ Clinical Applicability Challenges

SHORT ANSWER QUESTIONS

1. Nurse Jacqui has just learned that a judge has ruled to dismiss a professional malpractice claim that was filed against her, because the patient alleged no damages that could form the basis of an award. What is the status of this patient's complaint against Jacqui?

2. A patient has filed a complaint with Nurse Jacqui's Board of Nursing, alleging that Jacqui failed to meet the standard of care. Jacqui learned of this by receiving an order informing her of the complaint and the decision of the Board to suspend her license. What is Jacqui's status now?

3. Nurse Port was on duty when she received a new admission with a diagnosis of "rule out pneumonia." The patient had several orders for an IV and for STAT medications. Nurse Port picked up the IV bag from the medication room and hung it. The patient died, and staff later discovered that Nurse Port had picked up the wrong bag. How should this situation be handled?

4. Nurse Good has a patient in intensive care who is in critical condition with uncontrolled bleeding after apparently becoming the victim of a hit-and-run driver. The patient is conscious but appears weak and confused. Nurse Good and law enforcement officers are desperately trying to find information about this patient. A visitor has just appeared who informs Nurse Good that the victim appears to be his brother. He is very distraught and asks whether his brother has had a blood transfusion. How should Nurse Good respond?

9 Building a Professional Practice Model for Excellence in Critical Care Nursing

Janie Heath

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Discuss nursing professionalism and nursing excellence.
2. Recognize characteristics of professional development.
3. Explore personal and professional attributes to build a professional practice model of critical care nursing excellence.

In today's fast-paced critical care environment, nurses respond to the needs of patients and families who have entered a chaotic and frightening world of illness, trauma, and pain. Often, finding the time for professional growth can be challenging. Building a professional practice of excellence requires a "passion" to profoundly affect the lives of patients and families. At the same time, it requires advancing the critical care nursing profession through evidence-based practice, best practice models of care, or both. This chapter discusses how a professional practice for excellence in critical care nursing can be built with the attributes of values, vision, mastery, passion, action, and balance as the framework.

▲ Defining the Critical Care Nurse

Like their patients and patients' families, critical care nurses are an exceptional and diverse group of people. Knowledgeable, highly skilled, and caring are a few of the professional attributes that can be applied to critical care nurses. However, the term *nursing professionalism* may bring to mind different images, especially to health care consumers. To some, nursing professionalism still means wearing a crisp, clean, white uniform, whereas to others, regardless of the uniform, it means demonstrating a high level of intellectual, interpersonal, ethical, and clinical skills. Kalisch and Kalisch[1] first reported on the image of nursing in the early 1980s. They found that "90% of the public thought nurses were nice ladies who help doctors."

Critical care nurses know all too well that responding to lethal dysrhythmias, administering blood products, and weaning patients from ventilators is more about having a specialized body of knowledge, competent skills, and clinical experience in holistic nursing than about just "helping doctors." For both the novice and the experienced critical care nurse, the journey of nursing professionalism and nursing excellence goes beyond the bedside skills required to take care of the sickest and most vulnerable patients and families.

Critical care nursing started being recognized as a specialty when the first intensive care units (ICUs) emerged in the 1950s, yet Buresh and Gordon[2] have found increasing evidence of a large communication gap between the profession and the greater public. If critical care nursing is to be recognized as a respected and valued profession, nurses must boldly speak up to define who they are and what they do.

A starting point to define who critical care nurses are can be found in the annual demographic membership survey conducted by the American Association of Critical-Care Nurses (AACN),[3] the world's largest specialty nursing organization. Since 1969, the AACN has been serving the needs of more than 500,000 nurses who care for critically ill patients and their families. With a steady membership of approximately 80,000 nurses, the majority of members (60%) are between the ages of 40 and 59 years of age and have a bachelor of science in nursing (Fig. 9-1A).[3] With an average income between $55,000 and $74,999 per year, the majority of members (25%) have been in critical care practice for more than 20 years (see Fig. 9-1B).[3] Although the profession continues to be predominantly female (90%), the number of men in critical care is increasing (11%), according to the AACN membership survey.[3] The largest ethnic background represented was Caucasian (78%), followed by Asian (12%), African American (4%), Hispanic (3%), and Native American (1%).[3] Of interest, the AACN membership data are consistent with the average findings of today's 3 million registered nurses (RNs) reported in the initial findings from the 2008 National Sample Survey of Registered Nurses.[4]

It is important to evaluate such data because this helps drive decision making and determine trends, issues, and policy and advocacy implications that affect critical care nursing practice, patients and families, and systems. Currently, the majority of AACN members (18%) work in ICU settings followed by 13% working in combined ICU and coronary care unit (CCU) settings, 12% working in progressive care settings, 10% in cardiovascular–surgical ICU settings, 6% working in CCU, 5% working in medical ICU, 4% working in medical–surgical ICU, and 4% working in pediatric ICU.

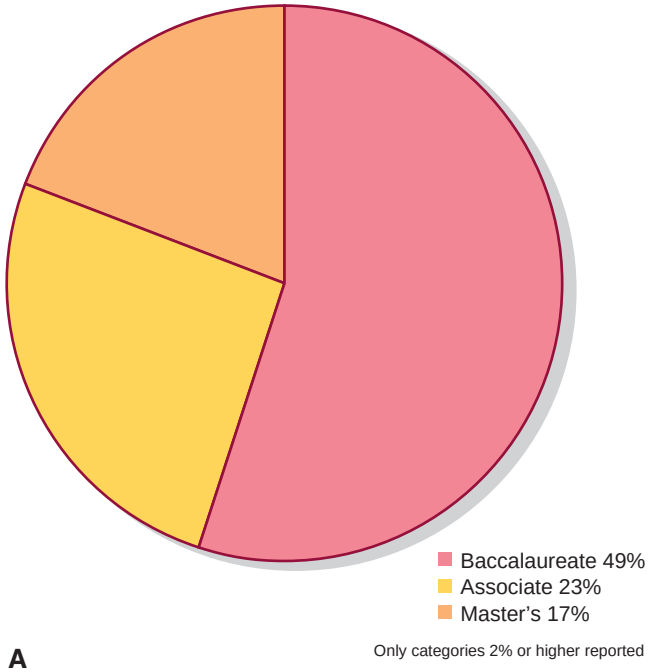

FIGURE 9-1 ▲ Mastery of the profession. **A**: The nursing degrees earned by critical care nurses. **B**: Years of experience in critical care nursing. (From American Association of Critical-Care Nurses: 2010 Demographics. Retrieved June 1, 2010, from http://www.aacn.org.)

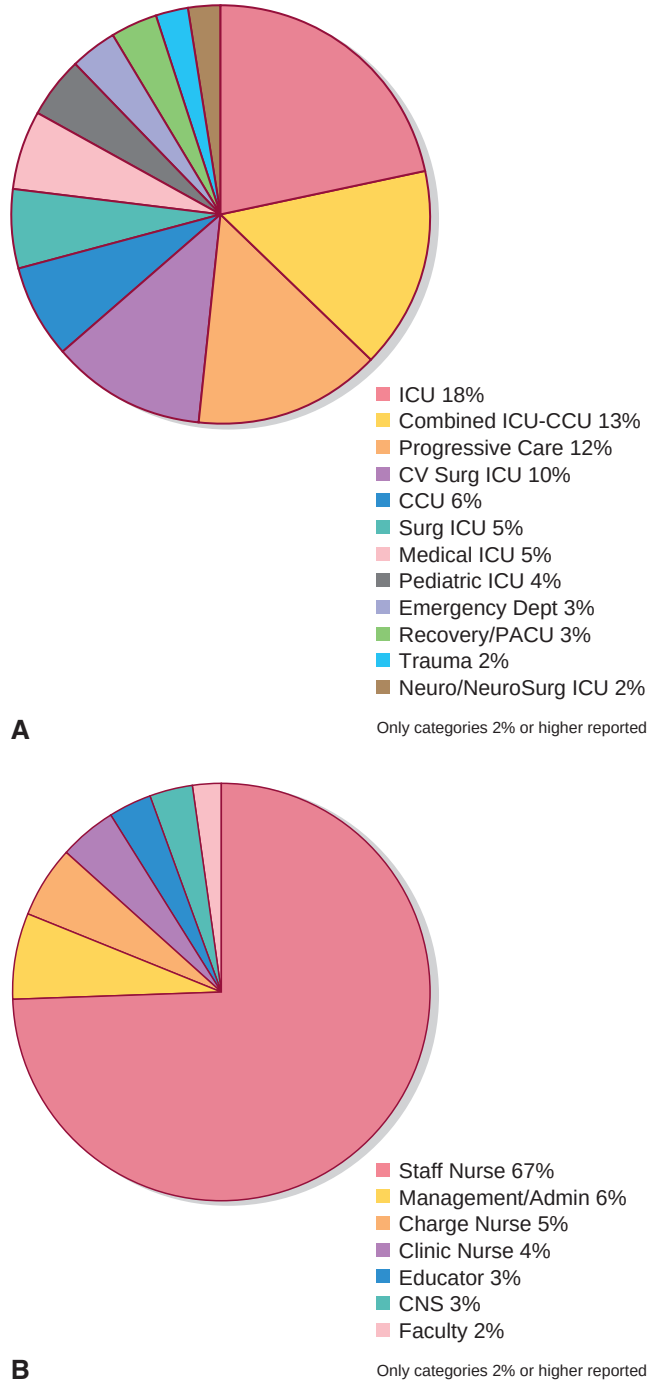

FIGURE 9-2 ▲ Who are critical care nurses? **A**: Practice settings for critical care nurses. **B**: The positions held by critical care nurses. (From American Association of Critical-Care Nurses: 2010 Demographics. Retrieved June 1, 2010, from http://www.aacn.org.)

The remaining top categories make up less than 4% of the total and include the emergency department, recovery room/postanesthesia care unit, trauma unit, and neuro/neurosurgical ICU (Fig. 9-2A).[3] The vast majority of the AACN members surveyed (67%) have positions providing direct care as staff nurses (see Fig. 9-2B). The AACN membership data are consistent with the average findings of Kirchhoff and Dahl's[5] national survey of facilities and units that provide critical care. Their study revealed that 74% of the facilities participating in the study were nongovernment, not-for-profit organizations with a mean of 217 operating beds and 13,000 admissions per year.[5]

▲ Defining Nursing Professionalism

The struggle to define nursing professionalism expands beyond critical care environments. There continues to be on going dialogue about whether nursing is a true profession. For more than two decades, Kelly emphasized that the status of nursing as a profession is important because it reflects the value society places on the work of nurses.[6] However,

some think that because entry into nursing practice does not require a baccalaureate degree, it is, at best, an emerging profession that requires new models of nursing education.[7] Such new models, the clinical nurse leader and doctorate of nursing practice, are believed to help ensure quality patient outcomes and patient safety.[7,8] However, others believe that the nursing profession has made adequate progress to meet full-fledged professional status with current models of nursing education.[9]

One of the first definitions of professionalism came from Abraham Flexner,[10] who wrote the classic Flexner Report in the early 1900s to reform medical education. Flexner defines professionalism as a process by which an occupation achieves professional status. Although other professions have developed their own criteria, Flexner's work remains the benchmark and foundation for many. In 1981, Kelly was the first to expand his work for the nursing profession by providing a theoretical framework from which professional nursing characteristics are defined today[6] (Box 9-1).

To a great extent, the criteria addressed by Flexner and Kelly are only as good as the person who takes personal responsibility and accountability for committing to a professional role. One legendary nurse leader, Margretta Styles, argued that professionalism of nursing can only be achieved through the "professionhood" of its members.[7] Like Kelly, Styles believes there must be a sense of social significance, commitment to the ultimacy of professional performance, and appreciation of collegiality and collectivity.[7] However, as Styles approached the end of her nursing career, she proposed a new term to phrase the work of nurses: *professionalist*.[7] In her words, "professionalists strive to build a solid foundation for their calling—an ethical, academic, political, and socioeconomic foundation to serve as the underpinning for a strong profession to evolve and serve." (p 89)[7]

Researchers have investigated how to describe professionalism among critical care nurses as well. In 1994, Holl[11] investigated such critical care nursing characteristics as professional beliefs, decision making, level of education, membership of professional nursing organization, and certification. Holl[11] found that nurses who continue their education and belong to professional organizations are more likely than others to be independent thinkers and to participate in creative problem solving. In a similar study, Heath et al[12] found that there was a high level of "passion about nursing and promoting the profession" and that self-motivation was the leading influential factor for fostering individual professional development among critical care nurses. Other professional development characteristics evaluated included participation in employing agency committees, community service, and recognition of peers.[12] Of note, several of the professional characteristics initially identified by Kelly and studied by others[13,14] are identified in this chapter as hallmarks of excellence for critical care nursing practice.

BOX 9-1 Kelly's Characteristics of a Profession

- The services provided are vital to humanity and the welfare of society.
- There is a special body of knowledge that is continually enlarged through research.
- The services provided involve intellectual activities where accountability is a strong feature.
- Practitioners are educated in institutions of higher learning.
- Practitioners are motivated by service, and work is an important component of their lives.
- There is a code of ethics to guide the decisions and conduct of practitioners.
- There is an association that encourages and supports standards of practice.

▲ Defining Nursing Excellence

The term *excellence* can be a misnomer similar to the expression *best practice*. No single definition captures the essence of excellence for everyone. For some, it is something that is seen, heard, or felt that describes excellence in nursing. For example, the way a critical care nurse sees a patient going "bad" before laboratory values or hemodynamic numbers are known may be evidence of excellence. Other descriptions of excellence may be the way a critical care nurse hears an S_3 or S_4 heart sound before a patient becomes symptomatic, or the way a critical care nurse "feels" the pain of a postoperative patient on neuromuscular blockade without analgesics.

Weston et al[15] define nursing excellence as a dynamic process that is continually redefined and reinforced. They further describe excellence as an ongoing comparison with a standard that one continuously tries to improve.[10] Six attributes for advanced-practice nursing excellence have been identified by Weston et al[15] as values, vision, mastery, passion, action, and balance. These attributes have been adopted and modified for this chapter to propose a professional practice model for critical care nursing (Fig. 9-3). The foundation for this model consists of strong values and a vision. The supporting structures of the model are composed of mastery, passion, action, and balance. The top of the model captures the essence of the structure: critical care nursing excellence. Each structure of the professional practice model has defining characteristics that are instrumental for ongoing self-reflection, which is necessary to develop and commit to excellence in critical care nursing.

Values

CASE STUDY

"Our lives begin to end the day we become silent about things that matter." (Martin Luther King Jr.)[16]

Reflection on "Values" for Critical Care Nursing Excellence

"A group of nurses, participating in a focus group for the AACN-VitalSmarts Silence Kills Study, describe a peer as careless and inattentive. Instead of confronting her, they double check her work—sometimes running into patient rooms to retake a blood pressure or redo a safety check. They have

(*continued on page 102*)

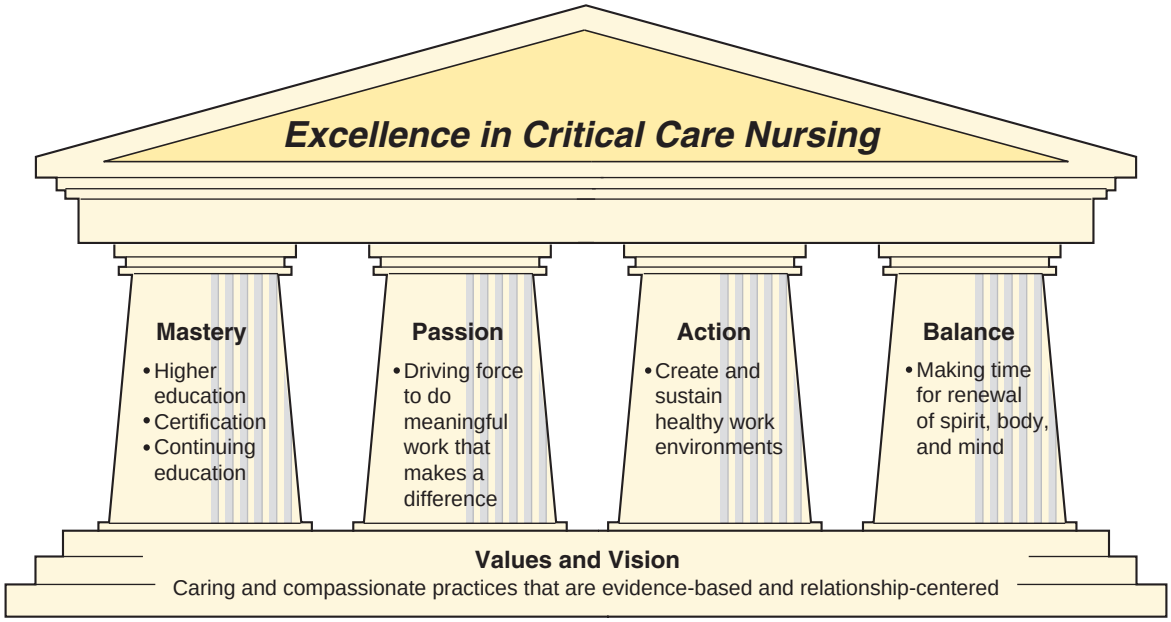

FIGURE 9-3 ▲ A professional practice model for critical care nursing.

'worked around' this nurse's weaknesses for over a year. The nurses resent her but never talk to her about their concerns, nor do any of the physicians who also avoid her and compensate for her." (p 2)[17] Further data reveal that out of 1,700 health care providers and administrators throughout U.S. hospitals, 84% of physicians and 62% of nurses and other clinical care providers have seen coworkers taking shortcuts that could be dangerous to patients.[17] McCauley summed the significance of the study well by stating, "This research (Silence Kills) validates what our 100,000 constituents have communicated to us as the number one barrier hindering optimal care for patients. Too often, improving workplace communications is seen as a 'soft' issue—the truth is, we must build environments that support and demand greater candor among staff if we are to make a demonstrable impact on patient safety."[18]

Do you value communication about competence and accountability? Do you value having a healthy work environment where skilled communication protects patients and fosters collaborative relationships? What are your values to foster care nursing excellence and make a difference in the lives of the acute and critically ill?

True excellence is seen when professionals reflect their core values. The values of one's profession, the values of one's employing organization, and one's own personal values are the behaviors that guide professional practice for excellence. The unique contributions that critical care nurses bring to the bedside are often a reflection of an inner core value of caring. It is this deep and personal connection to caring that brings many into the nursing profession. The word *nursing* is derived from the Latin word *nutrire*, which means "to nourish." The term *nurturing* describes an ability to care for, sustain, and provide for another. Critical care nurses are privileged to care for individuals who face life-threatening conditions during the most vulnerable and private times of their lives. It is through this value of altruism (the desire to help others) that critical care nurses have the ability to creatively bridge high-tech and high-touch with everyday practice.

The everyday busyness of critical care nursing is labor intensive, but taking the time to share joyful, painful, and tearful experiences with complex patients and families is the core of critical care nurses' existence. The art of nursing is probably what dominates the image of nursing for the public. For 8 years in a row, Gallup polls have reported that the public rates nursing as the most honest and ethical profession.[19] In their book *From Silence to Voice*, Buresh and Gordon[2] reported that the Gallup poll results about nurses reflect a paradox. As nonnurse authors, they discuss how the public holds nurses in the highest regard, even though the public has limited information about the science that nurses really practice.[2]

There is power in the nursing profession when nurses articulate not only the core values of caring but also evidence-based practice, advocacy, accountability, autonomy, and collaboration. It is now well established that nurses have been silent for too long and that the days of "It is just my job" or "I am just a nurse" need to come to an end.[2,17,20] Themes such as AACN's "Powered by Insight," "Reclaim our Priorities," "With Confidence," and "Act with Intention" help empower nurses to make their voice heard for their patients, families, and profession.[21–24] Strong personal and professional core values at AACN (Box 9-2) inspired a nine-person panel to develop the AACN Healthy Work Environment Standards to help address work environments that tolerate ineffective interpersonal relationships resulting in medical errors, ineffective delivery of care, and conflict and stress among health professionals.[20] Creating and sustaining healthy work environments ensure safe patient care and set a path toward the AACN core value to "commit to quality and excellence."[25]

BOX 9-2 Core Values: American Association of Critical-Care Nurses (AACN)

- **Be accountable** to uphold and consistently act in concert with ethical values and principles.
- **Advocate** for organizational decisions that are driven by the needs of patients and families.
- **Act with integrity** by communicating openly and honestly, keeping promises, honoring commitments, and promoting loyalty in all relationships.
- **Collaborate** with all essential stakeholders by creating synergistic relationships to promote common interest and shared values.
- **Provide leadership** to transform thinking, structures, and processes to address opportunities and challenges.
- **Demonstrate stewardship** through fair and responsible management of resources.
- **Embrace lifelong learning,** inquiry, and critical thinking to enable each to make optimal contributions.
- **Commit to quality and excellence** at all levels of the organization, meeting and exceeding standards and expectations.
- **Promote innovation** through creativity and calculated risk taking.
- **Generate commitment and passion** to the organization's causes and work.

Vision

CASE STUDY

"There is no power greater than a community discovering what it cares about." (Margaret Wheatley)[16]

Reflection on "Vision" for Critical Care Nursing Excellence

What would a reality show film crew see if they followed you for a day? Someone focused and intentional in his/her actions? Or an endless string of hit-and-runs? "Intention is the why." It's the reason we do something. When our intentions are straightforward and confident, we carry them out because we know they will keep our patients safe and lead to best outcomes. Sometimes our intentions are clear-cut. Caring for someone with a gastrointestinal hemorrhage has three initial goals: Find the bleed. Stop the bleed. Replenish volume loss. Lack of intention has obvious negative consequences. Inability to tolerate an endoscopy delays finding and stopping the bleed. A clotted type and cross sample delays blood replacement. An overwhelmed family requires additional information and refocused energy.

Other times, intentions aren't so clear. Caring for someone with acute coronary syndrome makes you stop and ask questions like "Why do patients wait so long to come to the hospital" and "What stops nurses and docs from getting that first ECG, initial blood samples, and a focused history during the critical first 10 minutes?" When we step back and take in the bigger picture, our intentions become clear.

Do you remember Yoda, the character from the movie *Star Wars*? Diminutive, pointy ears, greenish hue, very wise. "Do or do not," he said, "There is no try." (p 22)[24]

Beth Hammer, RN, MSN, APRN-BC, Past President of AACN, Act with intention and speak with a bold voice.

Do you have a vision to act with intention and live that vision in all of your actions? Do you have a vision to have a bold voice for a culture in which people hold themselves and others accountable to professional standards and collaborative relationships? What is your vision to foster nursing excellence and make a difference in the lives of the acute and critically ill?

A clear vision, based on core values, is essential to building a professional practice model of critical care nursing excellence. It requires envisioning the future's possibilities and then taking the challenge of making the vision a reality. In 2001, the AACN made a strategic decision to promote the creation of healthy work environments that embrace a culture of excellence when taking care of acute and critically ill patients.[20] Based on the escalating evidence from the Institute of Medicine and the Joint Commission about unhealthy work environments and how they contribute to medical errors, the AACN had a vision to propose solutions to improve patient safety.[26–28] Through a partnership with VitalSmarts, a national study was conducted to evaluate communication and collaboration challenges among hospital providers of care. The findings of the study resulted in the need to develop standards addressing six essential areas: skilled communication, true collaboration, effective decision making, appropriate staffing, meaningful recognition, and authentic leadership.[20]

As risk takers and agents for change, today's critical care nurses are making history by embracing the AACN Healthy Work Environment Standards. Winston Churchill once said, "The pessimist sees difficulty in every opportunity and the optimist sees the opportunity in every difficulty."[16] It is challenging to create and sustain work environments of excellence, especially when there are concerns about nurse-to-patient ratios, mandatory overtime, unionization, nursing recruitment, and retention. It is also difficult to provide critical care nurses with the tools, resources, and support they need to meet patient and family needs effectively and at the same time enhance their own professional growth, learning, and satisfaction. Nursing has a long tradition of taking "bumpy" roads to make a vision reality. No matter how many times nurses fall down and get bruised on the way to reach a vision, they maintain their resilience by having the courage to listen, learn, and act for themselves, their patients, and their professional practice.

Mastery

CASE STUDY

"Education is our passport to the future, for tomorrow belongs to the person who prepares for today." (Malcolm X)[16]

Reflection on "Mastery" for Critical Care Nursing Excellence

"At 3:30 AM in a busy ICU, a nurse prepares to give insulin to a patient with an elevated blood glucose level. The sliding scale doses of insulin on the medication sheet are unclear, and the physician's order sheet is difficult to read. From past experience, the nurse knows how late night calls to this physician often result in verbal outbursts and demeaning slurs, no matter how valid the inquiry. Needing to act but not wanting another harassing encounter with the physician, she makes a judgment of the appropriate dose and administers the insulin. Two hours later, she finds the patient completely unresponsive. To treat the critically low blood glucose level, she administers concentrated injections of glucose and calls for additional emergency help. Despite all attempts to restore the patient's brain to consciousness, he never awakens and his brain never functions normally again." (p 10)[20] Barden summed this scenario well by stating, "Nurses must be as proficient at handling personal

(*continued on page 104*)

communication as they are in clinical skills. A culture of safety and excellence requires that individual nurses and healthcare organizations make it a priority to develop communication skills that are on par with expert clinical skills."[18]

What mastery of knowledge and skills have you achieved to stop verbally abusive behavior in the workplace? What mastery of knowledge and skills have you achieved to seek solutions that preserve a nurse's personal integrity and ensure a patient's safety? What are you mastering to foster nursing excellence and make a difference in the lives of the acute and critically ill?

Studer,[29] author of *Hardwiring Excellence*, believes that excellence in health care occurs when "employees feel valued, physicians feel their patients are getting great care, and patients feel the service and quality they receive are extraordinary." (p 45) Studer[29] further believes that creating and sustaining a culture of excellence requires the willingness to take individual ownership (be an owner, not a renter of an organization) of problems and opportunities. To value lifelong learning and to have a vision for personal mastery is essential to building a professional practice model for critical care nursing excellence (see Fig. 9-3). There are many pathways for personal mastery. Weston et al[15] believe that seeking feedback and peer review for self-improvement is one of the most effective pathways for building mastery. Other pathways for personal mastery include seeking a degree in higher education, making a commitment to ongoing continuing education, and demonstrating competence through certification. The rewards of mastery often go beyond these pathways. Mastery combines expert professional skills with leadership and interpersonal and organizational proficiency and often leads to the most coveted role of all, the role of mentoring.

The importance of demonstrating personal mastery of knowledge and skills can also be seen in the mounting evidence about how poor communication and lack of collaboration among health care professionals contributes to medical errors and staff turnover.[17,26,27] The Silence Kills Study revealed that 88% of physicians and 48% of nurses and other providers work with people who show poor clinical judgment, and unfortunately, fewer than 10% of them confront their colleagues about their concerns.[17] Avoiding crucial conversations about incompetent or inappropriate practices such as observing violation of infection standards or verbal abuse impairs patient safety and impedes quality care. It is essential that critical care nurses achieve the personal mastery of knowledge and skills that promote high-quality health care delivery and patient safety.

To emphasize the importance of validating clinical competency, on December 11, 2002, a compelling white paper on the benefits that specialty certification brings to the public, employers, and nurses was released.[28] The document, *Safeguarding the Patient and the Profession: The Value of Critical Care Nurse Certification*, raises awareness about the responsibility nurses have to honor and validate the public's trust for patient safety. The AACN believes that certification validates competency of knowledge, skills, and experience for quality patient care.[28] Consumers of nursing services must be able to recognize the contributions critical care nurses make to ensure high-quality and competent care to patients and families.

Barden (2003)[30] believes that there should be two types of critical care nurses at the bedside: (1) those who are certified, and (2) those who are in the process of becoming certified. Certification is a process of achieving the highest recognition of excellence. It is more than "another initial"[31]; it is a mark of excellence that can be referred to as "the Good Housekeeping Seal of Approval." Credentials on name badges, such as CCRN (critical care registered nurse), PCCN (progressive care certified nurse), or CCNS (clinical nurse specialist in acute and critical care), make personal mastery visible to the consumer and ensure public protection.

Since 1975, the AACN Certification Corporation has promoted and enhanced mastery of patient health and safety by certifying and recertifying nurses in the care of acute and critically ill patients.[32] Throughout the United States and Canada, nurses have received more than 410,000 certifications in 134 specialties. A total of 67 different certifying bodies granted these certifications and use at least 95 different credentials.[33] Currently, there are more than 40,000 certified critical care nurses with the credentials of CCRN, PCCN, CCNS, CMC (cardiac medicine certification), CSC (cardiac surgery certification), ACNPC (acute care nurse practitioner), or CNML (certified nurse manager and leader).[32]

Achieving a culture of excellence requires meaningful recognition of achievements such as mastery of certification.[20,28] Cary[33] reported four avenues through which certification status can be recognized: public acknowledgment, financial compensation, career advancement, and retention. In addition, findings revealed that there is a perception, especially among newly certified nurses, that certification gives autonomy, enhances collaboration with other health care providers, allows control over practice, and results in higher patient satisfaction ratings.[33]

A growing body of knowledge related to the value of specialty certification in critical care is being developed to determine the effect of certified nursing practice. Fitzpatrick et al[34] recently found AACN-certified nurses with higher empowerment scores were less likely to leave their current position, which demonstrates the importance of administrative support for certification. Kirchhoff and Dahl[5] found that 42% of CCUs provided public acknowledgment of certification and that 25% provided financial compensation with a certification bonus, whereas Ulrich and colleagues reported less support for an initial certification bonus (13.8%) and slightly higher support for certification recognition (45%) among critical care nurses.[35]

Passion

CASE STUDY

"Perpetual optimism is a force multiplier." (General Colin Powell, U.S. Army, retired, and former Secretary of State)[16]

Reflection on "Passion" for Critical Care Nursing Excellence

Excerpt from Dave Hanson RN, MSN, CCNS 2009 AACN President Speech: "Reclaiming our Priorities"

Throughout history it has been proven that one person, courageous and determined, can be the catalyst for great and lasting change. One person. Florence Nightingale. Rosa Parks. Martin Luther King, Jr. You know these names. You know the history they've made. You know their courageous

(*continued on page 105*)

acts and the priorities they reclaimed to change the course of the world we live in. Let me introduce names you may not know yet... Anne Marie McCarthy. One person. One nurse who has learned how to build good relationships with the family members of her patients, even the most difficult ones. When the staff nurse advisory team members were sharing their stories about how challenging some of their patients' families are to deal with, Anne Marie shared her approach: "I make it a point to meet my families at the door of the ICU. I introduce myself, being sure to shake their hands. Then I share with them the care plan for the day, what I think they can expect and how they can play a role in achieving the day's goals. I confidently assure them that I'm going to take really good care of their loved one. Since I started approaching families proactively like this, it seems as if they don't get in the way anymore. In fact, they often help me. Now, I actually ask for patients with the most difficult families." (p 6)[22]

Do you have a passion to reclaim your priorities and influence the care of patients and families by putting their care first regardless of the challenges? Do you have a passion to follow and/or lead evidence-based and relationship-centered initiatives at your organization? What are you passionate about to foster nursing excellence and make a difference in the lives of the acute and critically ill?

Just as a link is seen between values, vision, and mastery, passion is the essential thread to link together all the professional practice attributes for critical care nursing excellence (see Fig. 9-3). Passion involves enthusiastically striving for what is best for ourselves and those we serve. In *You Are the Leader You've Been Waiting for,* Klein described how to enjoy high performance and high fulfillment at work by being passionate about your calling or purpose.[36] He stated, "When your values, gifts, and calling operate in unison your work has a sense of inner congruence and outer effectiveness. You are clear about who you are and enjoy the ways in which you bring your gifts to life through your work." (p 119)[36] Similarly, others believe passion fuels results so that there is a "flywheel" effect, building in momentum with every step, action, decision, and turn.[36,37]

Weston et al[15] stated that "passion involves ardently striving for the best, even when repeated efforts seem tedious or appear exceedingly strenuous." (p 310) The truly passionate critical care nurse is not satisfied with providing less than the highest quality care possible to patients and families. Achieving this goal often requires going beyond an 8- or 12-hour shift. Acts of passion for critical care nursing excellence can be seen in bringing the latest research findings to the bedside, revising unit policy and procedure books with the most up-to-date procedures, and teaching coworkers the most effective therapies to produce the best outcomes for patients and families. Acts of passion for critical care nursing excellence can be seen when people take ownership to become engaged and transform work environments so that they are respectful, healing, and humane.

Passion can be felt in critical care nursing not only at the bedside but throughout the profession. Nursing leaders in critical care are partnering with interdisciplinary groups and talking to legislators to improve patient safety issues such as the workforce shortage, computerized physician and provider order entry, intensivist models of practice, evidence-based practice, and appropriate staffing. Being passionate about something requires time, energy, and commitment. The journey to excellence for healthy work environments started in 2001 for AACN because leadership was passionate about its mission of providing the highest-quality resources to maximize nurses' contribution to caring and improving the health care of critically ill patients and their families.[20]

In *Good to Great,* Collins describes why some organizations make the leap and sustain the leap from being a good organization to a great organization.[37] He challenges people and organizations to pick up their rocks and look at the "ugly squiggly things" underneath them, rather than putting the rocks back down and covering them up. Using resources from AACN, critical care nurses are picking up their rocks and addressing the "ugly squiggly things" in their workplace environments that impede quality patient care. Acts of passion for healthy work environments are taking place as the AACN standards for skilled communication, true collaboration, effective decision making, appropriate staffing, meaningful recognition, and authentic leadership are established.[20]

Action

CASE STUDY

"We are what we repeatedly do. Excellence then is not an act but a habit." (Aristotle)[16]

Reflection on "Action" for Critical Care Nursing Excellence

Excerpt from Mary Fran Tracey RN, PhD, CCNS, CCRN, FAAN 2007 AACN President Speech: "Empowered by Insight"

Our role is not simple. Our patients are really sick. We don't work on an assembly line doing exactly the same thing every day, knowing exactly what the result of our actions will be. Our patients count on us to maintain good judgment and the energy we need to be a part of solving our most complex problems. We can't fulfill this promise if we are allowing ourselves to work in constant crisis mode. It will take some doing to build in that much-needed slack time in our organizations. In the meantime, we must immediately begin employing a new strategy to maintain our good judgment every day. I call it stopping for a "thought pause."

A thought pause requires us to take a moment to *think* rather than *do*. To use our knowledge and the knowledge of our colleagues. To ask the right questions before we take action—especially high-risk actions like giving medications. To rise above the task for a moment.

We are not cogs in a machine. We are not a service that just comes with the bed. We as nurses are the creators and sharers of insights that ensure our patients' wishes are honored—that they are not in pain and that they are better for the care we provide. (pp 3,4)[23]

What action have you taken from a powerful insight to ensure safety becomes the norm and excellence the goal for managing the care of patients and their families? When was the last time you took time to think before taking action? What action will you take to foster nursing excellence and make a difference in the lives of the acute and critically ill?

Florence Nightingale once said, "One's feelings waste themselves in words, they ought all to be distilled into action which brings results." (p 44)[38] In other words, part of professionalism in critical care nursing is "to walk the talk" for excellence. As values, vision, mastery, and passion for critical care nursing excellence build, the attribute of action (see Fig. 9-3) becomes another essential pillar for the framework and one that resonates well for tangible results in critical care. Recognizing that so many vulnerable patients' lives are at risk and the invaluable contributions that nurses make, the AACN leadership decided it was time to act deliberately and definitively. In 2003, AACN launched the Beacon Award for Critical Care Excellence, an award specifically designed to recognize the leading critical care units in the United States.[39] Currently, more than 315 critical care units have been recognized for demonstrating high-quality standards, exceptional care of patients, families, and healthy work environments. Of those units, 41 have received the Beacon Award more than twice.[40]

When the Beacon Award was first launched, a *beacon* was defined as "a source of light, an inspiration, or signal of guidance" with the belief that "every critical care unit could be a Beacon unit."[40] Since that time, the 42-item Beacon application has been modified to a new application with 38 items, and any hospital unit that has high acuity and critically ill patients and meets evidence-based standards of excellence and patient safety is now eligible to apply. Although the new application includes three levels (bronze, silver, and gold) for units to chart their journey and receive a 3-year designation, the Beacon application continues to address innovation, excellence, or both in six categories: recruitment and retention; education, training, and mentoring; evidence-based practice and research; patient outcomes; creating and promoting healing environments; and leadership and organizational ethics. In addition, the Beacon Award provides a mechanism for individual and collective critical care units to measure progress against evidence-based initiatives and national criteria for performance, learn and refine their processes and systems, and be recognized for their achievements.[39] What bolder action or stronger message can be conveyed to the public and the patients whom critical care nurses serve than to validate excellence in practice?

Seeking opportunities and partnerships to further extend action to ensure optimal health outcomes for individuals experiencing an acute and life-threatening illness requires a relentless and fearless voice by critical care nurses. These nurses have been using their innate gift of inquiry for decades to tackle patient care issues. However, Nightingale is perhaps nursing's most famous leader who first used research to change practice.[38] Even though she lacked the theoretical bases that are known today, she had a core set of values, a vision, the mastery, and a passion to improve England's hospital care in the mid-19th century. Today, critical care nurses are seeing "sacred cows" that were once revered being thrown out of practice. For example, nursing research has well demonstrated that using dye in enteral feeding, restricting family presence during cardiopulmonary resuscitation, and restricting visitation hours in ICUs need to be eliminated from practice.

Even though new models of nursing education are evolving, it does not take a doctorate-prepared critical care nurse to raise questions and put a plan in place for collecting, analyzing, and reporting patient and family outcomes. Outcome-based practice is the responsibility of all nurses, whether one is actually doing the research, disseminating the research to the bedside, or reporting the research findings. In addition, it is important for all nurses to celebrate and showcase high-quality nursing outcomes, no matter what nursing specialty provided the body of knowledge. Focusing on quality indicators and performance improvement in acute and critical care settings as daily practice is a bold and powerful action for improving patient care.

This is the commitment and voice that needs to be heard about critical care nursing. Practice alerts from AACN are another example of efforts to prevent and minimize infection, reduce complications from critical illness, promote patient safety, and establish best practices. First launched in 2004, the AACN practice alerts are succinct dynamic directives that are well supported with current authoritative evidence to ensure best practice. There are more than a dozen practice alerts that (1) bridge the gap between practice and research, (2) provide guidance, (3) standardize care, and (4) identify and inform new trends and provide information about them.[41] A few recent practice alerts include oral care in the critically ill, noninvasive blood pressure monitoring, and severe sepsis.[41] Because critical care nurses have a great opportunity to promote the science of nursing through the AACN practice alerts, it is helpful to remember that "the public cannot protect a social resource that it does not know and understand; only nurses can give the public the knowledge and understanding necessary to protect human care giving." (p 42)[2]

Balance

CASE STUDY

"Balance isn't either/or, it's AND." (Steven Covey)[16]

Reflection on "Balance" for Critical Care Nursing Excellence

Excerpt from Caryl Goodyear-Bruch RN, PhD, CCRN 2009 AACN President Speech: "With Confidence"

With purpose come all kinds of possibilities for taking confident actions that matter to our patients. CCRN Marie Lasater recently wrote a short article for the *American Journal of Nursing* describing a difficult day on her step down unit. She vividly described the patients, the realities of our health care system and of her decision to prioritize being with a dying patient who was alone, without family. She wrote: "I have six patients this morning. One with a self-inflicted gunshot wound to the head who's expected to die on my shift. Two with recent strokes, one with a lumbar drain after back surgery, and one with a possible prion disease. Because of a sick call, we have only one patient care technician for 20 patients. I will be doing total patient care... As I'm paging the physician [regarding another patient]... I get a page that the oxygen saturation level of my dying patient is dropping. I race to don protective gear and help my stroke patient to the bedside commode and back to bed. I then check on my dying patient. I hold his hand for a moment. As I'm telling him he is in a safe place, that his family is safe, and that people care about him, I'm paged again. I'm getting another admission. I have been at work for an hour and 15 minutes, but I haven't even begun to give scheduled medications. We were recently told that we will be 'counseled' if we clock out late from our shifts. I tell the unit secretary I will be in my dying patient's room and ask the other nurses to handle my pages. I hold my patient's hand and keep repeating, 'I'm here'." (pp 3,4)[24]

How confident are you to put balance in your professional and personal life for renewal? When was the last time you had full presence with a dying patient in the midst of a chaotic workday? How will you start balancing your life to foster nursing excellence and make a difference in the lives of the acute and critically ill?

Balance is the final component of the professional practice model for critical care nursing excellence (see Fig. 9-3, p. 102). Balance can bring renewal to the spirit and allow for more moments of "full presence," which often breaks down in our busy professional and personal lives. Taking the time to care for one's self is essential to keeping the body and mind in balance. Otherwise, it can be difficult to keep perspectives clear. Today, nurses are increasingly blurring the lines between home and work and work and leisure. The lines of communication are continuously open because of the proliferation of pagers, cell phones, facsimile machines, text messages, e-mail, and voicemail. It is time to say "no" to being "supernurse" and "supermom" or "superdad" and find the time to take care of oneself. Nurses do not do their patients, their families, or themselves any good if they consistently place the needs of others above their own. Critical care nurses listen to patients and families 24 hours a day, 7 days a week. They must also have time to listen to their own minds and hearts and those who love them most.

In *You Are the Leader You've Been Waiting for,* Klein stresses the importance of letting go.[42] He believes letting go of the old can make space for something new. It is during a time of transformation that he believes one should not act but be still.[42] Nurses cannot stop the beeps, alarms, and phone calls at work, but when the shift is over, it is time to "let go." As difficult as it may be, it is time for nurses to let go of the complex, vulnerable, and unstable patients who were in their hands during their shift. It is a time to be "still;" nurses may turn the television off and read to the children, take a leisurely walk with a pet, or sit quietly listening to the sounds of life. The minds and hearts of nurses need time to renew and be recharged for the next day of taking care of critically ill patients and their families. When nurses are balanced, it is easier not to give in to the cynicism and frustration that abound in the workplace or home. To be truly engaged and energized requires nurturing oneself first and then empowering others to do the same. Look around your unit today and ask yourself some questions. Who are the critical care nurses who reach out to others the most? Who are the critical care nurses who smile the most? Who are the critical care nurses who say "thank you" and give compliments the most? You may find that your answer is with nurses who have discovered how to make balance a priority in their professional and personal lives.

BOX 9-3 Closing Thoughts on Critical Care Nursing Excellence

REMEMBER… Ready or not, someday it will all come to an end.
There will be no more sunrises, no shift work, no change of report.
All the things you valued, whether treasured or forgotten, will pass to someone else.
It will not matter what you owned or what you were owed.
Your challenges, frustrations, and disappointments will finally disappear.
So too your hopes, ambitions, and plans.
What will matter is not your success, but your significance.
What will matter is not what you learned, but what you taught.
What will matter is every act of integrity, compassion, courage, or sacrifice that enriched, empowered, or encouraged others to emulate your example of critical care nursing excellence.
Living a life that matters doesn't happen by accident.
It's not a matter of circumstance but of choice.
Live your contribution and choose to live a life that matters.
Become engaged and transform your practice for critical care nursing excellence

Modified from Josephson M: What will matter. Retrieved June 1, 2010, from http://www.charactercounts.org

▲ Conclusion

In today's fast-paced critical care environment, finding the time for professional growth can be challenging yet rewarding (Box 9-3). Building a professional practice of excellence requires a passion to profoundly affect the lives of those who trust critical care nurses most: complex, unstable, and vulnerable patients and their families. At the same time, it requires advancing the critical care nursing profession through a healthy work environment that is patient centered, collaborative, interdisciplinary, and evidence based. The desire and commitment for critical care nursing excellence requires self-reflection about the values, vision, mastery, passion, action, and balance in one's practice (see Fig. 9-3, p. 102). Critically ill patients and their families expect and deserve nothing but the best care.

Building a professional practice model of excellence can give critical care nurses the confidence to use their bold voice and presence to make significant contributions for improving the delivery of care to the patients and families who have entered a chaotic and frightening world of illness, trauma, and pain. Even in the fastest-paced critical care environments of today, finding the time for professional growth is challenging but, as evidence demonstrates, essential. For the profession of critical care nursing to advance, nurses must acquire the necessary clinical experience and competencies to provide best practice models of care for critically ill patients and their families. Whether it is participating on a patient safety hospital committee or recruiting youth to critical care nursing, endless opportunities exist for building a professional practice of excellence. The days of landmark studies reporting that nursing is a silent and unknown profession[43,44] will soon come to an end as more bold and committed voices are heard about excellence in critical care nursing practice.

▲ Clinical Applicability Challenges

SHORT ANSWER QUESTIONS

1. How can nurses speak up boldly about a model of practice for critical care nursing excellence that optimizes the contributions they make in the lives of acute and chronically ill populations, families, and systems?
2. How would patients and families identify an inner core value of clinical competence among critical care nurses at the bedside?
3. What would a potential new hire critical care nurse think about a health care organization that requires name badges to carry all nursing credentials including certification?

PART 3

Special Populations in Critical Care

10

The Critically Ill Pediatric Patient

Patricia A. Moloney-Harmon

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Analyze anatomical and physiological differences in the infant and child that necessitate the modification of physical assessment parameters and intervention techniques.
2. Describe special considerations in ventilatory management and medication administration for the critically ill child.
3. Evaluate pain assessment tools that can be used for the critically ill child.
4. Examine important aspects of interaction with the critically ill child and family that will enhance interventions.

Many critical care clinicians feel ill equipped to care for children seen in adult intensive care units (ICUs), emergency departments, procedural suites, and recovery rooms. To facilitate smooth and optimal care of the critically ill child, it is wise to adopt a framework for the modification of the adult critical care practice to include the pediatric patient. A comprehensive framework is beyond the scope of this chapter, but readers are referred to the PEDS framework, discussed in more detail elsewhere.[1] This chapter highlights prominent anatomical and physiological differences and related implications, equipment selection, recognition of the decompensating child, and unique challenges in caring for the pediatric patient in a critical care environment.

▲ Prominent Anatomical and Physiological Differences and Implications

Vital Signs

Infants and young children have an age-appropriate, but higher, heart rate and respiratory rate than adults. The higher heart and respiratory rates assist in meeting the need for a higher cardiac output, despite a smaller stroke volume and a higher basal metabolic rate. Blood pressure in children is lower than that of adults. Vital signs (Table 10-1), although important parameters, should not be evaluated in isolation but rather in a trending fashion.

Tachycardia is a nonspecific response to a variety of entities, such as anxiety, fever, shock, and hypoxemia. Although the child is predisposed to bradycardia, tolerance is poor. Persistent bradycardia produces significant changes in perfusion because cardiac output is heart rate dependent. Bradycardia is most often caused by hypoxemia, but any vagal stimuli, such as suctioning, nasogastric tube insertion, and defecation, may precipitate an event.

As for respiratory rate, an infant or child increases his or her respiratory rate to compensate for an increased oxygen demand. Tachypnea is often the first sign of respiratory distress. A slow respiratory rate in a sick child often indicates impending respiratory arrest. Associated conditions, such as fever and seizure activity, which further increase the metabolic rate, also increase oxygen requirements. These conditions can cause rapid deterioration in an already compromised child.

Table 10-1 Pediatric Vital Signs

Age	Heart Rate (beats/min)	Respirations (breaths/min)	Systolic Blood Pressure (mm Hg)
Newborn	100–160	30–60	50–70
1–6 wk	100–160	30–60	70–95
6 mo	90–120	25–40	80–100
1 y	90–120	20–30	80–100
3 y	80–120	20–30	80–110
6 y	70–110	18–25	80–110
10 y	60–90	15–20	90–120
14 y	60–90	15–20	90–130

Unlike the adult, the child's blood pressure is the last parameter to fall in the face of shock. Children can compensate for up to a 25% blood loss before the systolic blood pressure falls. A normal blood pressure should never discourage interventions for the child showing signs of circulatory failure. The pulse pressure is often a more reliable indicator for assessing the adequacy of perfusion. Hypertension is uncommon unless the child has renal disease.

Neurological System

Brain growth occurs at a rapid rate during the first few years of life. Because brain growth is rapid during this time, measurement of head circumference is important in the child until 2 years of age. The circumference of the child's head is related to intracranial volume and estimates the rate of brain growth.

The child's cranial sutures are not completely fused until 18 to 24 months of age. The posterior fontanelle closes by 3 months of age, and the anterior fontanelle closes by 9 to 18 months of age. The fontanelles provide a useful assessment tool in the infant. The characteristics of the fontanelles can be used to assess hydration status or the presence of increased intracranial pressure (ICP). Bulging fontanelles may indicate increased ICP or fluid overload. Sunken fontanelles may be seen with fluid deficit.

Like adults, infants and children have protective reflexes (eg, the cough and gag reflexes). There are also several newborn reflexes (ie, the Moro, rooting, grasp, and Babinski reflexes), which differ from adult reflexes. For example, the Babinski reflex is present until 9 to 12 months of age or until the child starts walking. A positive Babinski reflex response (fanning of the toes and dorsiflexion of the big toe when the lateral aspect of the sole of the foot is stroked) is expected in an infant, yet is considered an abnormal finding in an older child or adult. In-depth discussion of these reflexes is beyond the scope of this chapter; the reader is referred to a developmental anatomy text for further information.

An infant's or child's mental status is assessed the same way as an adult's, by noting the level of consciousness, interaction with the environment, and appropriateness of behavior for age. Level of consciousness is assessed by noting whether the child is arousable and oriented. This can be done by observing for spontaneous arousability or by providing verbal, tactile, or noxious stimuli. Even though the assessment is the same, the assessment techniques must be age appropriate. Specific techniques are provided in the section in this chapter on interaction. An important difference to note when interacting with the child is paradoxical irritability (ie, the inability of the child to be calmed with normal comfort measures, such as cuddling). Paradoxical irritability, when present with meningeal irritability, nuchal rigidity, and positive Brudzinski's and Kernig's signs, may indicate meningitis.

Infants and young children are at high risk for ineffective thermoregulation, resulting in physiological instability from a variety of maturational and environmental factors. Closely monitoring body temperature and providing a temperature-controlled environment help manage temperature regulation. The temperature is measured at regular intervals, and external factors affecting body temperature should be controlled.

Cardiovascular System

Decreased perfusion to the skin is an early and reliable sign of shock. Because a child's skin is thinner than an adult's, skin characteristics change easily and rapidly with changes in perfusion. Skin color, texture, and temperature and capillary refill are of great significance during assessment of the child. Before assessing the skin, it is important to note the room temperature because some findings may be a normal response to the environment (such as mottling in a drafty operating room). Mottling in a bundled infant or warm environment is reason for further investigation. The nurse assesses skin temperature and the line of demarcation between extremity coolness and body warmth. Coolness or the progression of coolness toward the trunk may be a sign of diminishing perfusion.

Peripheral cyanosis is normal in newborns but abnormal in young children and adults. Central cyanosis (circumoral) is always abnormal. Capillary refill time is normally recorded in seconds rather than as "brisk, normal, or slow" and normally is no longer than 2 seconds. Estimated blood volume varies with age; despite a higher volume per kilogram of body weight in children, the overall total circulating volume is small. A small amount of blood loss can be significant in a child.

Respiratory System

The infant's or child's large head (in proportion to body size); weak, underdeveloped neck muscles; and lack of cartilaginous support to the airway lead to an easily compressible or obstructed airway. The nurse must avoid overextending or overflexing the neck because the airways are easily collapsible. Head and neck position alone can facilitate a patent airway. Ideal positioning for the decompensating child is in a neutral ("sniffing") position and can be accomplished by placing a small roll horizontally behind the shoulders (Fig. 10-1).

Infants, until 6 months of age, are obligate nose-breathers, so any obstruction of nasal passages can produce significant airway compromise and respiratory distress. Secretions, edema, inflammation, poorly taped nasogastric tubes, or occluded nasal cannulas can cause obstructed

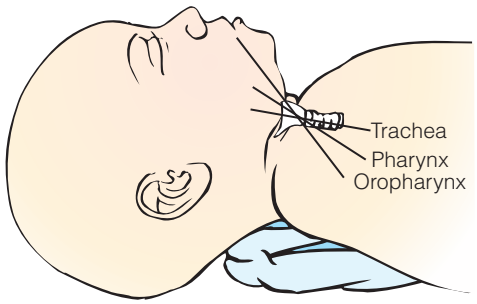

FIGURE 10-1 ▲ The neutral ("sniffing") position can improve airflow in a decompensating child by aligning the oropharynx (O), pharynx (P), and trachea (T) with the mouth.

nasal passages in an infant. The infant's and young child's airways are smaller in diameter and in length, thus requiring smaller artificial airways. Airway compromise can be caused by the slightest amount of inflammation or edema of the natural airway or from a mucus plug in either the natural or artificial airway. The narrowest part of the child's airway (until approximately 8 years of age) is at the level of the cricoid ring, as opposed to the glottic opening in the adult.

The young child's thin, compliant chest wall allows for easy assessment of air entry, which is assessed by observing the rise and fall of the child's chest with adequate ventilatory efforts. Unequal chest movement may indicate the development of a pneumothorax or atelectasis but also may indicate endotracheal tube obstruction or displacement into the right mainstem bronchus. The child's flexible rib cage and poorly developed intercostal muscles offer little stability to the chest wall; therefore, suprasternal, sternal, intercostal, and subcostal retractions may be seen during respiratory distress. The presence and location of retractions should be noted. Accessory muscles also are poorly developed, so an infant or child may use the abdominal muscles to assist with breathing. This gives the appearance of "seesaw" breathing, a paradoxical movement of the chest and abdomen. Seesaw breathing becomes more exaggerated with respiratory distress. As in the adult, the major muscle of respiration is the diaphragm. However, the child is more diaphragm dependent.

Because of the thin chest wall, breath sounds are more audible than in the adult. In addition, obstructed airways often produce sounds that are easily heard during assessment. The nurse listens for expiratory grunting, inspiratory and expiratory stridor, and wheezing. Expiratory grunting is a sound produced in an attempt to increase physiological positive end-expiratory pressure to prevent small airways and alveoli from collapsing. The infant's and child's thin chest wall may allow breath sounds to be heard over an area of pathology when sounds are actually being referred from another area of the lung. The nurse listens for changes in the breath sounds as well as for their presence or absence.

Gastrointestinal System

Children normally have a protuberant abdomen; however, there are numerous causes of abnormal abdominal distention. A nasogastric or orogastric tube should be inserted early rather than later in a critically ill child to minimize the risk for distention. Abdominal distention can interfere with respiratory excursion and may even cause respiratory arrest. Active removal of air with a syringe may be necessary if distention is not relieved by putting the tube to straight drainage. In addition, the abdominal girth is measured every shift or more often if there is a concern about abdominal distention.

Stomach capacity varies with the age of the child. A newborn's stomach capacity is 90 mL, a 1-month-old's is 150 mL, a 12-month-old's is 360 mL, and an adult's is 2,000 to 3,000 mL. Because stomach capacity is smaller, care is taken when formula and other fluids are instilled into the abdomen. Bolus feedings are of an appropriate amount, consistent with the child's stomach capacity.

The infant and young child have a gastric emptying time of 2.5 to 3 hours, which increases to 3 to 6 hours in the older child. An appropriate amount of time to allow for absorption of formula is taken into account when measuring residuals. If the child is receiving chest physiotherapy, the amount of time between therapy and feeding is considered, or the gastric contents are checked to avoid problems with reflux and aspiration.

Renal System

Infants have less ability to concentrate urine and therefore have a normal urine output of 2 mL/kg/h. For children and adolescents, normal urine output is 1 mL/kg/h and 0.5 mL/kg/h, respectively. Because of the infant's limited ability to concentrate urine, a low specific gravity does not necessarily mean that the infant is adequately hydrated. The immaturity of the child's kidney means that the child may not process fluid as efficiently as the adult and is less able to handle sudden large amounts of fluid, leading to fluid overload.

Infants and young children have a larger body surface area in relation to body weight. Maintenance fluid requirements are determined based on body weight (Table 10-2). Children have a higher percentage of total body water, most of which is composed of extracellular fluid (ECF), compared with adults. The ECF makes up 50% of the body weight in infants but 20% in adults. In addition, children have a higher insensible water loss because of a higher basal metabolic rate, higher respiratory rate, and larger body surface area. The child's higher percentage of total-body water and higher insensible water loss increase the risk for dehydration. Sudden weight

Table 10-2 Calculation of Maintenance Fluid

Body Weight (kg)	Fluid Requirements per Day	Fluid Requirements per Hour
Less than 10	100 mL/kg	4 mL/kg
10–20	1,000 mL + 50 mL/kg for each kg above 10	2 mL/kg for each kg above 10
More than 20	1,500 mL + 20 mL/kg for each kg above 20	1 mL/kg for each kg above 20

Table 10-3 Clinical Assessment of Severity of Dehydration

Patient	Mild Dehydration	Moderate Dehydration	Severe Dehydration
Infant	5%	10%	15%
Adolescent	3%	6%	9%
Infants and young children	Thirsty, alert, restless	Thirsty, restless, or lethargic but irritable to touch or drowsy	Drowsy, limp, cold, sweaty, cyanotic extremities, may be comatose
Older children and adults	Thirsty, alert, restless	Thirsty, alert, postural hypotension	Usually conscious, apprehensive, cold, sweaty, cyanotic extremities, wrinkled skin of fingers and toes, muscle cramps
Signs and Symptoms			
Tachycardia	Absent	Present	Present
Palpable pulses	Present	Present (weak)	Decreased
Blood pressure	Normal	Orthostatic hypotension	Hypotension
Cutaneous perfusion	Normal	Normal	Reduced and mottled
Skin turgor	Normal	Slight reduction	Reduced
Fontanelle	Normal	Sunken	Very sunken
Eyes	Normal	Slightly depressed	Sunken
Tears	Present	Present or Absent	Absent
Mucous membranes	Moist	Dry	Very dry
Respirations	Normal	Deep, may be rapid	Deep and rapid
Urine output	Normal	Oliguria	Anuria and severe oliguria
Estimated fluid deficit (mL/kg)	30–50	60–90	≥100

Adapted from Greenbaum LA. Fluids and electrolytes. In Kliegman RM, Jenson HB, Marcdante KJ, et al (eds): Nelson Essential of Pediatrics, 5th ed. St. Louis: Elsevier Health Sciences, 2006, p 162, with permission from Elsevier Science.

loss or gain may indicate fluid imbalance. Children should be weighed daily at the same time using the same scale.

Signs of dehydration include dry mucous membranes, decreased urine output, increased urine concentration, sunken fontanelles and eyes, and poor skin turgor (Table 10-3). The severity of dehydration varies with the degree of dehydration and the child's fluid and electrolyte status. Circulatory compromise accompanies severe dehydration. Treating a child's dehydration in an adult ICU requires pediatric consultation. Fluid overload is manifested by bulging fontanelles, taut skin, edema (usually periorbital and sacral), hepatomegaly, and other signs of congestive heart failure.

Endocrine System

Infants and young children have smaller glycogen stores and increased glucose demand because of their larger brain-to-body size ratio. The smaller stores and increased demand predispose infants and young children to the development of hypoglycemia. Blood glucose levels are closely monitored, especially when the infant or child is not permitted to have anything by mouth and numerous adjustments are being made to nutritional support.

Immune System

Immunological differences in infants and small children may predispose them to infection. The skin of newborns is thinner; therefore, it provides less of a barrier to outside pathogens. Because infants and young children have fewer stored neutrophils, they are less able to repeatedly replenish white blood cells in the face of an overwhelming infection. The complement levels are lower, which affects the chemotactic activity of phagocytes and the opsonization of bacteria. There is also a relative deficiency of immunoglobulins, making infants and young children more susceptible to infections caused by viruses, *Candida* species, and acute inflammatory bacteria. In addition, infants may not demonstrate fever and leukocytosis in response to an infection. It is important to observe for subtle signs, such as changes in feeding behaviors, altered glucose metabolism, and hypothermia.

Integumentary System

Expected differences in the skin, hair, nails, and glands depend on the age of the child. Infants and children, without exposure to the sun or wind, are expected to have smooth-textured skin without coarse adult terminal hair. Infants, up to about 14 days of age, may be covered with lanugo, a fine, silky-textured hair. Infants also have less developed hypodermal fat and, as a result, are at risk for hypothermia. The sweat glands do not begin to function until 1 month of age and are not fully functional until adolescence.

In the young child, the most noticeable variation may be that of bruising as the child increases activity and play becomes more aggressive. It is very important to attend to

bruising seen in the child because it may be associated with abusive situations. The nurse notes the location and color changes of bruising indicating the stage of healing. Bruising is more common and not unexpected on the lower legs and the face. Bruising on the upper arms, buttocks, and abdomen occurs less often and may indicate abuse.

In the adolescent, the sweat glands and sebaceous glands become fully functional. The adolescent may be expected to experience body odor, increasing axillary perspiration, and acne. The development of axillary and pubic hair is expected related to the increasing levels of circulating androgen levels in both male and female adolescents.

▲ Selected Pediatric Challenges

Ventilatory Issues

The most common cause of cardiopulmonary arrest in children is respiratory in nature. This fact mandates that respiratory distress and failure be recognized early and that airway management interventions be immediate (Table 10-4). Signs of respiratory decompensation include diminished level of consciousness, tachypnea, minimal or no chest movement with respiratory effort, evidence of labored respirations with retractions, seesaw breathing, minimal or no air exchange noted on auscultation, and the presence of nasal flaring, grunting, stridor, or wheezing.

The initial intervention for respiratory decompensation is positioning the child to open the airway. If the child does not respond to position alone, manual ventilation with 100% oxygen using a bag-mask device is initiated. There are several sizes of pediatric manual resuscitation bags; the correct size is determined by noting the child's tidal volume and deciding whether the bag is capable of delivering 1.5 times the child's tidal volume. Even though a pressure manometer may assist in minimizing pressure, the true indicator of delivery of an adequate tidal volume is a clinical one. The adequate amount of tidal volume delivered during a manual resuscitation breath is the amount that causes rise and fall of the child's chest.

If bag-mask ventilation is not successful in restoring the child's ventilatory status, endotracheal intubation is required. Numerous sizes of endotracheal tubes are available for infants and children. To estimate the correct size of endotracheal tube, the size of the child's little finger or the following formula can be used:

$$\text{Internal diameter} = (16 + \text{age in years}) / 4$$

A cuffed tube can be used safely in the in-hospital setting.[2] For cuffed endotracheal tubes, the formula used to estimate the internal diameter is as follows:

$$\text{Internal diameter} = (16 + \text{age in years}) / 4 + 3$$

Because these are both estimations of endotracheal tube size, tubes one-half size smaller and larger should be available for immediate use. Table 10-5 on page 117 provides information regarding endotracheal tube sizes and other equipment issues.

Monitoring the patient during intubation is critical to assess for desaturation or bradycardia. Once the child is intubated, observation of chest movement and auscultation of the lungs help determine correct placement. A radiograph is used to confirm proper placement. When placement is confirmed, the tube is securely taped to avoid accidental displacement. In addition, soft restraints should be used to prevent the child from removing the tube. Adequate sedation and analgesia are provided to increase the child's comfort and manage anxiety during intubation.

Medication Administration

Because a child may differ in weight significantly from the average child in the associated age group, medications are prescribed on a microgram, milligram, or milliequivalent per kilogram of body weight basis rather than on a standard dose according to age. Confirming the weight (in kilograms) that is being used to determine drug dosages is important. This same weight should be used during the child's entire hospitalization unless there is a significant change in the child's weight. Because pediatric dosages may be unfamiliar to the adult clinician, precalculated emergency drug sheets are helpful. The emergency drug sheet should include the recommended resuscitation medication dosages, medication concentration, and final medication dose and volume the individual child is to receive. The recommended dosages should reflect the American Heart Association's Pediatric Advanced Life Support standards.

An important recommendation for medication administration in the pediatric patient is the single-dose system. The single-dose system involves preparing one syringe to contain only the prescribed medication dose. The syringe should be properly labeled with the drug name and dose. The nurse administers the entire volume of the syringe to ensure that the prescribed dose has been given. The single-dose system prevents overmedication or undermedication of the child.

Medication errors have received increased attention since the publication of the 2000 Institute of Medicine report, "To Err Is Human." The most common reason for harm to pediatric patients, medication errors result in a higher risk for death.[3] The prescribing phase is associated with the most errors (dosing errors), and the administration phase results in the second most errors.[4] Nurses are the last potential barrier between an occurrence and an adverse outcome; they are most likely to intercept the error. Preventing medication errors is especially important in children because there is a much smaller margin for error in this patient population. Risk reduction strategies such as ensuring staff competency and computerized physician order entry should be in place as best practice. All providers must use vigilance in ordering and administering medications to a pediatric patient.[5]

Pain Management

Because of the nature of the environment and associated procedures, the critically ill child is at high risk for pain. The first

Table 10-4 Quick Examination of a Healthy Versus Decompensating Child

Assessment	Healthy Child	Decompensating Child
Airway		
Patency	Child requires no interventions; child verbalizes and is able to swallow, cough, gag.	Child self-positions and requires interventions, such as head positioning, suctioning, adjunct airways. Unmaintainable airway requires intubation.
Breathing		
Respiratory rate	Breathing is within age-appropriate limits.	Breathing is tachypneic or bradypneic compared with age-appropriate limits and conditions.* *Note:* Warning parameter: more than 60 breaths/min
Chest movement (presence)	Chest rises and falls equally and simultaneously with abdomen with each breath.	Child has minimal or no chest movement with respiratory effort.
Chest movement (quality)	Child has silent and effortless respirations.	Child shows evidence of labored respirations with retractions. Asynchronous movement (seesaw) is observed between chest and abdomen with respiratory efforts.
Air movement (presence)	Air exchange is heard bilaterally in all lobes.	Despite movement of the chest, minimal or no air exchange is noted on auscultation.
Air movement (quality)	Breath sounds are of normal intensity and duration.	Nasal flaring, grunting, stridor, and/or wheezing are noted.
Circulation		
Heart rate (presence)	Apical beat is present and within age-appropriate limit.*	Heart rate is absent; bradycardia or tachycardia occurs as compared with age-appropriate limits.* *Note*: Warning parameters: Infant: <80 beats/min Child <5 y: more than 180 beats/min Child older than 5 y: more than 150 beats/min
Heart rate (quality)	Heart rate is regular with normal sinus rhythm.	Heart rate is irregular, slow, or very rapid; common dysrhythmias include supraventricular tachycardia, bradyarrhythmias, and asystole.
Skin	Extremities are warm, pink with capillary refill 2 s or less; peripheral pulses are present bilaterally with normal intensity.	Child has pallor, cyanosis, or mottled skin color and cool-to-cold extremities. Capillary refill time is 2 s or more; peripheral pulses are weak or absent; central pulses are weak.
Cerebral perfusion	Child is alert to surroundings, recognizes parents or significant others, is responsive to fear and pain, and has normal muscle tone.	Child is irritable, lethargic, obtunded, or comatose; has minimal or no reaction to pain; and/or has loose muscle tone (floppy).
Blood pressure	Blood pressure is within age-appropriate limits.	Blood pressure falls from age-appropriate limits,* a late sign of decompensation. *Note*: A fall of 10 mm Hg systolic pressure is significant. Lower systolic blood pressure limit: Infant 1 mo or less, 60 mm Hg Infant 1 y or less, 70 mm Hg Child, 70 mm Hg + (2 × age in years)

*All vital signs are interpreted within the context of age, clinical condition, and other external factors, such as the presence of fever.

Adapted from Moloney-Harmon PA, Rosenthal CH: Nursing care modifications for the child in the adult ICU. In Stillwell S (ed): Mosby's Critical Care Nursing Reference. St. Louis, MO: Mosby-Year Book, 1992, pp 588–670, with permission from Elsevier Science.

step in assessing pain in children is to understand the child's response to, and communication of, pain. This is based on a variety of factors, including the child's developmental level, past and present experience with pain, cultural aspects, personality, parental presence, and age, as well as the nature of the illness or injury.[6] For instance, critically ill children may be in severe pain but may be unable to communicate because of sedation, paralytic agents, mechanical ventilation, or coma.

Table 10-5 Recommended Resuscitation Equipment for Infants and Children

Equipment	Child's Weight						
	4–8 kg (8.8–17.6 pounds)	8–11 kg (17.6–24.2 pounds)	11–14 kg (24.2–30.8 pounds)	14–18 kg (30.8–39.6 pounds)	18–24 kg (39.6–52.8 pounds)	24–32 kg (52.8–70.4 pounds)	32+ kg (70.4 + pounds)

Pain assessment is multidimensional. Synthesis of a variety of parameters provides information that can be used to make a decision about the level of the child's pain and the most appropriate intervention. Assessment of pain by nurses is influenced by factors such as educational level, skills, experience, personal beliefs, and different strategies adopted for assessment.[6] Infants and young children cannot communicate verbally, which makes pain assessment challenging. This inability to communicate is also an issue in the sedated or chemically paralyzed child. This requires that the nurse assesses pain using different cues, which include physiological and behavioral changes.[7]

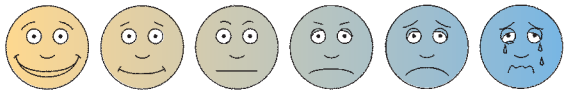
Physiological parameters used in pain assessment include heart rate, respiratory rate, blood pressure, and oxygen saturation. Other parameters described by Anand and Carr[8] include sweating, increased muscle tone, and skin color changes. These parameters return to normal as physiological adaptation occurs. This adaptation can actually occur within minutes, and the nurse must realize that the child may still be in pain. The physical signs are not necessarily specific for pain but may be the only parameter available to the nurse caring for the critically ill child.

Behavioral responses may be helpful for pain assessment, especially in the child who cannot communicate. The next section on interaction with children and families discusses the continuum of responses related to pain and comfort.

Another dimension of pain assessment is self-report. Many tools are available. However, these often require children to interact or use their hands and are not usually helpful in the critical care setting. Examples of self-report tools include the numerical rating scale (see Chapter 5, Fig. 5-1), the FACES scale (Fig. 10-2), and the color scale. If the child is unable or unwilling to give a report, the parent's report of pain is often helpful. Multidimensional scales, such as the COMFORT, Modified Motor Activity Assessment, and FLACC (face, legs, activity, cry, consolability) scales (see Fig. 10-2), are helpful because they combine dimensions of behavioral and physiological distress and do not require interaction or use of the hands.

Pain management interventions are multidimensional whenever possible, including nonpharmacological and pharmacological approaches. However, pharmacological intervention is never withheld when it is appropriate. Opioids are usually the first-line drugs for pain

A



0 1 2 3 4 5

B

	0	1	2
Face	No particular expression or smile	Occasional grimace or frown, withdrawn, disinterested	Frequent to constant frown, clenched jaw, quivering chin
Legs	Normal position or relaxed	Uneasy, restless, tense	Kicking, or legs drawn up
Activity	Lying quietly, normal position, moves easily	Squirming, shifting back and forth, tense	Arched, rigid, or jerking
Cry	No cry (awake or asleep)	Moans or whimpers, occasional complaint	Crying steadily, screams or sobs, frequent complaints
Consolability	Content, relaxed	Reassured by occasional touching, hugging, or "talking to," distractable	Difficult to console or comfort

FIGURE 10-2 ▲ Tools for assessing pain in children. **A:** The FACES scale. This scale may be used in children 3 years and older. Explain that FACE 0 is a very happy face because there is no pain. FACE 1 hurts just a little bit. FACE 2 hurts a little bit more. FACE 3 hurts even more. FACE 4 hurts a whole lot. FACE 5 hurts very much; the pain can make you cry. Ask the child to choose the face that best describes the pain he or she is feeling. **B:** The FLACC (face, legs, activity, cry, consolability) scale. This scale can be used with children younger than 3 years. To use the FLACC scale, assess the child in each category, assigning a score between 0 and 2. Total the score, and then evaluate the total using the 0–10 pain scale parameters. (**A** from Wong DL, Hockenberry-Eaton M, Wilson D, et al: Wong's Essentials of Pediatric Nursing, 7th ed. management in the critically ill child. A variety of pharmacological drugs are available, and the choice of medication depends on the child's response and the practitioner's preference. Nursing responsibilities include assessing the child's need for the drug, administering the appropriate dose, and monitoring the child's response. Sedation and analgesia are part of the daily management of the critically ill child. However, inherent in the use of these drugs is the risk for adverse responses. The nurse is responsible for vigilant monitoring and for implementing changes based on the child's response and recommendations by the multidisciplinary team.[9]

Other methods of pain control include intravenous patient-controlled analgesia (PCA) and epidural analgesia. PCA helps the child maintain a steady state of pain relief and also gives the child some control over pain. Epidural analgesia is also helpful for a variety of children. Epidural narcotics provide selective analgesia but do have associated side effects, including respiratory depression, nausea and vomiting, pruritus, and urinary retention.

Nurses may consider the use of nonpharmacological methods, such as distraction, relaxation, massage, and hypnosis, in conjunction with pharmacological drugs. The method must be age appropriate, and parental presence is considered. Whatever methods are used, a critical determinant of their effectiveness is the child's response.

▲ Interaction with Children and Families

Interacting with children demands familiarity with their developmental capabilities and psychosocial needs. Categorization of children into groups according to physical and cognitive age can assist the nurse in predicting the child's expected social, cognitive, and physical capabilities. Developmental and psychosocial assessment is beyond the scope of this chapter; therefore, the reader should consult an appropriate growth and development reference. Although each age group of children has common developmental capabilities, tasks, and fears, it is helpful to recognize the common fears of all children despite their age. These fears include loss of control, threat of separation, painful procedures, and communicated anxiety.

Unlike the adult patient, the young child does not consciously screen most behavior and spoken words. The young

Table 10-6 Contrasting Nonverbal Behavioral Cues of the Healthy and the Critically Ill Child

Healthy	Critically Ill
Posture	
Moves, flexes	May be loose, flaccid May prefer fetal position or position of comfort
Gestures	
Turns to familiar voices	Responds slowly to familiar voices
Movement	
Moves purposefully Moves toward new, pleasurable items Moves away from threatening items, people	Exhibits minimal movement, lethargy Shows increased movement, irritability (possibly indicating cardiopulmonary or neurological compromise, pain, or sleep deprivation)
Reactions/Coping Style	
Responds to parent(s) coming, leaving Responds to environment and equipment Cries and fights invasive procedures	Exhibits minimal response to parent presence, absence Exhibits minimal response to presence or absence of transitional objects Displays minimal defensive responses
Facial Expressions	
Looks at faces and makes eye contact Changes facial expressions in response to interactions Responds negatively to face wash Blinks in response to stimuli Widens eyes with fear Is fascinated with own mouth Holds mouth "ready for action"	May not track faces, objects Avoids eye contact or has minimal response to interactions Minimally changes facial expression during face wash Exhibits increased or decreased blinking Avoids eye contact Avoids or dislikes mouth stimulation Drools or displays loose mouth musculature Sucks intermittently or weakly

Taken from Moloney-Harmon P, Rosenthal CH: Nursing care modifications for the child in the adult ICU. In Stillwell S (ed): Critical Care Nursing Reference Book. St. Louis, MO: Mosby-Year Book, 1992, p 590, with permission from Elsevier Science.

child subconsciously communicates behaviorally through verbal, nonverbal (body language, behaviors), and abstract (play, drawing, story telling) cues. Although the child's behavior is more natural in a familiar environment, the cues available to the clinician can suggest how a child is feeling or perceiving an event or the presence of a person. In general, the child's behavior is more activity oriented and more emotional than that of adults. These qualities of a child's behavior should be expected as the norm of average, healthy children and may be used as parameters against which to contrast the behavior of the critically ill child (Table 10-6).

Behavioral responses are particularly helpful during the assessment of pain or comfort. The infant or child may display body movement that spans the entire activity continuum from minimal movement, such as rigidity and guarding, to high activity, such as thrashing and kicking. Assessing various behavioral responses (eg, gestures, posture, movement, and facial expression) and examining the congruency between these responses are particularly helpful.

Interaction with pediatric patients and their families is also facilitated by the appreciation of the child's significant others. The philosophy of family centered care is essential to the optimal care of the pediatric patient. Gone are the days when parents dropped their children for care at the entrance of the hospital. Although there are several components of family centered care, the salient concept is to value, recognize, and support the family in the care of their child. The family is the constant in the child's life and is ultimately responsible for responding to the child's emotional, social, developmental, physical, and health care needs. Appropriate support and incorporation of parents may buffer the threats of the ICU environment on the child. Parents may assist or influence the child's cognitive appraisal of the environment, personnel, and events. The child often uses the reactions of the parent as a barometer in interpreting events in ways ranging from threatening to beneficial.[10]

The tone and manner in which the clinician approaches the bedside of a pediatric patient and his or her family are important. Communicated anxiety refers to the anxious feelings conveyed to the child by the parents, the health care team members, or both. Interventions to relieve the anxiety of parents and fellow health care team members have a direct impact on the child's well-being. Interventions may include assisting parents and staff in anticipating the child's responses to therapy and illness and guiding parents and staff in therapeutic communication techniques.

Parents depend on nurses to humanize the critical care experience for their child. A recent study examined parents' perceptions of nurses' caring practices in the pediatric ICU. Parents reported that nurses used behaviors that demonstrated affection, caring, watching, and protecting. Parents stated that the most desirable nursing behaviors were those that complemented the parental role, which preserved family integrity during a time of crisis.[11] Clinical practice guidelines that support the parents of children in pediatric ICUs facilitate family involvement.[12]

Examples of nursing diagnoses for the pediatric patient in the ICU are given in Box 10-1.

BOX 10-1 EXAMPLES OF NURSING DIAGNOSES

For the Critically Ill Pediatric Patient

- Ineffective Airway Clearance related to obstructed airway
- Anxiety related to environment
- Risk for Imbalanced Body Temperature
- Interrupted Family Processes related to shift in health status of a family member
- Deficient Fluid Volume related to active fluid volume loss, failure of regulatory mechanisms
- Delayed Growth and Development related to separation from significant others

▲ Clinical Applicability Challenges

CASE STUDY

S. is a 2-year-old, 13-kg girl admitted for respiratory distress. On admission, her vital signs are as follows: heart rate, 170 beats/min; respiratory rate, 56 breaths/min; blood pressure, 105/65 mm Hg; axillary temperature, 101.4°F (38.5°C); and oxygen saturation, 90%. Physical examination reveals an agitated, irritable, and crying young girl with intercostal and substernal retractions and nasal flaring. Her expiratory wheezing can be heard across the room. The child's respiratory rate is high for her age, although tachypnea is to be expected for her clinical condition. She has a fever and is anxious, which may also account for the tachypnea. The anxiety, agitation, and increased work of breathing increase the oxygen demand while the lower airway obstruction decreases oxygen transport. The warning parameters of tachypnea, nasal flaring, retractions, and wheezing indicate a child with respiratory distress who is at risk for respiratory failure.

Initial management priorities include positioning S. for comfort and administering oxygen while assessing her response. Albuterol, an inhaled β_2-agonist, is administered. After these interventions, her vital signs are as follows: heart rate, 154 beats/min; respiratory rate, 40 breaths/min; blood pressure, 110/64 mm Hg; and oxygen saturation, 98% on 40% oxygen by face mask.

One hour later, S's vital signs are as follows: heart rate, 80 beats/min; respiratory rate, 20 breaths/min; blood pressure, 90/50 mm Hg; and oxygen saturation, 88%. Retractions are more pronounced, and wheezing is not audible by auscultation. She is extremely lethargic and is not responding to her parents. Arterial blood gas values reveal the following: pH, 7.22; $PaCO_2$, 58 mm Hg; PaO_2, 78 mm Hg; and HCO_3^-, 28 mEq/L on a fraction of inspired oxygen of 0.6. The child is demonstrating signs of fatigue and respiratory failure. Warning parameters include an unmaintainable airway, bradypnea, worsening retractions, lethargy, no air movement (indicated by lack of wheezing), and failure to recognize her parents. Management priorities at this time include bag-mask ventilation and intubation if she does not respond to bag-mask ventilation.

Treatment is directed toward ensuring oxygenation and ventilation while reversing bronchospasm. Medications include inhaled bronchodilators and corticosteroids. Mechanical ventilation is also provided until S. shows improvement, as demonstrated by arterial blood gas values, vital signs, and clinical condition.

1. S. is demonstrating signs of impending respiratory failure. Describe the signs that indicate respiratory failure in this child.

2. Discuss the management priorities for S. related to her impending respiratory failure.

3. Describe assessment parameters to determine S.'s response to intervention.

11 The Critically Ill Pregnant Woman

Cathleen R. Maiolatesi

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Summarize normal physiological changes that occur in the cardiovascular, respiratory, renal, and hematological systems during pregnancy.
2. Differentiate the signs and symptoms of preeclampsia and severe preeclampsia.
3. Explain the pathophysiology of severe preeclampsia.
4. Describe parameters of nursing assessment of a severely preeclamptic patient on intravenous magnesium sulfate.
5. Discuss three obstetrical conditions that predispose a woman to development of disseminated intravascular coagulation.
6. Describe the initial care of an obstetrical trauma patient.
7. Summarize the psychosocial support needed for an obstetrical patient in the intensive care unit.

Most women experience a normal pregnancy. However, a small percentage of women experience life-threatening complications that may result from the pregnancy itself or develop as a result of a preexisting (comorbid) condition. Such critically ill pregnant women provide a unique challenge to nurses. The physical assessment of these patients includes the interaction between the maternal host and the fetus. Critical care nurses are not expected to have the knowledge and skills associated with fetal heart rate monitoring, and perinatal nurses may not possess the knowledge and skills required for patients needing ventilator support or hemodynamic monitoring. It is important when a critically ill pregnant woman is in the intensive care unit (ICU) that a collaborative approach be used to provide care.[1]

The general principles of diagnosis and management are similar to those used for other ICU patients. However, physiological changes inherent in pregnancy must be considered to decrease morbidity and mortality.[2] Critical care nurses caring for these patients must understand the physiological changes that occur as the body adapts to pregnancy and distinguish normal from abnormal responses. Table 11-1 outlines these changes.

▲ Physiological Changes in Pregnancy

Cardiovascular Changes

Normal cardiovascular changes that occur during pregnancy affect pulse, blood pressure, cardiac output, and blood volume (see Table 11-1). Maternal blood volume increases 40% to 50% above baseline values. This increase, which consists mostly of plasma, begins in the first trimester and continues throughout pregnancy. The increase is necessary to provide adequate blood flow to the uterus, fetus, and changing maternal tissues and to accommodate blood loss at birth. Red blood cell volume increases by 20% and is disproportionate to the plasma increase, resulting in maternal physiological anemia. Heart rate increases 10 to 15 beats/min as early as 7 weeks of gestation and returns to the prepregnancy level by 6 weeks postpartum.[3] Changes in blood volume and heart rate lead to an increase in cardiac output of 30% to 50% (6 to 7 L/min) during pregnancy.[3] Cardiac output increases slightly more intrapartum as a result of the shunting of blood from the placental–fetal unit. Immediately after birth, a larger increase in cardiac output (59% to 80%) occurs when the empty uterus contracts and shunts approximately 1,000 mL of blood back into the systemic circulation[2] (Table 11-2). A woman loses approximately 500 mL of blood during a vaginal birth and approximately 1,000 mL of blood during a cesarean birth. This is usually well tolerated.

Development of the uteroplacental unit provides a low-resistance network for the expanded blood volume, which reduces cardiac afterload.[4] The pulmonary vascular resistance, or right afterload, also decreases in response to increased blood volume and vasodilation. Under hormonal influence, smooth muscles and vascular beds relax, lowering systemic vascular resistance (SVR). Blood pressure decreases during the first and second trimesters and returns to prepregnancy levels by the third trimester. Blood pressure during pregnancy is affected by maternal position more so than in the nonpregnant state. Supine hypotension occurs when the

Table 11-1 Physiological Changes in Pregnancy

	Change	Pregnancy Levels
Cardiovascular Changes		
Blood volume	>40%–50%	1,260–1,625 mL
Red blood cells	>20%	250–450 mL
Blood pressure Systolic Diastolic	 <5–12 mm Hg <10–20 mm Hg	
Cardiac output	>30%–50%	6–7 L/min
Heart rate	>10%–30%	Increased by 15–20 beats/min
Systemic vascular resistance	<20%–30%	1,210 ± 266 dynes/s/cm^{-5}
Pulmonary vascular resistance	<34%	78 ± 22 dynes/s/cm^{-5}
Colloid osmotic pressure	<10%–14%	<22.4 ± 0.5
Respiratory Changes		
Functional residual capacity	<10%–21%	1,343–1,530
Tidal volume	>30%–35%	600 mL
Renal Changes		
Renal blood flow	>25%–50%	1,500–1,750 mL/min
Glomerular filtration rate	>50%	140–170 mL/min
Creatinine clearance	>50%	100–150 mL/min

Table 11-2 Cardiac Output Changes in Pregnancy and Labor and Delivery

Stage of Pregnancy, Labor, or Delivery	Cardiac Output
By 8 weeks of gestation	22%–30% increase
By 20 weeks of gestation	50% increase
Repositioned from supine to left lateral decubitus	21% increase
Early first stage of labor (dilated <3 cm)	13%–17% increase
Late first stage of labor (dilated 4–7 cm)	23% increase
Second stage of labor (dilated >8 cm)	34% increase
During each contraction	11%–15% increase
Immediately after delivery (10 min)	59%–80% increase (dependent on type of anesthesia)
Within 1 h of delivery	49% increase

mother remains in a flat position. The side-lying position is recommended, but if the patient must be supine, the uterus should be tilted away from the inferior vena cava by using a wedge under the hip.

Respiratory Changes

Respiratory changes as seen in Table 11-1 occur to accommodate the enlarged uterus and the increased oxygen demands of the mother and fetus. Structural changes include the upward shift of the diaphragm, which decreases functional residual capacity, and rib cage volume displacement, which increases tidal volume by 30% to 35%.[5] Airway mucosal changes include hyperemia, hypersecretion, increased friability, and edema. These changes are significant when inserting nasogastric tubes or nasotracheal tubes because of the risk for epistaxis. Respiratory rate remains unchanged, although some women experience tachypnea or shortness of breath at some time during their pregnancy. The exact cause of dyspnea is unknown, but it may be related to hyperventilation, increased oxygen consumption, or decreased partial pressure of arterial carbon dioxide ($PaCO_2$).

Oxygen consumption increases by 15% to 20% during pregnancy and may increase by 300% during labor.[2] This results in an increased partial pressure of arterial oxygen (PaO_2) to 104 to 108 mm Hg. $PaCO_2$ decreases to 27 to 32 mm Hg and allows for the increased diffusion of carbon dioxide from the fetus to the mother.[5] Renal excretion of bicarbonate causes a slight increase in maternal pH, which is usually insignificant.

Renal Changes

Changes in renal function, also outlined in Table 11-1, accommodate the increase in metabolic and circulatory requirements of pregnancy. Renal blood flow increases by 30% and glomerular filtration rate (GFR) by 50%.[3] These increases allow elevations in the clearance of many substances, such as creatinine and urea, and are reflected in lower serum levels.

Gastrointestinal and Metabolic Changes

Gastrointestinal changes in pregnancy occur as a result of the growing uterus. Displacement of the esophageal sphincter into the thoracic cavity allows stomach contents to enter the esophagus passively. The pregnant woman is prone to passive regurgitation and aspiration, especially when under general anesthesia or any time she may be unconscious.[2] Hormonal influences cause delayed gastric emptying and increased gastric acid secretion in the third trimester. Smooth muscle relaxation contributes to nausea, heartburn, and constipation. Pregnancy creates a diabetogenic state because the body becomes increasingly resistant to insulin and hyperinsulinemia occurs. Hepatic and maternal fasting blood glucose levels decrease owing to the constant transfer of glucose to the fetus.

Hematological Changes

Hematocrit laboratory values decrease because of the hemodilution effect of increased plasma volume. Normal hematocrit values are 32% to 40% during pregnancy.[2] The white blood cell count is elevated from the normal range of 5,000–10,000/mm^3 to 6,000–16,000/mm^3.[4] There is an increase in clotting factors VII through X and a decrease in factors XI and XIII, which inhibit coagulation. Fibrinogen increases to 300 to 600 mg/dL. Bleeding and clotting times and platelet counts remain the same in pregnancy.

Fetal and Placental Development Considerations

Clinicians must carefully balance the effects and risks of all treatment decisions on the pregnant woman and her fetus. Maternal circulation and nutrition and exposure to teratogens influence embryonic and fetal development.

There are three stages in fetal development: pre-embryonic (first 14 days), embryonic (day 15 through 8 weeks), and fetal (8 weeks through 40 weeks and delivery). During the embryonic stage, vital organs such as the heart and brain are in development. It is during this stage that the fetus is most vulnerable to teratogens (Fig. 11-1).

Certain medications used in treating the critically ill pregnant woman may cross the placenta and have teratogenic effects on the fetus. For this reason, the clinician must consider the risks and benefits of medication therapy. In 2001, the U.S. Food and Drug Administration revised the five risk categories for labeling drug use in pregnancy (Table 11-3).

The placenta is the organ responsible for the metabolic exchange of oxygen, nutrition, and waste removal between the pregnant woman and the fetus. In early pregnancy, the placenta produces four hormones necessary to maintain the pregnancy. The hormone human chorionic gonadotropin is the basis for pregnancy tests and preserves the function of the corpus luteum. Another hormone, human placental lactogen, stimulates maternal metabolism to supply needed nutrients for fetal growth. This hormone is responsible for the increase in insulin resistance associated with pregnancy. The hormones progesterone and estrogen are eventually produced by the placenta and are responsible for uterine growth and uteroplacental blood flow.

Placental function depends on maternal blood flow. Diseases and conditions that cause vasoconstriction, such as hypertension, cocaine use, or smoking, can diminish blood flow to the placenta and fetus. Even excessive maternal exercise can shunt blood away from the placenta and fetus.

▲ Critical Care Conditions in Pregnancy

During pregnancy, normal physiological changes occur to provide for growth of the fetus and prepare the mother for birth.

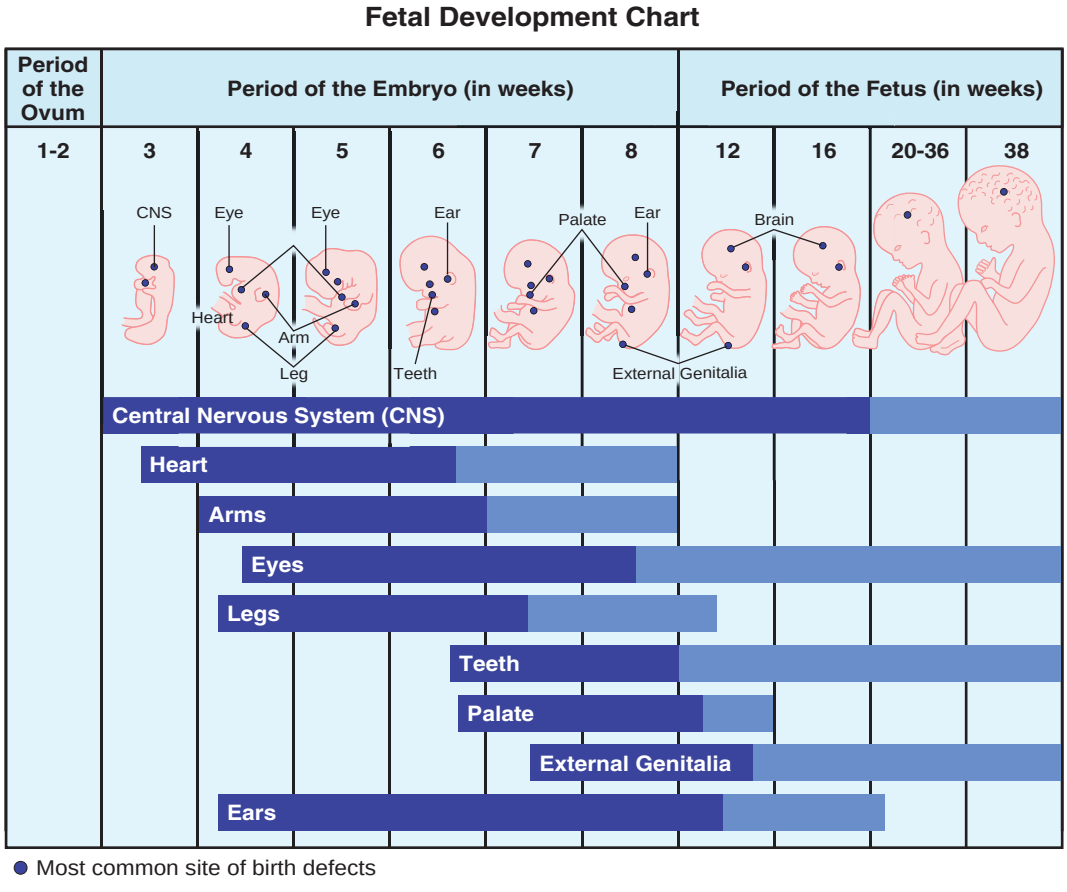

FIGURE 11-1 ▲ Critical periods of development. *Dark blue* denotes highly sensitive periods. (Adapted from the National Organization on Fetal Alcohol Syndrome.)

Table 11-3 Teratogenic Medication Risk Categories

Category	Description
A	Adequate, well-controlled studies in pregnant women have not shown an increased risk for fetal abnormalities.
B	Animal studies have revealed no evidence of harm to the fetus; however, there are no adequate and well-controlled studies in pregnant women. **OR** Animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus.
C	Animal studies have shown an adverse effect, and there are no adequate and well-controlled studies in pregnant women. **OR** No animal studies have been conducted and there are no adequate and well-controlled studies in pregnant women.
D	Studies, adequate well-controlled or observational, in pregnant women have demonstrated a risk to the fetus. However, the benefits of therapy may outweigh the potential risk.
X	Studies, adequate well-controlled or observational, in animals or pregnant women have demonstrated positive evidence of fetal abnormalities. The use of the product is contraindicated in women who are or may become pregnant.

Medical or obstetrical complications may alter this adaptation and shift an uncomplicated pregnancy into a critical situation. ICU admissions become necessary in 1% to 3% of pregnancies, with the majority of indications being hemodynamic instability, obstetrical hemorrhage, and respiratory failure.[6] The most common obstetrical complications requiring ICU admission are severe preeclampsia, disseminated intravascular coagulation (DIC), amniotic fluid embolus, acute respiratory distress syndrome (ARDS), and trauma. Box 11-1 contains sample nursing diagnoses for patients with high-risk pregnancies.

Severe Preeclampsia

Hypertensive disorders of pregnancy occur in approximately 3% to 7% of all pregnancies.[7,8] They are the third leading cause of maternal death in the United States. Terms used to describe the different types of hypertension that may occur in pregnancy are listed in Box 11-2. Preeclampsia is a hypertensive disorder occurring in 5% to 7% of pregnancies.[9] The etiology of preeclampsia is unknown; however, predisposing risk factors include nulliparity, multiple gestation, diabetes, age younger than 18 years or older than 35 years, and chronic hypertension.

Preeclamptic symptoms include hypertension, edema, and proteinuria. Hypertension in pregnancy is defined as a blood pressure of greater than 140/90 mm Hg.[9] In the past, increases of 30 mm Hg systolically or 15 mm Hg diastolically were used to diagnose hypertension in pregnancy. These criteria have become unreliable and should no longer be used. If the prepregnancy blood pressure is unknown, a blood pressure measurement of 140/90 mm Hg obtained twice at intervals of 6 hours apart in the same position and using the same arm is appropriate to diagnose this complication. In severe preeclampsia, the systolic blood pressure is greater than 160 mm Hg, and the diastolic blood pressure is greater than 110 mm Hg.[8] Edema may be generalized but is more pronounced in the hands and face. Proteinuria is diagnosed by protein concentrations of 5 g or greater in a 24-hour urine specimen. Oliguria may occur and is defined as a urine output less than 30 mL/h or less than 500 mL/24 h. Other symptoms of severe preeclampsia include visual and cerebral disturbances, such as blurred vision and headaches, epigastric pain, impaired liver function, thrombocytopenia, and pulmonary edema.

Physiological Principles

Severe preeclampsia is associated with vascular endothelial damage caused by arteriolar vasospasms and vasoconstriction.[9]

BOX 11-1 EXAMPLES OF NURSING DIAGNOSES

For Critically Ill Pregnant Patients

- Anxiety related to poor/uncertain pregnancy outcomes
- Stress Overload related to poor/uncertain pregnancy outcomes
- Grieving related to threat to self
- Fear related to fetal well-being
- Risk for Injury related to infection
- Interrupted Family Processes related to intensive care hospitalization
- Decreased Cardiac Output related to increased intrathoracic pressures (patient receiving mechanical ventilation)
- Risk for Disturbed Maternal-Fetal Dyad related to maternal position, blood loss, or placental trauma

BOX 11-2 Clinical Terminology: Hypertensive Disorders During Pregnancy

- *Preeclampsia:* a pregnancy-specific syndrome observed after the 20th week of pregnancy with systolic blood pressure of greater than or equal to 140 mm Hg or diastolic blood pressure of greater than or equal to 90 mm Hg, accompanied by significant proteinuria. In women with preeclampsia, blood pressure usually returns to baseline within days to weeks after delivery.
- *Eclampsia:* the occurrence, in a woman with preeclampsia, of seizures that cannot be attributed to other causes. Convulsions usually occur after midpregnancy and may occur postpartum.
- *Gestational hypertension:* a blood pressure elevation detected for the first time after midpregnancy, distinguished from preeclampsia by the absence of proteinuria.
- *Chronic hypertension:* elevated blood pressure in the mother that predated the pregnancy. It can also be diagnosed in retrospect when preeclampsia or gestational hypertension fails to normalize after delivery.

From National Institutes of Health, National Heart Lung and Blood Institute: Report of the Working Group on Research on Hypertension During Pregnancy, April 2001.

Arterial circulation is disrupted by alternating areas of constriction and dilation. Damage to the endothelium results in leakage of plasma into the extravascular space and allows platelet aggregation to occur. Colloidal osmotic pressure decreases as protein enters the extravascular space, and the woman is at risk for hypovolemia and altered tissue perfusion and oxygenation.[10] Physiologic changes in the maternal cardiovascular system such as increased plasma volume, cardiac output, heart rate and capillary permeability, and a decrease in colloid osmotic pressure are exaggerated in preeclampsia and predispose the women to develop pulmonary edema.[11] Symptoms of pulmonary edema include coughing, dyspnea, chest pain, tachycardia, cyanosis, and pink, frothy sputum.[11]

Arterial vasospasm and endothelial damage also decrease perfusion to the kidneys. The decreased kidney perfusion results in a decreased GFR and leads to oliguria. Oliguria may not be an indication of hypovolemia and should not be treated with diuretics. Glomerular capillary endothelial damage permits protein to leak across the capillary membrane and into the urine, resulting in proteinuria, increased blood urea nitrogen, and increased serum creatinine. If vasospasm and hypercoagulability are long lasting, ischemia occurs in the glomeruli. Complete recovery of renal function usually occurs after delivery.[12]

The liver is also affected by multisystem vasospasm and endothelial damage. Decreased perfusion to the liver can cause ischemia and necrosis. The liver may become edematous as a result of inflammatory infiltrates and obstructed blood flow.[12] Liver damage is reflected in elevated liver function study results, such as serum aspartate aminotransferase, lactate dehydrogenase, and serum alanine aminotransferase.[2]

Neurological sequelae may include seizures, cerebral edema, and cerebral hemorrhage. Symptoms associated with neurological progression are headaches, blurred vision, hyperreflexia and clonus, and changes in the level of consciousness. Increased intracranial pressure and decreased perfusion can lead to hypoxia, coma, and death.[10]

Management

The only cure for severe preeclampsia is delivery of the fetus. The decision to deliver the fetus versus continuing expectant management (ie, to maintain the pregnancy and monitor changes) is individualized.[8]

Usually these patients require invasive hemodynamic monitoring, frequent blood pressure measurements, strict intake and output monitoring, laboratory report monitoring, aggressive anticonvulsant and antihypertensive drug therapy, and, if undelivered, fetal surveillance. Management is focused on preventing seizures and respiratory complications, controlling hypertension, monitoring cardiovascular status, and maintaining fluid status. If the woman does not deliver, fetal monitoring is necessary. Critical care and obstetrical staff must collaborate to provide close fetal observation. It is important that they consider the fetus to be another patient.

Hemodynamic monitoring permits accurate assessments of cardiac output and fluid volume status. Normal hemodynamic values in pregnancy are listed in Table 11-4.[13] Elevated pulmonary artery occlusion pressure (PAOP) and pulmonary artery pressure (PAP) values may indicate hypervolemia, thereby placing the woman at risk for cardiogenic pulmonary edema. (See Chapter 17 for a more detailed discussion of hemodynamic monitoring.) Interventions to reduce preload include restricting intravenous (IV) fluids, repositioning the patient on her side, and administering diuretics when fluid overload or pulmonary edema is present. Decreased central venous pressure, PAP, and PAOP values indicate hypovolemia, and the patient may need a fluid challenge.

Table 11-4 Hemodynamic Values in Nonpregnant and Pregnant Women

	Nonpregnant	Pregnant
Central venous pressure	5–10 mm Hg	1.1–6.1 mm Hg
Pulmonary Artery Pressure		
Systolic	20–30 mm Hg	18–30 mm Hg
Diastolic	8–15 mm Hg	6–10 mm Hg
Mean	10–20 mm Hg	11–15 mm Hg
Pulmonary artery occlusion pressure	6–12 mm Hg	5.7–9.3 mm Hg
Cardiac output	4.3–6.0 L/min	5.2–7.2 L/min

Drug therapy is directed at preventing seizures and hypertensive crises. IV magnesium sulfate is the drug of choice for severe preeclampsia to prevent maternal seizures (Box 11-3). Magnesium sulfate blocks the reuptake of acetylcholine at the nerve end synapses and relaxes smooth muscles. Side effects include drowsiness, flushing, diaphoresis, hyporeflexia, hypocalcemia, and respiratory paralysis.[14] A therapeutic serum level of 4 to 7 mg/dL is maintained through a continuous infusion of 1 to 3 g/h. Serum levels higher than 15 mg/dL may result in respiratory arrest.

Hydralazine hydrochloride (Apresoline) is the antihypertensive agent most commonly used during pregnancy. It causes arterial vasodilation and decreases mean arterial pressure and SVR. Hydralazine increases cardiac output, heart rate, and renal blood flow. Doses are commonly given in 5- to 10-mg boluses intravenously every 20 minutes until a satisfactory reduction in blood pressure is achieved.[14] Other antihypertensive agents used include nitroprusside (Nitropress), nifedipine (Procardia), and labetalol hydrochloride (Normodyne). These drugs may be used when hydralazine therapy fails.

Nursing Interventions

The nurse must assess the patient for increased risk for seizures by evaluating neurological symptoms. To reduce the risk for seizures, the nurse can decrease light and sound stimulation to the patient. Treatments and interventions are coordinated to optimize rest periods. If seizures occur, the nurse protects the

BOX 11-3 Magnesium Sulfate Administration

Dose concentration: 20 g in 500 mL normal saline solution or D_5W = 2 g/50 mL
Loading dose: 4 to 6 g intravenous bolus over 10 to 20 minutes
Maintenance dose: 2 to 3 g/h by intravenous infusion

BOX 11-4 NURSING INTERVENTIONS

For Severe Preeclampsia

Strict Bed Rest in Left Lateral Tilt
- Explain rationale and expected benefits.
- Encourage family and friends to visit and provide activities that may prevent boredom.
- Explain seizure precautions.

Medications
- Explain the action of drugs such as magnesium sulfate and antihypertensive drugs.
- Explain the frequency of laboratory tests, vital sign assessment, and urinary output measurement.

Fetal Surveillance
- Explain external fetal monitoring and tests used to monitor fetal well-being, such as the nonstress test, the biophysical profile, Doppler flow studies, and fetal pulse oximetry.
- Explain the rationale used to determine adequate uteroplacental function.

Delivery
- Prepare the patient for the possibility of cesarean delivery.
- Explain the rationale for the need to deliver.
- Explain neonatal intensive care unit (NICU) if unable to physically take the patient on a unit tour.
- Arrange for a discussion with a neonatologist if the infant is premature or expected to be admitted to NICU.

patient from injury, ensures a patent airway, provides adequate oxygenation, and evaluates possible aspiration. After stabilizing the patient, uterine and fetal activities are quickly assessed. In most instances, immediate delivery of the fetus is indicated.

If the patient is receiving magnesium sulfate therapy, the nurse continuously assesses for symptoms of magnesium toxicity, such as respiratory depression and hyporeflexia. Magnesium is excreted in the urine, and prolonged oliguria allows magnesium to accumulate to toxic blood levels.

If the patient has delivered, magnesium sulfate therapy should be continued for 24 hours. The nurse must assess uterine bleeding. The uterus should be firm after delivery, and if not, uterine massage and oxytocin therapy are needed. Box 11-4 summarizes some of the key nursing interventions for patients with severe preeclampsia.

HELLP Syndrome

HELLP syndrome (*h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets) accompanies severe preeclampsia and eclampsia in approximately 10% to 20% of diagnosed cases. Maternal mortality rates may be as high as 30%.[15] It is often considered a variation of severe preeclampsia. Women in whom HELLP syndrome develops are usually older than 27 years, white, and multiparous. Patients with HELLP syndrome are at an increased risk for developing complications such as renal failure, pulmonary edema, DIC, placental abruption, ARDS, and liver hematoma and rupture.

Signs and symptoms of HELLP syndrome may be similar to those of severe preeclampsia and include epigastric pain, nausea, malaise, and right upper quadrant tenderness. Laboratory results reveal decreased platelets (<100,000/mm^3) and elevated liver enzymes.

Physiological Principles

Hemolysis occurs when red blood cells pass through vasospastic vessels, producing burr cells or schistocytes.[15] Liver enzyme levels become elevated as liver damage occurs resulting from ischemia secondary to vasospasm. Prolonged vasospasm can lead to hepatic necrosis. Platelets are consumed because of the aggregation at endothelial damage sites.

Management

As with severe preeclampsia, delivery is the treatment of choice for HELLP syndrome; however, the timing of delivery remains controversial. Most clinicians recommend expectant management occur no longer than 48 hours after the diagnosis of HELLP is established.[12] If delivery does not occur, management includes bed rest, frequent blood pressure assessments, frequent laboratory evaluation of liver function, coagulation status, and intensive fetal surveillance.[15] The patient is managed in the same manner as severe preeclampsia, and magnesium sulfate and antihypertensive agents are given as needed. Blood products may be given to correct coagulation abnormalities.

HELLP syndrome may mimic other disease entities, and differential diagnosis must be made to rule out autoimmune thrombocytopenic purpura, chronic renal disease, pyelonephritis, cholecystitis, gastroenteritis, hepatitis, pancreatitis, thrombotic thrombocytopenic purpura, hemolytic–uremic syndrome, or acute fatty liver disease of pregnancy.[15]

Monitoring changes in vital signs, bleeding, pain, and laboratory values is necessary when caring for patients with HELLP syndrome. Fetal surveillance is important and should include assessments for fetal heart rate and signs and symptoms of placental abruption. Nurses must be aware of the complications that can occur in patients with HELLP syndrome. Signs of worsening pain, vascular collapse, or shock may indicate liver hematoma or rupture. Accurate monitoring of intake and output must be maintained to assess renal status.

Disseminated Intravascular Coagulation

Several conditions predispose a pregnant woman to DIC because of changes in the coagulation and fibrinolytic systems. These conditions include preeclampsia, abruptio placentae, amniotic fluid embolus, fetal death, and sepsis.[16] Although the incidence of sepsis has decreased because of antibiotic therapy, it is responsible for 3% to 8% of the maternal deaths in the United States.[16] Sepsis during pregnancy is a result of bacterial invasion of the uterine cavity.

Immunosuppression is a normal consequence of pregnancy and thought to occur so that the fetus is not rejected by the maternal immune system. This alteration increases the susceptibility to infection and decreases the body's ability to fight infection. Septic shock may develop in a few days or several hours. Manifestations of septic shock include tachycardia, tachypnea, temperature instability, increased cardiac output, and decreased peripheral resistance.

Abruptio placentae is the premature separation of the placenta from the uterine wall and is one of the most common

causes of DIC. Blood collects between the uterus and placenta, causing consumption of clotting factors. The placental unit contains high concentrations of thromboplastin. When the placenta prematurely separates, thromboplastin continues to be released systemically, activating the clotting and fibrinolytic systems throughout the body. Parallel to the activation of the fibrinolytic system, the hemostatic system initiates clot formation at the site of the separation.[16] Clinical signs of abruption include acute abdominal pain, uterine tenderness, premature contractions, and vaginal bleeding. Abruptions may be subtle, and blood may not be visible.

Intrauterine fetal death can also lead to DIC. Tissue thromboplastin is released from the dead fetus into the maternal circulation activating the procoagulant system. Coagulopathy is gradual and consistent with chronic, low-grade DIC.

Management

Management of patients with DIC includes identifying the underlying condition and initiating appropriate therapy, evaluating and monitoring the coagulation system to restore hemostasis, and preventing further hemorrhage and thrombosis. Management of DIC caused by sepsis includes prompt delivery of the fetus and IV administration of broad-spectrum antibiotics. For abruptio placentae, prompt delivery of the fetus is necessary to control further bleeding.

Nursing care is aimed at preventing further bleeding, monitoring coagulation studies, and assessing the patient for multisystem involvement, altered tissue perfusion, and fluid volume deficits.[16] Nursing care includes monitoring respiratory status, administering IV fluids to prevent hypovolemia, assessing hemodynamic values, and administering and evaluating antibiotics, blood replacement products, and antipyretics.[14] (See Chapter 49 for a more detailed discussion of DIC.)

Amniotic Fluid Embolism

Amniotic fluid embolism (AFE), although rare, is responsible for approximately 10% of maternal deaths in the United States.[10] AFE occurs when amniotic fluid gains entry into the maternal circulation. This entry may occur during cesarean birth or uterine rupture or through small tears in the endocervical veins during a vaginal delivery. Once amniotic fluid enters the maternal circulation, it is rapidly transported to the pulmonary vasculature, resulting in pulmonary emboli. The pulmonary response to AFE is vasospasm, which produces transient pulmonary hypertension and profound hypoxia. The maternal system becomes hemodynamically compromised, similar to anaphylactic shock, with elevated PAP and left ventricular failure.[10] Predisposing factors that may lead to AFE include preeclampsia, multiple gestation, polyhydramnios (excess amniotic fluid), low insertion of placenta, postterm pregnancy, hypertonic contractions during labor, abruptio placentae, uterine rupture, maternal seizures, and umbilical cord prolapse. Clinical manifestations of AFE include sudden onset of dyspnea, cyanosis, and hypotension, followed by cardiopulmonary arrest.

Management

Management of AFE is directed at maintaining left ventricular output and an adequate airway.[10] Interventions include intubation and ventilation with 100% oxygen, IV administration of vasopressors and crystalloid fluids, cardiopulmonary resuscitation (CPR), administration of blood products, and pulmonary artery catheterization. In extreme cases, extracorporeal membrane oxygenation (ECMO) may be used to provide adequate oxygenation and ventilatory support during treatment of the AFE. Potential sequelae include acute pulmonary edema, respiratory distress, DIC, hemorrhage, and multisystem failure.

The nurse must react quickly when AFE is suspected. Following the basic ABCs (airway, breathing, and circulation), the nurse can prioritize interventions needed in this stressful situation. If the patient is not intubated, oxygen must be administered using a face mask, and oxygen saturation assessed using a pulse oximeter. The nurse can anticipate that after intubation, a resuscitation bag or mechanical ventilation will be needed. To maximize venous return, the woman should be positioned on her side or a wedge placed under her hip. A large-bore IV line is needed to administer IV fluids and blood products and to correct hypotension. Assessment focuses on the cardiovascular, pulmonary, hematological, and neurological systems.

Acute Respiratory Distress Syndrome

ARDS is characterized by progressive respiratory distress, severe hypoxemia, low lung compliance, noncardiogenic pulmonary edema, and diffuse infiltrates on chest radiography.[1] Precipitating factors of ARDS associated with pregnancy include abruptio placentae, severe preeclampsia, pyelonephritis, DIC, sepsis, AFE, aspiration, systemic infections, and fetal death in utero. Maternal hypoxemia can lead to spontaneous labor and fetal hypoxia, acidosis, and death; therefore, it should be aggressively managed. Perfusion to vital organs, including the fetus, must be maintained to reduce morbidity and mortality. Adequate fetal oxygenation requires a maternal arterial oxygen saturation (SaO_2) of at least 95%.

Management

Pregnant women with ARDS require cardiovascular support and mechanical ventilation using positive end-expiratory pressure (PEEP). Hemodynamic monitoring is essential for evaluating changes associated with ARDS, such as central hypovolemia and noncardiogenic pulmonary edema. Ventilator settings include a rate of 12 breaths/min, a tidal volume of 12 to 15 mL/kg body weight, 100% oxygen, and a PEEP of 5 cm H_2O.[1]

Nursing care of pregnant women with ARDS is primarily supportive. Interventions are directed at optimizing oxygen transport to tissues and restoring pulmonary capillary integrity. A complete respiratory assessment is made, including evaluation of SaO_2 using pulse oximetry; observation of respiratory rate, character, and effort; and auscultation of lungs. The symptoms of noncardiogenic pulmonary edema are similar to those of cardiogenic pulmonary edema (ie, tachypnea, tachycardia, rales, shortness of breath); however, the nurse should be aware that a decrease in PAOP and PAP (from the obstetrical normal; see Table 11-4, p. 126) may indicate noncardiogenic pulmonary edema. Noncardiogenic pulmonary edema in obstetrical patients can be caused by aspiration of gastric contents, sepsis, blood transfusion reactions, DIC, and AFE.

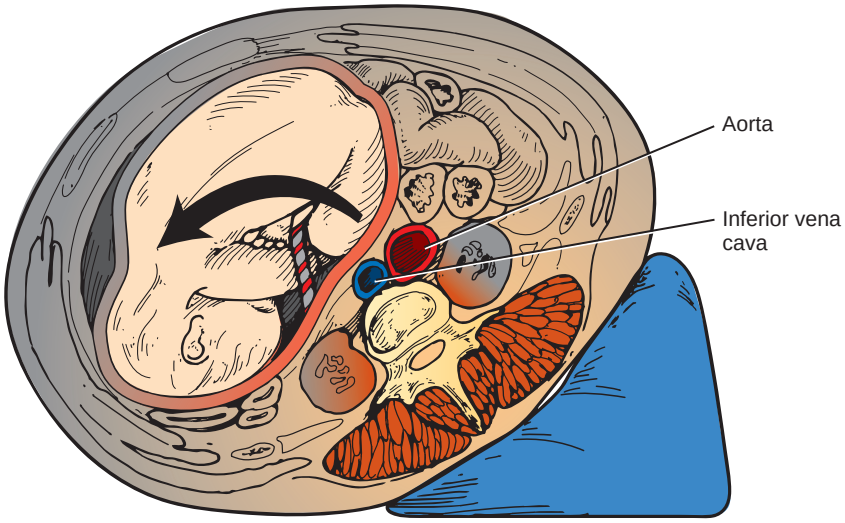

FIGURE 11-2 ▲ Placing a wedge under the woman's right hip decompresses the major abdominal vessels, maximizing the cardiopulmonary resuscitation effort.

Nursing interventions to improve uteroplacental blood flow include positioning the patient on her side and maintaining adequate fluid volumes.[11]

Nursing care for women who are mechanically ventilated includes psychosocial support to help relieve anxiety, fear, and separation from family. Nurses can facilitate communication between the patient and family and keep them informed about maternal and fetal conditions. In extreme cases of ARDS in the postpartum period, ECMO may be used to provide adequate oxygenation and ventilatory support.

Trauma

Accidental injuries occur in 6% to 7% of all pregnancies and are associated with spontaneous abortion, preterm labor, abruptio placentae, and fetal death. Trauma is the leading cause of nonobstetrical maternal death.[2] Common types of trauma include blunt trauma from motor vehicle crashes (49%), falls, and domestic violence (18% to 25%) and penetrating trauma from stab wounds or gunshots (4%).[17] Fetal survival depends on maternal survival, so immediate care and stabilization of the pregnant woman are essential.

Hemodynamic instability may not be initially apparent because of the normal physiological cardiovascular changes during pregnancy. A pregnant woman can lose up to 2,000 mL of blood before becoming hemodynamically unstable.[2]

Management

Management consists of immediate stabilization and care. Immediate stabilization of all trauma patients consists of applying the ABCs of resuscitation: establishment of airway, breathing, and circulation. First an airway is established, and oxygen is provided at a rate of 10 to 12 L/min to produce a PaO_2 level of 60 mm Hg or higher. This PaO_2 level is necessary for optimal fetal oxygenation. A nasogastric tube should be inserted to avoid aspiration.

If CPR is necessary, the anatomical and physiological changes in pregnancy must be considered to maximize efforts. The uterus compresses major abdominal vessels and displaces abdominal contents, which decreases chest compliance. Placing a wedge under the woman's right hip displaces the uterus and decompresses the vessels (Fig. 11-2). This intervention can increase cardiac output up to 30%.[2] Standard advanced cardiac life support procedures are used, including defibrillation and most drugs. The administration of vasopressors should be avoided because the vasoconstrictive action can impair uteroplacental perfusion.[21] Medical antishock trousers or pneumatic antishock garment equipment is rarely used; however, if they are employed, the abdominal compartment should not be inflated.[18]

IV access using large-bore catheters is needed, and aggressive IV infusions are used to increase stroke volume and maintain cardiac output. If hemorrhage occurs, bleeding must be controlled. A decrease in arterial blood pressure may not be an indication of hypovolemia because of low resistance in the uteroplacental system. A 30% to 35% loss can occur with severe consequence to the fetus before hypotension is noted. Fluid replacement therapy must be administered at a higher rate.[2]

Once the pregnant woman has been stabilized, her neurological status is assessed. After this assessment, a fetal assessment, including determination of life, is made. The fetal heart rate can be auscultated using a fetoscope, stethoscope, fetal Doppler, or ultrasonography. Additional assessments can be made on arrival at the hospital or trauma center. These assessments include electrocardiography, a complete physical examination, and laboratory tests, such as arterial blood gases (Table 11-5), complete blood count, platelet count, electrolytes, blood type and crossmatch, and the Kleihauer-Betke test. Used to detect fetomaternal hemorrhage, the Kleihauer-Betke

Table 11-5 Arterial Blood Gas Values in Nonpregnant and Pregnant Women

	Nonpregnant	Pregnant
PaO_2	80–100 mm Hg	87–106 mm Hg
$PaCO_2$	36–44 mm Hg	27–32 mm Hg
pH	7.35–7.45	7.40–7.47
HCO_3^-	24–30 mEq/L	18–21 mEq/L

test identifies red blood cells from the fetus that have entered the maternal circulatory system. This is primarily of concern in the Rh-negative pregnant patient.[2] Assessments should include parameters such as the onset of regular contractions (indicating labor may have begun), vaginal bleeding, and leakage of fluid from the vagina (indicating ruptured membranes).

▲ Providing Emotional Support

Emotional support is very important to all critically ill pregnant women and their families. If the woman labors in the ICU, her coach or significant other should be allowed to remain at the bedside. When she gives birth, breastfeeding and bonding can be encouraged when feasible. The mother needs access to her newborn and family during this time. If the newborn is not able to be at the bedside, frequent updates about the newborn are important and can be provided by the staff. Providing a flexible and individualized atmosphere to a new family is a challenge in the ICU. The importance of coordinating obstetrical and critical care cannot be overemphasized. Box 11-5 outlines strategies for promoting emotional well-being in high-risk pregnancies.

BOX 11-5 Strategies for Promoting Emotional Well-Being in High-Risk Pregnancies

- Shift orientation from the health care team to family centered care.
- Incorporate cultural beliefs into the environment. Maintain family rituals when possible.
- Understand the role of the pregnant woman and her family members and assist them with their tasks to optimize family function.
- Provide names of family support groups.
- Provide information and education to family members.
- Encourage the family when they are coping well.
- Validate the family's emotions.

If the fetus dies as a result of maternal complications, grief support may be needed. The nurse may collaborate with Labor and Delivery staff (who may have additional grief training), psychiatric liaison nurses, social workers, psychologists, psychiatrists, or clergy to offer emotional support to a grieving mother and family.

▲ Clinical Applicability Challenges

CASE STUDY

Ms. W. is a 41-year-old para 2032 (two previous full-term pregnancy, two children are living, three miscarriages) admitted at 37 weeks and 4 days of gestation for an induction of labor due to oligohydramnios (very low amniotic fluid). Until recently, she received routine prenatal care, and the pregnancy was uneventful. Her obstetrical history is significant for a cesarean section for breech presentation, a vaginal birth, and three spontaneous miscarriages. Once Ms. W. was admitted, an external fetal monitor was applied, an intravenous (IV) line was inserted, and IV infusion of Pitocin was begun for induction of labor. Her vital signs were BP 121/74, respiration rate 20, pulse rate 79, and temperature 37°C. Several hours later, it was decided that Ms. W. would need a cesarean section for failure to dilate. After the baby was delivered by cesarean section, excessive bleeding was noted on the right side of the uterine incision. Despite attempts to control hemostasis by suturing various areas that were extensions of the surgical incision, the uterus became atonic and a cesarean hysterectomy was necessary. The patient continued to bleed with an estimated 7-liter blood loss. Ms W.'s hematocrit was 23.1%, hemoglobin was 8.3 g/dL, platelet count was 49, fibrinogen was 113 mg/dL, prothrombin time was 15.1 seconds, and activated partial thromboplastin time was 59.4. She received 12 units of packed red blood cells (PRBCs), 7 units of fresh frozen plasma, 1 pack of platelets, and factor VII in the operating room. Packing with Gelfoam was performed and the patient was transferred immediately to the surgical intensive care unit (SICU).

On admission to the unit, Ms. W. was tachycardic (145 beats/min), hypotensive (BP 80/40), and tachypneic (36 breaths/min). Her urine output was less than 30 mL in an hour. She was unconscious and intubated. Her lab results did not show improvement initially and additional fresh frozen plasma, platelets, and factor VII were administered. She was diagnosed with DIC. Her vital signs and lab results improved over the first 24 hours and by postoperative day 3, she was transferred to the postpartum unit. On postoperative day 4, she was ambulating, voiding, and tolerating a regular diet. She was discharged home on postoperative day 5.

1. What signs and symptoms led to the diagnosis of DIC?
2. How can the SICU staff provide a family centered environment for this patient?
3. What outcomes would be expected following the successful response to the therapy provided?

12 The Critically Ill Older Patient

Barbara Resnick

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Explain general physical changes that occur as a result of the normal aging process.
2. Describe the developmental tasks of the older person.
3. Discuss specific conditions that affect the major body systems of the older person.
4. Explain cognitive changes that may occur in the older patient.
5. Compare and contrast delirium and dementia in the older patient.
6. Describe assessment indicators of potential abuse or neglect of the older person.
7. Describe why the principle *start low, go slow* is important for the older patient in regard to the absorption, distribution, metabolism, and excretion of medications.

America is growing older. Between 2002 and 2030, the older population will more than double, increasing to 71.5 million from 35.6 million (Fig. 12-1). Almost one in five people will be 65 years old or older,[1] and more people will seek medical care for chronic disease, the leading cause of disability among older adults. When older adults have acute exacerbations of their diseases, they often require hospitalization in an intensive care unit (ICU).

As a result, critical care nurses need to understand the many physiological changes that occur normally with aging. These alterations are progressive and usually are not apparent or pathological. However, these age-related changes put the critically ill older adult at increased risk for complications. Preventive nursing care, focused on avoiding potential problems, is necessary.

The leading causes of death among older patients are heart disease, malignant neoplasms, cerebrovascular accidents (CVAs), influenza, and chronic obstructive pulmonary disease. Chronic conditions (eg, arthritis, hearing and visual deficits) are prevalent among older people. With advancing age, these conditions become more common and result in increased hospitalizations. A longer life span has been the single most important cause of the increased numbers of older people with multiple chronic and acute illnesses.

▲ Normal Psychobiological Characteristics of Aging

Biological Issues

Intrinsic aging refers to characteristics and processes that occur universally with all older adults. Changes resulting from the aging process must be distinguished from those resulting from a particular disease process, disuse, or environmental factors, such as ultraviolet radiation. Extrinsic aging is composed of factors that influence aging to varying degrees in different people. Extrinsic factors include such things as lifestyle or exposure to environmental influences. Normal aging is defined as the sum of intrinsic aging, extrinsic aging, and idiosyncratic or individual genetic factors specific to each individual.[2]

In most physiological systems, the normal aging processes do not result in significant impairment or dysfunction in the absence of disease and under resting conditions. It is only in response to stress that an age-related reduction in physiological reserves causes a loss of homeostatic balance. The following are some examples of intrinsic age changes:

- Reduced resistance to stress
- Poor tolerance of extremes of heat and cold because of hypothalamic and skin changes
- Reduced sensory perceptions
- Greater fluctuation in blood pH

Aging, in one organ or the entire body, may be premature or delayed in relation to actual chronological age. The effect of aging on cellular tissues is asymmetrical. For example, the changes resulting from aging in relation to the brain, bone, cardiovascular, and lung tissues may be fairly obvious, whereas changes affecting the liver, pancreas, gastrointestinal tract, and muscle tissues are less obvious. Several organic changes that result from aging are listed in Box 12-1.

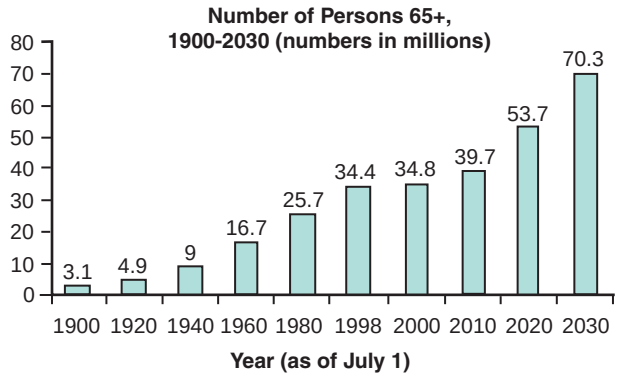

FIGURE 12-1 ▲ Profile of Americans age 65 years and older (based on data from the United States Bureau of the Census). Data from the year 1900 to present were used to predict the number of Americans aged 65 years and older in the year 2030. (From www.aoa.gov/aoa/stats/profile/default.htm.)

Psychosocial Issues

In addition to physical signs of aging, nurses caring for acutely ill older patients must be aware of the older person's normal developmental tasks and the specific dreams or wishes of a particular senior. Developmental tasks of older people are listed in Box 12-2.

The need for support and meaningful relationships continues throughout life. Support can be described as a feeling of belonging or a belief that one is an active participant in the surrounding world. The feeling of mutuality with others in the environment lends strength and helps decrease the sense of isolation. Support by family, friends, and the community can provide an older patient with a greater sense of stability and security.

Self-worth and perceived well-being are feelings that usually coincide in older adults. The perception of well-being arises from the satisfaction of meeting an acceptable proportion of one's life goals. It can be described as an inner contentment one has in life as a whole. Related to this, a feeling of self-worth is derived not only from a sense of well-being but also from satisfaction with one's image or acceptance by others. Self-worth also reflects the quality of interactions with family and friends.

Family environment for the older adult includes, among others, dimensions of interpersonal relationships, personal growth, integrity of the family unit, and adaptation to stress. As family members age, all these areas of concern intensify because of changes in roles of family members, alterations in the family power structure, and changes in financial and decision-making dynamics. Acute illness increases the urgency for effective cooperation among all family members as the traditional family structure is suddenly challenged.

When older patients are admitted to intensive care, issues of family cohesion and adaptability often surface. Frequently, families face immediate changes in roles, with adult children and grandchildren assuming the roles of caretakers and nurturers for the older family members. The family must suddenly adjust to dramatically different demands. Frequent visits to the hospital; dialogues with nurses, physicians, and social workers; and efforts to support and communicate with the patient become primary tasks. Amid these activities, family members (particularly those who have been given power of attorney) find themselves being pressed for decisions about immediate and long-term care. At this time, the issue of the person's end-of-life care preferences, competency, and ability to be involved in treatment decisions may arise. Effective communication and a willingness to listen to and respect the wishes of the older patient become foremost. If this is achieved, the stress on families is reduced because of increased acceptance of the plan of care by all family members.

BOX 12-2 Developmental Tasks of the Older Person

- Deciding where and how to live for his or her remaining years
- Preserving supportive, intimate, and satisfying relationships with spouse, family, and friends
- Maintaining an adequate and satisfying home environment relative to health and economic status
- Providing sufficient income
- Maintaining a maximum level of health
- Attaining comprehensive health and dental care
- Maintaining personal hygiene
- Maintaining communication and adequate contact with family and friends
- Maintaining social, civic, and political involvement
- Initiating new interests (in addition to former activities) that increase status
- Recognizing and feeling that he or she is needed
- Discovering the meaning in life after retirement and when confronted with illness of self or spouse and death of spouse and other loved ones; adjusting to death of loved ones
- Developing a significant philosophy of life and discovering comfort in a philosophy or religion

BOX 12-1 Organic Changes With Aging

- The amount of connective and collagen tissue is increased.
- Cellular elements in the nervous system, muscles, and other vital organs disappear.
- The number of normally functioning cells is reduced.
- The amount of fat is increased.
- Oxygen use is decreased.
- During rest, the amount of blood pumped is decreased.
- Less air is expired by the lungs.
- Excretion of hormones is decreased.
- Sensory and perceptual activity is decreased.
- Absorption of lipids, proteins, and carbohydrates is decreased.
- Presbyesophagus occurs.
- The arterial lumen thickens.

▲ Physical Challenges

Chronic changes in one organ system may be associated with changes in other systems. Moreover, there is individual variation in age-related changes. Therefore, each person must be evaluated based on the age-related changes actually present rather than on those that are "normal" for a particular age.

It is equally important to distinguish age-related changes from those associated with a chronic disease or acute illness and to avoid prematurely attributing some findings to age if they are caused by illness. A discussion of the effects of aging on various body systems follows; age-related changes and the clinical implications of the changes are summarized in Table 12-1.

Table 12-1 Summary of Age-Related Changes, Clinical Implications, and Key Nursing Interventions

System	Clinical Implications	Key Nursing Interventions
Cardiovascular		
• Atrophy of muscle fibers that line the endocardium • Atherosclerosis of vessels • Increased systolic blood pressure • Decreased compliance of the left ventricle • Decreased number of pacemaker cells • Decreased sensitivity of baroreceptors	• Increased blood pressure • Increased emphasis on atrial contraction with an S_4 heard • Increased dysrhythmias • Increased risk for hypotension with position change • Valsalva maneuver may cause a drop in blood pressure • Decreased exercise tolerance	• To prevent falls related to positional hypotension, make sure the person changes position slowly and waits before ambulating.
Neurologic		
• Decreased number of neurons and increase in size and number of neuroglial cells • Decline in nerves and nerve fibers • Atrophy of the brain and increase in cranial dead space • Thickened leptomeninges in spinal cord	• Increased risk for neurologic problems: CVA, parkinsonism • Slower conduction of fibers across the synapses • Modest decline in short-term memory • Alterations in gait pattern: wide based, shorter stepped, and flexed forward • Increased risk for hemorrhage before symptoms are apparent	• To compensate for the decline in short-term memory, provide more time to complete memory-associated tasks.
Respiratory		
• Decreased lung tissue elasticity • Thoracic wall calcification • Cilia atrophy • Decreased respiratory muscle strength • Decreased partial pressure of arterial oxygen (PaO_2)	• Decreased efficiency of ventilatory exchange • Increased susceptibility to infection and atelectasis • Increased risk for aspiration • Decreased ventilatory response to hypoxia and hypercapnia • Increased sensitivity to narcotics	• To prevent infection and atelectasis, encourage deep breathing and coughing.
Integumentary		
• Loss of dermal and epidermal thickness • Flattening of papillae • Atrophy of sweat glands • Decreased vascularity • Collagen cross-linking • Elastin regression • Loss of subcutaneous fat • Decreased melanocytes • Decline in fibroblast proliferation	• Thinning of skin and increased susceptibility to tearing • Dryness and pruritus • Decreased sweating and ability to regulate body heat • Increased wrinkling and laxity of skin • Loss of fatty pads protecting bone and resulting in pain • Increased need for protection from the sun • Increased time for wound healing	• To prevent damage to fragile skin, avoid shearing forces. • To counteract dryness, immerse skin in water daily and apply emollients. • To minimize pain, pad thinned areas with additional layers (eg, extra socks for feet). • Encourage sunscreen use.
Gastrointestinal		
• Decreased liver size • Less efficient cholesterol stabilization and absorption • Fibrosis and atrophy of salivary glands • Decreased muscle tone in bowel • Atrophy of and decrease in number of taste buds • Slowing in esophageal emptying • Decreased hydrochloric acid secretion • Decreased gastric acid secretion • Atrophy of the mucosal lining • Decreased absorption of calcium	• Change in intake due to decreased appetite • Discomfort after eating related to slowed passage of food • Decreased absorption of calcium and iron • Alteration of drug effectiveness • Increased risk for constipation, esophageal spasm, and diverticular disease	• Encourage small, frequent meals to avoid discomfort and improve intake. • Encourage fluids and fiber to improve bowel function.

(continued on page 135)

Table 12-1 **Summary of Age-Related Changes, Clinical Implications, and Key Nursing Interventions (continued)**

System	Clinical Implications	Key Nursing Interventions
Urinary		
• Reduced renal mass • Loss of glomeruli • Decline in number of functioning nephrons • Changes in small vessel walls • Decreased bladder muscle tone	• Decreased GFR • Decreased sodium-conserving ability • Decreased creatinine clearance • Increased BUN • Decreased renal blood flow • Altered drug clearance • Decreased ability to dilute urine • Decreased bladder capacity and increased residual urine • Increased urgency	• To prevent complications from medical therapy, monitor drug clearance and alter dosing as necessary. • Monitor for UTI
Reproductive		
• Atrophy and fibrosis of cervical and uterine walls • Decreased vaginal elasticity and lubrication • Decreased hormones and reduced oocytes • Decreased seminiferous tubules • Proliferation of stromal and glandular tissue • Involution of mammary gland tissue	• Vaginal dryness and burning and pain with intercourse • Decreased seminal fluid volume and force of ejaculation • Reduced elevation of the testes • Prostatic hypertrophy • Connective breast tissue is replaced by adipose tissue, making breast examinations easier	• To compensate for vaginal dryness or pain, encourage the use of lubricating creams, estrogen cream, or both. • Monitor for urinary retention in men.
Musculoskeletal		
• Decreased muscle mass • Decreased myosin adenosine triphosphatase activity • Deterioration and drying of joint cartilage • Decreased bone mass and osteoblastic activity	• Decreased muscle strength • Decreased bone density • Joint pain and stiffness • Loss of height • Increased risk for fracture • Alterations in gait and posture	• Encourage resistive exercises to reverse a decline in muscle strength. • Encourage exercise and intake of calcium and vitamin D. • Encourage activity and exercise.
Sensory		
Vision		
• Decreased rod and cone function • Pigment accumulation • Decreased speed of eye movements • Increased intraocular pressure • Ciliary muscle atrophy • Increased lens size and yellowing of the lens • Decreased tear secretion	• Decreased visual acuity, visual fields, and light/dark adaptation • Increased sensitivity to glare • Increased incidence of glaucoma • Distorted depth perception with increased falls • Less able to differentiate blues, greens, and violets • Increased eye dryness and irritation	• Provide materials with large print. • Make sure there is adequate lighting without glare. • Use contrasting colors for print material.
Hearing		
• Loss of auditory neurons • Loss of hearing from high to low frequency • Increased cerumen • Angiosclerosis of ear	• Decreased hearing acuity and isolation (specifically, decreased ability to hear consonants) • Difficulty hearing, especially when there is background noise, or when speech is rapid • Cerumen impaction may cause hearing loss.	• Make sure to face the person; use touch and visual cues to facilitate communication. • Evaluate for cerumen impaction, and remove cerumen as necessary.
Smell		
• Decreased number of olfactory nerve fibers	• Inability to smell noxious odors • Decreased fowod intake	• Present odors the patient can smell. The ability to smell fruity odors, for example, are retained. Also use spices in foods to augment the sense of taste.

(continued on page 136)

Table 12-1 **Summary of Age-Related Changes, Clinical Implications, and Key Nursing Interventions (continued)**

System	Clinical Implications	Key Nursing Interventions
Taste		
• Altered ability to taste sweet and salty foods; bitter and sour tastes remain		• Use alternative seasonings.
Touch		
• Decreased sensation	• Safety risk with regard to recognizing dangers in the environment: hot water, fire, small objects on floor that may result in tripping	• Avoid a cluttered environment.
Endocrine		
• Decreased testosterone, GH, insulin, adrenal androgens, aldosterone, and thyroid hormone • Decreased thermoregulation • Decreased febrile response • Increased nodularity and fibrosis of thyroid • Decreased basal metabolic rate	• Decreased ability to tolerate stressors such as surgery • Decreased sweating and shivering and temperature regulation • Lower baseline temperature; infection may not cause an elevation in temperature • Decreased insulin response, glucose tolerance • Decreased sensitivity of renal tubules to ADH • Weight gain • Increased incidence of thyroid disease	• Monitor the temperature of the room. • Provide adequate clothing and blankets to keep the patient warm. • Closely monitor blood glucose levels of patients with diabetes.
Immune		
• Decline in both T-cell and B-cell function • The decreased numbers of B cells secreting immunoglobulin G • The thymus gland involutes, and there is a decrease in thymic hormone levels. • The number of autoantibodies increases.	• Poor immune response and risk for infection	• There is some evidence that exercise helps to boost the immune system and should be encouraged. Also, meticulous use of universal precautions and infection control techniques should be encouraged.

Auditory Changes

With age, there is a change in the shape of the ear: the auricle becomes elongated and broader, the cartilage is less elastic and less flexible, and tophi may appear on the pinna. The hairs on the external ear canal become longer and coarser, the tympanic membrane is thicker and more fixed, and there are fewer cerumen glands (leading to thicker, drier cerumen). In the cochlea, hair cells, neuron-supporting cells, ganglion cells, and fibers are decreased, causing decreased hearing and balance. An estimated 7 million people older than 65 years have significant hearing loss, and continuation of current trends indicates that in 2010, more than 11 million people have this problem.[3] Specifically, the aging process affects hearing in two critical ways: reduction in threshold sensitivity and reduction in the ability to understand speech. Threshold elevations that occur between 8,000 and 20,000 Hz are not detectable with a routine hearing test. Therefore, hearing loss because of aging or other factors is not documented clinically until frequencies are at or below 8,000 Hz.

Presbycusis is a sensorineural hearing loss and is the most common form of hearing loss in older adults. Presbycusis is characterized by a gradual, progressive, bilateral, symmetrical, high-frequency sensorineural (perceptive) hearing loss with poor speech discrimination. Sensorineural hearing loss is due to degeneration or changes in the neural receptors in the cochlea, cranial nerve VIII (the acoustic nerve), and central nervous system. Treatment may vary dramatically from simple removal of impacted earwax to surgical removal of an auditory nerve tumor. Thirteen percent of people 65 years of age and older, if tested, would show signs of presbycusis.[3]

Conductive hearing loss is due to the blockage of sound transmission from the external ear through the tympanic membrane and small bones in the middle ear. Like presbycusis, conductive hearing loss is commonly found in older adults, and it is not unusual for older people to have both sensorineural and conductive hearing loss.

Findings on Physical Examination and Management

The ear canal of the older adult should be evaluated at regular intervals (every few months) because of the tendency to have thicker, drier cerumen, which can occlude the canal and affect hearing. The older patient may retain the ability to hear pure tones, but if these pure tones are grouped to form words, the ability to understand and perceive these sounds as intelligible speech may be lost. This loss is known as impairment of discrimination ability. The patient has increased difficulty hearing high-frequency, stimuli-sibilant sounds

(-f-, -s-, -th-, -ch-, and -sh-). Noisy environments further hamper the ability to hear certain sounds. Therefore, the person may respond inappropriately to questions, withdraw, or frequently ask for the speaker to repeat what is said. Eliminating background noise, speaking lower and louder, and using multiple means of getting information across (eg, verbal as well as written formats) can facilitate communication. People with impaired discrimination may also have problems with balance during transfers and ambulation, and they experience frequent falls. Activity and exercise interventions should be implemented as soon as possible to strengthen muscles and bones and improve balance.

Visual Changes

Like all other body systems, the eye is affected by aging. Structural and functional changes occur slowly and gradually. Visual perception depends on the integration of various neurosensory systems and structures that age at different rates.

Normal changes associated with aging may include a loss of elasticity in the eyelids and subsequent wrinkling, ptosis (upper eyelid drooping), and "pouches" resulting from changes in the tissues beneath the eyelid skin and the subsequent formation and accumulation of fatty tissue. The conjunctiva may develop a yellowish or discolored membrane or become thickened as a result of environmental hazards, such as dust and exposure to drying and irritating pollutants. Arcus senilis, which is a white or gray ring around the limbus (junction of the cornea and sclera), may be related to a high blood level of fatty substances accumulated with advancing age. Although there is a decrease in the amount of lacrimation with age, overflow of tears may occur because of impaired drainage of the ductal system.

The iris loses its ability to accommodate rapidly to light and dark and develops an increased need for light. With age, the pupil becomes smaller and fixed. The lens becomes inflexible with less complete accommodation for near and far vision. The vitreous humor behind the lens may pull on the retina, producing holes or tears and predisposing the older person to retinal detachment. The ciliary muscle becomes stiff, which contributes to the problems of accommodating to distances. By the age of 60 years, presbyopia may develop. Presbyopia is the inability to shift focus from far to near. A possible rationale for this loss is that the older, aging lens, which is less flexible, cannot easily change shape from the action of the focusing muscle to which it is attached.

In older adults, dark–light adaptation slows as the pupillary response slows and rods degenerate. As the lens yellows with increasing age, color discrimination becomes less acute, especially in the blue-green tones. Peripheral vision may decline because of decreased extraocular muscle strength, and depth perception may decline because of a thickening lens. Therefore, time must be provided for the person to adapt when moving between dark and light environments and when getting out of bed.

In addition to normal changes in vision, there is an increased incidence of cataracts, glaucoma, senile macular degeneration, and diabetic retinopathy. These diseases must be studied in relation to normal aging of the eye structure. A cataract is a clouding of the normally clear and transparent lens of the eye. When a cataract interferes with the transmission of light to the retina, some loss in visual acuity may result. The older patient may complain of increased sensitivity to glare, a blurring of vision, halo images, cloudiness, decreased visual acuity, and decreased contrast sensitivity. Risk factors for cataract formation include diabetes mellitus, heredity, ultraviolet-B radiation exposure, smoking, corticosteroid drugs, alcohol use, and insufficient ingestion of antioxidant vitamins. The visual changes can progress to complete loss of vision. Cataracts account for one sixth of all cases of visual impairment in the United States and mostly occur in people older than 50 years.

Glaucoma is one of the major causes of blindness and is especially prevalent in the older adult. Glaucoma is due to increased intraocular pressure. This pressure may result in compression of the optic disc of the eye and damage to cranial nerve II (the optic nerve). This results in loss of peripheral vision and visual acuity. Risk factors for glaucoma include African American race, a family history of glaucoma, ocular hypertension, advanced age, myopia, retinal vascular disturbance, corticosteroid drug use, diabetes mellitus, and vascular crisis (elevation in blood pressure). Age-related changes in the canal of Schlemm, infection, injury, swollen cataracts, and tumors are also etiological factors for glaucoma. Glaucoma is classified based on whether the angle of the anterior chamber is open or narrow and whether the glaucoma is primary or secondary. Primary, open-angle glaucoma is the most common type found in older adults. This type progresses slowly. Primary, angle-closure glaucoma is less common and is characterized by a sudden and marked increase in intraocular pressure with accompanying redness and pain in the eye, headache, nausea or vomiting, corneal edema, and decreased vision. Secondary glaucoma is characterized by an anatomical or functional blockage of the outflow channels. These types of glaucoma can be open angle (such as those that occur from corticosteroid-induced pressure increases) or closed angle (such as those caused by a swollen cataract). Early diagnosis is important because the earlier that treatment is started, the easier it is to control the disease.

Retinal degeneration, or macular degeneration, is the third major source of visual disability in the older adult. Macular degeneration is a pigmentary change of the macular area of the retina caused by small hemorrhages. People see a gray shadow in the center of the visual area but can see well at the outer border. This condition rarely results in total blindness; however, visual loss can progress to legal blindness. Early symptoms include a slight blurring of vision, followed by a blind spot. Compensation techniques include wearing sunglasses or visors, looking to the side, and using magnifiers.

Diabetic retinopathy is the leading cause of blindness in the United States. It is caused by the deterioration of the blood vessels nourishing the retina at the back of the eye. Microaneurysms and small hemorrhages in the eye may leak fluid or blood and cause swelling of the retina. If this leaking blood or fluid damages or scars the retina, the image sent to the brain becomes blurred, and the condition eventually can progress to blindness.

Findings on Physical Examination and Management

The older adult is likely to have smaller pupils, decreased visual acuity, difficulty with depth perception, decreased peripheral vision, and dry eyes. Ectropion and entropion

BOX 12-3 NURSING INTERVENTIONS

For Visually Impaired Patients

- Identify yourself on approach.
- Approach blind patients from the front.
- Assess impact of failing vision and patient's ability to adapt during hospitalization and after discharge.
- Assess stress level because increased stress can necessitate higher dosages of eye medication for patients with glaucoma.
- Be alert to side effects that other medications may have on the eyes (ie, medications containing antihistamines, caffeine, and atropine-like substances).
- Provide eye lubrications when eyes are dry.
- Instill all prescribed medications.

are commonly noted with age. Ectropion is eversion of the eyelid (usually the lower lid) resulting in exposure of the lid, thickening and keratinization, and chronic irritation. Entropion is inversion of the eyelid and results in the eyelashes rubbing against and scratching the cornea. Entropion can result in corneal trauma and scarring and ultimately may result in decreased vision. When cataracts are present, there is opacity of the lens, and the red reflex may be absent during funduscopic examination. The older adult with cataracts presents with dimming of his or her vision and complains that everything appears clouded. People who have glaucoma present with complaints of blurred vision, halos around lights, or decreased peripheral vision. Funduscopic examination in these people shows cupping of the optic disc and atrophy of the optic nerve. Last, older adults with macular degeneration present with a gradual decline in vision, particularly central vision, without a change in peripheral vision. Good lighting, avoiding glare, and using contrasting colors (eg, black letters on white paper) and large print can facilitate vision. As with interventions for hearing changes, providing information in various ways is effective for facilitating vision and compensating for losses. Selected nursing interventions for people with impaired vision are listed in Box 12-3.

Other Sensory Changes

Although hearing and vision changes are the most researched sensory changes occurring in older people, there also may be declines in other senses. The number of taste buds is reported to decrease with age, in conjunction with a decline in the ability to taste substances. Sweet and salty substances are less detectable as one ages; therefore, many older adults complain that food tastes bitter or sour. There is very little information on smell sensation, but it is thought that a decrease in the sense of smell can result from atrophy of the olfactory organ and increased hair in the nostrils.[4] The loss of taste and smell affects the older person's ability to identify food and make odor discriminations.

The threshold of touch varies with the part of the body stimulated. There is a loss of tactile sensation as one ages, although this varies individually. Older adults may not feel the effects of lying too long in one position. A key nursing intervention is to vary the positions of the immobile older patient. The older adult also has decreased kinesthetic sense, which is the person's awareness of his or her body in space. Decreased kinesthetic sense results in postural instability and difficulty reacting to bodily changes in space.

Findings on Physical Examination and Management

With age, the lips tend to become thin and pale, and the tissue of the oral mucosa is thinner, paler, and less elastic. Small yellow sebaceous glands may be seen in the buccal mucosa. The dorsum and margins of the tongue may have decreased number and size of papillae and may be coated with a thin white film. There may also be increased fissures on the dorsal aspect of the tongue, whereas the undersurface is smooth with a bluish-purple hue from increased varicosities. Taste buds and the submaxillary, pituitary, and salivary glands atrophy. The gums are thinner and receded, and there is decreased tooth enamel, dry and less translucent dentin, decreased dental pulp, and diminished perfusion and sensitivity of the gums. Decreased taste sensitivity (especially for sweets and salt) and increased difficulty swallowing food (due to less saliva production) may cause the older adult to present with weight loss. To facilitate taste and improve oral intake, the nurse provides frequent mouth care (before meals), offers foods in a pleasant setting using liberal seasonings to stimulate taste, and encourages the use of interventions, such as sugar-free candies, to stimulate salivation.

Older adults with decreased sensation may present with complaints of increased difficulty performing fine motor activities such as buttoning clothes or picking up objects. They may also have pressure sores and decreased balance. Frequent position changes of older patients are essential and should be instituted every 30 minutes.

Sleep Changes

It is estimated that sleep disturbances occur in more than half of those older than 65 years.[5] An important aspect of the critical care nurse's assessment is to determine whether sleep problems are the result of normal aging, sleep disorders, or sleep disturbances due to the acute care environment.

Although some age-related changes in sleep patterns are the normal consequences of aging, the prevalence and potential for severe sleep disorders calls for increased clinical awareness and evaluation. Such complaints as habitual snoring, frequent awakening, nocturnal sweating, and awakening with anxiety may be signs of a genuine sleep disorder.

The loss of neurons in the brain may be responsible for the normal age changes in the sleep cycle. These include the following:

- A longer time to fall asleep
- Increased time spent in the lighter stages of sleep (stages 1 and 2)
- Decreased time spent in the deeper stages of sleep (stages 3 and 4) and in rapid eye movement sleep
- Increased and shorter repetitions of the sleep cycle

The amount of sleep needed for each person does not change with age. However, there is an increased tendency for older adults to sleep less at night, to be somnolent late in the day

or early evening, and to awaken early in the morning. This has been referred to as the advanced sleep phase syndrome.[6] Older adults also have shortened sleep latency, resulting in daytime napping. Daytime napping further compounds the problem because it reduces the need for nighttime sleep. Common complaints (eg, anxiety, waking up due to choking, headaches, sweating at night, nocturia, and snoring) are not normal age-related changes and should be assessed more thoroughly.

The most prevalent and most serious age-related sleep disorder is sleep apnea. There is evidence of an association between sleep apnea and circulatory disorders, including hypertension, stroke, and angina pectoris. There also may be a link between sleep apnea and reduced life expectancy. The prevalence of disordered breathing in the older patient is high. Moreover, there may be an association among habitual snoring, stroke, and angina pectoris in older men.[6]

Findings on Physical Examination and Management

Older adults with sleep disorders present with an inability to fall asleep, an inability to stay asleep, or both. They may exhibit daytime napping, and fall asleep during activities. Conversely, there may be evidence of sleep deprivation with altered mental status being the major presenting sign. Loud snoring with multiple apnea–hypopnea events is indicative of sleep apnea. These people may have daytime hypersomnolence, fatigue, irritability, and decreased cognitive function because of impaired nighttime sleep patterns.

Normal aging, chronic illness, and drug therapy increase the older person's susceptibility to insomnia. Treatment depends on the problem. Before drug therapy is considered, poor sleep hygiene habits should be addressed. Good sleep hygiene includes the following:

- Avoiding daytime naps that are longer than 30 minutes
- Maintaining regular bedtimes and rising times
- Avoiding heavy evening meals, excessive fluids, alcohol, and caffeine
- Increasing daytime activity, even if this is as simple as sitting up out of bed for extended periods of time
- Keeping the sleep environment quiet, sufficiently dark, at a comfortable temperature, and safe
- Maintaining a day–night schedule such that the period of time in bed for sleep is separate from daytime activities (although this is difficult in the acute care setting when the person is acutely ill; however, as recovery progresses, the person should be out of bed except for brief rest periods and sleeping at night).

Behavior modification has been used successfully for many sleep problems. The conservative use of medications may be indicated in more problematic sleep disorders, periodic movements of sleep, and dementia-related illness.[7] Drug treatment is best when accompanied by improved sleep hygiene and patient education about age-related changes in sleep.

Care should be taken in dispensing sedative-hypnotics for people with risk factors for sleep apnea. Nursing interventions include encouraging older patients with disordered breathing to sleep on their sides and to lose weight if obese. Other interventions include giving supplemental oxygen if hypoxemia, caused by chronic lung disease or hypoventilation, is present.

Skin Changes

Although a variety of cutaneous changes have been associated with age, some of these changes are due to normal or intrinsic age factors, whereas others are due to chronic solar exposure.[8] Photoaging is the combined effect of repeated sun exposure and intrinsic aging on the skin, and it is the cause of what is generally associated with the clinical (and histological) changes that are consistent with "aging." With age, there is a thinning of the skin and a decrease in skin flexibility. This puts the older adult at risk for epidermal tearing from shearing forces. Likewise, there is a loss of elasticity resulting in fine wrinkling, looseness, and sagging. Over time, there is a decrease in the number of dermal blood vessels, and these blood vessels become thinner and more fragile. These changes result in the hemorrhaging (known as senile purpura) commonly seen in older adults, in impaired body temperature management and healing of wounds, and in decreased absorption of topical treatments. With age, there is decreased density and activity of the eccrine and apocrine glands and decreased sebum production.

Overall, because of a combination of skin changes in older adults, there tends to be a quicker breakdown in the skin barrier and a slower recovery of skin integrity. Common interventions to maintain skin integrity are shown in Box 12-4.

Findings on Physical Examination and Management

The skin of older adults tends to sag, especially on the hands and forearms, and causes underlying tissue injury. The person may appear pale and may not be able to correctly perceive surface temperature (eg, how hot water is). The hair becomes gray and is coarser, and the nails may break and become more brittle. Additional hairs develop on the eyebrows, nose, and ears. Wound healing is prolonged, and there is increased risk for contact dermatitis due to increased skin sensitivity. Xerosis, or dry skin, is a common problem for the older adult and is the most common cause of pruritus in this group. The treatment of dry skin focuses

BOX 12-4 NURSING INTERVENTIONS

For Maintaining Skin Integrity in the Older Adult

- Avoid shearing forces when turning the patient.
- Turn the patient frequently.
- Keep the patient appropriately covered for warmth.
- Bathe the patient daily, preferably with total immersion in water 32.2°C to 40.5°C (90°F to 105°F).
- Apply oil-based emollient to the patient's skin after bathing.
- Monitor responses from transdermal medications.
- Monitor wounds closely for healing and signs and symptoms of infection.

primarily on the replacement of water, which is the major cause of dryness.

Older adults should be encouraged to do the following:

- Maintain a sufficient oral intake of fluid, approximately 2,000 mL of liquids daily.
- Increase bathing time so that there is total-body water immersion 10 minutes daily, with water temperature ranging from 90°F to 105°F (32.2°C to 40.5°C).
- Avoid the use of soaps.
- Use an emollient after bathing.

Skin lesions are more common in the older adult, and certainly any change in a skin growth or any lesion that does not heal in a reasonable time should be suspect for malignancy. Malignant lesions tend to occur in sun-exposed areas but may also be present in other areas.

Cardiovascular Changes

A number of cardiovascular changes occur with aging (see Table 12-1). These age-related changes, overt and occult cardiovascular disease, and reduced physical activity all affect cardiovascular function in elderly people. With age, there is a loss of myocytes in both the left and right ventricles, with a progressive increase in myocyte cell volume per nucleus in both ventricles.[9] With age, there is also a progressive reduction in the number of pacemaker cells in the sinus node, with only 10% of the number of cells at age 20 years still remaining at age 75 years. Aging changes in the heart have an impact on afterload, preload, contractility, diastolic function, and the cardiovascular response to exercise.

Afterload is the resistance to the ejection of blood by the left ventricle and is composed of (1) peripheral vascular resistance and (2) characteristic aortic impedance. With age, the large elastic arteries become dilated, with a reduction in compliance. Progressive thickening of the aortic media and intima is associated with aortic enlargement. There is an age-associated increase in arterial stiffness resulting from changes in the arterial media (eg, thickening of the smooth muscle layers, increased fragmentation of elastin, an increase in the amount and characteristics of collagen, and increased calcification). These structural changes are associated with a reduction in aortic distensibility due to increased aortic stiffness with an increase in pulse wave velocity. The reduction in arterial compliance contributes more to the age-related increase in afterload than does the loss of peripheral vascular beds.

The decrease in vessel compliance affects large and small arteries. As a result, even a small increase in intravascular volume can be accompanied by a substantial rise in aortic pressure (and, in turn, systolic blood pressure), which may lead to pressure-produced ventricular hypertrophy.[10]

Circulating levels of catecholamines increase with age, especially related to stress. Specifically, β-adrenergic vasodilation of vascular smooth muscle decreases with aging, and α-adrenergic vasoconstriction of vascular smooth muscle does not change with aging. The impaired vasodilator response to β-adrenergic stimulation with age is particularly important during exercise.

With aging, there is an increase in systolic blood pressure and a widened pulse pressure. A slight reduction in diastolic blood pressure occurs after the sixth decade.[11] The increase in systolic blood pressure is due to an interaction of many factors, with age being only one of them.

Posterior left ventricular wall thickness increases (ie, left ventricular hypertrophy develops) with age, and this is mediated by an increase in systolic blood pressure.[11] This hypertrophy is due to volume, not the number of cardiac myocytes. Fibroblasts undergo hyperplasia, and collagen is deposited in the myocardial interstitium. Increased afterload causes an increase in left ventricular systolic stress and the addition of sarcomeres. These changes result in an increased left ventricular wall thickness with a normal or decreased left ventricular chamber size and an increased relative wall thickness.

Preload is the filling volume of the left ventricle and is determined by numerous factors that influence blood return to the heart. Resting preload does not change with age[12] although left ventricular early diastolic filling is reduced with age. With age, left ventricular stiffness is increased, left ventricular compliance is decreased, left ventricular wall thickness is increased, left ventricular relaxation is impaired, and left ventricular diastolic filling is decreased. An age-related increase in systolic blood pressure also impairs left ventricular early diastolic filling, leading to hypotension if preload is reduced. Despite this age-related reduction, preload is maintained because left atrial contraction becomes more vigorous and thereby increases late diastolic filling of the left ventricle.[12]

An age-related increase in left atrial size from increased wall stress counteracts the effects of decreased left ventricular compliance with aging. Left atrial contraction can contribute up to 50% of left ventricular filling in a poorly compliant left ventricle. Consequently, in older adults, development of atrial fibrillation may cause a marked reduction in cardiac output because of the loss of left atrial contribution to left ventricular late diastolic filling.

The intrinsic ability of the heart to generate force does not change with age, although the duration of contraction and relaxation is prolonged in older adults. There is no reduction of resting left ventricular ejection fraction or circumferential fiber shortening in healthy older adults.

Aging is associated with prolongation of isovolumic relaxation time, a reduction in early diastolic filling of the left ventricle, and augmentation of the late diastolic filling of the left ventricle.[12] Also with aging, there is a slowing of the rate at which calcium enters the sarcoplasmic reticulum after myocardial excitation, and a subsequent decrease in relaxation of the left ventricle.[13] Reduced oxidative phosphorylation and cumulative mitochondrial peroxidation occurring with aging may also impair left ventricular diastolic function.

The maximum amount of oxygen uptake (VO_2max) decreases with age, although the degree to which oxygen uptake decreases is affected by physical conditioning, subclinical coronary artery disease (CAD), smoking, and body weight. With exercise, older adults have a decrease in heart rate, cardiac index, and left ventricular ejection fraction and increases in the left ventricular end-diastolic and end-systolic volume indices.[14]

Findings on Physical Examination and Management

In the absence of vascular disease, these changes should not interfere with normal tissue perfusion. In the older patient, however, the likelihood of atherosclerosis increases. The narrowing of vessels, coupled with their decrease in compliance, may produce tissue ischemia. These changes, along with bed rest, contribute to tissue injury and pressure ulcer formation.

The increased vascular stiffness of aging causes the upstroke of the arterial pulse to appear brisker than usual, potentially masking the slowly rising carotid pulse of aortic stenosis. Older adults commonly present with an early-peaking basal systolic murmur of aortic stenosis, typically accompanied by an S_4 sound at the cardiac apex as evidence of reduced ventricular compliance. These people report and demonstrate a limited ability to tolerate physical activity. Older patients may also have a greater amount of pooling in the lower extremities because of decreased muscle mass and poor venous return. If the patient is placed on bed rest, this fluid pool is redistributed and may cause an overload in the cardiovascular system. The nurse must be alert for vascular overload and congestive heart failure.

Another factor to consider is the shifting of fluids when a patient arises after having been on bed rest. The sudden shift in fluid to the lower extremities and the lowered fluid volume that results from bed rest can produce extreme lightheadedness. This is further complicated by a decrease in baroreceptor sensitivity with age. A slow progression of head elevation and dangling the legs before moving the patient to sitting or standing is necessary to prevent syncope and possible injury from falling.

Although chest pressure is the classic symptom of angina in older adults, there is an increased incidence of silent ischemia in these people. If angina or a myocardial infarction is suspected, a comprehensive history, vital signs, and electrocardiogram (ECG) should be obtained, and a laboratory workup (including cardiac enzymes) should be ordered. If at all possible, it is important to obtain a prior ECG for comparison.

About half of all older adults have abnormalities on the resting ECG, most commonly PR- and QT-interval prolongation, intraventricular conduction abnormalities, reduction in QRS voltage, and a leftward shift of the frontal plane QRS axis. Common age-related changes to the ECG are shown in Table 12-2. Elderly men more frequently have major ECG abnormalities than do elderly women, and these abnormalities increase with age.[15]

Respiratory Changes

It is particularly difficult to distinguish age-related changes in the structure and function of the lungs from those changes caused by disease because the lungs are continually exposed to environmental stressors. However, some commonly identified lung changes with physiological aging include dilation of alveoli, enlargement of airspaces, a decrease in exchange surface area, and loss of supporting tissue for peripheral airways. These changes result in decreased static elastic recoil of the lung and increased residual volume (RV) and functional residual capacity (FRC). Chest wall compliance decreases and thereby increases the work of breathing for the older adult. The most important age-related change in the large airways is a reduction in the number of glandular epithelial cells. This results in reduced production of protective mucus and thus impaired defense against respiratory infection. There are few changes in the bronchi, but the area of the alveoli decreases and the alveoli and alveolar ducts enlarge. The FRC and RV increase, and compliance decreases. There is deposition of amyloid in lung vasculature and alveolar septa, although the significance of this is unclear. Small airways change so that there is dilation of the alveolar ducts and airspaces and an increased tendency for the small airways to collapse during expiration. There is as much as a 20% reduction in alveolar surface area with consequent reduction in respiratory reserve. The major age-related change in the respiratory muscles is a reduction in the proportion of type II A fibers, with consequent impairment of strength and endurance.

Lung volumes fall gradually with age. Specifically, the forced expiratory volume in 1 second/forced vital capacity (FEV_1/FVC) ratio falls by approximately 0.2% per year.[16] The FEV_1/FVC ratio declines less rapidly in older men than in older women, and maximal expiratory flow and maximum voluntary ventilation decline less rapidly in women. The ventilation/perfusion ratio heterogeneity increases, and carbon monoxide transfer decreases with age.

The most clinically important functional changes in the aging respiratory system are as follows:

- The increased tendency for small airways to collapse sooner during expiration
- Reduction in respiratory muscle strength and endurance
- Changes in the monitoring and control of breathing

Table 12-2 Common Age-Related Changes in the ECG

ECG Variable	Age under 30 y	Age 30–39 y	Age 40–49 y	Age over 49 y
R-wave amplitude (mm)	10.4	10.5	9.0	9.3
S-wave amplitude (mm)	15.2	14.2	12.2	12.4
Frontal plane axis (degrees)	48.9	48.1	36.5	38.8
PR duration (ms)	15.9	16.2	16.0	16.2
QRS duration (ms)	7.6	7.5	7.4	8.0
QT duration (ms)	37.8	37.5	37.9	39.6
T-wave amplitude (ms)	5.2	4.6	4.3	4.4

Data from, Bachman S, Sparrow D, Smith LK. Age-related changes in electrocardiographic variables. Am J Cardiol 48:513, 1981.

There is a tendency for older adults to have relative inefficiency in control and monitoring of ventilation. This is especially true with regard to responses to both hypoxia and hypercapnia at rest. Elderly people tend to have increased ventilatory response to exercise-induced carbon dioxide production.[14]

The VO_2max declines with age owing to a decrease in the diffusing capacity and alveolar capillary volume along with ventilation–perfusion mismatch. Mucociliary clearance is reduced with age, although there is some evidence to suggest that the cough reflex is unaffected by aging.[17] However, older adults tend to have more frequent and severe bacterial, viral, and fungal infections, but this is due to pathological processes commonly seen in older people, changes in other body systems, and some of the functional and structural changes identified.

Pulmonary function studies in healthy older adults have shown an increase in the RV and a decline in the total lung capacity. The actual declines in FVC and maximum expiratory flow rates are attributed more to changes in body weight and strength than to changes in the pulmonary tissue. There tends to be an increase in the partial pressure of arterial carbon dioxide ($PaCO_2$) and a decrease in the partial pressure of arterial oxygen (PaO_2) with age. The gradual decline in PaO_2 is caused by a loss of elastic recoil and a subsequent reduction in airway caliber, early airway closure, and maldistribution of ventilation.

However, despite all these changes, the respiratory system remains capable of maintaining adequate gas exchange at rest and during exertion throughout the life span. Aging does tend to result in diminished reserve of the respiratory system in cases of acute disease. Specifically, decreased sensitivity of respiratory centers to hypoxia or hypercapnia results in a diminished ventilatory response in cases of heart failure, infection, or aggravated airway obstruction. Moreover, decreased perception of bronchoconstriction and diminished physical activity may result in less awareness of the disease and delayed diagnosis.[18]

Findings on Physical Examination and Management

Older adults commonly present with barrel chest (an increased anteroposterior diameter), which has a significant impact on appearance as well as chest wall compliance (particularly in patients who are supine) and may result in lung sounds being more distant and less discernible. It may be helpful to use a pediatric diaphragm to listen for breath sounds in older adults with prominent ribs. This allows for a more firm application of the stethoscope between the interspaces.

Dyspnea is a common complaint, and the causes may be cardiac, pulmonary, metabolic, mechanical, or hematological, or due to deconditioning. Increased lung sounds are also common with age and may be due to deconditioning and age-related fibrotic changes rather than acute disease, such as congestive heart failure. When evaluating the older adult, it is particularly important to match clinical signs and symptoms of disease with objective diagnostic findings, such as chest radiography and laboratory testing.

Pulmonary infections are more common with age because of the changes described previously. However, expectorated tissue specimens in older adults are often unreliable because of pharyngeal colonization. To prevent infection, careful attention to nutrition, especially to sufficient calories, protein, and fluid intake, is needed. Moreover, frequent position changes assist in clearing secretions and aid ventilation and perfusion of the lungs.

Renal Changes

Age-associated kidney changes can be categorized as anatomical or functional. Anatomical changes include the loss of renal glomeruli, decreased kidney size, renal tubular changes, and renal vascular changes. There are also functional kidney changes, as described in Box 12-5.

The total number of glomeruli decreases by 30% to 40% by the eighth decade. The loss of glomeruli, in conjunction with decreased kidney perfusion, results in a decreased glomerular filtration rate (GFR). However, one longitudinal study revealed that not all people exhibit a decline in GFR.[19] Changes are likely due to a combination of lifestyle factors and associated chronic illness. The decrease in filtration may result in decreased clearance of substances normally excreted. An increase in blood urea nitrogen (BUN) or creatinine may indicate the extent to which the GFR is diminished. However, creatinine levels from muscle breakdown may be less than in younger patients and could mask an elevated creatinine level. Creatinine clearance is a more accurate measure of renal function in the older patient. Corrected GFRs can easily be calculated for older adults using the Modification of Diet in Renal Disease formula:

$$\begin{aligned} \text{mL/min/1.73 m}^2 = {} & 175 \times (\text{SCr})^{-1.154} \times (\text{age})^{-0.203} \\ & \times 0.742 (\text{if female}) \\ & \times 1.210 (\text{if black}) \end{aligned}$$

where SCr equals serum creatinine (see also Chapter 31, Box 31-3).

GFR calculators are available to assist with the calculations at http://kidney.org or http://nephron.com/cgi-bin/MDRD.cgi. Evaluation of renal function is extremely important if the patient is receiving drugs normally excreted by the kidney. Table 12-3 provides an overview of normal laboratory values, including renal function, and how these change with age.

BOX 12-5 Age-Associated Functional Kidney Changes

- Decreased GFR
- Decreased mean creatinine clearance rate
- Increased mean creatinine concentrations
- Decreased blood flow through the kidneys
- Decreased tubular transport capacity
- Decreased functional nephrons
- Decreased concentrating ability
- Decreased diluting ability
- Decreased plasma renin activity
- Impaired sodium conservation

Table 12-3 Normal Laboratory Values and Age-Related Changes

Laboratory Test	Normal Values	Age-Related Changes
Urinalysis		
Protein	0–5 mg/100 mL	Rises slightly
Glucose	0–15 mg/100 mL	Glycosuria appears after high plasma levels and is very unreliable
Specific gravity	1.005–1.020	Lower maximum of 1.016–1.022
Sedimentation rate	Men 0–20 mm/h Women 0–30 mm/h	Increases with age; no clinical significance
Iron	50–60 mcg/dL	Slight decrease
Iron binding	230–410 mcg/dL	Decrease
Hemoglobin	Men 13–18 g/100 mL Women 12–16 g/100 mL	No normal decline with age
Hematocrit	Men 45%–52% Women 37%–48%	No normal decline with age
Leukocytes	4,300–10,800/mm^3	No normal decline with age
Lymphocytes	500–2,400 T cells/mm^3 50–200 B cells/mm^3	Both T- and B-cell levels decrease
Platelets	150,000–350,000/mm^3	No change with age
Albumin	3.5–5.0 g/100 mL	Declines because of a decrease in liver size and enzymes
Globulin	2.3–3.5 g/100 mL	Slight increase
Serum protein	6.0–8.4 g/100 mL	No change with age
Blood urea nitrogen (BUN)	Men 10–25 mg/100 mL Women 8–20 mg/100 mL	Can increase with age
Creatinine	0.6–1.5 mg/100 mL	Increases, although this is related to lean body mass
Creatinine clearance	104–124 mL/min	Decreases by 10% per decade after age 40 y
Glucose	<200 mg/dL fasting	Slight increase in glucose tolerance of 10 mg/dL per decade after age 30 y
Triglycerides	40–150 mg/100 mL	20–200 mg/100 mL
Cholesterol	120–220 mg/100 mL	Increases with age, more so in women than in men
Thyroxine (T_4)	4.5–13.5 mcg/100 mL	No change
Triiodothyronine (T_3)	90–220 ng/100 mL	Decreases 25%
Thyroid-stimulating hormone (TSH)	0.5–5.0 mcg/mL	No significant change with age
Alkaline phosphatase (AP)	13–39 IU/L	Increases by 8–10 IU/L, although elevations >20% are likely due to disease
Prostate-specific antigen (PSA)	4 ng/mL	No change with age, although elevated levels may be seen in nonmalignant disease
Uric acid	Men 44–76 mg/L Women 23–66 mg/L	Slight increase with age

With age, there is also a decrease in renal blood flow, decreased tubular function, and decreased ability to concentrate urine. Basal renin is diminished by 30% to 50% in older adults. Renin alterations and other renal changes diminish the capability of the older adult to maintain sodium and water balance, especially in the presence of stress. There may also be a lessened response to antidiuretic hormone (ADH), which can result in a decreased ability to concentrate urine. This decreased ability may lead to problems of fluid–electrolyte balance as sodium, potassium, and water are lost. Loss of hydrogen ions may also make the acid–base balance more difficult to maintain.

Findings on Physical Examination and Management

Older adults tend to have decreased sensations of thirst and consequently drink less fluid. This change leaves them vulnerable to dehydration, especially when medications

with diuretic actions are administered. To prevent renal damage, care must be taken to ensure that the hospitalized older patient has adequate fluid intake by oral, enteral, or parenteral routes. Fluid balance may also be precarious because disease states such as diabetes can produce diuresis. Further, potassium and sodium levels may already be low when the patient arrives in the unit. Care must be taken to ensure that electrolyte balance remains stable or is restored. Confusion, dysrhythmias, coma, and death can occur quickly in the older patient with altered electrolyte balance.

As bladder muscle tone is lost, incomplete emptying with retention can foster the development of urinary tract infections (UTIs) that can ascend and become renal infections. Hypertrophy of the prostate gland also places older men at risk for UTI because the enlarged gland interrupts urine flow. Loss of muscle tone, retention with overdistention, and loss of sphincter control lead to incontinence in the older man or woman. For older patients, this loss of control is embarrassing and disconcerting.

If any type of incontinence or retention develops in an older patient during the stay in the ICU, the nurse should perform a comprehensive evaluation to determine the underlying cause of the urinary problem. Specifically, consideration should be given to drugs, particularly anticholinergic drugs, metabolic and neurological problems, and bladder inflammation as potential causes (Table 12-4). If an indwelling (Foley) catheter is necessary during acute illness, it should be removed as soon as the primary reason for inserting it (eg, hourly urine measurements) has passed. Early removal may prevent deterioration of bladder function and UTI. See Evidence-Based Practice Highlight 12-1 for information about how to prevent catheter-associated UTIs.

Gastrointestinal Changes

The gastrointestinal system undergoes many age-related changes (see Table 12-1). The mechanical and chemical processes of digestion that begin in the mouth may be impaired because of loss of teeth, poor hygiene, and a decrease in salivary secretions. Many older adults experience diminished senses of taste and smell, which may lead to decreased food intake.[20]

Flattening of the gastric mucosae and secretory changes have been noted in normal older adults. This influences active transport mechanisms for calcium, iron, and vitamin B_{12} absorption. The gastrointestinal fluid pH, gastric emptying time, intestinal transit rates, and gastrointestinal blood flow and surface area are all altered in the older adult.

Slowing of peristalsis may interfere with swallowing, gastric emptying, and passage through the bowel. The decrease in hydrochloric acid, digestive enzymes, and bile may contribute to incomplete digestion of nutrients. In some older adults, diminished intrinsic factor and decreased vitamin B_{12} synthesis may produce pernicious anemia.

Data are insufficient to make assumptions regarding changes in absorption in the large and small bowel. Some evidence indicates that absorption is somewhat impaired. Given that the eating patterns of older adults may not include all food groups, deficiencies may arise from lack of intake rather than malabsorption.

The decreased motility of the large bowel is probably not sufficient to produce constipation in the active adult. However, older adults who are on bed rest, have decreased intake of food and fluids, and are exposed to multiple medications may experience constipation and fecal impaction. Dependence on or misuse of laxatives must be assessed when

Table 12-4 Causes of Incontinence

Cause	Explanation
Drug Side Effects	
Diuretics	Urgency
Caffeine and alcohol	Diuretic effect and irritation
Sedatives	Inhibition of micturition, functional changes
Anticholinergics	Constipation causing obstruction
Calcium channel blockers	Constipation causing obstruction, smooth muscle relaxation
Nonsteroidal anti-inflammatory drugs (NSAIDs)	Blockage of prostaglandin receptors causing decreased force of contraction
Physiological Changes	
Hypoxemia	Depressed function of brain
Delirium	Depressed function of brain
Hyperglycemia	Diuretic effect of glycosuria
Hypercalcemia	Diuretic effect of hypercalciuria
Functional impairment	Inability to get to the toilet in time
Bladder Inflammation	
Infection	Uninhibited bladder contractions
Atrophic vaginitis	Uninhibited bladder contractions

EVIDENCE-BASED PRACTICE HIGHLIGHT 12-1

Catheter-Associated Urinary Tract Infections

△ Expected Practice

- Prior to placement of any indwelling urinary catheter, assess patient for accepted indications and alternatives. (Level C)
- Adhere to aseptic technique for placement, manipulation, and maintenance of indwelling urinary catheters. (Level E)
- Document all instances of indwelling urinary catheters, including insertion date, indication, and removal date. (Level C)
- Promptly discontinue indwelling urinary catheters as soon as indications expire. (Level C)

△ Supporting Evidence

- Prolonged catheterization is the major risk factor for catheter-associated urinary tract infections (CAUTIs).[7,8]
- Twenty-five percent of inpatients and up to 90% of patients in an ICU have a urinary catheter during hospitalization, often without an appropriate indication.[4] Indwelling urinary catheters are placed without sufficient rationale, and/or remain in place after indications expire.[9]
- CAUTIs can be decreased by interventions that facilitate removal of unnecessary catheters.[10,11]
- Most hospitals have not implemented effective strategies for preventing CAUTIs.[12,13]

AACN Levels of Evidence

Level A Meta-analysis of quantitative studies or metasynthesis of qualitative studies with results that consistently support a specific action, intervention, or treatment
Level B Well-designed, controlled studies with results that consistently support a specific action, intervention, or treatment
Level C Qualitative studies, descriptive or correlational studies, integrative reviews, systematic reviews, or randomized controlled trials with inconsistent results
Level D Peer-reviewed professional organizational standards with clinical studies to support recommendations
Level E Multiple case reports, theory-based evidence from expert opinions, or peer-reviewed professional organizational standards without clinical studies to support recommendations
Level M Manufacturer's recommendations only

the history is taken because this may further exacerbate the constipation and management of bowel function.

Findings on Physical Examination and Management

Examination of the mouth in an older adult commonly reveals a wearing of dental enamel and gum recession, thereby exposing more of the teeth and increasing the likelihood of decay. Oral care is critical given the associated risk for pneumonia with poor oral care. The oral mucous membranes also tend to be very dry, making eating difficult. Swallowing disorders are common and can be due to functional abnormality of the oral, pharyngeal, or esophageal stage of swallowing.

Older adults commonly report constipation, and stool may be palpable in the large bowel. In addition to an abdominal examination, a rectal examination must be performed to determine the consistency of stool and the anal tone, and to establish an appropriate treatment plan. Heartburn (which may present as chest pain) is also a common complaint and is often associated with epigastric tenderness. Aortic aneurysms are more common in older adults and present as a pulsatile mass in the abdomen.

Acute abdominal pain in this population is a particularly challenging complaint, and causes include diverticulitis, bowel obstruction, appendicitis, pancreatic disease, infarction, and cancer. However, identifying older adults with acute abdominal problems is even more challenging because these people often present without pain or any other significant signs and symptoms of an acute problem (eg, fever, anorexia). Careful evaluation of the abdomen in older adults is essential to monitor for acute changes.

Nursing interventions for gastrointestinal changes begin with a careful history. Eating habits, including time and frequency of food intake, food preferences, usual intake, food intolerances, and taste and smell changes must be assessed. Use of laxatives, enemas, and vitamin supplementation also should be explored. Evaluation of the teeth and gums helps to establish how well food can be handled mechanically.

When planning care, the nurse must consider that bed rest slows peristalsis and aggravates any preexisting condition related to motility. Adequate fluid intake, bulk in the diet, use of natural laxatives (eg, prune juice, warm liquids), and as much active or passive exercise as the condition of the patient allows may help maintain a normal pattern of bowel movements. Laxatives may need to be included in the regimen once constipation does occur.

Hospitalized patients of any age can become rapidly malnourished secondary to the stress of acute illness, an increased demand for energy, and lack of nourishment. Therefore, it is important to look for indicators of nutritional risk. Indicators include a history of recent weight loss, a diet lacking in protein and calories, an albumin level less than 3.5 g/dL, and a lymphocyte count less than 1,500/mm^3. The older patient who enters the hospital already mildly to moderately malnourished and who has a poor intake of protein and calories may quickly become severely malnourished. This malnourished state can markedly compromise the immune response and increase the incidence and severity of infection. Therefore, it is crucial to see that critically ill older patients maintain adequate nutritional intake.

Musculoskeletal Changes

An estimated 43 million Americans (one in every 7 persons) have some form of diagnosed arthritis or other rheumatic condition, and this number is expected to rise to 60 million

during the next 20 years. Arthritis affects people of all ages, although it is more prevalent among older adults and women. The disease causes pain, stiffness, and tenderness around the joints and typically affects the hands, feet, knees and hips. Symptoms can range from mild to severe. While arthritis rarely kills, it is a chronic disease that causes significant disability and reduces quality of life. A large percentage of older adults have some form of arthritis, with this becoming more prevalent if the person is female and older. Arthritis is not a normal age change, although it does contribute to mobility problems. Mobility also is often limited among hospitalized older adults and results in a decrease in muscle protein synthesis, strength, and lower extremity and whole body mass. Muscle mass may be lost also because of a reduction in the number and size of muscle fibers or an increase in connective tissues. These changes result in less muscle tension and decreased strength of the contraction. The decrease of lean muscle mass and the loss of elasticity contribute to lost flexibility and increased stiffness.

Skeletal calcium losses are a universal concomitant of aging and reflect an imbalance of bone remodeling, with osteoclastic bony resorption exceeding osteoblastic new bone formation. After approximately 30 years of age, when peak skeletal bone mass has been achieved, resorption begins to exceed formation with subsequent skeletal calcium losses and a decline in bone density. The rate of bone loss is approximately 0.5% to 1% yearly from age 60 years onward. The bone changes that occur are likely due to a multitude of factors in addition to normal age-related changes: lack of exercise, poor nutrition, and calcium malabsorption. Known age-related changes in factors influencing bone homeostasis occur in calcium, vitamin D, and gonadal hormone status. Dietary intake of calcium, gastrointestinal absorption of calcium, and vitamin D synthesis are all decreased with age. Decreased intake of vitamin D_2 and decreased skin absorption of 7-dehydrocholesterol as a result of inadequate sunlight exposure also may contribute to vitamin D deficiency with age. The patient on bed rest may rapidly lose bone mineral concentration. The calcaneus (heel) and spine are most susceptible, with a loss of approximately 1% per week. This loss is related to lack of weight bearing.

Musculoskeletal function is dictated largely by the size of the muscle mass that is contracting, and to a lesser extent by changes in surrounding connective tissue in the joint and neural recruitment, conduction velocities, and fatigue. Sedentary people lose large amounts of muscle mass over time. Unfortunately, muscle mass cannot be maintained into old age even with habitual aerobic activities in either normal or athletic adults.[21] Only loading of muscle with weight-lifting exercise has been shown to reverse loss of muscle mass and strength in older adults.[22,23] There is also a decrease in oxidative and glycolytic enzyme capacity with age, a decrease in total number of muscle fibers, selective atrophy of type 2 (fast-twitch) fibers, and shortening of tendons and ligaments with decreased tissue elasticity. Bone changes, as evidenced by osteoporosis, present with decreased height, kyphosis, and scoliosis.

Findings on Physical Examination and Management

Older adults with osteoporosis may have spontaneous fractures, occurring simply from moving in bed. In general, older adults have a decrease in overall muscle strength and an increased tendency to have muscle cramping. Crepitus and pain with range of motion of the joints is common, particularly in the weight-bearing joints (eg, the knee). Gait and posture changes are frequently present, and older adults tend to have a stooped posture with a slow, shuffling gait.

Forced fasting of the critically ill hospitalized patient may further accelerate muscle loss through catabolism and gluconeogenesis. The added burden of bed rest leads to a rapid loss of mobility, strength, and energy in the older patient. Maintaining nutrition, changing position frequently, active and passive exercise, and getting out of bed as much as permitted by condition are essential to preserving strength, energy, and bone mass. If the patient is comatose or has suffered loss of function, proper positioning and splinting can help prevent permanent deformity.

Endocrine Changes

The equilibrium concentrations of the principal hormones are not necessarily altered with age; however, for older adults, there may be a change in how hormonal equilibrium is achieved. Therefore, with advancing age, some alterations in hormone production, metabolism, and action occur. Subtle changes are noted in pituitary dynamics, adrenal gland physiology, and thyroid function; however, the changes in glucose homeostasis, reproductive function, and calcium metabolism are more apparent.[24]

Most of the principal neuroendocrine nuclei in the hypothalamus are structurally intact in old age, although there is some loss of morphologic integrity of the suprachiasmatic nucleus. Morphometric variables associated with increased cellular functional activity have been measured in several hypothalamic nuclei. Certain neurons in the human paraventricular nuclei seem activated, and the neurons that produce arginine vasopressin (AVP) increase in size, and the number of neurons that express both AVP and corticotropin-releasing hormone increases with age.

The anterior pituitary shows unchanged output of stimulating hormones, although the peripheral levels of target hormones decrease. For example, circulating levels of daytime and nighttime thyroid-stimulating hormone and growth hormone (GH) are greatly diminished in old age.[25] In contrast, prolactin and melatonin are decreased only at night. Age-related decreases in hormonal levels are associated with a decrease in the amplitude but not the frequency of secretory pulses.

The decline in GH with age is believed to be associated with the decrease in lean body mass, increase in body fat (especially in the visceral and abdominal compartment), adverse changes in lipoproteins, and reduction in aerobic capacity commonly noted in older adults. Research is ongoing to determine whether replacement of GH in healthy older adults can reverse these changes.[25]

Normal aging is associated with insulin resistance and reduced β-cell function, but it is not known whether changes in proinsulin and the proinsulin/immunoreactive insulin ratio are also related to reduced β-cell function.[26] Glucose tolerance decreases with age. An increase in blood glucose to 200 mg/dL occurs in about half of people older than 70 years.[26] Interpretation of this glucose intolerance requires

the use of age-adjusted parameters to avoid the inappropriate diagnosis and treatment of diabetes mellitus. Evaluating glycosylated hemoglobin (HbA_{1c}) or glycosylated albumin may help establish the presence or absence of diabetes mellitus in the older patient with elevated blood glucose levels. Because the renal threshold for reabsorption of glucose increases with age, higher degrees of hyperglycemia must be present before glucose spills into the urine. Therefore, monitoring for hyperglycemia with urine testing should be avoided.

Throughout life, the adrenal cortex shows significant morphogenic and steroidogenic changes. There is a subtle decline in aldosterone with age and a subtle increase in cortisol; however, the adrenal androgens dehydroepiandrosterone and dehydroepiandrosterone sulfate decline with age in a process similar to menopause. This decline is believed to aggravate some age-related diseases.[27]

The thyroid gland undergoes a progressive decrease in size with aging, although enlargement because of nodules is not uncommon. The concentration of thyroid hormones found in the blood of older adults is variable and influenced by disease. There may, however, be an alteration in the responsiveness of target tissues. Specifically, there may be an age-related reduction in the ability of aged tissues to increase receptor numbers in response to a reduction in hormone levels.[28]

Findings on Physical Examination and Management

The reduction in thyroid hormone levels with increasing age is correlated with many physiological and pathological sequelae: changes in cholesterol metabolism, heart rate, cardiac output, and strength of cardiac contraction and alterations in basal metabolic rate and thermoregulation. The symptoms of thyroid disease, such as apathy, weakness, and weight loss, may not be as pronounced in older adults as they are in younger people. Moreover, these symptoms are often attributed to old age rather than to hyperthyroidism or hypothyroidism. The older patient with hyperthyroidism is likely to present with atrial tachycardia and is more likely to be anorexic than hyperphagic; this person usually does not experience heat intolerance. The hypothyroid older adult may present with increased susceptibility to hypothermia if exposed to cold, a change in cognitive status, fatigue, dizziness, and a tendency to fall.

Being aware of the atypical presentation of thyroid disease in older adults leads the critical care nurse to recognize endocrine imbalance. Once identified, the imbalance can easily be corrected by replacing thyroid hormone or changing the dosage of thyroid replacement.

Diabetes mellitus is frequently seen with acute illness, trauma, or surgery. The end-organ damage of diabetes mellitus is a factor in stroke, myocardial infarction, decreased renal function, and peripheral vascular disease. Long-standing non–insulin-dependent diabetes may be diagnosed only when the patient presents with a stroke or acute myocardial infarction. Therefore, it is important to distinguish among the impaired glucose tolerance of aging, a transient rise in glucose related to acute illness, and the disease process of diabetes.

Recognition of the underlying diabetes and possible end-organ damage may alter the course of the acute illness. For example, knowing that the incidence of congestive heart failure after myocardial infarction is higher in diabetic than in nondiabetic patients, the nurse can be alert for early signs of fluid retention.

BOX 12-6 NURSING INTERVENTIONS

For Preventing Problems in the Older Adult With Diabetes

Skin Alterations
- Monitor for decreased circulation and skin breakdown.
- Provide foot care to maintain skin integrity. Bathe the feet daily and apply emollient.

Hyperglycemia
- Maintain a controlled diet.
- Monitor blood glucose levels.
- Monitor for urinary frequency.
- Monitor for hyponatremia.
- Monitor for dry mouth.
- Monitor for changes in cognition.

Hypoglycemia
- Monitor for acute changes in cognition.

Hydration Status
- Monitor hydration.
- Encourage the intake of 2,000 mL of fluid daily.

End-Organ Disease
- Monitor kidney function.
- Monitor for visual changes (eg, blurred or decreased vision).

Older people with diabetes are, for the most part, not insulin dependent. Therefore, even if they have extremely high blood glucoses, they are rarely ketoacidotic. In fact, the coma of this age group is usually hyperglycemic, hyperosmolar, and nonketotic (HHNK). Managing this state requires a delicate balance of hydration and rapid reduction of blood glucose without massive brain edema and death. The critical care nurse must be aware that HHNK coma can be triggered by acute illness or surgery. Common problems found in older adults with diabetes, and nursing interventions to prevent these problems, are shown in Box 12-6. It should be particularly recognized that the most prevalent sign of either hypogylcemia or hyperglycemia among these people is a change in cognitive status.

Immunological Changes

With age, there is a decline in immune function. Specifically, there is a decline in both T-cell and B-cell function, with a dramatic effect on cell-mediated immunity. The decline in B-cell function may be indirectly related to a decline in T-cell function. The decreased numbers of B cells secreting immunoglobulin G result in a generally poor humoral immune response. With aging, the thymus gland involutes and there is a decrease in thymic hormone levels, and the number of autoantibodies increases.[29] With age, there is also a decrease in the production of antibodies by cells located in mucosal tissues further increasing risk of infection. Lastly, with age, there is a decrease in the production of IgE, the antibody associated with allergic responses, and thus, these responses decrease in older individuals.

Findings on Physical Examination and Management

The usual symptoms of infection such as chills, fever, leukocytosis, or tachycardia may be absent or blunted in the older adult. Instead, these people may present with an acute change in cognition, function, or behavior. Delirium, for example, may be the only sign or symptom of a UTI in an older adult. The most common areas of infection in older adults are the lungs, urinary tract, and skin, and when subtle changes are noted in an older patient, consideration should be given to each of these areas.

▲ Psychological Challenges

Cognitive Changes

Cognition refers to the process of obtaining, storing, retrieving, and using information. The neuroanatomical and neurophysiological underpinnings of cognitive change are unclear. Studies[30,31] have shown that younger people have larger ventricular volumes and smaller gray and white matter volumes compared with older people. There is also greater prefrontal cortex activity in younger adults compared with older adults in the dorsolateral area during memory retrieval. These changes are believed to account for the changes in working memory[31] and executive abilities[32] associated with normal aging. As age increases, there is some decline in perceptual motor skills, concept formation, complex memory tasks, and quick-decision tasks. However, age itself is not the criterion for making decisions about a patient's cognitive functions. Each person's abilities must be judged individually rather than against a norm. Moreover, interventions such as exercise (aerobic and resistive) can improve executive control processes in older adults, particularly older women.[32]

Cognitive function should be assessed and described on admission and monitored routinely over time and whenever the patient's condition changes. While assessing cognitive functions during the patient's stay in intensive care, it is important to remember that physiological deficits, some medications, and internal and external stress, such as environmental stressors, affect cognitive skills. In older adults, acute physical changes frequently initially present as changes in cognitive status. For example, an older adult with pneumonia may not have symptoms such as fever or cough. Rather, this person may present with changes in cognitive status.

The Mini-Cog,[33] which is available for free use, provides the practitioner with a consistent assessment tool to compare responses and monitor results over time. The main drawback to the use of a questionnaire is that some critically ill patients may not be able to hear, see, talk, or write well enough to respond to the questions. Longer, more sensitive tools may also be more fatiguing for the critically ill older patient. When completing the Mini-Cog, if the patients are unable to recall any of the three words, they are categorized as "probably demented." If they can recall all three words, then they are categorized as "probably not demented." People who can recall one or two words are categorized based on their clock drawing test. If the patient draws a clock that is in any way abnormal, he or she is considered "probably demented." If the clock is normally constructed, then he or she is considered "probably not demented."

Several common syndromes cause cognitive impairment, including dementia, delirium, and depression (discussed later). Dementia is based on impairment of memory plus at least one of the following: a personality change or impairment in abstract thinking, judgment, or higher cortical functions. Delirium is the abrupt onset of clouding of consciousness and is a medical emergency. Table 12-5 identifies factors to differentiate dementia from delirium. Reversible causes of dementia and delirium are listed in Box 12-7. Tools to evaluate memory and differentiate between dementia and delirium are available at http://www.geronurseonline.org. See Evidence-Based Practice Highlight 12-2 for the assessment and management of delirium.

Learning

Older adults may take longer to respond to and assimilate new material. They may also be hesitant to take on new tasks. Motivation continues to be an important aspect of learning new material. If the material is irrelevant or meaningless, motivation is decreased, which is often interpreted as an inability to learn. The person's sensory and cognitive abilities are taken into account when teaching older patients. It may be necessary to present information in small segments using varied stimuli, including touching, seeing, hearing, and (if vision permits) writing. If movements are slowed, allow time for the completion of motor tasks, such as manipulating equipment or carrying out exercises.

Memory

The older person's memory decline involves short-term memory rather than long-term and remote memory. Recall of memory from the past is least impaired by age. Remote memory recall (items learned many years ago) can be a positive therapeutic strategy for older patients. Reminiscence is an adaptive mechanism that helps the nurse learn about the patient and increases the patient's feelings of self-worth and competence.

Depression

Depression disorders are among the most common complaints of older adults and the leading cause of suicide in later life. Symptoms of depression are listed in Box 12-8 on page 151. Based on the diagnostic criteria for major depression, at least five of these symptoms should occur almost daily for at least 2 weeks. These symptoms of depression in the older adult can be masked by normal age-related changes or disease states. For example, difficulty sleeping, early morning awakening, and lethargy are common physical complaints of the normal aging person. Alternatively, depression in the older adult may more commonly present with pseudohypochondriasis, preoccupation with past life events, and changes in cognitive ability. In some patients, the dominant emotional mood may not be sadness but anger, anxiety, or irritability.

Causes of depression are multifaceted and include multiple losses associated with aging, underlying illness, or drugs. Box 12-9 on page 151 lists drug groups that may cause depression. Screening tools, such as the Geriatric Depression Scale,[34] shown in Box 12-10 on page 152, are useful to identify people who are depressed. Once depression is identified, appropriate interventions, including drug therapy, behavioral modification, and counseling, can be initiated.

Table 12-5 Summary of Differences Between Dementia and Delirium

	Dementia		Delirium
	Alzheimer's Disease (AD)	Vascular (Multi-Infarct) Dementia	
Etiology	Familial (genetic [chromosomes 14, 19, 21]) Sporadic	Cardiovascular (CV) disease Cerebrovascular disease Hypertension	Drug toxicity and interactions; acute disease; trauma; chronic disease exacerbation Fluid and electrolyte disorder
Risk factors	Advanced age; genetics	Preexisting CV disease	Preexisting cognitive impairment
Occurrence	50%–60% of dementias	20% of dementias	6%–56% of hospitalized older people
Onset	Slow	Often abrupt Follows a stroke or transient ischemic attack	Rapid, acute onset A harbinger of acute medical illness
Age of onset (y)	Early-onset AD: 30s–65 Late-onset AD: 65+ Most commonly: 85+	Most commonly 50–70 y	Any age, but predominantly in older persons
Gender	Males and females equally	Predominantly males	Males and females equally
Course	Chronic, irreversible; progressive, regular, downhill	Chronic, irreversible Fluctuating, stepwise progression	Acute onset Hypoalert–hypoactive Hyperalert–hyperactive Mixed hypo–hyper
Duration	2–20 y	Variable; years	Lasts 1 d to 1 mo
Symptom progress	Onset insidious. *Early*—mild and subtle *Middle and late*—intensified Progression to death (infection or malnutrition)	Depends on location of infarct and success of treatment; death due to underlying CV disease	Symptoms are fully reversible with adequate treatment; can progress to chronicity or death if underlying condition is ignored
Mood	Early depression (30%)	Labile: mood swings	Variable
Speech/language	Speech remains intact until late in disease *Early*—mild anomia (cannot name objects); deficits progress until speech lacks meaning; echoes and repeats words and sounds; mutism.	May have speech deficit/ aphasia depending on location of lesion	Fluctuating; often cannot concentrate long enough to speak May be somnolent
Physical signs	*Early*—no motor deficits *Middle*—apraxia (70%) (cannot perform purposeful movement) *Late*—dysarthria (impaired speech) *End stage*—loss of all voluntary activity; positive neurologic signs	According to location of lesion: focal neurologic signs, seizures Commonly exhibits motor deficits	Signs and symptoms of underlying disease
Orientation	Becomes lost in familiar places (topographic disorientation) Has difficulty drawing three-dimensional objects (visual and spatial disorientation) Disorientation to time, place, and person—with disease progression		May fluctuate between lucidity and complete disorientation to time, place, and person
Memory	Loss is an early sign of dementia; loss of recent memory is soon followed by progressive decline in recent and remote memory		Impaired recent and remote memory; may fluctuate between lucidity and confusion
Personality	Apathy, indifference, irritability *Early disease*—social behavior intact; hides cognitive deficits *Advanced disease*—disengages from activity and relationships; suspicious; paranoid delusions caused by memory loss; aggressive; catastrophic reactions		Fluctuating; cannot focus attention to converse; alarmed by symptoms (when lucid); hallucinations; paranoid
Functional status, activities of daily living	Poor judgment in everyday activities; has progressive decline in ability to handle money, use telephone, function in home and workplace		Impaired
Attention span	Distractable; short attention span		Highly impaired; cannot maintain or shift attention
Psychomotor activity	Wandering, hyperactivity, pacing, restlessness, agitation		Variable; alternates between high agitation, hyperactivity, restlessness, and lethargy
Sleep–wake cycle	Often impaired; wandering and agitation at nighttime		Takes brief naps throughout day and night

BOX 12-7 Reversible Causes of Dementia and Delirium

Drugs
Emotional illness (including depression)
Metabolic/endocrine disorders
Eye/ear/environment
Nutritional/neurological disorders
Tumors/trauma
Infection
Alcoholism/anemia/atherosclerosis

The nurse must also be aware of cardiovascular side effects of antidepressants. The tricyclic antidepressive drugs are less commonly used owing to the risk for side effects. For example, tricyclic antidepressants can result in ST-segment and T-wave changes, although these are not necessarily indicative of myocardial damage. Ventricular dysrhythmias and disturbances in cardiac conduction are potential serious side effects and may result in the drug being reduced or discontinued. Anticholinergic effects, especially in patients with Alzheimer's disease, benign prostatic hypertrophy, or CAD, may also be seen. The selective serotonin reuptake

EVIDENCE-BASED PRACTICE HIGHLIGHT 12-2
Delirium Assessment and Management

△ Expected Practice

- Implement delirium assessment for all critically ill patients using validated tools such as the Confusion Assessment Method for the ICU (CAM-ICU) or Intensive Care Delirium Screening Checklist (ICDSC) (Level B)
- Create strategies to decrease delirium risk factors, including early exercise (Level B)
- Be cautious with benzodiazepine use, giving only what is needed (Level C)
- Consider whether to adopt a core bundle like the ABCDE bundle (Level E)

△ Supporting Evidence

- In the absence of a validated tool, delirium goes undetected by both doctors and nurses in more than 65% of ICU patients.[16–19] The reports underscore the need for systematic utilization of standardized assessment tools, which is in concert with the recommendations from national (Society of Critical Care Medicine) and international guidelines.[20–23] Systematic use of validated assessment tools is necessary to detect delirium, which would otherwise go undetected and consequently untreated.
  - Two tools with robust validity and reliability are the Confusion Assessment Method for the ICU (CAM-ICU)[4,24–26] and the Intensive Care Delirium Screening Checklist (ICDSC).[27,28]
  - Implementation of both tools has been described in the literature; both have high accuracy and favorable compliance, and require minimal education.[29–33]
- Risk factors for ICU delirium have been understudied and underreported, with few available studies and little consensus among them.[34]
  - The following baseline risk factors are the only ones reported as significant in two or more multivariate analyses: preexisting dementia, history of baseline hypertension, alcoholism, and admission severity of illness.[2,35–37,38,39]
  - Although age has been identified as one of the most significant risk factors for delirium development in non-ICU literature, there is conflicting evidence in critical care literature to support this claim.[34] Thus, further research is required to verify age as a risk factor for delirium in the ICU.
  - Although immobility has not been reported as a risk factor for the development of delirium in the ICU, it has been reported in non-ICU cohorts.[40] Recent studies have reported that early mobility in critically ill patients results not only in improved physical functions, but improved cognitive function as well, reducing delirium duration by 2 days.[41–43] "Early" is defined by these protocols as within the first 3 days of the ICU stay and focuses on progressive mobility pathways, starting with passive range of motion and progresses to active range of motion, sitting on the side of the bed, and ambulating as tolerated.[44] Early exercise is a primary nonpharmacologic intervention shown to reduce delirium duration in critical care patients and should be considered a cornerstone of any delirium-reduction protocol.
- Iatrogenic risk factors are often modifiable and are referred to as precipitating factors.[45] Sedatives have been the only consistently identified ICU delirium risk factor and are discussed here[3,35,36,38,46]
  - Benzodiazepines. Studies have reported benzodiazepines to be an independent risk factor for the transition to delirium.[3,36]
  - Dexmedetomidine. Two recent studies, "Maximizing Efficacy of Targeted Sedation and Reducing Neurological Dysfunction (MENDS)" and "Safety and Efficacy of Dexmedetomidine Compared With Midazolam (SEDCOM)," reported a significant reduction in delirium duration in patients receiving dexmedetomidine when compared to benzodiazepines (lorazepam and midazolam, respectively).[47–49] Both studies utilized dexmedetomidine at higher doses and for longer durations than the current Food and Drug Administration (FDA) labeling approval, which is a maximum dose of 0.7 mcg/kg/h for a 24-hour duration. These studies suggest that a benzodiazepine-sparing sedation strategy using an alternative sedative, such as dexmedetomidine, may result in better outcomes, including reduced duration of delirium.
  - Opioids and propofol. The data concerning opioids are difficult to interpret, because some studies show a dose-dependent relationship, while other studies indicate there is no relationship between the use of these drugs and delirium development in the ICU.[3,36–39] Only one study has explicitly addressed propofol, and it reports no significant relationship with the drug and ICU delirium.[34,36] More research is needed with both propofol and opioids to fully understand their relationship to the development and duration of delirium.
- **Management of ICU Delirium**
  - **No drug has been approved by the FDA to treat delirium**. In fact, the FDA has issued an alert that atypical antipsychotic medications are associated with mortality risk among older patients, and another analysis has reported that haloperidol had an even higher mortality risk in non-ICU older patients than atypical antipsychotics.[50–53]
  - Clinical practice guidelines traditionally recommended antipsychotics as the medication class of choice for delirium, yet very little evidence exists to support this internationally adopted treatment.[20–23,54–57] Currently, there are only two placebo-controlled pilot studies involving antipsychotics and delirium treatment in the ICU. The "Modifying the Incidence of Delirium (MIND)" study compared

(continued on page 151)

EVIDENCE-BASED PRACTICE HIGHLIGHT 12-2

Delirium Assessment and Management (continued)

haloperidol, ziprasidone, and placebo and reported no differences in regard to delirium resolution or any other outcomes or safety concerns in the three treatment groups.[58] Another study compared quetiapine to placebo in patients already determined to be delirious who had an as-needed haloperidol order and found that the patients who received quetiapine experienced a faster resolution of delirium, less delirium, less agitation, and more somnolence.[59]

- These two studies are the first steps in understanding the best pharmacologic treatment; however, larger trials are needed to confirm these findings in order to systematically direct the choice for delirium treatment.
- All patients receiving antipsychotics (haloperidol or any of the atypical antipsychotics) should be routinely and systematically monitored for side effects, especially QT prolongation.[20]
- Rivastigmine, a cholinesterase inhibitor, has not been shown to be superior to placebo for the treatment of ICU delirium. A large European trial was stopped prematurely because of increased mortality in the rivastigmine group.[60]
- The Society of Critical Care Medicine suggests identification of causes as the first step in delirium management. The following THINK pneumonic may be helpful in determining the cause when delirium is found to be present in ICU patients:
  - Toxic situations
    - CHF, shock, dehydration
    - Deliriogenic meds (tight titration of sedatives)
    - New organ failure (eg, liver, kidney)
  - Hypoxemia
  - Infection/sepsis (nosocomial)
  - Immobilization
  - Nonpharmacologic interventions (Are these being neglected?)
    - Hearing aids, glasses, sleep protocols, music, noise control, ambulation K+ or electrolyte problems
- Putting it all together: ABCDE bundle. Several recent reviews have described the idea of implementing a core model of care combining multiple evidence-based practice strategies subsequently incorporated into routine daily care for the purpose of improving overall patient outcomes and allowing a systematic reduction in the modifiable risk factors for delirium.[61–63] The ABCDE bundle includes spontaneous awakening and breathing trial coordination, careful sedation choice, delirium monitoring, and early progressive mobility and exercise. The intent of combining and coordinating these individual strategies is to "(1) improve collaboration among clinical team members, (2) standardize care processes, and (3) break the cycle of oversedation and prolonged ventilation, which appear causative to delirium and weakness."[61] The ABCDE bundle is a helpful paradigm for critical care nurses to consider when focusing on implementing strategies to improve patient care and reduce the impact of modifiable delirium risk factors.
  - Awakening and Breathing Trial Coordination (the Wake Up and Breathe Protocol)
  - Choice of Sedative
  - Delirium Detection
  - Early Progressive Mobility and Exercise

AACN Levels of Evidence

Level A Meta-analysis of quantitative studies or metasynthesis of qualitative studies with results that consistently support a specific action, intervention, or treatment

Level B Well-designed, controlled studies with results that consistently support a specific action, intervention, or treatment

Level C Qualitative studies, descriptive or correlational studies, integrative reviews, systematic reviews, or randomized controlled trials with inconsistent results

Level D Peer-reviewed professional organizational standards with clinical studies to support recommendations

Level E Multiple case reports, theory-based evidence from expert opinions, or peer-reviewed professional organizational standards without clinical studies to support recommendations

Level M Manufacturer's recommendations only

inhibitors are much more commonly used now to treat depression. Side effects to monitor include changes related to sleep, appetite, personality or behavior, and blood pressure readings.

Untreated depression may result in suicide, which is a serious problem among older adults. Of all suicides committed in this country annually, 25% involve people older than age 65. White men older than age 85 are at particular risk.[35] Because of their many losses and changes, older adults may view suicide as a means of fulfilling a fantasy of "reunion" with a dead spouse or significant other. The nurse must monitor signs and symptoms of depression, explore the causes of depression, facilitate treatment, and watch for suicide attempts or warnings.

BOX 12-8 *PATIENT SAFETY*

Symptoms of Depression

- Depressed mood
- Decreased interest in activities
- Weight changes
- Sleep changes
- Psychomotor changes
- Fatigue
- Feelings of worthlessness or guilt
- Decreased concentration
- Suicidal ideation

Antiparkinsonian drugs
Hormones
Immunosuppressive drugs
Tranquilizers

BOX 12-10 Geriatric Depression Scale

Patient _____ Examiner _____ Date _____

Directions to Patient: Please choose the best answer for how you have felt over the past week.
Directions to Examiner: Present questions VERBALLY. Circle answer given by patient. Do not show to patient.

1.	Are you basically satisfied with your life?	yes	**no** (1)
2.	Have you dropped many of your activities and interests?	**yes** (1)	no
3.	Do you feel that your life is empty?	**yes** (1)	no
4.	Do you often get bored?	**yes** (1)	no
5.	Are you hopeful about the future?	yes	**no** (1)
6.	Are you bothered by thoughts you can't get out of your head?	**yes** (1)	no
7.	Are you in good spirits most of the time?	yes	**no** (1)
8.	Are you afraid that something bad is going to happen to you?	**yes** (1)	no
9.	Do you feel happy most of the time?	yes	**no** (1)
10.	Do you often feel helpless?	**yes** (1)	no
11.	Do you often get restless and fidgety?	**yes** (1)	no
12.	Do you prefer to stay at home rather than go out and do things?	**yes** (1)	no
13.	Do you frequently worry about the future?	**yes** (1)	no
14.	Do you feel you have more problems with memory than most?	**yes** (1)	no
15.	Do you think it is wonderful to be alive now?	yes	**no** (1)
16.	Do you feel downhearted and blue?	**yes** (1)	no
17.	Do you feel pretty worthless the way you are now?	**yes** (1)	no
18.	Do you worry a lot about the past?	**yes** (1)	no
19.	Do you find life very exciting?	yes	**no** (1)
20.	Is it hard for you to get started on new projects?	**yes** (1)	no
21.	Do you feel full of energy?	yes	**no** (1)
22.	Do you feel that your situation is hopeless?	**yes** (1)	no
23.	Do you think that most people are better off than you are?	**yes** (1)	no
24.	Do you frequently get upset over little things?	**yes** (1)	no
25.	Do you frequently feel like crying?	**yes** (1)	no
26.	Do you have trouble concentrating?	**yes** (1)	no
27.	Do you enjoy getting up in the morning?	yes	**no** (1)
28.	Do you prefer to avoid social occasions?	**yes**	(1) no
29.	Is it easy for you to make decisions?	yes	**no** (1)
30.	Is your mind as clear as it used to be?	yes	**no** (1)

TOTAL: Please sum all bolded answers (worth one point) for a total score. _____

Scores: 0–10 Normal **11–20 Moderate Depression** **21–30 Severe Depression**

From Yesavage JA, Brink TL: Development and validation of a geriatric depression screening scale: A preliminary report. J Psychiatr Res 17:37–49, 1983. Available also at http://en.wikipedia.org/wiki/Geriatric_Depression_Scale

Abuse of the Older Person

Mistreatment of older people is a problem that affects more than 4% of the older adults in the United States.[36] Abuse of older adults occurs in homes and institutions and takes many forms. Abuse may be blatant or subtle; it may be physical, psychological, or material (eg, financial). Abuse may involve neglect (by others or by self), exploitation, or abandonment. The abused older person is often physically or mentally frail and unable to report the abusive situation. Abuse can also happen to emotionally and intellectually stable older people who are unable to stop the abuse or report it because of their financial or emotional dependence on the abuser. They may also be afraid of being abandoned.

Abuse can occur because of lack of knowledge about the older person's basic needs, a lack of resources to help, or a desire to protect an inheritance. People who may or may not live with the older person may be responsible for the abuse. Care givers who are extremely stressed may become abusive. In some situations, the abused older adult is the caretaker.

The nurse must be alert to the signs and symptoms of elder abuse as outlined in Box 12-11. Any suggestion by the patient or family that things are not well at home is pursued. A statement such as, "My son hasn't been here yet. He sometimes forgets his commitments," should open the door

BOX 12-11 PATIENT SAFETY

Signs and Symptoms of Elder Abuse

- Lack of compliance with management of health problems
- Unexplained injuries, such as fractures, bruises, lacerations
- Burns
- Poor personal hygiene
- Sexually transmitted disease
- Altered mood
- Depression
- Failure to thrive (underhydration/impaired nutritional status)
- Impaired skin integrity/fungal rashes

BOX 12-12 The HEAT Screening Method for Indications of Alcohol Abuse

How do you use alcohol?
Have you ever thought you used alcohol to **E**xcess?
Has **A**nyone else ever thought you used too much?
Have you ever had any **T**rouble resulting from your use of alcohol?

for further conversation. It might uncover a mother who is worried about her son's drinking and perhaps about the way he treats her when he has been drinking. Attempts are made to compare the history given by the patient with that given by the family. Inconsistencies need to be explored further. Likewise, it is helpful to ask caretakers if they are able to give the care they feel is needed. Indications that the patient is "getting to be a handful" may be a clue to mismanaged care or a caretaker in need of support and assistance. In either situation, the nurse can provide information and support and refer the patient and care giver to a social worker or mental health nurse for further assistance. All health care workers, including nurses, must know their responsibility under state law for reporting abuse of the older patient.

Alcohol Abuse

Alcohol abuse occurs in the aging population. Clinical studies estimate that 15% of men and 12% of women are high-risk drinkers based on information provided by the National Institute on Alcohol Abuse and Alcoholism.[37] Problem drinking in older adults occurs for similar reasons as it does in younger adults. However, smaller amounts of alcohol create larger problems for older people, and they may be more susceptible to alcohol-induced disease. Differences in metabolism of alcohol in older people, the smaller volume of body water, and the decrease in lean body tissue may increase the propensity to alcoholism or alcohol problems. In addition, older adults are high consumers of psychotropic drugs and are at risk for drug–alcohol interactions.

Nursing interventions include screening the older adult for alcohol use. The HEAT screening method,[38] shown in Box 12-12, is useful for screening purposes. A positive response on any item is a reason to obtain a more detailed history of alcohol use. When alcohol abuse is suspected, the immediate goal is to stabilize physiological and psychological responses to alcohol withdrawal and determine the impact of alcohol abuse on whatever other diagnoses have resulted in the need for critical care. As soon as possible, the nurse should refer the patient to a social worker, psychiatric liaison nurse, or alcohol counselor.

▲ Challenges in Medication Use

The rule for giving therapeutic medications to the older patient is *start low, go slow*. In other words, be patient. Changes related to aging can have a great impact on drug response. Changes in renal function, gastrointestinal secretions and motility, and cell receptor sites and concurrent disease states can alter the absorption, distribution, and excretion of drugs. These changes are summarized in Table 12-6.

Before admission to the ICU, older patients may have been taking many different medications, including over-the-counter (OTC) medications such as vitamins, tonics, herbals (eg, Saint John's wort, glucosamine), laxatives, antacids, and pain relievers. They may also have a history of heavy alcohol intake. Any of these drugs can cause problems if combined with medications administered in the hospital.

The nurse needs to elicit a careful history of drug use from the patient and family. The family can be asked to bring in all medications the patient has been using; these include OTC medications and herbal remedies. Although alcohol use may be a sensitive topic, establishing the pattern of use can be essential in preventing untoward drug interactions and anticipating problems with liver damage or withdrawal.

Special considerations concerning administration of drugs to the older patient include knowing the drugs the patient has been taking; assessing renal, hepatic, endocrine, and digestive systems; and evaluating lean body mass. Impaired body systems may affect the absorption, metabolism, and excretion of drugs. Additional considerations are listed in Box 12-13 on page 155. A decrease in lean body mass and an increase in total body fat may alter the distribution of the drug in the body.

Drug Absorption

Drug absorption is affected by the following age-related changes: decreased gastric acid, decreased gastrointestinal motility, decreased gastric blood flow, changes in gastrointestinal villi, and decreased blood flow and body temperature in the rectum. The increased pH of gastric secretions and delayed stomach emptying time can alter the degradation, and thus the absorption, of drugs. Drugs that are not stable in an acid medium can be severely reduced in bioavailability if they remain in the stomach for long periods. Drugs that are designed to be acted on in the small intestine may be affected by the higher pH of the aging stomach. A coated, pH-sensitive medication, such as erythromycin, may lose its coating in the stomach and be degraded before reaching the absorption sites in the small intestine. Coated gastric irritants may lose their coatings and cause bleeding or nausea and vomiting.

Some drugs are eliminated from the body before they enter the systemic circulation by a process called *first-pass metabolism*. In general, the enzymes responsible for this first-pass effect are decreased in the elderly so that bioavailability of drugs with high hepatic extraction may be increased with age. These drugs require dosage reduction in older adults.

Drug Distribution

Distribution of drugs in the body can be affected by a decrease in lean body mass, an increase in total body fat, or a decrease in total body fluid, all of which may accompany aging. Drugs that bind to muscle (eg, digoxin) become more bioavailable as lean body mass diminishes, increasing the risk for toxicity. Fat-soluble drugs (eg, flurazepam [Dalmane], chlorpromazine [Thorazine], phenobarbital) can be deposited in fat and result in cumulative effects of oversedation. In patients with a volume deficit, drugs that are water soluble (eg, gentamicin

Table 12-6 **Altered Drug Responses in Older People**

Age-Related Changes	Effect of Age-Related Change	Applicable Medications
Absorption		
Reduced gastric acid; increased pH (less acid)	Rate of drug absorption—possibly delayed	Vitamins
Reduced gastrointestinal motility; prolonged gastric emptying	Extent of drug absorption—not affected	Calcium
Distribution		
Decreased albumin sites	Serious alterations in drug binding to plasma proteins (the unbound drug gives the pharmacologic response); highly protein-bound medications have fewer binding sites, leading to increased effects and accelerated metabolism and excretion	Selected highly protein-binding medications: Oral anticoagulants (warfarin) Oral hypoglycemic drugs (sulfonylureas) Barbiturates Calcium channel blockers Furosemide (Lasix) Nonsteroidal anti-inflammatory drugs (NSAIDs) Sulfonamides Quinidine Phenytoin (Dilantin)
Reduced cardiac output	Decreased perfusion of many bodily organs	
Impaired peripheral blood flow	Decreased perfusion	
Increased percentage of body fat	Proportion of body fat increases with age, resulting in increased ability to store fat-soluble medications; this causes drug accumulation, prolonged storage, and delayed excretion	Selected fat-soluble medications: Barbiturates Diazepam (Valium) Lidocaine Phenothiazines (antipsychotics) Ethanol Morphine
Decreased lean body mass	Decreased body volume allows higher peak levels of medications	
Metabolism		
Decreased cardiac output and decreased perfusion of the liver	Decreased metabolism and delay of breakdown of medications, resulting in prolonged duration of action, accumulation, and drug toxicity	All medications metabolized by the liver
Excretion		
Decreased renal blood flow; loss of functioning nephrons; decreased renal efficiency	Decreased rates of elimination and increased duration of action; danger of accumulation and drug toxicity	Selected medications with prolonged action: Aminoglycoside antibiotics Cimetidine (Tagamet) Chlorpropamide (Diabinese) Digoxin Lithium Procainamide

From, Smeltzer SC, Bare BG, Hinkle JL, et al: Brunner and Suddarth's Textbook of Medical–Surgical Nursing, 12th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 213.

[Garamycin]) may have a higher concentration and may reach toxic levels rapidly.

Drug Metabolism

The liver is the major organ for biotransformation and detoxification of medications. Drug-metabolizing reactions are classified as phase I reactions, which involve adding or unmasking a polar chemical group to increase water solubility, and phase II or conjugation reactions, which involve linking the drug to another molecule such as glucose, acetate, or sulfate. In older adults, phase I metabolism is often impaired, whereas phase II metabolism is usually unaffected. In the older patient, there may be some decrease in the metabolism of drugs requiring hepatic enzymes for transformation. This results in an increased plasma level and prolonged half-life of the drug. The benzodiazepines (eg, diazepam [Valium], flurazepam), for example, have a half-life increase from 20 to 90 hours in the older patient.

BOX 12-13 Considerations for Medication Use in Older People

- Drug dosage guidelines are usually based on studies in younger people, and recommended adult dosage guidelines may not be appropriate for older patients.
- Older people may be taking numerous prescription drugs and may self-medicate with borrowed, old, and OTC drugs.
- The effects of alcohol use must be considered.
- The potential for drug interactions and adverse reactions is increased because of the effects of aging on drug absorption, distribution, metabolism, and excretion.
- Drug toxicities are different from those in younger people. Fewer symptoms may be identified, and they may develop more slowly but be more pronounced once they occur.
- Behavioral side effects are more common in older people because the blood–brain barrier becomes less effective. When there is an acute change in mental status, medication should always be considered as the cause.

Hepatic oxidation of these drugs can further be affected by alcohol-induced changes in the liver. There may be a decrease in drug metabolism with occasional alcohol use. In chronic alcohol use, however, drug metabolism is increased, and excretion is accelerated.

Drug Excretion

The kidney is the primary excretory organ for clearing drugs. Drugs that are excreted unchanged (eg, digoxin, cimetidine, antibiotics) or have renally excreted active metabolites require dosage reduction in the older adult to avoid accumulation and toxicity. Serum creatinine alone is not a good determinant of renal function in older people. A creatinine clearance study reflects a more accurate estimation for drug clearance.

▲ Clinical Applicability Challenges

CASE STUDY

Mrs. Z., an 85-year-old white woman, is admitted to the acute care unit with wheezing, increased shortness of breath, decreased physical function (eg, activities of daily living such as bathing and dressing) and increased confusion. She lives in an assisted living facility and over the past few days was noted as "not being herself" in that she was less responsive, ate and drank less, fell twice trying to ambulate to the bathroom, and was less engaged in usual activities. She denied any specific complaints of difficulty with breathing, cough, or bowel or bladder changes. Her past medical history includes degenerative joint disease, Parkinson's disease, dementia associated with Parkinson's (baseline Mini-Cog showed 1/3 recall and an inability to draw a clock, thus screening her as "probably demented"), hypertension, coronary artery disease, overactive bladder, decreased hearing, gastroesophageal reflux disease, depression, vascular insufficiency, and irritable bowel syndrome. Her physical function at baseline was described as "minimum assistance with activities of daily living with help including verbal encouragement and cueing for bathing and dressing upper extremity, and moderate assistance to reach feet for bathing and dressing" She ambulated with a walker and supervision due to balance problems. Current medications included acetaminophen (Tylenol) 1,000 mg PO three times per day PRN for pain; namenda 10 mg PO twice a day; nitroglycerin patch 0.4 mg/h; vitamin D_3 1,000 units daily, olanzapine (Zyprexa) 5 mg daily, aspirin 81 mg PO daily, bupropion (Wellbutrin XL) 300 mg PO daily, losartan (Cozaar) 100 mg PO daily, duloxetine (Cymbalta) 60 mg PO daily; folic acid 1 mg PO daily, and furosemide (Lasix) 40 mg PO daily.

On admission, Mrs. Z denied any specific symptoms. She was pleasant when addressed and answered simple questions appropriately although she initiated no conversation and passively waited for others to address her or intervene. On physical examination, she was febrile with a temperature of 100.1°F and pulse oximetry score of 85% on room air at rest; blood pressure was 128/70 and heart rate 102 bpm and regular. She was noted to have decreased breath sounds in both lung bases and expiratory wheezes throughout. Her respiratory rate was 18. She responded well to oxygen at 2 l via nasal cannula, and her pulse oximetry score improved to 92%. Blood samples were drawn for laboratory testing, and results included white blood cell (WBC) 13.0, hemoglobin 13.4, hematocrit 41.0, platelet count 236.0, neutrophils 10,413, lymphocytes 1,599, creatinine 1.17, BUN 21, calcium 9.3, glucose 200 (nonfasting), sodium 146, potassium 3.9, chloride 109, and carbon dioxide 17; estimated GFR was 46. Mrs. Z.'s chest radiograph showed a normal heart size. There was haziness seen in the right lung base consistent with an early infiltrate. Neurological findings, per Mini-Cog, indicated that she probably has some dementia. She had a bilateral pill-rolling tremor that was worse at rest and when she was stressed to perform. She required moderate assistance to stand, and bradykinesia and retropulsion were noted. Using her rolling walker, she was able to ambulate 10 ft with moderate assistance. She was admitted for pneumonia, and treatment was initiated with ceftriaxone (Rocephin) 1 g IV every 12 hour.

1. What is your immediate concern related to Mrs. Z.'s pulmonary status and underlying complaints?
2. How do you answer Mrs. Z.'s daughter's questions in terms of explaining the laboratory work?

(continued on page 156)

CASE STUDY *(Continued)*

3. How would you encourage Mrs. Z.'s daughter to help her mother optimize her hospital experience and prevent complications?
4. What nursing care interventions are essential to help Mrs. Z. maintain and restore functional ability?
5. What nursing care interventions are appropriate related to pulmonary status and comorbidities?
6. Specifically, what nursing care interventions would you implement related to preventing falls?

13 The Postanesthesia Patient

Nathaniel M. Apatov and E. Jane McCarthy

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. List anesthetic techniques used for surgery and interventional procedures.
2. Describe nursing interventions and assessment strategies for the patient recovering from anesthesia.
3. Explain common complications encountered during the immediate postanesthetic period and the necessary nursing interventions.
4. Compare and contrast moderate IV sedation and general anesthesia.

The time immediately after surgery is the most crucial period in the patient's recovery from anesthesia. Patients are taken to the postanesthesia care unit (PACU) to receive nursing care from a PACU nurse or directly to the intensive care unit (ICU) to receive nursing care from an ICU nurse. The purpose of this chapter is to describe anesthetic techniques used during surgery and the complications that can occur during the immediate postoperative time to help the critical care nurse better understand the nursing care needs of the immediate postanesthetic patient. To help better understand anesthesia techniques used intraoperatively, common clinical terms related to the use of anesthesia are listed in Box 13-1.

▲ Preoperative Anesthesia Patient Assessment

The anesthesia provider interviews and examines the patient before surgery. From this preanesthetic examination and discussions with the patient and surgeon, the anesthesia provider decides the anesthetic technique. This decision is based on the patient's age, anesthetic history, medical history, and the operation to be performed. The anesthesia provider's options range from conscious sedation with the use of regional or intravenous (IV) agents to general anesthesia with the use of IV or inhalational anesthetic agents. Whenever possible, the patient and family are part of the decision-making process. These options are illustrated in Table 13-1 and Figure 13-1.

▲ Postanesthesia Report to PACU or ICU Nurse

What happens in the operating room (OR) affects the patient's immediate postoperative care and overall recovery. To convey what has occurred during surgery, the anesthesia provider gives a detailed report to the nurse who is assuming immediate postoperative care of the patient. Information given in the report is listed in Box 13-2. Initial assessment parameters reported to the anesthesia provider by the nurse are the patient's blood pressure, pulse rate, respiratory rate, temperature, oxyhemoglobin saturation (SaO_2), and level of consciousness. The anesthesia provider gives a report on intraoperative hemodynamic parameters, anesthetic technique, surgical procedure, urine output, blood loss, and fluid replacement. While receiving the report from the anesthesia provider, the nurse simultaneously assesses the patient and develops a nursing plan of care. In the PACU or ICU, vital signs are monitored every 15 minutes or more often if the patient's condition warrants. Box 13-3 on page 161 provides collaborative care guidelines for the postanesthesia patient. The American Society of Peri Anesthesia Nurses, endorsed by the American Society of Anesthesiologists and the American Association of Nurse Anesthetists, recommends that all assessment data be collected and documented on the patient's postoperative record.[1]

In addition, while assessing the patient and taking vital signs, the nurse uses the "stir-up" regimen that involves encouraging the patient to deep-breathe, cough, and move as allowed by the surgical procedure or intervention. The nurse also assesses pain levels and implements appropriate interventions to assist the patient in participating in the "stir-up" regimen. This regimen also allows the nurse to identify changes in the patient's cognitive function.

▲ Complications in the Postanesthesia Patient

The nurse must be able to assess and treat common complications in the postanesthesia patient. Postanesthesia patient care focuses primarily on cardiopulmonary assessment and management. The following are the common complications seen in the nursing care of the immediate postoperative patient.

BOX 13-1 Clinical Terminology

Sedation: An induced state of quiet, calm, or sleep by means of a medication. The degree of sedation ranges from anxiolysis to anesthesia.
Minimal sedation: The patient responds normally to verbal stimuli. Impairment to cognition and coordination may exist.
Moderate sedation: A drug-induced depression of consciousness during which the patient responds purposefully to verbal commands either alone or in conjunction with tactile stimulation. There is some alteration of mood, drowsiness, and sometimes analgesia. The patient's protective reflexes remain intact.
Deep sedation: A drug-induced depression of consciousness during which the patient cannot be easily aroused but responds purposefully after repeated or painful stimulation. Spontaneous ventilation and the ability to maintain a patent airway may be impaired. The patient may require assistance in maintaining a patent airway.
General anesthesia: A drug-induced loss of consciousness during which a patient cannot be aroused, even by painful stimulation. The ability to independently maintain ventilatory function may be impaired. The patient may require assistance in maintaining a patent airway and positive-pressure ventilation may be required. Cardiovascular function may be depressed.
Monitored anesthesia care (MAC): A specific anesthesia service in which an anesthesia provider has been requested to participate in the care of a patient undergoing a therapeutic or diagnostic procedure. It does not describe the depth of sedation.
Regional anesthesia: Regional anesthesia is achieved by placing local anesthetics close to appropriate nerves to achieve a conduction block that provides analgesia and numbness.
Spinal anesthesia: A local anesthetic is injected into the lumbar intrathecal space. The anesthetic blocks conduction in spinal nerve roots and dorsal ganglia. Anesthesia and analgesia usually occur below the level of injection.
Epidural anesthesia: A local anesthetic is injected via a catheter into the epidural space. The effects are similar to spinal analgesia.
Peripheral nerve block: A local anesthetic is injected at a specific nerve site to achieve a defined area of anesthesia.

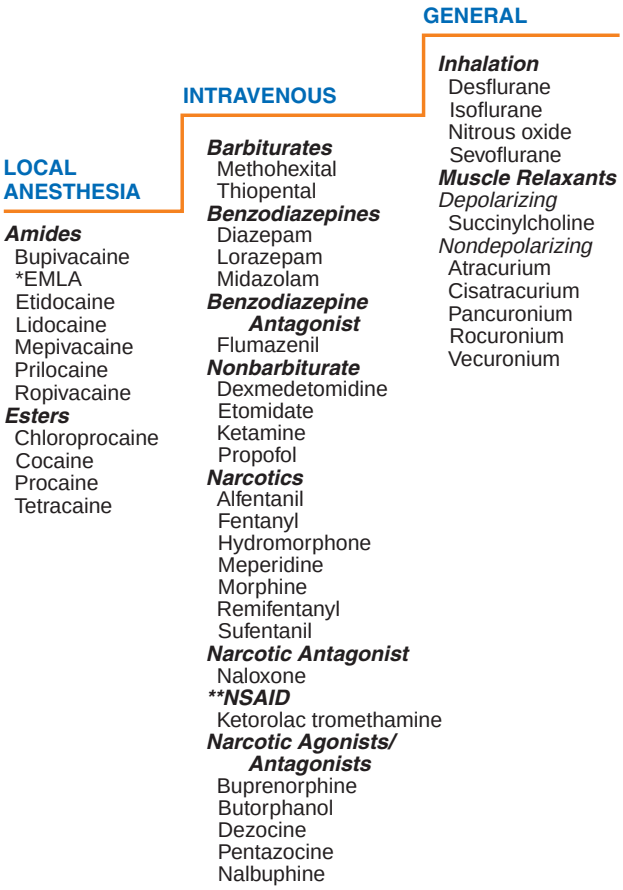
Hypoxemia

Hypoxemia characterized by an oxyhemoglobin saturation (SaO_2) of less than 90% or a partial pressure of arterial oxygen (PaO_2) of less than 60 mm Hg is life threatening. General anesthetic drugs can cause hypoxemia in the immediate postoperative period as a result of ventilation–perfusion mismatch.[2] Signs and symptoms of hypoxemia include tachycardia, cardiac dysrhythmias, dyspnea, tachypnea, disorientation, agitation, and cyanosis. Hypoxemia and hypoventilation may also occur postoperatively following the use of a spinal or epidural regional anesthetic that has blocked the spinal nerves innervating the muscles of respiration and weakening the respiratory effort.[3]

When nitrous oxide is used for general anesthesia, 100% oxygen is administered in the OR for 3 to 4 minutes at the discontinuance of this anesthetic. These patients are transported receiving oxygen to prevent diffusion hypoxia in the PACU. Patients who receive a general anesthetic or sedation receive supplemental oxygen in the immediate postoperative period because general anesthesia and sedation cause a compromise in respiratory function. Patients in the immediate postoperative period are routinely monitored for adequate oxygenation by using the pulse oximeter, a noninvasive device that continuously monitors oxygen hemoglobin saturation (SaO_2). This device has been used in the OR since the 1980s and more recently in the PACU, resulting in a significant decrease in anesthesia and postanesthesia respiratory mishaps.[4]

Table 13-1 Anesthetic Options for Surgical and Interventional Procedures

Conscious State	Sedated State	Unconscious State
Modalities		
Conscious sedation Monitored anesthesia care (MAC) Local anesthesia Regional anesthesia	MAC Local anesthesia Regional anesthesia	Regional anesthesia General anesthesia
Medications		
Local anesthetics Intravenous (IV) medications	Local anesthetics IV medications	Local anesthetics IV medications Inhalation anesthetics Muscle relaxants
Effect on Patient		
Patient cooperative Follows commands Maintains protective reflexes	May follow commands Usually maintains protective reflexes	Unconscious Diminished or loss of protective reflexes Alterations in cardiopulmonary dynamics



* EMLA, Eutectic mixture local anesthetics
** NSAID, Nonsteroidal anti-inflammatory drugs

FIGURE 13-1 ▲ Medication choices for anesthetic options

Reversal agents are used intraoperatively to reverse the effects of muscle relaxants, sedatives, and opioids. The effects of muscle relaxants, sedatives, and opioids may last longer than the reversal agent resulting in hypoventilation and hypoxemia even though a reversal agent has been administered. For this reason, it is important to know the onset and duration of action of drugs used to reverse the effects of the sedative, muscle relaxant, or narcotic. This knowledge allows for appropriate assessment and intervention when a change in the patient's condition occurs.

BOX 13-2 Anesthesia Provider-to-Nurse Report: Information to Convey

Name of patient
Surgical procedure
Type of anesthetic (agents and reversal agents used)
Estimated blood loss
Fluid and blood replacement
Intraoperative blood pressure and heart rate range
Intraoperative complications
Preoperative patient history
Language barrier

Note: The anesthesia provider should not leave the patient until the nurse is satisfied with the patient's immediate postoperative condition.

Hypoventilation

Hypoventilation leading to hypercarbia ($PaCO_2$ > 45 mm Hg) may result from the following:

- Inadequate respiratory drive secondary to the effects of residual anesthesia, such as opioids, sedatives, and general anesthesia inhalational agents
- Inadequate functioning of respiratory muscles causing inadequate tidal volume due to residual neuromuscular blockade
- Chronic pulmonary disease, such as chronic obstructive pulmonary disease, which may require postoperative ventilatory support
- Laryngospasm or upper airway obstruction resulting from residual general anesthesia (Box 13-4)

The nurse institutes the "stir-up" regimen in the immediate postoperative phase to stimulate the patient, especially if opioids or sedatives were used during surgery. The nurse considers the length of time since reversal agents were administered to antagonize neuromuscular blockade. The patient may not be fully reversed and may exhibit signs of residual neuromuscular blockade assessed by the inability to maintain a head lift for 5 seconds. Moreover, inappropriate use of chest and abdominal wall muscles will result in air hunger, anxiety, and tachycardia. Neuromuscular blocking agents are summarized in Box 13-5. The respiratory effect of neuromuscular nondepolarizing drugs is prolonged with hypothermia. Other conditions that increase the effects of nondepolarizing muscle relaxants are listed in Box 13-6 on page 163.

Hypotension

The most common cardiovascular complication seen in the postoperative period is hypotension due to decreased blood volume resulting from preoperative fasting and intraoperative blood loss. Intervention is indicated if the pressure decreases by more than 30% of the baseline blood pressure.[5] Risk factors for postanesthesia hypotension are listed in Box 13-7 on page 163.

General and regional anesthetics also decrease blood pressure. Spinal and epidural regional anesthetic techniques cause vasodilation and decrease blood pressure resulting from the sympathetic blockade. Opioids cause histamine release and vasodilation resulting in lowered blood pressure. Droperidol and chlorpromazine hydrochloride produce sympathetic blockade and hypotension. Barbiturates and anesthetic inhalational agents, such as isoflurane, sevoflurane, and desflurane, cause myocardial depression. Often, postoperative orthostatic hypotension is due to hypovolemia and decreased venous return to the heart because of inadequate intraoperative volume replacement, blood loss, loss of fluid into the interstitial space, and diuretics. The patient is evaluated for orthostatic hypotension by measuring blood pressure and heart rate in the supine position and in a position with the head of the bed raised 60 degrees, if not contraindicated by the surgical procedure or the patient's status. With orthostatic hypotension, there will be a significant decrease in blood pressure with the head of the bed raised. Cardiac dysrhythmias, such as supraventricular tachycardia and marked bradycardia, can cause a decrease in cardiac output leading to hypotension. Other causes of postoperative

BOX 13–3 *COLLABORATIVE CARE GUIDE for the Postanesthesia Patient*

Outcomes	Interventions
Oxygenation/Ventilation	
Adequate respiration after extubation SaO_2 returns to the preoperative value without supplemental O_2. Airway maintained with intact protective reflexes. No evidence of aspiration.	• Monitor respiratory rate and breathing pattern every 15 min and PRN. • Assess weaning parameters before extubation. • Monitor end-tidal CO_2 and pulse oximetry of mechanically ventilated patients. • Encourage patient to cough and deep-breathe. • Elevate head of bed if not contraindicated. • Use jaw thrust, head tilt, or oral, oropharyngeal, or nasopharyngeal airway to maintain airway. • Stimulate patient every few minutes (eg, call name, touch). • Administer antiemetic as indicated. • Position patient on side; suction and maintain airway if patient is vomiting.
Circulation/Perfusion	
Heart rate and blood pressure returned to preoperative values within 1–2 h after anesthesia. Body temperature within normal limits. No evidence of malignant hyperthermia.	• Monitor vital signs every 15 min and PRN. • Assess pulse quality and regularity. • Monitor for dysrhythmias. • Monitor for hypotension related to bleeding. • Monitor for hypotension related to warming and vasodilation. • Administer IV solution and blood products as ordered. • Anticipate hypothermia; have warming devices readily available. • Measure temperature on admission and PRN until normal. • Warm patient at 1°C–2°C/h. • Monitor for malignant hyperthermia and immediately notify anesthesia provider of temperature increase of 0.5°C. • Administer dantrolene and initiate cooling measures. • Assist with malignant hyperthermia protocol.
Fluids/Electrolytes	
Patient has stable blood pressure and heart rate. Urine output will be 0.5–2 mL/kg/h. No evidence of hypervolemia or hypovolemia.	• Maintain patient IV. • Monitor intake and output. • Assess skin and mucous membranes for signs of hypovolemia. • Measure specific gravity if indicated. • Assess for signs of hypervolemia (eg, pulmonary crackles, neck vein distention). • Measure serum electrolytes if indicated.
Mobility/Safety	
Patient will arouse easily and respond appropriately to commands. Patient will move all extremities purposefully and with normal strength.	• Assess level of consciousness every 15 min and PRN. • Monitor motor and sensory function to assess reversal of neuromuscular blockade. • Assess level of regional block, epidural, or spinal anesthesia.
Skin Integrity	
Skin will remain intact.	• Assess skin immediately postoperatively for pressure areas and burns.
Nutrition	
Nutritional intake will be reestablished without nausea or vomiting.	• Resume enteral feeding with return of bowel sounds. • Begin oral fluids with return of protective airway reflexes.
Comfort/Pain Control	
Pain will be <4 on numeric pain scale or visual analog.	• Assess location, type, and severity of pain. • Administer opioids as indicated. • Monitor response to analgesics. • Institute nonpharmacological pain relief strategies and comfort measures. • Evaluate patient-controlled analgesia IV or epidural as postoperative pain management option.

(continued on page 162)

BOX 13-3 COLLABORATIVE CARE GUIDE for the Postanesthesia Patient (continued)

Outcomes	Interventions
Psychosocial	
Personal support systems will be used to reduce anxiety.	• Encourage significant other visits in early postoperative phase. • Validate patient's significant other's understanding of surgery and illness. • Initiate referrals to social services, clergy, and so forth.
Teaching/Discharge Planning	
Discharge from postanesthesia care phase will occur within 1–2 h. Exercises to prevent postoperative pulmonary complications will be demonstrated. Patient or significant other will state understanding of surgical procedure and outcome of surgery.	• Orient patient frequently. • Explain procedures and pain management treatment plan. • Teach coughing, deep breathing, and incentive spirometer use. • Teach early mobilization. • Teach pain control strategies. • Provide information regarding the procedure, and discuss probable outcomes.

hypotension include sepsis, pulmonary embolism, and transfusion reaction.

Deliberate, controlled hypotensive intraoperative anesthetic techniques are used during surgical procedures, such as neurosurgery, shoulder arthroscopy, and maxillofacial surgery. This hypotensive technique minimizes blood loss, decreases intraoperative blood transfusions, decreases oozing, and minimizes hematoma formation. These patients must be monitored closely postoperatively until blood pressure returns to normal.

Treatment of immediate postoperative hypotension depends on the underlying cause. A priority is to ensure adequate oxygenation and ventilation of the patient while the blood pressure is addressed. Anesthetic drugs may require reversal, including muscle relaxant reversal with anticholinesterase agents, opioid reversal with naloxone (Narcan), and benzodiazepine reversal with flumazenil (Romazicon). IV fluids, blood products, plasma expanders,

BOX 13-4 Managing Laryngospasm and Airway Obstruction

Laryngospasm

Laryngospasm is often caused by blood, mucus, or other oral secretions irritating the vocal cords. Suctioning of the oropharynx before extubation helps to prevent laryngospasm. Laryngospasm is treated with positive-pressure ventilation using 100% FiO_2 via a bag-valve mask with a tight seal. If this does not break the spasm, a small dose of depolarizing muscle relaxant (succinylcholine) may be given IV.

Upper Airway Obstruction

Upper airway obstruction must be identified and treated promptly and effectively. Airway obstruction may range from minimal to complete. Signs of obstruction include

- Paradoxical breathing
- Stridor
- Lack of, or change in, breath sounds
- Hypoxemia
- Change in level of consciousness

Treatment to relieve obstruction must be provided in a systematic fashion.

1. Tilt head/lift chin.
2. Thrust jaw.
3. Call for assistance.
4. Insert an oropharyngeal or nasopharyngeal airway. (An oropharyngeal airway may not be tolerated by the partially anesthetized patient.)
5. Apply positive-pressure ventilation.
6. Perform endotracheal intubation if necessary.

BOX 13-5 Neuromuscular Blocking Agents

Muscle Relaxants

- Muscle relaxant drugs used in anesthesia paralyze patients but provide no sedation or analgesia.
- Muscle relaxants facilitate endotracheal intubation, relax muscles for surgical procedures, terminate laryngospasm, eliminate chest wall rigidity, and provide for ease of mechanical ventilation if indicated.
- Depolarizing and nondepolarizing muscle relaxants are used in anesthesia and work at the myoneural junction by blocking nicotinic acetylcholine receptors.

Depolarizing Agent (Succinylcholine)

- Succinylcholine combines with acetylcholine receptors at the myoneural junction and mimics the action of acetylcholine.
- Onset of action is 1 to 2 minutes and duration of action is 4 to 6 minutes.
- The enzyme pseudocholinesterase removes succinylcholine from plasma, so in conditions involving a decrease in pseudocholinesterase, the length of action of succinylcholine increases, keeping patients paralyzed for longer periods.
- Decreased pseudocholinesterase enzyme may be seen in pregnancy, liver disease, malnutrition states, severe anemia, cancer, and with other pharmacological agents, such as quinidine, phospholine eye drops, and propranolol.

Nondepolarizing Agents

- Nondepolarizing agents (atracurium, cisatracurium, pipecuronium, vecuronium, pancuronium, doxacurium, rocuronium) compete with acetylcholine at the myoneural junction for muscle membrane receptors.
- Onset of action is within 2 to 3 minutes, depending on dose.
- Duration of action ranges from 20 minutes to 2 hours, depending on the drug and dosage.
- Muscle relaxant reversal agents (neostigmine, edrophonium) duration of action may be shorter than the duration of action of muscle relaxants, resulting in respiratory muscle weakness and respiratory insufficiency. Anticholinesterases cause muscarinic side effects including bradycardia and increased salivary secretions. These side effects are counteracted with the administration of an anticholinergic drug (atropine, glycopyrrolate) in conjunction with the anticholinesterase.

BOX 13-6 Conditions and Drugs That Increase the Effects of Nondepolarizing Muscle Relaxants

Local anesthetics
General anesthetics
Antibiotics: aminoglycosides, polypeptides, polymyxin
Antiarrhythmics: quinidine, procainamide
Furosemide (Lasix)
Acid–base status: respiratory acidosis, metabolic alkalosis
Electrolyte imbalance: hypokalemia, hypocalcemia, dehydration, magnesium administration
Hypothermia

crystalloids, and vasopressor drugs are administered to increase blood pressure caused by intraoperative blood loss. The nurse also inspects wound dressings, drains, and surgical sites for postoperative bleeding. If there is significant postoperative bleeding, the surgeon must be notified and the patient may have to return to the OR.

When assessing and treating a patient with hypotension, the nurse must also rule out the possibility of a technical problem rather than physiological problems. Is the blood pressure cuff the correct size and is it positioned correctly? Is the stethoscope positioned correctly? Is the patient's position a factor? If an arterial line is present, is the patient peripherally constricted or does the patient have significant peripheral vascular disease? Is the transducer correctly calibrated? Troubleshooting for device errors occurs simultaneously with patient assessment.

Hypothermia

Heat loss during surgery is due to reduced basal metabolism and the anesthetized patient's inability to shiver to produce heat to maintain body temperature. Inhalational anesthetic agents depress the thermoregulatory center resulting in hypothermia. Vasodilation occurs with regional anesthesia because of the sympathetic blockade resulting in heat loss and hypothermia. Other intraoperative causes of hypothermia include heat loss through radiation, convection, and conduction because of prolonged skin exposure, saturated surgical drapes, cold antiseptic prepping solutions, cold irrigation solutions, and cold IV solutions. Geriatric patients are at greater risk for hypothermia because of alterations in their hypothalamic function. Neonates are more at risk for hypothermia because of their immature thermoregulatory center and their high body surface to volume ratio. Hats, warm blankets, forced air warming devices, and IV fluid warmers are used to prevent hypothermia preoperatively, intraoperatively, and postoperatively.

Patients admitted to the PACU or ICU with hypothermia have prolonged postoperative recovery time and higher incidence of postoperative complications such as wound infection.[6] Rewarming of the postoperative patient is done immediately using heated blankets, warm IV fluids, and warming devices such as the forced air warmer.

BOX 13-7 *PATIENT SAFETY*

Factors That May Cause Postoperative Hypotension

Drug and Conditional Factors
- Epidural or spinal anesthetic blockade
- Inhalation anesthetic agents
- Hypovolemia
- Hypothermia
- Myocardial depression
- Sepsis
- Transfusion reaction
- Increased intrathoracic pressure from mechanical ventilation
- Dysrhythmias (supraventricular tachycardia)
- Myocardial infarction
- Congestive heart failure
- Bradycardia
- Pain
- Bladder/abdominal distention

Technical Factors
- Blood pressure cuff size and position
- Tight abdominal dressing
- Transducer balance and calibration
- Stethoscope position

Postoperative Nausea and Vomiting

Postoperative nausea and vomiting (PONV) is one of the more common problems in the PACU and is a frequent cause of postoperative hospital admission.[7] Although not life threatening, PONV leaves the patient with a lasting unpleasant memory and may have an impact on future surgical and anesthetic decisions. Frequent causes include use of preoperative and intraoperative opioids, increased gastric secretions, spinal anesthesia, and surgical procedures involving manipulation of eye muscles, abdominal muscles, or genitourinary muscles. Laparoscopic techniques and procedures involving the breast are also associated with an increase in PONV.

Vomiting is regulated by the vomiting center located in the medulla and receives stimuli from the gastrointestinal tract, the chemoreceptor trigger zone, the labyrinthine apparatus (motion sickness), and cortical and visual input. Examples of stimuli that cause vomiting are gastric distention, opioids, anesthetic drugs, hypoxemia, postoperative pain, and hypotension. PONV can usually be relieved by identifying the causative factor and making the appropriate intervention. Antiemetic drugs given to treat PONV in the immediate postoperative period may have a synergistic effect on opioids, and decreasing the dose of narcotic is indicated. Patients at increased risk for PONV are treated using a multimodal pharmacologic approach perioperatively beginning in the preoperative period. The anesthetized patient is not only prone to vomiting but, because of the unprotected reflexes, there is a greater chance of regurgitation and pulmonary aspiration. Proper positioning of patients with altered levels of consciousness is essential. The ideal position is on the side with the head and neck extended. If the surgical procedure precludes turning the patient on the side or the patient is unable to comply, then the patient must not be left unattended until consciousness is regained. A Yankaeur suction device attached to wall suction should be immediately available.

Postoperative Pain

Postoperative surgical pain is caused by several factors including the surgical incision, tissue manipulation, the

BOX 13-8 Factors Influencing Pain

Surgical procedure: site and nature of the operation
Anxiety level: fear of surgery, disfigurement, death, loss of control, previous experiences
Patient expectations: effectiveness of preoperative teaching, adequately prepared for outcome
Pain tolerance: prior use of medications, including analgesics, individual differences
Anesthesia technique: analgesics used during the intraoperative period, use of naloxone

psychological state of the patient, and the anesthetic technique used intraoperatively. Adequate pain relief is important during the postoperative period because it allows the patient to cough, deep-breathe, and ambulate sooner, thus reducing the incidence of postoperative complications such as atelectasis pneumonia. If the anesthetic was an inhalation anesthetic agent without opioids or local anesthetics, a patient may have more pain than a patient who received intraoperative opioids or a regional anesthetic. Patients who have been given analgesics during surgery and who then receive naloxone, an opioid antagonist, at the end of surgery may experience severe pain because the opioid antagonist reversed the analgesic effects of any prior opioid drugs. Because these patients may experience hypoventilation again, the nurse must wait 15 to 45 minutes after the administration of naloxone before giving an analgesic drug. Box 13-8 lists factors that influence the patient's response to pain. The following are types and methods of administration of analgesic drugs commonly used for the immediate postoperative patient.

Intravenous Opioid Drugs

Intravenous (IV) titration of opioids, such as morphine, fentanyl, or hydromorphone, in the immediate postoperative period offers the fastest and most effective method of pain relief. Because the patient's basal metabolic rate decreases during surgery and the patient may be hypothermic, the uptake of intramuscular medication is often difficult to predict.

Toradol

Tordadol (ketorolac tromethamine) may also be administered during surgery and has been found effective in treating immediate mild to moderate postoperative pain. Torodol is a nonsteroidal anti-inflammatory drug that exhibits analgesic, anti-inflammatory, and antipyretic activity. Peak analgesia occurs in 45 to 60 minutes after intramuscular or IV injection, and the analgesic effect lasts 6 to 8 hours. This drug is given in doses up to 30 mg and is not used for more than 5 days postoperatively. The drug is contraindicated in patients with active peptic ulcers, recent gastrointestinal bleeding, or renal insufficiency.

Patient-Controlled Analgesia

The use of patient-controlled analgesia (PCA) in the PACU allows the patient to administer his own analgesic IV using a PCA device. Clinical studies show that patients report less pain when they are able to control the administration of opioids for their pain relief.[8] PCA analgesia may be used to inject analgesic drugs IV; alternatively, it may be used to inject analgesic drugs into the epidural space. Both modalities are effective ways for patients to control their own analgesic needs.

Epidural Opioid Drugs

Epidural opioid analgesia is effective in treating acute postoperative pain.[9] Patients who receive epidural opioids are less sedated, able to ambulate sooner, and have improved respiratory function. Epidural opioids are administered as a bolus injection at the end of surgery or by a continuous epidural infusion via an epidural catheter postoperatively. When administering continuous epidural infusions, an infusion pump is used. Epidural drugs must be preservative free. To ensure patient safety during epidural opioid infusion, infusion sets are used that have no injection ports. The infusing pump, infusion bag, and infusion tubing are clearly labeled with the word *epidural*. The reason for these safeguards is that accidental infusion of other drugs with preservatives could cause neural damage resulting in paralysis or death. Frequently used preservative-free epidural drugs include morphine, hydromorphone, and fentanyl. The duration of analgesia varies with the narcotic administered. Frequently used opioids for epidural administration are preservative-free morphine, which has a duration of action from 2 to 24 hours; hydromorphone, which has a duration of 10 to 14 hours; and fentanyl, which has a duration of 4 to 6 hours.

Epidural Local Anesthetic Drugs

Dilute local anesthetic solutions using lidocaine, ropivacaine, bupivacaine, or etidocaine are given epidurally for postoperative pain either with opioids or alone. The combination of local anesthetics and opioids has been used to optimize analgesia and minimize the side effects of local anesthetics and opioids using minimal doses for both. Nurses are responsible for recognizing and treating the side effects (Box 13-9) of patients who are receiving epidural analgesia.

Hypertension

The most common causes of postoperative hypertension are pain and hypothermia. Hypertension is seen with hypothermia because of the peripheral vasoconstriction and shivering. Hypertension also occurs with hypoxemia and hypercarbia because of the endogenous catecholamine release. Ketamine, a nonbarbiturate drug, which is used as a dissociative anesthetic, stimulates the sympathetic nervous system and may cause tachycardia and hypertension. Naloxone, if given too rapidly, may cause hypertension leading to pulmonary edema or cerebral hemorrhage. Other causes of hypertension include anxiety, urinary bladder distention, fluid overload, a too-narrow blood pressure cuff, and withholding antihypertensive drugs before surgery. Unless instructed otherwise, patients should take their antihypertensive drugs up to the day of surgery.

Hypertensive patients require reassurance and close observation. Mild to moderate hypertension in the immediate postoperative period is usually treated with IV vasoactive drugs such as hydralazine (Apresoline) and labetalol (Trandate). Hypertensive crises do occur in the immediate postoperative period, and continuous IV infusions of nicardipine, sodium nitroprusside, or nitroglycerin are used to keep the blood pressure in a safe range. When hypertension

BOX 13-9 Side Effects of Epidural Analgesia and Possible Remedies

Urinary Retention
- Catheterize as needed.

Postural Hypotension
- Give fluid (volume) replacement.
- Administer ephedrine 5 mg or phenylephrine 50 mcg IV as ordered.

Pruritus (Itching of Face, Head, and Neck)
- Treat with diphenhydramine (Benadryl) 25 mg PO, IM, IV.
- Treat with naloxone (Narcan) 0.1 mg IV.
- Treat with propofol 10 mg IV.

Nausea and Vomiting
- Administer metoclopramide (Reglan) 10 mg IV.
- Administer scopolamine patch.
- Administer a 5HT-3 antagonist

Respiratory Depression
- Administer naloxone 0.1 mg up to a maximum of 0.4 mg IV.
- Monitor for 30 minutes after naloxone administration because opioid half-life may be longer

accompanies emergent delirium, IV sedatives may be required. If the patient is hypertensive because of anxiety and verbal reassurance is ineffective, benzodiazepines, such as midazolam (Versed), may be necessary. If the hypertension results from fluid overload during surgery, the patient may require urinary catheterization and diuretics, such as furosemide (Lasix).

Cardiac Dysrhythmias

The cardiac dysrhythmias covered in this chapter are those induced by anesthetic agents and complications frequently seen in the immediate postoperative period (Table 13-2). Chapter 17 provides detailed information on cardiac dysrhythmias. The most common causes of cardiac dysrhythmias in the immediate postoperative period are hypoventilation, electrolyte imbalances, hypoxemia, hypovolemia, fluid overload, hypothermia, and pain (Box 13-10).

Malignant Hyperthermia

Malignant hyperthermia (MH) is an autosomal dominant, pharmacogenetic disorder of skeletal muscle characterized by a hypermetabolic response to an anesthetic triggering agent resulting in skeletal muscle damage, hyperthermia, and death if untreated (see Spotlight on Genetics 13-1). With an MH episode, not every patient responds the same and not every anesthetic will cause MH in an MH susceptible patient. Most MH episodes occur in the OR during general anesthesia and less frequently in the immediate postoperative period. MH is triggered in susceptible individuals by halogenated inhalational anesthetic agents and the depolarizing muscle relaxant succinylcholine. Other anesthetic agents such as nitrous oxide, local anesthetics, opioids, propofol, sodium thiopental, and the nondepolarizing muscle relaxants do not trigger MH episodes.

The prevalence of MH is unknown and can vary by geographic location. The states with the highest incidence are Michigan, West Virginia, and Wisconsin.[10] MH is more prevalent in people with muscular abnormalities, such as

Table 13-2 Cardiac Dysrhythmias Associated With Anesthetics

Anesthetic Agent	Dysrhythmia
Local anesthesia with epinephrine	Tachycardia
Spinal and epidural	Bradycardia secondary to vagal response
Barbiturates	
Sodium pentothal	Bradycardia, AV dissociation, occasional PVCs
Nonbarbiturate etomidate	Sinus tachycardia
Morphine sulfate	Transient brachycardia
Meperidine hydrochloride	Transient tachycardia
Fentanyl	Bradycardia
Opioid antagonist	PVCs, ventricular tachycardia, occasional ventricular fibrillation
Ketamine	Tachycardia
Isoflurane	Tachycardia
Enflurane, Sevoflurane, Desfluran1e	AV dissociation, tachycardia
Muscle relaxants	
Succinylcholine	Sinus bradycardia, junctional rhythms, PVCs Patients with burns, trauma, paraplegia or quadriplegia prone to ST-segment depression, peaked T waves, widening QRS complex leading to ventricular tachycardia, ventricular fibrillation, or asystole
Pipecuronium bromide	Atrial fibrillation, ventricular extrasystole
Pancuronium	Tachycardia and nodal rhythms
Anticholinesterases	Bradycardia, slowed AV conduction, PVCs
Anticholinergics	Tachycardia

AV, atrioventricular; PAC, premature atrial contraction; PVC, premature ventricular contraction.

BOX 13-10 Causative Factors for Dysrhythmias

- Hypoxemia (sinus bradycardia, sinus tachycardia, premature ventricular contractions [PVCs], supraventricular tachycardia)
- Hypoventilation/hypercarbia (sinus tachycardia, PVCs, sinus bradycardia)
- Hypovolemia (sinus tachycardia)
- Fluid overload (PVCs, supraventricular tachycardia, premature atrial contractions [PACs], atrial fibrillation/flutter)
- Hyperthermia (sinus tachycardia, PVCs)
- Hypothermia (sinus bradycardia, atrial fibrillation, atrioventricular nodal blocks)
- Pain (sinus tachycardia, PVCs)

muscular dystrophy. The incidence of MH has been estimated to be as low as 1 in 250,000 patients receiving anesthetics to as high as 1 in 4,200 patients receiving anesthetics using triggering agents. MH was first observed in the 1960s with the introduction of inhalational anesthetic agents with resultant mortality of 80%. Today, with the use of intraoperative monitoring of end-tidal CO_2 ($ETCO_2$), SaO_2, and dantrolene sodium treatment, the mortality has decreased to about 5%.

The pathophysiology of MH occurs when the MH susceptible skeletal muscle is exposed to an MH triggering agent, and calcium is released at an abnormally high rate resulting in excessive muscle contraction, increased metabolism, high oxygen consumption, high CO_2 production, and heat production. This leads to generalized muscle rigidity including masseter muscle rigidity, increased end tidal CO_2 ($ETCO_2$), acidosis, hypoxemia, tachycardia, and myoglobinuria.

The classic presentation of MH includes a rapid rise in $ETCO_2$, generalized muscle rigidity including masseter muscle rigidity of the jaw, unexplained tachycardia, hyperthermia, myoglobinuria, acidosis, and hyperkalemia. Masseter muscle rigidity after the administration of succinylcholine may be the earliest sign of MH. Temperature elevation is a late sign of MH and is preceded by an elevation of $ETCO_2$. If these symptoms occur, the anesthetic is discontinued and treatment rapidly instituted.

SPOTLIGHT ON GENETICS 13-1

Malignant Hyperthermia Susceptibility (MHS)

- Is a rare reaction that occurs with the use of volatile inhalation agents such as isoflurane, enflurane, sevoflurane, and desflurane.
- Is due to the genetic mutation of the *RYR1* gene that codes for the ryanodine receptor that regulates calcium release
- The mutation of the *RYR1* gene, in the presence of the inhalation agent, affects the skeletal muscle, leading to the sustained release of calcium from the sarcoplasmic reticulum causing the hypermetabolic state to occur in the tissue.
- Can now be identified via genetic testing of those patients and/or family members who have experience complications during or immediately postoperative

- Methylprednisolone
- Furosemide
- Sodium bicarbonate
- Dextrose (50%)
- Sterile water
- Insulin
- Mannitol
- Refrigerated intravenous (IV) fluids
- Dantrolene sodium
- New oxygen tubing and delivery devices
- Foley catheter tray
- Nasogastric tubes
- Blood specimen tubes
- Arterial blood gas kits
- MHAUS guidelines and contact information booklet

MHAUSv, Malignant Hyperthermia Society of the United States.

MH is treated by discontinuance of the anesthetic triggering agent, 100% inspired oxygen, hyperventilation, correction of acid–base imbalances, and cooling measures with a cooling blanket and cool IV fluids. Dantrolene sodium, 2.5 mg/kg IV, is given and may be repeated up to 10 mg/kg as necessary to control MH signs and symptoms. Dantrolene sodium is reconstituted with preservative-free sterile water and is labor intensive because of its difficulty in reconstituting with an aqueous solution. Most ORs and PACUs have an MH kit, and Box 13-11 lists the common contents of an MH kit.

Recrudescence or return of the signs and symptoms of MH can occur in the ICU or PACU hours after resolution of the initial event.[11] For that reason, after an episode of MH, the patient is observed in the ICU for 24 hours after the temperature has returned to normal. Dantrolene sodium is administered 1 mg/kg every 6 hours as needed. During this time, monitoring is maintained including temperature. Upon discharge, patients are referred to the Malignant Hyperthermia Association of the United States (MHAUS) for support and continued education about this disorder.[11,12]

▲ Moderate IV Sedation Administered by an Registered Nurse Versus Monitored Anesthesia Care

Moderate sedation using midazolam (Versed) and small doses of opioids IV provides a drug-induced depression of consciousness with the patient responding to verbal commands, either alone or associated with light tactile stimulation. No interventions are required to maintain airway patency or spontaneous ventilation. In addition, cardiovascular function is maintained. A patient who has been given moderate sedation has the ability to maintain a patent airway, retain protective airway reflexes, and respond to verbal commands. If these three conditions are not met, the patient is not receiving moderate sedation. The advantage of moderate

Table 13-3 Comparison of Moderate Sedation and Monitored Anesthesia Care

Characteristics	Moderate Sedation	Monitored Anesthesia Care (MAC)
Responsiveness	Purposeful response to repeated or painful verbal or tactile stimulation	May have purposeful response after stimulation
Airway	No intervention required	Intervention may be required
Spontaneous ventilation	Adequate	May be inadequate
Cardiovascular function	Usually maintained	Usually maintained

sedation is that it allows the patient to respond to verbal commands and physical stimulation. Moderate sedation is used for ambulatory surgical, therapeutic, and diagnostic procedures. The regimen usually consists of a narcotic, a sedative, and a local anesthetic.[13]

The goal of moderate sedation is to decrease patient anxiety associated with the surgical procedure or intervention using the least amount of drug necessary. Moderate sedation enhances patient cooperation, maintains stable vital signs, elevates the pain threshold, provides amnesia, and allows for rapid postoperative recovery.[13]

Propofol is used for sedation for surgical procedures and interventional procedures, such as endoscopies because of its short onset time and fast recovery time. A disadvantage of propofol is the risk for rapid loss of consciousness and apnea resulting in cardiopulmonary compromise. In a clinical study by Schilling et al,[14] propofol was found to cause a greater incidence of decline in SaO_2 and blood pressure compared to midazolam in patients requiring moderate sedation. Because propofol is an IV general anesthetic, those administering propofol must be trained in the administration of general anesthesia and airway management.[14] Several entities regulate standards for the administration of moderate sedation including state boards of nursing, the Joint Commission, and health care facilities. The following skills are required of the registered nurse (RN) who is administering the sedation and managing the care of patients receiving moderate sedation:

- Demonstrate knowledge of anatomy, physiology, pharmacology, cardiac dysrhythmia recognition, and complications related to moderate sedation and sedative drugs.
- Assess patient care requirements during moderate sedation and recovery. Physiological measurements include respiratory rate and effort, oxyhemoglobin saturation, blood pressure, heart rate and rhythm, and patient's level of consciousness.
- Understand the principles of oxygen delivery and respiratory and cardiovascular physiology and demonstrate the ability to use oxygen delivery and monitoring devices.
- Anticipate and recognize complications of moderate sedation related to the sedative drugs administered.
- Assess, diagnose, and intervene in undesired outcomes of moderate sedation in compliance with orders (including standard orders) or institutional protocols.
- Demonstrate skills in airway management.
- Demonstrate knowledge of the legal responsibilities of administering IV moderate sedation and monitoring patients receiving IV moderate sedation, including the RN's liability for any untoward reactions or life-threatening complications.

Monitored anesthesia care (MAC) describes a service in which an anesthesia provider has been requested to provide anesthesia care for a patient undergoing a therapeutic or diagnostic procedure usually requiring sedation. The difference between moderate sedation and MAC is that the anesthesia provider is present to recognize and treat the patient who becomes anesthetized following IV sedation and who develops apnea or an obstructed airway. Sedative drugs including propofol and fentanyl are given by the anesthesia provider and local anesthetics are injected into the surgical site by the surgeon. Postoperative care of the patient who has received moderate sedation or MAC is similar, although the patient who has received MAC may require more intervention in the postanesthesia phase. Table 13-3 provides a comparison of moderate sedation and MAC.

▲ Clinical Applicability Challenges

CASE STUDY

Mrs. K. is a 69-year-old woman who was taken to the emergency room after falling at home.

A hip arthroplasty had to be performed and she is admitted to the PACU from the OR. She has a history of congestive heart failure, chronic ethanol abuse, asthma, and hypertension. Induction of anesthesia was uneventful with the exception of a labile blood pressure intraoperatively. The anesthesia provider's report yields the following information:

- Patient 5 ft, 5 inches tall, weight 66 kg
- Hemoglobin 46 g/100 mL; hematocrit 15%
- Medications include hydrochlorothiazide, captopril, albuterol

(*continued on page 168*)

CASE STUDY *(Continued)*

- No known drug allergies
- OR time 1 hour, 35 minutes
- General endotracheal anesthesia
- Heart rate 90s, systolic blood pressure 120 to 80 mm Hg, diastolic blood pressure 55 to 75 mm Hg intraoperatively
- Estimated blood loss of 650 mL
- Total crystalloid administered: 1,450 mL of lactated Ringer's solution
- Urine output of 0.25 mL/kg/h
- Midazolam 2 mg was given IV as a premedicant/anxiolytic.

The patient received a total of 350 mcg of fentanyl. Neostigmine and glycopyrrolate were given to antagonize rocuronium. Further, the patient received cefazolin 1 g before incision and had bilateral lower extremity sequential compression stockings on at all times. The patient's initial PACU blood pressure was 90/57 mm Hg with a heart rate of 107 bpm. After the patient was medicated for pain with morphine sulfate 4 mg IV, her blood pressure decreased to 74/43 mm Hg, and her heart rate increased to 115 bpm. Following the drop in blood pressure, the patient complains of intense nausea.

1. What is the most likely cause of the hypotension?
2. What are other factors that may be contributing to the hypotension?
3. What is the initial intervention to treat hypotension in this patient?
4. What would be the pharmacologic agent of choice for treating the hypotension?
5. What is the likely cause of the patient's nausea?

PART 4

SPECIAL SITUATIONS IN CRITICAL CARE

14

Rapid Response Teams and Transport of the Critically Ill Patient

Dennis W. Jones and Christine N. Lynch

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Explain the indications for a rapid response team (RRT).
2. Discuss the role of the RRT and considerations before establishing an RRT system.
3. Describe the indications for interfacility transport of the critically ill patient.
4. Compare and contrast the advantages and disadvantages of air versus ground transport.
5. Discuss the specific considerations and implications for care for air transport.
6. Explain the Emergency Medical Transfer Active Labor Act requirements for an appropriate interhospital transfer.
7. Describe the indications and key factors necessary for an effective interfacility transfer plan.
8. Analyze the role of the registered nurse in the five phases of the interfacility transport of the critically ill.

The patients being cared for in hospitals today are older, sicker, and have more comorbidities. A large percentage of these patients experience an adverse event during their hospitalization. Many of these events are preceded by warning signs in the form of hemodynamic instability.[1] A system to reach these patients at the first sign of instability could prevent deterioration before cardiac arrest and improve patient outcomes. The need for early detection and rapid treatment of unstable patients led to the development of the rapid response team (RRT).

▲ Rapid Response Teams

The first RRTs, called medical emergency teams (METs), were introduced at Liverpool Hospital in Australia in 1990. The METs were established to enable early identification and aggressive management of the seriously ill patient before cardiac arrest.[2] Since 1990, RRTs have been growing in popularity not only in Australia but also around the world.

Rationale for the Need

The National Registry of Cardiopulmonary Resuscitation (NRCPR), the largest registry of its kind, is an American Heart Association–sponsored, prospective, multisite, observational study of in-hospital resuscitation.[3] The NRCPR showed that despite advances in resuscitation practices and outcomes in the prehospital settings, little progress has been made with regard to improving in-hospital survival following cardiac arrest. This study found in-hospital survival following cardiac arrest to be a dismal 17%, essentially unchanged for the past 40 years.[3]

Most hospitals treat hundreds of patients each day, and there is a great deal of variability in the care provided. In addition, the level of monitoring may vary because those providing care have varying levels of skill. The performance of health care providers and of the system in which they work has a direct impact on patient care and outcomes. The variability in the care provided not only has an impact on both quality and safety, but also contributes to the differences seen in hospital mortality rates. In a review of the literature, the Institute of Healthcare Improvement (IHI), as part of its 5 Million Lives campaign (2006), found that three main systemic issues contribute to the differing hospital mortality rates. These include:

- Failure in planning (including assessments, treatments, and goals)
- Failure to communicate (eg, patient-to-staff, staff-to-staff, staff-to-physician)
- Failure to recognize the deteriorating patient condition

These fundamental problems often lead to a failure to rescue.[4]

The challenge for hospitals is to create a 24-hour system to recognize the seriously ill early and respond rapidly with personnel skilled in advanced resuscitation. It is estimated that 15% to 20% of all hospitalized patients develop serious adverse events, including cardiac arrest.[1] These adverse events are rarely sudden or unforeseen. In fact, they are usually preceded by at least one sign or symptom of physiological deterioration that occurs in the hours before the critical change in status (Box 14-1).[1]

The Role of the Rapid Response Team

The RRT brings critical care expertise to the bedside. In an effort to promote the implementation of RRTs in all hospitals in the United States, the IHI has written a *Rapid Response Teams: How-To Guide* (http://www.ihi.org). The members of the RRT perform the following functions:

- Assess the patient
- Stabilize the patient using RRT protocols (Fig. 14-1)
- Collect data (eg, vital signs, radiographic and laboratory data)
- Communicate with the health care team
- Provide education and support to the nurse initiating the call
- Assist with triage decisions
- Assist with transfer to a higher level of care, if needed[5]

The early intervention of RRTs has been shown to decrease the incidence of cardiac arrest and improve mortality rates.[5]

BOX 14-1 Rapid Response Team Calling Criteria

- Threatened airway
- Respiratory rate less than 8 breaths/min or more than 28 breaths/min
- SpO_2 less than 90%
- Heart rate less than 40 beats/min or more than 130 beats/min
- Systolic blood pressure less than 90 mm Hg
- Urine output less than 50 mL in 4 hours
- Acute mental status change
- Any patient about whom you are worried or concerned

The RRT system is based on three major components: early recognition of the deteriorating patient, rapid response with swift provision of care by clinical staff trained in advanced resuscitation, and a means by which to measure the system. When establishing an RRT system, several factors must be considered (Box 14-2, p. 172; Box 14-3, p. 173).[6]

▲ Interfacility Transport

Critically ill patients often must be transported between health care facilities. To ensure safe and expeditious transport, it is important to consider both the method of transport and the people involved in the transport process.

Typically, transport is indicated when the patient's need for complex diagnostic procedures or sophisticated medical and nursing expertise exceeds what can be provided at a facility. Family requests may also initiate a patient transport. For example, a family may want their family member transferred to a hospital closer to home.

Outcomes of evolving health care reform also have increased the demands for interfacility transport of critically ill patients. Third-party payers may require patients to be transported to a facility that is a member of their network. In addition, many hospitals vie for fewer patients and have developed their own transport teams to provide a flow of patients to their particular facility.

Whatever the reason for transporting a patient, a risk–benefit analysis of the transport should always be performed. Risks for the patient range from physical safety to physiological compromise to emotional distress.[7] When the benefits for the patient exceed the risks, an interfacility transport is warranted. Figure 14-2 on page 174 provides an algorithm for interfacility transfer.

The American College of Emergency Physicians (ACEP) has outlined physician responsibilities at this point. These responsibilities are as follows:

- The sending physician performs the patient assessment and determines the appropriate level of care during transfer.
- The receiving physician ensures that his or her facility is capable of providing necessary patient services to care for the patient.

The medical director of the critical care transportation agency provides medical direction during transport as well as all medical oversight of the transportation operation, which includes, but is not limited to, determining minimal team composition and equipment requirements, education, and practice.[8]

Modes of Interfacility Transport

Once the decision has been made to transport, the method of transport must be determined. The two primary methods of interfacility transport are ground and air.

Ground Transport

Ground transport includes ambulances and mobile intensive care units (ICUs). Air transport occurs by either a

FIGURE 14-1 ▲ Example of rapid response team (RRT) protocols used with a nurse-led team. (Courtesy of Union Memorial Hospital, Baltimore, MD.)

rotary-wing vehicle (helicopter) or a fixed-wing vehicle (airplane). When selecting the mode of transport, the following factors must be considered:

- Distance
- The safety of the transport environment
- Patient "out of hospital" time
- The patient's condition and the potential for complications
- The patient's need for critical or time-sensitive intervention (eg, rescue angioplasty)
- Traffic conditions
- Weather conditions[9]

In addition, the advantages and disadvantages of ground versus air transport must be considered when selecting the mode of transport. Table 14-1 on page 175 summarizes the advantages and disadvantages of ground versus air transport.

Air Transport

Table 14-2 on page 175 summarizes the special considerations for air transport. It is important for the nurse who may be caring for a patient to have a basic understanding of these considerations to aid in patient preparation prior to flight team arrival and promote a smooth transfer of care upon the team's arrival.

The environment in which the patient is transported differs greatly from the in-hospital setting. Because the patient is transported at a higher altitude, where the barometric pressure is reduced, the possibility of hypoxia increases. However, the flight team will assess the patient upon arrival and determine how much oxygen the patient will need during the transport based on the patient's clinical condition and the flight plan.

Any air-filled cavity in the patient's body, such as the stomach, lungs, or containers (air splint, glass intravenous bottle),

BOX 14-2 Considerations When Implementing a Rapid Response Team System

Gaining leadership support. The support of senior leadership is essential for the success of the proposed RRT system. Advantages of an RRT system include:

- Marketing advantage in a competitive health care environment
- Greater medicolegal protection and decreased liability
- Decreased patient and family complaints
- Improved identification of patients in need of palliative care
- Avoidance of unnecessary intensive care unit (ICU) admissions
- Decreased job-related stress for nurses and residents
- Decreased number of in-hospital arrests

Determining team structure. The structure of the RRT varies according to facility size, level of patient acuity, availability of resources, and the frequency of adverse events and cardiac arrest. Examples of different models include:

- ICU registered nurse (RN) and respiratory therapist (RT)
- ICU RN, RT, and nurse practitioner, clinical nurse specialist, or physician assistant
- ICU RN, RT, and intensivist or hospitalist

Establishing communication tools and protocols. Communication tools provide the RRT leader with a template for gathering pertinent information, facilitating communication with the physician, and facilitating triage decision making. If the RRT is led by a nurse, the use of protocols is essential for the quick delivery of indicated therapies and tests (see Fig. 14-1).

Training for responders. Members of the RRT must receive the proper training. Areas to be reviewed include:

- The benefits of early rescue
- Teamwork with non–critical care staff
- Protocols available to guide RRT therapy
- Triage skills and advanced cardiac life-support certification
- The importance of the linkage to palliative care
- What is expected of RRT members when responding to a call
- The use of communication tools, such as SBAR (see Box 14-3)
- The chain of command for nurse-led teams

Training for staff. Staff members must be made aware that the RRT exists, educated about the role of the RRT, and taught how to activate the RRT system. Methods of raising staff awareness include the following:

- Formal teaching and in-service training
- Newsletters
- Posters with the RRT calling criteria
- Pocket cards and badge holder with calling criteria
- Brochures with RRT concepts and calling criteria
- Inclusion of RRT education in employee orientation sessions

Calling criteria and the mechanism for activating the RRT system. Many studies have been done to establish those physiological signs that are often displayed before an adverse event or cardiac arrest.[5] When considering the RRT calling criteria that will be used in your institution, these evidence-based data should be considered. (See Box 14-1 for examples of calling criteria.) The mechanism for activating the RRT system should be clear, quick, and easy so that the staff will use it and the team will respond rapidly.

Feedback mechanisms. Feedback promotes continued improvement of the RRT system and can be used to drive educational programs. Feedback can be obtained by:

- Tracking patient outcomes
- Conducting satisfaction surveys with the staff

Evaluation of effectiveness. A means by which to measure the success of the RRT system is imperative. Three key measures that are used include

- Codes per 1,000 discharges
- Codes outside the ICU
- Utilization of the RRT system

Adapted from Institute for Healthcare Improvement: 5 Million Lives Campaign. Getting Started Kit. Rapid Response Teams: How-To Guide, 2006. Available at: http://www.ihi.org/IHI/Programs/Campaign/.

can be affected physiologically by changes in barometric pressure. The degrees to which any deleterious effects may occur to the patient during transport depend on the type of aircraft and altitude flown. The flight team screens the patient carefully and takes preventive measures to ensure a safe and uneventful transport.

Other environmental factors affecting the patient during the transport include changes in temperature and humidity as well as the presence of noise and vibration. The mode of transport will dictate the degree to which each of these factors occurs—that is, whether the vehicle is a fixed-wing or rotary-wing aircraft—and the type of aircraft. The flight crew takes the necessary steps to either prevent or decrease the effects of each of these factors on the patient.

If the critically ill patient is conscious and aware of the need for air transport, the sending nurse screens the patient for fear or anxiety related to flying and a history of motion sickness while in a moving vehicle. Medical consultation is indicated when any of these factors exist since treatment with an anxiolytic or antiemetic medication could aid in preventing clinical problems during the flight. Again, the flight crew screens the patient for these factors during the preflight assessment.

Transfer Guidelines and Legal Implications

To facilitate the appropriate transfer of patients, the ACEP has developed guidelines. These principles of appropriate patient transfer are listed in Box 14-4 on page 176.

Legislation exists that provides guidelines, regulations, and penalties for patient transfer. One such law, the Consolidated Omnibus Reconciliation Act (COBRA) of 1985, contains provisions addressing the transfer of patients from hospital to hospital. The purpose of the legislation is to prevent inappropriate transfers of patients who seek emergency department care. As a result, this legislation has become known as the "antidumping" law. The following provisions of the COBRA legislation prevent any patient from being denied an initial screening in an emergency department, transferred to another hospital, or discharged without receiving care:

1. Hospitals must provide screening examinations for every person who comes to the emergency department and requests care.
2. If the patient has an emergency medical condition, the hospital must provide stabilizing treatment or transfer the patient to another medical facility. The physician must document that the medical benefits outweigh the risks of the transfer.

BOX 14-3 SBAR Communication Tool

SBAR is an acronym for Situation, Background, Assessment, and Recommendation. Communication tools such as the SBAR provide the RRT leader with a template for gathering pertinent information, facilitating communication with the physician, and facilitating triage decision making.

Situation:	State your name and unit. State the name of the patient you are calling about. State the problem for which the team was consulted.
Background:	State the admission diagnosis and the date of admission. State the pertinent medical history. Provide a brief synopsis of the patient's hospital course. State the code status of the patient.
Assessment:	Most recent vital signs BP: _____; pulse: _____; respirations: _____; temp: _____; Any change from prior assessments: Mental status: Quality of respirations: Pulse rate/rhythm change: Pain: Skin color: Neurologic changes: Nausea and vomiting, output:
Recommendation:	State your triage recommendations. For example: Transfer to coronary care unit Have the physician come see the patient at this time Arrange for specialist to see the patient now Arrange for tests (eg, chest x-ray, arterial blood gas, ECG, complete blood cell count)

Adapted from Duncan KD: Nurse-led medical emergency teams: A recipe for success in community hospitals. In DeVita MA, Hillman K, Bellomo R (eds): Medical Emergency Teams: Implementation and Outcome Measurement. New York, NY: Springer, 2006, pp 122–133.

3. The receiving medical facility agrees to accept the patient and provide appropriate medical treatment. The receiving medical facility must have adequate space and qualified personnel to care for the patient.
4. The transfer is conducted by qualified personnel, and appropriate equipment needed to provide care during the transfer is available.[10]

Situations in which a patient is not stabilized, yet conditions are appropriate for transfer occur when:

1. The risks of remaining at the initial facility are outweighed by the benefits of transfer.
2. The patient or family requests the transfer.
3. A physician is not present at the initial facility but a qualified medical person certifies that the benefits outweigh the risks.
4. The transfer occurs with appropriate equipment and qualified personnel.[10]

Figure 14-3 on page 177 presents the requirements for evaluating a patient's suitability for transfer, as outlined by the Emergency Medical Transfer Active Labor Act (EMTALA). In addition, the Air and Surface Transport Nurses Association (ASTNA, formerly known as the National Flight Nurses Association, or NFNA) developed nursing standards for transport of the critically ill patient by rotary-wing transport.[11]

Phases of Interfacility Transport

Five phases of transport have been identified: (1) notification and acceptance by the receiving facility, (2) preparation of the patient by the transport team, (3) the actual transport, (4) turnover of the patient to the receiving hospital, and (5) continuous quality improvement monitoring after transport. Each phase will be described in detail as it applies to the transport.

Phase One: Notification and Acceptance by the Receiving Facility

The first phase of transport requires contacting the receiving facility and confirming that it is willing to accept the patient and provide an accepting physician and an appropriate patient care unit to receive the patient. Additionally, the mode of transport is determined at this time. Communication is a key element in this phase of the process. All personnel (sending, transporting, and receiving) must have the necessary information to make the appropriate transport decision. Standards of care and/or protocols are necessary for the transport process to be carried out in an organized way. A transfer checklist is helpful to ensure that no steps in the transfer process are missed. In addition, an awareness of the policies and procedures of the transporting agencies used in an area is needed for a smooth transport process.[7]

The identification of a responsible physician is essential so that a medical provider is available for consultation while en route and on arrival. The ACEP has described medical direction for interfacility transfers as a shared responsibility. The transferring physician ensures that the transport team is composed of professionals appropriate to the needs of the patient and that an appropriate vehicle and equipment are used for transport.[8] If the local emergency medical system is not providing medical direction en route, then the responsible physician must be identified as being part of the hospital-based or private ambulance program.

The Commission of Air Medical Transport Services, which is the certifying body for the air medical industry, maintains the staffing standard on critical care transports; either a registered nurse (RN) or a licensed physician must be present as the primary care provider.[12] Transport teams should have standard orders or protocols if they are unable to contact a physician during transport. The transport flight team has practice protocols that guide their practice; however, they may also receive medical direction from the medical director of the transport program.

Once the specific transporting agency is determined, an overview of the patient's condition and specific clinical needs is communicated. Necessary information includes the patient's

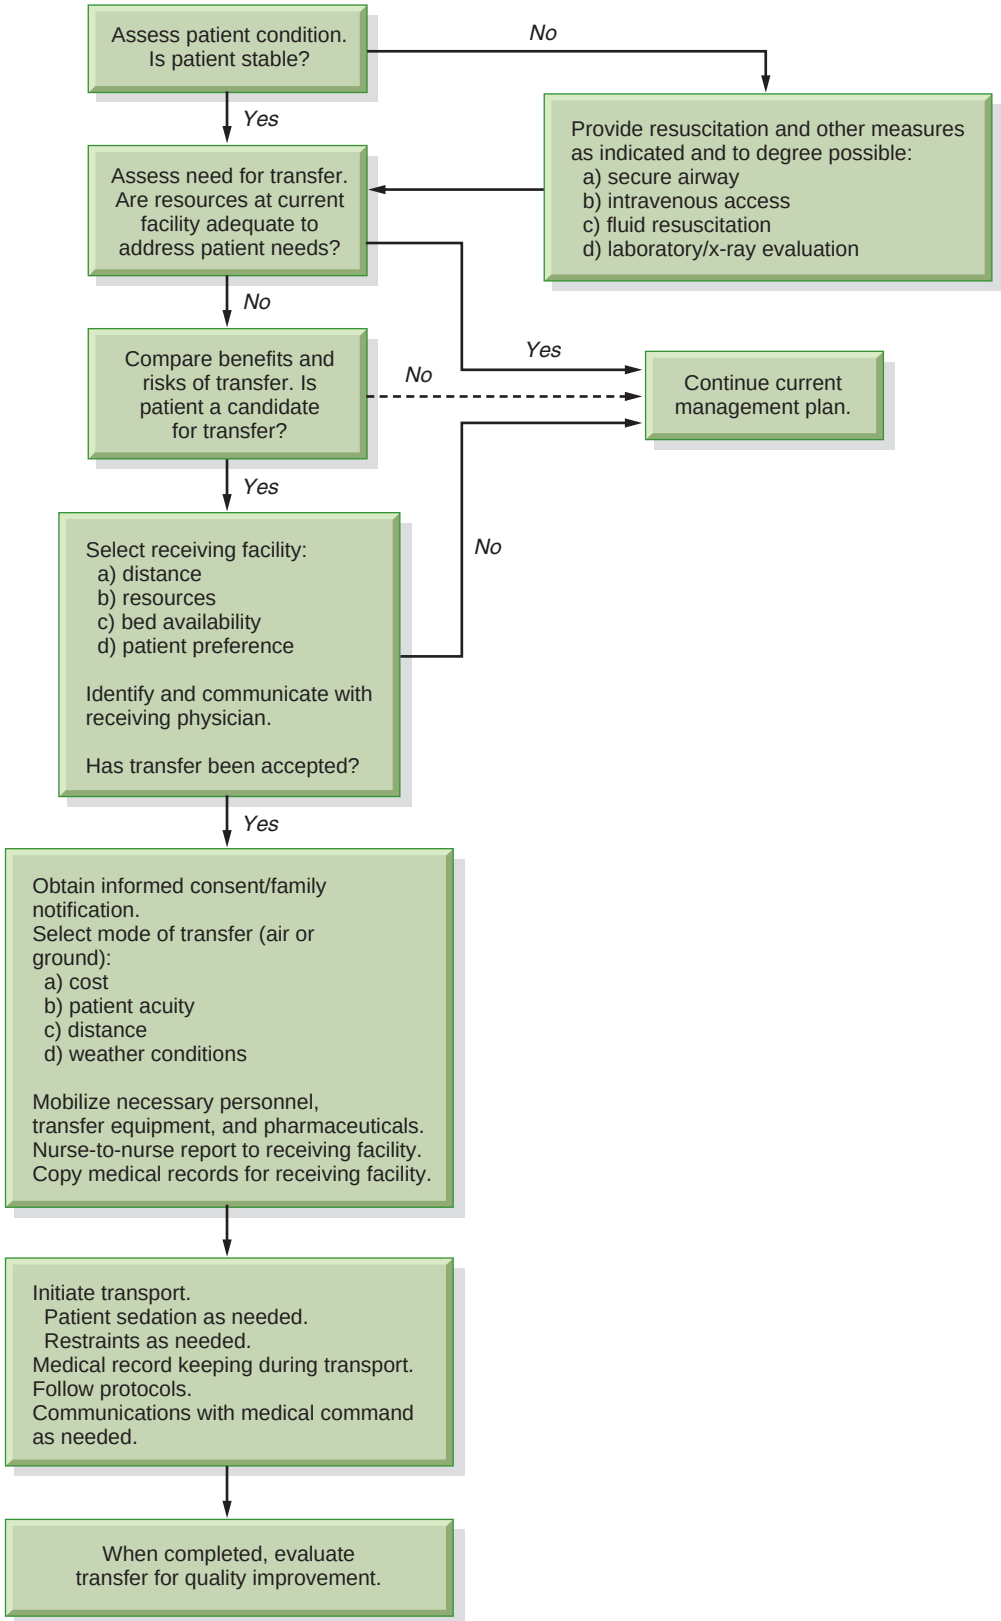

FIGURE 14-2 ▲ Interfacility transfer algorithm. (From Warren J, Fromm RE, Orr RA, et al: Guidelines for the inter- and intrahospital transport of critically ill patients. Crit Care Med 32(1):256–262, 2004.)

Table 14-1 Advantages and Disadvantages of Ground Versus Air Transport

Mode of Transport	Advantages	Disadvantages
Ground	Adequate work space for personnel and equipment Sensitive monitoring equipment may work better No weight restrictions Adequate lighting Able to travel in most types of weather	Longer transport time Unfavorable road conditions may make transport uncomfortable for patient Interventions difficult to perform in a moving vehicle Ambulance unavailable for other calls in the community
Air	May shorten "out of hospital" time Crew generally composed of advanced-level care providers Improved communication capability Ground emergency medical services remain available in the community	Weather conditions restrict availability of the vehicle Potentially more costly Limited space (helicopters) Weight limitations Physiological impact on patient and crew Psychological impact on patient (eg, fear of flying)

From Holleran R: Prehospital Nursing: A Collaborative Approach. St. Louis, MO: CV Mosby, 1994.

name, age, diagnosis, reason for transfer, vital signs, intravenous and special monitoring devices, continuous infusion medications, airway and oxygenation or ventilation status, and special equipment needs (eg, intra-aortic balloon pump). This information assists in determining the composition of the transport team as well as the equipment and medications needed. The American Association of Critical-Care Nurses (AACN), the American College of Critical Care Medicine, and the Society of Critical Care Medicine (SCCM) offer guidelines for accompanying personnel for interfacility transfers[7] (Box 14-5, p. 178).

Interhospital critical care transport is a highly specialized nursing practice area which requires specific knowledge and

Table 14-2 Special Considerations for Air Transport

Stressors	Effect	Nursing Interventions
Altitude change	Hypoxia is due to the following: Decrease in the partial pressure of oxygen Decrease in the diffusion gradient for oxygen molecules to cross the alveolar membrane Decrease in oxygen availability	Provide supplemental oxygen. Use pulse oximeter and end-tidal CO_2 monitor.
Barometric pressure (atmospheric pressure) change	With increasing altitude, the barometric pressure decreases and gases expand. Expansion of gases affects eardrums, sinuses, gastrointestinal tract, pleural spaces, and hollow organs. Expansion of gases affects air splints, pressure bags or cuffs, balloon cuffs on endotracheal tubes, intravenous fluid bags and bottles, pneumatic antishock garments.	Insert a nasogastric tube to decompress the stomach. If possible, fill cuffs with water or saline solution rather than air. Monitor equipment and decompress with higher altitudes. Vent glass bottles and wrap to protect against breakage. Apply pressure cuffs to intravenous solution bags.
Thermal change	As altitude increases, temperature decreases. Oxygen demand increases as the body tries to maintain warmth.	Use blankets to keep the patient warm.
Humidity change	As air is cooled, it loses moisture. Mucous membranes dry.	Humidify supplemental oxygen. Provide adequate fluid intake.
Gravitational change	Gravitational change affects acceleration and deceleration forces. Transient increase in venous return occurs for patients positioned with head at the back of the aircraft. Potential exists for motion sickness.	Use a head-forward position for patients with fluid overload or increased intracranial pressure. To minimize motion sickness, provide oxygen, cool cloth to face, cool air to face. Administer medications, such as transdermal scopolamine patches and promethazine.
Noise	It is difficult to monitor blood pressure, breath sounds, endotracheal tube air leak.	Explain sounds to patient. Monitor blood pressure by Doppler device. Provide continuous airway assessment. Wear head sets or ear plugs.
Vibration	Vibration may distort readings on equipment. Equipment may loosen or move.	Secure all equipment. Check equipment function frequently.

From Harrahill M: Interfacility transfer. In Kitt S, Selfridge-Thomas J, Proehl J, et al (eds): Emergency Nursing: A Physiologic and Clinical Perspective, 2nd ed. Philadelphia, PA: WB Saunders, 1995, pp 12–18.

BOX 14-4 Principles of Appropriate Patient Transfer

- The health and well-being of the patient must be the overriding concern when any patient transfer is considered.
- Emergency physicians and hospital personnel should comply with state and federal regulations regarding patient transfer. A medical-screening examination should be performed by a physician or by properly trained ancillary personnel according to written policies and procedures.
- The patient should be transferred to another facility only after medical evaluation and, when possible, stabilization.
- The physician should inform the patient or responsible party of the reasons for and the risks and likely benefits of transfer, and document this in the medical record.
- The hospital and medical staff should identify individuals responsible for transfer decisions and clearly delineate their duties regarding the patient transfer process.
- The patient should be transferred to a facility appropriate to the medical needs of the patient, with adequate space and personnel available.
- A physician or other responsible person at the receiving hospital must agree to accept the patient before transfer.
- The patient transfer should not be refused by the receiving hospital when the transfer is medically indicated and the receiving hospital has the capability and/or responsibility to provide care for the patient.
- Communication to exchange clinical information between responsible persons at the transferring and receiving hospitals must occur before transfer.
- An appropriate medical summary and other pertinent records should accompany the patient to the receiving institution.
- The patient should be transferred in a vehicle that is staffed by qualified personnel and contains appropriate equipment.
- When transfer of patients is part of a regional plan to provide optimal care of patients at specified medical facilities, written transfer protocols and interfacility agreements should be in place.

Adapted from American College of Emergency Physicians: Principles of appropriate patient transfer. Ann Emerg Med 19(3):337–338, 1990.

skills. Nurses who have not received training or are inexperienced in this practice area must be aware of possible regulations governing their practice, should they be requested to accompany a patient during interhospital transport. Practice standards or regulations promulgated by a state board of nursing may exist, which the RN must be aware of prior to agreeing to transport the patient.

The AACN and the SCCM have developed a transfer curriculum and competencies for accompanying staff, which may assist in identification of issues related to the role of the nurse in the field.[7] Current regulations require that the patient or a legally authorized representative give informed consent for the transport. If consent cannot be obtained, documentation of the indications for the transport and the reason that consent was not obtained must appear in the medical record.[7]

Phase Two: Preparation of the Patient by the Transport Team

Phase two begins upon arrival of the transport team. A thorough patient report is provided to the arriving team and should include chief complaint, allergies, medical history, reason for transport, patient's age, vital signs, treatments already provided, and their outcomes. Copies of the chart and all radiographs are sent with the patient. To avoid duplication of efforts, the sending and transporting nurses decide who will provide a patient report to the receiving hospital. If the transport is arranged by the sending nurse, the transport nurse updates the receiving nurse as needed.

The transport team performs an assessment of the patient and compares its findings to the previous assessment and plan of care. If interventions are indicated prior to transport, the transport team and the referral facility personnel determine who assumes responsibility for the interventions. It is important that all stabilization procedures, for example, endotracheal intubation, are completed before departure from the referring facility to ensure the procedures are completed successfully. Completion of these procedures in the less-controlled transport environment increases the risk for error related to unpredictable lighting, movement, and vibration. Although resuscitation and stabilization are initiated at the referral hospital, full stabilization may not be achieved until the patient arrives at the receiving hospital.[10]

The psychosocial preparation of the patient and family for transport is an important step before transport begins. The sending nurse ensures that the patient and family understand all facets of the transport process including the reason, transport mode, time of transport, and transport destination. Information about the family is also communicated at this time and includes identification of a family spokesperson and the family's plan for getting to the receiving hospital. If the transport team is unable to meet with the family, the sending nurse supplies information about how to contact the family. The transport team, particularly the flight team, in order to allay any further anxiety related to flying, explains all procedures, safety precautions, and the need for preflight medications (eg, antiemetics) to the patient and family before departure.

Physical preparation of the patient is the next important step to ensure a safe transport. The ABCs of care (airway, breathing, and circulation) are the top priority. Adequate oxygenation and ventilation are ensured before transport begins. As noted earlier, procedures deemed necessary, such as intubation are performed prior to departure. Most intubated patients are sedated to prevent them from dislodging the endotracheal tube and to decrease fear and discomfort during transport. Further, a nasogastric tube may be inserted to prevent aspiration of stomach contents into the airway. Because auscultation of breath sounds is difficult en route, end-tidal carbon dioxide levels and oxygen saturation are used to monitor respiratory status. Supplemental oxygen is almost universally administered during transport to maintain adequate oxygenation.

The patient's circulatory and hemodynamic statuses are stabilized before transport. Any bleeding is controlled, and adequate intravenous access is established and well secured. For a patient with an unstable volume status, several large-bore intravenous lines are indicated. If the patient is already on intravenous drips, the transport team transfers the drips over to its own equipment and will remix drips as needed. The patient's circulatory status is continuously assessed through blood pressure and cardiac monitoring during the entire transport process. Cardiac arrest medications and a defibrillator should be easily accessible.

Patients with actual or potential spinal injuries should have immobilization devices in place prior to transport. The transport team may request that the staff of the sending

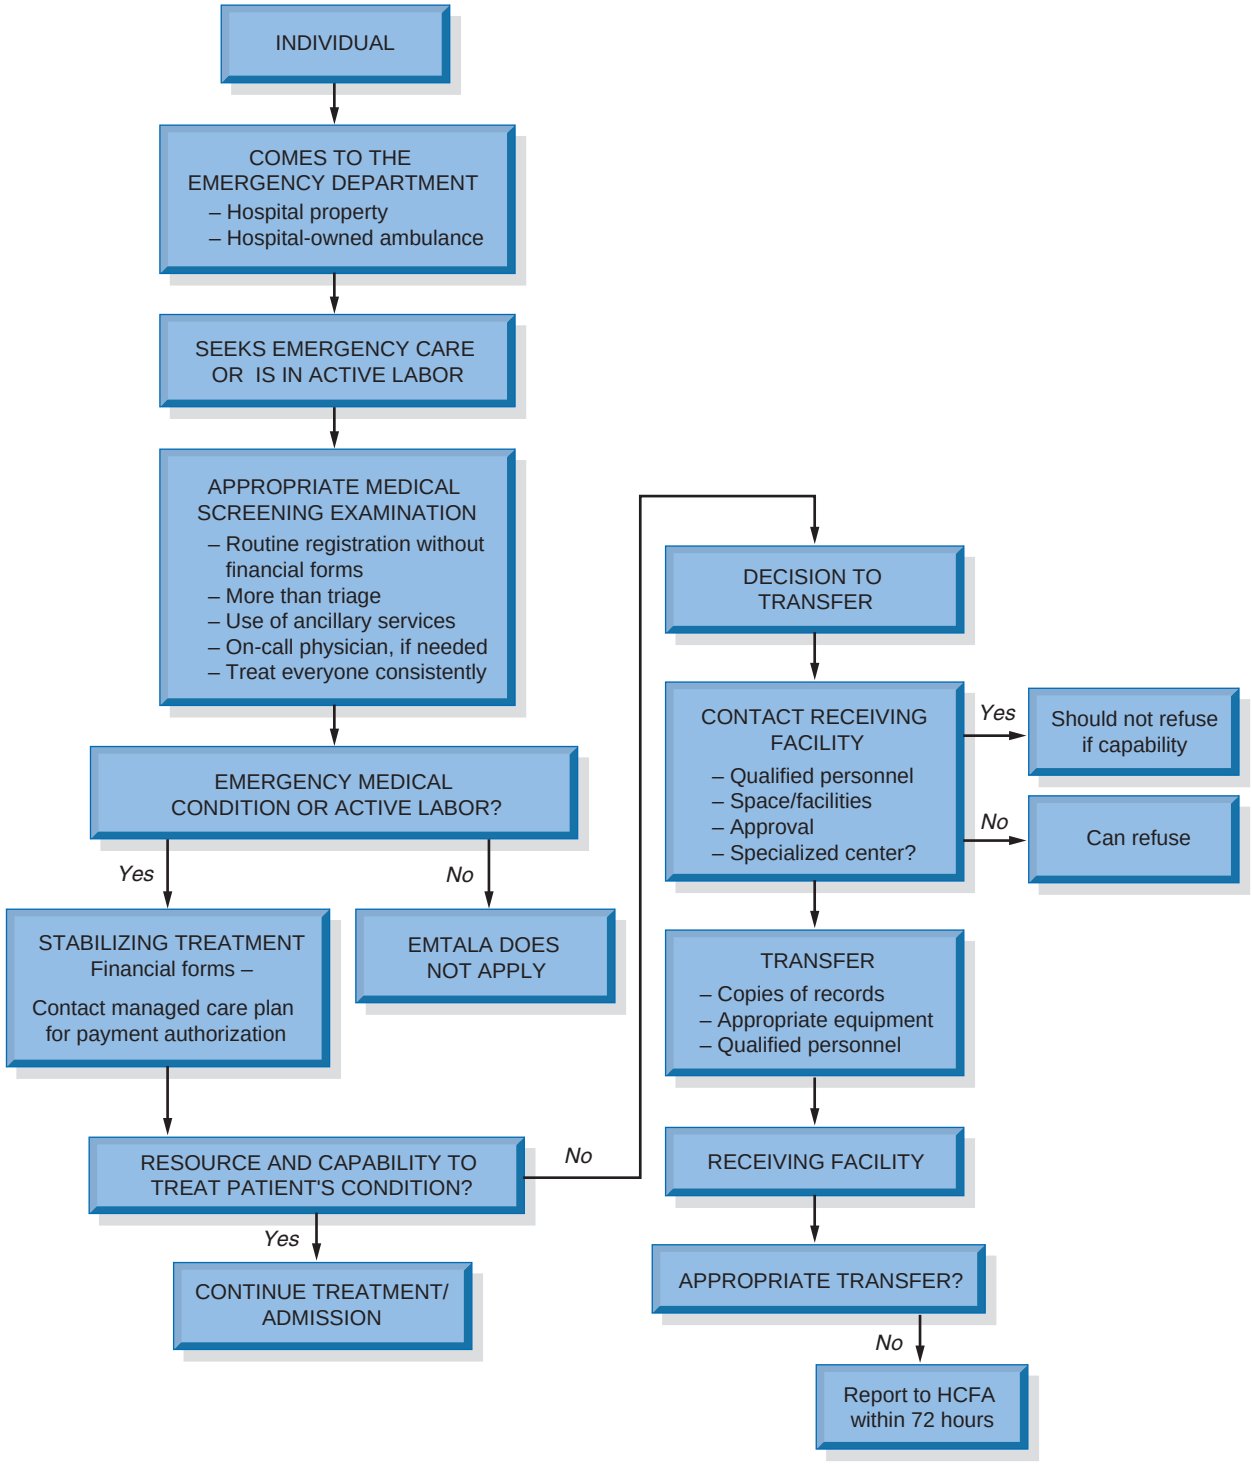

FIGURE 14-3 ▲ Emergency Medical Transfer Active Labor Act (EMTALA) flow chart. HCFA (formerly Health Care Finance Administration) is now Center for Medicare and Medicaid Services. (Reprinted from Lee NG: Legal Concepts and Issues in Emergency Care. Philadelphia, PA: WB Saunders, 2001, p 140, with permission.)

facility facilitate this before the arrival of the transport team. Patients with skeletal long-bone fractures must have the fractured limb immobilized before departure to prevent pain and further complications.

Pain control during transport is also addressed through transport orders or medical protocols. The best agents for pain management are those with a rapid onset, short duration, and ease of administration and storage.

Phase Three: The Transport Process

Phase three is the actual transport of the patient. The time spent in careful planning of the transport and stabilization of

BOX 14-5 Guidelines for Accompanying Personnel for Interfacility Transfer

- A minimum of two people in addition to the vehicle operator should accompany the patient.
- At least one of the accompanying personnel should be a RN, physician, or advanced emergency medical technician.
- When a physician does not accompany the patient, there should be a mechanism available to communicate with the physician any changes in the patient status and obtain additional orders. If an accompanying physician is not possible, advanced authorization by standing orders to perform acute life-saving interventions must be established.

From Warren J. Fromm RE, Orr RA, et al: Guidelines for the inter- and intra-hospital transport of critically ill patients. Crit Care Med 32(1):256–262, 2004.

the patient eases the transport process. The transport vehicle must contain the essential equipment needed for transporting a critically ill patient. Box 14-6 lists the minimal necessary equipment.[9]

The ABCs of care continue to be the primary focus of the transport team. Box 14-7 lists the minimum and recommended standards for monitoring the critically ill patient during the transport. Each member of the transport team must have a clear understanding of their role in the continuous assessment, planning, and intervention that takes place when caring for the patient. Throughout the transport, the team also provides explanations and reassures the patient because transport can be very stressful. The transport team is responsible for documenting all facets of care provided during transport as well as the patient's response to the care.

Before arriving at the receiving facility, if able, the transport nurse calls either a full or updated report to the

BOX 14-6 Minimally Essential Equipment Necessary for Transport

- Airway and ventilatory management equipment:
  - Resuscitation bag and mask of proper size and fit for the patient
  - Oral airways, laryngoscopes, and endotracheal tubes of proper size for the patient
  - Oxygen source with a quantity sufficient to meet the patient's anticipated consumption with at least 1-hour reserve in addition

  Suction apparatus and catheters
- Cardiac monitor/defibrillator/transcutaneous pacemaker
- Blood pressure cuff and stethoscope
- Materials for intravenous therapy and devices for regulation of infusion
- Drugs
  - For advanced cardiac resuscitation
  - For the management of acute physiological derangements
  - For special needs of the patient
- Spinal immobilization devices
- Communication equipment

From Warren J. Fromm RE, Orr RA, et al: Guidelines for the inter- and intra-hospital transport of critically ill patients. Crit Care Med 32(1):256–262, 2004.

BOX 14-7 Standards for Monitoring Patient Transport

Minimal Standard for Monitoring Parameters During Interhospital Transport

- Blood pressure
- Continuous pulse oximetry
- Electrocardiographic monitoring
- Respiratory rate

Recommended Monitoring Parameters for Select Patients

- Intra-arterial blood pressure
- Central venous pressure
- Pulmonary artery pressure
- Intracranial pressure
- Capnography

From Warren J. Fromm RE, Orr RA, et al: Guidelines for the inter- and intra-hospital transport of critically ill patients. Crit Care Med 32(1):256–262, 2004.

RN on the receiving unit. This report includes an estimated time of arrival at the receiving facility. The nurse also communicates any special needs, changes in patient status, and unchanged but pertinent findings. In some situations, a flight nurse may not be able to provide a patient update; therefore, an updated bedside report is provided on arrival.

Phase Four: Turnover of the Patient to the Receiving Facility

Phase four of transport involves handing over the patient to the receiving unit staff at the receiving facility. Backup plans on how to handle an acutely deteriorating patient in transit between the transport vehicle and the ICU should also be identified. This plan may include stopping at the emergency department to stabilize the patient; it is essential for the emergency department staff to be aware of this possibility. Once the patient arrives safely in the receiving unit, the transport team and the receiving staff determine when the receiving staff will take over the responsibility for the patient's care. A final verbal update and all medical documents and patient belongings are given to the receiving staff. The written report of the transport is also completed.

Phase Five: Posttransport Continuous Quality Improvement Monitoring

The final phase of transport is very important and involves continuous quality improvement monitoring. Ideally, the referring facility, the transport team, and the receiving facility are involved in the review process. The first phase of the quality improvement monitoring involves evaluation of the current transport, including any quality indicators developed by the transporting agency. These indicators may include appropriateness of the transfer, accompanying personnel, timeliness of the transfer, patient outcome, management of complications, and transfer outcome. The second phase entails the ongoing review of the transport system. Such reviews focus on system functioning. Indicators may include complications, deaths in transport, and deaths after transport.[7]

The multidisciplinary continuous quality improvement monitoring team scrutinizes the collected data for patterns and trends, identifies solutions to patient care problems, initiates corrective action, and communicates such action to all involved in the transport process. Through a quality improvement plan, the transport process is improved and results in optimal care of the critically ill patient during the transport process.[7]

▲ Intrafacility Transport

The transport of a critically ill patient for diagnostic evaluation or treatment within the hospital is often necessary for optimal care. When this occurs, associated risks are involved.[13] It is imperative that the benefits of the transport outweigh the risks. Although a complete discussion regarding this topic is beyond the scope of this chapter, important factors should be considered when planning a transfer of a critically ill patient outside the ICU. One factor, for example, is the rate of adverse events that occur during intrahospital transport, which ranges from 5.9% to 70%; these events usually fall into two categories.[13] Category one involves monitoring equipment and its use (eg, equipment failure, disconnected leads, depleted oxygen). Category two involves physiological changes in the patient, which may include changes in blood pressure, hypoxia, dysrhythmias, or increased intracranial pressure.[14]

Because of the inherent risks during intrahospital transport, some hospitals are forming specially trained transport teams organized with two specific goals: to reduce risk and to improve patient safety.[13] Justification for these transport teams may be based on inadequate ICU staffing and an inability to effectively manage a clinically complex patient while out of the ICU setting.[13]

In one retrospective study it was demonstrated that having a specialized transport team reduces adverse clinical events during transport.[14]

To provide safe and effective intrahospital transport of a critically ill patient, the critical care nurse prepares for the transport and communicates[5] with the receiving location when necessary. Appropriate personnel and equipment must accompany the patient. The SCCM guidelines recommend that a competent critical care nurse and at least one other person accompany the patient. The additional person may be a respiratory therapist, RN, or critical care technician. The decision should be based on the patient's needs. The SCCM strongly recommends that a physician with training in airway management, advanced cardiac life support, and critical care or equivalent accompany any unstable patient.[9] Essential equipment that must be sent with the patient includes a blood pressure monitor, a pulse oximeter, a cardiac monitor–defibrillator, airway management equipment, an oxygen source, basic resuscitation drugs, and appropriate intravenous fluids and infusion pumps.

▲ Clinical Applicability Challenges

CASE STUDY

Mr. J., a 60-year-old African American male, was admitted to the coronary care unit (CCU) an hour ago from the emergency department with the diagnosis of anteroseptal myocardial infarction, congestive heart failure, and cardiogenic shock. His wife and family are present. The patient is intubated and sedated; placed on a ventilator; and given an infusion of dopamine, dobutamine, and amiodarone. Shortly after arrival in the CCU, the cardiologist decides to insert an intra-aortic balloon catheter and place the patient on an intra-aortic balloon pump.

The hospital where Mr. J. is being treated is a large community hospital, but it does not have the capability to perform interventional cardiac procedures. The cardiologist decides to transfer the patient to the closest tertiary care facility, which is 40 miles away. Transfer is indicated for cardiac catheterization; percutaneous transluminal coronary angioplasty with possible stent placement; and the need for cardiac surgery, which cannot be performed in the facility currently treating Mr. J.

The cardiologist at the community hospital has contacted the attending cardiology interventionalist, who has agreed to accept Mr. J. This physician has agreed that Mr. J. should be transferred via air medical service. The patient will be transferred directly to the cardiac catheterization laboratory and then to an awaiting bed in the CCU. The air medical service that will be transporting Mr. J. is staffed by a critical care flight RN and paramedic. They will bring all necessary equipment for the transport, including but not limited to a transport ventilator, intravenous infusion pump, and intra-aortic balloon pump.

The attending cardiologist for Mr. J. obtains consent for transport from Mr. J.'s wife. The consent form explains reasons for, as well as the risks and benefits associated with, the transfer.

1. What are the indications for transfer of Mr. J. to a tertiary facility?

2. Why is air medical transport indicated for Mr. J.?

3. What is the most appropriate nursing diagnosis for Mr. J.?

15 Disaster Management: Implications for the Critical Care Nurse

Nancy Blake and Jeffrey S. Upperman

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Describe the nurse's role in mass casualty incidents.
2. Explain the nurse's role in triage.
3. Describe how a radiological attack can occur and how to treat patients who have experienced a radiological attack.
4. Discuss how a chemical attack can occur and how to treat patients who have experienced a chemical attack.
5. Describe how a biological attack can occur and how to treat patients who have experienced a biological attack.

Communities rely on hospitals particularly in times of disaster. When recent disasters and terrorist attacks in the United States exposed weaknesses in emergency planning in hospitals, lawmakers passed legislation for federal funding for hospital-based disaster preparedness planning and resources. In 2005, the catastrophic hurricane Katrina surprised and shocked many hospital administrators and health care workers, revealing potentially how vulnerable the nation's health care system is. The Oklahoma City bombing and the attacks on the World Trade Center and the Pentagon alerted the nation to the major terrorist threats that exist around the world and that could easily overwhelm hospitals if hundreds or thousands of survivors need emergency treatment. The devastating earthquake in Haiti and the earthquake and tsunami in Japan demonstrated that in the event of widespread destruction, there may be numerous patients with traumatic injuries needing hospitalization and care in intensive care units (ICU). A similar large-scale disaster in the United States, involving thousands of casualties would stretch resources beyond capacity.

▲ Fundamentals of Disaster Science

The critical care nurse's role is crucial in all phases of the disaster planning and response cycle. Critical care nurses should participate in their facility's disaster planning process. When the disaster strikes, the job of critical care nurses depends on the impact of the disaster on the facility's structures, its surrounding environment, and the available staffing. For instance, if the hospital's electricity is out and the generators do not work, important equipment in the ICU, such as ventilators and monitors, will not function. In other disaster circumstances, critical care nurses may need to evacuate patients from the ICU when structures are unstable and resources are scarce. At this critical time, these nurses will cap intravenous (IV) lines for use at a later time. After the initial crisis, resources may be scarce, and vital medications may be unavailable and thus need to be rationed; in this case, critical care nurses must work closely with physicians and pharmacists to determine alternative methods or medications. Under austere conditions, critical care nurses caring for the sickest patients face a daunting task. These nurses need to consider altered standards of care and work with the health care team when faced with futile care decisions. During the recovery phases, critical care nurses are a crucial resource in leading and participating in the transitional delivery of care in their facilities. A Pediatric and Emergency Mass Critical Care Task Force published guidelines for triage and treatment, supplies and equipment, neonatal and pediatric regionalized systems, education, community preparedness, legal considerations, family-centered care, ethical issues and the reality of pediatric and mass critical care in the developing world in September of 2011.[1]

In catastrophic disaster situations, such as Haiti after the earthquake and Japan after the earthquake and tsunami, in which entire communities are devastated, the level of care for the community depends on the equipment, supplies, and facilities on hand. For example, if all buildings have been destroyed, physicians and nurses must care for patients in alternative care sites, such as tents or shelters. In these situations, the goal becomes providing the highest care possible, with limited resources and equipment. Wall oxygen and suction may not be available. Portable oxygen tanks become a vital resource. Nurses may need to attach a syringe to a suction catheter to provide manual suction. Portable or disposable handheld short-term ventilators may be all that is available. In major disasters, one must not forget the psychological and social distress that health care workers are experiencing. In cases of severe disruption, psychosocial resources are needed to assist the critical care nurses because many critically ill patients may die.

As a valued health resource during a disaster response, critical care nurses dictate how and when patients move in the facility for internal evacuation and surge capacity (see Triage, on pages 184–186). Nurses perform best with adequate training and preparation; therefore, as this chapter discusses, plans must delineate the appropriate deployment of nurses during a disaster and the resources needed for them to be successful.

▲ Response to Mass Casualty Incidents

By definition, a mass casualty incident (MCI) is characterized by large numbers of patients needing medical treatment that exceeds the capabilities of local emergency and health care personnel. To be integrated as part of the community's plan for emergency preparedness in MCIs, nurses must have a basic level of skills and education to appropriately respond and protect themselves and others, particularly during chemical, biological, radiological, nuclear, and explosive events. Critical care nurses may be among the first responders to large MCIs because public health teams and the emergency medical system (EMS) are overwhelmed. However, every nurse must have sufficient knowledge and skill to understand the potential for an MCI, identify when such an incident may have occurred, and protect himself or herself while caring for victims. The trauma and public health system in the United States is continuously improving its ability to respond to MCIs and critically ill patients who have suffered multiple traumas. During an MCI, nurses must perform the primary and secondary surveys as with any other trauma patient. They must know how to recognize their own roles and limitations as well as where to seek additional information and resources. A group initially known as the International Nursing Coalition for Mass Casualty Education (INCMCE) has developed basic competencies for entry-level registered nurses related to MCIs (Box 15-1). This group is now known as the Nursing Emergency Preparedness Education Coalition.[2]

▲ Response to Terrorism

Terrorism is the unlawful use of force or violence against persons or property to intimidate civilians or coerce government or a civilian population while promoting political and social objectives.[3] Ultimately, terrorists aim to make people fearful. Terrorism can overwhelm a nation's health care system.

In 2002, the American Association of Critical-Care Nurses (AACN) released a Statement of Commitment to Mass Casualty and Bioterrorism Preparedness recognizing that critical care nurses will be called on to respond to disaster and mass casualty situations. This statement includes the following:

"Bioterrorism and the potential of mass casualties is a significant public health threat facing the United States. The nation's capacity to respond to this threat depends in part on the ability of the health care professionals and public health officials to rapidly and effectively detect, manage, and communicate during an event resulting in mass casualties."[4] The AACN works closely with the Red Cross to help support critical care nurses during times of disaster.

In August 2003, a report to the Congressional Committee from the United States General Accounting Office (GAO) regarding Hospital Preparedness for a Bioterrorist Incident was published. Some of the GAO's findings were alarming. Although most urban hospitals across the country reported that they participated in basic planning and coordination of activities for bioterrorism response, they did not have the medical equipment, especially ventilators, to handle the number of people who would likely require care following a bioterrorist incident. Most hospitals stated they lacked the necessary resources to handle a large influx of patients.[5] Because many facilities would not be prepared to handle an attack, even fewer would be able to handle a large influx of critically ill patients who needed critical care. The GAO report also recounted many projected scenarios surrounding a possible influenza pandemic suggesting that the United States would be severely short of ventilators and trained staff to care for patients on ventilators.

In 2004, a working group in Pittsburgh, Pennsylvania, made recommendations to hospital and clinical leaders regarding the delivery of critical care services in the wake of a bioterrorist attack resulting in hundreds or thousands of critically ill patients. In these situations, traditional hospital and clinical care standards in general, and critical care standards in particular, likely could no longer be maintained. The study group came up with no clinical guidelines to deal with these situations. However, it did develop the following six planning assumptions regarding the current critical care medicine response for bioterrorism:

1. Future bioterrorist attacks may be covert and could result in hundreds, thousands, or more, critically ill victims.
2. Critical care will play a key role in decreasing morbidity and mortality rates after a bioterrorist attack.
3. Mass critical care cannot be provided without substantial planning and new approaches to providing critical care.
4. A hospital has limited ability to divert or transfer patients to other hospitals in the aftermath of a bioterrorist attack.
5. Currently deployable medical teams of the federal government have a limited role in increasing a hospital's immediate ability to provide critical care to large numbers of victims of a bioterrorist attack.
6. Hospitals may need to depend on nonfederal sources or reserves of medications and equipment necessary to provide critical care for the first 48 hours following discovery of a bioterrorist attack.[6]

▲ Role of Hospital Emergency Incident Command System

Hospitals respond to MCIs using the Hospital Emergency Incident Command System (HEICS), which is now referred to as the Hospital Incident Command System (HICS). HICS is an incident management system based on the Incident Command System (ICS) that assists hospitals in improving their emergency management planning as well as response and recovery capabilities for unplanned and planned events. HICS is consistent with ICS and the National Incident Management System principles, which allow for multiagency response to events. The HICS organizational chart is shown in Figure 15-1 on page 185. Critical care nurses need to be aware of how they specifically fit into their hospital disaster plan; they may be called on to take on a major role in the HICS organizational system.

BOX 15-1 Competencies for Entry-Level Registered Nurses Related to Mass Casualty Incidents

Core Compentencies

I. Critical Thinking

1. Use an ethical and nationally approved framework to support decision making and prioritizing needed in disaster situations.
2. Use clinical judgment and decision-making skills in assessing the potential for appropriate, timely individual care during a mass casualty incident (MCI).
3. Use clinical judgment and decision-making skills in assessing the potential for appropriate, individual ongoing care after an MCI.
4. Describe at the predisaster, emergency, and postdisaster phases the essential nursing care for
   a. individuals,
   b. families,
   c. special groups (eg, children, elderly, and pregnant women), and
   d. communities.
5. Describe accepted triage principles specific to MCIs, for example, the START or Simple Triage and Rapid Treatment System.

II. Assessment

A. General

1. Assess the safety issues for self, the response team, and victims in any given response situation in collaboration with the incident response team.
2. Identify possible indicators of a mass exposure (ie, clustering of individuals with the same symptoms).
3. Describe general signs and symptoms of exposure to selected chemical, biological, radiological, nuclear, and explosive (CBRNE) agents.
4. Demonstrate the ability to access up-to-date information regarding selected nuclear, biological, chemical, explosive, and incendiary agents.
5. Describe the essential elements included in an MCI scene assessment.
6. Identify special groups of patients that are uniquely vulnerable during an MCI (eg, very young, aged, and immunosuppressed).

B. Specific

1. Conduct a focused health history to assess potential exposure to CBRNE agents.
2. Perform an age-appropriate health assessment including
   a. airway and respiratory assessment;
   b. cardiovascular assessment, including vital signs and monitoring for signs of shock;
   c. integumentary assessment, particularly a wound, burn, and rash assessment, and pain assessment;
   d. injury assessment from head to toe;
   e. gastrointestinal assessment, including stool specimen collection and basic neurological assessment;
   f. musculoskeletal assessment; and
   g. mental status, spiritual, and emotional assessment.
3. Assess the immediate psychological response of the individual, family, or community following an MCI.
4. Assess the long-term psychological response of the individual, family, or community following an MCI.
5. Identify resources available to address the psychological impact (eg, Critical Incident Stress Debriefing [CISD] teams, counselors, Psychiatric/Mental Health Nurse Practitioners [P/MHNPs]).
6. Describe the psychological impact on responders and health care providers.

III. Technical Skills

1. Demonstrate the safe administration of medications, particularly vasoactive and analgesic agents, via oral (PO), subcutaneous (SC), intramuscular (IM), and intravenous (IV) administration routes.
2. Demonstrate the safe administration of immunizations, including smallpox vaccination.
3. Demonstrate knowledge of appropriate nursing interventions for adverse effects from medications administered.
4. Demonstrate basic therapeutic interventions including
   a. basic first aid skills,
   b. oxygen administration and ventilation techniques,
   c. urinary catheter insertion,
   d. nasogastric tube insertion,
   e. lavage technique (ie, eye and wound), and
   f. initial wound care.
5. Assess the need for and initiate the appropriate CBRNE isolation and decontamination procedures available, ensuring that all parties understand the need.
6. Demonstrate knowledge and skill related to personal protection and safety, including the use of personal protective equipment (PPE), for
   a. level B protection,
   b. level C protection, and
   c. respiratory protection.
7. Describe how nursing skills may have to be adapted while wearing PPE.
8. Implement fluid and nutrition therapy, taking into account the nature of injuries and/or agents exposed to and monitoring hydration and fluid balance accordingly.
9. Assess and prepare the injured for transport, if required, including provisions for care and monitoring during transport.
10. Demonstrate the ability to maintain patient safety during transport through splinting, immobilization, monitoring, and therapeutic interventions.

IV. Communication

1. Describe the Incident Command System (ICS) during an MCI.
2. Identify your role, if possible, within the ICS.
3. Locate and describe the emergency response plan for the place of employment and its role in community, state, and regional plans.
4. Identify one's own role in the emergency response plan for the place of employment.
5. Discuss security and confidentiality during an MCI.
6. Demonstrate appropriate emergency documentation of assessments, interventions, nursing actions, and outcomes during and after an MCI.
7. Identify appropriate resources for referring requests from patients, media, or others for information regarding MCIs.
8. Describe principles of risk communication to groups and individuals affected by exposure during an MCI.
9. Identify reactions to fear, panic, and stress that victims, families, and responders may exhibit during a disaster situation.
10. Describe appropriate coping strategies to manage self and others.

Core Knowledge

I. Health Promotion, Risk Reduction, and Disease Prevention

1. Identify possible threats and their potential impact on the general public, emergency medical system (EMS), and the health care community.

(continued on page 184)

BOX 15-1 Competencies for Entry-Level Registered Nurses Related to Mass Casualty Incidents (continued)

2. Describe community health issues related to CBRNE events, specifically limiting exposure to selected agents, contamination of water, air, and food supplies, and shelter and protection of displaced persons.

II. Health Care Systems and Policy

1. Define and distinguish the terms *disaster* and *MCI* in relation to other major incidents or emergency situations.
2. Define relevant terminology, including
   a. CBRNE,
   b. WMD,
   c. triage,
   d. Incident Command Service (ICS),
   e. personal protective equipment,
   f. scene assessment, and
   g. comprehensive emergency management.
3. Describe the four phases of emergency management: preparedness, response, recovery, and mitigation.
4. Describe the local emergency response system for disasters.
5. Describe the interaction between local, state, and federal emergency response systems.
6. Describe the legal authority of public health agencies to take action to protect the community from threats, including isolation, quarantine, and required reporting and documentation.
7. Discuss principles related to an MCI site as a crime scene (eg, maintaining integrity of evidence and chain of custody).
8. Recognize the impact MCIs may have on access to resources and identify how to access additional resources (eg, pharmaceuticals and medical supplies).

III. Illness and Disease Management

1. Discuss the differences and similarities between an intentional biological attack and that of a natural disease outbreak.
2. Assess, using an interdisciplinary approach, the short-term and long-term effects of physical and psychological symptoms related to disease and treatment secondary to MCIs.

IV. Information and Health Care Technologies

1. Demonstrate use of emergency communication equipment that you will be required to use in a MCI response.
2. Discuss the principles of containment and decontamination.
3. Describe procedures for decontamination of self, others, and equipment for selected CBRNE agents.

V. Ethics

1. Identify and discuss ethical issues related to CBRNE events:
   a. Rights and responsibilities of health care providers in MCIs, for example, refusing to go to work or report for duty, refusal of vaccines.
   b. Need to protect the public versus an individual's right for autonomy, for example, right to leave the scene after contamination.
   c. Right of the individual to refuse care, informed consent.
   d. Allocation of limited resources.
   e. Confidentiality of information related to individuals and national security.
   f. Use of public health authority to restrict individual activities, require reporting from health professionals, and collaborate with law enforcement.
2. Describe the ethical, legal, psychological, and cultural considerations when dealing with the dying and or the handling and storage of human remains in an MCI.
3. Identify and discuss legal and regulatory issues related to
   a. abandonment of patients,
   b. response to an MCI and one's position of employment, and
   c. various roles and responsibilities assumed by volunteer efforts.

VI. Human Diversity

1. Discuss the cultural, spiritual, and social issues that may affect an individual's response to an MCI.
2. Discuss the diversity of emotional, psychosocial, and sociocultural responses to terrorism or the threat of terrorism on one's self and others.

Professional Role Development

1. Describe these nursing roles in MCIs:
   a. Researcher
   b. Investigator/epidemiologist
   c. EMT or First Responder
   d. Direct care provider, generalist nurse
   e. Direct care provider, advanced practice nurse
   f. Director/coordinator of care in hospital/nurse administrator or emergency department nurse manager
   g. On-site coordinator of care/incident commander
   h. On-site director of care management
   i. Information provider or educator, particularly the role of the generalist nurse
   j. Mental health counselor
   k. Member of planning response team
2. Identify the most appropriate or most likely health care role for oneself during an MCI.
3. Identify the limits to one's own knowledge, skills, abilities, and authority related to MCIs.
4. Describe essential equipment for responding to an MCI, for example, stethoscope, registered nurse license to deter imposters, packaged snack, change of clothing, bottles of water.
5. Recognize the importance of maintaining one's expertise and knowledge in this area of practice and of participating in regular emergency response drills.
6. Participate in regular emergency response drills in the community or place of employment.

▲ Triage

Triage is a system for rationing resources in response to an overwhelming medical emergency event. Effective triage is one of the first procedures that the critical care nurse uses in responding to a disaster. Patients are quickly categorized into minimal, delayed, immediate, and expectant or morgue categories (see Box 15-2).

In addition to triage occurring outside the facility, health care workers should also perform triage inside the facility and ensure that salvageable patients are appropriately categorized. As patients are triaged, personnel should send them to the area where they will receive the appropriate level of care

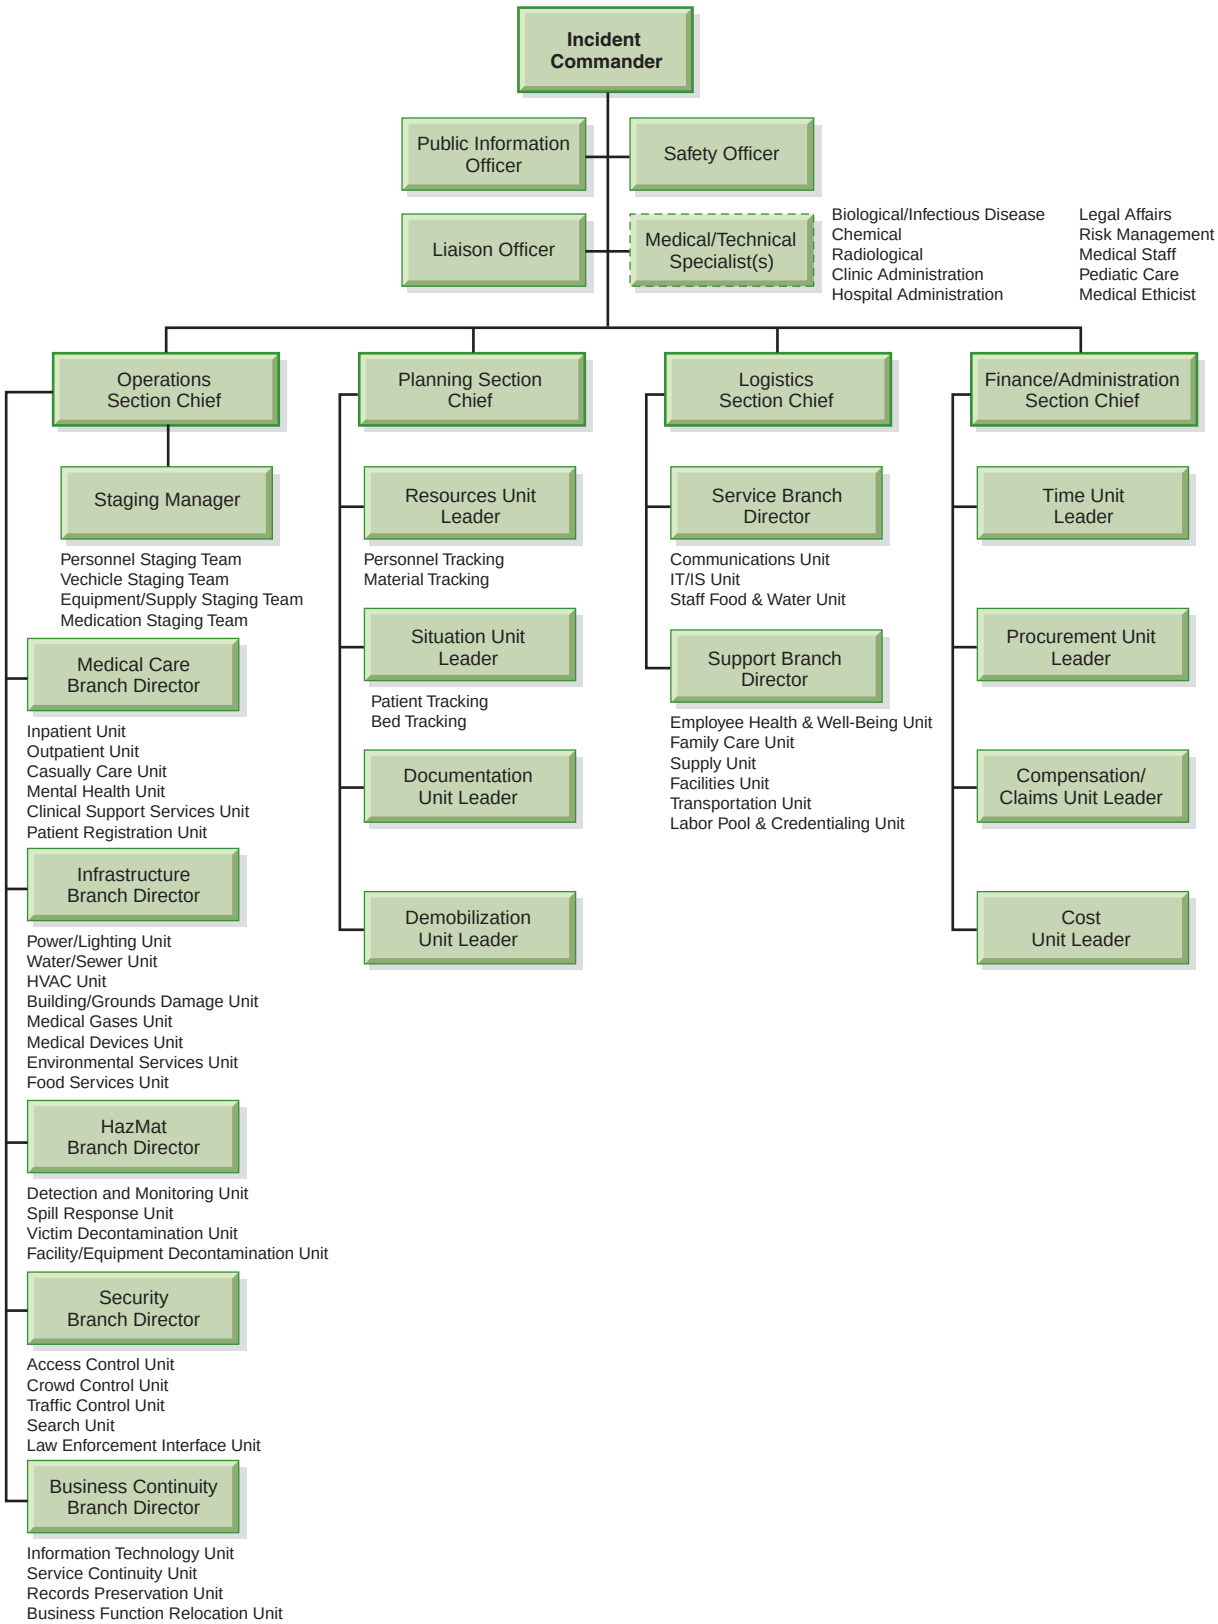

FIGURE 15-1 ▲ Hospital Incident Command System organizational chart. (From the Hospital Incident Command System Training Manual. Available at: http://www.emsa.ca.gov.)

BOX 15-2 START: Triage Categories

In disaster situations, the Simple Triage and Rapid Treatment (START) system offers a quick and efficient way to prioritize victims' treatment needs based on respiratory, perfusion, and mental status observations. Categories include

- Minor: Victims who can get up and walk are determined to be in less need and care may be delayed for up to 3 hours.
- Delayed: Victims who are breathing have an irregular or absent pulse but who can respond to commands, such as "open your eyes; close your eyes" may be considered for care that can be delayed up to 1 hour
- Immediate: Victims whose breathing indicates impending shock or possible suffocation need immediate care
- Dead: Victims whose breathing, perfusion, and mental status are absent and/or unresponsive to stimuli may be considered dead, and therefore, not in need of urgent care.

Source: Community Emergency Response Team Unit, LAFD Disaster Preparedness Section, www.cert-la.com.

for their triage category. The latter form of triage requires policy, education, and practice for desirable results.

An emerging concept as a result of triage is surge capacity. Surge capacity is a health care system's ability to expand quickly above and beyond normal services to meet an increased demand for medical care in the event of large-scale health emergencies. Nursing responsibility and patient care ratios will also adjust during a disaster event, and surge capacity depends on nurses caring for more patients. In some instances, disasters or surge capacity needs may require staff to move patients inside facilities to safer zones or to temporary clinical care areas.

Nurses serve as a focal point for assessing patients for movement and assembling the necessary materials for continuing the care of these patients at the new site. It is important to practice the movement of patients for internal evacuation periodically.

▲ Unnatural Disasters

Unnatural disasters include terrorist acts. Terrorism can take many forms.

Explosions and Blast Attacks

Explosives and bombs are the weapons of choice for terrorists. As a result, blast injuries occur and victims typically require evaluations by hospital personnel. Although some injured victims do not need hospital admission, more severely injured victims will need critical care.

The injuries can result from primary, secondary, or tertiary blast effects. Primary blast injuries are the result of sudden changes in atmospheric pressure caused by an explosion. Examples of primary blast injuries are as follows:

- Ear injuries, such as perforated eardrums
- Pulmonary injuries, including hemorrhagic contusion and hemopneumothorax
- Gastrointestinal hemorrhage or bowel perforation or rupture

Secondary blast injury occurs when victims are struck by flying objects and debris. Tertiary blast injuries occur when the body is hurled through the air and struck by another object.

Nuclear or Radiological Attacks

The medical consequences of a nuclear or radiological attack or accident depend on the nuclear or radiation source. Radiation accidents or attacks can occur as the result of problems with nuclear reactors, industrial sources, and medical sources. It is important that clinicians understand how a radiological attack can occur and how to treat patients. A radiological or nuclear attack can occur in one of five ways:

1. *Simple radiological device* (SRD): An SRD is a device designed to spread radioactive material without the use of explosives, thereby exposing many people to various levels of radiation.
2. *Radiological dispersal device* (RDD): An RDD is a device formed by combining an explosive agent with radioactive materials. The initial explosion kills or injures those closest to the bomb, and the radioactive material remains to expose and contaminate survivors and possibly emergency responders.
3. *Nuclear reactor sabotage:* This type of incident is low because of sophisticated shielding, but it could occur with an attack on a nuclear reactor.
4. *Improvised nuclear device* (IND): An IND is any device designed to cause a nuclear detonation. It is not easy to make such a weapon detonate correctly. This type of incident is actually an RDD. Although an IND is unlikely because of the necessary engineering sophistication, a stolen device would generate high levels of radiation.
5. *Nuclear weapon:* This method of exposure could occur if a weapon were stolen. This is another example of a remote radiological attack, but it could happen.[7]

There are two categories of radiation incidents: (1) *External exposure* is irradiation from a source distant or in close proximity to the body. External irradiation can be divided into *whole-body* exposure or *local* exposure. (2) *Contamination* is unwanted radioactive material in or on the body.[8]

Response to Attack

Based on the type of incident, the response is different. Most external exposures result in irradiation of the victim. Once the person is removed from the source of radiation, the irradiation ceases. A person exposed to external radiation does not become radioactive and poses no hazard to people nearby.

Contamination incidents require an entirely different approach to dealing with the victim than external radiation. Care givers and support personnel must be careful not to spread the contamination to uncontaminated parts of the victim's body, to themselves, or to the surrounding area. Internal contamination can result from inhalation, ingestion, direct absorption through the skin, or penetration of radioactive materials through open wounds. Serious or significant medical condition treatment should always take precedence over radiological assessment or patient decontamination.

After radiation exposure, individuals may develop acute radiation syndrome (ARS). Strong, healthy people are often

Table 15-1 Phases of Effects of Radiation Exposure

Phase	Time of Occurrence	Signs and Symptoms
Prodromal phase (presenting symptoms)	48–72 h after exposure	Nausea, vomiting, loss of appetite, diarrhea, fatigue High-dose radiation: fever, respiratory distress, increased excitability
Latent phase (a symptom-free period)	After resolution of prodromal phase; can last up to 3 wk With high-dose radiation, latent period is shorter	Decreasing lymphocytes, leukocytes, thrombocytes, red blood cells
Illness phase	After latent period phase	Infection, fluid and electrolyte imbalance, bleeding, diarrhea, shock, and altered level of consciousness
Recovery phase *Or* Death	After illness phase After illness phase	Can take weeks to months for full recovery Increased intracranial pressure is a sign of impending death

From Smeltzer SC, Bare BG, Hinkle JL, et al (eds): Brunner & Suddarth's Textbook of Medical-Surgical Nursing, 12th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 2007.

resistant to minimal exposure. The factors that determine whether ARS occurs include exposure to high-dose radiation (minimum, 100 cGy) and rate of radiation with whole-body exposure and penetrating-type radiation. There are several stages of radiation exposure (Table 15-1).

Management

Treatment priorities after a radiological attack:

1. *Treat and stabilize life-threatening injuries.* It is essential to stabilize the patient and treat life-threatening injuries first. Once that is done, a health care provider with radiological health training should perform a radiological assessment. Use a Geiger counter for radiological measurements.
2. *Prevent and minimize internal contamination.* Time is critical to prevent radioactive uptake. Administration of potassium iodide within 2 hours of contamination prevents radioiodine from accumulating in the thyroid gland (Table 15-2).
3. *Assess internal contamination and decontamination.* This information is covered in the following section on Chemical Attacks. Contaminated patients who are not seriously injured should be decontaminated before treatment.
4. *Contain contamination and decontamination.*
5. *Minimize external contamination to medical personnel.* Staff should wear personal protective clothing. Respirators are necessary if the patient is highly contaminated.
6. *Assess local radiation injuries/burns and flush them if contaminated.*
7. *Follow up on patients with significant whole-body irradiation or internal contamination.*
8. *Counsel patient and family about the potential for long-term risks and effects.*[9]

Table 15-2 Potassium Iodide (KI) Administration

Patient	KI Dose (mg)
Adults	130
Women who are breastfeeding	130
Children 3–18 y	65
Infants and children 1 mo to 3 y	32
Newborns to 1 mo	16

Chemical Attacks

Chemical warfare agents are hazardous chemicals designed to irritate, incapacitate, injure, or kill.[10] Although several of these agents were used during wartime, many of the most recent uses have been in terrorist attacks. For example, the sarin gas attacks in Japan in the mid-1990s resulted in few deaths but an overwhelming influx of contaminated patients to medical facilities. Combinations of chemical attacks with explosions and blast attacks are sometimes called "dirty bombs." To have chemical contamination associated with explosions, the victims need to be in close proximity to the explosion or blast attack.

Chemical agents pose a genuine threat for many reasons. First, they are readily accessible; for example, tear gas is sold in stores. Second, they are easy to find and easy to transport without being considered unusual; for example, transport of many nerve agents occurs on a daily basis by truck or rail. By the time a chemical attack is completed, the terrorist or criminal can be gone.

These toxic chemicals can be absorbed through the eyes, skin, airways, or a combination of these routes. Table 15-3 summarizes the common types of chemical agents, their mechanisms of action, signs and symptoms of exposure, and treatment for exposure.

Types of Chemical Agents

NERVE AGENTS. Nerve agents are the most toxic of all weaponized military agents. Examples of these agents are tabun, sarin, soman, and VX. Nerve agents inhibit cholinesterase, and they can cause sudden loss of

Table 15-3 Common Chemical Agents and Antidotes

Agent	Action	Signs and Symptoms	Decontamination and Treatment
Nerve agents: sarin, soman, organophosphates	Inhibition of cholinesterase	Increased secretions, gastrointestinal motility, diarrhea, bronchospasm	Soap and water Supportive care Benzodiazepine Pralidoxime Atropine
Blood agent: cyanide	Inhibition of aerobic metabolism	Inhalation—tachypnea, tachycardia, coma, seizures; can progress to respiratory arrest, respiratory failure, cardiac arrest, and death	Sodium nitrate Sodium thiocyanate Amyl nitrate Hydroxocobalamin
Vesicant agents: lewisite, sulfur mustard, nitrogen mustard, phosgene	Blistering agents	Superficial to partial-thickness burn with vesicles that coalesce	Soap and water Blot; do not rub dry
Pulmonary agents: phosgene, chlorine, ammonia	Separation of alveoli from capillary bed	Pulmonary edema, bronchospasm	Airway management Ventilatory support Bronchoscopy
Skin and eye irritants: mace (CN), tear gas (CS)	Local reaction to skin and eyes; may cause respiratory difficulties	Tearing of the eyes; burning of the skin; possible respiratory difficulty	Irrigate eyes—water only Soap and water to skin

From Slota M (ed): Core Curriculum for Pediatric Critical Care Nursing. St. Louis, MO: Elsevier, 2006; and Smeltzer SC, Bare BG, Hinkle JL, et al (eds): Brunner & Suddarth's Textbook of Medical-Surgical Nursing, 12th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 2203.

consciousness, seizures, apnea, and death. Diagnosis is usually made on the basis of clinical signs and symptoms.

VESICANTS. Vesicants cause blistering. The most commonly used vesicants are sulfur, mustard, and lewisite. These agents injure the eyes, skin, airways, and some internal organs. Vesicants may be commonly used as a mass casualty weapon because they are potent and difficult to detect, have delayed effect, produce prolonged disability, are stable in storage, can be transported easily, and are inexpensive to produce. They remain active in an area for up to 1 week. Some may have an odor of mustard or garlic.

CYANIDE. Cyanide is a widely used chemical in the United States. Terrorists use cyanide in confined spaces, such as subway cars, shopping centers, convention centers, and small buildings. Shortly after inhaling cyanide, victims may become anxious and hyperventilate. Inhalation of cyanide can cause convulsions, asystole, and death. Antidotes must be administered immediately.

PULMONARY INTOXICANTS. Pulmonary intoxicants cause severe life-threatening lung injury after inhalation. The effects are generally delayed for several hours. Examples are phosgene, perfluoroisobutylene (PFIB), ammonia, and chlorine. In 1984, an industrial accident, not a terrorist attack, involving a pulmonary intoxicant occurred at the Union Carbide plant in Bhopal, India. The released chemicals, for example, methyl isocyanate, caused great morbidity and death. To this day, this industrial accident remains one of the worst to occur in India. Pulmonary intoxicants are irritating to the eyes and respiratory tract. These agents can cause severe pulmonary edema of a noncardiac nature. The pathophysiology involves a permeability defect in the alveolar capillary membrane, and there may be a clinical latency period following exposure.

RIOT CONTROL AGENTS. Riot control agents, which have an immediate effect, irritate the eyes, nose, mouth, skin, and respiratory tract. They stimulate tear production by the lacrimal glands. The effect lasts about 30 minutes. Examples of these agents, which are routinely used by police, are chloroacetophenone (CN; Mace), oleoresin capsicum (OC; pepper spray), and chlorobenzylidenemalononitrile (CS; tear gas).[10]

Management

In the event of chemical exposure, decontamination is necessary. Staff need to be trained to decontaminate patients appropriately and should have access to appropriate personal protective equipment (PPE). With most chemical agents, only a splash-resistant gown, much like that used everyday in hospitals, and an N95 mask used for respiratory isolation in hospitals are necessary. Some of the more potent chemicals also require a self-contained breathing apparatus and a chemical-resistant suit. People who use these specialty suits and breathing devices should receive training in putting on the suit and have a respiratory evaluation annually.

As required by the Joint Commission hospitals should have decontamination protocols and procedures in place. Decontamination shelters can either be a room designated at the entrance to the emergency department with appropriate drainage and shower capability or a trailer; the latter appears to be the most popular choice in the United States. Decontamination trailers are advantageous because they are mobile and can be moved to the area designated for decontamination. Decontamination shelters should:

1. Have a water connection. Most are compatible with the facility's water lines.
2. Have the ability to collect and contain large quantities of water.

3. Have something to mix with the water to remove the various chemical agents. Most chemical agents respond to soap and water.
4. Have adequate lighting in the shelter.
5. Have some connection to electricity, whether through the hospital or a generator.
6. Have a conveyor system for nonambulatory patients.
7. Allow for patient privacy.
8. Have room for about two or three personnel. These personnel are preferably not health care providers because all clinical staff will be needed to provide medical care.
9. Have sufficient room for families. It may be necessary to decontaminate parents as well as children. (Parents can also help decontaminate their children.)[11]

Decontamination of children involves some special considerations. Because children may not understand what is happening, they may be uncooperative or even combative. Size may be an issue. Children are lower to the ground, which means that they may be exposed to more of the contaminant. Children have a large surface-to-volume ratio, which places them at higher risk for absorption and exposure to the contaminant. In addition, because even a small dose may be lethal in a child, children need to be decontaminated as quickly as possible. Children are also at a higher risk for cold stress from a rapid drop in temperature or fever from exposure to very warm temperatures. It is necessary to get them into a neutral thermal environment and out of extreme heat or cold. Finally, whenever possible, it helps to keep the family unit together so that the parents can keep the smaller children safe. If the parents are not present, appropriate arrangements must be made for supervision.

Biological Attacks

A biological attack is referred to as bioterrorism or the deliberate release of microorganisms (bacteria, viruses, fungi, or microbial toxins) into a community to produce death, disease, or poisoning.[10] Humans, animals, or plants may be affected. Biological weapons are often called the "poor man's bomb" because they are relatively inexpensive to produce and disseminate. A bioterrorist attack is a real threat, as evidenced by the anthrax attacks of 2001. Letters with anthrax spores arrived by post at some media and legislative offices, closing down many post offices and federal buildings for long periods. The attack resulted in 22 cases of anthrax, 5 deaths, and a nation on high alert.

Many biological substances result in specific signs and symptoms, and every nurse should know the basics of caring for affected patients. In 1999, the Association of Professionals in Infection Control developed a template, the *Bioterrorism Readiness Plan: A Template for Healthcare Facilities*, for hospitals to follow when dealing with bioterrorism.[12] In 2002, this group made some minor modifications to this plan. Table 15-4 summarizes the diseases associated with bioterrorism and management protocols for victims of biological attacks. Many bioterrorist agents are readily accessible. For example, anthrax can be found on some farms, and terrorists can pick it up and haul it away without being noticed.

Smallpox, a viral disease, is a strong bioterrorism threat because it has a high morbidity in an otherwise healthy population. Figure 15-2 on page 191 shows the smallpox rash. In 1980, the World Health Organization (WHO) declared smallpox eradicated.[10] In 2003, a smallpox vaccine became available for health care workers, but the U.S. Food and Drug Administration recalled it, and few people received the vaccine because of issues related to the exclusion criteria and the occurrence of some cardiac problems after administration of the vaccine.

The plague has a negative historical connotation because people still remember references to biblical references and deaths caused by bubonic plague. Animals, such as squirrels and other rodents that live on farmland, city parks, and campgrounds, still carry the bacteria that cause plague. Humans bitten by infected animals can become ill.

Botulism still occurs today in developed countries. A person can contract the disease from eating food that has been infected with the botulism toxin. Treatment is available. Children who develop infantile botulism can take an antidote, commonly known as "Baby Big," if the disease is diagnosed early and verified by a laboratory approved by the Centers for Disease Control and Prevention (CDC). At the time of diagnosis, the local health department sells the hospital the necessary dosage. The main issue is that the botulism is not always diagnosed promptly enough.

One of the more common viral hemorrhagic fevers is the Ebola virus. This virus is found more commonly in Third World countries. It is treatable but carries a negative connotation.

▲ Natural Disasters

A natural disaster is a result of the combination of a natural event (eg, earthquake, extreme heat, flood, hurricane, landslide, tornado, tsunami, volcanic eruption, wildfire, winter storm) and human involvement. By definition, a natural disaster does not occur without human involvement; therefore, an earthquake that destroys an uninhabited island is technically not a natural disaster. Another important feature of a natural disaster is that an unprepared or ill-prepared population is vulnerable, and therefore, a lack of preparation amplifies the unfortunate outcomes as result of a natural disaster.

Hospitals and other health care facilities play a unique role in the community because these facilities already contain an unhealthy, weak population and yet are expected to receive casualties resulting from disasters. Therefore, hospital personnel and administrators must actively prepare for any event that threatens the structure, function, and recovery of their organization and practice the appropriate responses to a hazardous event.

Some experts consider pandemic influenza a potential natural disaster, suggesting that it is a real possibility. Currently, the health care and corporate industries are working together to address the problem; and new vaccines and antiviral agents have been developed. Nurses are critical to the disaster response because they have direct patient care roles and will be present if an unforeseen event arises.

The H1N1 virus outbreak in 2009 increased the census in hospitals and ICUs across the country. Within 3 months of the first identified H1N1 case, the WHO raised it to a level of pandemic because there were community level outbreaks in at least one country other than where it was first identified. Cases spread quickly, especially in the younger population (25 years and younger).[13] The H1N1 outbreak helped address a potential outbreak that became a global emergency.

Table 15-4 Diseases Associated With Bioterrorism

Disease	Etiology	Mode of Transmission (Route of Exposure)	Incubation Period	Clinical Features	Treatment	Prophylaxis
Anthrax	*Bacillus anthracis*	Direct contact with bacterium or spores	1–7 d	**Cutaneous:** itchy papular lesions that turn into vesicles and within 2–6 d form black eschar; lesions most often seen on head, chest, and forearms	Antibiotic therapy **Adults:** ciprofloxacin, 500 twice daily, or doxycycline, 100 mg twice daily for at least 60 d **Children:** ciprofloxacin, 15 mg/kg twice daily, or doxycycline: more than 8 y and <45 kg: 100 mg twice daily more than 8 y and 45 kg or less: 2.2 mg/kg twice daily 8 y or less: 2.2 mg/kg twice daily	None
		Inhalation of spores	2–60 d	**Pulmonary:** nonspecific flu-like symptoms followed by the abrupt onset of respiratory failure (2–4 d after initial symptoms) and hemodynamic collapse	**Adults:** ciprofloxacin, 400 mg every 12 h *and* one or two additional microbials; switch to oral when appropriate. Ciprofloxacin, 50 mg, or doxycycline, 100 mg twice daily **Children:** Ciprofloxacin, 10 mg/kg every 12 h *or* doxycycline, same as for cutaneous except every 12 h instead of twice daily Switch to oral therapy when appropriate.	
		Ingestion of contaminated food, usually meat	1–7 d	**Gastrointestinal:** abdominal pain, nausea, fever, hematemesis, and bloody diarrhea		
Smallpox	Variola virus	Airborne	7–17 d (average, 12 d)	Nonspecific flu-like symptoms, fever, myalgia, skin lesions that progress from macules to papules to vesicles and then scab over in 1–2 wk	Supportive care, after 3 d can try variola immune globulin, negative isolation	Vaccination before exposure or within 3 d of exposure
Plague	*Yersinia pestis*	Flea-borne (bubonic plague), airborne (pneumonic plague)	2–8 d (flea-borne); 1–2 d (airborne)	Fever, cough, chest pain, hemoptysis, mucopurulent or watery sputum with Gram-negative rods on Gram stain, bronchopneumonia on x-ray	Streptomycin, 1 g IM twice daily, *or* gentamycin, 5 mg/kg IM or IV daily, or 3 mg/kg loading dose followed by 1.7 mg/kg IM or IV three times a day; droplet precautions in effect until patient has completed 72 h of antimicrobial therapy	Doxycycline, 100 mg PO twice daily, *or* ciprofloxacin, 500 mg PO twice daily
Tularemia	*Francisella tularensis*	Contact with infected animals (rabbits, deer) or vectors (fleas, ticks, mosquitos); airborne	2–14 d	Fever, chills, headache, muscle pain, nonproductive cough, pneumonia; regional lymphadenopathy if ingested	Same as for plague	Same as for plague

(continued on page 191)

Table 15-4 Diseases Associated With Bioterrorism (*continued*)

Disease	Etiology	Mode of Transmission (Route of Exposure)	Incubation Period	Clinical Features	Treatment	Prophylaxis
Botulism	*Clostridium botulinum*	Foodborne (most common); airborne	**Foodborne:** 12–36 h **Airborne:** 24–72 h	Gastrointestinal symptoms, drooping eyelids, jaw clench, difficulty swallowing or speaking, descending paralysis, blurred vision, no sensory deficits	Supportive care; antitoxin may halt progression of symptoms but is unlikely to reverse them	None
Viral hemorrhagic fevers	Diverse group of viruses (eg, Ebola virus, yellow fever)	Variable, may be person-to-person, via flea or animal bite; or airborne	2–22 d	Variable; usually a nonspecific illness lasting <1 wk with high fever and headache followed by flushing maculopapular rash and conjunctival infection, progressing to diffuse hemorrhagic disease and multiorgan system failure	Supportive care, ribavirin may be helpful in some cases	None

Data from Los Angeles County EMS and Public Health Agencies: Terrorism Agent Information and Treatment Guidelines for Clinicians and Hospitals, 2003.

Together, hospitals and government agencies set up plans to identify the issues and plan strategies to protect the public. The most common symptoms of H1N1 virus are fever, cough, and sore throat. A small percentage of patients required hospitalization and the patients who ended up in the critical care units were put on extracorporeal membrane oxygenation (ECMO), as pulmonary bypass, to treat respiratory failure. A small percentage of the patients treated in the critical care units died. Excellent resources are available for H1N1 and are noted on the CDC and the WHO Web sites. The Association of Infection Control Practitioners (APIC) also developed a reference document for infection prevention in alternate care sites; it can be found on their Web site at www.apic.org.

▲ Psychological Effects of Terrorism

It is natural to be fearful during and after a major disaster, whether or not it is a terrorist incident. People exhibit various responses to stress and stressful events, such as a terrorist attack or a major natural disaster. The responses include fear, grief, and deep sadness. People may complain that they feel "sick to their stomach" and have no appetite. Their sleep pattern and conduct in daily activities may change. Several weeks to months may pass before they feel normal and stable again.

In severe cases, the psychological stress remains months after the event. Multiple factors affect how people respond. The perception of numerous losses generally has a negative impact and may be related inversely to disaster recovery. Research has found that when there are large numbers of deaths and high levels of symptoms, the presence of long-term psychiatric disorders may be quite high.[14] These people should undergo screening for posttraumatic stress disorder (PTSD). PTSD is an intense emotional and physical response to thoughts and reminders of the event that last for many weeks or months after the traumatic event. Victims of PTSD may complain of nightmares, flashbacks, and severe emotional and physical reactions to thoughts of the event.

▲ Clinical Applicability Challenges

CASE STUDY

It is a holiday weekend, and several rock bands are playing in concert in the local amphitheater. The emergency department has been notified by the paramedics that an explosion has occurred in the theater and they are expecting to transport at least 20 critical victims to area hospitals. Your hospital has responded that it can take five critically injured victims. As the casualties arrive and the emergency department begins to triage these patients, many more begin to arrive unescorted by the paramedics. Some of the patients arriving by themselves appear to have serious injuries including severe shortness of breath, confusion, bleeding from the ears, and objects impaled in their chest and torso.

1. You are the critical care charge nurse. What responsibilities might you have in this situation?
2. The Emergency Department staff is overwhelmed and needs assistance in triaging the critical care patients. What are some examples of secondary blast injuries? What are some examples of primary blast injuries?
3. The police department has just notified your emergency department that this is a terrorist attack and an SRD was used. How does the initial treatment change for these patients? Is decontamination necessary?

PART 5

CARDIOVASCULAR SYSTEM

16

Anatomy and Physiology of the Cardiovascular System

Patricia Gonce Morton

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Briefly describe the characteristics of cardiac muscle cells.
2. Differentiate the electrical events from the mechanical events in the heart.
3. Explain depolarization and repolarization.
4. Describe the normal conduction system of the heart.
5. Explain the formula for calculating cardiac output.
6. Compare and contrast the role of the parasympathetic and sympathetic nervous systems in the regulation of heart rate.
7. Explain the three factors involved in the regulation of stroke volume.
8. Describe the coronary artery blood source for the cardiac chambers and conduction system.
9. Discuss the influence of blood volume and blood pressure on peripheral circulation.

During the 70 years in the life of the average person, the heart will pump approximately 70 times per minute, 24 hours a day, 365 days a year. The heart pumps about 5 quarts of blood a minute, 75 gallons an hour, and 1,800 gallons in a day.[1] Although the work accomplished by this organ is out of proportion to its size, for most people, the heart functions normally throughout the life span. The pumping action of the heart moves blood, a vital substance, throughout the body, supplying oxygen and nutrients to cells and removing waste. Without this action, cells die. For people in whom cardiac problems develop, the results may be dramatic and the outcome drastic. This chapter reviews the principles of cardiovascular anatomy and physiology.

▲ Cardiac Microstructure

Microscopically, cardiac muscle contains visible stripes, or striations, similar to those found in skeletal muscle (Fig. 16-1). The ultrastructural pattern also resembles that of striated muscle. The cells branch and connect freely and form a three-dimensional, complex network. The elongated nuclei, like those of smooth muscle, are found deep in the interior of the cells and not next to the cell membrane as they are in striated muscle.

Cardiac muscle (myocardial) cells are endowed with extraordinary characteristics, most of which belong to the cell membrane or sarcolemma. To pump effectively, the heart muscle must begin contraction as a single unit. To contract myocardial cells simultaneously, cell membranes must depolarize at the same time. The heart does this, without using much neural tissue, by rapidly conducting impulses from cell to cell through intercalated disks. At each end of every myocardial cell, adjacent cell membranes are folded elaborately and attached strongly. These areas comprise the intercalated disks, where depolarization is conducted extremely rapidly from one cell to the next (see Fig. 16-1).

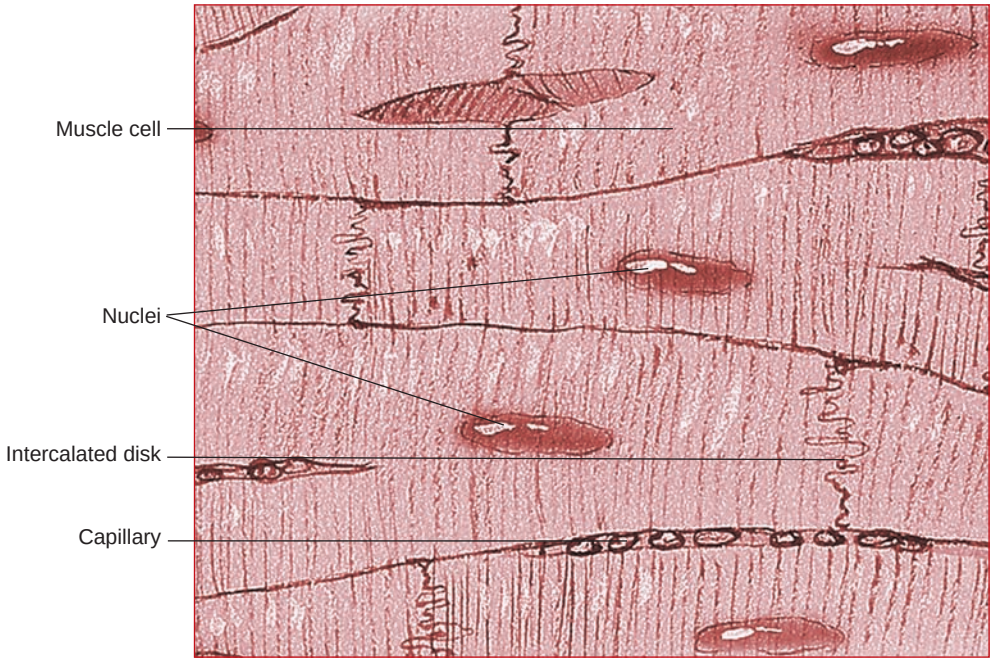

FIGURE 16-1 ▲ Cardiac muscle fibers, showing the branching structure and intercalated disks. (From Anatomical Chart Company: Atlas of Human Anatomy. Springhouse, PA: Springhouse, 2001, p 167.)

Another extraordinary characteristic of myocardial cells, seen mainly in cell membranes, is automaticity. Selected groups of cardiac cells are capable of initiating rhythmic action potentials, and thus waves of contraction, without any outside humoral or nervous intervention. Automaticity and other terms used to describe cardiac tissue functions are listed in Box 16-1.

Within each cardiac cell lie thousands of contractile elements, the overlapping actin and myosin filaments. Figure 16-2 illustrates these elements and the changes seen during diastole and systole. Not shown are the many cross-bridges that extend like rows of oars from the surface of the thicker myosin filaments. During diastole, these bridges are unattached to other filaments. The arrangement of actin and myosin filaments gives cardiac muscle its banded or striated appearance. One grouping of actin and myosin filaments is called a *sarcomere*.

BOX 16-1 Terms Used to Describe Cardiac Tissue Function

Automaticity: the ability of specialized cells in the heart known as pacemaker cells to spontaneously generate an action potential, thus causing depolarization
Conductivity: the ability of cardiac cells to conduct action potentials, thus transmitting the electrical signal from one cell to another
Contractility: the ability of cardiac muscle to shorten in response to depolarization
Excitability: the ability of cardiac tissue to respond to a stimulus and generate an action potential
Rhythmicity: the ability of cardiac cells to spontaneously generate an action potential at a regular rate

▲ Mechanical Events of Contraction

Before mechanical contraction, an action potential travels quickly over each cell membrane and down into each cell's sarcoplasmic reticulum. When an action potential causes depolarization of the sarcoplasmic reticulum, calcium ions move from the sarcoplasmic reticulum into the myocardial cell cytoplasm and bind to troponin molecules on actin filaments. Calcium-bound troponin moves slightly to uncover binding sites on the actin, to which myosin filaments then attach. With a release of energy stored in adenosine triphosphate (ATP), these binding sites move so that actin and myosin slide past each other and new couplings between actin and myosin occur. Rapid, successive uncoupling of cross-bridges and their reattachment to new actin-binding sites lead to rapid and dramatic shortening of the sarcomere (see Fig. 16-2). This shortening is the essence of myocardial contraction (systole). Contraction ceases when the calcium ions return to their storage sites on the sarcoplasmic reticulum, thereby causing the binding sites on the actin filaments to be covered again. The separated actin and myosin filaments then slip past each other in the reverse direction, lengthening the sarcomere to its relaxed state.

Contraction requires calcium and energy. The presence of adequate ATP stores and the movement of calcium provide the essential link between the electrical events of depolarization and the mechanical events of contraction in the heart.

▲ Electrical Events of Depolarization

Membranes of all the cells in the human body are charged, that is, they are polarized and therefore have electrical

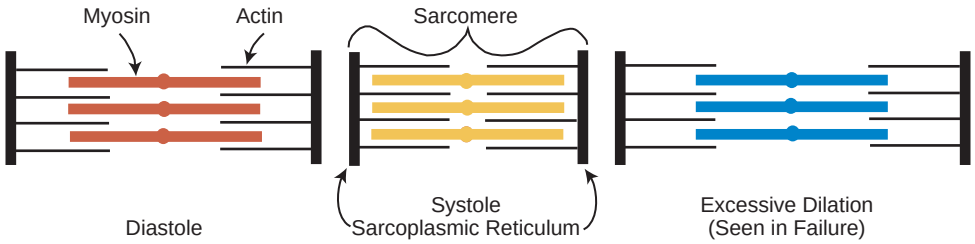

FIGURE 16-2 ▲ Contractile elements lying inside a single sarcomere of a myocardial cell.

potentials. The charges are separated at the membrane. In humans, all cell membranes, regardless of type, are positively charged at rest, with more positively charged particles at the outer surface of the cell membrane than at the inner surface. Figure 16-3A illustrates this "resting stage."

In the depolarized state, the cell membrane is negatively charged, with more negatively charged particles at the outer surface of the cell membrane than at the inner surface. Figure 16-3B illustrates this "depolarized stage." *Excitability* is the term used to describe the ability of a cell to depolarize in response to a given stimulus.

Cardiac muscle membranes are polarized, and the electrical potential can be measured, as it can in any of the cells in the human body. The potential results from the difference between intracellular and extracellular concentrations of electrolytes. When salt compounds of various elements are dissolved in aqueous solutions, they dissociate into their charged particles, called *ions*.

In the resting myocardial cell, there are more potassium ions inside than outside the cell and more sodium and unbound calcium ions outside than inside the cell. All three of these cations (positively charged ions) may diffuse through pores, or channels, in the cell membrane. If each ion freely obeyed the law of diffusion, however, potassium would diffuse out of the cell, whereas sodium and calcium would diffuse into it. Very soon there would be equal concentrations of each ion between the intracellular and extracellular fluids, and no resting potential would exist. It is through selective regulation of the concentrations of these ions on either side of the membrane that the resting membrane potential is maintained. Several factors contribute to this regulation. The first factor is the presence of sodium–potassium "pumps" in the cell membrane. These pumps move sodium out of the cell and potassium into the cell, with both movements occurring against the concentration gradients for each of these ions. The second factor is the active movement of calcium out of the cell against the concentration gradient in response to the passive diffusion of sodium into the cell. The third factor is the regulation of membrane channels, whereby calcium ions can enter the resting myocardial cell. The fourth factor is the presence of intracellular anions (negatively charged particles) that are too large to exit from the cell.

▲ Physiological Basis of the Resting Potential

The cardiac cell contains large anions that cannot exit the cell. These anions attract sodium and potassium cations, which diffuse through membrane channels into the cell. The anions would attract the calcium cation also, except that the membrane channels for the entry of this ion are closed when the cell is at rest. The potassium ions remain within the cell, but the sodium ions are pumped out of the cell almost as fast as they can enter by the sodium–potassium pumps located in the cell membrane. While forcing sodium out of the cell, these pumps actively transport potassium ions into the cell against their concentration gradients. This increase in intracellular potassium still is insufficient to offset all the intracellular anions. Thus, the inside of the myocardial cell remains negative with respect to the outside—as long as the pumps are operative. As a result, the resting potential is approximately −80 mV. For each molecule of an ion pumped from the cell, one molecule of ATP is required to provide the energy necessary to effect the chemical bond between ion and carrier. Maintaining a resting potential thus requires energy. Factors that maintain resting membrane potential of myocardial cells are listed in Box 16-2.

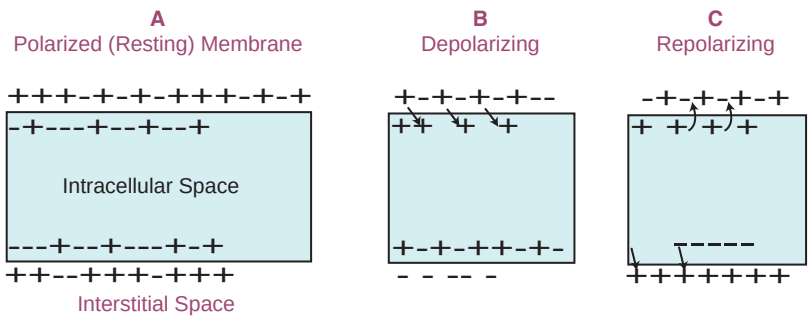

FIGURE 16-3 ▲ Electrical events at rest (diastolic) and preceding contraction (systolic).

BOX 16-2 Factors That Maintain Resting Membrane Potential of Myocardial Cell

- Sodium–potassium pumps within the cell membrane
- Active movement of Ca^{2+} out of cell against its concentration gradient in response to passive diffusion of Na^{+} into cell
- Regulation of membrane channels so that Ca^{2+} ions can enter resting myocardial cell
- Presence of intracellular anions too large to exit from cell

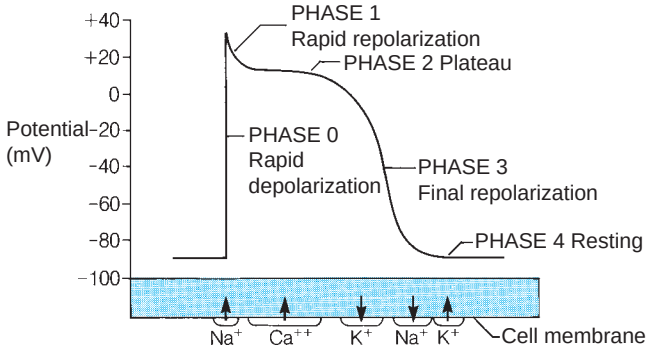

FIGURE 16-4 ▲ Cardiac action potential. Phase 0 is the rapid depolarization phase. During this phase, the fast sodium channels in the cell membranes are stimulated to open, resulting in the rapid influx of sodium. Contraction of the myocardium follows depolarization. Phase 1 is the rapid repolarization phase and occurs at the peak of the action potential. This phase indicates the inactivation of the fast sodium channels with an abrupt decrease in sodium permeability. Phase 2 represents the plateau of the action potential. During this phase, potassium permeability is low, allowing the membrane to remain depolarized throughout phase 2. The influx of calcium that occurs during the plateau phase is much slower than that of sodium and lasts for a longer time. Phase 3 is the final repolarization phase and begins with the downslope of the action potential curve. During this phase, the influx of calcium and sodium ends, and there is a rapid outward movement of potassium. By the end of phase 3, sodium and potassium return to their normal resting state. Phase 4 is the resting membrane potential and corresponds to diastole. During this phase, the sodium–potassium pump is activated, resulting in the active transport of sodium out of the cell, and potassium is moved back into the cell. The *arrows* below the diagram indicate the approximate time and direction of movement of each ion influencing membrane potential. The phase of calcium moving out of the cell is not well defined but is thought to occur during phase 4.

▲ Physiological Basis of the Action Potential

When a stimulus is applied to the polarized cell membrane, the membrane that ordinarily is only slightly permeable to sodium permits sodium ions to diffuse rapidly into the cell. This rapid diffusion occurs because of inactivation of the sodium active transport enzymes (pumps). The result is a reversal of net charges. The outer surface is now more negative than positive, and the membrane is said to be depolarized (see Fig. 16-3B).

When the sodium influx changes the polarity from −80 mV to approximately −35 mV, the electrical change opens the previously closed "calcium channels" in the myocardial cell membrane. Once opened, these channels permit the influx of calcium. The entry of this cation, together with the continued entry of sodium, is responsible for the remainder of the depolarization, which continues until the polarity of the extracellular side equals approximately +30 mV. Such a maximal depolarization inactivates sodium–potassium pumps in nearby membranes. This can cause depolarization in these areas. When the original depolarization becomes self-propagating in this way, it is termed an *action potential*. In a myocardial cell, an action potential triggers the release of intracellular calcium from its storage sites on the sarcoplasmic reticulum. This release plus the calcium influx across the sarcolemma elevates intracellular calcium levels, thereby initiating muscular contraction, as previously described.[1]

If the depolarization remains below a certain critical (threshold) point, it dies out without having opened any calcium channel or inactivated any adjacent sodium–potassium pumps. Because it does not become self-propagating and remains localized, such a depolarization is termed a *local depolarization*.

During depolarization, the elevated intracellular sodium concentration frees potassium ions to diffuse out of the cell in accordance with their concentration gradient. Just as this potassium efflux gains some momentum, however, the sodium–potassium pumps automatically reactivate (they can be inactivated only temporarily). Once reactivated, the pumps begin to restore the original resting potential, a process termed *repolarization* (see Fig. 16-3C). During the initial phase of repolarization, the efflux of potassium and sodium ions exceeds their influx, but as the intracellular sodium ions are removed from the cell, potassium ions remain as the major cation to be electrostatically held within the cell by the intracellular anions. This halts the potassium efflux. The remainder of repolarization consists of pump activity that increases intracellular potassium and decreases intracellular sodium; thus, the resting potential is re-established. The electrical events at the start of repolarization also reclose the calcium entry channels, thereby halting calcium influx. Intracellular calcium levels are reduced when the diffusion of sodium into the cell causes a movement of calcium out of the cell against the latter's concentration gradient.[1] The phases of the action potential are shown in Figure 16-4.

▲ Cardiac Macrostructure

The heart is about the size of a clenched fist and lies in the chest between the lungs in the mediastinal space of the intrathoracic cavity. The right side of the heart is almost entirely in front of the left side of the heart, and the right ventricle occupies most of the anterior cardiac surface (Fig. 16-5). Only a small portion of the left ventricle is in the frontal plane of the heart. The left ventricle forms the left lateral margin of the heart with a tapered inferior tip that is often termed the *cardiac apex*.[2]

The heart is made up of four layers: the endocardium, the myocardium, the epicardium, and the pericardium. The inner layer, known as the *endocardium*, consists of endothelial

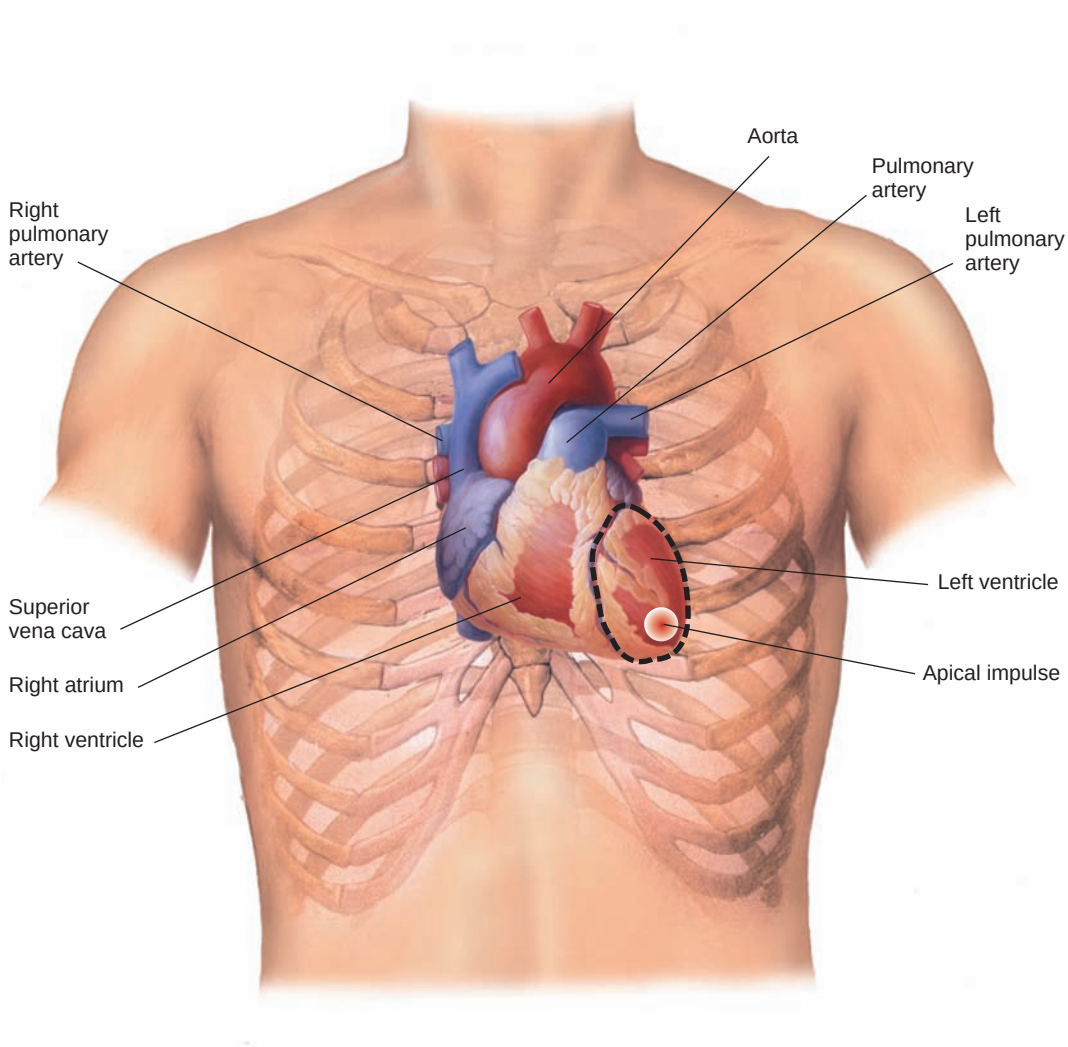

FIGURE 16-5 ▲ Structure of the heart. (From Bickley LS: Guide to Physical Examination and History Taking, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 324.)

tissue that lines the inner surface of the heart and the cardiac valves. The middle layer, known as the *myocardium*, is composed of muscle fibers that enable the heart to pump. The outer layer, known as the *epicardium*, is tightly adherent to the heart and the base of the great vessels. A thin, fibrous, double-layered sac, known as the *pericardium*, surrounds the heart. This structure has two parts: an outer layer called the *parietal pericardium* and the inner layer called the *visceral pericardium*. Between these two layers is a small amount of pericardial fluid (30 to 50 mL) that serves as a lubricant between the two layers.[1]

The heart consists of four chambers: right and left atria, and right and left ventricles. The atria are smaller, thinner-walled, low-pressure chambers. Approximately 30% of blood flow to the ventricles is the result of atrial contraction, also known as *atrial kick*. The remaining 70% of blood that reaches the ventricles is the result of pressure differences between the atria and the ventricles. The ventricles are larger, higher-pressure chambers with thicker walls than the atria. The walls of the left ventricle are thicker than the right ventricle because the left ventricle must generate a large amount of force to eject blood into the aorta. Deoxygenated blood enters the right atrium from the superior and inferior venae cavae. The blood passes through the tricuspid valve into the right ventricle, which then pumps the blood through the pulmonic valve into the pulmonary circulation. After gas exchange in the lungs, oxygenated blood returns to the left atrium, passes through the mitral valve, enters the left ventricle, passes through the aortic valve, and finally enters the aorta (Fig. 16-6).

The cardiac valves are composed of fibrous tissue and allow blood to flow in one direction. The valves open and close as a result of blood flow and pressure differences. The tricuspid and mitral valves are known as the *atrioventricular (AV) valves* because they are located between the atria and the ventricles. The chordae tendineae and the papillary muscles attach to the AV valves and help maintain closure and prevent eversion of the valve leaflets during ventricular contraction so that blood does not move into the atria. The pulmonic and aortic valves are known as the *semilunar valves* because each has three leaflets shaped like half-moons.

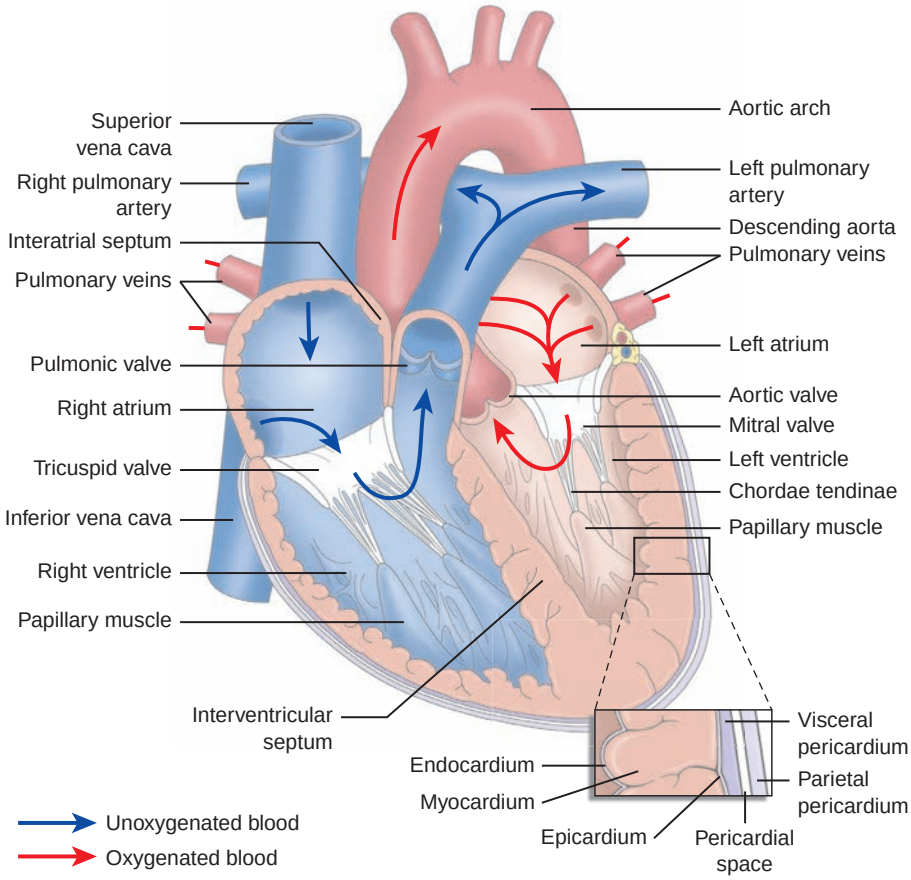

FIGURE 16-6 ▲ Structure of the heart. *Arrows* show course of blood flow through the heart chambers. (From Smeltzer SC, Bare BG, Hinkle JL, et al: Textbook of Medical–Surgical Nursing, 12th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 685.)

▲ Cardiac Conduction

To pump effectively, large portions of cardiac muscle must receive an action potential nearly simultaneously. Special cells that conduct action potentials extremely rapidly are arranged in pathways through the heart. All these cells have automaticity (see Box 16-2, p. 196).

The heart chambers and specialized tissues are diagrammed in Figure 16-7. The sinoatrial (SA) node is located between the opening of the inferior and superior venae cavae in the right atrial wall. The cells of the SA node have the property of automaticity. Because the SA node normally discharges faster than any other heart cell with automaticity (60 to 100 beats/min), this specialized tissue acts as a normal cardiac pacemaker. Atrial action potentials travel through atrial cells by intercalated disks, although some specialized conductive tissue in the atria has been discovered.

In the lower right portion of the interatrial septum is the AV node, also known as the AV junction. This tissue conducts, yet delays, the atrial action potential before it travels to the ventricles. Action potentials reach the AV node at different times. The AV node slows conduction of these action potentials until all potentials have exited the atria and entered the AV node. After this slight delay, the AV node passes the action potential all at once to the ventricular conduction tissue, allowing for nearly simultaneous contraction of all ventricular cells. This AV node delay also allows time for the atria to eject fully their load of blood into the ventricles in preparation for ventricular systole.

From the AV node, the impulse travels down the bundle of His in the interventricular septum into either a right or left bundle branch and then through one of many Purkinje fibers to the ventricular myocardial tissue itself. An action potential can traverse this conducting tissue three to seven times more rapidly than it can travel through the ventricular myocardium. Thus, the bundle branches and Purkinje fibers enable a near-simultaneous contraction of all portions of the ventricle, thereby allowing a maximal unified pump action to occur.[1]

Electrocardiograms

Conduction of an action potential through the heart can be shown by an electrocardiogram (ECG; Fig. 16-8). Because ECGs are extensively covered in Chapter 17, discussion here is brief. An ECG does not show mechanical events of the heart, but in the normal heart, coupling of electrical and mechanical events can be assumed (see Chapter 17).

In Figure 16-8, point 1 shows early ventricular diastole, when the atria and ventricles are at rest. Blood from the large veins is passively filling both atria. As the atria fill, the pressure in the atria exceeds the pressure in the ventricles, and the AV valves open in response to the pressure gradient. The blood from the atria now passively fills the ventricles.

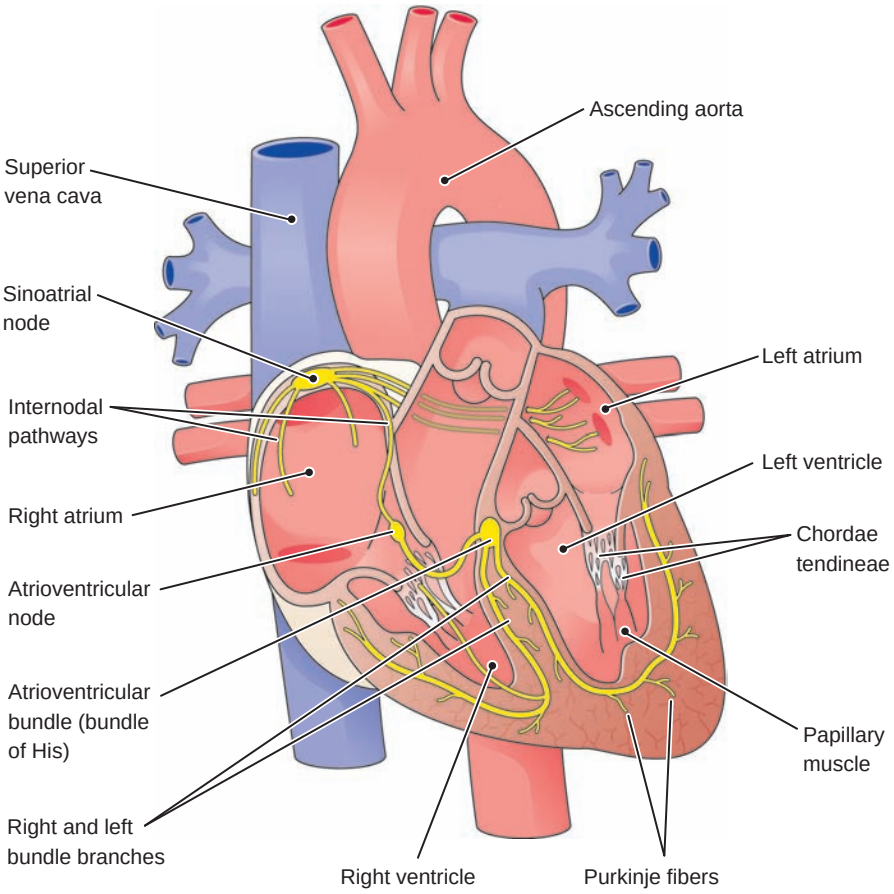

FIGURE 16-7 ▲ The electrical conduction system of the heart begins with impulses generated by the sinoatrial node (*yellow*) and circuited continuously over the heart. (From Weber J, Kelley K: Health Assessment in Nursing, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, 352.)

At point 2, the beginning of late ventricular diastole, both ventricles remain relaxed and are about three fourths full. The SA node fires spontaneously (due to automaticity), and both atria depolarize, generating a P wave. The atria contract, and blood is actively moved from the atria into the ventricles: this "atrial kick" supplies approximately 20% to 30% of the ventricular blood volume.

At point 3, late in the PR interval, the action potential begun in the SA node is being delayed and "collected" in the AV node and travels to the bundle of His. The atria and ventricles are at rest.

At point 4, the action potential moves to the septum, which depolarizes and leads to the Q wave. Septal depolarization is rapidly followed by action potential movement down the right and left bundles into the Purkinje fibers to all cardiac muscle cells. These electrical events are seen as the RS wave on the ECG and are followed rapidly by mechanical contraction of both ventricles. The AV valves close, and the aortic and pulmonic valves open.

At point 5, the heart returns to early ventricular diastole, and the ventricles repolarize. This repolarization shows as a large, wide T wave. The aortic and pulmonic valves close about midway through repolarization.[1]

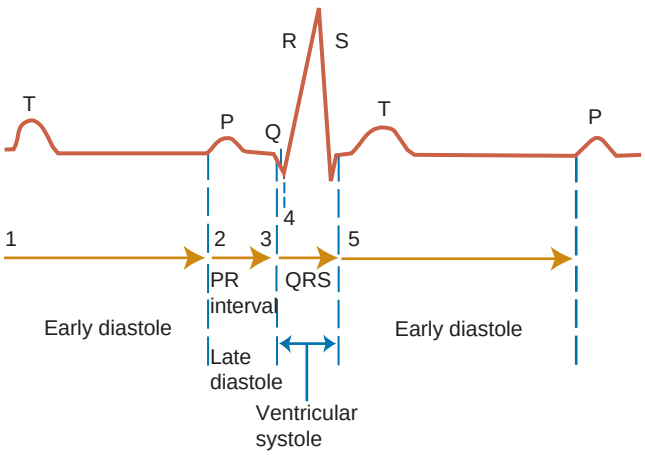

FIGURE 16-8 ▲ Comparison of electrical and mechanical events during one cardiac cycle, using a normal electrocardiogram tracing.

Rhythmicity and Pacing

Automaticity is an inherent property of myocardial conduction cells and occurs as a result of a spontaneous and rhythmic inactivation of the sodium pumps. Under abnormal conditions, cardiac muscle cells also gain automaticity and can produce their own rhythmic series of action potentials and thus their own stimulus for contraction. Coordination of automaticity is important for rhythmic cardiac contraction and is achieved through the varying rates of automaticity found in different cardiac tissues.

The SA node discharges normally in an adult at a resting rate of 60 to 100 times per minute. The remainder of the conduction system and ventricles have progressively slower rates of firing.

The AV node discharges at a rate of 40 to 60 times per minute. The conduction tissues in the ventricles fire about 20 to 40 times per minute. The group of cells with the fastest rate of automaticity paces the heart. Normally, this is the SA node.

If the SA node should fail to fire, a pacemaker site lower in the heart should take control because of the automaticity of cardiac tissue. This new pacemaker site is usually the AV node; however, the heart rate (HR) will most likely be slower. If conduction from the SA node is blocked (unable to pass through the AV node), the fastest pacemaker tissue on both sides of this interruption will govern their respective areas, and the ECG may show independent atrial and ventricular rhythms. Atrial systole is not needed for the ventricle to fill with blood because most ventricular filling is passive and occurs in early diastole. The clinically important rhythm is that of the ventricles; they are the chambers that supply the lungs and the rest of the body with blood. Their systolic rate helps determine true perfusion. The slower the rate, the less able are the ventricles to meet the perfusion needs of the body during exercise or activities of daily living. A very rapid ventricular rhythm also compromises perfusion needs because the shorter the diastole, the less time for filling of the chambers. Decreased ventricular filling reduces cardiac output (CO).

▲ Cardiac Output

A traditional measure of cardiac function, CO is the amount of blood, in liters, ejected from the left ventricle each minute. Cardiac output (CO) is the product of heart rate (HR) and stroke volume (SV), which is the volume of blood ejected per ventricular contraction:

$$CO = HR(\text{beats/min}) \times SV(\text{L/beat})$$

Normal CO for an adult ranges from 4 to 8 L/min. The output can be altered to meet changing bodily demands for tissue perfusion, but the CO equation does not account for differences in body size. An output of 5 L/min may be adequate for a 50-kg man but insufficient for a 120-kg man. Because perfusion is a function of body size, a more accurate measure of cardiac function is cardiac index (CI), which represents the amount of blood, in liters, ejected each minute from the left ventricle (or CO) per square meter of body surface area. CI typically averages 3.0 ± 0.2 L/min and ranges from 2.8 to 4.2 L/min/m^2:

$$CI = CO\ (\text{L/min}) / \text{body surface area}\left(m^2\right)$$

Regulation of Heart Rate

Although the heart has the ability to beat independently of any extrinsic influence, cardiac rate is under autonomic and adrenal catecholamine influence. Parasympathetic and sympathetic fibers innervate the SA and AV nodes. In addition, some sympathetic fibers terminate in myocardial tissues.

Parasympathetic stimulation releases acetylcholine near the nodal cells and decreases the rate of depolarization, thereby slowing cardiac rate. Stimulation of sympathetic fibers causes the release of norepinephrine. This chemical increases the rate of nodal depolarization and has inotropic effects on myocardial fibers, which are discussed later. Thus, sympathetic stimulation increases HR (Table 16-1). The adrenal medulla also releases norepinephrine and epinephrine into the bloodstream. These circulating catecholamines act on the heart in the same way as sympathetic stimulation.

Table 16-1 α and β Effects of Autonomic Nervous System on the Heart and Vascularity

		Noradrenergic Impulses	
Effector Organ	**Cholinergic Impulses Response**	**Receptor Type**	**Response**
Heart			
Sinoatrial (SA) node	Decrease in heart rate (HR); vagal arrest	β_1	Increase in HR
Atria	Decrease in contractility and (usually) increase in conduction velocity	β_1	Increase in contractility and conduction velocity
Atrioventricular (AV) node and conduction system	Decrease in conduction velocity; AV block	β_1	Increase in conduction velocity
Ventricles	—	β_1	Increase in contractility and conduction velocity
Arterioles			
Coronary, skeletal muscle, pulmonary, abdominal viscera, renal	Dilation	α β_2	Constriction Dilation
Skin and mucosa, cerebral, salivary glands	—	α	Constriction
Systemic Veins			
	—	α β_2	Constriction Dilation

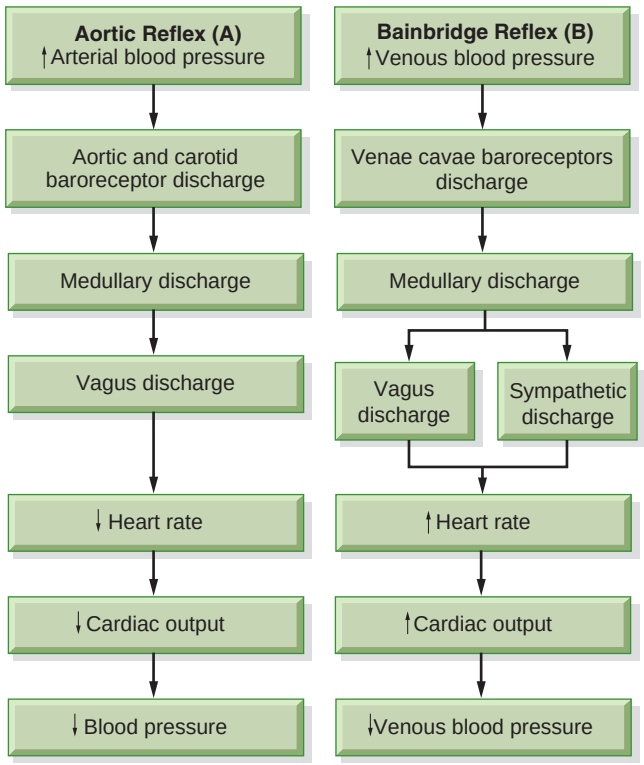

FIGURE 16-9 ▲ Effects of aortic reflex (**A**) and Bainbridge reflex (**B**) on heart rate.

Two reflexes adjust HR to blood pressure: the aortic reflex and the Bainbridge reflex. In the aortic reflex (Fig. 16-9A), a rise in arterial blood pressure stimulates aortic and carotid sinus baroreceptors to fire sensory impulses to the cardioregulatory center in the medulla. The result is an increase in parasympathetic stimulation or a decrease in sympathetic stimulation to the heart. Thus, a rise in arterial blood pressure reflexively causes a slowing of cardiac rate. The decrease in HR results in a decrease in output, which can decrease arterial blood pressure. Conversely, a fall in arterial blood pressure, such as in shock, reflexively increases HR. This aortic reflex is an ongoing regulatory mechanism for homeostasis of arterial blood pressure.

The Bainbridge reflex (see Fig. 16-9B) uses receptors in the venae cavae. An increase in venous return stimulates these receptors, which then fire sensory impulses that travel to the cardioregulatory center. These reflexively cause a decrease in parasympathetic cardiac stimulation and an increase in sympathetic cardiac stimulation, thereby increasing cardiac rate. A fall in venous return causes a decrease in HR. Thus, the Bainbridge reflex adjusts cardiac rate to handle venous return.

Regulation of Stroke Volume

SV is the amount of blood ejected by the left ventricle during systole. Normal values range from 60 to 100 mL/beat. Three factors are involved: preload, afterload (or wall tension), and inherent inotropic myocardial contractility.

Preload

Preload is the amount of stretch placed on a cardiac muscle fiber just before systole. Usually, the amount of stretch in any chamber is proportional to the volume of blood the chamber contains at the end of diastole, before systole. However, in some situations, the chamber can hold a large amount of volume with little change in pressure.

The concept of preload is related to the Frank-Starling law of the heart, which states that the force of myocardial contraction is determined by the length of the muscle cell fibers (Fig. 16-10). Within a certain range, increasing myofibril stretch increases the force of systole. Beyond optimal fibril length, it is hypothesized that too few actin–myosin binding sites overlap to provide an adequate contraction. Below optimal shortening, there is little room for filaments to slide, and cell walls limit further sliding. Also, actin filaments may have begun to overlap, decreasing the number of binding sites available to myosin fibers.

When the force of systole decreases, the chamber pumps poorly and does not empty properly. Excessive blood is left in the chamber at the end of systole. During diastole, when the chamber fills, this extra blood causes overfilling of the chamber and increases stretch. The next systole will be even weaker, as preload increases during every diastole.

Because preload is affected by the volume at the end of diastole, it often is equated with end-diastolic volume or pressure. Thus, left ventricular preload is represented by left ventricular end-diastolic pressure.

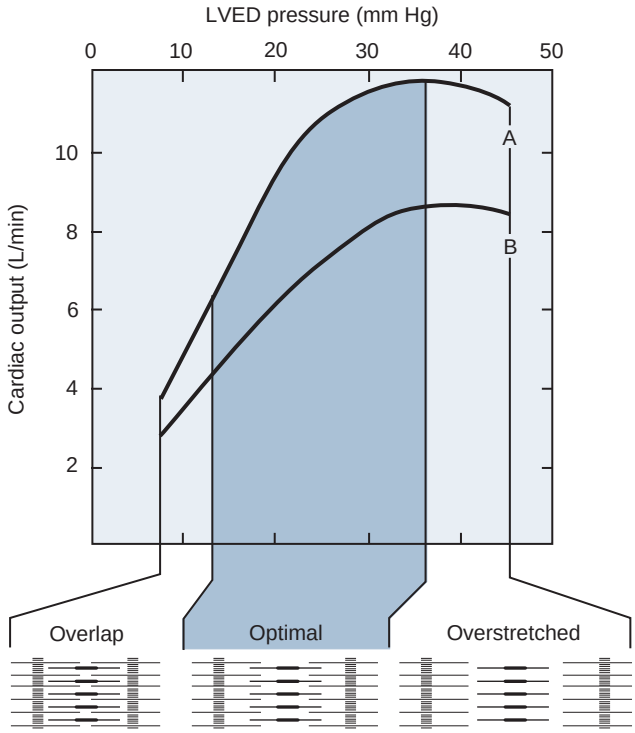

FIGURE 16.10 ▲ **Top:** Starling ventricular function curve in normal heart. An increase in left ventricular end-diastolic (LVED) pressure produced an increase in cardiac output (CO) *(curve B)* by means of the Frank-Starling mechanism. The maximal force of contraction and increased stroke volume are achieved when diastolic filling causes the muscle fibers to be stretched about 2-1/2 times their resting length. In *curve A,* an increase in cardiac contractility produces an increase in CO without a change in LVED volume and pressure. **Bottom:** Stretching of the actin and myosin filaments at the different LVED filling pressures. (From Porth CM: Pathophysiology: Concepts of Altered Health States, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 464.)

An example of rapid and normal adjustments to changes in preload occurs during the Valsalva maneuver. The first part of the Valsalva occurs when one holds one's breath and bears down, such as during defecation or heavy lifting. Bearing down increases intra-abdominal and intrathoracic pressures, decreasing venous return to the right atrium and ventricle. Right heart preload decreases. Bearing down also stimulates the vagus nerve, and the HR slows.

On exhalation, during the second part of the Valsalva maneuver, intrathoracic pressures decrease rapidly, allowing a sudden increase in venous return. Right atrial and ventricular preloads increase dramatically, stretch increases, and the right ventricular SV increases. Atrial stretch receptors also signal the medulla and lead to sympathetic nervous discharge. HR increases.

Afterload

Afterload is the force or pressure against which a cardiac chamber must eject blood during systole. The most critical factor determining afterload is vascular resistance, in the systemic or pulmonic vessels. Afterload often is equated with systemic vascular resistance or pulmonary vascular resistance.

Afterload affects SV by increasing or decreasing the ease of emptying a ventricle during systole. A decrease in systemic vascular resistance, through vasodilation, presents the left ventricle with relatively large, open, relaxed arteries into which it can pump. Because it is easier to pump, the left ventricle empties easily, which increases SV.

If systemic vascular resistance increases, for example through catecholamine-induced constriction of arteries, it takes a great deal more force for the left ventricle to pump into such a tightened vasculature. SV decreases.

Contractility

Inotropic capabilities and cardiac workload refer to contractile forces. Cardiac muscle forces change in response to neural stimuli and circulating levels of catecholamines. It is thought that through cyclic adenosine monophosphate mechanisms, cardiac cells change intracellular levels of calcium and ATP. These changes lead to increased inotropic actions, although the mechanisms remain unknown.

However, increased inotropic action increases the oxygen consumption of heart cells. This increased consumption also is called *increased workload* and *increased oxygen demand*.

CO depends on HR and SV. Regardless of the initial cause of increased SV (increased preload, increased afterload, or increased inotropic force), an increase in SV increases workload. Similarly, an increased HR, no matter what the cause, increases oxygen demand.

▲ Coronary Circulation

Blood supply to the myocardium is derived from the two main coronary arteries, the left and the right (Fig. 16-11). These arteries originate from the aorta, immediately above the aortic valve. The left main coronary artery has two major branches known as the left anterior descending (LAD) and the left circumflex artery (LCA). The LAD passes down the anterior wall of the left ventricle toward the apex of the myocardium. The LAD supplies blood flow to the anterior two thirds of the ventricular septum, the anterior left ventricle, the apex, and most of the bundle branches (Table 16-2).

The LCA, the other branch of the left main coronary artery, sits in the groove between the left atrium and the left ventricle and wraps around the posterior wall of the heart. The LCA supplies blood flow to the left atrium, the lateral wall of the left ventricle, and the posterior wall of the left ventricle. In about 10% of the population, the LCA is the source of blood flow to the posterior descending coronary artery; when this pattern of flow occurs, the patient is referred to as left dominant. Branches of the LCA provide blood flow to the SA node in about 45% of people and to the AV node in about 10% of people.

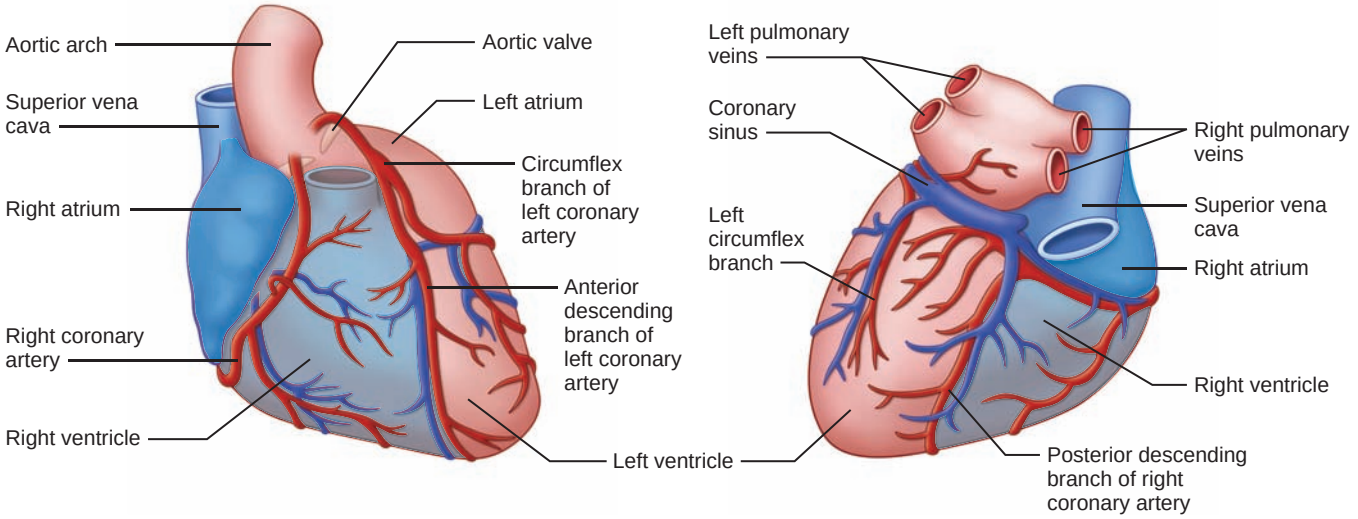

FIGURE 16-11 ▲ Coronary arteries and some of the coronary sinus veins. (Adapted from Porth CM: Pathophysiology: Concepts of Altered Health States, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 547.)

Table 16-2 Coronary Artery Blood Supply for Cardiac Muscle and Conducting System

Coronary Artery	Cardiac Muscle Supplied	Conducting Tissue Supplied
Left Main Coronary Artery		
Left anterior descending	Anterior ventricular septum Anterior left ventricle The apex	Bundle branches
Left circumflex	Left atrium Left ventricular lateral wall Left ventricular posterior wall	SA node in 45% of hearts AV node in 10% of hearts
Right Coronary Artery		
	Right atrium Right ventricle Posterior ventricular septum Inferior wall of left ventricle	SA node in 55% of hearts AV node in 90% of hearts

The right coronary artery (RCA) also comes off the aorta and branches toward the right atrium; the anterior, lateral, and posterior regions of the right ventricle; and the posterior ventricular septum. The RCA provides blood flow to the right atrium, the right ventricle, and the inferior wall of the left ventricle. In about 90% of the population, the RCA is the source of blood flow to the posterior descending coronary artery, a pattern of flow known as right dominant. The RCA supplies oxygenated blood to the SA node in about 55% of people and to the AV node in about 90% of people.

The coronary arteries initially supply the epicardial layer of the heart and then pass deeper into the heart muscle to provide blood flow to the endocardium. As a result of this flow pattern, poor coronary blood flow initially deprives the subendocardial area of oxygenated blood. If the interruption to flow continues, the effects of decreased oxygenation expand throughout the thickness of the wall of the heart to the subepicardial surface.

Because the coronary arteries derive from the aorta (above the aortic valve) and lie between myocardial fibers, blood flow through the coronary arteries occurs when the aortic valve is closed during ventricular diastole, not systole. Therefore, anything that decreases the diastolic time (eg, tachycardia) decreases coronary perfusion.

▲ Peripheral Circulation

The biological significance of the cardiovascular system is tissue perfusion. Such perfusion supplies the body's cells with oxygen and nutrients while carrying away metabolic wastes, including carbon dioxide. Tissue perfusion is directly proportional to the rate of blood flow, which depends on several factors. One factor is the difference between the mean arterial blood pressure and right atrial pressure (usually represented by the central venous pressure [CVP]). The greater this difference, the faster the flow rate (all else being unchanged). Conversely, if arterial pressure falls or venous pressure rises, flow rate, and thus tissue perfusion, will be decreased.

Another factor affecting flow rate is vascular resistance. The relationship between vascular resistance and blood flow has two general applications. The first describes the flow rate through vessels of differing diameters (eg, arteries, capillaries). The second concerns the ongoing regulation of blood flow by means of adjustments in arteriole diameters (ie, constriction, dilation). Arteriole constriction reduces the radius, thereby increasing resistance and decreasing the flow rate. Conversely, arteriole dilation increases the flow rate.

The other two factors that can affect the flow rate normally are held constant. They are the sum of all vessel lengths and blood viscosity. Because these factors do not normally change significantly, they usually are omitted from flow rate considerations. However, their relationships are obvious. The greater the length of a vessel, the more the resistance and thus the slower the flow rate. Also, the more viscous the blood, the slower the rate of its flow. Blood viscosity is determined by the proportion of solvent (water) to solute and other particles, including blood cells and platelets. The less water and more particles that exist, the more viscous is the blood. The complete equation that describes all four factors is as follows:

$$\text{Flow rate} = \frac{\text{mean arterial pressure} - \text{central venous pressure}}{(\text{resistance} \times \text{viscosity} \times \text{vessel length})}$$

Because blood volume and pressure have such an important influence on tissue perfusion, the factors that alter and regulate them are examined.

Blood Volume

Urinary output and fluid input are the major normal mechanisms for regulating volume. If output is greater or fluid input is less, the volume is less—if all else is held constant. Factors that alter the volume of urine excreted every 24 hours include those that alter the glomerular filtration rate and the tubular reabsorption of water, with or without electrolytes. (For a more detailed explanation of these factors see Chapter 42, specifically the discussion of normal endocrine physiology that considers the antidiuretic hormone.) Pathological conditions that promote any type of fluid loss (eg, burns, severe diarrhea, osmotic diuresis) or a shift of water from the vascular to the interstitial compartment have the potential to reduce blood volume.

Blood Pressure

Because the difference between arterial and venous pressures is the driving force for blood circulation and tissue perfusion, factors that influence CVP are examined first, followed by the factors that regulate arterial blood pressure. CVP is, strictly speaking, the pressure of blood in the venae cavae just before its entry into the right atrium. CVP can be increased by an increase in blood volume (eg, intravenous fluid overload) or a decrease in the pumping ability of the heart (eg, cardiac failure). Because the pulsatile effects of the cardiac cycle are removed by capillary networks, venous pressure is recorded as an average, or mean, and reported in millimeters of mercury (mm Hg).

Arterial blood pressure is the pressure of blood in the arteries and arterioles. It is a pulsatile pressure due to the cardiac cycle, and systolic (peak) and diastolic (trough) numbers are reported in millimeters of mercury. Average or mean arterial blood pressure can be clinically useful as an indicator of average perfusion pressures.

Arterial blood pressure is regulated by the vasomotor tone of the arteries and arterioles, the amount of blood entering the arteries per systole (ie, CO), and blood volume itself. The greater the volume or output, the greater the blood pressure, and vice versa, if vasomotor tone were held constant. The normal regulation of vasomotor tone involves neural and hormonal mechanisms.

Neural regulation is mediated by the vasomotor center of the medulla oblongata. This center consists of vasopressor and depressor subdivisions. The vasomotor center receives neural input from baroreceptors in the carotid sinuses and aorta, atrial diastolic stretch receptors, the limbic system and hypothalamus, the midbrain, and pulmonary stretch receptors. In addition, the center is directly responsive to local hypoxia or hypercapnia. Neural outputs from the vasopressor center result in increased sympathetic stimulation to arterial smooth muscle cells. This increase in sympathetic stimulation results in arterial constriction and an increase in arterial blood pressure. Stimulation of the depressor area decreases such sympathetic stimulation.

Rapid adjustments in arterial blood pressure are effected primarily by the baroreceptor reflexes. An increase in the pressure on these receptors (directly by elevated blood pressure or manual compression and indirectly by increased blood volume) reflexively stimulates the depressor area. This stimulation of the depressor area results in decreased sympathetic stimulation to major arteries and the aorta, which causes a decrease in arterial blood pressure. The decreased baroreceptor stimulation caused by a fall in arterial blood pressure reflexively stimulates the pressor area and results in increased sympathetic stimulation to arterial muscles, causing a rise in arterial blood pressure. Thus, homeostasis of arterial pressure is maintained.

In orthostatic hypotension, the baroreceptor reflex is sluggish. Because arterial pressure is not elevated rapidly enough, the postural change results in a temporary decrease in brain perfusion that leads, in extreme cases, to syncope.

Other factors may alter arterial blood pressure reflexively by their influences on the vasomotor center. Nerve fibers from the limbic system and hypothalamus are believed to mediate emotionally produced alterations in blood pressure. An example of this is fainting, caused by neurally mediated vasodilation in response to the sight of blood or very bad (or good) news. Neural inputs from the midbrain and possibly from ascending spinothalamic fibers in the medulla result in the elevation in arterial pressure that initially accompanies severe pain and in the later decrease in arterial pressure that occurs when severe pain is prolonged. Lung inflation stimulates pulmonary stretch receptors. Their input to the vasomotor center reflexively decreases arterial pressure. Hypercapnia and, to a lesser extent, hypoxia of vasomotor neurons stimulate the pressor area, reflexively causing an increase in arterial pressure. Such stimuli obviously are not part of a normal daily regulatory mechanism but can operate as a normal compensatory mechanism in certain pathological situations. Elevated intracranial pressure can promote medullary hypercapnia and hypoxia. The increase in arterial pressure reflexively produced by these stimuli (Cushing's reflex) increases medullary perfusion, which can ameliorate the medullary hypoxia, hypercapnia, or both. Hormonal regulation of arterial blood pressure is effected by adrenal medullary catecholamines and the renin–angiotensin system. In the former, adrenal medullary catecholamines mimic the action of sympathetic fibers innervating the muscle layer of arteries (tunica media), causing arterial constriction and elevating arterial pressure. The renin–angiotensin system is discussed in Chapter 28. Briefly, a decreased glomerular filtration rate, which can result, for example, from a decrease in blood volume or renal perfusion, stimulates the secretion of renin from the juxtaglomerular apparatus. This stimulation of renin leads to the production of angiotensin II, which acts directly on the tunica media to promote vasoconstriction. Thus, renin elevates arterial pressure, which increases renal perfusion and glomerular filtration.

Finally, arterial blood pressure can be influenced by alterations in the level of unbound calcium in tunica media cells. Such levels are influenced by factors that open or close calcium channels in the membranes of these muscle cells. Drugs that block calcium channels ("calcium blockers") inhibit the entry of calcium into cells. Such decreased calcium influx can lower intracellular calcium levels sufficiently to decrease muscle contractility, including contractility of the heart, thereby promoting a degree of vasodilation and lowering the arterial pressure.

▲ Clinical Applicability Challenges

SHORT ANSWER QUESTIONS

1. Mr. S. was diagnosed with failure of his SA node to fire. How will his heart be electrically excited if the SA node is not functioning?

2. Mrs. J. has been diagnosed with 90% occlusion of her left anterior descending (LAD) coronary artery. Describe which anatomical walls of the heart are affected. Explain which parts of her cardiac conducting system may be affected by the occlusion.

3. Ms. M. has a long history of systemic hypertension. Which of the factors that regulate SV are most affected by her history of hypertension?

17 Patient Assessment: Cardiovascular System

Patricia Gonce Morton, Kim Reck, Jillian Hamel, Amanda S. Walther, Kathryn T. Von Rueden, and Jan M. Headley

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Explain the components of the cardiovascular history.
2. Describe the steps of the cardiovascular physical examination.
3. Discuss the mechanisms responsible for the production of the first, second, third, and fourth heart sounds and their timing in the cardiac cycle.
4. Explain the attributes of heart murmurs.
5. Describe components of hematologic studies, coagulation studies, blood chemistries, and serum lipid studies.
6. Compare and contrast the usefulness of serum enzymes and myocardial proteins in diagnosing an acute myocardial infarction.
7. Describe current techniques used for diagnostic purposes in cardiology.
8. Discuss the nursing care and patient education before and after cardiac diagnostic studies.
9. Describe potential complications of cardiac diagnostic procedures.
10. Explain the major features of an electrocardiogram (ECG) monitoring system and steps to troubleshoot the system.
11. Describe the components of the ECG tracing and their meaning.
12. Explain the steps used to interpret a rhythm strip.
13. Describe the causes, clinical significance, and management for each of the dysrhythmias discussed.
14. Describe the parameters of a normal 12-lead ECG.
15. Define electrical axis, and determine the direction of the axis for a 12-lead ECG.
16. Explain the causes, clinical significance, and treatment of bundle branch blocks, atrial enlargement, and ventricular enlargement.
17. Describe the ECG changes associated with serum potassium and calcium abnormalities.
18. Describe the system components required to monitor hemodynamic pressures.
19. Analyze the characteristics of normal systemic arterial, right atrial, right ventricular, pulmonary artery, and pulmonary artery occlusion pressure waveforms.
20. State nursing interventions that ensure accuracy of pressure readings.
21. Discuss the major complications that can occur with an indwelling arterial, central venous, and pulmonary artery catheter.
22. Describe the thermodilution method of measuring cardiac output.
23. Describe alternative minimally invasive and noninvasive methods of obtaining hemodynamic data.
24. Evaluate the factors influencing oxygen delivery and consumption.
25. Use SvO_2 or $ScvO_2$ monitoring to assess oxygen delivery and consumption.

The application of complex technology to the assessment and management of cardiovascular and cardiopulmonary conditions has increased greatly in the past several decades. Use of advanced and complex technologies is an integral part of the care of critically ill patients. Nevertheless, the value of a comprehensive cardiovascular assessment should never be underestimated. The chapter begins with a discussion of the components of cardiovascular assessment that includes the cardiac history, physical examination, and laboratory and diagnostic studies. Among the studies in particular are electrocardiographic monitoring and hemodynamic monitoring.

CARDIAC HISTORY AND PHYSICAL EXAMINATION

The cardiovascular nursing assessment and health history provide physiological and psychosocial information that guides the physical assessment, the selection of diagnostic tests, and the choice of treatment options. During the history, the nurse asks about the patient's chief complaint and the history of the present illness, including a complete analysis of each sign and symptom. Next, the nurse asks about the patient's past health history, family history, and personal and social history. The history concludes with a review of systems that provides additional clues to the patient's health status. The information gathered during the history gives the nurse insight into risk factors and behaviors that promote or jeopardize cardiovascular health. The nurse uses this information to guide health teaching. During the process of taking a thorough history and performing a physical examination, the nurse has an opportunity to establish rapport with the patient and to evaluate the patient's general physical and emotional status.

▲ History

Chief Complaint and History of Present Illness

The nurse begins the history by investigating the patient's chief complaint, asking the patient to describe the problem or reason for seeking health care in his or her own words. The nurse then asks for more information about the present illness, using the NOPQRST format and the questions presented in Box 17-1. Answers to these questions are essential to understanding the patient's perception of the problem. To gain a better understanding of the current illness, the nurse also asks the patient about any associated symptoms, including chest pain, nausea or vomiting, dyspnea, edema of feet or ankles, palpitations, syncope or dizziness, cough and hemoptysis, nocturia, cyanosis, and extremity pain or paresthesias.

Chest Pain

Chest pain is one of the most common symptoms of patients with cardiovascular disease (CVD). Therefore, it is an essential component of the assessment interview. Chest pain is often a disturbing or even frightening experience for a patient, so the patient may be hesitant to initiate a discussion of chest pain. The questions listed in Box 17-1 are particularly useful when assessing chest pain because the answers help determine whether the pain is cardiac in origin.

BOX 17-1 Assessment Parameters: Questions to Ask in a Symptom Assessment

N Normal: Describe your normal baseline. What was it like before this symptom developed?
O Onset: When did the symptom start? What day? What time? Did it start suddenly or gradually?
P Precipitating and palliative factors: What brought on the symptom? What seems to trigger it—factors such as stress, position change, or exertion? What were you doing when you first noticed the symptom? What makes the symptom worse? What measures have helped relieve the symptom? What have you tried so far? What measures did not relieve the symptom?
Q Quality and quantity: How does it feel? How would you describe it? How much are you experiencing now? Is it more or less than you experienced at any other time?
R Region and radiation: Where does the symptom occur? Can you show me? In the case of pain, does it travel anywhere such as down your arm or in your back?
S Severity: On a scale of 0 to 10, with 0 being the absence of pain and 10 being the worst ever experienced, rate your symptom. How bad is the symptom at its worst? Does it force you to stop your activity and sit down, lie down, or slow down? Is the symptom getting better or worse, or staying about the same?
T Time: How long does the symptom last? How often do you get the symptom? Does it occur in association with anything, such as before, during, or after meals?

Because cardiac pain (angina pectoris) is the result of an imbalance between oxygen supply and oxygen demand, it usually develops over time. Typically, anginal pain does not start at maximal intensity. Not all chest pain is cardiac in origin, and careful reporting of the characteristics of the pain and the behaviors (or lack thereof) that precede the onset of pain is required. The nurse asks the patient about his or her normal baseline status before the symptoms developed. It is also important to ask about the onset of the symptoms to determine the date and time of the start of symptoms and whether the onset was sudden or gradual. Symptoms that may accompany chest pain caused by heart disease include nausea and vomiting.

Chest pain caused by coronary artery disease (CAD) is often precipitated by physical or emotional exertion, a meal, or being out in the cold. Palliative measures to relieve anginal pain may include rest or sublingual nitrates; these measures usually do not relieve the pain of a myocardial infarction (MI). The quality of cardiac chest pain is often described as heaviness, tightness, squeezing, or a choking sensation. If the pain is reported as superficial, knifelike, or throbbing, it is not likely to be anginal. Cardiac chest pain is usually located in the substernal region and often radiates to the neck, left arm, back, or jaw. Although the pain is often referred to other areas, anginal pain is visceral in origin, and most complaints include a reference to a "deep, inside" pain. When the patient is asked to point to the painful area, the painful area is about the size of a hand or clenched fist. It is unusual for true anginal pain to be localized to an area smaller than a fingertip. Using a scale of 0 to 10, with 10 being the worst pain the patient has ever experienced and 0 being the absence of pain, the patient is asked to rate the severity of the pain. When asked about time, the patient with cardiac chest pain reports the pain lasting anywhere from 30 seconds to hours.

Pain may be secondary to cardiovascular problems that are unrelated to a primary coronary insufficiency. Therefore, when obtaining the patient's history, the nurse must consider other causes. For example, if the patient reports the pain is made worse by lying down, moving, or deep breathing, it may be caused by pericarditis. If the pain is retrosternal and accompanied by sudden shortness of breath and peripheral cyanosis, it may be caused by a pulmonary embolism.

Dyspnea

Dyspnea occurs in patients with both pulmonary and cardiac abnormalities. In patients with cardiac disease, it is the result of inefficient pumping of the left ventricle, which causes a congestion of blood flow in the lungs. During history taking, dyspnea is differentiated from the usual breathlessness that follows a sudden burst of physical activity (eg, running up four flights of stairs, sprinting across a parking lot). Dyspnea is a subjective complaint of true difficulty in breathing, not just shortness of breath. The nurse determines whether the breathing difficulty occurs only with exertion or also at rest. If dyspnea is present when the patient lies flat but is relieved by sitting or standing, it is orthopnea. If dyspnea is characterized by breathing difficulties starting after approximately 1 to 2 hours of sleep and relieved by sitting upright or getting out of bed, it is paroxysmal nocturnal dyspnea.

Edema of the Feet and Ankles

Although many other problems can leave a patient with swollen feet or ankles, heart failure may also be responsible because the heart is unable to mobilize fluid appropriately. Because gravity promotes the movement of fluids from intravascular to extravascular spaces, the edema becomes worse as the day progresses and usually improves at night after lying down to sleep. Patients or families may report that shoes do not fit anymore, socks that used to be loose are now too tight, and the indentations from sock bands take more time than usual to disappear. The nurse inquires about the timing of edema development (eg, immediately after lowering the extremities, only at the end of the day, only after a significant salt intake) and duration (eg, relieved with temporary elevation of the legs or with constant elevation).

Palpitations and Syncope or Dizziness

Palpitations refer to the awareness of irregular or rapid heart beats. Patients may report the "skipping" of beats, a rushing of the heart, or a loud "thudding." The nurse asks about onset and duration of the palpitations, associated symptoms, and any precipitating events that the patient or family can remember. Because a cardiac dysrhythmia may compromise blood flow to the brain, the nurse asks about symptoms of dizziness, fainting, or syncope that accompany the palpitations.

Cough and Hemoptysis

Abnormalities such as heart failure, pulmonary embolus, or mitral stenosis may cause a cough or hemoptysis. Side effects of medications such as angiotensin-converting enzyme (ACE) inhibitors may also include a cough. The nurse asks the patient about the presence of a cough and inquires about the quality (wet or dry) and frequency of the cough (chronic or occasional, only when lying down or after exercise). If the cough produces expectorant, the nurse inquires about its color, odor, consistency, and amount perceived by the patient. If the patient reports spitting up blood (hemoptysis), the nurse asks if the substance spit up was streaked with blood, frothy bloody sputum, or frank blood (bright or dark).

Nocturia

Kidneys that are inadequately perfused by an unhealthy heart during the day may finally receive sufficient flow during rest at night to increase their output. The nurse asks about the number of times the patient urinates during the night. If the patient takes a diuretic, the nurse also evaluates frequency of urination in relation to the time of day the diuretic is taken.

Cyanosis

Cyanosis reflects the oxygenation and circulatory status of the patient. Central cyanosis is generally distributed and best found by examining the mucous membranes for discoloration and duskiness, and reflects reduced oxygen concentration. Peripheral cyanosis is localized in the extremities and protrusions (hands, feet, nose, ears, and lips) and reflects impaired circulation.

Extremity Pain or Paresthesias

Extremity pain results when the blood supply to exercising muscles is inadequate, and this type of pain is known as claudication. Usually, the cause of claudication is significant atherosclerotic obstruction to the lower extremities. The limb is asymptomatic at rest unless the obstruction is severe. Blood supply to the legs is inadequate to meet metabolic demands during exercise, and ischemic pain results. The patient describes a cramping, "charley horse" ache, or weakness in the foot, calf, thigh, or buttocks that improves with rest. The patient is asked to describe the severity of the pain and how much exertion is required to produce the pain.

Past Health History

The history includes information about the patient's past health. When assessing the patient's past health history, the nurse inquires about childhood illnesses and other previous illnesses, as well as past surgeries, previous diagnostic tests and interventions, medication use, allergies, and transfusions (Box 17-2). The nurse also asks about risk factors (Box 17-3, p. 210).[1,2]

Family History

The nurse asks about the age and health, or age and cause of death, of immediate family members, including parents, grandparents, siblings, children, and grandchildren. The nurse inquires about cardiovascular problems, such as CAD, hypertension, diabetes mellitus, sudden cardiac death, stroke, peripheral vascular disease, and lipid disorders (see Box 17-2).

Personal and Social History

Although the physical symptoms provide many clues regarding the origin and extent of cardiac disease, the personal and social history also adds to the patient's health status. An

BOX 17-2 HEALTH HISTORY for Cardiovascular Assessment

Chief Complaint
- Patient's description of the problem

History of the Present Illness
- Complete analysis of the following signs and symptoms (using the NOPQRST format; see Box 17-1, p. 207)
- Chest pain
- Nausea and/or vomiting
- Dyspnea
- Edema
- Palpitations
- Syncope/dizziness
- Cough and hemoptysis
- Nocturia
- Cyanosis
- Extremity pain or paresthesias

Past Health History
- Relevant childhood illnesses and immunizations: rheumatic fever, murmurs, congenital anomalies, streptococcal infections
- Past acute and chronic medical problems including treatments and hospitalizations: heart failure, hypertension, coronary artery disease (CAD), myocardial infarction (MI), hyperlipidemia, valve disease, cardiac dysrhythmias, diabetes mellitus, endocarditis, thrombophlebitis, deep venous thrombosis, peripheral vascular disease, chest injury, pneumonia, pulmonary embolism, thyroid disease, tuberculosis
- Risk factors: age, heredity, gender, race, tobacco use, elevated cholesterol, hypertension, physical inactivity, obesity, diabetes mellitus (see Box 17-3, p. 210)
- Past surgeries: coronary artery bypass grafting, valvular surgery, peripheral vascular surgeries
- Past diagnostic tests and interventions: electrocardiogram (ECG), echocardiogram, stress test, electrophysiology studies, myocardial imaging studies, thrombolytic therapy, cardiac catheterization, percutaneous transluminal cardiac angioplasty, stent placement, atherectomy, pacemaker or implantable cardioverter defibrillator implantation, valvuloplasty
- Medications, including prescription drugs, over-the-counter drugs, vitamins, herbs, and supplements: angiotensin-converting enzyme (ACE) inhibitors, anticoagulants, antihypertensives, antiplatelets, antiarrhythmics, angiotensin II receptor blockers (ARBs), β-blockers, calcium channel blockers, antihyperlipidemics, diuretics, electrolyte replacements, nitrates, inotropes, hormone replacement therapies, oral contraceptives
- Allergies and reactions to medications, foods, contrast dye, latex or other materials
- Transfusions, including type and date

Family History
- Health status or cause of death of parents and siblings: CAD, hypertension, diabetes mellitus, sudden cardiac death, stroke, peripheral vascular disease, lipid disorders

Personal and Social History
- Tobacco, alcohol, and substance use
- Family composition
- Occupation and work environment
- Living environment
- Diet: restrictions, supplements, caffeine intake
- Sleep patterns: number of pillows used
- Exercise
- Cultural beliefs
- Spiritual or religious beliefs
- Coping patterns and social support systems
- Leisure activities
- Sexual activity: use of agents for erectile dysfunction
- Recent travel

Review of Other Systems
- HEENT: retinal problems, visual changes, headaches, carotid artery disease
- Respiratory: shortness of breath, dyspnea, cough, lung disease, recurrent infections, pneumonia, tuberculosis
- Gastrointestinal: nausea, vomiting, weight loss, change in bowel habits
- Genitourinary: incontinence, erectile dysfunction
- Musculoskeletal: pain, weakness, varicose veins, change in sensation, peripheral edema
- Neurological: transient ischemic attacks, stroke, change in level of consciousness, changes in sensations
- Endocrine: thyroid disease, diabetes mellitus

understanding of the topics listed in Box 17-2 contributes to the nurse's knowledge of the patient as a person and guides interaction with the patient and family as well as patient education.

Review of Other Systems

The health history concludes with a review of relevant systems. This information gives the nurse a better understanding of the patient's total health status, and it also helps the nurse determine the impact of CVD on the functioning of other body systems (see Box 17-2).

▲ Physical Examination

Cardiac assessment requires examination of all aspects of the individual, using the standard steps of inspection, palpation, percussion, and auscultation. A thorough and careful examination helps the nurse detect subtle abnormalities as well as obvious ones.

Inspection

General Appearance

Inspection begins as soon as the patient and nurse interact. General appearance and presentation of the patient are key elements of the initial inspection. Critical examination reveals a first impression of age, nutritional status, self-care ability, alertness, and overall physical health. It is necessary to note the ability of the patient to move and speak with or without distress. Consider the patient's posture, gait, and musculoskeletal coordination.

Jugular Venous Distention

Pressure in the jugular veins reflects right atrial pressure (RAP) and provides the nurse with an indication of heart hemodynamics and cardiac function. The height of the level of blood in the right internal jugular vein is an indication of RAP because there are no valves or obstructions between the vein and the right atrium.

BOX 17-3 Risk Factors for Cardiovascular Disease

Major Uncontrollable Risk Factors

- **Age:** There is an increased incidence of all types of atherosclerotic disease with aging. More than 83% of people who die from CAD are age 65 or older. Women at older ages who have a MI are twice as likely as men to die of it within a few weeks.
- **Heredity (including race):** The tendency for development of atherosclerosis seems to run in families. The risk is thought to be a combination of environmental and genetic influences. Even when other risk factors are controlled, the chance for development of CAD increases when there is a familial tendency. African Americans have more severe hypertension than Caucasians and a higher risk of heart disease. The risk of heart disease is higher in Mexican Americans, American Indians, native Hawaiians, and some Asian Americans.
- **Gender:** Men have a greater risk for development of CAD than women at earlier ages. After menopause, women's death rate from MI increases but is not as great as men's.

Major Risk Factors That Can Be Modified, Treated, or Controlled

- **Tobacco smoking:** A smoker's risk for developing heart disease is two to four times that of nonsmokers. For smokers with coronary heart disease, cigarette smoking is a powerful independent risk factor for sudden cardiac death. Cigarette smoking, combined with other risk factors, greatly increases the risk of coronary heart disease. Exposure to smoke from others increases the risk of coronary heart disease for nonsmokers.
- **High blood cholesterol levels:** The risk for coronary heart disease increases as the blood cholesterol level rises. When other risk factors are present, this risk increases even more.
- **Hypertension:** Known as the "silent killer," hypertension is a risk factor with no specific symptoms and no early warning signs. Men have a greater risk for hypertension than women until the age of 55 years. The risk for development of hypertension is about the same for men and women between the ages of 55 and 75 years. After the age of 75 years, hypertension is more likely to develop in women than in men. African Americans are more likely to have hypertension than whites. Hypertension increases the risk for stroke, MI, kidney failure, and heart failure.
- **Physical inactivity:** A lack of physical exercise is a risk factor for CAD. Moderate to vigorous regular exercise plays a significant role in preventing heart disease and blood vessel disease. Even moderate-intensity exercise is beneficial if performed regularly and long-term. Physical activity also plays a role in controlling cholesterol, diabetes, obesity, and hypertension.
- **Obesity:** People who have excess body fat, especially at the waist, are more likely to develop heart disease and stroke even if they have no other risk factors. Excess weight raises blood pressure, blood cholesterol, and blood triglyceride levels. Excess weight lowers high-density lipids and makes diabetes more likely to develop.
- **Diabetes mellitus:** Even when blood glucose levels are under control, diabetes greatly increases the risk for heart disease and stroke. If blood glucose is not well controlled, the risk is even greater. Most people with diabetes die of some form of heart or blood vessel disease. Many people with diabetes also have high blood pressure, increasing their risk even more.

Other Contributing Factors

- **Stress:** A person's response to stress may be a contributing factor to heart disease. Stress in a person's life, his or her health behaviors, and socioeconomic status may all contribute to established risk factors. For example, individuals under stress may overeat, smoke, and not exercise.
- **Excessive alcohol intake:** Drinking too much alcohol can raise blood pressure, cause heart failure, lead to stroke, contribute to high triglycerides and obesity, and produce dysrhythmias. The risk for heart disease in individuals who drink moderate amounts of alcohol (an average of one drink for women and two drinks for men per day) is lower than in those who do not drink alcohol.

Adapted from American Heart Association: Risk Factors and Coronary Heart Disease and American Heart Association: Heart and Stroke Facts 2011 (see http://www. AHA.org).

The internal jugular veins are not directly visible because they lie deep to the sternomastoid muscles in the neck (Fig. 17-1). The goals of the examination are to determine the highest point of visible pulsation in the internal jugular veins, to note the level of head elevation, and to measure this point of visible pulsation as the vertical distance above the sternal angle. The patient is positioned supine in the bed with the head of the bed elevated 30, 45, 60, and 90 degrees. The patient is examined at each elevation with the head slightly turned away from the examiner. The nurse uses tangential light to observe for the highest point of visible pulsation.[3,4]

Next, the angle of Louis is located by palpating where the clavicle joins the sternum (suprasternal notch). The examining finger is slid down the sternum until a bony prominence is felt. This prominence is known as the angle of Louis. A vertical ruler is placed on the angle of Louis. Another ruler is placed horizontally at the level of the pulsation. The intersection of the horizontal ruler with the vertical ruler is noted, and the intersection point on the vertical ruler is read.

Normal jugular venous pulsation should not exceed 3 cm above the angle of Louis. See Figure 17-2 for an illustration of the procedure for assessment of jugular venous pressure. A level more than 3 cm above the angle of Louis indicates an abnormally high volume in the venous system. Possible causes include right-sided heart failure, obstruction of the superior vena cava, pericardial effusion, and other cardiac or thoracic diseases. An increase in the jugular venous pressure of more than 1 cm while pressure is applied to the abdomen for 60 seconds (hepatojugular or abdominojugular test) indicates the inability of the heart to accommodate the increased venous return.

Chest

The chest is inspected for signs of trauma or injury, symmetry, chest contour, and any visible pulsations. The inspection may reveal the location of the point of maximal impulse (PMI). In most patients, the apical pulse is the PMI; however, in some pathological conditions, these may be two distinct areas on the chest.[3] Thrusts (abnormally strong precordial pulsations) are noted. Any depression (sternum excavatum) or bulging of the precordium is recorded.

Extremities

A close inspection of the patient's extremities can also provide clues about cardiovascular health. The extremities

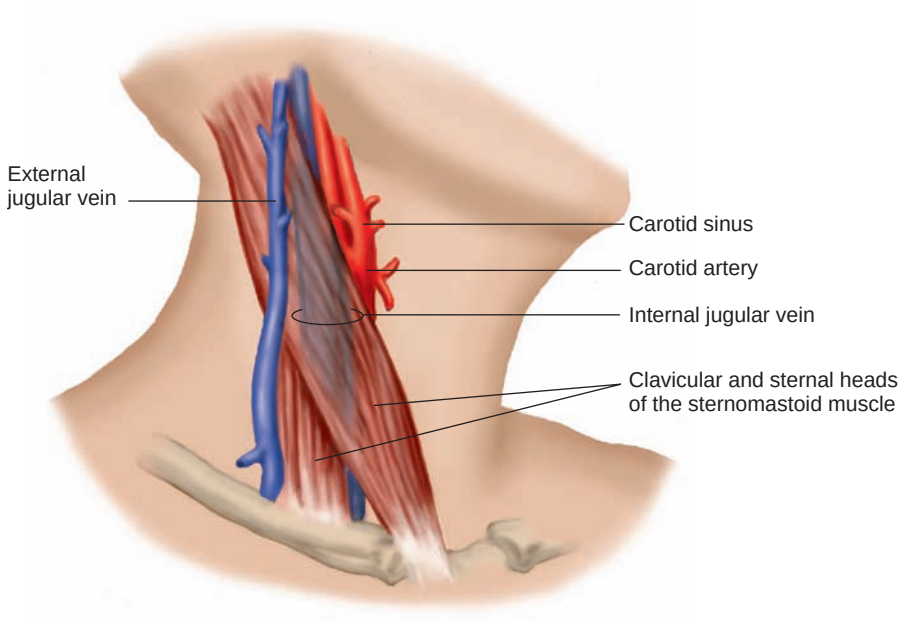

FIGURE 17-1 ▲ Internal jugular veins. (From Bickley L: Bates' Guide to Physical Examination and Health History, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 237.)

are examined for lesions, ulcerations, unhealed sores, and varicose veins. Distribution of hair on the extremities also is noted. A lack of normal hair distribution on the extremities may indicate diminished arterial blood flow to the area.

Skin

Skin is evaluated for moistness or dryness, color, elasticity, edema, thickness, lesions, ulcerations, and vascular changes. Nail beds are examined for cyanosis and clubbing, which may indicate chronic cardiac or pulmonary abnormalities. (For a further discussion of nail assessment, see Chapter 51). General differences in color and temperature between body parts may provide perfusion clues.

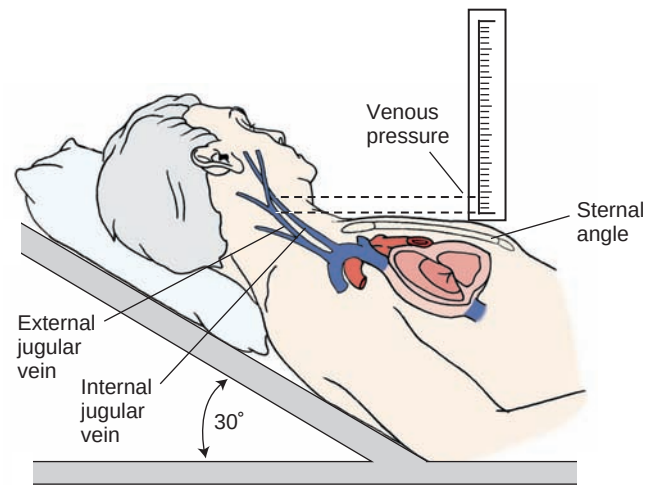

FIGURE 17-2 ▲ Assessment of jugular venous pressure. Place the patient supine in bed and gradually raise the head of the bed to 30, 45, 60, and 90 degrees. Using tangential lighting, note the highest level of venous pulsation. Measure the vertical distance between this point and the sternal angle. Record this distance in centimeters and the angle of the head of the bed.

Palpation

Pulses

Cardiovascular assessment continues with palpation and involves the use of the pads of the finger and balls of the hand. Using the pads of the fingers, the carotid, brachial, radial, femoral, popliteal, posterior tibial, and dorsalis pedis pulses are palpated (Fig. 17-3). The peripheral pulses are compared bilaterally to determine rate, rhythm, strength, and symmetry. The 0-to-4 scale described in Box 17-4 is used to rate the strength of the pulse. The carotid pulses should never be assessed simultaneously because this can obstruct flow to the brain.

Pulses can also be described according to their characteristics. For example, pulsus alternans is a pulse that alternates in strength with every other beat; it is often found in patients with left ventricular failure. Pulsus paradoxus is a pulse that disappears during inspiration but returns during expiration. To determine whether the condition is pathological, the sphygmomanometer is deflated until the pulse is heard only during expiration and the corresponding pressure noted. As the cuff continues to deflate, the point at which the pulse is heard throughout the inspiratory and expiratory cycle is noted. The second systolic pressure reading is subtracted from the first; if the difference is greater than 10 mm Hg during normal respirations, it is considered pathological. During the assessment of pulses, the nurse compares the warmth and size of the palpated areas to monitor perfusion.

Precordium

The chest wall is palpated to assess for the PMI, thrills, and abnormal pulsations. Palpation starts with locating the PMI. In most patients, the PMI represents the point at which the apical pulse is most readily felt. Using light pressure, the nurse first uses the palmar surface of the hand to feel for pulsations and then uses the pads of the finger to palpate the

FIGURE 17-3 ▲ **A:** Palpating the dorsalis pedis pulse. **B:** Palpating the posterior tibial pulse. (From Weber J, Kelley J: Health Assessment in Nursing, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 401.)

apical pulse (Fig. 17-4). The PMI is palpated, noting its location, diameter, amplitude, and duration. Usually, the PMI is located in the midclavicular line at about the fourth or fifth intercostal space. If the pulse is difficult to palpate, it may be necessary to ask the patient to turn on the left side (left lateral decubitus position).

Next, the nurse palpates the lower left sternal border area, the upper left sternal border area, the sternoclavicular area, the right upper sternal border area, the lower right sternal border area, and finally the epigastric area. During palpation of these areas, the nurse feels for a thrill, which is a palpable vibration. A thrill usually represents a disruption in blood flow related to a defect in one of the semilunar valves.

Percussion

With the advent of radiological means of evaluating cardiac size, percussion is not a significant contributor to cardiac assessment. However, a gross determination of heart size can be made by percussing for the dullness that reflects the cardiac borders.

BOX 17-4 Rating Scale Used for Assessing Strength of Pulses

0 Absent
1 Palpable but thready and weak, easily obliterated
2 Normal, not easily obliterated
3 Increased
4 Bounding, cannot obliterate

Auscultation

Data obtained by careful and thorough auscultation of the heart are essential in planning and evaluating care of the critically ill patient. In this section, the following topics are discussed: the basic principles underlying cardiac auscultation; the factors responsible for the production of normal heart sounds; and the pathophysiological conditions responsible for the production of extra sounds, murmurs, and friction rubs.

To facilitate accurate auscultation, the patient should be relaxed and comfortable in a quiet, warm environment with adequate lighting. The patient is placed in a recumbent position with the trunk elevated 30 to 45 degrees. To help hear abnormal sounds, the patient may be asked to roll partly onto the left side (left lateral decubitus position). This position helps bring the left ventricle closer to the chest wall. The patient also may be asked to sit up, lean forward, and exhale. In this position, it may be easier to hear murmurs caused by aortic regurgitation (Fig. 17-5).

A good-quality stethoscope is essential. The earpieces should fit the ears snugly and comfortably and follow the natural angle of the ear canals. Sound waves that travel a shorter distance are more intense and less distorted, therefore, the tubing of the stethoscope should be approximately 12 inches long and somewhat rigid. It is best to have two tubes leading from the head of the stethoscope, one to each ear. The head of the stethoscope should be equipped with both a diaphragm and a bell on a valve system that allows the clinician to switch easily between the two components. The diaphragm is used to hear high-frequency sounds, such as the first and second heart sounds (S_1, S_2), friction rubs, systolic murmurs, and diastolic insufficiency murmurs. The diaphragm should be placed firmly on the chest wall to create a tight seal. Low-frequency sounds, such as the third and

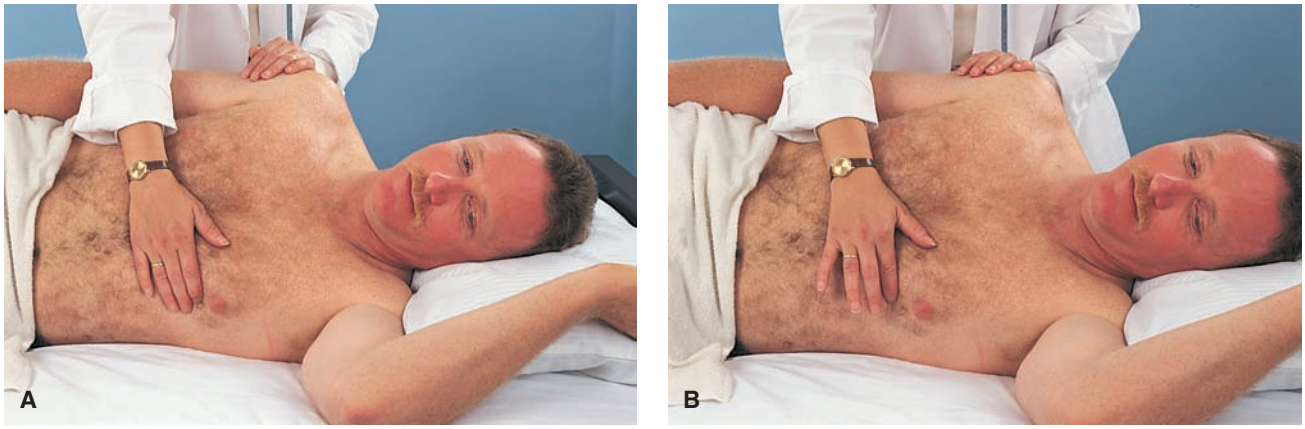

FIGURE 17-4 ▲ Locate the apical impulse with the palmar surface (**A**), then palpate the apical pulse with the fingerpad (**B**). (From Weber J, Kelley J: Health Assessment in Nursing, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 367.)

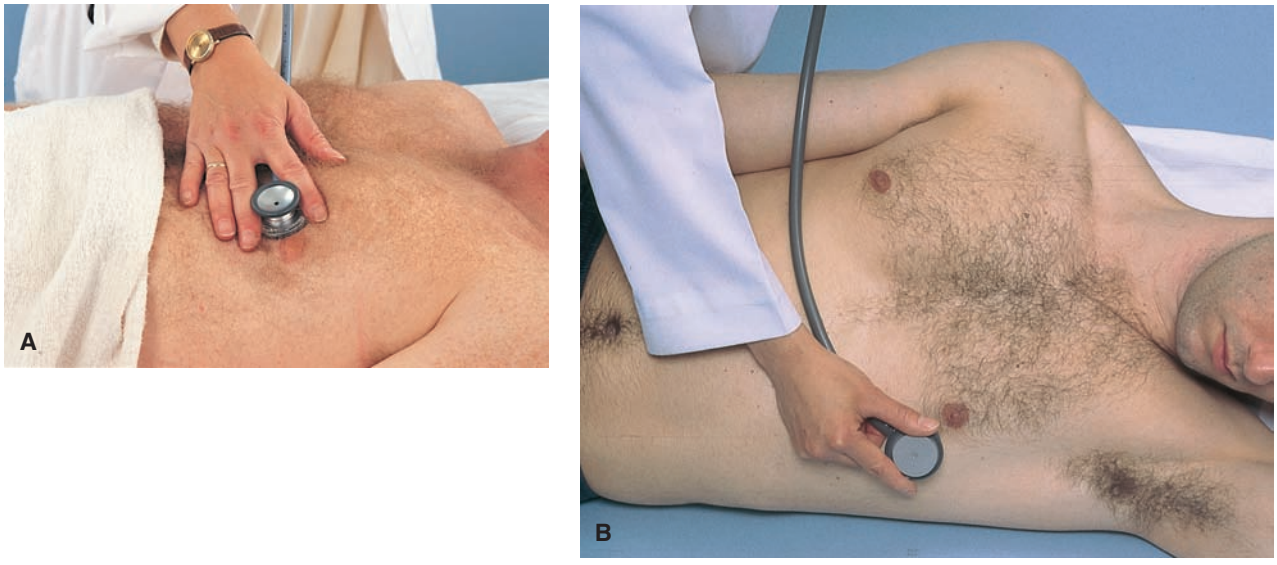

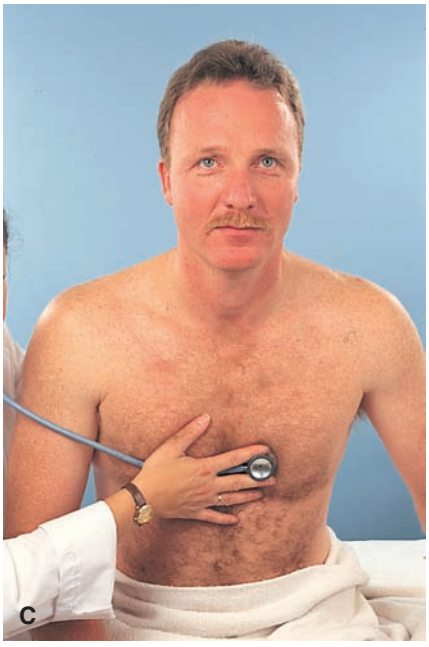

FIGURE 17-5 ▲ **A:** Auscultating the heart with the patient in a recumbent position. **B:** Auscultating the heart with the patient in a left lateral decubitus position. **C:** Auscultating the heart with the patient sitting up, leaning forward, and exhaling. (**A** and **C,** From Weber J, Kelley J: Health Assessment in Nursing, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 368–369. **B,** From Bickley L: Bates' Guide to Physical Examination and Health History, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 363.)

fourth heart sounds (S_3, S_4) and the diastolic murmurs of mitral and tricuspid stenosis, are best heard with the stethoscope bell, which should be placed lightly on the chest wall only to seal the edges.

The precordium is auscultated systematically (see Fig. 17-6). Some authorities suggest the use of anatomical names for the auscultation areas (eg, aortic and pulmonic), whereas others discourage the use of such labels because murmurs of more than one origin can be heard in a given area.[3,4] Instead, some suggest the use of anatomical landmarks such as intercostal spaces and relationship to the sternal border.[3,4]

The nurse begins the examination by listening with the stethoscope diaphragm in the right second intercostal space along the sternum. This area is sometimes called the aortic area and is the place where S_2 is loudest. Next, the nurse places the stethoscope in the left second intercostal space along the sternum, which is known as the pulmonic listening area, and from there moves the stethoscope down the left sternal border between the second and fifth spaces, one intercostal space at a time. The lower left sternal border area is sometimes referred to as the tricuspid area. Finally, the nurse moves the stethoscope to the mitral area or apex of the heart, where S_1 is the loudest. This pattern is then repeated with the stethoscope bell.

In each area auscultated, the nurse identifies S_1, noting the intensity of the sound, respiratory variation, and splitting. S_2 should then be identified and the same characteristics assessed. After S_1 and S_2 are identified, the presence of extra sounds is noted—first in systole, then in diastole. Finally, each area is auscultated for murmurs and friction rubs.

First Heart Sound

S_1 is timed with the closure of the mitral and tricuspid valves at the beginning of ventricular systole (Fig. 17-7A). Because mitral valve closure is responsible for most of the sound produced, S_1 is heard best in the mitral or apical area. The upstroke of the carotid pulse correlates with S_1 and can be used to help distinguish S_1 from S_2.

The intensity (loudness) of S_1 varies with the position of the atrioventricular (AV) valve leaflets at the beginning of ventricular systole and the structure of the leaflets (thickened or normal). A loud S_1 is produced when the valve leaflets are wide open at the onset of ventricular systole and corresponds to a short PR interval on the surface electrocardiogram (ECG) tracing. A lengthening of the PR interval produces a soft S_1 because the leaflets have had time to float partially closed before ventricular systole. Mitral stenosis also increases the intensity of S_1 due to a thickening of the valvular structures.

In general, S_1 is heard as a single sound. However, if right ventricular systole is delayed, S_1 may be split into its two component sounds. The most common cause of this splitting is delay in the conduction of impulses through the right bundle branch; the splitting correlates with a right bundle branch block (RBBB) pattern on the ECG. Splitting of S_1 is heard best over the tricuspid area.

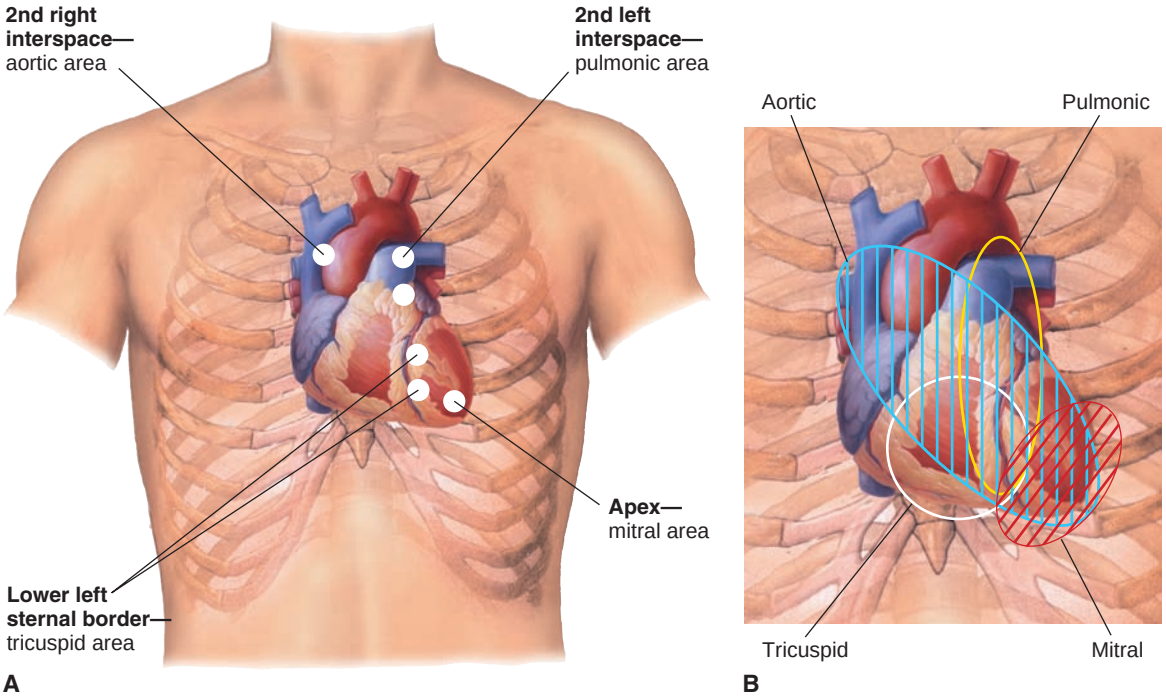

FIGURE 17-6 ▲ **A:** Areas of auscultation. Aortic area (second intercostal space to the right of the sternum). Pulmonic area (second intercostal space to the left of the sternum). Tricuspid area (fifth intercostal space to the left of the sternum). Mitral or apical area (fifth intercostal space, midclavicular line). **B:** Heart sounds and murmurs that originate in the four valves range widely. Use anatomical location rather than valve area to describe where murmurs and sounds are best heard. (**A** From Bickley L: Bates' Guide to Physical Examination and Health History, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 362. **B** Redrawn from Leatham: Introduction to the Examination of the Cardiovascular System, 2nd ed. Oxford, Oxford University Press, 1979.)

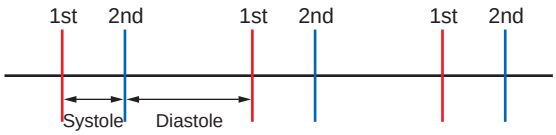
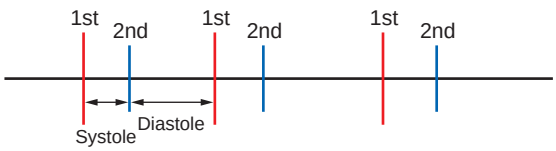
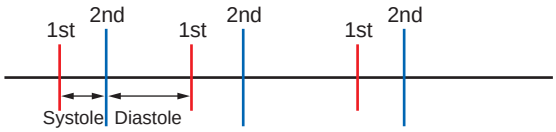


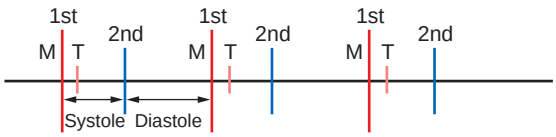
Normal: S_1 is produced by the closure of the AV valves and correlates with the beginning of ventricular systole. It is heard best in the apical or mitral area.



Loud First Sound: The intensity of the first heart sound may be incerased when the PR interval is shortened, as in tachycardia, or when the valve leaflets are thickened as in mital stenosis.

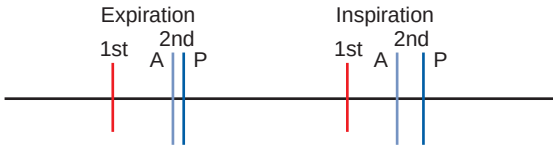


Soft First Sound: A soft S_1 is heard when the PR interval is prolonged.

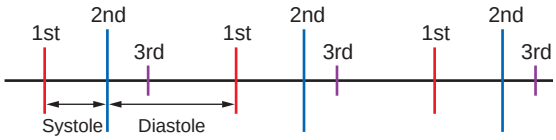


Split First Sound: A split S_1 is heard when right ventricular emptying is delayed. The mitral valve closes before the tricuspid valve and "splits" the sound into its two components.

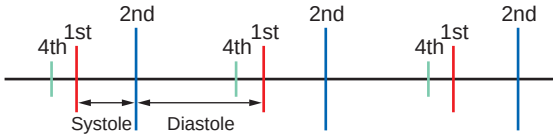
A. First heart sound (S_1)



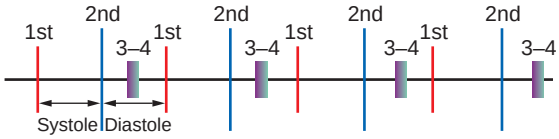
B. Second heart sound (S_2)



C. Third heart sound (S_3)



D. Fourth heart sound (S_4)



E. Summation gallop

FIGURE 17-7 ▲ A: First heart sound. **B:** Second heart sound. The second heart sound is produced by the closure of the semilunar valves (aortic and pulmonary). During inspiration, there is an increase in venous return to the right side of the heart, which causes a delay in the emptying of the right ventricle and the closure of the pulmonic valve. This allows the two components of the second heart sound to separate or split during inspiration. **C:** Third heart sound. An S_3 or ventricular gallop is heard in early diastole, shortly after the second heart sound. The presence of a pathological S_3 may be indicative of heart failure. **D:** Fourth heart sound. An S_4 is a late diastolic sound that occurs just before S_1. It is a low-frequency sound heard best with the bell of the stethoscope. **E:** Summation gallop. With rapid heart rates, S_3 and S_4 may become audible as a single, very loud sound that occurs in middiastole. This sound is a summation gallop.

Second Heart Sound

S_2 is produced by the vibrations initiated by the closure of the aortic and pulmonic semilunar valves and is heard best at the base of the heart (The term "base of the heart" is a clinical term that refers to the superior aspect of the heart at right and left second intercostal spaces next to the sternum.) (Fig. 17-7B). This sound represents the beginning of ventricular diastole.

Like S_1, S_2 consists of two separate components. The first component of S_2 is aortic valve closure; the second component is pulmonic valve closure. With inspiration, systole of the right ventricle is slightly prolonged because of increased filling of the right ventricle. This causes the pulmonic valve to close later than the aortic valve and S_2 to become "split" into its two components. This normal finding is termed physiological splitting and is heard best on inspiration with the stethoscope placed in the second intercostal space to the left of the sternum.

The intensity of S_2 may be increased in the presence of aortic or pulmonic valvular stenosis or with an increase in the diastolic pressure forcing the semilunar valves to close, as occurs in pulmonary or systemic hypertension.

Third Heart Sound

An S_3 may be physiological or pathological (Fig. 17-7C). A physiological S_3 is a normal finding in children and healthy young adults; it usually disappears after 25 to 35 years of age. An S_3 in an older adult with heart disease signifies ventricular failure.

An S_3 is a low-frequency sound that occurs during the early, rapid-filling phase of ventricular diastole. A noncompliant or failing ventricle cannot distend to accept this rapid inflow of blood. This causes turbulent flow, resulting in the vibration of

the AV valvular structures or the ventricles themselves, producing a low-frequency sound. An S_3 associated with left ventricular failure is heard best at the apex with the stethoscope bell. The sound may be accentuated by turning the patient slightly to the left side. A right ventricular S_3 is heard best at the xiphoid or lower left sternal border and varies in intensity with respiration, becoming louder on inspiration.

Fourth Heart Sound

An S_4 or atrial gallop is a low-frequency sound heard late in diastole just before S_1. It is rarely heard in healthy patients (Fig. 17-7D). The sound is produced by atrial contraction forcing blood into a noncompliant ventricle that, by virtue of its noncompliance, has an increased resistance to filling. Systemic hypertension, MI, angina, cardiomyopathy, and aortic stenosis all may produce a decrease in left ventricular compliance and an S_4. A left ventricular S_4 is auscultated at the apex with the bell of the stethoscope. Conditions affecting right ventricular compliance, such as pulmonary hypertension or pulmonic stenosis, may produce a right ventricular S_4 heard best at the lower left sternal border; it increases in intensity during inspiration.

Summation Gallop

With rapid heart rates, as ventricular diastole shortens, if S_3 and S_4 are both present, they may fuse together and become audible as a single diastolic sound. This is called a summation gallop (Fig. 17-7E). This sound is loudest at the apex and is heard best with the stethoscope bell while the patient lies turned slightly to the left side.

Heart Murmurs

Murmurs are sounds produced either by the forward flow of blood through a narrowed or constricted valve into a dilated vessel or chamber or by the backward flow of blood through an incompetent valve or septal defect. Murmur classification is based on several attributes (Box 17-5). Timing in the cardiac cycle is an important attribute that refers to the presence of the murmur during either systole or diastole. Systolic murmurs occur between S_1 and S_2. Diastolic murmurs occur after S_2 and before the onset of the following S_1. Location of maximum intensity refers to the anatomical location on the anterior chest where the sound of the murmur is heard the loudest. Anatomical landmarks are used to describe the radiation of the sound. The pitch of the sound helps further differentiate the type of murmur. The shape of the murmur refers to any changes in intensity over time. The intensity or loudness of a murmur is described using a grading system from 1 to 6. The quality of the sound produced is described as blowing, harsh, rumbling, vibratory, or musical. The effect of ventilation or a change in body position on the murmur is another important attribute.

Systolic Murmurs

As previously described, S_1 is produced by mitral and tricuspid valve closure and signifies the onset of ventricular systole. Murmurs occurring after S_1 and before S_2 are therefore classified as systolic murmurs.

During ventricular systole, the aortic and pulmonic valves are open. If either of these valves is stenotic or narrowed, a sound classified as a midsystolic ejection murmur is heard. Because the AV valves close before blood is ejected through the aortic and pulmonic valves, there is a delay between S_1 and the beginning of the murmur. The murmurs associated with aortic stenosis and pulmonic stenosis are described as crescendo–decrescendo or diamond shaped (Table 17-1), meaning that the sound increases and then decreases in intensity. The quality of these murmurs is harsh, and they are of medium pitch. The murmur caused by aortic stenosis is heard best in the aortic area and may radiate into the neck. The murmur of pulmonic stenosis is heard best over the pulmonic area. In severe pulmonic stenosis, S_2 may be widely split.

BOX 17-5 Attributes of Heart Murmurs

Timing: A systolic murmur is heard between S_1 and S_2. A diastolic murmur is heard between S_2 and S_1.
Systolic murmurs are classified into three groups:
Midsystolic murmur begins after S_1 and stops before S_2.
Pansystolic (holosystolic) murmur starts with S_1 and stops with S_2 without a gap between the murmur and the heart sound.
Late systolic murmur starts in mid to late systole and continues up to S_2.
Diastolic murmurs also are divided into three categories:
Early diastolic murmur starts right after S_2 and fades before the next S_1.
Middiastolic murmur starts a short time after S_2 and fades away or merges into a late diastolic murmur.
Late diastolic murmur starts late in diastole and continues up to S_1.
Location of maximal intensity: The anatomical location where the murmur is heard best. The location is identified based on intercostal space and its relation to the sternum, the apex, the mid-clavicular line, or one of the axillary lines.
Radiation or transmission from the point of maximal intensity: The nurse notes the site farthest from the location of the greatest intensity at which the sound is still heard. The farthest site is identified using anatomical landmarks as described previously.
Pitch: The terms *high, medium,* and *low* are used to describe the pitch of the murmur.
Shape: The shape of a murmur is determined by its intensity over time. A *crescendo murmur* grows louder. A *decrescendo murmur* grows softer. A *crescendo-decrescendo murmur* first rises in intensity, then falls. A *plateau murmur* has the same intensity throughout.
Intensity: A grading system is used to describe the intensity of the murmur.
Grade 1: barely audible in a quiet room, very faint; may not be heard in all positions.
Grade 2: quiet, but clearly audible.
Grade 3: moderately loud.
Grade 4: loud with palpable thrill.
Grade 5: very loud with an easily palpable thrill; may be heard when the stethoscope is partly off the chest.
Grade 6: very loud with an easily palpable thrill; may be heard with stethoscope entirely off the chest.
Quality: The terms such as *harsh, rumbling, vibratory, blowing,* and *musical* are used to describe the quality of the sound.
Ventilation and position: Note if the murmur is affected by inspiration, expiration, or a change in body position.

Table 17-1 Common Systolic and Diastolic Murmurs

Type	Possible Causes	Where to Auscultate	Radiation	Pitch	Shape	Quality	Ventilation and Position
Systolic Murmurs							
Aortic stenosis	Calcification, rheumatic fever, congenital malformation of valve cusps, degenerative process	Aortic area, right second intercostal space	Neck, upper back, right carotid, down the left sternal border to the apex	Medium	Crescendo–decrescendo May be diminished 	Harsh, may be musical at the apex	Heard best with the patient sitting and leaning forward, loudest during expiration
Pulmonic stenosis	Congenital malformation	Pulmonic area, second and third left intercostal spaces	Left side of neck, toward left shoulder	Medium	Crescendo–decrescendo 	Often harsh	Loudest during inspiration
Mitral regurgitation	Chronic rheumatic fever, acute bacterial endocarditis, myocardial ischemia or infarction, calcification, dilation of valvular apparatus secondary to dilated left ventricle (eg, heart failure), mitral valve prolapse	Mitral area, apex	Left axilla, less often to the left sternal border	Medium to high	Plateau Diminished 	Blowing, harsh	Heard best with patient in the left lateral decubitus position, does not become louder with inspiration
Tricuspid regurgitation	Right ventricular failure, dilation of valvular apparatus secondary to dilated right ventricle, bacterial endocarditis (rare)	Tricuspid area, lower left sternal border	Right sternal border, to the xiphoid area, and perhaps to the left midclavicular line, but not to the axilla	Medium	Plateau Diminished 	Blowing, harsh	May increase slightly with inspiration
Diastolic Murmurs							
Aortic regurgitation	Bacterial endocarditis, trauma, rheumatic fever, congenital malformation	Aortic area, right second intercostal space	Sternal border, apex	High	Decrescendo 	Blowing	Heard best with the patient sitting, leaning forward, with breath held after exhalation
Mitral stenosis	Rheumatic fever, congenital malformation (rare)	Mitral area, apex	Usually none	Low	Decrescendo–crescendo Loud 	Rumbling	Best heard with the patient in a left lateral position Mild exercise and listening during exhalation also make the murmur easier to hear

Systolic regurgitant murmurs are caused by the backward flow of blood from an area of higher pressure to an area of lower pressure. Mitral or tricuspid valvular insufficiency or a defect in the ventricular septum produces systolic regurgitant murmurs, which are harsh and blowing in quality. The sound is described as holosystolic, meaning that the murmur begins immediately after S_1 and continues throughout systole up to S_2 (see Table 17-1).

Mitral insufficiency produces a murmur, heard most easily in the apical area with radiation to the left axilla. The type of murmur associated with tricuspid regurgitation is heard loudest at the left sternal border and increases in intensity during inspiration (see Table 17-1). Both types of regurgitant murmurs are often accompanied by a diminished S_1.

Diastolic Murmurs

Diastolic murmurs occur after S_2 and before the next S_1. During diastole, the aortic and pulmonic valves are closed while the mitral and tricuspid valves are open to allow filling of the ventricles.

Aortic or pulmonic valvular insufficiency produces a blowing diastolic murmur that begins immediately after S_2 and decreases in intensity as regurgitant flow decreases through diastole. These murmurs are described as early diastolic decrescendo murmurs (see Table 17-1).

The murmur associated with aortic regurgitation is heard best in the aortic area and may radiate along the sternal border to the apex. Pulmonic valve regurgitation produces a murmur that is loudest in the pulmonic area.

Stenosis or narrowing of the mitral or tricuspid valve also produces a diastolic murmur. The AV valves open in middiastole shortly after the aortic and pulmonic valves close, causing a delay between S_2 and the start of the murmur of mitral and tricuspid stenosis. This murmur decreases in intensity from its onset and then increases again as ventricular filling increases because of atrial contraction; this is termed decrescendo–crescendo (see Table 17-1).

The murmur associated with mitral stenosis is heard best at the apex with the patient turned slightly to the left side. Tricuspid stenosis produces a murmur that increases in intensity with inspiration and is loudest in the fifth intercostal space along the left sternal border.

Friction Rubs

A pericardial friction rub can be heard when the pericardial surfaces are inflamed. This high-pitched, scratchy sound is produced by these inflamed layers rubbing together. A rub may be heard anywhere over the pericardium with the diaphragm of the stethoscope. The rub may be accentuated by having the patient lean forward and exhale. A pericardial friction rub, unlike a pleural friction rub, does not vary in intensity with respiration.

CARDIAC LABORATORY STUDIES

Knowledge of the purpose and significance of laboratory values in relation to the diagnosis and prognosis of CVD can enhance the quality of nursing care available to patients. Laboratory studies include both routine serum analysis and special studies, such as serum and cardiac enzymes. Nurses who have a basic understanding of laboratory studies can exercise judgment in interpreting results relative to other information about the patient. The ability to use this kind of judgment may well affect the patient's clinical course or prognosis.

▲ Routine Laboratory Studies

Appropriate assessment of normal and compromised cardiac function is essential to ensure accurate evaluation and correct diagnosis of the patient experiencing symptoms consistent with a cardiovascular disorder or CAD. Nurses can more appropriately plan the care of the patient and initiate interventions if they have an understanding of these laboratory tests and recognize their implications. Valuable information may be obtained by assessing levels of hematological components, coagulation factors, electrolytes, and phospholipids. Determination of these laboratory studies may vary with institutional techniques and equipment used. Normal and abnormal assay ranges have been universally established, and a brief listing of frequently ordered laboratory studies with their normal values can be found in Table 17-2. A more extensive explanation of the effects of abnormal laboratory determinations is provided in other parts of this text and is not addressed here.

Hematological Studies

Accurate assessment of the patient with a possible cardiac disorder merits review of hematological function. It is important for the critical care nurse to understand the role of blood cells in cardiac function and their contribution to the maintenance of healthy tissue. Blood is the transport medium for nutrients, such as oxygen and glucose, as well as electrolytes, plasma proteins, hormones, and medications. It is also the vehicle for removal of the products of metabolism. Changes in blood cell integrity and total cell count may reflect specific disorders of the cardiac system and should be considered an integral part of the laboratory assessment.

Knowledge of normal blood values is vital to understand deviations from normal that can be seen with various cardiac disruptions. It is necessary to review both the red blood cell count, which assesses cellular nutrition, and the white blood cell (WBC) count, which assesses defensive capability against infections, when diagnosing specific insults. Table 17-2 lists the components of these helpful hematological studies.

Coagulation Studies

Coagulation studies are also warranted in the laboratory assessment of patients with cardiac disease. Establishment of a baseline for coagulation function provides important information about the patient's ability to form, maintain, and dissolve blood clots. Such information may prove

Table 17-2 **Normal Reference Ranges for Laboratory Blood Tests**

Blood Test	Reference Range
Hematological Studies	
Red blood cell count	
Men	4.6–6.2 × 10^6
Women	4.2–5.4 × 10^6
Hematocrit	
Men	40%–50%
Women	38%–47%
Hemoglobin	
Men	13.5–18.0 g/100 mL
Women	12.0–16.0 g/100 mL
Corpuscle indices	
Mean corpuscular volume	82–98 FL
Mean corpuscular hemoglobin	27–31 pg/cell
Mean corpuscular hemoglobin concentration	32%–36%
White blood cell count	
Total	4,500–11,000/mm^3
Differential (in number of cells/mm^3 blood)	
Total leukocytes	5,000–10,000 (100%)
Total neutrophils	3,000–7,000 (60%–70%)
Lymphocytes	1,500–3,000 (20%–30%)
Monocytes	375–500 (2%–6%)
Eosinophils	50–400 (1%–4%)
Basophils	0–50 (0.1%)
Sedimentation rate	0–30 mm/h
Coagulation Studies*	
Platelet count	250,000–500,000/mm^3
Prothrombin time	12–15 s
Partial thromboplastin time	60–70 s
Activated partial thromboplastin time	35–45 s
Activated clotting time	75–105 s
Fibrinogen level	160–300 mg/dL
Thrombin time	11.3–18.5 s
Blood Chemistries	
Serum electrolytes	
Sodium	135–145 mEq/L
Potassium	3.3–4.9 mEq/L
Chloride	97–110 mEq/L
Carbon dioxide	22–31 mEq/L

Blood Test	Reference Range
Blood Chemistries (cont.)	
Blood gases	
pH	7.35–7.45
PaO_2	80–105 mm Hg
$PaCO_2$	35–45 mm Hg
Bicarbonate	22–29 mEq/L
Base excess, deficit	0 ± 2.3 mEq/L
SaO_2	98%
$Sv–CO_2$	75%
Bilirubin	
Total	0.2–1.3 mg/dL
Direct	0–20 mg/dL
Calcium	
Total	8.9–10.3 mg/dL
Free (ionized)	4.6–5.1 mg/dL
Creatinine	
Men	0.9–1.4 mg/dL
Women	0.8–1.3 mg/dL
Glucose (fasting)	65–110 mg/dL
Magnesium	1.3–2.2 mEq/L
Phosphorus	2.5–4.5 mg/dL
Phosphatase, alkaline	35–148 units
Protein (total)	6.5–8.5 g/dL
Urea nitrogen	8–26 mg/dL
Uric acid	65–110 mg/dL
Men	4.0–8.5 mg/dL
Women	2.8–7.5 mg/dL
Serum Enzymes*	
CK-MM	95%–100%
CK-MB	0%–5%
CK-BB	0%
Aspartate aminotransferase	<50 units/L
Myocardial Proteins	
Troponin-I	<0.1 ng/mL
Troponin-T	<0.1 mcg/mL
Myoglobin	
Men	20–90 ng/mL
Women	10–75 ng/mL

instrumental in patient care decisions. This is especially true in relation to the administration of anticoagulation agents, whether for long-term management, such as warfarin for the management of atrial fibrillation, or for emergency interventions, such as the use of fibrinolytic therapy during an acute MI. Coagulation studies are listed in Table 17-2.

Blood Chemistries

Mechanisms that ensure homeostatic function at the cellular and tissue level depend on the appropriate production and modulation of intracellular and extracellular electrolytes. It is important that the nurse understand normal electrolyte functions and the unique, perhaps life-threatening, situations that may occur when they are significantly abnormal. A thorough analysis of basic electrolyte chemistries is always appropriate in screening of the patient with cardiac disease, whether in the inpatient or outpatient setting. These studies are almost universally obtained during the initial clinical examination. The blood chemistries most commonly assessed are sodium, potassium, chloride, carbon dioxide, calcium, glucose, magnesium, and phosphorus. Table 17-2 provides the normal assay values for common electrolytes.

Common Electrolytes

Sodium is the most abundant cation in the body. It is essential in the maintenance of acid–base balance and osmolality of extracellular fluids as well as in the transmission of nerve impulses. It plays a pivotal role in fluid balance, and its concentration is primarily regulated by the kidneys. Significant alterations of cellular function are evident when sodium levels are lower than normal (hyponatremia) or greater than normal (hypernatremia).

Potassium is the major intracellular cation. Its role in the evaluation of cardiac patients is important because it is released when cells are damaged. It is essential for maintenance of oncotic pressure, intracellular osmolality, and acid–base balance, as well as for its role in cellular reactions. In addition, potassium is vital to the normal functioning of skeletal, smooth, and cardiac muscle. It is particularly important in the regulation of cardiac rate and force of contraction.

Chloride is another major extracellular cation. Like sodium and potassium, it plays a role in acid–base balance and is an important component in the evaluation of acid–base balance.

The carbon dioxide electrolyte is a reflection of carbon dioxide content (mainly bicarbonate), not carbon dioxide gas. In some settings, carbon dioxide is reported as bicarbonate (HCO_3^-).

Other Blood Chemistries

Calcium, like potassium, is important for cardiac function. It plays a significant role in the initiation and propagation of electrical impulses and in myocardial contractility. It is also important for blood clotting, teeth and bone formation, and intracellular energy production. Ionized calcium (free calcium) is responsible for cardiac and neuromuscular excitability. Calcium is reported as total and free (ionized) values.

Glucose levels are important to monitor with baseline laboratory studies because they reflect the nutritive status of the cell. Alterations in glucose, such as in diabetes mellitus, can provide the clinician with both diagnostic as well as prognostic information.

Magnesium is the second major intracellular cation after potassium. It is important in many metabolic processes and is necessary for the normal functioning of the neuromuscular system. It facilitates enzyme activities that help maintain protein synthesis and metabolism, carbohydrate and lipid metabolism, and nucleic acid synthesis. Alterations in normal magnesium levels are reflected in disruptions in neuromuscular activity, such as in the patient with dysrhythmia.

Phosphorus reflects levels of serum phosphate. It is controlled by the parathyroid gland and regulated in the kidneys. Phosphate is important for normal cellular function and for oxygen delivery. It is reciprocal to calcium. Abnormalities can be seen with alterations in heart rate, alterations in neuromuscular function, and reciprocal changes in serum calcium.

Serum Lipid Studies

A review of serum lipid levels is a critical part of the information needed by the nurse to assess cardiovascular risk in any given patient. Patients without a history of CAD need lipid analysis for primary prevention (ie, prevention of the development of CAD). Patients with a new or past history of CAD need lipid analysis for secondary prevention to prevent progression of known disease after a cardiac event. Standard elements of a lipid profile are total cholesterol, low-density lipoprotein (LDL) cholesterol, very–low-density lipoprotein (VLDL) cholesterol, high-density lipoprotein (HDL) cholesterol, and triglycerides. All treatment of lipids for primary and secondary prevention is based on LDL cholesterol.

In 2004, the American Heart Association (AHA) and American College of Cardiology (ACC) updated their guidelines for care of patients with a history of coronary and other atherosclerotic diseases.[5,6] Their guidelines, along with the National Cholesterol Education Program (NCEP) Adult Treatment Panel (ATP) III, set standards for identification and treatment of elevated cholesterol in patients with and without known CAD.[7] Patients who present with a suspected or confirmed acute cardiovascular or coronary event should have a lipid panel sent to a laboratory within 24 hours of presentation. The nurse is ideally positioned to advocate for this element of care.

Cholesterol, a pearly, fatlike substance, is a precursor of bile acids and steroid hormones. Most of the body's cholesterol is synthesized in the liver, but some is absorbed from the diet. The NCEP III recommends total cholesterol less than 200 mg/dL to lower the probability of CAD in patients with no history of cardiac disease, and to slow the progression of disease in patients with known CAD. Patients with known CAD should have a blood cholesterol less than 160 mg/dL.[7]

LDLs constitute 60% to 70% of the total cholesterol in the bloodstream. Based on numerous large-scale studies, LDL cholesterol is known to be directly correlated with the development of CAD and subsequent CVD in susceptible individuals. The target LDL cholesterol is less than 130 mg/dL as primary prevention and less than 100 mg/dL as secondary prevention; values less than 70 mg/dL are considered reasonable.[7]

Triglycerides originate from VLDLs. Although VLDL cholesterol is not considered to be atherogenic, elevated levels can be a marker for a genetic form of cholesterol disorder. The NCEP ATP III recommends treatment of triglycerides above 500 mg/dL because of the association between hypertriglyceridemia and pancreatitis.[7]

Standard cholesterol tests measure only the percentages of the lipid elements mentioned previously. Particles of LDL cholesterol and HDL cholesterol come in various sizes, and accumulating data suggest that particle size affects atherogenicity. Particle sizes are measured by a test called subfraction analysis, which is used most frequently as an investigative tool and a guide for therapy in patients with known CAD. This test has become increasingly available. It costs about $100 and may not be covered by insurance unless the patient has a diagnosis of CAD.

Table 17-3 summarizes the various serum cholesterol levels, and Table 17-4 describes lipid abnormalities and associated mechanisms.

▲ Enzyme Studies

Enzymes are found in all living cells and act as catalysts in biochemical reactions. They are present in low amounts

Table 17-3 Serum Cholesterol Levels

Cholesterol Level (mg/dL)	Description
Low-Density Lipoprotein	
<100 (<70)	Optimal (optional)
100–129	Near or above optimal
130–159	Borderline high
160–189	High
190 or more	Very high
Total Cholesterol	
<200	Desirable
200–239	Borderline high
240 mg/dL or more	High
High-Density Lipoprotein	
<40	Low
60 or more	High
Serum Triglycerides	
<150	Normal
150–199	Borderline high
240–499	High
500 or more	Very high

From Grundy SM, Cleeman JI, Merz NB, et al: Implications of Recent Clinical Trials for the National Cholesterol Education Program Adult Treatment Panel III Guidelines. Circulation 110:227–239, 2004

Table 17-4 Lipid Abnormalities and Associated Mechanisms

Lipid Abnormality	Mechanisms
Elevated total cholesterol	High dietary intake of saturated fat and cholesterol LDL receptor deficiency or downregulation
Elevated LDL cholesterol	LDL receptor deficiency Apoprotein B-100 genetic defect High dietary intake of saturated fat and cholesterol
Elevated triglycerides	Deficiency in lipoprotein lipase Obesity, physical inactivity, insulin resistance, glucose intolerance Excessive alcohol intake
Low HDL	Apoprotein A-1 deficiency Reduced VLDL clearance Cigarette smoking, physical inactivity Insulin resistance Elevated triglycerides Overweight and obesity Very high CHO intake (more than 60% total calories), certain drugs (beta-blockers, anabolic steroids, progestational agents)
Increased lipoprotein remnants	
(VLDL is a surrogate marker for lipoprotein remnants when Tg is more than 200 mg/dL)	Defective apolipoprotein E, seen in familial combined hyperlipidemia
Lipoprotein(a)	Level is genetically determined
Small LDL particles	Particle size is determined by level of Tg; LDL particle is denser and more atherogenic at higher levels of Tg
HDL subspecies	Low levels of HDL 2 and 3 may increase CVD risk, genetically determined vs. lifestyle and other lipid levels
Apolipoprotein B	May be potential marker for all atherogenic lipoprotein
Apolipoprotein A-1	Increased CVD risk when Apo A-1 is low
Combined dyslipidemias small, dense LDL, high triglycerides, low HDL, elevated LDL and triglycerides	Defects in VLDL and LDL receptor activities coexisting with environmental influences such as obesity, physical inactivity, diet high in saturated fat, and cigarette smoking

HDL, high-density lipoprotein; LDL, low-density lipoprotein; Tg, triglycerides; VLDL, very-low-density lipoprotein; CHO, cholesterol; CVD, cardiovascular disease

in the serum of healthy people. However, when cells are injured, enzymes leak from damaged cells, resulting in serum enzyme concentrations greater than the usual low levels. No single enzyme is specific to the cells of a single organ. Each organ contains a variety of enzymes, and there is considerable overlap among organs in the enzymes they contain. However, the distribution of enzymes in the cells of organs is relatively organ specific. When organ damage occurs, the presence of abnormally high levels of enzymes in the serum, their distribution, and the timing of their appearance and disappearance make the clinical use of serum enzyme studies relevant.

Cardiac enzymes are enzymes found in cardiac tissue. When cardiac injury occurs, as in acute MI, these enzymes are released into the serum, and their concentrations can be measured (Fig. 17-8). Cardiac tissue enzymes are present in other organs as well, so elevation of one or more of these enzymes is not a specific indicator of cardiac injury. However, because cardiac damage does result in above-normal serum concentrations of these enzymes, the quantification of cardiac enzyme levels, along with other diagnostic tests and the clinical presentation of the patient, is routinely used for diagnosing cardiac disease, particularly acute MI.

The challenge is to identify an enzyme or "marker" that correctly identifies cardiac cell death. In essence, a cardiac marker is a surrogate for thrombus formation in the coronary arteries. An ideal marker for cardiac injury should have several important characteristics. It should be easy to measure; be inexpensive; be cardiac specific, with a direct proportional relationship between the extent of myocardial injury and the measured level of the marker (zero blood concentration in the absence of cardiac injury); have rapid serum levels after the onset of injury; and stay in the serum long enough to be measured in patients who delay seeking

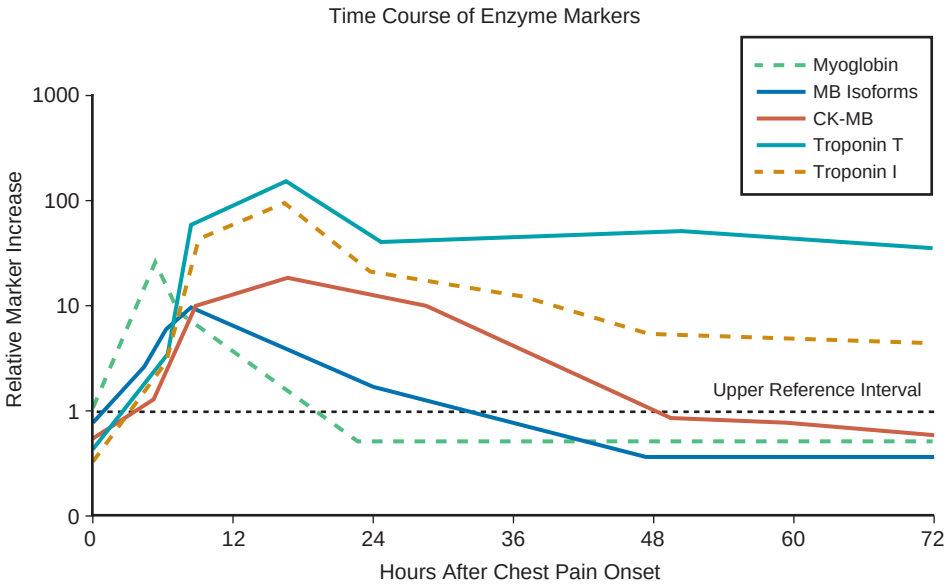

FIGURE 17-8 ▲ Peak elevation and duration of serum enzymes after acute myocardial infarction. (Data from Antman EM: Acute myocardial infarction. In Braunwald E [ed]: Heart Disease: A Textbook of Cardiovascular Medicine, 5th ed. Philadelphia, PA: WB Saunders, 1997, pp 1184–1228.)

treatment. No available biomarkers fit these criteria, but troponins, discussed later in this text, have several important features, making them the most useful of the biomarkers at present.

Creatine Kinase

Creatine kinase (CK) is an enzyme that is found in heart muscle, skeletal muscle, and brain tissue. CK values start rising 4 to 6 hours after the onset of myocardial necrosis, typically peak at 18 to 24 hours, and return to baseline at 36 to 40 hours. To rule out an MI, blood samples may be drawn every 8 hours for 24 hours. Given the wide tissue distribution of CK, the currently published guidelines of the ACC/AHA do not recommend serial measurements of total CK to diagnose MI.[8] However, total CK remains a relevant test because it provides the basis for calculation of the mass of the more specific CK enzymes.

The three CK isoenzymers routinely reported are CK-MM, CK-MB, and CK-BB, which are found in skeletal muscle, heart muscle and brain, respectively. CK-MB in amounts greater than 5% of total CK generally is considered diagnostic for myocardial damage in the presence of chest pain or other symptoms believed to represent myocardial ischemia. Negative values 10 to 12 hours after the onset of pain indicate the absence of myocardial necrosis. Patients who present more than 24 hours after the onset of symptoms may not benefit from measurement of CK isoenzymes because the levels already may have returned to normal (see Table 17-5). Cardiac disorders other than MI, and some noncardiac disorders can elevate CK and CK-MB (see Box 17-6).

▲ Biochemical Markers: Myocardial Proteins

Troponins are cardiac proteins that are released into the circulation after necrosis and rupture of myocardial cells.

Table 17-5 Molecular Biomarkers for the Evaluation of Patients With ST-Elevation Myocardial Infarction

Biomarker	Range of Times to Initial Elevation	Mean Time to Peak Elevations (Nonreperfused)	Time to Return to Normal Range
Frequently used in clinical practice			
CK-MB	3–12 h	24 h	48–72 h
cTnI	3–12 h	24 h	5–10 d
cTnT	3–12 h	12 h to 2 d	5–14 d

CK-MB, MB isoenzyme of creatine kinase; cTnI, cardiac troponin I; cTnT, cardiac troponin T.

J Am Coll Cardiol 54:2205–2241, 2009.

BOX 17-6 Other Causes of CK-MB Elevation

- Pericarditis
- Myocarditis
- Cardioversion
- Defibrillation
- Prolonged supraventricular tachycardia
- Hypothyroidism
- Myocardial contusion
- Collagen disorders
- Alcoholism
- Cardiac surgery

Three subforms have been identified: cardiac troponin-I (cTnI), troponin-T (cTnT), and troponin-C (cTnC). Both cTnI and cTnT are highly specific to cardiac tissue. Assays for both isoforms have become increasingly sensitive, and very minute elevations of the troponins can be detected. Both cTnI and cTnT have equal sensitivity and specificity in detecting myocardial necrosis. Some clinicians believe that very low troponin values in the absence of CK-MB elevations indicate minor myocardial damage, but may be markers for other conditions that can cause troponin elevations (see Box 17-7).[8] In critically ill patients, elevated troponins signify a worse overall outcome.

▲ Neurohumoral Hormones: Brain-Type Natriuretic Peptide

Brain-type natriuretic peptides (BNP) and pro-BNP are neurohormonal hormones released by the heart in response to decompensation. BNP and pro-BNP are sometimes used in evaluating patients with heart failure. BNP and pro-BNP are discussed more thoroughly in Chapter 20.

▲ Newer Diagnostic Markers

C-reactive protein, a newer marker of inflammation and necrosis, has been implicated as a factor that can cause disruption of fibrous cap lesions underlying acute coronary events. An acute-phase protein and marker of systemic inflammation, C-reactive protein has been shown to be elevated in patients with acute coronary syndromes. Normal values are 0 to 2 mg/dL. Serum values greater than 3 mg/dL in patients with acute coronary syndrome or greater than 5 mg/dL in patients after a coronary interventional procedure may indicate a higher risk and merit closer monitoring or more thorough evaluation.[9,10]

D-dimer is another physiological marker that may be useful in predicting the risk for cardiac events. It represents the end product of thrombus formation and dissolution that occurs at the site of active plaques in acute coronary syndromes; this process precedes myocardial cell damage and release of protein contents.[11] This marker has also been extensively studied for the diagnosis of deep venous thrombosis and pulmonary embolism. Although D-dimer can be elevated in MI and congestive heart failure, it is being used more commonly to detect other organ thromboembolic events.

BOX 17-7 Other Conditions Causing Troponin Elevations

- Sepsis/Systemic Inflammatory Response Syndrome
- Hypovolemia
- Supraventricular tachycardia
- Stroke
- Heart failure
- Pulmonary embolism
- Myocarditis
- Pulmonary hypertension
- Myocardial contusion
- Renal failure
- Left ventricular hypertrophy
- Chronic obstructive pulmonary disease

CARDIAC DIAGNOSTIC STUDIES

Cardiovascular diagnostic techniques have expanded dramatically in the past few years, especially in the area of noninvasive testing. The critical care nurse often cares for patients who undergo one or more of these procedures. Understanding the principles on which the procedures are based enables the nurse to answer questions, incorporate diagnostic findings into the patient's plan of care, and provide high-level nursing care. The critical care nurse also can decrease the anxiety of patients and their families by providing an explanation of the procedure.

▲ Standard 12-Lead Electrocardiogram

The standard ECG records electrical impulses as they travel through the heart. In patients with normal conduction, the first electrical impulse for each cardiac cycle originates in the sinus node and is spread to the rest of the heart through the specialized conduction system—the intra-atrial tracts, AV node, bundle of His, and right and left bundles. As the impulse traverses the conduction system, it penetrates the surrounding myocardium and provides the electrical stimuli for atrial and ventricular contraction. The change in electrical potential in cells of the specialized conduction system as the impulse proceeds is very small and cannot be measured from electrodes outside the body. However, the change in electrical potential of myocardial cells produces an electrical signal that can be recorded from the surface of the body, as is done with an ECG.

Impulses that originate in sites other than the sinus node or impulses that are prevented from traversing the conduction system because of disease or drugs interrupt the normal order of electrical sequences in the myocardium. An ECG

may be used to record these abnormal patterns of impulse formation or conduction. A clinician then has a visual record of the abnormal pattern from which to identify the dysrhythmia.

In addition, an abnormal ECG tracing may result from diseased myocardial cells. For example, in patients with left ventricular enlargement, impulses traversing the enlarged muscle mass of the left ventricle produce a larger electrical signal than normal. In contrast, impulses are unable to traverse myocardial cells that are irreversibly damaged, such as in MI, and no electrical signal is present in the infarcted cells of the left ventricle.

Procedure

The standard 12-lead ECG is so named because the usual electrode placement and recording device permit the electrical signal to be registered from 12 different views. The four limb and six precordial lead wires are attached to the patient as shown in Figure 17-9. For the limb leads, the recording device alternates the combination of electrodes that are active during recording of electrical signals from the heart (Fig. 17-10). This results in six standard views or leads (I, II, III, augmented voltage of the right arm [aVR], augmented voltage of the left arm [aVL], and augmented voltage of the left foot [aVF]) that are recorded in the heart's frontal plane. The six precordial leads (V_1, V_2, V_3, V_4, V_5, and V_6) are arranged across the chest to record electrical activity in the heart's horizontal plane (see Fig. 17-9).

Used routinely in intensive care unit (ICU) patients, ECGs assess dysrhythmias and myocardial ischemia or MI. An ECG is performed easily at the bedside, with the patient ideally placed in the supine position and the electrodes arranged as previously described. In some patients, chest bandages may preclude placement of the precordial leads. It is important that the patient remain still during the ECG recording so that skeletal muscle movement does not result in extraneous noise or artifact in the electrical signal. Additional horizontal plane leads may be recorded by placing electrodes on the right side of the chest to view right ventricular activity or the back of the chest to view left ventricular posterior wall activity (see Fig. 17-9).

In the clinical setting, it is important that the nurse remember where the positive electrode is located in each of the 12 leads of the ECG. The positive electrode is like a camera and provides a view of the heart from that

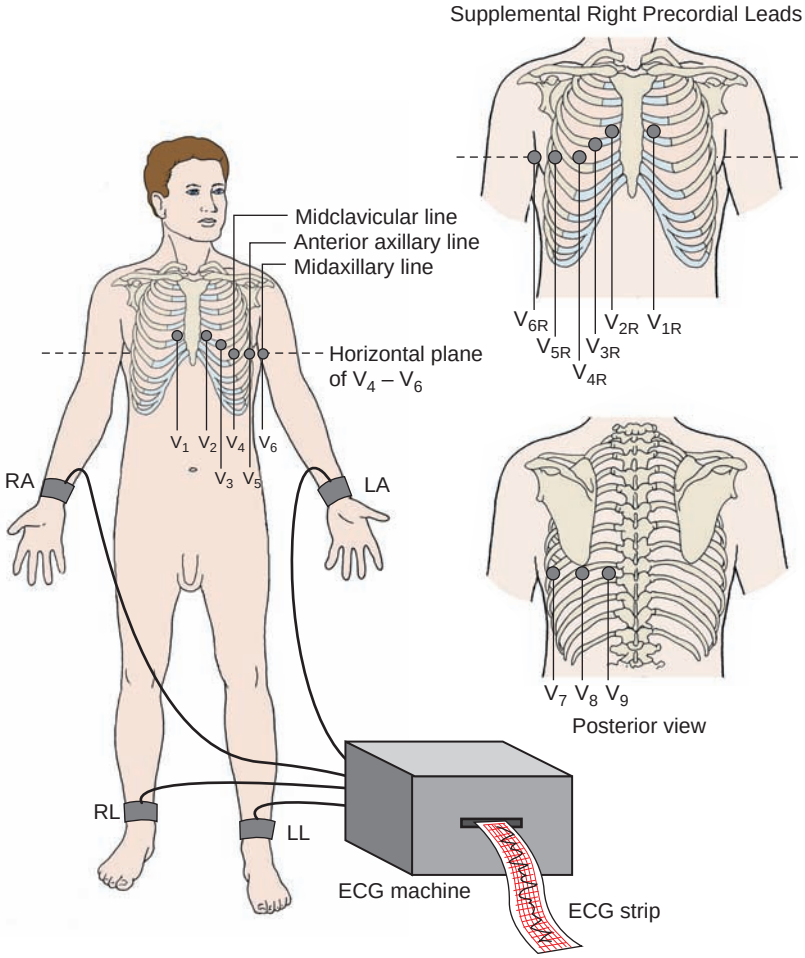

FIGURE 17-9 ▲ Electrocardiogram (ECG) electrode placement. The standard left precordial leads are V_1, fourth intercostal space, right sternal border; V_2, fourth intercostal space, left sternal border; V_3, diagonally between V_2 and V_4; V_4, fifth intercostal space, left mid-clavicular line; V_5, same horizontal line as V_4, anterior axillary line; V_6, same horizontal line as V_4 and V_5, mid-axillary line. The right precordial leads, placed across the right side of the chest, are the mirror opposite of the left leads. For the posterior leads, V_7 is placed at the left posterior axillary line, V_8 is placed at the left mid-scapular line, and V_9 is placed at the left border of the spine. All are placed on the same horizontal line as V_6.

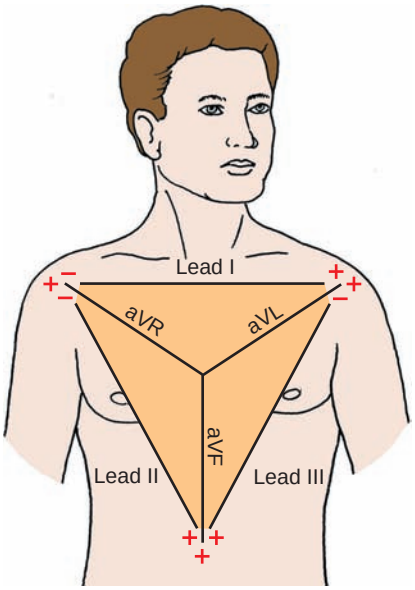

FIGURE 17-10 ▲ Frontal plane leads: standard limb leads, I, II, III, plus augmented leads aVR, aVL, and aVF. This allows an examination of electrical conduction across a variety of planes (eg, left arm to leg, right arm to left arm).

perspective. In lead I, the positive electrode is on the patient's left arm, giving a left lateral view of the heart. In leads II and III, the positive electrode is on the patient's left leg, resulting in an inferior view of the heart. For the augmented leads, the name of the lead corresponds with the placement of the positive electrode. In lead aVR, the view of the heart is poor because the positive electrode is far from the heart on the right arm. In lead aVL, the positive electrode is on the left arm, providing a left lateral view of the heart. In lead aVF, the positive electrode is placed on the patient's left leg, resulting in an inferior view of the heart. Each of the electrodes placed on the patient's chest is a positive electrode. Therefore, V_1 through V_4 provide a view of the anteroseptal wall of the heart, and V_5 and V_6 provide a view of the left lateral wall of the heart. Figure 17-11A and B shows the six limb leads in the frontal plane and the six chest leads in the horizontal plane, and the location of the positive electrode in each. The right-sided chest leads V_4R through V_6R offer the best view of the right ventricle. Leads V_7 through V_9 give the best view of the posterior wall of the heart (see Fig. 17-9). Table 17-6 summarizes the electrocardiographic leads and the corresponding views of the heart.

Nursing Assessment and Management

Critical care nurses often record an ECG in the event of a change in patient status. This change in status includes the development of dysrhythmias. Evaluation of a rhythm strip in relationship to dysrhythmias is discussed later in this chapter. Often, an ECG is obtained during episodes of chest pain before and after the administration of sublingual nitroglycerin. The ECG provides documentation of ST-segment changes associated with the pain.

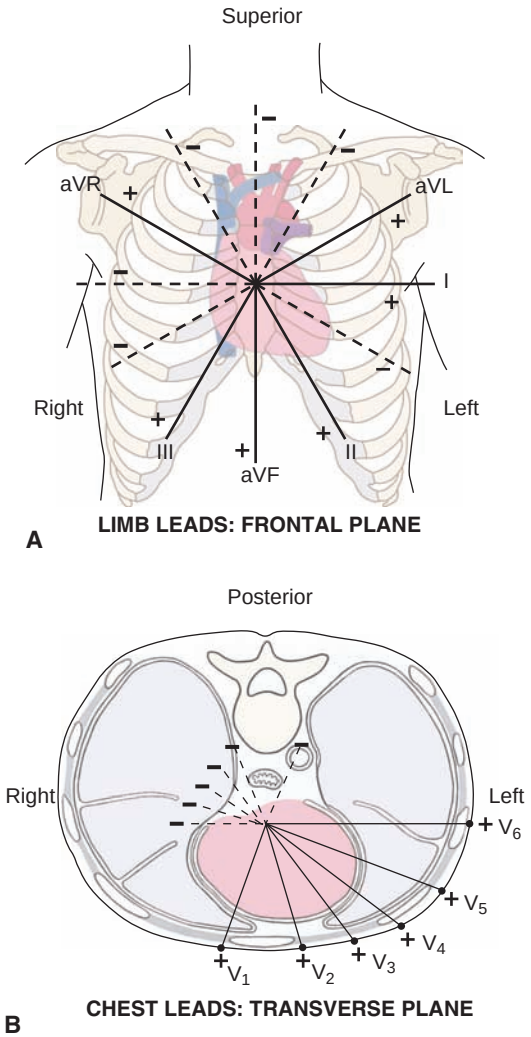

FIGURE 17-11 ▲ **A:** Positioning of the positive and negative electrodes for the limb leads in the frontal plane. **B:** Positioning of the positive electrodes on the chest wall giving a horizontal plane view. (From Bickley L: Bates' Guide to Physical Examination and Health History, 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 331.)

Some patients fear being shocked by the ECG recorder. Preparatory instruction for patients should include an explanation of the manner in which the electrical impulses of the heart are recorded and that the patient will feel no sensation during the recording of the ECG.

Table 17-6 Electrocardiographic Leads and Corresponding Views of the Heart

Lead	View of the Heart
II, III, aVF	Inferior
I, aVL, V_5, and V_6	Left lateral
V_1 through V_4	Anteroseptal
Right-sided V_4 through V_6	Right ventricle
V_7 through V_9	Posterior

▲ Electrophysiologic Studies

Holter or 24-Hour Monitoring

Holter monitoring involves the use of ECG monitoring to quantify the frequency and complexity of cardiac ectopic activity that occurs during a patient's usual activities. It is a noninvasive method of assessing for dysrhythmias, response to antiarrhythmic therapy, and development of ECG changes suggestive of ischemia. Holter monitoring is indicated for patients with syncope, near syncope, dizziness, or palpitations. Patients with infrequent symptoms may not benefit from this method of gathering data because Holter monitoring is most useful in patients who are experiencing their dysrhythmias multiple times in a day. Holter monitoring is rarely used in the inpatient setting where telemetry monitoring is also available.

Holter monitoring involves placement of anterior chest electrodes that are then connected to a portable recording device, or Holter monitor. The Holter monitor is a small recording device that may be carried in a shirt pocket. Commonly, two leads are recorded continuously on tape through four or five electrodes placed on the patient's anterior chest; the electrodes are arranged so that one lead reflects the anterior wall and the other reflects the inferior wall of the heart. Data are collected from two leads simultaneously to minimize the effect of artifact on the final analysis. Continuous recording of the ECG leads is usually performed for 24 to 48 hours, and the electrodes must remain in place for the entire session. At the completion of the test, the recorder is returned for analysis.

Optimal skin preparation and electrode placement are crucial to obtaining high-quality ECG readings. Patients must bathe before placement of the electrodes. Bathing is prohibited while the electrodes are in place because contact with water can cause them to loosen. Fishnet placed over the electrodes helps keep them in place. It is necessary to caution patients against removal of the electrodes because loss of electrical contact can mimic dysrhythmias.

Holter monitoring requires significant patient participation. Patients receive instructions about keeping a diary to record medications, activities, and symptoms during the monitoring period. Usually, patients should maintain normal activities while wearing the monitor and record an entry in the diary at least every 2 hours. An understanding of the physical and emotional stressors, as well as the patient's symptoms, enhances analysis of the recordings. Compliance with record keeping is necessary. Hospitalized patients may require the assistance of nursing staff to maintain their diaries.

Event (Continuous Loop) Monitoring

In event (continuous loop) monitoring, the patient wears electrodes and a recording device, but the device does not record continuously. Instead, the patient is required to activate the recorder when a symptom occurs, and recording can go on for the duration of symptoms. The ECG is recorded on a continuous loop tape so that information before, during, and after the event is recorded. Results can be communicated to a monitoring agency by telephone, allowing for rapid analysis and feedback to patient and caregiver. Cardiac event recorders can be worn for up to 1 month.

Cardiac event recorders are most useful for patients who have relatively infrequent episodes of dysrhythmias, who are aware and able to respond to symptoms, and who are willing to wear electrodes and carry the recorder, possibly for as long as a month. As with Holter monitoring, electrode placement on clean, intact skin is crucial. Electrodes must be kept in place for the duration of the study, making immersion bathing impractical. The patient diary, a source of detailed information, requires significant participation on the part of the patient.

Implantable Loop Monitoring

The implantable loop monitor (ILR) is a device that is implanted subcutaneously and provides continuous ECG monitoring for up to 14 months. ILRs were developed to provide long-term monitoring for patients with presyncope and syncope. The major limitations of the ILR are its requirement for subcutaneous implantation and cost. The use of the device requires familiarity with implantation techniques and programming. The ILR is used for patients in whom less expensive tests, such as Holter monitoring, have failed to provide a diagnosis.

Implantation of the ILR is a surgical procedure that exposes the patient to the risk of infection and bleeding. Patients undergoing ILR implantation must understand the potential risks of the procedure. They need instruction regarding postoperative site care and use of the device.

Signal-Averaged Electrocardiography

Signal-averaged electrocardiography (SAECG) is performed in the same manner as a resting ECG, except that the heart's electrical activity is monitored for 15 to 20 minutes. The purpose of SAECG is to filter out random noise and to allow very low levels of electrical activity, called late potentials, to be recorded. This electrical activity, which is not detected by standard ECG, is thought to be coming from the cardiac substrate. Late potentials have been shown to be useful in identifying patients at risk for lethal heart rhythms.

SAECG must be performed by specially trained personnel in a very quiet room, with no extraneous electrical or electromagnetic signal-emitting equipment present. The patient must be cooperative and restful for the duration of the study.

Diagnostic Electrophysiology Study

The diagnostic electrophysiology study is a type of heart catheterization during which access to the heart is obtained through the femoral veins, or, for some more complex studies, the upper extremity (brachial, external jugular, or subclavian) veins. Multiple catheters are usually placed in one or more vessels. An arterial line is typically placed to provide continuous blood pressure monitoring during the case.

Diagnostic electrophysiology studies are performed to evaluate a broad spectrum of cardiac dysrhythmias. They can help assess the function of the sinoatrial (SA) node, the AV node, and the His-Purkinje system; determine the characteristics of reentrant dysrhythmias; map the location

of dysrhythmogenic foci for potential ablation; and assess the efficacy of antiarrhythmic drugs and devices. The basic electrophysiology protocol involves measurement of baseline conduction intervals; atrial pacing to assess SA node and AV node properties; assessment of the His-Purkinje system conductivity; ventricular pacing to evaluate for retrograde conduction and ventricular dysrhythmia potentials; and drug testing.[12]

Diagnostic electrophysiology studies are very safe. The risks associated with the procedure are similar to those encountered with cardiac catheterization and include hemorrhage, thromboembolism, phlebitis, and infection. Because most diagnostic electrophysiology studies do not require arterial puncture, the risk for serious vascular damage is very low. The risk for death due to the induction of lethal dysrhythmias is close to zero, in part because the procedural setting is uniquely equipped to terminate hemodynamically unstable dysrhythmias.

The following preprocedure preparations are necessary for patients undergoing diagnostic electrophysiology studies:

- The physician or nurse reviews the procedure so that the patient clearly understands its purpose and nature. Appropriate personnel obtain informed consent.
- Because sedation is used, the patient must be NPO for 8 hours before the procedure.
- The ordering physician or nurse practitioner must review patient medications to be sure they are to be administered on the day of the procedure. Antiarrhythmic drugs are typically withdrawn before the procedure.
- Excessive anxiety can increase catecholamine release and affect sympathetic tone, so the nurse should alert the ordering physician or nurse practitioner to signs of anxiety.

Postprocedure, the following nursing care applies:

- The nurse checks the patient's blood pressure and heart and respiratory rates frequently according to the institution's protocols.
- If the diagnostic electrophysiology study failed to induce dysrhythmias, the patient may not require telemetry monitoring. If dysrhythmias were induced, the patient does need continuous telemetry monitoring.
- The nurse monitors venous and arterial access sites for bleeding. This monitoring may include serial complete blood counts to ensure stable hemoglobin and hematocrit counts.

Tilt Table Testing for Syncope

Tilt table testing, or upright tilt table testing, refers to maintaining the patient in a head-up position for a brief period to provoke syncope, bradycardia, or hypotension. In tilt table testing, the patient is positioned on a tilt table in the supine position and tilted upright to a maximum of 60 to 80 degrees for 20 to 45 minutes. Isoproterenol may be given to provoke syncope in patients who do not become symptomatic within the testing period.

Tilt table testing is performed on patients who are suspected of having vasodepressor or vasovagal syncope. Upright posture is associated with gravitational pooling of blood, which results in a decline in central venous pressure (CVP), stroke volume (SV), and blood pressure. These effects normally lead to activation of arterial and cardiopulmonary baroreceptor reflexes that maintain blood pressure. In people susceptible to vasovagal syncope, these reflexes are reversed, resulting in bradycardia and hypotension that leads to syncope.

The patient experience during tilt table testing can be unpleasant, particularly if the patient has syncope during the study. Patients undergoing tilt table testing need to be NPO for 8 hours before the study. They need intravenous (IV) access and should be informed that they may receive a vasoactive agent such as isoproterenol.

▲ Chest Radiography

Chest radiography is a routine diagnostic test used to assess critically ill patients with cardiac disease. The test can be performed easily at the bedside in patients too ill to be transported to the radiology department. The image obtained on a radiograph that allows visualization of vascular and cardiac shapes is based on the premise that thoracic structures vary in density and permit different amounts of radiation to reach the film.

Chest radiography may be used for the evaluation of cardiac size, pulmonary congestion, pleural or pericardial effusions, and position of intracardiac lines, such as transvenous pacemaker electrodes or pulmonary artery (PA) catheters. Figure 17-12 shows the structures that can be seen on a normal posteroanterior chest radiograph.

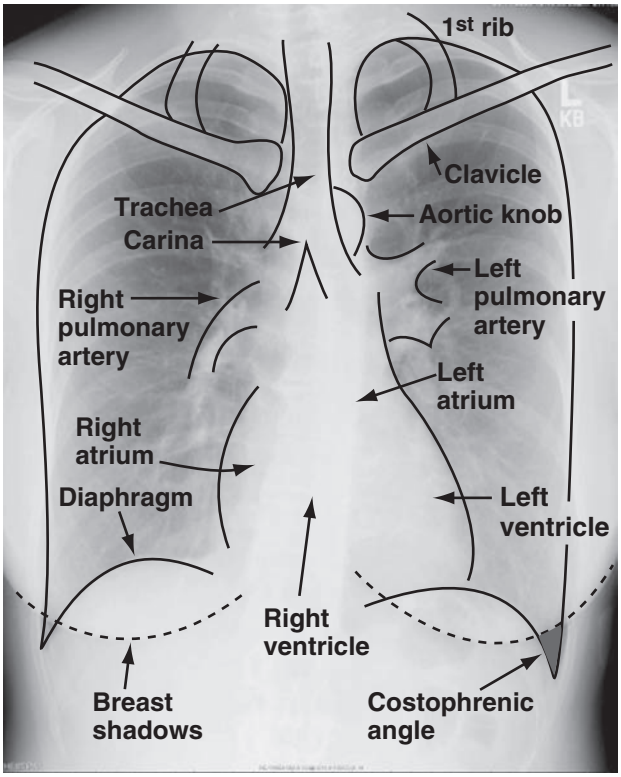

FIGURE 17-12 ▲ Outline of structures visible on normal posteroanterior chest radiograph. (Adapted from Woods SL, Froelicher ESS, Motzer SU, Bridges EJ: Cardiac Nursing, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, p 268.)

Procedure

Cardiac size is evaluated best in the radiology department, where the procedure can be standardized with the patient standing and the radiograph taken from posterior and lateral views at a distance of 6 feet. Portable bedside chest radiographs usually are taken only from an anterior view with the patient lying supine or sitting erect and are not standardized.

Patients undergoing radiography of the chest are instructed not to move while the radiograph is being taken. Proper positioning of the radiographic plate behind the patient is important to ensure that thoracic structures are aligned on the film. Care is taken to remove all metal objects, including fasteners on clothing, from the field of view because metal blocks the x-ray beam. Patients usually are asked to take a deep breath and hold it when the radiograph is taken to displace the diaphragm downward; this may be uncomfortable for patients who have undergone recent thoracic surgery.

Nursing Assessment and Management

The critical care nurse's role in obtaining diagnostic thoracic radiographic films often is limited to the ICU, where portable radiographs are made. With unstable patients, the nurse must decide when the film can be taken. It is important that IV lines not become tangled or loosened while one is trying to place the radiographic plate in the proper position.

Female patients of childbearing potential should have a lead drape placed over the abdomen to protect the ovaries from any radiation scatter. For the same reason, caregivers and family members should leave the patient's room when the radiograph is taken. When caregivers cannot leave the patient's bedside, a lead apron should be worn.

▲ Echocardiography

Echocardiography refers to a group of tests that use ultrasound technology to provide information about cardiac structures. Specifically, a transducer emits ultrasound waves and receives a signal from the reflected sound waves; it alternates periods of sound transmission and reception. As the sound waves are emitted and travel through tissues with a homogeneous density, such as when the sound waves move through the left ventricular wall, the signal travels in a straight line. When the density of the structures changes, such as when the waves move from the ventricular wall into the blood-filled left ventricle, the direction of the sound waves changes, and this difference is recorded by the receiver. These density changes are called interfaces, and they form the basis for distinguishing one structure from another. Ultrasound waves do not travel well through bone; thus, bony paths are avoided during the examination.

Echocardiography is most often used to assess ejection fraction, wall motion and thickness, systolic and diastolic ventricular volumes, valvular function and disease, vegetations, intracardiac masses or thrombi, and pericardial fluid. It is a helpful diagnostic tool in the presence of sudden clinical deterioration in acute MI, in which significant complications may be observed or suspected. In addition, it also may be used in evaluating function of all four cardiac valves, including calculation of gradients and orifice size, intracardiac tumors, and aortic dissection. Contrast echocardiography is a technique for improving resolution during echocardiographic studies. Agitated saline solution, injected intravenously, is used to identify intracardiac shunts. In addition, several phospholipid IV contrast agents have been developed to improve visualization of the endocardial border. These agents would be used when visualization of the endocardial border is hindered by body habitus or artifact.

The quality and usefulness of echocardiographic studies depend on the relative age of the technology being used, the skill of the technologist performing the study, the habitus of the patient, and the skill of the study's interpreter. Accuracy may decrease up to 20% in patients who are obese or who have chronic obstructive pulmonary disease or chest wall deformities. These physical features increase the distance the ultrasound waves must travel and thus increase the likelihood of artifact. Transthoracic echocardiography is of limited usefulness in investigating the left atrium and left atrial appendage because these structures are at the back of the heart.

Echocardiography is performed in a specifically designed laboratory with dim lighting and minimal sound distraction. It can also be performed at the bedside with lighting optimized to enhance the quality of the study. Patients should be able to tolerate lying flat or nearly flat. The technician asks them periodically to change position, and they should be able to turn onto their left side for several minutes at a time. In addition, they should be able to breathe in deeply or hold their breath. They do not need to be fasting.

M-Mode Echocardiography

Motion mode, or M-mode, echocardiography allows recording of amplitude and of the rate of motion of moving objects with great accuracy. It is often referred to as an "ice pick" view because it uses a single beam of sound that allows a small region of the heart to be visualized at any point in time. The four positions of the transducer depicted in Figure 17-13 are the typical views used during an M-mode echocardiogram. It provides rapid assessment of valvular motion and chamber wall thickness. The transmitter is placed on the anterior chest in an intercostal space or subcostal position to avoid bony structures.

Two-Dimensional Echocardiography

Two-dimensional (2D) images of cardiac structures can be obtained by using multiple crystals to generate a cross-sectional imaging plane. The ultrasound beam is pie shaped, resulting in a "plane" of reflected echoes. Visually, 2D echocardiography creates a cross-sectional slice of the heart from parasternal, subcostal, apical, and suprasternal positions. This approach is useful for evaluating the thickness of the left ventricular wall, left ventricular wall mass, and wall motion abnormalities.

Three-Dimensional Echocardiography

Three-dimensional (3D) echocardiography allows for the imaging and analysis of cardiac structures as they move in time and space. 3D echocardiography uses the principles of

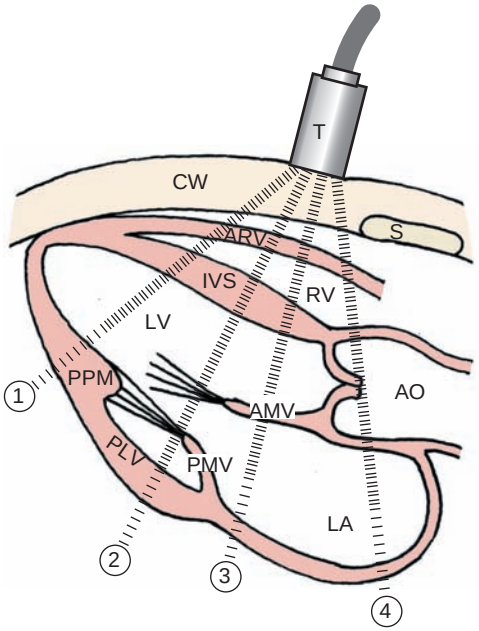

FIGURE 17-13 ▲ Echocardiographic views of the heart. A cross-section of the heart shows the structures through which the ultrasonic beam passes as it is directed from the apex (*1*) toward the base (*4*) of the heart. AMV, anterior mitral valve; AO, aorta; ARV, anterior right ventricular wall; CW, chest wall; IVS, interventricular septum; LA, left atrium; LV, left ventricle; PLV, posterior left ventricular wall; PMV, posterior mitral valve; PPM, posterior papillary muscle; RV, right ventricular cavity; S, sternum; T, transducer.

ultrasound imaging with advanced real-time reconstruction capabilities to generate a more authentic representation of the heart. Early in the evolution of 3D echocardiography, the generated images required lengthy postprocedure processing, which meant that immediate results were not available. Current technology allows for real-time images, making this modality a valuable diagnostic and treatment tool.

Doppler Echocardiography

Doppler echocardiography superimposes Doppler techniques on either M-mode or 2D images. The direction of blood flow can be assessed by measuring echoes reflected from red blood cells as they move away from or toward the transducer. This type of study is particularly useful in patients with valvular disease. Stenotic valves cause turbulence in the forward flow of blood through the heart, and regurgitant valves cause turbulence in blood flowing retrograde through the cardiac chambers. When the direction of flow is color encoded, the study is known as a color Doppler echocardiogram. Audio signals usually are recorded during Doppler studies. Contrast material may also be used in conjunction with M-mode or 2D echocardiography. Although many agents have been used as contrast material, almost any liquid injected intravenously contains microbubbles. As the microbubbles travel through the heart, they produce multiple echoes. This technique is especially useful in identifying right-to-left intracardiac shunts because of the early appearance of the microbubble echoes on the left atrium or ventricle.

Transesophageal Echocardiography

Transesophageal Echocardiography (TEE) involves the placement of a 2D transducer at the end of a flexible endoscope to obtain high-quality images of cardiac structures. Because the heart rests directly on the esophagus, the ultrasound signal travels millimeters to reach the heart. This reduces the amount of signal artifact and attenuation, yielding a clearer image. TEE is useful in patients with emphysema, obesity, and chest wall deformities. In addition, TEE provides a posterior approach to the heart; thus, it also allows for better imaging of the aorta, PA, valves of the heart, both atria, atrial septum, left atrial appendage, and coronary arteries.

Patients undergoing TEE should be NPO for 6 hours before the study. IV sedation is given, and several staff members, including technicians, nurses, and a physician, are required throughout the study. TEE takes substantially longer than a transthoracic echocardiogram and can be uncomfortable for patients. There is also a risk for esophageal perforation (1 in 10,000) associated with the procedure. Table 17-7 summarizes nursing considerations for caring for the patient undergoing TEE.

Bedside Vascular Access Testing

Obtaining vascular access in a critically ill patient frequently represents a challenge to clinicians. Portable devices have been designed for use at the bedside to locate vascular anatomy in real time, allowing placement of IV lines with great accuracy.

Intravascular Ultrasound

Intravascular ultrasound (IVUS) uses ultrasound technology to visualize the lumen and wall structure of the coronary arteries. It is an adjunct to cardiac catheterization and is discussed more fully in that section (see Cardiac Catheterization, Coronary Angiography, and Coronary Intervention).

▲ Stress Testing

Stress testing is an important tool in the evaluation of the patient with suspected ischemic CVD. Stress testing is used to assess prognosis and to determine functional capacity. Stress testing involves monitoring physiological parameters, such as blood pressure and ECG, when the heart is in a resting state and again when the heart has been stressed either by exercise or by a pharmacological agent chosen to simulate exercise. A great deal more information can be obtained by also looking at images of the heart at rest and with activity. These images can be obtained by a variety of methods, including radioactive tracers and echocardiography. Boxes 17-8 and 17-9 present indications and contraindications for stress testing, respectively. These contraindications largely relate to advanced disease states; stress testing in patients with these conditions could precipitate a catastrophic event.

Table 17-7 **Nursing Interventions for the Patient Undergoing Transesophageal Echocardiography (TEE)**

Nursing Action	Rationale
Preprocedure	
1. Evaluate patient for contraindications.	Patients with history of dysphagia or esophageal disease are not candidates for TEE.
2. Instruct patient and family about procedure.	Some discomfort may occur; patient will receive moderate sedation but will be closely monitored.
3. Ensure that documented patient history is adequate and informed consent has been signed.	Medication allergies should be noted; procedure requires consent signature.
4. Ensure that patient has been NPO for 6 h before procedure.	Aspiration precaution is vital.
5. Prepare patient for procedure.	Remove oral prosthetics, as indicated; have patient void.
6. Insert peripheral intravenous (IV) catheter.	IV access is required for routine medication administration; emergency vascular access line should be available.
7. Place patient on cardiac monitor with blood pressure and pulse oximetry.	Patient must be continually monitored during procedure.
8. Ensure that emergency resuscitation equipment is nearby, including medications, defibrillator, and suction apparatus.	Cardiac arrest precaution.
During Procedure	
1. Monitor cardiac rhythm, blood pressure, pulse oximetry, and airway patency per institutional policy.	Continuous observation is required after moderate sedation.
2. Assist physician with patient positioning and endoscope placement.	Allaying fears enhances patient cooperation.
3. Monitor for complications.	Vagal stimulation may occur with a resultant vasovagal reaction; transient tachycardia/ bradycardia and blood pressure alterations may appear; patient may experience hypoxia or laryngospasm.
4. Reassure patient throughout procedure.	Allaying fears enhances patient cooperation.
5. Document patient response to procedures.	Per institutional protocol.
Postprocedure	
1. Assess vital signs at conclusion of procedure; document per institutional policy.	Comparison with baseline is necessary to monitor sedation recovery.
2. Assist patient to position of comfort or on one side.	Position provides comfort and patent airway support.
3. Keep patient NPO until gag reflex is assessed.	Prudent, given aspiration risk.
4. If gag reflex is present, encourage patient to cough; offer lozenges or ice to soothe sore throat; keep NPO per physician order.	Interventions provide patient opportunity to clear residual secretions and obtain comfort.
5. If outpatient, instruct patient not to drive for at least 12 h.	If patient was sedated during procedure, it is best if family member or another drives patient home.
6. Instruct patient to seek care or contact physician in event of dyspnea, hemoptysis, or severe pain.	If symptoms of complications occur, patient should be reevaluated.

Fundamentally, stress testing provides information about the heart's response to activity. The heart extracts 70% of the oxygen carried by each unit of blood perfusing the myocardium. Cardiac metabolism is nearly entirely aerobic, meaning that the heart is unable to create energy in anaerobic conditions or when the oxygen supply is insufficient. Therefore, an increase in oxygen demand on the heart requires additional coronary artery blood flow to meet the new metabolic requirements. Narrowing of the coronary arteries can limit the amount of blood delivered to a portion of the myocardium, resulting in ischemia.

BOX 17-8 Indications for Stress Testing

1. Differential diagnosis of chest pain (ie, evaluation of patients with suspected ischemic heart disease)
2. Assessment of the level of exercise at which ischemic manifestations occur in a patient with known ischemic heart disease
3. Evaluation of therapy for dysrhythmias and angina
4. Evaluation of functional disability secondary to organic heart disease (eg, valvular heart disease)
5. Risk stratification of the asymptomatic patient with multiple risk factors for ischemic heart disease

BOX 17-9 Contraindications for Stress Testing

1. Recent MI (4 to 6 weeks), except when submaximal protocols are used (65% of maximum predicted heart rate or symptom-limited exercise stress testing before hospital discharge)
2. Unstable angina or angina at rest
3. Rapid ventricular or atrial dysrhythmias
4. Advanced atrioventricular block, unless chronic
5. Uncompensated congestive heart failure
6. Acute noncardiac illnesses
7. Severe aortic stenosis
8. Blood pressure greater than 170/100 mm Hg before the onset of exercise

Exercise Stress Testing

Patients must be ambulatory to participate in exercise stress testing. Functional limitations due to orthopedic, neurological, pulmonary, or peripheral vascular issues can affect the patient's ability to complete the stress test protocol.

Procedure

In exercise stress testing, the heart rate is monitored continuously while exercise is performed on a treadmill or bicycle. The patient is exercised to a target heart rate that is 85% of the maximum predicted for that individual. By convention, the maximum predicted heart rate is calculated as 220 beats/min for men (210 beats/min for women) minus the patient's age in years. Attainment of maximum heart rate is a good prognostic sign.

The blood pressure, heart rate and rhythm, ECG, presence or absence of symptoms, and workload performed are monitored. Workload is determined by metabolic equivalents (METs) or by the double product (blood pressure × heart rate). METs are defined as the resting respiratory oxygen uptake for a 70-kg, 40-year-old man, and 1 MET is equivalent to 3.5 mg/min/kg of body weight. Work activities are calculated in terms of METs. Stair climbing, for example, is approximately equivalent to 4 METs. A reasonable workload for most active adults is 10 METs. Although the double product correlates well with the degree of CVD, it is less often used as a measure of workload.

Initial ECG readings are performed before exercise to document a baseline, with continuous 12-lead monitoring used throughout the study. The lead system is the same as used for the standard 12-lead ECG. However, it is necessary to move the limb leads to the torso to prevent arm or leg movement during exercise from interfering with ECG recording. Skin preparation and electrode attachment require careful attention to permit interpretable recordings during maximal exercise. It may be necessary to wrap material or fishnet over the electrodes and cables on the patient's torso to reduce movement artifact. Treadmill stress testing without a concomitant imaging modality is less reliable in females; therefore, exercise stress testing in females is typically paired with radionuclide or echocardiographic imaging. Baseline ECG abnormalities, such as left bundle branch block (LBBB), make analysis of exercise-induced ECG changes more complex.

The treadmill protocol chosen should reflect the patient's physical capacity and the purpose of the test. All treadmill protocols are multistaged, using increments in time, speed, and elevation of the treadmill platform. The protocol is selected based on the condition of the patient and the purpose of the study. For example, the Ellestad protocol uses small increments in workloads of shorter duration, whereas the Bruce protocol uses larger workload increments of longer duration. The Ellestad protocol may be better suited to a patient with less exercise tolerance. The Bruce protocol is among the most popular in use for reasonably functional people; a large body of diagnostic and prognostic data supports its use.

Patients who have not previously undergone exercise testing should be allowed briefly to practice walking on the treadmill or riding the bicycle. Before starting the test, a resting baseline ECG and blood pressure are obtained with the patient in sitting and standing positions. The ECG and heart rate are monitored continuously throughout the test, and blood pressure is monitored every few minutes. The monitoring continues for at least 6 to 10 minutes into recovery, or until symptoms or blood pressure and ECG changes have resolved to document the patient's return to baseline values.

It is mandatory that emergency personnel and equipment be available in areas where exercise testing is performed. Indications of myocardial ischemia during exercise testing are the development of ST-segment depressions, chest pain or the anginal equivalent, or failure to increase blood pressure to 120 mm Hg or the sustained decrease of 10 mm Hg with progressive stages of exercise. The test is terminated for any of the following reasons:

1. The target heart rate is reached.
2. The patient is unable to continue exercising because of shortness of breath, fatigue, claudication, or severe chest pain.
3. There is ECG evidence of complete AV block, ventricular Tachycardia (VT), or premature ventricular contractions (PVCs).
4. There is ECG evidence of ST-segment changes consistent with ischemia or infarction.
5. The patient's systolic blood pressure is greater than 220 mm Hg or diastolic blood pressure is greater than 120 mm Hg during exercise, or the patient's blood pressure drops below baseline at any time during the exercise protocol.

In the absence of ECG evidence of ischemia or the development of life-threatening dysrhythmias, every effort should be made to reach the maximum predicted heart rate to improve the diagnostic accuracy of the test. When the maximum predicted heart rate is not reached, the diagnostic reliability of the study is low. Exercise stress test results are considered reliable only if patients reach the maximum predicted heart rate value (85% of their maximal predicted effort).

Nursing Assessment and Management

Adequately preparing patients for the stress test maximizes the information obtained from the study. Patients should be NPO for 4 to 6 hours before the test to minimize blood diversion to the gastrointestinal tract, which decreases available coronary blood supply. In particular, they should not drink caffeine-containing beverages because of the effect of caffeine on the heart rate. Beta blockers blunt the heart rate response to exercise and may prevent achievement of the maximum predicted heart rate, so they should be withheld on the day of the test. Digitalis may also be withheld because of its negative chronotropic effects. Badly deconditioned patients, or those with comorbidities that could affect their ability to ambulate, may not be able to complete the required exercise. Appropriate attire, including comfortable walking shoes, is necessary to maximize patient comfort and performance.

The critical care nurse may be responsible for explaining the general format of the exercise test to the patient and family. It is important that patients understand why the test is indicated and what will be expected of them. The nurse reassures patients that someone will observe them closely

throughout the test and encourages them to express any concerns before, during, and after the procedure. Patients should also understand that they may have to continue exercising after angina develops but will not be expected to exercise more than is safe.

Pharmacological Stress Testing

Pharmacological stress testing is performed in patients who are unable to bike or walk on a treadmill. Patients referred for stress testing may have limitations that prevent them from performing adequate physical exercise. This has led to the development of alternative methods of simulating the effect of exercise on the heart using adrenergic agents, such as dobutamine, or vasodilators, such as adenosine or dipyridamole. These studies require no activity on the part of the patient. There is continuous monitoring of the ECG, along with frequent blood pressure measurements. In addition, an imaging modality, such as echocardiography or nuclear imaging, is always used.

Pharmacological agents used include several drugs. Dobutamine increases myocardial oxygen demand by increasing contractility, heart rate, and systemic blood pressure. Because dobutamine has some heart rate–blunting characteristics, supplemental atropine may be required to achieve target heart rate values. With the infusion of dobutamine, coronary blood flow increases up to twofold in normal coronary arteries but less so in arteries with flow-limiting lesions. Vasodilators, such as adenosine and dipyridamole, also cause an increase in coronary blood flow. They simulate the effects of exercise on the heart by producing arteriolar and coronary artery vasodilation. Regadenoson is a selective adenosine agonist that incites coronary vasodilation, producing maximal effects quickly, and maintaining hyperemia for the duration of perfusion imaging.[13] Although information on functional capacity is not obtained during pharmacological stress testing, it is expected to provide a reasonable equivalent to that gathered during physical exercise.

ECG changes, secondary to the infusion of dobutamine, adenosine, and dipyridamole, have a very low sensitivity for the detection of significant CAD. Therefore, pharmacological stress testing is always accompanied by a nuclear or echocardiographic imaging modality to increase the sensitivity of the study.

Nuclear Imaging with Stress Testing

Noninvasive, rapid, and accurate imaging of cardiac structure and function using radiotracers is a routine part of inpatient assessment of patients with known or suspected CVD. Broadly speaking, this is known as radionuclide cardiac imaging. Single-photon emission computed tomography (SPECT) and positron emission tomography (PET) are both widely available types of radionuclide imaging. SPECT and PET cameras capture the photons emitted by infused radiotracers and provide information on the magnitude and location of the uptake. The images are ECG gated, or collected in synchrony with ongoing ECG monitoring, so that the final data interpretation can be presented in the context of the full cardiac cycle of contraction and relaxation. In SPECT imaging, the final result is also referred to as myocardial perfusion imaging (MPI). PET is discussed at greater length later in this chapter (see Positron Emission Tomography).

Nuclear imaging is combined with exercise or the infusion of a pharmacological agent in a variety of protocols. Protocols may involve the injection of several radiotracers over several hours, with imaging performed 24 hours later. The purpose of the protocols is to obtain information on the heart at rest and with stress. Protocols vary widely because of patient comorbidities, patient size, and available personnel and equipment.

Myocardial Perfusion Imaging

MPI uses SPECT technology to look at coronary blood flow, giving information about the location, quantity, and severity of cardiac disease. MPI uses radiopharmaceutical agents that, once injected into the venous bloodstream, accumulate in viable myocardium in proportion to the blood flow to a particular area. After injection of the tracer, the SPECT camera is used to record an image of radioactive counts from the entire myocardium.

During MPI studies, images are obtained of the heart at rest and with stress. Typically, at rest in the normal heart, the radiotracer is spread uniformly throughout the myocardium, and the camera reads counts equally from throughout the myocardium. During exercise, a similar scan is obtained in patients without significant coronary artery stenosis because blood flow increases uniformly to meet myocardial oxygen demands.

However, in patients with significant CAD, the image obtained during exercise is altered. The amount of coronary blood flow is limited in stenotic arteries, and the quantity of tracer in myocardial segments supplied by stenotic arteries is diminished or absent compared with segments supplied by nonstenotic arteries. An area of decreased tracer uptake during exercise compared with at rest is known as a reversible perfusion defect. Reversible perfusion defects are suggestive of impaired blood flow, or ischemia, in a region. In patients with previous infarction, decreased uptake may be present on both the rest and exercise scans in the infarcted segments; this pattern is known as a fixed perfusion defect and usually signifies nonviable myocardium. It is possible for patients to have fixed perfusion defects in some myocardial segments, reversible defects in others, and normal perfusion in the remaining segments.

Because of the many patients who are physically unable to exercise, pharmacological agents may be used to mimic the heart's response to exercise. Vasodilating agents, such as dipyridamole, adenosine, and dobutamine, administered IV mimic exercise conditions in the heart by dilating nonstenotic coronary arteries. Coronary blood flow is increased preferentially through normal, nonstenosed arteries; this results in relative hypoperfusion in myocardial segments supplied by stenosed coronary arteries. A radiotracer injected during the peak action of the pharmacological agent produces images similar to those seen with exercise. As of this writing, only dipyridamole is approved by the U.S. Food and Drug Administration (FDA) for use in perfusion imaging.

PROTOCOLS. Three radioactive tracers, thallium-201, technetium (Tc)-99m, and sestamibi are approved for perfusion imaging. Characteristics of the three agents differ and are responsible for the varying imaging protocols used.

Thallium Protocol. The cardiac half-life of thallium is approximately 7.5 hours, meaning that 50% of the tracer still is present in myocardial cells 7.5 hours after it is administered. It also redistributes readily, so thallium in normally perfused areas moves to previously underperfused areas after the myocardial blood flow demands in that territory have decreased. The standard protocol for thallium perfusion studies begins first with the exercise portion; thallium is injected at the peak of exercise, and imaging starts within 5 minutes of injection. The rest portion is obtained 2 to 4 hours later. Because of redistribution, no additional thallium is required. However, in some patients with perfusion defects on both the rest and exercise scans, significant redistribution may not occur, and it is recommended that an additional dose of thallium be administered.

Sestamibi Protocol. Perfusion imaging with sestamibi typically begins with the rest scan. Because significant uptake also occurs in the liver, imaging is delayed for approximately 60 minutes. This delay allows sestamibi to be cleared from the liver but not the heart. In addition, a glass of milk or small fatty meal is taken shortly after radiotracer injection to enhance hepatic clearance. A second dose of sestamibi is administered during peak exercise, and the exercise scan is obtained 60 minutes after injection, again allowing time for hepatic clearance. Because sestamibi redistributes very slowly, the image obtained 60 minutes after peak exercise reflects the perfusion conditions at the time of injection. Initially, perfusion studies with sestamibi were performed on two different days, but it now is customary to complete both portions of the study in one day. It has been shown that exercise sestamibi myocardial perfusion SPECT can provide incremental prognostic information in patients who have not suffered a previous MI or undergone cardiac catheterization and who are determined to be at low risk.

Nursing Assessment and Management

All the directions and precautions that pertain to exercise ECG also apply to exercise radionuclide imaging. When pharmacological agents are used in place of exercise, minor side effects, such as flushing, headache, and nausea, may occur. Serious side effects due to the radiotracer are extremely rare. Medications to counteract serious side effects should be readily available. Some patients who receive sestamibi report a metallic taste several minutes after injection. Patients often are anxious about the radiation involved and the appearance of the equipment. It is important for the nurse to allay these anxieties.

Table 17-8 outlines some of the tests that are used to detect the presence of myocardial ischemia.

Radionuclide Angiocardiography

A radionuclide ventriculogram or multigated acquisition (MUGA) is a precise means of calculating both right and left ventricular ejection fraction. MUGA scan has, for many years, been the gold standard for measuring ejection fraction, but other technologies, such as cardiac magnetic resonance imaging (MRI), echocardiography, and angiography, can now provide equally useful information. MUGA is performed by labeling the patient's red blood cell pool with a radioactive tracer, usually technetium 99m, and measuring

Table 17-8 Diagnostic Tests Used to Detect Myocardial Ischemia

Procedure	Abnormal Findings	Special Considerations
Standard 12-lead electrocardiogram (ECG)	Transient ST-segment and T-wave changes in patients with chest pain at rest or of prolonged duration	
Holter monitoring	Transient ST-segment and T-wave changes occurring at rest or with activity	Only two ECG leads monitored
Stress echocardiogram	Segmental wall motion abnormality associated with echocardiogram obtained during exercise	May be used in patients with ventricular conduction defects Pharmacological agents may be used in patients who cannot exercise
Exercise ECG	Transient ST-segment and T-wave changes occurring with exercise	Cannot be used in patients who are unable to exercise or who have left bundle branch block (LBBB) or paced rhythm Does not provide good information on the location of the coronary artery disease
Radionuclide perfusion stress study	"Cold spot" image or perfusion defect associated with scan obtained during exercise	May be used in patients with ventricular conduction defects Pharmacological agents may be used in patients who cannot exercise
Online ischemia analysis	Myocardial ischemia dynamic analysis (MIDA)* analyzing eight leads to detect ST-segment levels indicating ischemia and QRS complex changes corresponding to infarct evolution	Noninvasive Hastens clinical decision making Graphic trends monitored online Reocclusion readily identified Helps differentiate chest pain related to ischemia from nonischemic symptoms

*MIDA CoroNet, Hewlett-Packard, Andover, MA, Product Literature.

radioactivity with a gamma camera positioned over the chest. The number of counts recorded per unit of time is proportional to the blood volume moving through the cardiac chambers. Information is collected on cardiac wall motion, dilation, and wall thickness.

A *first pass MUGA* is performed specifically when information is required regarding right ventricular function. In this study, the gamma camera is positioned to begin counting before the radioactive tracer is injected. That way, when the venous blood makes its first pass through the right side of the heart, information can be obtained on right ventricular function. Once the tracer completes a circulatory cycle, leading to labeled blood in both the right and left ventricles, right ventricular function is obscured by the left ventricle.

Nurses caring for patients who have undergone radionuclide imaging should be aware of precautions; this information is available through the radiation safety department of their institution. The length of time that any precautions may be necessary is related to the half-life of the radiotracer used. In general, nurses who are pregnant should avoid caring for patients for 24 to 48 hours after the study, and all nurses should wear gloves when handling body fluids during the 24- to 48-hour period.

Stress Echocardiography

There are several important advantages to the use of echocardiography as the imaging modality with stress testing. The echocardiogram identifies regional wall motion abnormalities, which are the final result of myocardium that is poorly perfused, secondary to CAD. Echocardiograms can be read immediately, do not involve ionizing radiation, and are more cost effective than nuclear imaging. The disadvantages of stress echocardiography include the difficulty in obtaining quality images secondary to the experience of the technologist and because of the patient's body habitus. Images must be obtained both at rest and at peak exercise for comparison.

Stress echocardiography can be used with exercise stress testing or pharmacological stress testing. A baseline 2D echocardiogram is performed before exercise is performed or the drug is infused. (For pharmacological stress testing, dobutamine or dipyridamole is used as the provocative agent.) The imaging is continued through and for 10 minutes after stopping the exercise or drug infusion. The echocardiogram is examined for wall motion abnormalities indicative of poor regional myocardial perfusion. A study is considered positive if, after exercise or drug infusion, new wall motion abnormalities are detected.

▲ Computed Tomography

Computed tomography (CT) scanning is a noninvasive technique used to evaluate the heart and its surrounding structures. CT scanning involves passing x-ray beams through a patient's body while a detector gathers and records images generated by the beams. Computers reconstruct the images into 2D or 3D images that provide strikingly detailed views of the anatomy. See Figure 17-14. Cardiac CT scanning is used to detect structural diseases of the heart, including congenital anomalies and aneurysms.

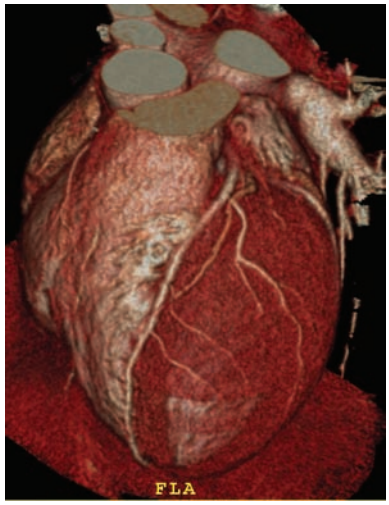

FIGURE 17-14 ▲ Multislice CT image of the heart, a 64-slice cardiac computed tomography scan of the heart, frontal plane.

Coronary artery calcium (CAC) is an indicator of atherosclerosis that can be assessed by CT. Atherosclerotic plaque evolves though stages where instability and rupture may be followed by calcification. Although arterial calcification indicates a later stage of vascular disease, its absence does not exclude the presence of noncalcified plaque that is vulnerable to rupture.[14] A CAC score (CACS) of zero, consistent with no detectable CAC, may be falsely reassuring as this measurement does not identify plaque that has yet to be calcified. There is no direct association between the CACS and degree of stenosis of atherosclerotic lesions. In other words, it is possible to have a very high CACS with no flow limiting intravascular lesions, or a very low CACS with significant flow limiting intravascular lesions. CACS is most useful in determining a patient's CVD event risk by virtue of its strong association with total coronary atherosclerotic disease burden.[9] The Agatston Score is used to measure the amount of calcium detected during a coronary CT. Scores of less than 10, 11 to 99, 100 to 400, and greater than 400 are used to categorize individuals into groups having minimal, moderate, increased, or extensive amounts of calcification, respectively. Although it has not replaced coronary angiograms as the gold standard of detection and quantification of CAD, the CACS adds independent prognostic information of all-cause mortality when used in conjunction with risk assessment algorithms (such as the Framingham risk score).[15]

Coronary computed tomography angiogram (CCTA) is a noninvasive method to visualize the actual lumen of the coronary arteries. CCTA can identify narrowings and stenoses of coronary arteries, whether or not calcium deposits are present. Patients undergoing ECG-gated CCTA may need heart rate modulation. Optimal heart rates are 55 to 60 beats/min and can be safely achieved in most patients with medications, particularly β-blockers. Patients require placement of an IV line for contrast administration. Monitoring for contrast-induced allergic reactions and renal toxicity is also necessary.

▲ Magnetic Resonance Imaging

MRI allows high-resolution assessment of cardiovascular anatomy, function, blood flow, metabolism, and perfusion. It permits assessment of cardiac structure and function at rest or during exercise or pharmacological stress testing. MRI is used in the diagnosis of CAD, coronary artery bypass graft disease, cardiomyopathy, valvulopathy, congenital heart disease, cardiac masses, intracardiac thrombi, and diseases of the pericardium. Myocardial viability studies can be performed using MRI; thus, viable or ischemic tissue can be distinguished from scarred or infarcted tissue. Centers performing electrophysiology procedures use MRI to map pulmonary veins before an atrial fibrillation pulmonary vein ablation procedure. Atrial septal defects can be characterized before the percutaneous placement of an occlusion device.

Cardiovascular MRI has other advantages. It is useful in patients unable to tolerate iodine-based contrast material because of allergy or renal insufficiency. Gadolinium, the MRI contrast medium, can cause both allergic reactions and nephrotoxicity, but the frequency of both complications appears to be less than that associated with iodinated contrast material. In addition, cardiovascular MRI with a stress testing protocol is being used to provide a comprehensive evaluation of cardiac structure, wall function, valvular function, myocardial perfusion, angiography, and viability. The provocative agent used for MRI stress testing can be adenosine, dobutamine, or dipyridamole.

Coronary MRI remains challenging because of several unique issues, including the small size of coronary arteries and their nearly constant motion during respiration and cardiac cycles. MRI requires expensive equipment that may not be available at all centers.

Obesity may be a contraindication for MRI (or magnetic resonance angiography) because the patient is required to fit into a fixed-sized tunnel within the scanner. The patient must be able to lie flat and remain composed despite confinement and loud noises generated by the scanner. Non–MRI-compatible aneurysm clips, implanted devices (including implanted cardiac defibrillators and pacemakers), and other body metal are all contraindications to MRI scanning. Patients with a history of metalworking may have metal shards in their eyes, making them unsuitable for MRI scanning. Contraindications to MRI are listed in Box 17-10. Although tattoo dye may contain metallic oxides that heat up during MRI, tattoos are not contraindicated in MRI scanning. Breath holding is required to avoid breathing artifacts at intervals during MRI, so cardiac MRI scanning may not be appropriate for patients who are unable to hold their breath. An IV line is required for instilling the contrast medium. Central catheters are not used because of the high pounds per square inch injection pressure used.

BOX 17-10 Contraindications to Magnetic Resonance Imaging

Absolute	Relative (Individual Assessment Required)
Cardiac pacemaker	Prosthetic joints
Aneurysm clips	Certain foreign objects in body (eg, dental braces)
Epicardial pacing wires	Nonmetallic prosthetic heart valves
Metal prosthetic heart valves	Surgical staples
Implanted cardioverter–defibrillator	Coronary stents (if recently deployed)
Implanted infusion pumps	
Cochlear implants	
Metal intrauterine devices	
Metal debris (eg, bullets, shrapnel)	

▲ Positron Emission Tomography

PET has significantly contributed to the knowledge of cardiac physiology and metabolism. It detects coronary stenoses (perfusion) and assesses myocardial viability (metabolism). PET scanning is the gold standard for testing myocardial viability.

Rubidium-82 and nitrogen-13–labeled ammonia are tracers used in evaluating regional myocardial blood flow. Fluorodeoxygenase (FDG) and carbon-11–labeled acetate are used for evaluating glucose and fatty acid metabolism, respectively. If perfusion testing with rubidium-82 and nitrogen-13 ammonia demonstrates decreased blood flow, and metabolic testing with FDG and carbon-11 acetate demonstrates absent metabolic activity, then that region of myocardium is considered nonviable. That is, there is a matched decrease in flow and metabolism. If, on the other hand, the flow appears reduced by the perfusion tracers but the metabolic activity is preserved, that region of myocardium is considered ischemic and viable. This would indicate a mismatch of flow and viability, and it would direct the patient's treatment to an intervention that would restore flow to a viable area of tissue.

The patient should be NPO for 6 hours before the study. Caffeinated beverages should be restricted for 24 hours before the procedure.

▲ Cardiac Catheterization, Coronary Angiography, and Coronary Intervention

During cardiac catheterization and related procedures, radiographic contrast is injected into the chambers of the heart and the coronary arteries under fluoroscopic guidance. These studies are commonly performed and are well established as the gold standard for evaluating the coronary artery lumen. Intracoronary lesions may be targets for a variety of interventions, including angioplasty and stenting, or coronary artery bypass. Coronary anomalies and other disease states, including aneurysms and myocardial bridging, can also be seen. Coronary interventions are performed based on the information gained during the diagnostic cardiac catheterization.

The major limitations related to cardiac catheterization involve cost, experience of the operator, level of risk afforded, and ability to determine whether an identified lesion can cause ischemia. The cost of cardiac catheterization, which is in the thousands of dollars, is much greater

than for noninvasive modalities. Extensive data indicate that the physician operator must perform at least 75 procedures annually to maintain the skills necessary to perform a safe and interpretable procedure. Although this procedure can locate blockages in the coronary arteries, more information may be required to understand the ischemic potential of a given lesion before an angioplasty is performed.

Patients undergoing cardiac catheterization require careful preprocedure evaluation, including a recent history and physical examination to identify a history of contrast media allergy as well as a recent set of laboratory studies, including a complete blood count, prothrombin and partial thromboplastin time, International Normalized Ratio, and chemistry panel (serum potassium, creatinine, and blood urea nitrogen levels). Women who are premenopausal and could be pregnant must have pregnancy tests performed within 48 hours of the procedure. The patient must also be NPO for at least 8 hours before the procedure; appropriate medications may be taken with a sip of water on the morning of the procedure. Patients need IV line placement, and consideration may be given to insertion of a Foley's catheter if the patient may have difficulty urinating postprocedure. Patients must be able to lie still and almost flat on a procedure table for the duration of the examination. For nursing considerations for the patient undergoing cardiac catheterization, see Box 17-11. After the procedure, the patient requires careful monitoring of vital signs (blood pressure, heart rate, and respirations with pulse oximetry). The percutaneous entry site of the procedure needs close monitoring for signs of bleeding. Any bleeding or hematoma formation must be managed to prevent serious vascular complications, including retroperitoneal bleeding. IV fluids after the procedure promote elimination of the renal-toxic contrast media and protect the patient from hypotension due to dehydration or increased vagal tone during potentially painful portions of the recovery. Bed rest for several hours after an arteriotomy is mandatory to allow the site to stabilize and further protect the patient from vascular bleeding complications. A summary of patient teaching for patients undergoing cardiac catheterization can be found in Box 17-12.

IVUS is an adjunctive technique performed in patients undergoing cardiac catheterization. IVUS uses ultrasound technology to obtain information regarding the lumen and wall structure of the coronary artery. It permits detailed cross-sectional imaging of coronary arteries and allows for a risk assessment of individual lesions. It is frequently performed in conjunction with coronary angiograms to determine lumen measurements and characteristics, including plaque morphology and burden. The information obtained from IVUS can be used to determine the need for coronary angioplasty or stenting. It is also used to evaluate the final outcome from coronary angioplasties with and without stenting.

The standard method for determining when to use angioplasty to treat an intracoronary lesion is angiography alone. However, determining which lesions cause ischemia can be difficult, and coronary angiography may under- or overestimate a lesion's functional severity. Fractional flow reserve (FFR) is a measurement that is obtained to help determine the ischemic potential of coronary stenoses. FFR is performed in the cardiac catheterization laboratory in conjunction with angiography and is defined as the ratio of maximal blood flow in a stenotic blood vessel compared with normal maximal blood flow. A pressure-sensor guidewire is threaded beyond the lesion in question, and the pressure gradient across the blockage is measured at peak hyperemia, usually induced by

BOX 17-11 NURSING INTERVENTIONS

For the Patient Undergoing Cardiac Catheterization

Preprocedure

- Explain procedure to patient and family.
- Verify that the patient has taken nothing by mouth for at least 6 hours before the procedure except prescribed medications as advised by the physician.
- Ensure that ordered preoperative laboratory studies have been completed and results are available.
- Verify patient, identify allergy information; alert physician if patient is allergic to radiographic dye, medications, or specific foods.
- Ensure that informed consent has been obtained.
- Establish intravenous (IV) access per institutional protocol or physician order.
- Place patient on cardiac monitoring system with blood pressure and pulse oximetry monitoring.
- Provide supplemental oxygen as ordered/indicated.
- Premedicate patient per physician order.
- Obtain vital signs before transfer to catheterization laboratory.

During Procedure

- Continually assess patient vital signs, oxygenation, level of consciousness, and cardiac rhythm per institutional protocol.
- Alert attending physician to significant changes in vital signs, oxygenation, and presence of malignant cardiac dysrhythmias (eg, premature ventricular contractions, ventricular tachycardia, ventricular fibrillation).
- Be prepared to initiate cardiac resuscitation with emergency equipment and medications.

Postprocedure

- Ensure that patient vital signs are stable before transfer.
- Check catheterization site dressing for bleeding and integrity.
- Check distal pulse below catheterization site; if femoral site was used, check distal pulse, extremity color, capillary refill, and neurosensory status.
- Keep extremity straight and instruct patient not to bend leg or arm.
- Maintain IV infusion per physician order or institutional protocol.
- Maintain supplemental oxygenation support as ordered or indicated.
- Encourage oral fluids as ordered.
- Check patient's coagulation status per institutional protocol before sheath removal.
- When catheter is removed:
  - Apply direct pressure over invasive site for 20 to 30 minutes to prevent bleeding or apply commercial hemostatic compression device per institutional protocol.
  - Check distal extremity for pulse, color, capillary refill, and sensorium.
  - Remind patient to lie flat for 4 to 6 hours per institutional protocol.
  - Check site dressing every 4 to 6 hours for bleeding and integrity.

BOX 17–12 TEACHING GUIDE Cardiac Catheterization

Preprocedure

- Instruct the patient not to take anything by mouth for at least 6 hours before the procedure, except prescription medications as advised by the physician to reduce the chance of nausea and vomiting during the procedure.
- Tell the patient that an IV line will be placed to allow fluid and medication administration before, during, and after the procedure.
- Tell the patient that preoperative medication will be given before transport to the catheterization laboratory.
- Inform the patient that only a patient gown will be worn during the procedure.
- Advise the patient that the catheterization laboratory is usually cool, and the procedure table is firm and may be uncomfortable after a prolonged time.
- Explain that the patient may be asked to turn the head, hold the breath, or cough during the procedure.
- Advise that some discomfort may be experienced during the procedure but that local anesthesia will be administered to minimize pain.
- Inform the patient that a cardiac monitor will be used for the duration of the procedure and for a few hours after the procedure.

During Procedure

- Instruct the patient to inform the physician and team of any chest pain experienced.
- Remind the patient to lie still.
- Reassure the patient and allay anxiety.
- Encourage and answer the patient's questions.

Postprocedure

- Remind the patient to lie still and keep the extremity straight.
- Instruct the patient to verbalize any chest pain or shortness of breath if present.
- Tell the patient when the catheter sheath is due for removal.
- Encourage the patient to take oral fluids as ordered.
- Advise the patient that the physician will review and explain the catheterization findings.
- Tell the patient that lying flat for several hours after the procedure will minimize the chance of bleeding from the catheter site.
- Inform the patient that oral fluids should be consumed as tolerated after the procedure to assist in eliminating the radiographic contrast material.
- Encourage the patient and family to ask questions.

intracoronary adenosine infusion. It is calculated as the mean distal coronary pressure divided by the mean aortic pressure during maximum blood flow. FFR in a normal coronary artery is a value of 1. An abnormal value of less than 0.75 indicates a flow-limiting lesion and is associated with ischemia. While not mandatory to perform, FFR-guided interventions have been associated with a reduced rate of primary composite end point of death, MI, and repeat vascularization at 1 year, when compared with standard percutaneous coronary interventions guided by angiography alone.[16]

Coronary interventions that may be necessary include percutaneous transluminal coronary angioplasty (PTCA), which involves the displacement of intracoronary plaque or thrombus for intracoronary blockages of 70% or greater. Intracoronary stents are intraluminal scaffolds placed after PTCA to decrease the reclosure rate of angioplasty sites. In directional coronary atherectomy (DCA), the plaque is removed rather than displaced. DCA is a specialized procedure, used far less frequently than PTCA in most centers. Extraction atherectomy is performed using a transluminal extraction catheter and suction to remove thrombi. A more detailed discussion of coronary interventions can be found in Chapter 18.

Left Heart Catheterization

Left heart catheterization provides information about the lumen of the aorta, coronary arteries, aortic and mitral valvular competencies, and wall motion of the left ventricle. Many studies also include pressure measurements in the left atrium and left ventricle, with pressure gradients measured across the aortic and mitral valves, as well as over the left ventricular outflow tract.

A diagnostic left heart catheterization is typically performed percutaneously from either the brachial or femoral artery. This procedure delineates baseline coronary anatomy, and it can identify abnormalities of the coronary arteries, great vessels, and cardiac chambers. Injection of the coronary vessels with radiographic contrast shows the actual lumen of the vessel and defines plaque, thrombus, and dissections that cause obstruction to blood flow. The left ventricular filling pressure is obtained as an indicator of the fluid status of the patient. A left ventriculogram, which involves rapid filling of the left ventricle with contrast media, provides the left ventricular ejection fraction as well as information regarding wall motion abnormalities and size of the left ventricle. Patients with valvular disease can have additional studies to measure valvular gradients and chamber pressures to allow for mathematical calculations of valve area and flow dynamics.

The risk profile for left heart catheterization is significant because the procedure involves cannulation of an artery and use of contrast media. The risks include bleeding at the percutaneous entry site, dissection of any of the vessels traversed during the procedure, perforation of peripheral or coronary arteries, mechanical irritation of the cardiac tissue, plaque embolization leading to MI or cerebrovascular accident, allergic reactions to the contrast media or any other drug given during the procedure, and renal compromise because of the renal toxic effects of the contrast media.

Right Heart Catheterization

Right heart catheterization aids in the differentiation of left ventricular failure versus pulmonary disease as a cause of dyspnea. It is performed in patients with a history of dyspnea, valvular heart disease, and intracardiac shunts.

Diagnostic right heart cardiac catheterizations can be performed from the right or left external jugular or the femoral veins. Right heart chamber pressures and information about the pulmonic valve and PA pressures are obtained. More commonly, the procedure may be performed through the inferior jugular vein to the superior vena cava. The goal is to

sample oxygen saturations and pressures in the right atrium, right ventricle, pulmonary capillary bed, and PA.

The most common problem during right heart catheterization is dysrhythmia resulting from stimulation of the myocardium. The dysrhythmias are self-limiting and usually do not require treatment. Postprocedure restrictions are minimal because a vein is accessed, and the risk for bleeding is low.

ELECTROCARDIOGRAPHIC MONITORING

Cardiac monitoring is used in a variety of settings. Traditionally used in ICUs and operating rooms, cardiac monitors are commonly found in many inpatient units where it is necessary to monitor continuously a patient's heart rate and rhythm or the effects of a therapy. In addition, cardiac monitors are used outside the hospital in settings such as paramedic ambulances, surgical centers, outpatient rehabilitation programs, and transtelephonic monitoring clinics.

Although the type of monitor may differ in each of these settings, all monitoring systems have three basic components: a display system, a monitoring cable, and electrodes. Electrodes are placed on the patient's chest to receive the electrical current from the cardiac muscle tissue. The electrical signal is then carried by the monitoring cable to a screen, where it is magnified and displayed. The display can be obtained both at the patient's bedside and at a central station, along with displays from other patients' monitors.

The capabilities of cardiac monitors have greatly expanded since they were first introduced nearly 50 years ago. Early monitoring systems were used merely for assessing the patient's heart rate and rhythm. Today's monitors have expanded capabilities that include the diagnosis of complex dysrhythmias, the detection of myocardial ischemia, and the identification of prolonged QT intervals. These expanded features are made possible through development of computerized dysrhythmia detection algorithms, ST-segment monitoring software, noise reduction features, multilead monitoring systems, and derived 12-lead ECGs with a minimum number of electrodes.

▲ Equipment Features

Two types of cardiac monitoring equipment are in use: continuous hard-wire monitoring systems and telemetry monitoring systems.

Hard-Wire Monitoring Systems

Hard-wire monitors, which are commonly used in ICU settings, require the patient to be linked directly to the cardiac monitor through the ECG cable. Information is displayed and recorded at the bedside along with simultaneous display and recording at a central station. Because this type of cardiac monitoring limits patient mobility, patients using this system usually are confined to bed rest or are allowed to be up at the bedside only. Hard-wire monitors operate on electricity but are well isolated so that water, blood, and other fluids do not pose an electrical hazard as long as the machine is maintained properly.

Telemetry Monitoring Systems

In telemetry monitoring, no direct wire connection is needed between the patient and the ECG display device. Electrodes are connected by a short monitoring cable to a small battery-operated transmitter. The ECG is then sent by radiofrequency signals to a receiver that picks up and displays the signal on an oscilloscope, either at the bedside or at a distant central recording station. Antennas are built into the receiver and may be mounted in the vicinity of the receiver to widen the range of signal pickup. Batteries are the power source for the transmitter and make it possible to avoid electrical hazards by isolating the monitoring system from potential current leakage and accidental shock. Telemetry systems are used primarily for dysrhythmia monitoring in areas where the patient is fairly mobile, such as a dysrhythmia surveillance or progressive care unit. Because the patient is mobile, stable ECG tracings often are more difficult to obtain. Some hard-wire systems have built-in telemetry capability so that patients may be switched easily from one system to another as monitoring needs change.

Display Systems

Modern electronic technology continues to make sophisticated advances in monitoring equipment, and current display systems incorporate features such as the following:

- Computerized storage capability that permits retrieval of dysrhythmia data
- Automatic chart documentation, in which the ECG recorder is activated by alarms or at preset intervals
- Expanded alarm systems for a variety of parameters
- Multilead or 12-lead ECG display, which facilitates interpretation of complex dysrhythmias
- ST-segment analysis for monitoring ischemic events
- Computer systems that store, analyze, and trend monitored data, allowing the information to be retrieved at any time to aid in diagnosis and to note trends in the patient's status
- Wireless communication devices carried by the nurse that provide data and alarms
- QT-interval monitoring

Monitoring Lead Systems

All cardiac monitors use lead systems to record the electrical activity generated by cardiac tissue. Each lead system is composed of a positive or recording electrode, a negative electrode, and a third electrode used as a ground. As the heart depolarizes, the waves of electrical activity move inferiorly because the normal route of depolarization moves from the SA node and atria, downward through the AV node, His-Purkinje system, and ventricles, and to the left because the

muscle mass in the left side of the heart is greater than the muscle mass of the right side of the heart. Each lead system views these waves of depolarization from a different location on the chest wall and thus produces P waves and QRS complexes of varying configuration.

The terminology used to describe lead systems can be confusing. The wires attached to the patient's chest are called leads, and the pictures produced by these wires are also called leads. A standard ECG uses 10 lead wires with electrodes at the ends (4 placed on the limbs, and 6 placed on the chest) and produces 12 electrical views of the heart, known as 12 leads.

Cardiac monitoring systems currently on the market vary from a simple three-electrode device to the more common five-electrode system. Other systems less commonly used aim to reduce the number of electrodes while monitoring all 12 leads. The discussion of monitoring in this chapter will focus on the three- and five-lead systems.

The three-electrode system produces limited selections of leads I, II, or III with only a single lead viewed on the screen at one time (single-channel recording). Five-electrode systems allow the possibility of viewing any of the 12 ECG leads and permit the nurse to view two or more leads on the monitor screen simultaneously (multichannel recording).

Three-Electrode Systems

Monitors that require three electrodes use positive, negative, and ground electrodes that are placed in the right arm (RA), left arm (LA), and left leg (LL) positions on the chest as designated by markings on the monitor cable. When the electrodes are placed appropriately, the standard leads (leads I, II, III) may be obtained by moving the lead selector on the bedside monitor to the lead I, II, or III position (Fig. 17-15). The lead selector automatically adjusts which electrode is positive, which electrode is negative, and which electrode is ground to obtain an appropriate tracing. When lead I is selected, the LA is positive, the RA is negative, and the LL is ground. For a lead II configuration, the LL is positive, the RA is negative, and the LA is ground. To obtain a lead III, the LL is positive, the LA is negative, and the RA is ground. The configuration of leads I, II, and III, known as Einthoven's triangle, is illustrated in Figure 17-16.

To obtain a chest lead on the monitor that replicates the chest lead from the 12-lead ECG, a five-wire system is needed. (See Fig. 17-9 on page 224 for a review of chest lead placement.) When only three wires are available, a modified version of any of the six chest leads may be obtained. To configure a modified chest lead (MCL), the goal is to position the positive electrode in the designated chest position. For example, an MCL_1 would require the positive electrode to be placed in a V_1 position (fourth intercostal space, right sternal border). The negative electrode is always positioned under the left clavicle. The ground electrode can be positioned anywhere.

To obtain an MCL_1 lead, the monitor is set to lead I (Box 17-13). (By setting the monitor to lead I, the LA electrode is positive, the RA electrode is negative, and the leg wire is ground [Einthoven's triangle].) The positive electrode (LA) is placed in a V_1 position (fourth intercostal space, right sternal border), and the negative electrode (RA) is positioned under the left clavicle. The ground electrode (LL) can be positioned anywhere, but if it is placed in a V_6 position, it is helpful when switching to an MCL_6 lead.

To obtain an MCL_6 lead, the goal is to place a positive electrode in a V_6 position, a negative electrode under the left

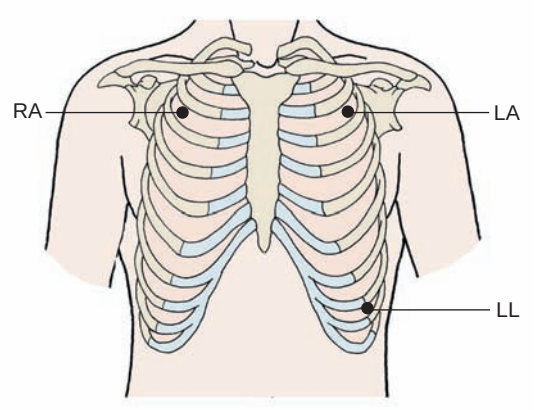

FIGURE 17-15 ▲ Three-electrode monitoring system. Leads placed in this position allow the nurse to monitor leads I, II, and III. The left leg electrode must be placed below the level of the heart. LA, left arm; LL, left leg; RA, right arm.

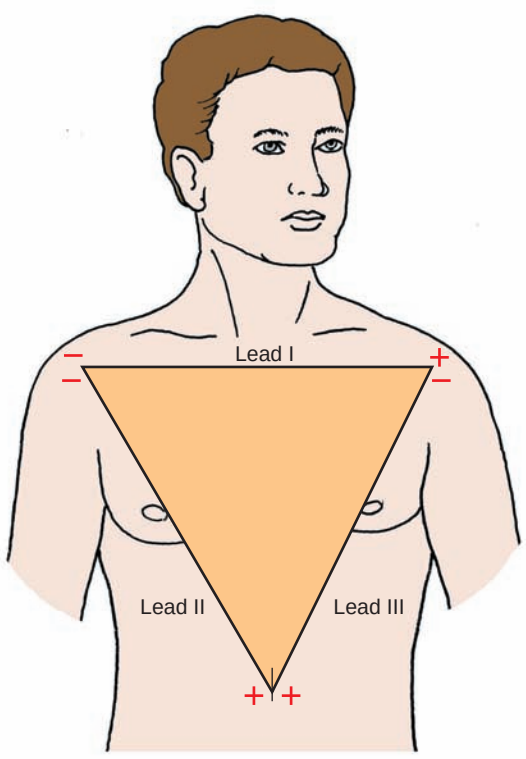

FIGURE 17-16 ▲ Einthoven's triangle. Leads I, II, and III are known as the standard leads. When placed together over the chest, they form what is known as Einthoven's triangle.

Lead I: LA is positive, and RA is negative.

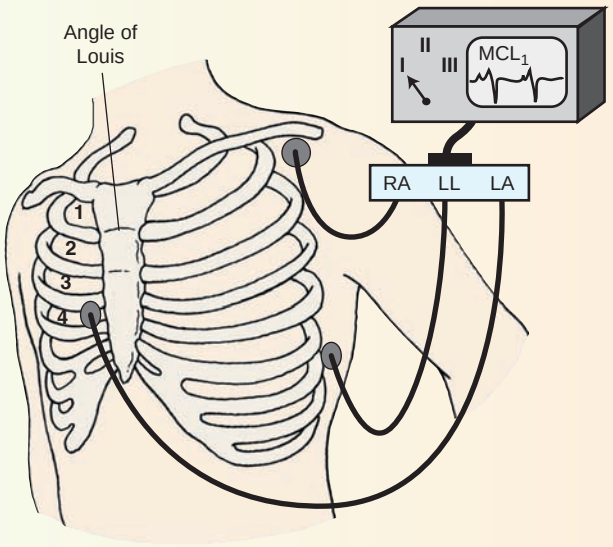
Lead II: LL is positive, and RA is negative.

Lead III: LL is positive, and LA is negative.

BOX 17-13 Three-Electrode System

To monitor modified chest lead $(MCL)_1$ using a three-electrode monitor:

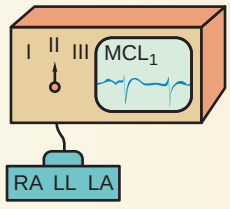
1. Select lead I on the monitor.
2. Refer to Einthoven's triangle to remember that LA is positive, RA is negative, and LL is ground for lead I.
3. Place the positive electrode (LA) in a V_1 position (fourth intercostal space, right sternal border).
4. Place the negative electrode (RA) under the left clavicle.
5. Place the ground wire (LL) in the V_6 position (fifth intercostal space, left midaxillary line).



To monitor MCL_6 using a three-electrode monitor:

1. Select lead II on the monitor.
2. Refer to Einthoven's triangle to remember that LL is positive, RA is negative, and LA is ground for lead II.
3. Place the positive electrode (LL) in the V_6 position (fifth intercostal space, left midaxillary line).
4. Place the negative electrode (RA) under the left clavicle.
5. Place the ground wire (LA) in a V_1 position (fourth intercostal space, right sternal border).

Note: The electrodes are in the same position on the chest for the MCL_1 lead and the MCL_6 lead. To view the two leads, the nurse merely switches the monitor from lead I to lead II.



clavicle, and a ground wire anywhere. By setting the monitor to lead II, the LL electrode is positive, the RA electrode is negative, and the LA electrode is ground (Einthoven's triangle). The positive electrode (LL) is placed in the V_6 position (midaxillary line, same horizontal level as V_4), and the negative electrode (RA) is placed under the left clavicle. The ground wire can be placed anywhere, but if it is placed in a V_1 position, it will be helpful when switching to an MCL_1 lead.

By arranging the electrodes as described, the nurse can monitor both MCL_1 and MCL_6 merely by switching the monitor from a lead I to a lead II without changing the electrode placement on the patient's chest. MCL_1 and MCL_6 are ideal leads for detecting bundle branch block (BBB) rhythms and for differentiating supraventricular wide-QRS tachycardias from VT.

Five-Electrode Systems

The five-electrode system that increases the monitor's capability beyond the three-electrode system is preferred over the three-electrode system. (The four-electrode monitor requires a right leg electrode that is the ground for all leads described in the three-electrode system.) The five-electrode monitor adds an exploring "chest" electrode that allows one to obtain any one of the six chest leads and the six limb leads. In essence, a five-wire monitor system provides all the capabilities of the 12-lead ECG machine. The only difference is that the five-wire monitor has only one chest electrode, whereas the 12-lead ECG machine has six chest electrodes. Newer cardiac monitors now have all six chest electrodes and allow the nurse to view all 12 leads of the ECG simultaneously on the monitor screen.

To monitor a patient with a five-wire system, the four limb electrodes are positioned on the body according to their designations. The fifth chest electrode is placed on the chest in the designated precordial position. For example, if the nurse wants to monitor V_1, the chest electrode is placed in the fourth intercostal space, right sternal border (Fig. 17-17). If the nurse wants to switch to a different chest lead for monitoring, the electrode must be repositioned on the patient's chest. A five-electrode monitor offers the additional advantage of allowing the nurse to view two or more different leads simultaneously on the monitor screen.

Lead Selection

No single monitoring lead is ideal for every patient. Table 17-9 summarizes the use of various leads and the reasons for their use. Lead II is used commonly because it records clear upright P waves and QRS complexes that are helpful in determining the underlying rhythm. In addition to lead II, leads III, aVF, and V_1 or MCL_1 show well-formed P waves and therefore are helpful in identifying atrial dysrhythmias. V_1 or MCL_1 is useful in recognizing RBBB and in differentiating ventricular ectopy from supraventricular rhythms with aberrancy. V_6 or MCL_6 is helpful in identifying LBBB and also is useful in differentiating ventricular ectopy from supraventricular rhythms with aberrancy. Lead I may be tried in the patient with respiratory disease who has much artifact on the tracing because there is less movement of the positive electrode in this lead than in a lead II or a V_1.

As mentioned, there is no one ideal monitoring lead for every patient, and in several situations, multilead recording is desirable. Multilead ECG systems offer multiple views of the heart because they reflect a tracing from each of the major heart surfaces. One of the major uses of multilead monitoring is in the interpretation of complex cardiac dysrhythmias, especially when differentiating aberrancy from ventricular ectopy

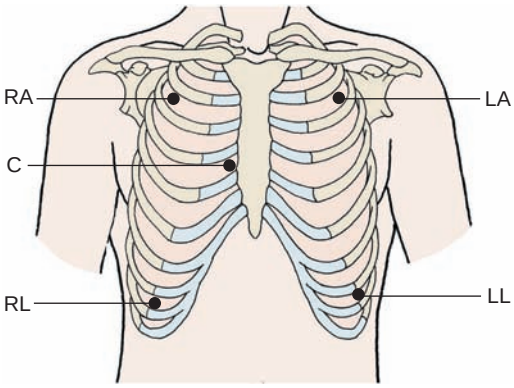


FIGURE 17-17 ▲ Five-electrode monitoring system. Using a five-electrode system allows the nurse to monitor any of the 12 leads of the ECG. The chest electrode must be moved to the appropriate chest location when monitoring the precordial leads.

and in identifying complex atrial dysrhythmias, uncharacteristic-looking ventricular premature beats, and fascicular blocks. Another use of multilead monitoring is in assessment of myocardial ischemia, injury, and infarction. By continuously viewing one lead from each area of the heart, episodes of anginal pain or silent ischemia can be documented. As soon as possible, these changes should be confirmed by a full 12-lead ECG.

Table 17-9 Suggested Monitoring Lead Selection

Lead	Rationale for Use
II	Produces large, upright visible P waves and QRS complexes for determining underlying rhythm
V_1 or modified chest lead $(MCL)_1$	Helpful for detecting right bundle branch block and to differentiate ventricular ectopy from supraventricular rhythm aberrantly conducted in the ventricles
V_6 or MCL_6	Helpful lead for detecting LBBB and to differentiate ventricular ectopy from supraventricular rhythm aberrantly conducted in the ventricles
III, aVF, V_1	Produce visible P waves; useful in detecting atrial dysrhythmias
I	Useful in patients with respiratory distress Left arm and right arm electrodes involved and placements less affected by chest motion compared with other leads
II, III, aVF	Helpful in detecting ischemia, injury, and infarction in the inferior wall Ischemia related to the right coronary artery is best seen in lead III
I, aVL, V_5, V_6	Helpful in detecting ischemia, injury, and infarction in the lateral wall
V_1 through V_4	Helpful in detecting ischemia, injury, and infarction in the anterior wall Ischemia related to the left anterior descending coronary artery or the left circumflex coronary artery is best seen in lead V_3

▲ Procedure

Electrode Application

Proper skin preparation and application of electrodes are imperative for good ECG monitoring. An adequate tracing should reflect (1) a narrow, stable baseline; (2) absence of distortion or "noise"; (3) sufficient amplitude of the QRS complex to activate the rate meters and alarm systems properly; and (4) identification of P waves.

The type of electrode currently used for ECG monitoring is a disposable silver- or nickel-plated electrode centered in a circle of adhesive paper or foam rubber. Most electrodes are pregelled by the manufacturer. They may have disposable wires attached to the electrodes or nondisposable wires that snap onto the electrodes. Electrodes should be comfortable for the patient. If not properly applied, undue artifact and false alarms may result.

When applying electrodes, the following procedure should be followed:

1. Select a stable site. Avoid bony protuberances, joints, and folds in the skin. Areas in which muscle attaches to bone have the least motion artifact.
2. Shave excessive body hair from the site.
3. Rub the site briskly with a dry gauze pad to remove oils and cellular debris. Skin preparation with alcohol may be necessary if the skin is greasy; allow the alcohol to dry completely before applying the electrode. Follow the electrode manufacturer's directions because the chemical reaction between alcohol or other skin-preparation materials and the adhesives used in some electrodes may cause skin irritation or nonadhesion to the skin.
4. Remove the paper backing and apply each electrode firmly to the skin by smoothing with the finger in a circular motion. Attach each electrode to its corresponding ECG cable wire. Sometimes it is necessary to tape over the cable wire connection or make a stress loop with the cable wire for extra stability.
5. Change electrodes every 2 to 3 days, and monitor for skin irritation.

While applying the electrodes, explain the purpose of the procedure to the patient. Reassure the patient that monitor alarm sounds do not necessarily indicate a problem with the patient's heart beat; alarms often occur when an electrode becomes loose or disconnected. See Evidence-Based Practice Highlight 17-1.

Monitor Observation

Cardiac monitors are useful only if the information they provide is "observed," either by computers with alarms for programmed parameters or by the human eye, and appropriately acted on by competent, responsible people. Some critical care units use monitor technicians whose main responsibilities are to observe monitors, obtain chart samples, and give appropriate information to the nurse about each patient's ECG status. Those observing the monitor should know the acceptable dysrhythmia parameters for each patient and should be notified of any interruptions in monitoring, such as those caused by changing electrodes or by changing the patient to

EVIDENCE-BASED PRACTICE HIGHLIGHT 17-1

Dysrhythmia Monitoring

△ Expected Practice

- Select the best monitoring leads for dysrhythmia identification (display two leads when possible).
  - Lead V_1 to diagnose wide QRS complex.
  - Lead II to diagnose atrial activity and measure heart rate.
- Proper electrode placement is required for accurate diagnosis.
- Prepare the patient's skin before attaching ECG electrodes.
- Measure QT interval and calculate QTc using a consistent lead if high risk for Torsades de Pointes.

△ Supporting Evidence

- V_1 is the lead of choice to diagnose wide QRS complexes (ventricular tachycardia vs. supraventricular tachycardia with aberrant conduction; left vs. right bundle branch block). A 5-lead monitoring system is required to monitor V leads. MCL_1 may differ in QRS morphology as compared to V_1 and should be used only when a 5-lead monitoring system is unavailable.[6–10] (Level V)
- When V_1 electrode placement is not possible, V_6 may be used. [7–11] (Level IV)
- Electrode site preparation includes clipping excessive hair and cleansing oily skin with alcohol.[3–4] (Level IV)
- QTc of more than 0.50 seconds (500 ms) is dangerously prolonged and associated with risk for Torsades de Pointes. The QT interval should be corrected for heart rate (QTc) and monitored with any of the following: [9,10,12–15] (Level IV)
  - Antidysrhythmic, antibiotic, antipsychotic, and other drugs that prolong QTc
  - Severe bradycardia
  - Hypokalemia or hypomagnesemia
  - Any drug overdose
- Perform an atrial electrogram (AEG) in cardiac surgical patients with atrial epicardial wires to assist in identifying atrial activity.[16–17] (Level V)

AACN Evidence Leveling System

Level A Meta-analysis of quantitative studies or metasynthesis of qualitative studies with results that consistently support a specific action, intervention or treatment.
Level B Well-designed, controlled studies with results that consistently support a specific action, intervention, or treatment.
Level C Qualitative studies, descriptive or correlational studies, integrative review, systematic reviews, or randomized controlled trials with inconsistent results.
Level D Peer-reviewed professional organizational standards with clinical studies to support recommendations.
Level E Multiple case reports, theory-based evidence from expert opinions, or peer-reviewed professional organizational standards without clinical studies to support recommendations.
Level M Manufacturer's recommendations only.

a portable monitor. The observer also should be aware of the presence of artifact from chest physical therapy or hiccups so that it may be considered in dysrhythmia diagnosis.

Regardless of the system used for monitor observation, certain practices always should be followed. If the monitor alarm sounds, the nurse evaluates the clinical status of the patient before doing anything else to see if the problem is an actual dysrhythmia or a malfunction of the monitoring system. Asystole should not be mistaken for an unattached ECG wire, nor should a patient inadvertently tapping on an electrode be misread as VT. In addition, monitor alarms always should be in the functioning mode. Only when direct physical care is being given to the patient can the alarm system safely be put on "standby." This ensures that no life-threatening dysrhythmia goes unnoticed. If the change on the monitor is not caused by an artifact or a disconnected wire, a full 12-lead ECG should be recorded to evaluate the rhythm change further.

▲ Troubleshooting Electrocardiogram Monitor Problems

Several problems may occur in monitoring the ECG, including baseline but no ECG trace, intermittent traces, wandering or irregular baseline, low-amplitude complexes, 60-cycle interference, excessive triggering of heart rate alarms, and skin irritation. Box 17-14 outlines the steps to follow when such problems occur.

DYSRHYTHMIAS AND THE 12-LEAD ELECTROCARDIOGRAM

Dysrhythmias and abnormalities of the 12-lead ECG commonly encountered in monitored patients can be recognized with a little practice. The types that occur most frequently are discussed in this chapter. Before presenting the individual dysrhythmias and 12-lead ECG abnormalities, the method for evaluating a rhythm strip is addressed.

To understand the causes, clinical significance, and treatment of dysrhythmias, knowledge of the conduction system is essential. Chapter 16 provides a review of the essential elements of the cardiac conducting system.

▲ Evaluation of a Rhythm Strip

Electrocardiogram Paper

An ECG tracing is a graphic recording of the heart's electrical activity. The paper consists of horizontal and vertical lines, each 1 mm apart. The horizontal lines denote time measurements. When the paper is run at a sweep speed of

BOX 17-14 Troubleshooting: ECG Monitor Problem Solving

Excessive Triggering of Heart Rate Alarms
- Is the high–low alarm set too close to the patient's heart rate?
- Is the monitor sensitivity level set too high or too low?
- Is the patient cable securely inserted into the monitor receptacle?
- Are the lead wires or connections damaged?
- Has the monitoring lead been properly selected?
- Were the electrodes applied properly?
- Are the R and T waves the same height, causing both waveforms to be sensed?
- Is the baseline unstable, or is there excessive cable or lead wire movement?

Baseline but No ECG Trace
- Is the size (gain or sensitivity) control properly adjusted?
- Is an appropriate lead selector being used on the monitor?
- Is the patient cable fully inserted into the ECG receptacle?
- Are the electrode wires fully inserted into the patient cable?
- Are the electrode wires firmly attached to the electrodes?
- Are the electrode wires damaged?
- Is the patient cable damaged?
- Call for service if the trace is still absent.
- Is the battery dead (for telemetry system)?

Intermittent Trace
- Is the patient cable fully inserted into the monitor receptacle?
- Are the electrode wires fully inserted into the patient cable?
- Are the electrode wires firmly attached to the electrodes?
- Are the electrode wire connectors loose or worn?
- Have the electrodes been applied properly?
- Are the electrodes properly located and in firm skin contact?
- Is the patient cable damaged?

Wandering or Irregular Baseline
- Is there excessive cable movement? This can be reduced by clipping to the patient's clothing.
- Is the power cord on or near the monitor cable?
- Is there excessive movement by the patient? Are there muscle tremors from anxiety or shivering?
- Is site selection correct?
- Were proper skin preparation and application procedures followed?
- Are the electrodes still moist?

Low-Amplitude Complexes
- Is size control adjusted properly?
- Were the electrodes applied properly?
- Is there dried gel on the electrodes?
- Change electrode sites. Check 12-lead ECG for lead with highest amplitude, and attempt to simulate that lead.
- If none of the preceding steps remedies the problem, the weak signal may be the patient's normal complex.

Sixty-Cycle Interference
- Is the monitor size control set too high?
- Are there nearby electrical devices in use, especially poorly grounded ones?
- Were the electrodes applied properly?
- Is there dried gel on the electrodes?
- Are lead wires or connections damaged?

25 mm/s, each small square measured horizontally is equal to 0.04 second, and a large square (five small squares) equals 0.20 second. Height or voltage is measured by counting the lines vertically. Each small square measured vertically is 1 mm, and the large square is 5 mm (Fig. 17-18). Some ECG paper also is marked by vertical slash marks across the top or bottom. The distance between two vertical markings represents 3 seconds. The distance between 6 seconds is used for rate calculation.

Waveforms and Intervals

During the cardiac cycle, the following waveforms and intervals are produced on the ECG surface tracing (see Fig. 17-18):

- P wave: The P wave is a small, usually upright and rounded deflection representing depolarization of the atria. It normally is seen before the QRS complex at a consistent interval.
- PR interval: The PR interval represents the time from the onset of atrial depolarization until the onset of ventricular depolarization. Included in the interval is the brief delay of the electrical signal at the AV node that allows time for the blood to move from the atria to the ventricles before the ventricles are depolarized. The interval is measured from the beginning of the P wave to the beginning of the QRS complex. A normal PR interval is 0.12 to 0.20 second.
- QRS complex: The QRS complex is a large waveform representing ventricular depolarization. Each component of the waveform has a specific connotation. The initial negative deflection is a Q wave, the initial positive deflection is an R wave, and the negative deflection after the R wave is an S wave. Not all QRS complexes have all three components, even though the complex is commonly called the QRS complex. A normal QRS complex is 0.06 to 0.11 second in width. Figure 17-19 illustrates different kinds of QRS complexes.
- ST segment: The ST segment is the portion of the tracing from the end of the QRS complex to the beginning of the T wave. It represents the time from the end of ventricular depolarization to the beginning of ventricular repolarization. Normally, it is isoelectric. An isoelectric ST segment means the ST segment joins the QRS complex at the baseline. ST segments may be elevated or depressed in a variety of conditions. Elevated ST segments could indicate acute myocardial injury. Depressed ST segments may signify acute myocardial injury or myocardial ischemia. For a more detailed discussion of ST-segment abnormalities, see Chapter 21.
- T wave: The T wave is the deflection representing ventricular repolarization or recovery. The T wave appears after the QRS complex. The atria also have a repolarization phase. However, there is no visible wave on the ECG to represent atrial repolarization because it occurs at the same time as the QRS complex.
- U wave: A U wave is a rarely seen, small, usually positive deflection after the T wave. Its significance is uncertain, but it typically is seen with hypokalemia.
- QT interval: The QT interval is the period from the beginning of ventricular depolarization to the end of ventricular repolarization. The QT interval is measured from the beginning of the QRS complex to the end of the T wave. Because the QT interval varies with heart rate, it is necessary to use a table in which QT intervals for various heart rates are listed. Tables are available for this

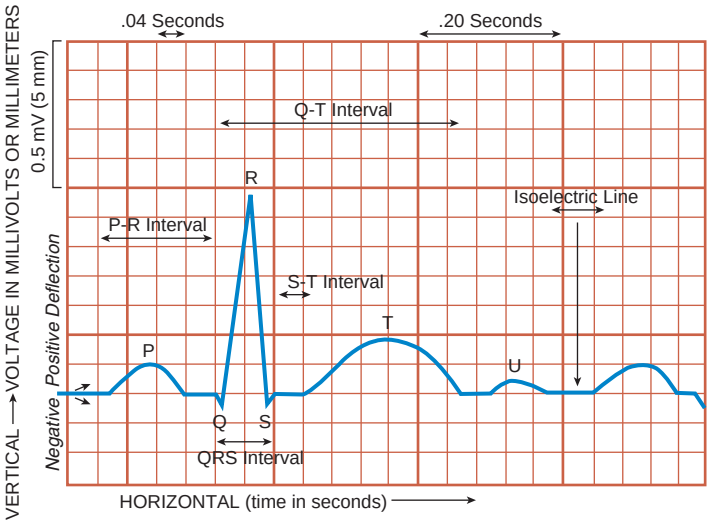

FIGURE 17-18 ▲ Waveforms of the ECG. Schematic representation of the electrical impulse as it traverses the conduction system, resulting in depolarization and repolarization of the myocardium.

purpose in most texts about dysrhythmias (Table 17-10). If such a table is not available, a corrected QT interval (QTc) can be calculated for comparison with normal values. Normal QTc usually does not exceed 0.42 second for men and 0.43 second for women. A quick method for obtaining a QTc is to use half of the preceding RR interval (described later).

Calculation of Heart Rate

Although cardiac monitors and ECG strips can be used to calculate heart rate, the calculated rate is merely an estimate of the number of times per minute the heart has been electrically excited. In the normal heart, each excitation should be followed by cardiac contraction. However, in some situations, electrical activity can occur without contraction, resulting in a lack of perfusion. Therefore, the heart rate obtained from the cardiac monitor or ECG strip should never be substituted for the determination of heart rate by palpating the pulse.

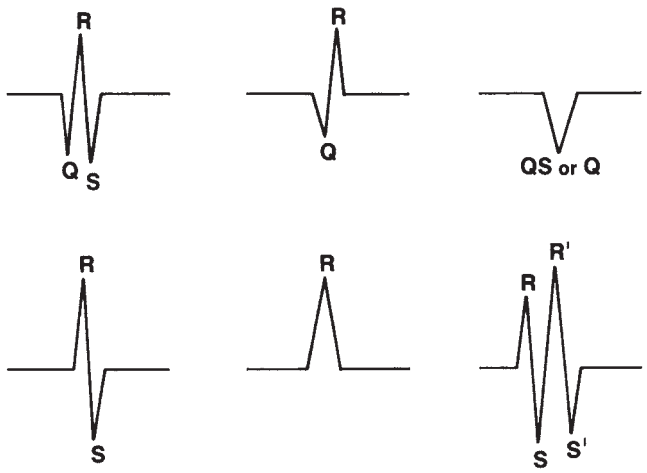

FIGURE 17-19 ▲ Configurations of the QRS complex. A Q wave is a negative deflection before an R wave, an R wave is a positive deflection, and an S wave is a negative deflection after an R wave.

Both the atrial and the ventricular rates can be estimated by examining the ECG. To determine the ventricular rate, count the number of QRS complexes in a 6-second strip and multiply by 10. To estimate the atrial rate, count the number of P waves in a 6-second strip and multiply by 10. In the normal patient, the atrial and the ventricular rates should be the same. This method of rate calculation provides an estimate of heart rate for regular and irregular rhythms.

Another method of rate calculation can be used if the rhythm is regular. The ventricular heart rate is estimated by dividing 300 by the number of large boxes on the ECG paper between two R waves (the RR interval).

Table 17-10 Approximate Normal Limits for QT Intervals in Seconds

Heart Rate per Minute	Men and Children	Women
40	0.45–0.49	0.46–0.50
46	0.43–0.47	0.44–0.48
50	0.41–0.45	0.43–0.46
55	0.40–0.44	0.41–0.45
60	0.39–0.42	0.40–0.43
67	0.37–0.40	0.38–0.41
71	0.36–0.40	0.37–0.41
75	0.35–0.38	0.36–0.39
80	0.34–0.37	0.35–0.38
86	0.33–0.36	0.34–0.37
93	0.32–0.35	0.33–0.36
100	0.31–0.34	0.32–0.35
109	0.30–0.33	0.31–0.33
120	0.28–0.31	0.29–0.32
133	0.27–0.29	0.28–0.30
150	0.25–0.28	0.26–0.28
172	0.23–0.26	0.24–0.26

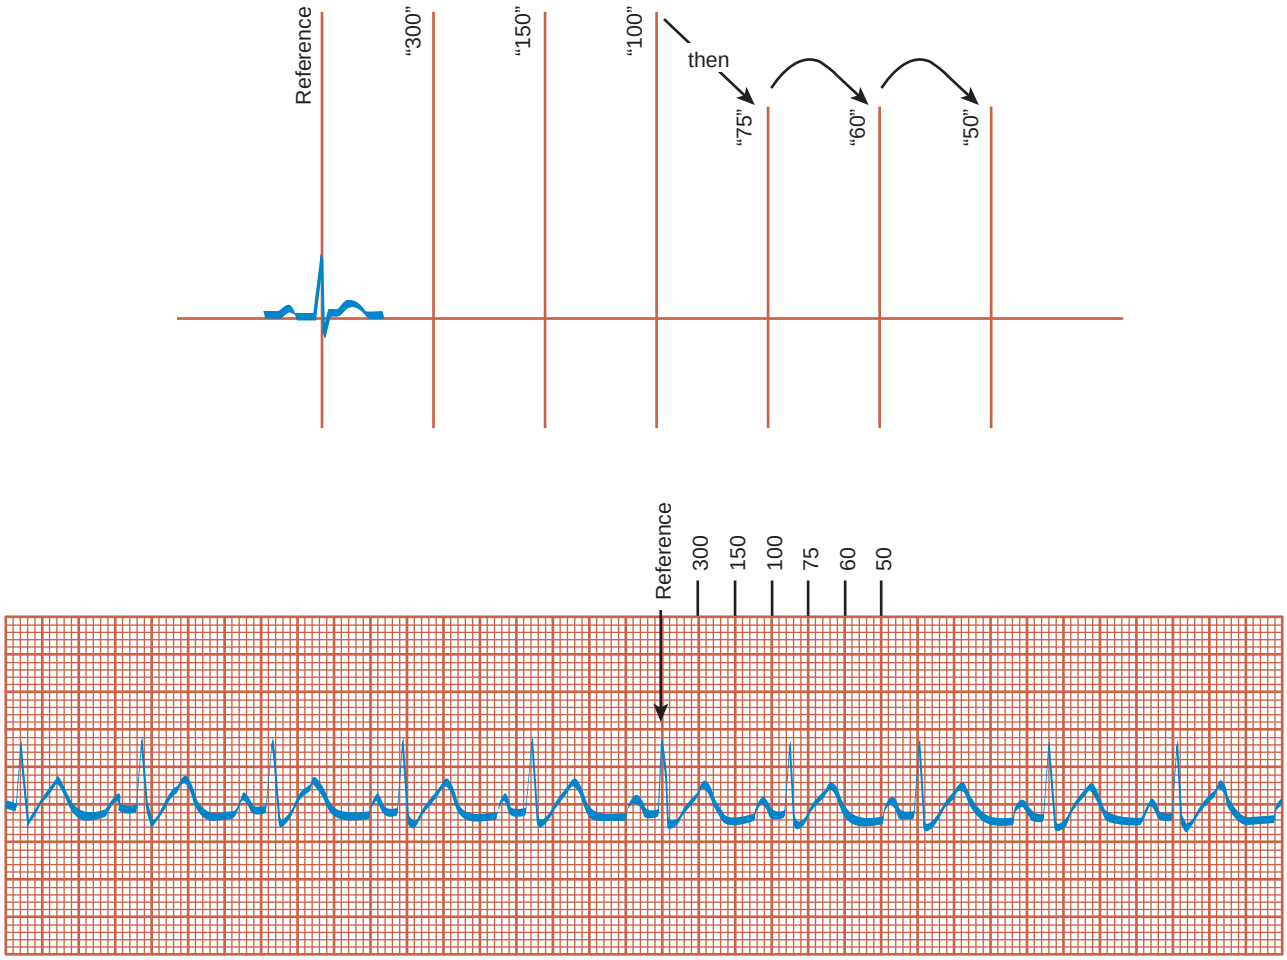

FIGURE 17-20 ▲ Method for estimating heart rate. Using this method, the heart rate is approximately 85 beats/min.

The atrial rate is calculated by dividing 300 by the number of large boxes on ECG paper between two P waves (the PP interval).

Another quick method for estimating rate involves the use of a series of numbers. To use this method for estimating ventricular rate, the nurse first finds a QRS complex that falls directly on a dark line of the ECG paper. This dark line is the reference point. The next six dark lines of the paper are labeled 300, 150, 100, 75, 60, and 50 (Fig. 17-20). Then, the nurse finds the next QRS complex immediately after the reference point and estimates the ventricular rate using the sequence of numbers. The same method can be used for estimating atrial rate by using the P waves.

Steps in Assessing a Rhythm Strip

The following analysis represents a systematic approach to assessment of a cardiac rhythm strip. Whether or not this method is used, it is important to take the time to complete each step because many dysrhythmias are not as they first appear.

1. Determine the atrial and ventricular heart rates.
   - Are they within normal limits?
   - If not, is there a relationship between the two (ie, one a multiple of the other)?
2. Examine the rhythm to see if it is regular.
   - Is there an equal amount of time between each QRS complex (RR interval)?
   - Is there an equal amount of time between each P wave (PP interval)?
   - Are the PP and RR intervals the same?
3. Look for the P waves.
   - Are they present?
   - Is there one or more P waves for each QRS complex?
   - Do all P waves have the same configuration?
4. Measure the PR interval.
   - Is it normal?
   - Is it the same throughout the strip, or does it vary?
   - If it varies, is there a pattern to the variation?
5. Evaluate the QRS complex.
   - Is it normal in width, or is it wide?
   - Are all complexes of the same configuration?
6. Examine the ST segment.
   - Is it isoelectric, elevated, or depressed?
7. Identify the rhythm and determine its clinical significance.
   - Is the patient symptomatic? (Check skin, neurological status, renal function, coronary circulation, and hemodynamic status or blood pressure.)
   - Is the dysrhythmia life-threatening?
   - What is the clinical context?
   - Is the dysrhythmia new or chronic?

▲ Normal Sinus Rhythm

Normal sinus rhythm (Fig. 17-21A) is the normal rhythm of the heart. The impulse is initiated at the sinus node in a regular rhythm at a rate of 60 to 100 beats/min. A P wave appears before each QRS complex. The PR interval is within normal limits and of equal duration (0.12 to 0.20 second), and the QRS is narrow (<0.12 second) unless an intraventricular conduction defect is present.

▲ Dysrhythmias Originating at the Sinus Node

Table 17-11 summarizes and compares ECG characteristics of sinus rhythms.

Sinus Tachycardia

In sinus tachycardia, the sinus node accelerates and initiates an impulse at a rate of 100 times per minute or more (see Fig. 17-21B). The upper limits of sinus tachycardia extend to 160 to 180 beats/min. All other ECG characteristics, except for heart rate, are the same as in normal sinus rhythm.

Sinus tachycardia usually is caused by factors relating to an increase in sympathetic tone. Stress, exercise, and stimulants such as caffeine and nicotine can produce this dysrhythmia. Sinus tachycardia also is associated with such clinical problems as fever, anemia, hyperthyroidism, hypoxemia, heart failure, and shock. Drugs, such as atropine, which blocks vagal tone, and the catecholamines (eg, epinephrine, dopamine) also can produce this rhythm.

The cause of the sinus tachycardia and the underlying state of the myocardium determine the prognosis. Sinus tachycardia alone is not a lethal dysrhythmia but often signals an underlying problem that should be pursued.

In addition, the rapid rate of sinus tachycardia increases oxygen demands on the myocardium and decreases the filling time of the ventricles. In people who already have depleted cardiac reserve, ischemia, or heart failure, the persistence of a fast rate may worsen the underlying condition.

Treatment of sinus tachycardia usually is directed at eliminating the underlying cause. Specific measures may include sedation, oxygen administration, digitalis, and diuretics if heart failure is present, or beta-blockers if the tachycardia is caused by thyrotoxicosis.

Sinus Bradycardia

Sinus bradycardia is defined as a rhythm with impulses originating at the sinus node at a rate of less than 60 beats/min (see Fig. 17-21C). The rhythm (RR interval) is regular, and all other parameters are normal.

Sinus bradycardia is common among people of all ages and may be normal in highly trained athletes. It is present in both healthy and diseased hearts. It may be associated with sleep, severe pain, inferior wall MI, acute spinal cord injury, and certain drugs (eg, digitalis, beta-blockers, verapamil, diltiazem). In people with healthy hearts, slow heart rates are tolerated well. However, in those with severe heart disease, the heart may not be able to compensate for a slow rate by increasing the volume of blood ejected per beat. In this situation, sinus bradycardia leads to a low cardiac output (CO).

No treatment is indicated unless symptoms are present. If the pulse is very slow and the patient is symptomatic, appropriate measures include atropine (to block the vagal effect) or cardiac pacing.

Sinus Dysrhythmia

Sinus dysrhythmia (formerly sinus arrhythmia) is a disorder of rhythm (see Fig. 17-21D) that is said to be present if the RR intervals on the ECG, from the shortest RR interval to

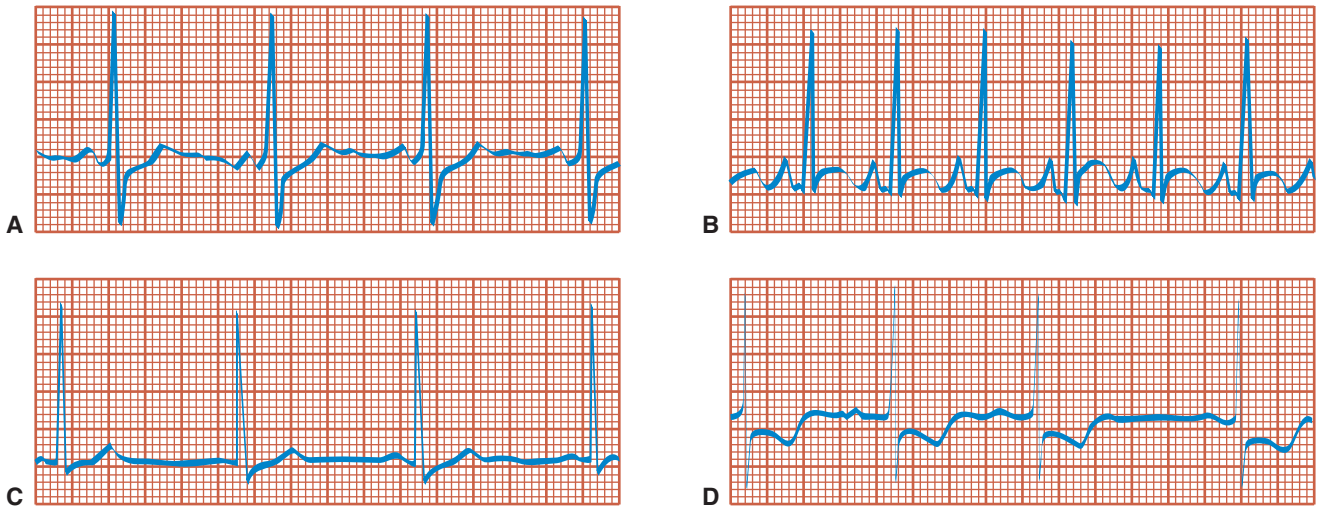

FIGURE 17-21 ▲ Sinus rhythms. **A:** Normal sinus rhythm. (Heart rate = 60 to 100 beats/min.) **B:** Sinus tachycardia. (Heart rate = 100 to 180 beats/min.) **C:** Sinus bradycardia. (Heart rate < 60 beats/min.) **D:** Sinus dysrhythmia. (Difference between shortest and longest RR interval.)

Table 17-11 A Comparison of the Electrocardiographic Characteristics of Sinus Rhythms

	Normal Sinus Rhythm	Sinus Tachycardia	Sinus Bradycardia	Sinus Dysrhythmia
Rate	60–100 beats/min	More than 100 beats/min	<60 beats/min	60–100 beats/min
Rhythm	Regular	Regular	Regular	Irregular
P waves	Present, one per QRS	Present, one per QRS	Present, one per QRS	Present, one per QRS
PR interval	<0.20 s, equal	<0.20 s, equal	<0.20 s, equal	<0.20 s, equal
QRS complex	<0.12 s	<0.12 s	<0.12 s	<0.12 s

the longest, vary by more than 0.12 second. This dysrhythmia is caused by an irregularity in sinus node discharge, often in association with phases of the respiratory cycle. The sinus node rate gradually increases with inspiration and gradually decreases with expiration.

Sinus dysrhythmia is a normal phenomenon, seen especially in young people in the setting of lower heart rates. It also occurs after enhancement of vagal tone (eg, with digitalis or morphine). Because it is a normal finding, sinus dysrhythmia does not imply the presence of underlying disease. Symptoms are uncommon unless there are long pauses between heart beats, and usually no treatment is required.

Sinus Arrest and Sinoatrial Block

Sinus arrest is a disorder of impulse formation. The sinus node fails to form a discharge, producing pauses of varying lengths because of the absence of atrial depolarization. The P wave is absent, and the resulting PP interval is not a multiple of the basic PP interval. The pause ends either when an escape pacemaker from the junction or ventricles takes over or when sinus node function returns.

An SA block often is difficult to differentiate from sinus arrest on a surface ECG tracing. In SA block, the sinus node fires, but the impulse is delayed or blocked from exiting the sinus node. If the block is complete, the duration of the pause is a multiple of the basic PP interval (Fig. 17-22).

Both dysrhythmias may result from disruption of the sinus node by infarction, degenerative fibrotic changes, drugs (digitalis, beta-blockers, calcium channel blockers), or excessive vagal stimulation. These rhythms usually are transient and insignificant unless a lower pacemaker fails to take over to pace the ventricles. Treatment is indicated if the patient is symptomatic. The goal is to increase the ventricular rate, which may require the use of atropine or, in the presence of serious hemodynamic compromise, a pacemaker.

Sick Sinus Syndrome

Sick sinus syndrome refers to a chronic form of sinus node disease (Fig. 17-23). Patients exhibit severe degrees of sinus node depression, including marked sinus bradycardia, SA block, or sinus arrest. Often, rapid atrial dysrhythmias, such as atrial flutter or fibrillation ("tachycardia–bradycardia syndrome"), coexist and alternate with periods of sinus node depression.

Management of sick sinus syndrome requires control of the rapid atrial dysrhythmias with drug therapy and, in selected cases, control of very slow heart rates, often requiring implantation of a permanent pacemaker.

▲ Atrial Dysrhythmias

Premature Atrial Contraction

A premature atrial contraction (PAC) occurs when an ectopic atrial impulse discharges prematurely and, in most cases, is conducted in a normal fashion through the AV conducting system to the ventricles (Fig. 17-24A). On the ECG tracing, the P wave is premature and may even be buried in the preceding T wave; it often differs in configuration from the sinus P wave. The QRS complex usually is of normal configuration. However, because of timing, the QRS complex may appear wide and bizarre if conducted with some

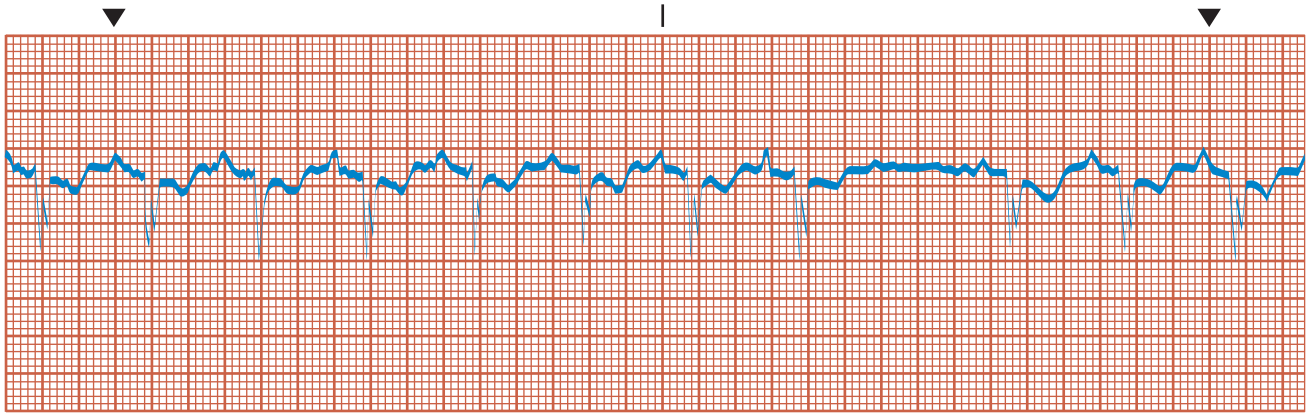

FIGURE 17-22 ▲ Sinoatrial block. The pause is a multiple of the basic PP interval.

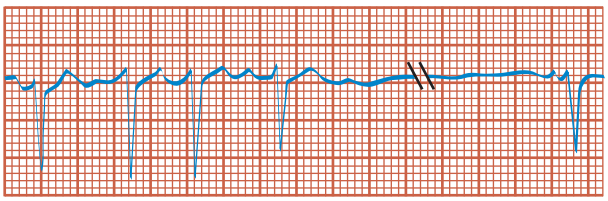

FIGURE 17-23 ▲ Sick sinus syndrome. Atrial fibrillation is followed by atrial standstill. A sinus escape beat is seen at the end of the strip.

degree of delay (aberrant PAC) or may not appear at all if the atrial impulse is blocked from being conducted to the ventricles (blocked PAC). A short pause, usually less than "compensatory," is present (see later definition of PVC on pages 250–253).

People of all ages experience PACs. PACs may occur in healthy people as a result of various stimuli, such as emotions, tobacco, alcohol, and caffeine. PACs also may be associated with rheumatic heart disease, ischemic heart disease, mitral stenosis, heart failure, hypokalemia, hypomagnesemia, medications, and hyperthyroidism.

Alternatively, PACs may be a precursor to an atrial tachycardia, atrial fibrillation, or atrial flutter, indicating an increasing atrial irritability. They also may indicate an underlying condition (eg, heart failure). Patients may have the sensation of a "pause" or "skip" in rhythm when PACs are present.

No treatment is necessary in many cases. The patient should be monitored and frequency of premature beats documented. In addition, the patient should be assessed for underlying conditions and treated.

Paroxysmal Supraventricular Tachycardia

Paroxysmal supraventricular tachycardia (PSVT) describes a rapid atrial rhythm occurring at a rate of 150 to 250 beats/min (Fig. 17-24B). The tachycardia begins abruptly, in most instances with a PAC, and it ends abruptly. P waves may precede the QRS complex but also may be hidden in the QRS complex or precede the T wave at faster rates. (If some of the P waves are not followed by a QRS complex, this is referred to as PSVT with block and usually is caused by digitalis toxicity.) The P waves may be negative in leads II, III, and aVF because of retrograde conduction from the AV node to the atria. The QRS complex usually is normal unless there is an underlying intraventricular conduction problem. The rhythm is regular, and the paroxysms may last from a few seconds to several hours or even days.

The term PSVT is used to identify rhythms previously called paroxysmal atrial tachycardia and paroxysmal nodal or junctional tachycardia, rhythms similar in all respects except in their sites of origin. PSVT also is known as AV nodal reentrant tachycardia because the mechanism most commonly responsible for this dysrhythmia is a reentrant circuit or chaotic movement at the level of the AV node.

PSVT must be differentiated from other narrow QRS complex (supraventricular) tachycardias. Table 17-12 is a guide to the differential diagnosis. The following points favor the diagnosis of PSVT versus a sinus tachycardia:

- An atrial premature beat often initiates the rhythm.
- The tachycardia begins and terminates abruptly.
- The rate often is faster than a sinus tachycardia and tends to be more regular from minute to minute.
- In response to a vagal maneuver, such as carotid sinus massage, the ectopic tachycardia either is unaffected or reverts to a normal sinus rhythm; however, sinus tachycardia slows slightly in response to increased vagal tone.

Like PACs, PSVTs often occur in adults with normal hearts for the same reasons (eg, emotions, tobacco, alcohol,

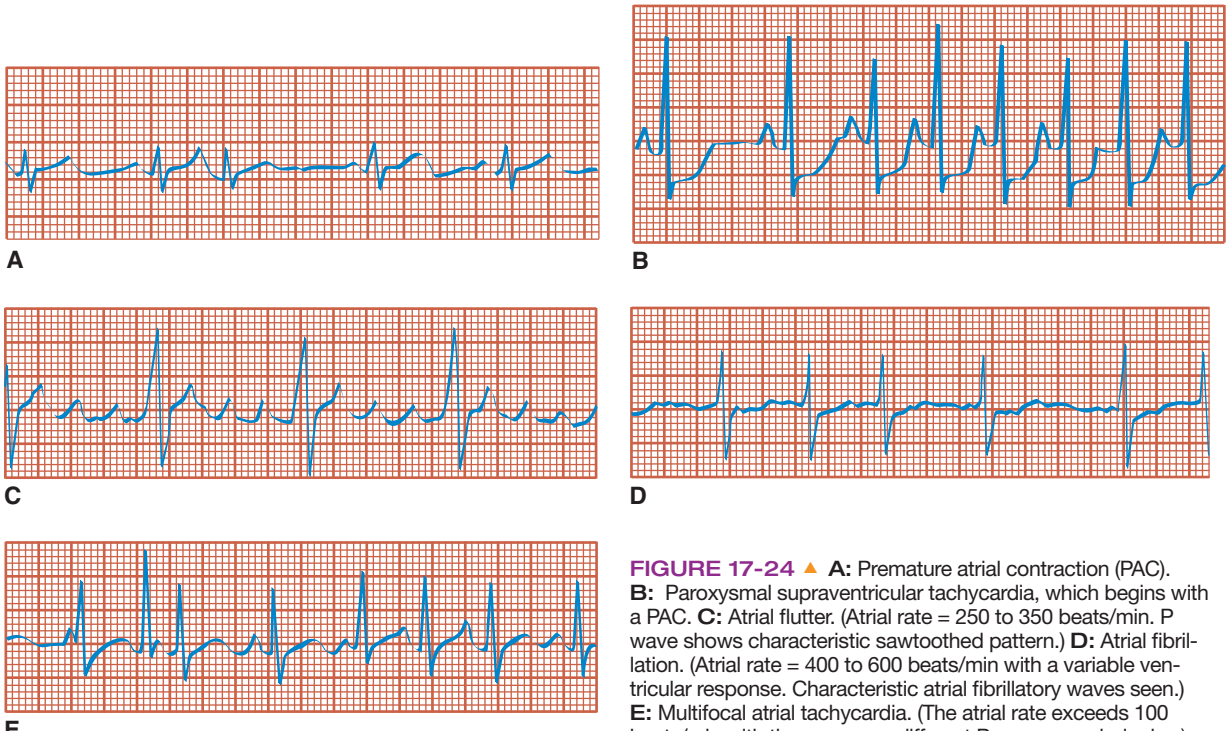

FIGURE 17-24 ▲ **A:** Premature atrial contraction (PAC). **B:** Paroxysmal supraventricular tachycardia, which begins with a PAC. **C:** Atrial flutter. (Atrial rate = 250 to 350 beats/min. P wave shows characteristic sawtoothed pattern.) **D:** Atrial fibrillation. (Atrial rate = 400 to 600 beats/min with a variable ventricular response. Characteristic atrial fibrillatory waves seen.) **E:** Multifocal atrial tachycardia. (The atrial rate exceeds 100 beats/min with three or more different P-wave morphologies.)

Table 17-12 Differential Diagnosis of Narrow QRS Tachycardia

Type of Supraventricular Tachycardia (SVT)	Onset	Atrial Rate	Ventricular Rate	RR Interval	Response to Carotid Massage
Sinus tachycardia	Gradual	100–180 beats/min	Same as sinus rate	Regular	Gradual slowing
Paroxysmal supraventricular tachycardia	Abrupt	150–250 beats/min	Usually same as atrial; block seen with digitalis toxicity and atrioventricular (AV) node disease	Regular, except at onset and termination	May convert to normal sinus rhythm
Atrial flutter	Abrupt	250–350 beats/min	Occurs with 2:1, 3:1, 4:1, or varied ventricular response	Regular or regularly irregular	Abrupt slowing of ventricular response; flutter waves remain
Atrial fibrillation	Abrupt	400–650 beats/min	Depends on ability of AV node to conduct atrial impulse; decreased with drug therapy	Irregularly irregular	Abrupt slowing of ventricular response; fibrillation waves remain

caffeine). When heart disease is present, such abnormalities as rheumatic heart disease, acute MI, and digitalis toxicity may serve as the background for a PSVT.

Often the patient has no underlying heart disease and may experience only palpitations and some lightheadedness, depending on the rate and duration of the PSVT. If the patient has underlying heart disease, dyspnea, angina pectoris, and heart failure may occur as ventricular filling time, and thus CO, is decreased.

Vagal stimulation often terminates the PSVT, either through carotid massage or the Valsalva maneuver. If vagal stimulation is unsuccessful, IV adenosine may be given. Cardioversion or overdrive pacing may be required if drug therapy is unsuccessful. Long-term prophylactic therapy may be indicated.

Atrial Flutter

Atrial flutter is a rapid atrial ectopic rhythm in which the atria fire at rates of 250 to 350 beats/min (Fig. 17-24C). The AV node functions as a "gatekeeper," preventing too many impulses from reaching the ventricle. If the ventricles are stimulated 250 to 350 times per minute, they are unable to respond with effective contractions, and CO is insufficient to sustain life. The AV node may allow only every second, third, or fourth atrial stimulus to proceed to the ventricles, resulting in what is known as a 2:1, 3:1, or 4:1 flutter block.

The rapid and regular atrial rate produces "sawtooth" or "picket-fence" P waves on the ECG. It is usual for a flutter wave to be partially concealed in the QRS complex or T wave. The QRS complex exhibits a normal configuration except when aberrant conduction is present.

When the ventricular rate is rapid, the diagnosis of atrial flutter may be difficult. Vagal maneuvers, such as carotid sinus massage or the administration of adenosine, increase the degree of AV block and allow recognition of flutter waves. Atrial flutter often is seen in the presence of underlying cardiac disease, including CAD, cor pulmonale, and rheumatic heart disease. If atrial flutter occurs in conjunction with a rapid ventricular rate, the ventricular chambers cannot fill adequately, resulting in varying degrees of hemodynamic compromise. Likewise, if atrial flutter is accompanied by a very slow ventricular rate, CO is diminished. The loss of "atrial kick," because atrial contraction is not occurring, is also a concern. The lack of atrial kick can compromise CO. Finally, without atrial contractions, thrombi can form on the walls of the atria. If these thrombi break loose, the result could be pulmonary embolus, cerebral embolus, or MI.

Treatment goals for atrial flutter are to reestablish sinus rhythm or to achieve ventricular rate control. When the ventricular rate is rapid, prompt treatment to control the rate or revert the rhythm to a sinus mechanism is indicated. Drugs may be selected to slow the conduction of the impulses through the AV node or to achieve pharmacological conversion of the rhythm. If pharmacological conversion is not successful, electrical cardioversion can be used. Synchronized cardioversion is especially useful in the prompt treatment of atrial flutter. The patient should be NPO before the procedure and receive sedation. (For a more detailed discussion of cardioversion, see Chapter 18.) If the patient has been experiencing atrial flutter for more than about 72 hours, anticoagulation may be needed before pharmacological or electrical conversion of the rhythm is attempted. Other modes of therapy may be indicated for the long-term management of atrial flutter, such as ablation, pacing, and implantable devices.

Atrial Fibrillation

Atrial fibrillation, which is a rapid atrial ectopic rhythm, occurring with atrial rates of 350 to 500 beats/min (Fig. 17-24D), is characterized by chaotic atrial activity with the absence of definable P waves. Instead, the P waves appear as small, quivering fibrillatory waves. Like atrial flutter, the ventricular rate and rhythm depend on the ability of the AV junction to function as a gatekeeper. If too many atrial stimuli pass through the AV junction, the ventricular response is rapid. If too few atrial stimuli pass through the AV junction, the ventricular response is slow. The ventricular rhythm is characteristically irregular.

Although atrial fibrillation may occur as a transient dysrhythmia in healthy young people, the presence of chronic atrial fibrillation is usually associated with underlying heart disease. One or both of the following are present in patients with chronic atrial fibrillation: atrial muscle disease or atrial distention together with disease of the sinus node. This rhythm commonly occurs in the setting of heart failure, ischemic or rheumatic heart disease, or pulmonary disease, and after open heart surgery. Atrial fibrillation also is seen in congenital heart disease.

The immediate clinical concern in patients with atrial fibrillation is the rate of the ventricular response. If the ventricular rate is too fast, end-diastolic filling time is decreased, and CO is compromised. If the ventricular rate is too slow, CO may again be decreased. As in atrial flutter, patients with atrial fibrillation have lost AV synchrony and atrial kick, resulting in a compromised CO. Patients also are at risk for the formation of mural thrombi and embolic events, such as stroke, MI, and pulmonary embolus.

The treatment principles for atrial fibrillation are the same as those for atrial flutter. The goal of therapy is to achieve rate control or to convert the rhythm to sinus.[17] If a patient has chronic atrial fibrillation, anticoagulant therapy is added to the drug regimen to prevent an embolic event. Cardioversion is indicated for rhythm control when drug therapy fails or in the setting of hemodynamic compromise. Ablation, pacing, and implantable devices are among the therapeutic options.[18]

Multifocal Atrial Tachycardia

Multifocal atrial tachycardia is a rapid atrial rhythm with varying P-wave morphology, resulting from the firing of three or more atrial foci (Fig. 17-24E). The atrial rate exceeds 100 beats/min, and the rhythm usually is irregular. The P waves vary in shape because of the multiple foci. The PR intervals may vary also, depending on the proximity of the focus to the AV node. The QRS complexes are normal unless an impulse is conducted with aberrancy.

This rhythm characteristically occurs in patients with severe pulmonary disease. Such patients often exhibit hypoxemia, hypokalemia, alterations in serum pH, or pulmonary hypertension. They usually manifest symptoms associated with the underlying disease rather than with the dysrhythmia itself. Treatment is directed at controlling the underlying pulmonary disease and slowing the ventricular rate if necessary.

▲ Junctional Dysrhythmias

Junctional Rhythm

A junctional rhythm, also known as a nodal rhythm, is a rhythm originating in the AV node. When the SA node fails to fire, the AV node usually takes control, but the rate is slower. The rate of a junctional rhythm ranges between 50 and 70 beats/min. The P wave in the dysrhythmia can have one of three possible configurations.

1. The AV node fires, and the wave of depolarization travels backward (retrograde conduction) into the atria. The impulse from the AV node then moves forward into the ventricle. When this sequence occurs, the P wave appears as an inverted wave before a normal QRS complex (Fig. 17-25A).
2. The retrograde conduction into the atria occurs at the same time as the forward conduction into the ventricles. The resulting rhythm strip shows an absent P wave with a normal QRS complex. In reality, the P wave is not absent. Instead, it is buried inside the QRS complex (see Fig. 17-25B).
3. Forward conduction of the ventricles precedes retrograde conduction of the atria. When this sequence occurs, a normal QRS complex is followed by an inverted P wave (see Fig. 17-25C).

A junctional rhythm may be the result of hypoxia, hyperkalemia, MI, heart failure, valvular disease, drugs (digoxin, beta-blockers, calcium channel blockers), or any cause of SA node dysfunction. Patients with a junctional rhythm may become symptomatic as a result of the slower rate. Hypotension, decreased CO, and decreased perfusion may occur. The benefit of AV synchrony and atrial kick may be lost when the atria are stimulated with or after ventricular depolarization.

Treatment should be directed at the underlying cause. Symptomatic patients may require immediate treatment. The heart rate can be increased through the use of atropine or cardiac pacing. Interventions are also directed toward improving CO.

Premature Junctional Contractions

A premature junctional contraction (PJC) is an ectopic impulse from a focus in the AV junction, occurring prematurely, before the next sinus impulse (Fig. 17-26). As in all rhythms originating in the AV junction, the QRS complex is narrow (<0.12 second), reflecting normal ventricular conduction. On rare occasions, the QRS complex may be wide if the impulse is conducted aberrantly. The atria are depolarized in a retrograde fashion before, during, or after ventricular excitation, producing inverted P waves that may occur before, during, or after the QRS complex. As with PACs, PJCs may occur in healthy people or in those with underlying heart disease. Ischemia or infarction may activate an ectopic focus in the AV junction, as may stimulants, such as nicotine or caffeine, or pharmacological agents (eg, digitalis).

Frequent PJCs may indicate increasing irritability and may be a precursor of a junctional rhythm. Although usually asymptomatic, patients may experience a "skipped beat." Treatment for PJCs is not necessary.

▲ Ventricular Dysrhythmias

Premature Ventricular Contractions

A PVC is an ectopic beat originating prematurely at the level of the ventricles (Fig. 17-27A). The beat is ventricular in origin and results in no electrical activity in the atria. As a result, no P waves appear. The ventricular depolarization does not travel through the normal rapid ventricular conduction system. Instead, ventricular conduction spreads more slowly through the Purkinje system, resulting in a wide

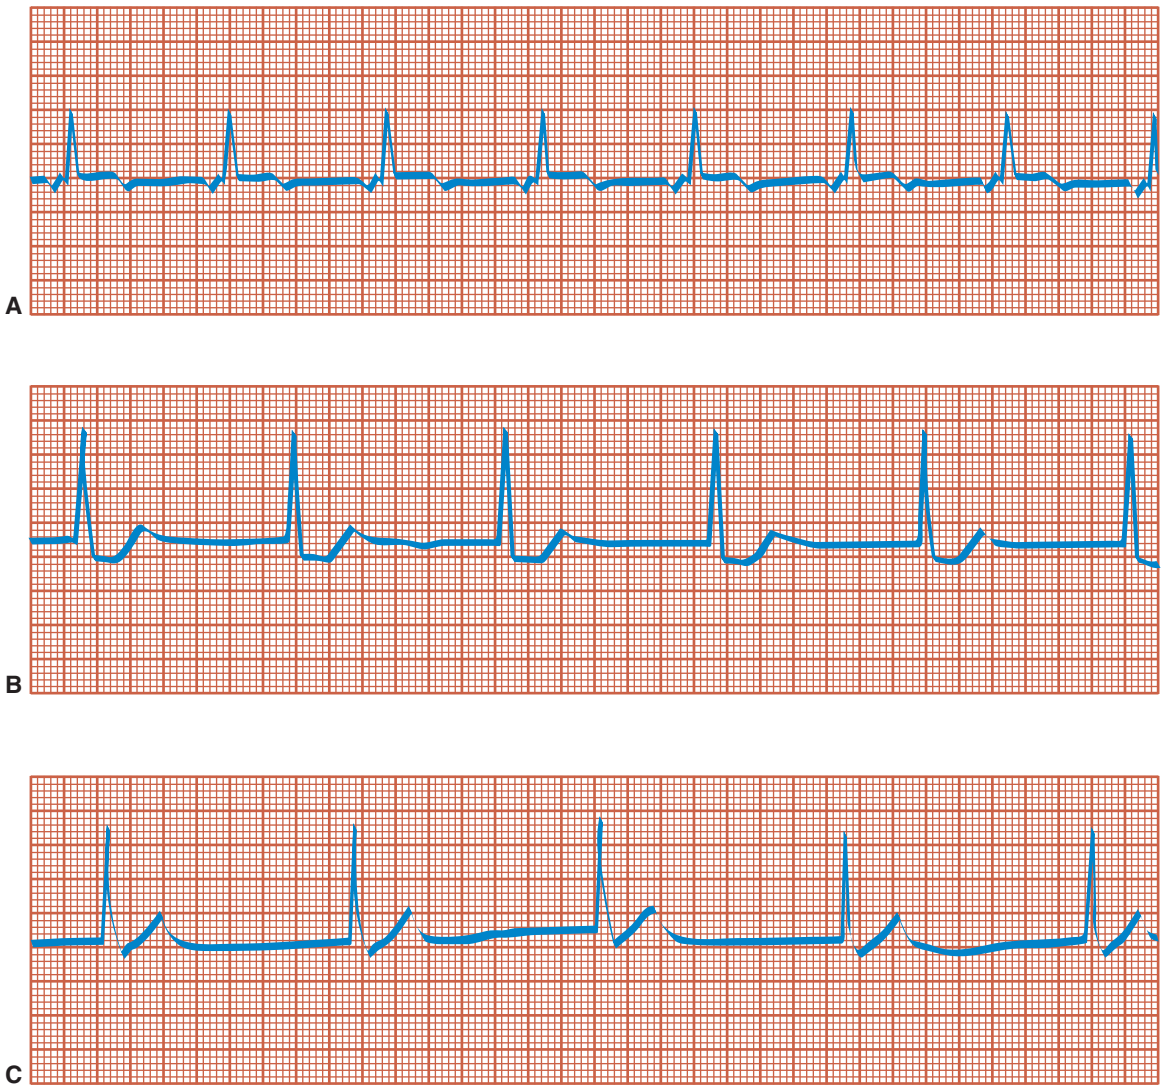

FIGURE 17-25 ▲ Junctional rhythm. **A:** A junctional rhythm in which the inverted P wave appears before a normal QRS complex. **B:** A junctional rhythm in which the inverted P wave is buried inside the QRS complex. **C:** A junctional rhythm in which the inverted P wave follows the QRS complex.

QRS complex with a T wave that is opposite in direction to the QRS complex. A compensatory pause often follows the premature beat as the heart awaits the next stimulus from the sinus node. The pause is considered fully compensatory if the cycles of the normal and premature beats equal the time of two normal heart cycles.

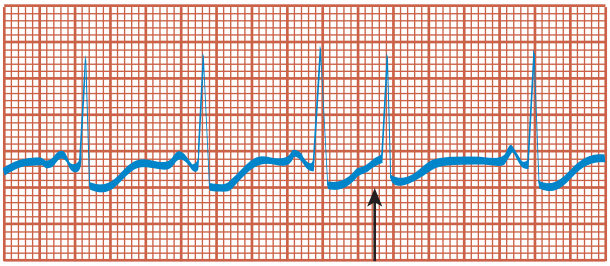

FIGURE 17-26 ▲ Premature junctional contraction.

Ventricular premature beats can be described by their frequency and pattern. They can be rare, occasional, or frequent; optimally, they are described as number of PVCs per minute. If PVCs occur after each sinus beat, ventricular bigeminy is present (see Fig. 17-27B). Ventricular trigeminy is a PVC occurring after two consecutive sinus beats. When PVCs appear in only one form (from one ventricular site), they are referred to as uniformed, as opposed to multiformed, when two or more forms (from more than one ventricular site) of the QRS complex are apparent (see Fig. 17-27C). Two PVCs in a row are a couplet (see Fig. 17-27D), whereas three in a row are a triplet, which is a short run of VT (see Fig. 17-27E).

The most common of all ectopic beats, PVCs can occur with or without heart disease in any age group. They are especially common in people with myocardial disease (ischemia or infarction) or with myocardial irritability (hypokalemia, increased levels of catecholamines, or mechanical irritation with a wire or catheter). The presence

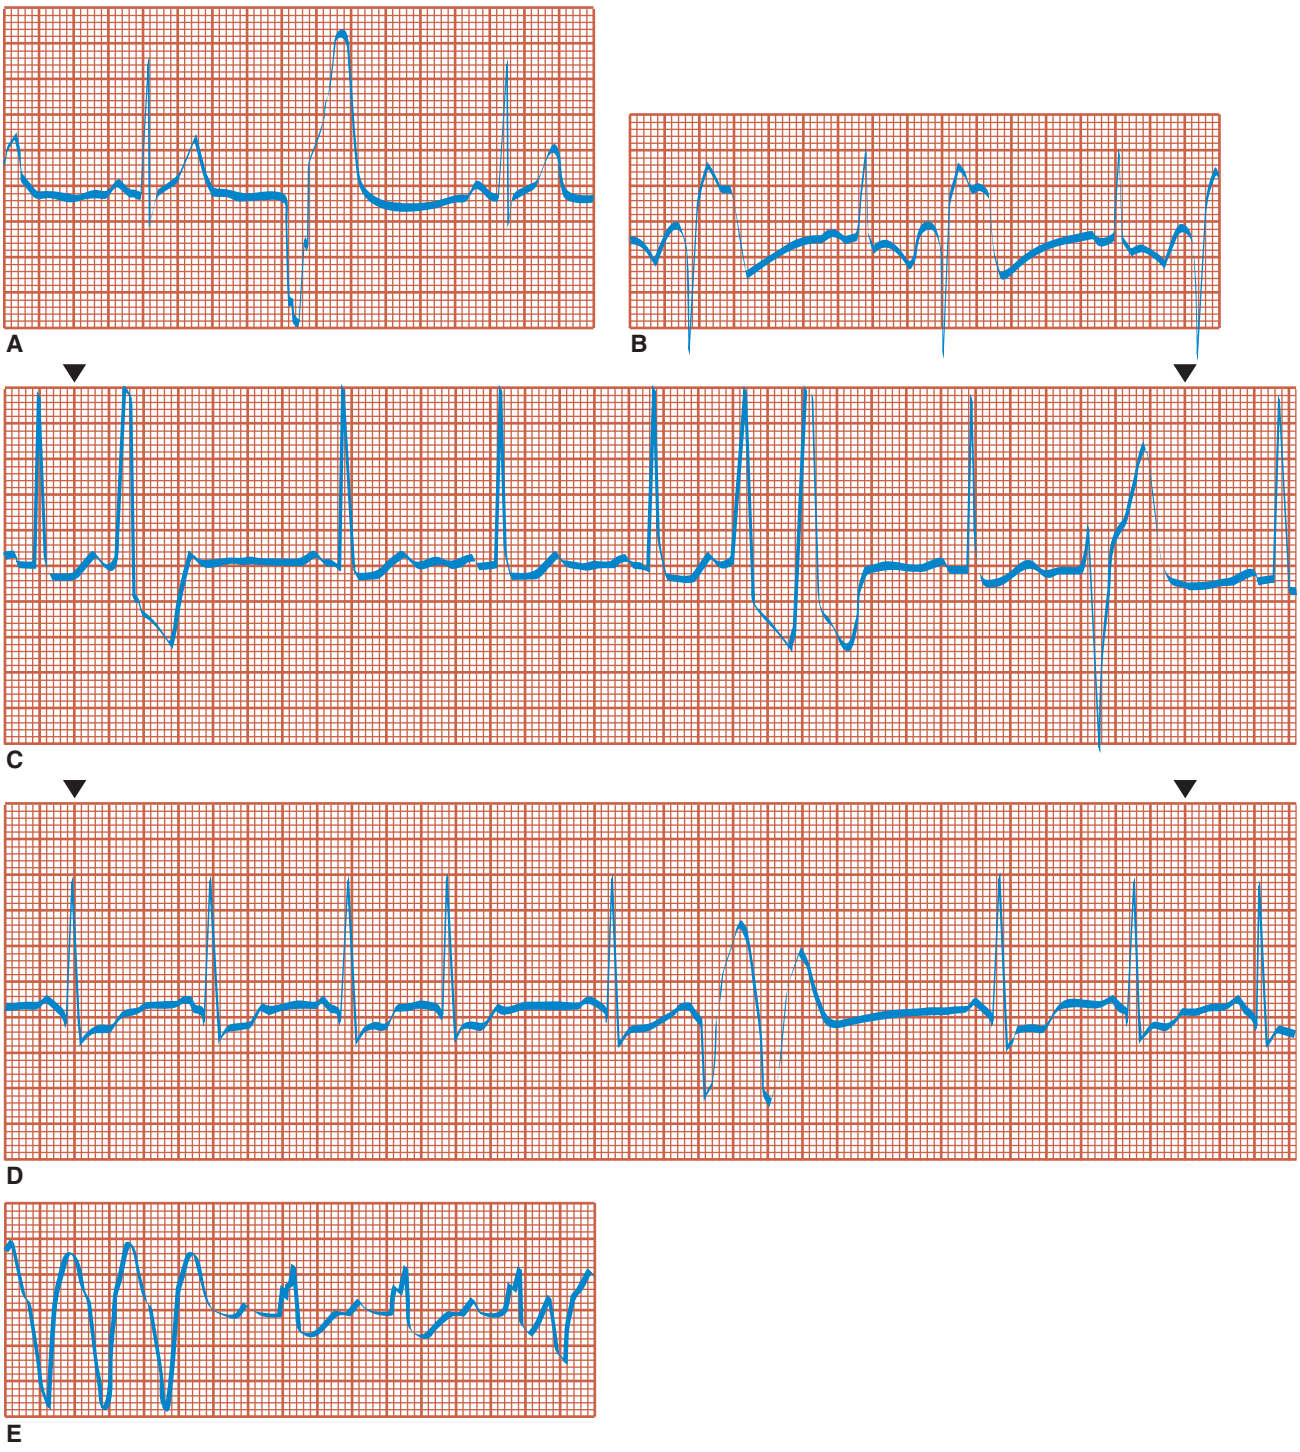

FIGURE 17-27 ▲ Ventricular dysrhythmias. **A:** Premature ventricular contractions (PVCs). **B:** Ventricular bigeminy. (Every other beat is a PVC.) **C:** Multiformed PVCs. **D:** Couplet (two PVCs in a row). **E:** Triplet. (Short run of ventricular tachycardia; the first three beats are VT with the rhythm converting to sinus rhythm with first-degree heart block.)

of PVCs is a sign of ventricular myocardial irritability and, in some patients, may lead to VT or ventricular fibrillation (VF). The nature of the patient's underlying heart disease, rather than the presence of PVCs as such, determines the treatment and prognosis. Numerous and multiformed PVCs in the presence of serious heart disease worsen the prognosis. PVCs approaching the apex of the preceding T wave (R-on-T phenomenon) are of clinical concern. The T wave represents ventricular repolarization, when the heart should not be stimulated. If stimulation occurs during this vulnerable period, VF and sudden death may result (Fig. 17-28).

Infrequent, isolated PVCs require no treatment. Multiple or consecutive PVCs may be managed with antiarrhythmic agents. In the emergency setting, amiodarone and lidocaine

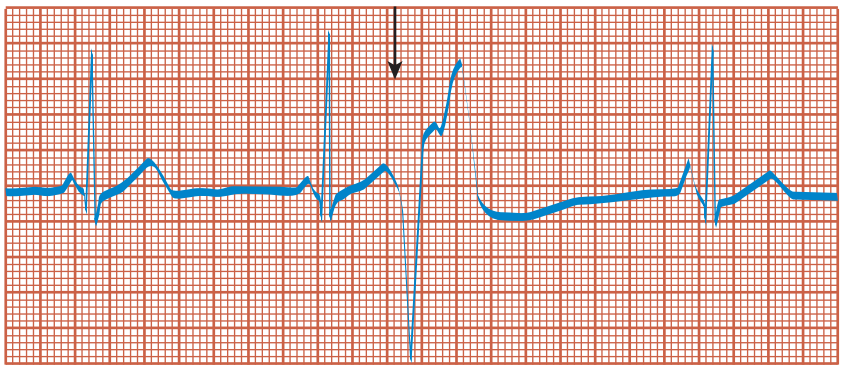

FIGURE 17-28 ▲ R-on-T premature ventricular contraction. (From Huff J: ECG Workout, 4th ed. Philadelphia, PA: Lippincott, Williams & Wilkins, 2002, p 195.)

are the drugs of choice. Many antiarrhythmic agents are available for chronic therapy. If serum potassium is low, potassium replacement may correct the dysrhythmia. If the dysrhythmia is caused by digitalis toxicity, withdrawal of the digitalis may correct it.

Ventricular Tachycardia

In the previous section, VT was defined as three or more PVCs in a row. VT is recognized by wide, bizarre QRS complexes occurring in a fairly regular rhythm at a rate greater than 100 beats/min (Fig. 17-29A). P waves usually are not seen and, if seen, are not related to the QRS complex. VT may be a short, nonsustained rhythm or longer and sustained.

In adults with normal hearts, VT is rare but is a common complication of MI. Other causes are the same as those described for PVCs. VT is a precursor of VF, and signs and symptoms of hemodynamic compromise (eg, ischemic chest pain, hypotension, pulmonary edema, and unconsciousness) may be seen if the rate is fast and the tachycardia is sustained. Serious dysrhythmia progression depends on the underlying heart disease.

If the patient is hemodynamically stable with the dysrhythmia, lidocaine may be administered intravenously. If the patient becomes unstable, synchronized cardioversion

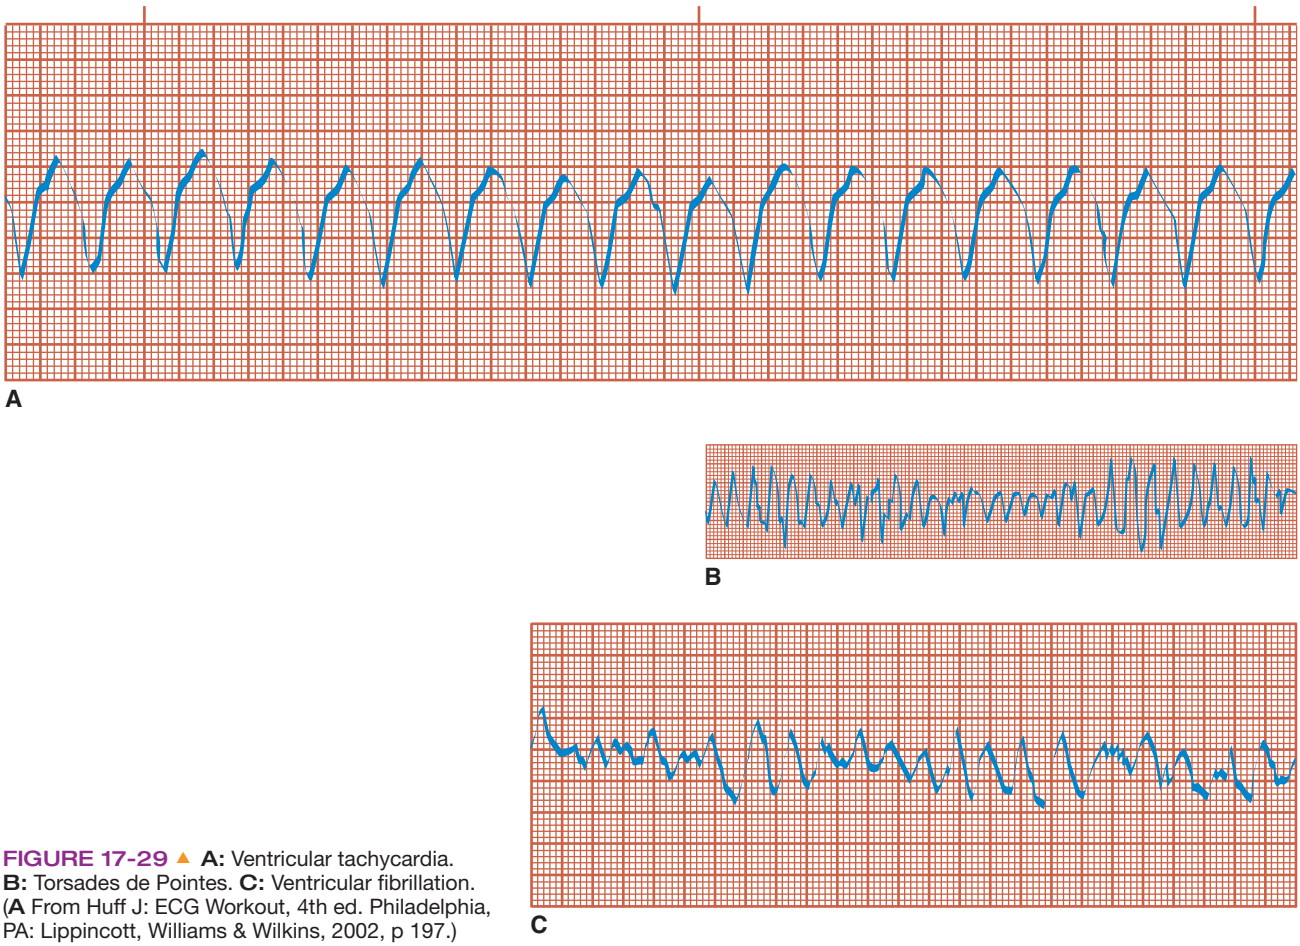

FIGURE 17-29 ▲ **A:** Ventricular tachycardia. **B:** Torsades de Pointes. **C:** Ventricular fibrillation. (**A** From Huff J: ECG Workout, 4th ed. Philadelphia, PA: Lippincott, Williams & Wilkins, 2002, p 197.)

(or in emergency situations, unsynchronized defibrillation) is indicated. Long-term treatment for this dysrhythmia may involve the use of an implantable cardioverter–defibrillator (ICD). See Chapter 18 for a more detailed discussion of ICDs.

Torsades De Pointes

Torsades de pointes ("twisting of the points") is a specific type of VT (Fig. 17-29B). The term refers to the polarity of the QRS complex, which swings from positive to negative and vice versa. The QRS complex morphology is characterized by large, bizarre, polymorphous, or multiformed QRS complexes of varying amplitude and direction, frequently varying from beat to beat and resembling torsion around an isoelectric line. The rate of the tachycardia is 100 to 180 beats/min but can be as fast as 200 to 300 beats/min. The rhythm is highly unstable; it may terminate in VF or revert to sinus rhythm. This form of VT is most likely to develop in myocardial disease when the underlying QT interval has been prolonged.

Torsades de pointes is favored by conditions that prolong the QT interval. Examples include severe bradycardia; drug therapy, especially with type IA antiarrhythmic agents; and electrolyte disturbances, such as hypokalemia and hypocalcemia. Other factors that can precipitate this dysrhythmia include intrinsic cardiac disease, familial QT-interval prolongation, drug-induced prolongation of the QT interval, hypokalemia, hypomagnesemia, and hypocalcemia.[19] Torsades de pointes may terminate spontaneously and may repeat itself after several seconds or minutes, or it may transform into VF.

Treatment for torsades de pointes consists of shortening the refractory period (and thus the QT interval) of the underlying rhythm. IV magnesium sulfate, magnesium chloride, or isoproterenol is effective in suppression of the dysrhythmia. Overdrive pacing also can be used. Treatment is directed at correcting the underlying problem and may necessitate stopping the offending pharmacological agent or correcting the electrolyte imbalance. Emergency cardioversion or defibrillation is indicated if the torsades does not revert spontaneously to sinus rhythm.

Ventricular Fibrillation

VF is defined as rapid, irregular, and ineffectual depolarizations of the ventricle (Fig. 17-29C). No distinct QRS complexes are seen. Only irregular oscillations of the baseline are apparent; these may be either coarse or fine in appearance.

VF may occur in the following circumstances: myocardial ischemia and infarction, catheter manipulation in the ventricles, electrocution, prolonged QT interval, or as a terminal rhythm in patients with circulatory failure. As in asystole, loss of consciousness occurs within seconds in VF. There is no pulse and no CO. VF is the most common cause of sudden cardiac death and is fatal if resuscitation is not instituted immediately.

If VF occurs, rapid defibrillation is the management of choice (see the discussion of cardiopulmonary resuscitation in Chapter 18). The patient should be supported with cardiopulmonary resuscitation and drugs if there is no response to defibrillation. An ICD may be indicated for long-term management of VF (see Chapter 18 for a discussion of ICDs).

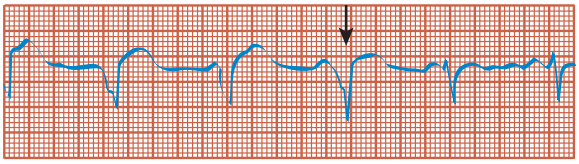

FIGURE 17-30 ▲ Accelerated idioventricular rhythm. The first three beats are of ventricular origin. The fourth beat (*arrow*) represents a fusion beat. The subsequent two beats are of sinus origin.

Accelerated Idioventricular Rhythm

Accelerated idioventricular rhythm (AIVR) is produced by a "speeding up" of ventricular pacemaker cells, which normally have an intrinsic rate of 20 to 40 beats/min (Fig. 17-30). When the idioventricular rate accelerates above the sinus rate, the ventricular pacemaker becomes the primary pacemaker for the heart. AIVR is characterized by wide QRS complexes occurring regularly at a rate of 50 to 100 beats/min. AIVR may last for a few beats or may be sustained.

Typically, AIVR is seen with acute MI, often in the setting of coronary artery reperfusion after thrombolytic therapy. It may occur less commonly as a result of ischemia or digitalis intoxication. Patients usually are not symptomatic. Adequate CO can be maintained, and degeneration into a rapid VT is rare.

In most cases, treatment is not necessary. If a patient is hemodynamically compromised, the sinus rate is increased with atropine or atrial pacing to suppress the AIVR.

▲ Atrioventricular Blocks

A disturbance in some portion of the AV conduction system causes an AV block. The sinus-initiated beat is delayed or completely blocked from activating the ventricles. The block may occur at the level of the AV node, bundle of His, or the bundle branches because the AV conduction system contains all of these structures. In first- and second-degree AV block, the block is incomplete; some or all of the impulses eventually are conducted to the ventricles. In third-degree or complete heart block, none of the sinus-initiated impulses is conducted. Table 17-13 summarizes and compares heart block rhythms.

First-Degree Atrioventricular Block

In first-degree block, AV conduction is prolonged and equal in time. All impulses eventually are conducted to the ventricles (Fig. 17-31A). P waves are present and precede each QRS complex in a 1:1 relationship. The PR interval is constant but exceeds the upper limit of 0.20 second in duration.

First-degree heart block occurs in people of all ages and in healthy and diseased hearts. PR prolongation may be

Table 17-13 A Comparison of the Electrocardiographic Characteristics of Heart Block Rhythms

	First-Degree Heart Block	Second-Degree Heart Block—Mobitz Type I (Wenckebach)	Second-Degree Heart Block—Mobitz Type II	Third-Degree Heart Block
Rate	Usually 60–100 beats/min	Usually 60–100 beats/min	May be slow depending on number of blocked P waves	Rate determined by ventricular focus, usually very slow
Rhythm	Regular	Irregular due to dropped QRS	Often regular but depends on pattern of block	May be regular or irregular ventricular focus
P waves	Present, one per QRS	Present, one per QRS until QRS is missed	Present, more than one P wave per QRS	Present, more than one P wave per QRS; P waves no relationship to QRS complexes
PR interval	>0.20 s, equal throughout	Progressively gets longer until QRS is missed; pattern repeats	May be normal or prolonged, equal throughout	May be normal or prolonged, unequal throughout
QRS complex	<0.12 s	<0.12 s	Usually more than 0.12 s	More than 0.12 s

caused by drugs, such as digitalis, β-blockers, or calcium channel blockers; CAD; a variety of infectious diseases; and congenital lesions. First-degree block is of no hemodynamic consequence but should be seen as an indicator of a potential AV conduction system disturbance. First-degree block may progress to second- or third-degree AV block.

No treatment is indicated for first-degree heart block. The PR interval should be monitored closely, watching for further block. The possibility of a drug effect also should be evaluated.

Second-Degree Atrioventricular Block—Mobitz I (Wenckebach)

Mobitz type I (Wenckebach) block occurs when AV conduction is delayed progressively with each sinus impulse until eventually the impulse is completely blocked from reaching the ventricles. The cycle then repeats itself (see Fig. 17-31B). Of the two types of second-degree block, Mobitz I (Wenckebach) and Mobitz II, Mobitz I occurs more commonly.

On the ECG tracing, P waves are present and related to the QRS complex in a cyclical pattern. The PR interval progressively lengthens with each beat until a QRS complex is not conducted. The QRS complex has the same configuration throughout the underlying rhythm.

A Mobitz type I block usually is associated with block above the bundle of His. Therefore, any drug or disease process that affects the AV node, such as digitalis, myocarditis, or an inferior wall MI, may produce this type of second-degree block.

Patients with Mobitz type I second-degree AV block rarely are symptomatic because the ventricular rate usually is adequate. Wenckebach block often is temporary, and if it progresses to third-degree block, a junctional pacemaker at a rate of 40 to 60 beats/min usually takes over to pace the ventricles. No treatment is required for this rhythm except to discontinue a drug if it is the offending agent. The patient should be monitored for further progression of block.

Second-Degree Atrioventricular Block—Mobitz II

Mobitz type II block is described as an intermittent block in the AV conduction, usually in or below the bundle of His. Mobitz type II block is characterized by a fixed PR interval when AV conduction is present and a nonconducted P wave when the block occurs (see Fig. 17-31C). This block in conduction can occur occasionally or be repetitive with a 2:1, 3:1, or even 4:1 conduction pattern. Because there is no disturbance in the sinus node, the PP interval is regular. Often there is accompanying BBB, so the QRS complex may be wide.

A Mobitz type II pattern is seen in the setting of an anterior wall MI and various diseases of the conducting tissue, such as fibrotic disease. A Mobitz type II block is potentially more dangerous than a Mobitz type I block. Mobitz type II block often is permanent, and it may deteriorate rapidly to third-degree heart block with a slow ventricular response of 20 to 40 beats/min.

Constant monitoring and observation for progression to third-degree heart block are required. Medications, such as atropine, or cardiac pacing may be required if a patient becomes symptomatic or if the block occurs in the setting of an acute anterior wall MI. Permanent pacing often is indicated for long-term management.

Third-Degree (Complete) Atrioventricular Block

In third-degree or complete heart block, the sinus node continues to fire normally, but the impulses do not reach the ventricles (see Fig. 17-31D). The ventricles are stimulated

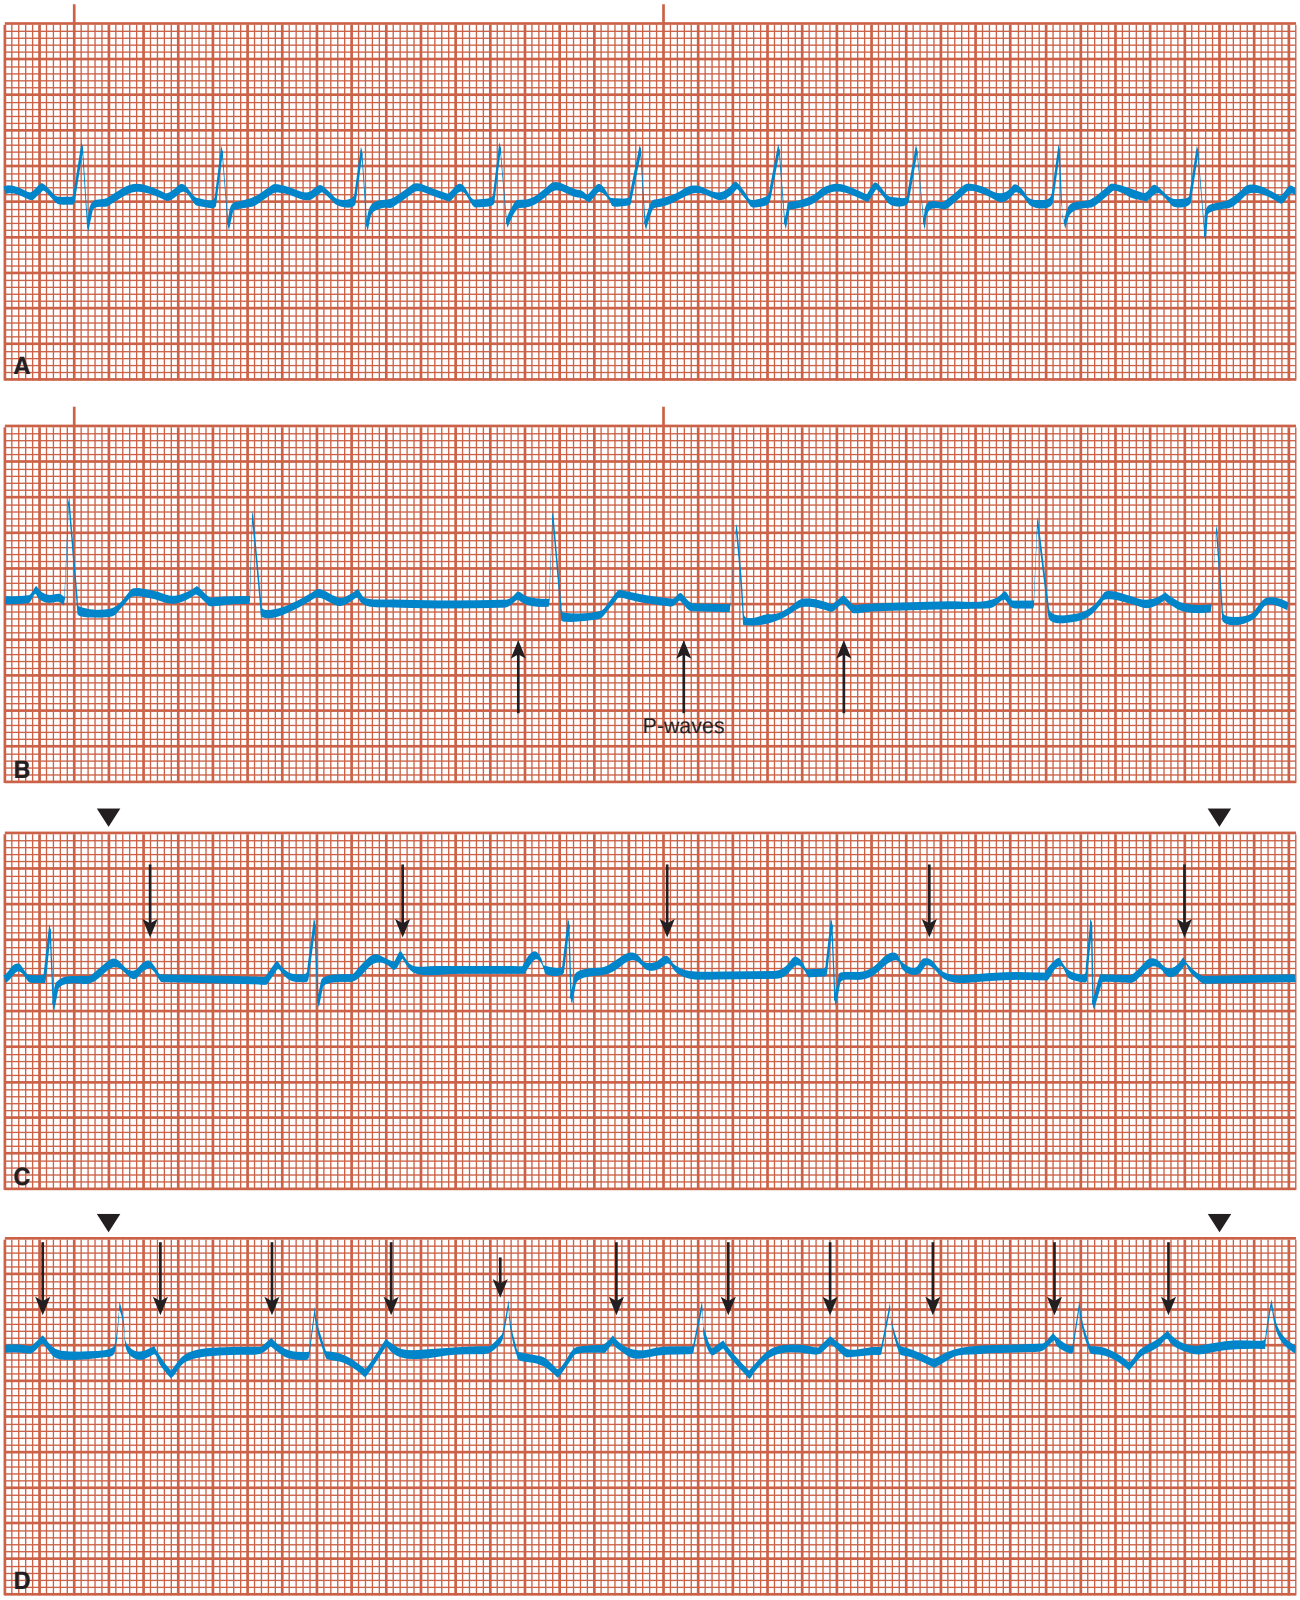

FIGURE 17-31 ▲ Heart block rhythms. **A:** First-degree heart block. **B:** Second-degree heart block: Mobitz type I. **C:** Second-degree heart block: Mobitz type II. *Arrows* denote blocked P wave (2:1 block). **D:** Third-degree heart block (complete atrioventricular block). *Arrows* denote P waves. Note the lack of relationship between the atria (P wave) and ventricles (QRS). (**A** and **B,** From Huff J: ECG Workout, 4th ed. Philadelphia, PA: Lippincott, Williams & Wilkins, 2002, pp 150, 156.)

from escape pacemaker cells either in the junction (at a rate of 40 to 60 beats/min) or in the ventricles (at a rate of 20 to 40 beats/min), depending on the level of the AV block.

On the ECG tracing, P waves and QRS complexes are both present, but there is no relationship between the two. Therefore, complete heart block is considered one form of AV dissociation. The PP and RR intervals are each regular, but the PR interval is variable. If a junctional pacemaker paces the ventricles, the QRS complex is narrow. A pacemaker site lower in the ventricles produces a wide QRS complex.

The causes of complete heart block are the same as for lesser degrees of AV block. Complete heart block is often poorly tolerated. The rate and dependability of the ventricular pacemaker depend on its location. If the escape rhythm is ventricular in origin, the rate is slow, and the pacemaker site is unreliable. The patient may be symptomatic because of a low CO. A pacemaker site high in the bundle of His may provide an adequate rate and is more dependable. The patient may remain asymptomatic if the escape rhythm supports a normal CO.

A temporary pacing wire is usually inserted immediately, and when the patient is stabilized, a permanent pacemaker is implanted.

▲ The 12-Lead Electrocardiogram

The Normal 12-Lead Electrocardiogram

As previously described, the ECG provides 12 electrical views of the heart. The first three electrical views are provided by the standard leads I, II, and III. The next three electrical views are provided by the augmented leads, aVR, aVL, and aVF. The standard and augmented leads are referred to as the limb leads and provide a view from a vertical plane. The remaining six electrical views of the heart, the precordial leads, chest leads, or V leads, V_1 through V_6, provide a horizontal plane view of the heart (Fig. 17-32).

In the normal 12-lead ECG, the P wave representing atrial depolarization is usually upright and rounded. Each component of the QRS complex (ventricular depolarization) is analyzed separately. The Q wave, the initial downward deflection of the QRS complex, should be absent or small. The R component is the tallest upright portion of the QRS complex in the limb leads except aVR. In the precordial leads, the R wave begins as a small wave in V_1 and gradually progresses to a tall wave by V_6. The S wave, the downward stroke after the R wave, is small or absent in the limb leads. The S wave begins as a deep wave in V_1 and gradually disappears by V_6 in the precordial leads. The ST segment is isoelectric but may be slightly elevated in V_1 through V_3. The T wave, representing ventricular repolarization, is usually upright, although a variety of configurations can be normal. Table 17-14 summarizes the normal 12-lead ECG.

The 12-lead ECG may be useful in determining the electrical axis of the heart and detecting abnormalities that require more than one electrical view. These abnormalities include BBB; atrial or ventricular enlargement; and patterns of ischemia, injury, or infarction.

Electrical Axis

Electrical axis refers to the general direction of the wave of excitation as it moves through the heart. In the normal heart, the flow of electrical forces originates in the SA node, spreads throughout atrial tissue, passes through the AV node, and moves throughout the ventricles. This flow of forces is normally downward and to the left, a pattern known as normal axis.

The ventricles make up the largest muscle mass of the heart and therefore make the most significant contribution to the determination of the direction of the flow of forces in the heart. For this reason, the QRS complex is examined when deciding the electrical axis.

A quick way to estimate the axis of the heart is to examine the direction of the QRS complex in leads I and aVF (Fig. 17-33). A QRS complex that is mainly upright in both leads represents a normal axis. A QRS complex that is upright in lead I and downward in lead aVF represents left

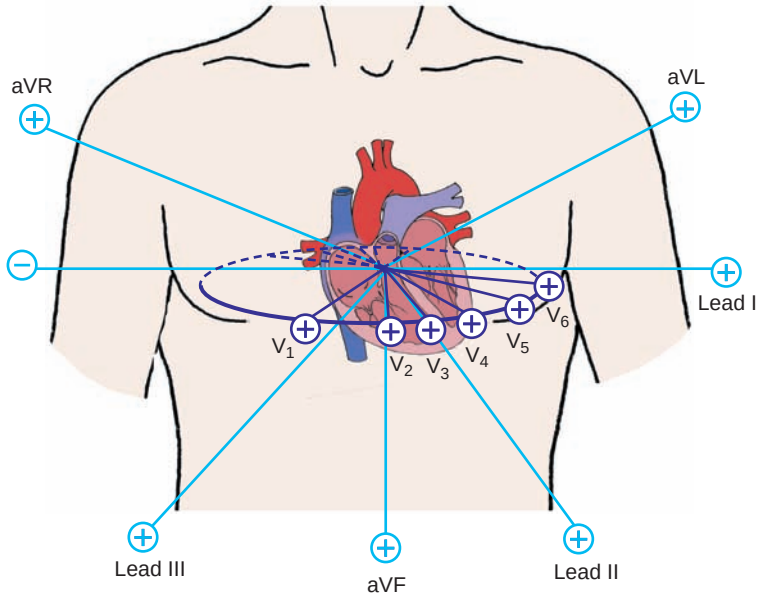

FIGURE 17-32 ▲ Electrocardiographic views of the heart.

Table 17-14 The Normal 12-Lead Electrocardiogram

Lead	P	Q	R	S	S-T	T
I	Upright	Small, 0.04 s, or none	Dominant	Less than R or none	Isoelectric +1 to –0.5 mm	Upright
II	Upright	Small or none	Dominant	Less than R or none	+1 to –0.5 mm	Upright
III	Upright Flat Diphasic Inverted	Small or none	None to dominant	None to dominant	+1 to –0.5 mm	Upright Flat Diphasic Inverted
aVR	Inverted	Small, or large	Small or none	Dominant	+1 to –0.5 mm	Inverted
aVL	Upright Flat Diphasic Inverted	Small, none, or large	Small, none, or dominant	Small, none, or dominant	+1 to –0.5 mm	Upright Flat Diphasic Inverted
aVF	Upright Flat Diphasic Inverted	Small or none	Small, none, or dominant	None to dominant	+1 to –0.5 mm	Upright
V_1	Upright Flat Diphasic	None May be QS	Small	Deep	0 to +3 mm	Inverted Flat Upright Diphasic
V_2	Upright	None			0 to +3 mm	Upright Diphasic Inverted
V_3	Upright	Small or none			0 to +3 mm	Upright
V_4	Upright	Small or none			+1 to –0.5 mm	Upright
V_5	Upright	Small			+1 to –0.5 mm	Upright
V_6	Upright	Small	Tall	Small or none	+1 to –0.5 mm	Upright

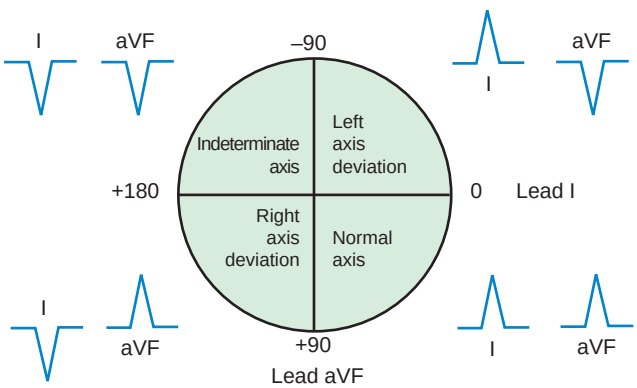

FIGURE 17-33 ▲ Determining electrical axis. To determine the axis of the heart, examine the direction of the QRS complex in leads I and aVF.

Lead I	*Lead aVF*	*Axis*
Negative	Negative	Indeterminate axis
Negative	Positive	Right axis deviation
Positive	Negative	Left axis deviation
Positive	Positive	Normal axis

axis deviation. A QRS complex that is downward in lead I and upright in lead aVF represents right axis deviation. A QRS complex that is downward in leads I and aVF is uncommon and represents indeterminate axis.

The direction of the flow of forces in the heart can change as a result of an anatomical shift of the heart in the chest wall. An anatomical shift may occur in very obese patients or in patients with large abdominal tumors or abdominal ascites. Left axis deviation can be caused by LBBB, left ventricular enlargement, or inferior wall MI. Right axis deviation can be caused by RBBB, right ventricular enlargement, or an anterior wall MI.

Patients with an axis shift are asymptomatic. The only way an axis shift can be detected is through a 12-lead ECG. The axis shift usually represents some underlying abnormality, and treatment is directed at the underlying cause.

Bundle Branch Block

A BBB develops when there is either a functional or pathological block in one of the major branches of the intraventricular conduction system. As conduction through one

bundle is blocked, the impulse travels along the unaffected bundle and activates one ventricle normally. The impulse is delayed in reaching the other ventricle because it travels outside of the normal conducting fibers. The right and left ventricles are thus depolarized sequentially instead of simultaneously. The abnormal activation produces a wide QRS complex, representing the increased time it takes for ventricular depolarization (Fig. 17-34). The broad QRS complex has two peaks (RSR′), indicating that depolarization of the two ventricles was not simultaneous.

An RBBB and LBBB are diagnosed on the 12-lead ECG but can also be identified on the bedside monitor using a V_1 or MCL_1 tracing and a V_6 or MCL_6 tracing (see section on Electrocardiographic Monitoring for description of lead selection). To identify the presence of a BBB, the QRS complex duration must be prolonged to 0.12 second or longer, representing the delay in conduction through the ventricles. An RBBB alters the configuration of the QRS complex in the right-sided chest leads, V_1 and V_2. Normally, these leads have a small, single-peaked R-wave and deep S-wave configuration. With an RBBB, depolarization of the right ventricle is delayed, and the ECG pattern changes. An RBBB is evidenced by an RSR′ configuration in V_1. If the initial peak of the QRS complex is smaller than the second peak, the pattern would be described as rSR′. An "r" is used to describe the first, smaller peak, and an "R" is used to describe the second, taller peak. Likewise, if the initial peak of the QRS complex is taller than the second peak, the pattern is described as an RSr'. Whenever ventricular depolarization is abnormal, so is ventricular repolarization. As a result, ST-segment and T-wave abnormalities may be seen in leads V_1 and V_2 for patients with an RBBB.

An LBBB changes the QRS complex pattern in the left-sided chest leads, V_5 and V_6. Normally, these leads have a tall, single-peaked R wave and a small or absent S wave. Instead, the double-peaked RSR′ pattern is noted. In addition, V_1 shows a small R wave with a widened S wave, indicating delayed conduction through the ventricles. Like RBBB, the ST segments and T waves may be abnormal in the left-sided chest leads V_5 and V_6 when the patient has an LBBB (see Fig. 17-34).

The most common causes of BBB are MI, hypertension, heart failure, and cardiomyopathy. RBBB may be found in healthy people with no clinical evidence of heart disease.

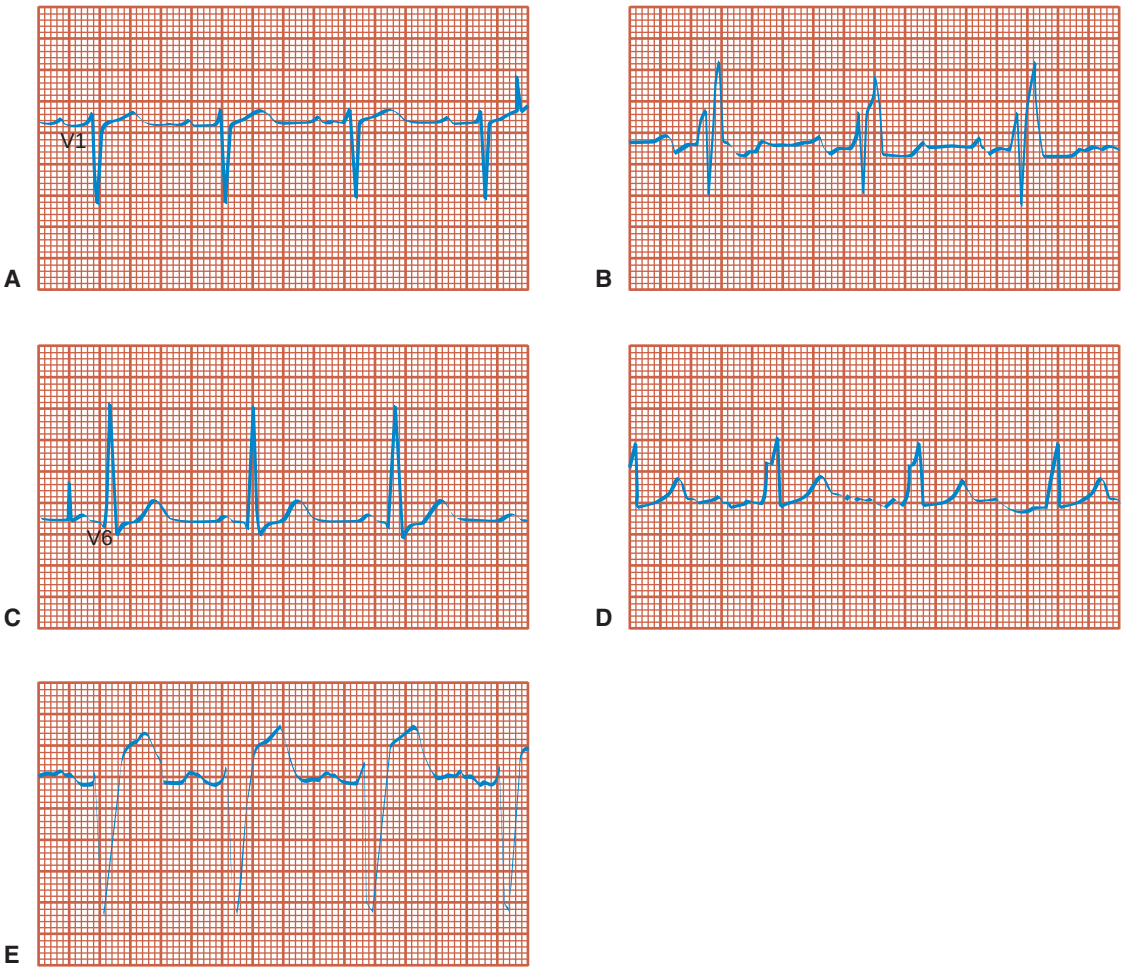

FIGURE 17-34 ▲ Comparison of right versus left bundle branch block (LBBB). **A:** A normal V_1 tracing. Note the small narrow R and deep narrow S wave. **B:** V_1 tracing showing the wide QRS complex and double-peaked R wave, indicating a right bundle branch block. **C:** A normal V_6 tracing. Note the tall narrow R wave and absent S wave. **D:** A V_6 tracing showing the wide QRS complex and double-peaked R wave, indicating a LBBB. **E:** A V_1 tracing. Note the small narrow R and deep wide S wave, indicating a LBBB.

Congenital lesions involving the septum and right ventricular hypertrophy (RVH) are other causes of RBBB. LBBB is usually associated with some type of underlying heart disease. Long-term CVD in the older patient is a common cause of LBBB.

BBB signifies underlying disease of the intraventricular conduction system. Patients should be monitored for involvement of the other bundles or fascicles or for progression to complete heart block. Progression of block may be very slow or rapid, depending on the underlying cause. A new-onset LBBB in conjunction with an acute MI is associated with a higher mortality rate.

The underlying heart disease determines treatment and prognosis. Patients with an MI and new-onset BBB are closely monitored for progression to a type of complete heart block. A temporary pacemaker may be inserted.

Enlargement Patterns

Enlargement of a cardiac chamber may involve hypertrophy of the muscle or dilation of the chamber. The most common causes include pumping for a prolonged period against high pressures or pumping for a prolonged period to move blood through narrowed valves. Electrocardiography is not an ideal diagnostic tool for determining the cause of the enlargement. Echocardiography is more helpful in determining if the enlargement is the result of hypertrophy or dilation. The terminology used to describe enlargement patterns on the ECG can be confusing. The term ventricular hypertrophy is commonly used because hypertrophy is the most frequent cause of the enlargement pattern in the ventricles. The general terms atrial abnormality and atrial enlargement are often used rather than the specific terms atrial hypertrophy or atrial dilation because atrial changes on the ECG may result from a variety of causes, including atrial dilation, hypertrophy, or other conditions. (See Fig. 17-35A for comparison.)

Right Atrial Enlargement

When the atria enlarge, changes are seen in the P wave because the P wave represents atrial depolarization. Right atrial (RA) enlargement is noted on the ECG by the presence of tall, pointed P waves in leads II, III, and aVF. The P wave in V_1 may show a diphasic wave with an initial upstroke that is larger than the downstroke (Fig. 17-35B).

The right atrium is more likely to enlarge as a result of pressures created by pulmonary causes, such as pulmonary hypertension and chronic obstructive pulmonary disease. For this reason, RA enlargement is often referred to as P pulmonale. RA enlargement is often associated with RVH.

Treatment is directed at the underlying cause. Often, however, the underlying cause may be a chronic condition that cannot be cured.

Left Atrial Enlargement

Left atrial enlargement is noted on the ECG by the presence of broad, notched P waves in leads I, II, and aVL. The P wave in V_1 may show a diphasic wave with a terminal downstroke that is larger than the initial upstroke (see Fig. 17-35C).

The left atrium is more likely to enlarge because of increased pressures created by trying to pump blood through a stenotic mitral valve. For this reason, left atrial enlargement is often referred to as P mitrale. When a left atrial enlargement pattern is noted on the ECG, the patient should be evaluated for the presence of mitral stenosis. An echocardiogram is a helpful diagnostic tool in addition to cardiac auscultation. Treatment is directed at the underlying cause. A valve replacement may be necessary.

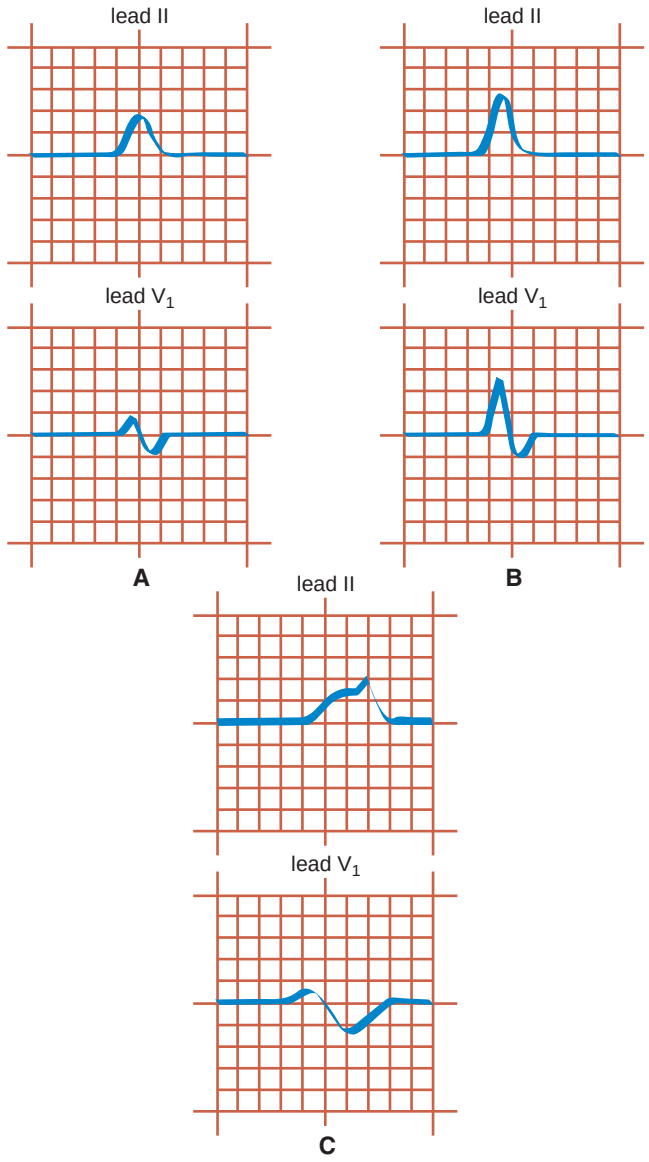

FIGURE 17-35 ▲ Right versus left atrial enlargement. **A:** The normal P wave in leads II and V_1. **B:** Right atrial (RA) enlargement. Note the increased amplitude of the early, RA component of the P wave in V_1 and the tall, pointed P wave in lead II. **C:** Left atrial enlargement. Note the increased terminal downstroke and duration of the P wave in V_1 and the broad, notched P wave in lead II.

Right Ventricular Hypertrophy

RVH may exist without clear evidence on the ECG because the left ventricle normally is larger than the right and can mask changes in the size of the right ventricle. ECG evidence suggestive of RVH includes RA enlargement and right axis deviation. In addition, the normal QRS complex pattern across the precordial leads is reversed. Normally, R waves are small in V_1 and gradually

grow tall by V_6. With RVH, the R wave is tall in V_1 and progresses to small by V_6. Precordial S waves persist rather than gradually disappear.

The presence of RVH is most likely an indicator of a chronic pulmonary condition, most likely chronic obstructive pulmonary disease, pulmonary hypertension, or pulmonic stenosis. RA enlargement is usually seen with an accompanying RVH. Treatment is directed at the underlying pulmonary disease.

Left Ventricular Hypertrophy

Numerous criteria exist for the detection of left ventricular hypertrophy (LVH) on the ECG. The simplest criterion involves remembering the number "35." LVH is determined by adding the deepest S wave in either V_1 or V_2 to the tallest R wave in either V_5 or V_6. If the sum is 35 mm or more and the patient is older than 35 years of age, LVH is suspected. In addition, the T waves in V_5 and V_6 may be asymmetrically inverted, and a left axis shift is likely.

Usually, LVH is the result of chronic systemic hypertension, a chronic cardiovascular problem, or aortic stenosis. LVH may result in a displacement of the PMI when palpating the apical pulse. Treatment of LVH is directed at the underlying condition.

Ischemia, Injury, and Infarction Patterns

The 12-lead ECG can be very useful in detecting evidence of myocardial ischemia, injury, or infarction. Ischemia is seen on the ECG by ST-segment depressions and T-wave inversions. Acute patterns of injury are noted by ST-segment elevations. The presence of significant Q waves indicates an MI. For a more detailed discussion of patterns of ischemia, injury, and infarction, see Chapter 21.

EFFECTS OF SERUM ELECTROLYTE ABNORMALITIES ON THE ELECTROCARDIOGRAM

Maintenance of adequate fluid and electrolyte balance assumes high priority in the care of patients in any medical, surgical, or coronary ICU. Patients being treated for renal or cardiovascular diseases are especially vulnerable to electrolyte imbalances. The cure may well be worse than the disease if electrolyte abnormalities go undetected or ignored because they frequently are caused by the treatment rather than by the disease itself.

Diuresis can very quickly cause major shifts in electrolytes. Certainly, the often insidious drop of serum potassium levels in the patient with cardiac disease, who has been taking digitalis and then starts diuretics, is well known. Diuretics also are used frequently as part of the medical regimen for the control of hypertension. Any addition, deletion, or change in diuretic therapy warrants close monitoring of serum electrolytes. A history of any of these problems should alert the nurse to check the patient's serum electrolytes on an ongoing basis.

Potassium and calcium are probably the two most important electrolytes involved in the proper function of the heart. Because of their effects on the electrical impulse in the heart, an excess or insufficiency of either electrolyte frequently causes changes in the ECG (Table 17-15). The nurse who is aware of and able to recognize these changes may well suspect electrolyte abnormalities before laboratory findings or clinical symptoms appear and hazardous dysrhythmias occur.

However, it is necessary to remember that just as a patient who sustains MI may not have chest pain, the patient with electrolyte abnormalities may not exhibit any of the ECG changes described in the following sections. The ECG manifestations are valuable primarily in arousing suspicion of electrolyte abnormalities. Not one of them even approaches being diagnostic.

▲ Potassium

Potassium is the primary intracellular cation found in the body. Inside the cardiac cell, potassium is important for repolarization and for maintaining a stable, polarized state.

Hyperkalemia

The earliest sign of hyperkalemia on the ECG is a change in the T wave. It usually is described as tall, narrow, and "peaked" or "tented" in appearance (Fig. 17-36). As the serum potassium level increases, the P-wave amplitude decreases and the PR interval is prolonged. Atrial asystole occurs, along with a widening of the QRS complex. At high, near-lethal potassium levels, the widened QRS complex merges with the T wave and starts to resemble a sine wave. Various dysrhythmias may occur during this time, with progression to VF and asystole. Clinically, the described changes in T waves begin to appear at serum levels of 6 to 7 mEq/L, and QRS complex widening is seen at serum levels of 8 to 9 mEq/L. Vigorous treatment must be instituted to reverse the condition at this point because sudden death may occur at any time after these levels are reached.

The ECG changes in hyperkalemia also may be associated with other conditions. Tall, peaked T waves may be a normal finding or may occur in the early stages of MI. QRS

Table 17-15 Electrocardiographic Changes Associated With Electrolyte Imbalances

Hyperkalemia	Tall, narrow, peaked T waves; flat, wide P waves; widening QRS complex	Sinus bradycardia; sinoatrial block; junctional rhythm; idioventricular rhythm; ventricular tachycardia (VT); ventricular fibrillation (VF)
Hypokalemia	Prominent U waves; ST segment depression; T-wave flattening or inversion	Premature ventricular beats; SVT; VT; VF
Hypercalcemia	Shortened QT interval	Premature ventricular contractions
Hypocalcemia	Lengthened QT interval; T-wave flattening or inversion	Ventricular tachycardia

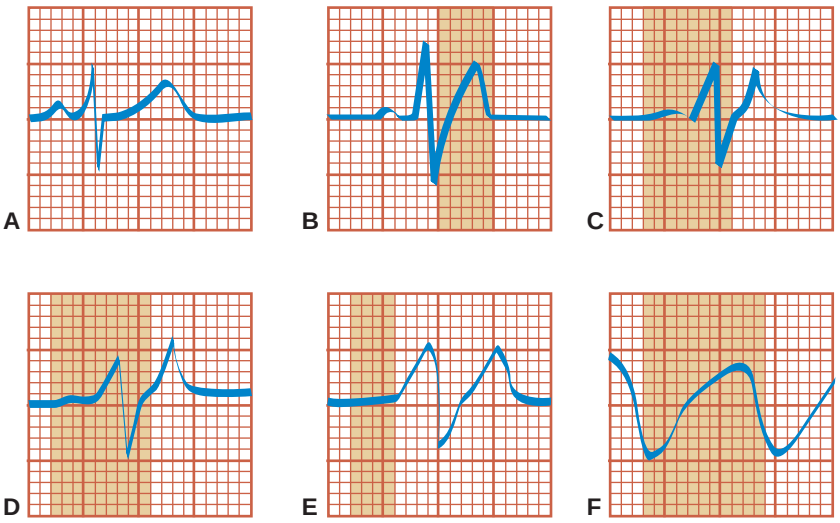

FIGURE 17-36 ▲ The effect of hyperkalemia on an ECG. **A:** This waveform is produced when the serum potassium level falls within the normal range—usually considered to be 3.5 to 5 mEq/L. **B:** When the serum potassium level rises above 5.5 mEq/L, the T wave begins to peak (*see highlighted area*). The P wave and QRS complex are normal. **C:** When the potassium level exceeds 6.5 mEq/L, the P wave grows wider, and its amplitude falls. The QRS complex also widens (*see highlighted area*) as intraventricular conduction velocity diminishes. **D:** When the potassium level reaches 10 mEq/L, the P wave becomes almost indiscernible; the QRS complex is slurred and widened (*see highlighted area*). **E:** When the potassium level ranges from 10 to 12 mEq/L, the P wave is undetectable (*see highlighted area*) because the atria are no longer excitable. **F:** When the potassium level exceeds 12 mEq/L, the QRS complex is no longer identifiable. The waves are known as sine waves (*see highlighted area*). Ventricular fibrillation and cardiac arrest follow. (From Springhouse: ECG Interpretation: Clinical Skillbuilders. Springhouse, PA: Author, 1990, p 113.)

complex widening may be seen with quinidine and procainamide toxicity.

Hypokalemia

Hypokalemia is associated with the appearance of U waves. Although the presence of U waves may be normal in many people, these waves also may be an early sign of hypokalemia (Fig. 17-37). Usually easily recognized (best seen in lead V_3), a U wave may encroach on the preceding T wave and go unnoticed. The T wave may look notched or prolonged when it is hiding the U wave, giving the appearance of a prolonged QT interval. With increased potassium depletion, the U wave may become more prominent as the T wave becomes less so. The T wave becomes flattened and may even invert. The ST segment tends to become depressed, somewhat resembling the effects of digitalis on the ECG. Only at very low serum levels is there reasonable correlation between ECG changes and serum potassium concentrations.

The changes seen in hypokalemia also are observed in other conditions. The U wave may be accentuated in association with digitalis, LVH, and bradycardia.

Untreated hypokalemia enhances instability in the myocardial cell. Ventricular premature beats are the most common manifestation of this imbalance, but supraventricular dysrhythmias, conduction problems, and eventually VT and VF may occur. Hypokalemia also increases the sensitivity of the heart to digitalis and its accompanying dysrhythmias, even at normal

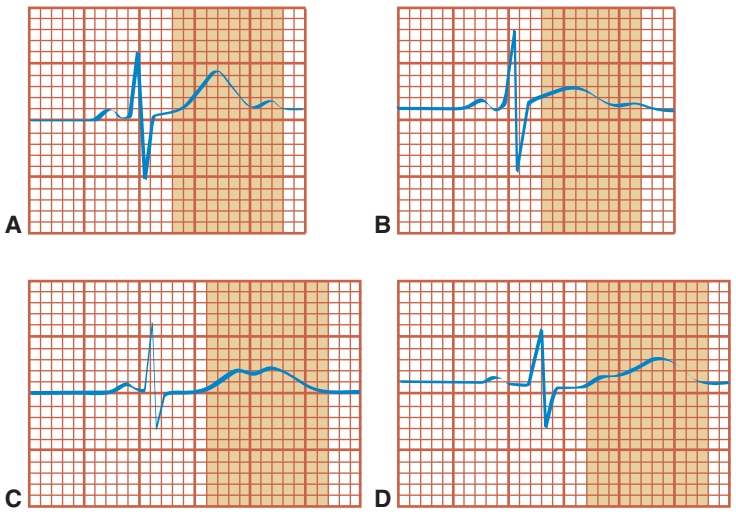

FIGURE 17-37 ▲ The effect of hypokalemia on an ECG. **A:** When the potassium level is normal—usually considered to be 3.5 to 5 mEq/L—the T wave is much higher than the U wave (*see highlighted area*). **B:** When the potassium level falls to 3 mEq/L, the T wave and U wave are almost the same height (*see highlighted area*). **C:** When the potassium level falls to 2 mEq/L, the U wave starts rising above the T wave (*see highlighted area*). **D:** As the potassium level reaches 1 mEq/L, the U wave starts to resemble a T wave (*see highlighted area*). The duration of the QT interval remains the same, but it cannot be measured because the two waves are fusing. (From Springhouse: ECG Interpretation: Clinical Skillbuilders. Springhouse, PA: Author, 1990, p 114.)

serum levels. The severity of the dysrhythmias associated with hypokalemia requires early recognition of this problem.

▲ Calcium

Like potassium, calcium is important in normal cardiac function. It is essential for the initiation and propagation of electrical impulses and for myocardial contractility. Abnormal calcium levels are not commonly seen unless they are associated with an underlying disease, and therefore they are not as common as serum potassium abnormalities.

Hypercalcemia

On an ECG, the major finding associated with hypercalcemia is shortening of the QT interval (Fig. 17-38). Because the QRS complex and T wave usually are unaffected by changes in serum calcium levels, the shortened QT interval is a result of shortening of the ST segment. QT-interval shortening also is seen in patients taking digitalis. In addition, ST-segment depression occasionally occurs, and T-wave inversion may be seen.

Hypocalcemia

On an ECG, low serum calcium levels prolong the QT interval because of a lengthening of the ST segment (see Fig. 17-38). The T wave itself is not prolonged but may be inverted in some cases. The prolongation of the QT interval in hypocalcemia should not be mistaken for a prolonged QTU interval seen in hypokalemia. In patients with chronic renal failure, hypocalcemia may be associated with decreased potassium levels.

QT interval prolongation also may be seen in cerebral vascular disease and after cardiac arrest. Several antiarrhythmic agents produce prolonged QT intervals and always should be considered when evaluating an ECG for hypocalcemic changes.

HEMODYNAMIC MONITORING

Hemodynamic monitoring is a means of evaluating intracardiac and intravascular volume, pressures, and cardiac function. The purposes of hemodynamic monitoring are to aid in the diagnosis of various cardiovascular disorders, guide therapies to optimize cardiac function, and evaluate the patient's response to therapy.

Because a primary goal of management of a critically ill patient is to ensure adequate oxygenation of tissues and organs, indications for hemodynamic monitoring include conditions in which CO is insufficient to deliver oxygen to the cells due to alterations in intravascular volume (preload), alterations in vascular resistance (afterload), or alterations in myocardial contractility. Hemodynamic monitoring may be indicated as a mechanism to assess the balance of oxygen supply (oxygen delivery) and demand as evaluated by measurement of oxygen consumption or venous oxygen saturation. The determinants of CO, oxygen delivery, and oxygen utilization are discussed in detail in the later portion of this section and in Chapters 16, 23, and 54.

Patients who are in cardiogenic shock, severe heart failure, severe sepsis or septic shock, multiple system organ dysfunction, or acute respiratory distress syndrome, or those who have had cardiac surgery, are examples of candidates for invasive and minimally invasive hemodynamic monitoring. In addition, noninvasive hemodynamic technology now affords clinicians the ability to evaluate cardiovascular performance in areas outside of the critical care arena and in the outpatient setting.

To incorporate hemodynamic data into the care of the critically ill, the nurse must understand the following:

- Cardiorespiratory anatomy and physiology
- Monitoring system components to measure cardiac and vascular pressures and CO
- Rationales for interventions directed toward enhancing CO, oxygen delivery, and oxygen consumption
- Potential complications
- Differences between physiological changes and mechanical or monitoring system problems

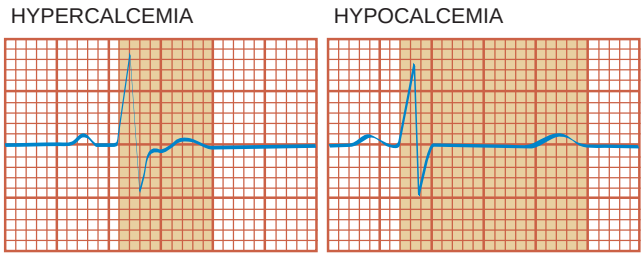

FIGURE 17-38 ▲ The effects of hypercalcemia and hypocalcemia on an ECG. Changes in serum calcium levels are reflected in phase 2 of the action potential. Hypercalcemia shortens the QT interval, whereas hypocalcemia lengthens it (*see highlighted areas*). (From Springhouse: ECG Interpretation: Clinical Skillbuilders. Springhouse, PA: Author, 1990, p 115.)

▲ Pressure Monitoring System

Basic equipment necessary to measure and monitor invasive hemodynamic pressures includes a hollow-tube catheter, a fluid-filled pressure monitoring system comprised of flush solution, IV tubing with drip chamber, noncompliant tubing, stopcocks, a flush device, one or more transducers, and a monitor that amplifies and displays the pressures and waveforms (Fig. 17-39). Pressures from the intravascular space or cardiac chambers are transmitted through the catheter and the fluid-filled noncompliant pressure tubing to the pressure transducer, which then converts the physiological signal from the patient into an electrical one. Transducers are usually disposable and precalibrated, and come packaged with the pressure system. The monitor converts and amplifies the electrical signal generated by the transducer to a pressure tracing and digital value. In general, bedside physiological monitoring systems have the capability to display several pressure digital readings and waveforms simultaneously. The monitors also include mechanisms to label waveform locations, set or adjust alarms and tracing scale size, and zero the system.

Using a continuous flush solution maintains a patent pressure system. The flush solution is typically normal saline or

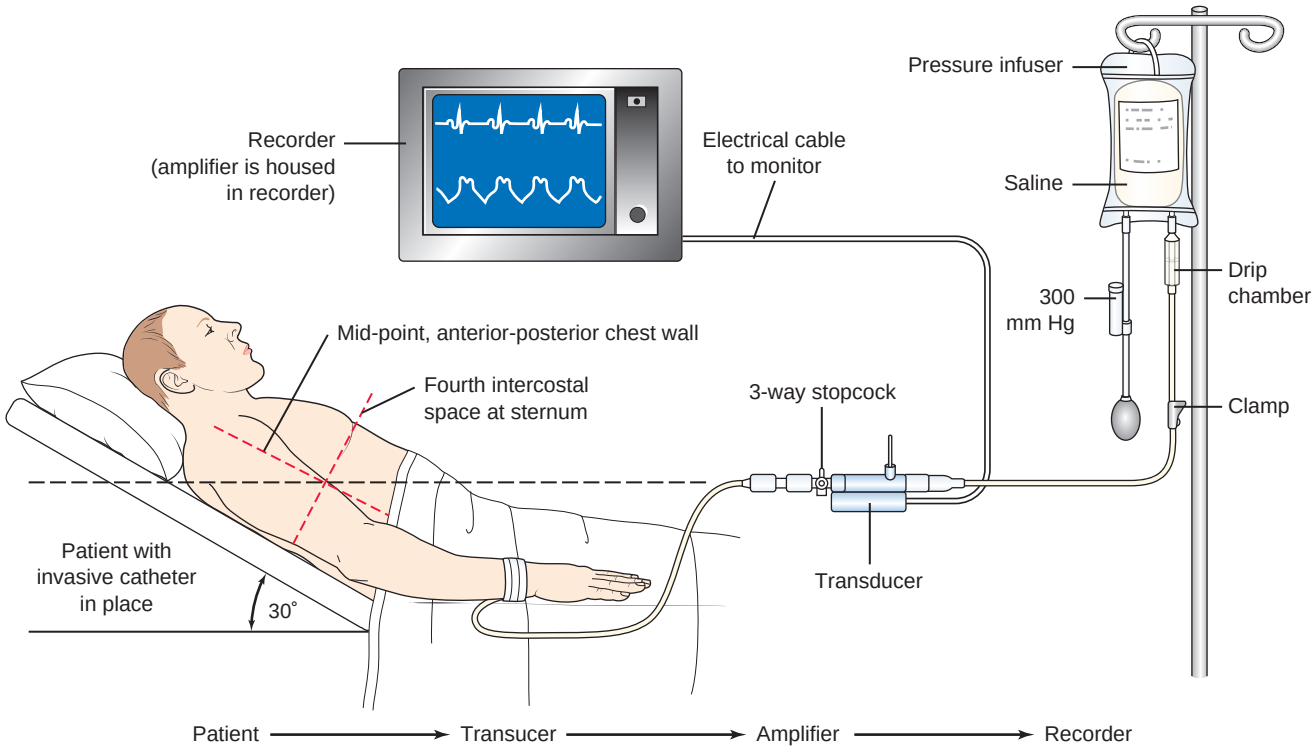

FIGURE 17-39 ▲ Invasive pressure monitoring. An indwelling catheter is attached by pressure tubing to a transducer. The transducer is connected to an amplifier/monitor that visually displays a waveform and systolic, diastolic, and mean pressure values. The system is composed of a flush solution under pressure, a continuous flush device, and a series of stopcocks. Typically, the stopcock closest to the insertion site is used to draw blood samples from the artery, and the stopcock located nearest the transducer is used for zeroing.

dextrose and water (D_5W) and may be heparinized. The bag of solution is placed in a continuous pressure infusion bag or device to exert approximately 300 mm Hg. This maintains a constant pressure through the restrictor in the flush device and system. A continuous flow of approximately 3 to 5 mL/h prevents backflow of blood through the catheter and tubing, thereby maintaining system patency and accurate transmission of pressures. The system is flushed manually by activating the flush device.

Optimizing the Pressure Monitoring System

An optimal pressure monitoring system is one that accurately reproduces the physiological signals transmitted through it. For optimal use of invasive monitoring systems, it is essential to ensure accurate pressure recordings and waveform display. Technical or mechanical factors can produce erroneously high or low pressures and altered waveforms. Before determining whether abnormal pressures are a result of altered physiology or a response to interventions, the nurse assesses the system to determine whether the pressures recorded are accurate. Table 17-16 describes causes of technical factors affecting invasive pressure monitoring and troubleshooting techniques. Any impedance between the patient and transducer, such as air bubbles, blood, or additional stopcocks, can alter the signal and subsequently the pressures and waveforms. Less than 300 mm Hg in the continuous pressure device, soft compliant IV tubing, or additional length of pressure tubing may also distort the signal to the transducer. Stopcocks, used for zeroing the transducer and blood sampling, as well as any other connectors, are kept to a minimum. Luer-Lok–type connections, rather than slip-lock connections, help preserve the integrity of the system.

After assessing the pressure system components to identify any potential mechanical problems, the nurse performs a square-wave test to determine the dynamic response of the system. In addition, the nurse ensures proper leveling of the air–fluid interface and zeroing of the transducer to optimize the system.[20–23]

Square-Wave Test: Dynamic Response Testing

For a rapid bedside assessment of the dynamic response of the system, a simple evaluation of dynamic response can be obtained by performing a square-wave test and observing the resultant oscillations. Checking the dynamic response of the system determines the natural frequency and damping coefficient. Factors affecting the response of the system include the natural frequency of the system itself, the pressure tubing quality, number of stopcocks, and other components, such as blood sampling systems. The steps required to measure the natural frequency and damping coefficient accurately are complex and time consuming. Other references describe the steps for performing this process.

Table 17-16 Troubleshooting Pressure Monitoring Systems and Measurements

Problem	Cause	Prevention	Intervention
1. No waveform	Transducer not open to catheter	Check stopcocks for proper position.	Check and correct stopcock position. Check scale setting and monitor setup. Aspirate blood clot. Do not fast flush or irrigate with syringe.
	Settings on bedside monitor incorrect or off		Check function with cable checking device.
	Catheter clotted	Use correct setting on bedside monitor.	Check function of transducer with mercury, water column, or supplemental pressure device.
	Faulty cable	Maintain continuous flush.	
	Faulty transducer	Use functioning cables.	Change transducer if necessary.
2. Overdamped waveforms	Improper scale selection		Change to proper scale.
	Air bubbles in tubing and near transducer	Flush system by gravity. Remove any air bubbles.	Flush air from system. On initial setup, expel all air from flush solution bag.
	Blood clot partially occluding catheter tip	Maintain continuous flush; use heparinized solution according to hospital protocol.	Aspirate clots with syringe. Use heparinized solution according to institution policy.
	Forward migration of catheter		Reposition patient. Check for kinks in catheters.
	Catheter tip occluded by balloon or vessel wall		Reposition by pulling back catheter while observing waveforms.
	Leak in pressure system	Tighten all connections and stopcock up on set up.	Tighten all connections and stopcocks. Change faulty system components if necessary.
	Pressure bag not inflated at 300 mm Hg	Inflate or apply pressure to device to 300 mm Hg.	Reinflate bag or activate device. Change device if faulty.
3. Underdamped waveforms; whip or ringing	Excessive movement of catheter	Correct catheter placement. Use appropriate catheter size for vessel.	Try different catheter tip position. Eliminate excessive tubing.
	Air bubbles in tubing	Eliminate excessive length of pressure tubing. Check for very rigid pressure tubing.	Change tubing. Eliminate excessive stopcocks.
4. False low readings	Leveling or zero reference (transducer) is too high	Check level periodically. Level air–fluid interface of stopcock nearest the transducer to the phlebostatic axis.	Relevel transducer air–fluid interface to phlebostatic axis.
	Improper zeroing	Check monitor settings. Observe waveforms.	Rezero monitor.
	Overdamped waveforms	Perform square-wave test.	Optimize length of pressure tubing.
5. False high readings	Leveling or zero reference (transducer) is too low	Check level periodically. Level air–fluid interface of stopcock nearest the transducer to the phlebostatic axis.	Relevel transducer air–fluid interface to phlebostatic axis.
	Improper zeroing	Check monitor settings. Observe waveforms.	Rezero monitor.
	Overdamped waveforms	Perform square-wave test.	Remove excessive length of pressure tubing.
6. Inappropriate pressure waveform	Incorrect catheter position		Reposition patient. Obtain chest x-ray. Reposition catheter.*
	Migration of PAC into mechanical wedge position	Establish optimal position carefully during the insertion process, ensuring use of 1.25–1.5 mL air for proper balloon inflation volume for obtaining a PAOP tracing.	Observe waveforms and confirm with initial insertion tracings. If right ventricular tracing is observed from PAC distal tip, slowly inflate balloon to allow PAC to "float" into pulmonary artery. If PAOP tracing is observed with balloon deflated, withdraw catheter slightly while observing waveforms. Stop withdrawing as soon as a pulmonary artery tracing is observed.
7. Bleed back into pressure tubing or transducer	Loose connections	Ensure all connections are tight.	Tighten connections.
	Stopcocks not returned to proper position	Return stopcocks to proper positions.	Ensure stopcocks are in correct position.
	Pressure bag not at 300 mm Hg	Maintain 300 mm Hg of pressure.	Check pressure device.

*Repositioning the PAC usually is done by a physician or advanced practice nurse such as a nurse practitioner and varies with hospital policies. PAC, pulmonary artery catheter; PAOP, pulmonary artery occlusion pressure.

To perform a square-wave test, a flush device that can be activated and released rapidly is required. Activating the flush device opens the internal restrictor and increases the fluid flow through the system. The nurse observes the bedside monitor for the increase in pressure. The waveform sharply rises and "squares off" at the top of the scale. After the flush device is released, the restrictor closes. The nurse observes the waveform as it returns to baseline, counts the number of oscillations, and observes the distance between them.

In an ideal system, also called optimally damped, the square wave has a straight vertical upstroke from the baseline, a straight horizontal component, and more importantly, a straight vertical downstroke back to the baseline with approximately one and one-half to two sharp oscillations. The distance between the oscillations is also close.[20] Figure 17-40 depicts a normal square wave and examples of square waves from nonoptimized hemodynamic monitoring systems. Overdamped systems produce lower than actual systolic pressures and potential loss of dicrotic notch identification. Underdamped systems produce artificially high systolic pressures and low diastolic pressures. By performing a square-wave test, the bedside clinician can quickly assess if the abnormal waveform tracing is a result of the patient's physiology or a less-than-optimal system.[20–23]

Leveling and Zeroing

After a square-wave test is performed, the system is leveled to an external landmark and then zeroed to atmospheric pressure to ensure accurate pressure monitoring. Typically, the stopcock nearest the transducer is used as the air–fluid interface for leveling and zeroing; however, any stopcock port in the system can be used as long as it is leveled to the phlebostatic axis. The phlebostatic axis is best described as the bisection of the fourth intercostal space and the midpoint of the anterior–posterior chest diameter (see Fig. 17-39, p. 264); it is often called the zero reference point. Zeroing the transducer is the action of opening the pressure system to atmospheric air and observing a reading of zero on the bedside monitor. With the stopcock turned off to the patient and opened to air, the influence of hydrostatic pressure is negated from the fluid-filled pressure system. Subsequent pressures recorded on the monitor now reflect those generated by the patient, not external forces. Bedside monitor manufacturers vary; however, most have a function key to ensure that the zeroing process has been successful. Newer disposable transducers come from the manufacturer precalibrated and do not require adjustment to an electronic zero. The term "zeroing" is used, however, when referencing to atmospheric pressure.

Once the zero reference point is established, the patient's chest is marked to ensure consistent leveling when other practitioners obtain subsequent pressure readings. With the patient positioned supine, a carpenter-type level or laser-light level device is used to align the air–fluid interface with the phlebostatic axis. Further pressure measurements are taken with the patient in the supine position.

If the alignment of the air–fluid interface changes after initial leveling and zeroing, an inversely related error of approximately 2 mm Hg for every inch misaligned occurs. For example, if the transducer air–fluid interface is raised from initial leveling, the values displayed will be about 2 mm Hg too low, and if lowered from initial leveling, the values recorded will be erroneously too high.

The head of the bed may be elevated as much as 60 degrees, provided that the air–fluid interface is releveled after any changes in patient position. Lateral or side-lying positions may be used if the external landmark is properly identified. Because some patients respond differently to head of bed elevation and side-lying positions, their hemodynamic values should be compared from supine.[20–23]

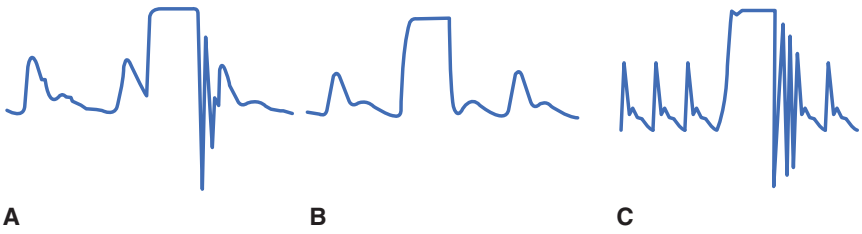

FIGURE 17-40 ▲ Steps to perform a square wave test include:
1. Activate the snap or pull tab of the flush device.
2. Observe the square wave generated on the bedside monitor.
3. Count the oscillations after the square wave.
4. Observe the distance between the oscillations.

A. Optimally damped system: Activation of the fast flush device generates a sharp vertical upstroke, horizontal line, and straight vertical downstroke ending with 1.5 to 2 oscillations close together before returning to baseline.
B. Overdamped system: Activation of the fast flush device generates a slurred upstroke and downstroke with less than 1.5 oscillations above or below the baseline. Causes include system leaks, blood clots, or large air bubbles in the tubing or transducer. Systolic pressures read erroneously low, diastolic pressures occasionally read low.
C. Underdamped system: Activation of the fast flush device generates more than 2 to 3 oscillations above and below the baseline. Causes include small air bubbles in the system, very rigid pressure tubing, and additional length of tubing. Systolic pressures read erroneously high, diastolic pressures read erroneously low.

(Courtesy of Edwards Lifesciences LLC.)

After the level and zero is verified, the only way to determine whether the pressures displayed on the monitor are accurate is to apply a known value to the transducer with a piece of external tubing and water column. Some transducer manufacturers provide a device that applies a known pressure to the transducer for rapid determination of accurate pressure recordings.

▲ Arterial Pressure Monitoring

Invasive arterial pressure monitoring uses an intra-arterial catheter connected to the pressure monitoring system. This allows continuous monitoring of the systemic arterial blood pressure and provides vascular access for obtaining blood samples by withdrawing blood from a stopcock or closed system device in the system. Indications for intra-arterial blood pressure monitoring include monitoring patients with vasoactive IV infusions; cardiovascular instability; and fluctuating, unstable blood pressures.

Arterial Line Insertion

The most common sites for arterial catheter insertions are the radial, brachial, and femoral arteries. Alternative and less frequent sites include the axillary and dorsalis pedis arteries in adults and the temporal and umbilical arteries in neonates. The following factors are considered for selecting the artery for cannulation:

- Size of the artery in relation to the size of the catheter; the artery should be large enough to accommodate the catheter without occluding or significantly impeding flow.
- Accessibility of the site; the chosen site should be easily accessible and free from contamination by body secretions.
- Blood flow to the limb distal to the insertion site; there should be adequate collateral flow in the event that the cannulated artery becomes occluded.

The radial artery, which satisfies these criteria, is the most frequent site for an arterial catheter. It is superficially located and therefore easy to palpate. Cannulation of this artery also usually poses the least limitation on the patient's mobility.

Before a catheter is inserted into the radial artery, the presence of adequate collateral circulation to the hand by the ulnar artery is assessed by performing Allen's test (Fig. 17-41). The Allen's test is performed by having the patient clench their fist several times while the nurse is occluding both the radial and ulnar arteries. The patient then extends their hand with the palm side up to show it is blanched. Pressure on the ulnar artery is released, and the hand is observed for return of color. If the hand remains blanched for longer than about 10 seconds, ulnar circulation is considered inadequate, in which case the radial artery should not be cannulated. Use of ultrasound devices for assessing blood flow in place of the Allen's test is becoming more common.

Regardless of the site chosen for arterial catheter placement, the insertion is performed using sterile technique. The pressure monitoring system is assembled and flushed, and the transducer is leveled and zeroed before the catheter is inserted. Once the catheter is in place, it should be secured and the site dressed according to institutional policy.[20–23]

Arterial Pressure Waveform

The normal arterial waveform should have a rapid upstroke, a clear dicrotic notch, and a definite end-diastole, as shown in Figure 17-42. The mechanical activity of systole and diastole follows the electrical activity of depolarization and repolarization, respectively. The initial sharp upstroke of the waveform results partly from the rapid ejection of blood from the left ventricle into the aorta. On a dual-channel tracing of both the ECG and arterial waveforms, the QRS complex precedes the rapid rise in arterial pressure. The dicrotic notch reflects a slight backflow of blood in the aorta, reflecting closure of the aortic valve or may be a reflective wave from the periphery.

Obtaining Arterial Pressures

The value measured at the peak of the waveform is the systolic pressure. A normal arterial systolic pressure is typically 90 to 140 mm Hg. The dicrotic notch typically indicates the end of ventricular systole and the beginning of

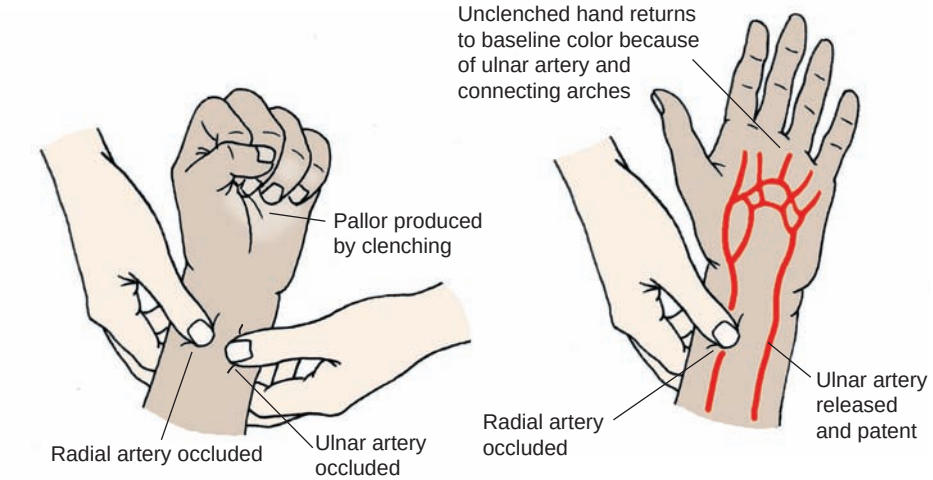

FIGURE 17-41 ▲ Modified Allen's test.

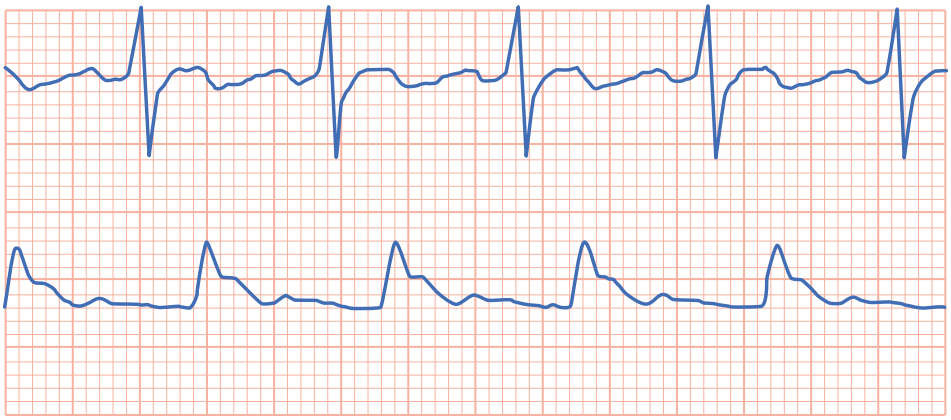

FIGURE 17-42 ▲ Normal relationship of ECG and arterial pressure waveform.

diastole. As blood flows to the periphery, the pressure in the arterial system decreases. The lowest point of the waveform is the diastolic pressure, which is normally between 60 and 90 mm Hg.

Mean arterial pressure (MAP) is used to evaluate perfusion of vital body organs. Normal MAP is 70 to 105 mm Hg. The MAP calculation incorporates the impact of diastolic time being approximately two times longer than systole during a cardiac cycle. Therefore, MAP = diastolic pressure +⅓ pulse pressure, or

$$\frac{\text{Systolic pressure} + (\text{Diastolic pressure} \times 2)}{3}$$

Most bedside monitors automatically calculate and continuously display the MAP. Manufacturer algorithms to determine MAP may vary; however, most incorporate assessment of the area under the full arterial waveform rather than a mathematical model.

The difference between the systolic and diastolic pressure is the pulse pressure (PP). This value more closely reflects the SV from the ventricle. SV is proportional to PP and inversely related to the aortic compliance. Bedside monitors do not automatically display this valuable parameter. Clinicians who want to assess the patient's volume status should include PP in their assessment because it is an indirect reflection of the SV. The range of PP may be as wide as 30 to 100 mm Hg at the far ends of the spectrum. A wide PP occurs typically with elevated systolic pressures resulting from aortic regurgitation and some vascular conditions. A narrow PP may result from hypovolemic states when the diastolic pressure rises.[22]

Complications

Infection

Proper attention to sterile technique during catheter insertion; care of the insertion site; blood sampling; and maintenance of a sterile, closed monitoring system reduce the risk of infection. The following should be performed according to institution policy: assessment of insertion site for signs of infection; use of sterile technique when changing dressings, tubing, and flush solution; and maintenance of the integrity of the system. Opening the pressure system to air for either zeroing or blood sampling provides opportunity for infection. Applying sterile nonvented or "dead-ender" caps to the stopcock ports helps eliminate contamination. Closed systems for blood sampling help reduce the potential for open stopcock infections and assist with managing potential blood loss.

Accidental Blood Loss

Accidental blood loss from an arterial catheter can be catastrophic and often can be prevented. All connections in the system should use a Luer-Lok–type connector. The extremity in which the catheter is placed may be immobilized (eg, placing the wrist on an arm board). If some type of patient self-protective device is used, it should not be placed over the insertion site. Easy access to the insertion site and connections is imperative.

Impaired Circulation to Extremity

Circulation to the extremity in which the arterial line is placed must be monitored frequently. Initial assessment of color, sensation, temperature, and movement of the extremity is made after insertion of the arterial catheter and as frequently as the institution policy states. Any indication of impaired circulation may be an indication for catheter removal and is reported immediately.

Nursing Considerations

Blood pressures obtained by an intra-arterial catheter and with an optimal pressure monitoring system are most accurate. Comparisons between intra-arterial and cuff pressures may be misleading because the methods of measurement reflect different physiological events and are therefore not truly comparable.[23] Direct or invasive monitoring measures pressure, and indirect cuff measurements are based on flow. In normotensive patients, intra-arterial pressures are typically higher by about 5 to 10 mm Hg than the pressures obtained using a cuff. Indirect methods tend to overestimate direct measurements in hypotensive patients and underestimate them in hypertensive patients. Variations as wide as 20 to 60 mm Hg occur, depending on specific patient conditions.[22]

For interventions when accurate values are important for therapeutic decisions, intra-arterial pressures remain the gold standard. Using a trend value from one source is often more helpful than comparing values obtained between different

technologies. Documenting the site of pressure measurements and the type of technique used is key.

Patient safety measures include the proper setting and activation of all alarms on the bedside physiological monitor. Bedside monitor alarms provide warning that a change has occurred either in the system or in the patient's physiological status. Alarms are set either around a patient's specific parameter or according to institution policy. Typically, high and low alarms are set for systolic, diastolic, and mean pressures and within 10 to 20 mm Hg of the patient's blood pressure. The alarms must be visible and audible to the caregiver for the specific patient environment. Troubleshooting steps for an alarm are listed in Table 17-16 on page 265.

General steps to ensure accurate pressures from invasive lines include assessing the patient first, then checking the pressure monitoring system, and then inspecting the monitor itself. Assess the insertion site: Is the catheter kinked? Are there any blood clots? Is there any sign of bleeding? Next, evaluate the pressure system: Are any stopcocks turned the wrong way? Is there sufficient pressure in the pressure bag (ie, does the pressure read 300 mm Hg)? Are there any air bubbles? Is the bedside monitor functioning properly? Are the alarms set correctly?

If catheter patency is in question, blood and fluid are aspirated from the blood-drawing port or stopcock in an attempt to remove a blood clot (if present), and then the system is flushed using the fast flush device. The system should not be flushed with a syringe. No additional IV solution or medication should be administered through the arterial pressure monitoring system at any time.

▲ Central Venous Pressure Monitoring

CVP is typically measured in the superior vena cava near the right atrium via a catheter placed in the jugular or subclavian vein. It therefore reflects the pressure of blood in the right atrium and provides information about intravascular blood volume, right ventricular end-diastolic pressure (RVEDP), and right ventricular function. To a limited degree in persons with normal pulmonary vasculature and left ventricular function, the CVP indirectly reflects left ventricular end-diastolic pressure (LVEDP) and function because the left and right sides of the heart are linked by the pulmonary vascular bed. Alterations in intravascular volume status or ventricular function usually are associated with abnormally high or low CVP measurements.[20–22]

Catheter Insertion

The CVP catheter is long and flexible. It is inserted under maximum sterile conditions with a chlorhexidine site preparation. The physician or nurse practitioner uses a sterile field with a full sterile drape, sterile gloves and gown, and a mask and cap. Those assisting the physician also should wear a cap and mask and sterile gloves if near the catheter or insertion site. The best insertion site to minimize infection risk is the subclavian vein.[24] Catheters also can be inserted into an antecubital, jugular, or femoral vein if necessary. It is threaded into position in the vena cava close to the right atrium. Occasionally, the catheter may advance into the right atrium. In this situation, the catheter is withdrawn several centimeters.

The hemodynamic monitoring system components and preparation for CVP monitoring are identical to those described for arterial pressure monitoring. After insertion of the catheter, the pressure tubing is connected to the catheter hub. The CVP waveform and value appear on the bedside monitor.

Complications

Infection

Infection may occur within the catheter or around the insertion site. Central venous catheter–associated bloodstream infection is diagnosed and verified by blood cultures. Occasionally after catheter removal, the tip is cut off with sterile scissors and sent to the microbiology laboratory. Signs and symptoms of infection include erythema at the insertion site, fever, or elevated WBC count. Primary measures to prevent infection include routine dressing and IV fluid tubing changes, as outlined by the Centers for Disease Control and Prevention[24] and hospital policy, as well as adherence to sterile technique during catheter insertion and dressing changes. When catheters are left in place for an extended period of time, antibiotic-impregnated catheters may be used to reduce the risk for infection. See Evidence-Based Practice Highlight 17-2.

Thrombosis

Thromboses occasionally form and may vary in size from a thin fibrin sheath over the catheter tip to a large thrombus. A small thrombus may be flushed away without causing harm, but a larger thrombus occluding the catheter and vein should not be flushed into the venous circulation. A large thrombus may be detected by loss of hemodynamic waveform and inability to infuse fluid or withdraw blood from the catheter. The patient may have edema of the arm closest to the catheter site, varying degrees of neck pain (that may radiate), and jugular vein distention. A large thrombus is classified as an emergency because it may impair circulation to a limb. A nurse may attempt to aspirate this clot if hospital policy permits. Frequently, hospitals also have protocols to administer small doses of thrombolytic agents to dissolve the clot. At the very least, the nurse is responsible for reporting suspected catheter occlusion to a physician.

Air Embolism

Air embolism occurs as a result of air entering the system and traveling through the vena cava to the right ventricle. Usually, air entry into the catheter is associated with disconnection of the catheter from the IV tubing. Changes in intrathoracic pressure with inspiration and expiration draw air into the catheter and vena cava. Sudden hypotension may be the first indicator of this sometimes lethal problem.

Approximately 10 to 20 mL of air must enter the venous system before the patient becomes symptomatic. Signs of such an emergency may include confusion, lightheadedness, anxiety, and unresponsiveness. The physiological event is the creation of foam in the ventricle with each heart contraction

EVIDENCE-BASED PRACTICE HIGHLIGHT 17-2

Preventing Catheter Related Bloodstream Infection

△ Expected Practice

- Cleanse hands with waterless cleaning solution or, if visibly soiled, with soap and water before and after patient contact.
- Disinfect clean skin utilizing friction with an appropriate antiseptic (preferably 2% chlorhexadine) before catheter insertion and during site care.
- Utilize full barrier precautions when inserting central venous access devices.
- Educate all staff inserting and caring for intravascular catheters, assess competency of same at regular intervals, and advocate adherence to standards of care.
- Replace peripheral IV sites in the adult patient population at least every 96 hours but no more frequently than every 72 hours. Leave peripheral venous catheters in children until IV therapy is completed, unless complications (eg, phlebitis and infiltration) occur.
- Replace IV tubing at least every 96 hours but no more frequently than every 72 hours.
- When adherence to aseptic technique during intravascular catheter insertion cannot be ensured (eg, prehospital, code situation), replace the catheter as soon as possible, but within 48 hours.

△ Supporting Evidence

- A substantial proportion of hospital-acquired infections result from cross-contamination from the hands of health care workers. Alcohol-based hand rub, compared with traditional handwashing with unmedicated soap and water or medicated hand antiseptic agents, may offer better results because it requires less time, acts faster, and is less likely to irritate skin. Thus, the Centers for Disease Control and Prevention recommends the use of alcohol-based hand rubs between patient contacts as an adjunct to traditional handwashing alone.
- Chlorhexidine gluconate solutions utilized for vascular catheter site care reduce catheter related bloodstream infections and catheter colonization more effectively than povidone-iodine solutions. Moreover, 80% of resident and transient skin flora are found in the first five epidermal layers of the skin. There is clinical evidence to support the efficacy of applying antiseptics with sufficient friction to assure that the solution reaches into the cracks and fissures of the skin. There is no evidence that supports use of traditional concentric prepping technique. Although a 2% chlorhexidine-based preparation is preferred, tincture of iodine, an iodophor, or 70% alcohol can be used. Allow any solution used to dry before the catheter is inserted.[1,4,5]
- Compared with peripheral venous catheters, CVCs carry a substantially greater risk for infection; therefore, the level of barrier precautions needed to prevent infection during insertion of CVCs should be more stringent. Maximal sterile barrier precautions (eg, cap, mask, sterile gown, sterile gloves, and full body sterile drapes) during the insertion of CVCs substantially reduce the incidence of CRBSI compared with standard precautions (eg, sterile gloves and small drapes)[1,3,2,10] There are some studies that demonstrate infection rates are lower when the subclavian site is used. Selection of central line insertion site, however, is based on patient risk factors.
- Healthcare workers who insert and care for intravascular devices should receive formalized education and training in indications for intravascular catheterization, proper placement, maintenance, and infection control. Educational programs focusing on central venous catheter insertion and care have lead to a substantial decrease in cost, morbidity, and mortality attributable to central venous catheterization. Ongoing education and reinforcement of appropriate technique serve as a reminder of current best practices, and studies demonstrate that consistent reinforcement of aseptic techniques leads to decreased CRBSI.[1,8,9,10,11]
- Studies of peripheral intravenous (IV) catheters show that there is not a substantial difference in phlebitis rates between catheters left in place 72 hours and those left in place 96 hours. There is no evidence to support that routine replacement of central venous catheters is more effective in decreasing bloodstream infections than replacing central venous catheters as needed.[1,12]
- Studies show that IV tubing containing crystalloids can be replaced every 72 to 96 hours. If monitoring using a transducer system, replace the transducer, tubing, flush device and flush solution every 96 hours.

and loss of SV due to air instead of blood in the ventricle, causing a sudden decrease in CO. Cardiac arrest may occur.

If this problem is suspected, turning the patient on the left side in the Trendelenburg position may allow the air to rise to the wall of the right ventricle and improve blood flow. Oxygen should be started unless contraindicated.

Strategies to prevent disconnections include having Luer-Lok connections on all central line catheters and tubings, careful manipulation of catheter and tubing during dressing changes, and routine monitoring of the connections. There is no substitute for close observation by skilled and educated nursing staff.

Nursing Considerations

Ensuring the integrity of the monitoring system, obtaining and documenting accurate data, and monitoring trends in CVP are critical to the interpretation and utilization of information to assess a patient's cardiovascular function and response to interventions. Evidence-Based Practice Highlight 17-3 summarizes current evidence related to obtaining accurate measurement of CVP pressure.

Normal CVP is less than 8 mm Hg. Low CVP indicates a hypovolemic state often requiring fluid administration. The anticipated response to fluid therapy is an increase in the CVP. Similarly, diuretic therapy reduces intravascular volume, and its administration is expected to be associated with a decrease in the CVP. Vasodilation from sepsis or vasodilating drugs may also lead to a low or decreasing CVP; both create a relative hypovolemia because the intravascular space has become greater relative to the blood volume, which has not changed. Increased CVP may be caused by a number of complex and interrelated factors, each of which requires scrutiny. Two of the more common causes of increased CVP are right ventricular failure and mechanical ventilation. Rarely is intravascular volume overload and hypervolemia alone a cause of increased CVP.

EVIDENCE-BASED PRACTICE HIGHLIGHT 17-3
Pulmonary Artery/Central Venous Pressure Measurement

△ Expected Practice

- Verify the accuracy of the invasive pressure monitoring system by performing a square waveform test at the beginning of each shift and anytime the system if disturbed (eg, blood draw).
- Position the patient in supine position with head of bed (HOB) between 0 and 60 degrees, lateral position 20, 30 or 90 degrees or prone before the pulmonary artery pressure (PAP), pulmonary artery occlusion pressure (PAOP), and central venous pressure (CVP) measurements. HOB elevation can be at any angle from 0 (flat) to 60 degrees if the patient is in the supine position. Allow the patient to stabilize 5 to 15 minutes after a position change.
- Level and reference the transducer air-fluid interface to the phlebostatic axis (supine or prone position), fourth intercostal space (ICS) ½ antero-posterior diameter of the chest or lateral angle specific reference using a laser or carpenters level before PAP/PAOP/CVP measurements.
- Obtain PAP/PAOP/CVP measurements from a graphic (analog) tracing at end-expiration or adjust the measurement point if the patient is receiving airway pressure release ventilation (APRV) or is actively exhaling.
- Use simultaneous ECG tracing to assist with proper PAP/PAOP/CVP waveform identification.
- PA catheters can be safely withdrawn and removed by competent registered nurses.

△ Supporting Evidence

- The square waveform test, or dynamic response test, determines the ability of the transducer system to correctly reflect invasive pressures.[14,15] The dynamic response is affected by system problems, such as air bubbles in the tubing, excessive tubing length, loose connections, and catheter patency. Removal of micro bubbles during system set up result in an "adequate" or "optimal" system in over 95% of cases.[16,17] Any of these problems affect the accuracy of PAP/PAOP/CVP measurements and must be corrected prior to pressure measurement. Perform the square waveform test: on the initial system setup, at least once each shift, after opening the catheter system (eg, for rezeroing, drawing blood, or changing tubing), and whenever the PAP/PAOP/CVP waveform appears to be damped or distorted.[14] (Level A)
- Consider the following changes in PA pressures as clinically significant (ie, not reflective of the normal variability in PA pressures): PAS more than 4 to 7 mm Hg; PAEDP more than 4 to 7 Hg; PAOP more than 4 mm Hg.[18–20] (Level B)
- Studies in a variety of patient populations found that PAP/PAOP/CVP measurements are accurate when the HOB is elevated to any angle between 0 and 60 degrees[21–27] or when the patient is in a 20 degree[28], 30[20,29] or 90 degree[30] lateral position with the HOB flat, as long as the correct angle-specific reference is used. PAP/PAOP/CVP measurements should not be performed when the patient is in Trendelenburg[31] position or if the legs are in a dependent position.[21] There are no studies to support PAP/PAOP/CVP measurements in reverse Trendelenburg. Reliable cardiac output (CO) measurements have been obtained only in the supine position with a backrest at 20[32] or 45 degrees[33] and in the prone position.[34–37] Clinically significant changes in CO may occur in the 20-degree lateral positon[32,38] that may limit concurrent PAP/PAOP/CVP and CO PAP/PAOP/CVP compared to the flat, supine position using a standardized approach.[17,39] (Level A)
- The use of position-specific reference is critical to accurate PAP/PAOP/CVP measurement.[20,40–44] In the supine position the phlebostatic axis (fourth ICS at ½ the anteroposterior diameter of the chest) is the most commonly used reference point.[45] In the lateral position, the following reference points should be used: 30 degrees lateral (half distance from surface of bed to the left sterna border); 90-degree right lateral position (fourth ICS /midsternum); and in the 90-degree left position (fourth intercostal space/Left parasternal border).[41,42,45] A laser or carpenter's level (not the eyeball technique) should be used to correctly reference the system.[45] Once the correct reference location is identified, a mark should be placed on the chest wall. (Level A)
- Before obtaining PAP/PAOP/CVP measurements, patients may require 5 to 15 minutes for stabilization depending on the patient's left ventricular function.[47] No specific recommendations are available for the stabilization period after proning; measurements have been performed 20 to 30 minutes after repositioning from supine to prone for patients with acute lung injury[35–37] and in patients with ARDS, measurements were performed 20 minutes after stabilization of the SvO_2 (60 to 90 minutes after proning).[34] (Level A)
- Changes in intrathoracic pressure during respiration alter intracardiac pressures. PAP/PAOP/CVP measurements are obtained by convention at end-expiration when pleural pressure is minimal.[48] For patients receiving APRV, the PAOP should be measured at the end of the positive pressure plateau, which can be observed on the ventilator and is the point immediately before the release of airway pressure and the initiation of inspiration.[49] With active exhalation (suspect if respiratory-induced fluctuation in PAOP is >10 to 15 mm Hg) read the PAOP at the midpoint between the end-expiratory peak and the end-inspiratory lowpoint.[50] The addition of the airway pressure tracing to the analog strip may further improve measurement accuracy.[51] (Level A)
- A simultaneous ECG should be used to facilitate correct PAP/PAOP/CVP waveform measurement[55–57] and should be read from analog tracings or using the stop cursor method.[52–54] Digital readouts should not be used as they reflect pressures obtained throughout respiration and may be significantly different from and expiratory pressures. (Level A)
- Registered nurses, who demonstrate competency, can safely withdraw and/or remove PA catheters.[58,59] Before incorporation withdrawing and/or removing PA catheters into nursing practice, verify that it is within your state's scope of practice for registered nurses. (Level B)

AACN Evidence Leveling System

Level A Meta-analysis of quantitative studies or metasynthesis of qualitative studies with results that consistently support a specific action, intervention, or treatment.
Level B Well-designed, controlled studies with results that consistently support a specific action, intervention, or treatment.
Level C Qualitative studies, descriptive or correlational studies, integrative reviews, systematic reviews, or randomized controlled trials with inconsistent results.
Level D Peer-reviewed professional organizational standards with clinical studies to support recommendations.
Level E Multiple case reports, theory-based evidence from expert opinions, or peer-reviewed professional organizational standards without clinical studies to support recommendations.
Level M Manufacturer's recommendations only.

Mechanical ventilation increases intrathoracic pressure, which is transmitted to the pulmonary vasculature, heart, and great vessels. This pressure may directly affect CVP, which may increase as well, because intrathoracic pressure compresses the pulmonary vessels, creating resistance to blood flow from the right side to the left side of the heart and causing blood to "back up" in the right ventricle, right atrium, and vena cava. In extreme cases, the increased intrathoracic pressure associated with mechanical ventilation causes significant right ventricular dysfunction, and the CVP is elevated because of reduced forward blood flow into the pulmonary vasculature, resulting in increased volume and pressure of the blood in the right atrium and vena cava.

Increased CVP is associated with right ventricular failure due to CAD or left ventricular failure. The inability of the right ventricle to pump blood through the pulmonary vasculature because of injured or infarcted myocardium results in increased volume and pressure in the right atrium and vena cava. Left ventricular failure may increase CVP as the pressure of blood volume congests the pulmonary vasculature and impairs flow from the right ventricle, causing right ventricular dilation and subsequent failure. Again, the increased pressure is reflected backward to the right atrium and vena cava. In these instances, interventions are directed toward facilitating forward blood flow by improving ventricular contractility and reducing the intravascular blood volume. A decrease in the CVP is an indication of the effectiveness of therapy.

CVP is always interpreted in conjunction with other clinical observations, such as auscultation of breath sounds, heart and respiratory rate, ECG, neck vein distention, and urine output. For example, increased CVP associated with pulmonary basilar crackles and decreased urine output is often indicative of left ventricular failure. Distended neck veins but clear breath sounds and a high CVP might be caused by increased intrathoracic pressure from mechanical ventilator effects. Patients who are septic may have a low CVP that is associated with fever, elevated WBC count, tachycardia, and tachypnea, whereas patients who are taking vasodilating agents may have a low CVP that is associated with an increased heart rate but none of the other aforementioned clinical signs. A CVP value alone is meaningless, but when used in conjunction with other clinical data, it is a valuable aid in managing and predicting the patient's clinical course.[22]

▲ Pulmonary Artery Pressure Monitoring

The PA catheter provides assessment of right ventricular function, pulmonary vascular status, and, indirectly, left ventricular function. RA, right ventricular (RV), and PA pressures, as well as pulmonary artery occlusion pressure (PAOP), are measured using a PA catheter. PA catheters with a thermistor have the capability of determining CO. The pressures and CO obtained allow the clinician to calculate derived parameters and facilitate diagnosis of cardiovascular and cardiopulmonary dysfunction, determine the therapy needed, and evaluate the effectiveness of the interventions.

Pulmonary Artery Catheters

Several types of flow-directed, balloon-tipped PA catheters are available in different sizes. The type of catheter used is determined by the parameters to be monitored and additional requirements governed by the patient's condition. The 7.5- or 8-French (F; a measure of catheter size) thermodilution catheter is the size most commonly used (Fig. 17-43). All PA catheters have several external ports or lumen hubs corresponding to internal lumens and lumen openings into the right side of the heart and PA. A typical PA catheter has four lumens with external hubs or ports: the proximal hub and lumen, distal hub and lumen, balloon inflation valve and lumen, and thermistor connector and lumen.

The proximal or RA lumen opens into the right atrium; in smaller patients, the location might be in the superior or inferior vena cava, depending on insertion location. The lumen is used for infusion of fluids and is often connected to a transducer to provide RAP measurements and display of the RAP waveform. The RA lumen port also is used as the injectate port for measuring COs.

The distal or PA lumen hub is always attached to a transducer and a continuous flush system. The PA waveform is displayed continuously, as are the PA systolic, diastolic, and mean pressures. The PA port is used for the withdrawal of mixed venous blood, which is necessary for venous oxygen saturation, oxygen extraction, oxygen consumption, and intrapulmonary shunt measurements. Use of the PA distal port for fluid or medication administration is not recommended.

The balloon inflation port and lumen enable inflation of the balloon near the catheter tip with a small volume of air to measure the PA occlusion pressure, known as the PAOP. The balloon capacity of most PA catheters is 1.5 mL, and the balloon should not be inflated with more than this amount of air. Fluid is never inserted into the balloon inflation port.

Near the tip of the PA catheter is a thermistor. A cable to the bedside monitor or to a CO computer connects to the external thermistor port. The thermistor permits measurement of the patient's temperature in the PA (core temperature), and it detects the blood temperature change when solution is injected through the RA port to obtain a CO.

Specialty PA catheters include the previously described components and additional features and lumens. Some of the features include additional lumens in the RA, RV, or both for added infusion. A distal lumen containing fiber-optic filaments allows continuous measurement of mixed venous oxygen saturation (SvO_2). The external optic connecting cable is attached to an optics module and then special oximetry monitor. Catheters modified with a thermal filament and combined with a thermal filament connector and special monitor provide and display CO on a continuous basis. Other advanced catheters with advanced monitor algorithms determine RV ejection fraction and additional derived parameters such as end-diastolic volume. Figure 17-44 shows various types of PA catheters.

Specially designed catheters may also be used for temporary pacing. There are PA catheters that house pacing electrodes for both atrial and ventricular pacing as well as PA catheters with lumens in the RA and RV for placing of special probes for pacing.[20]

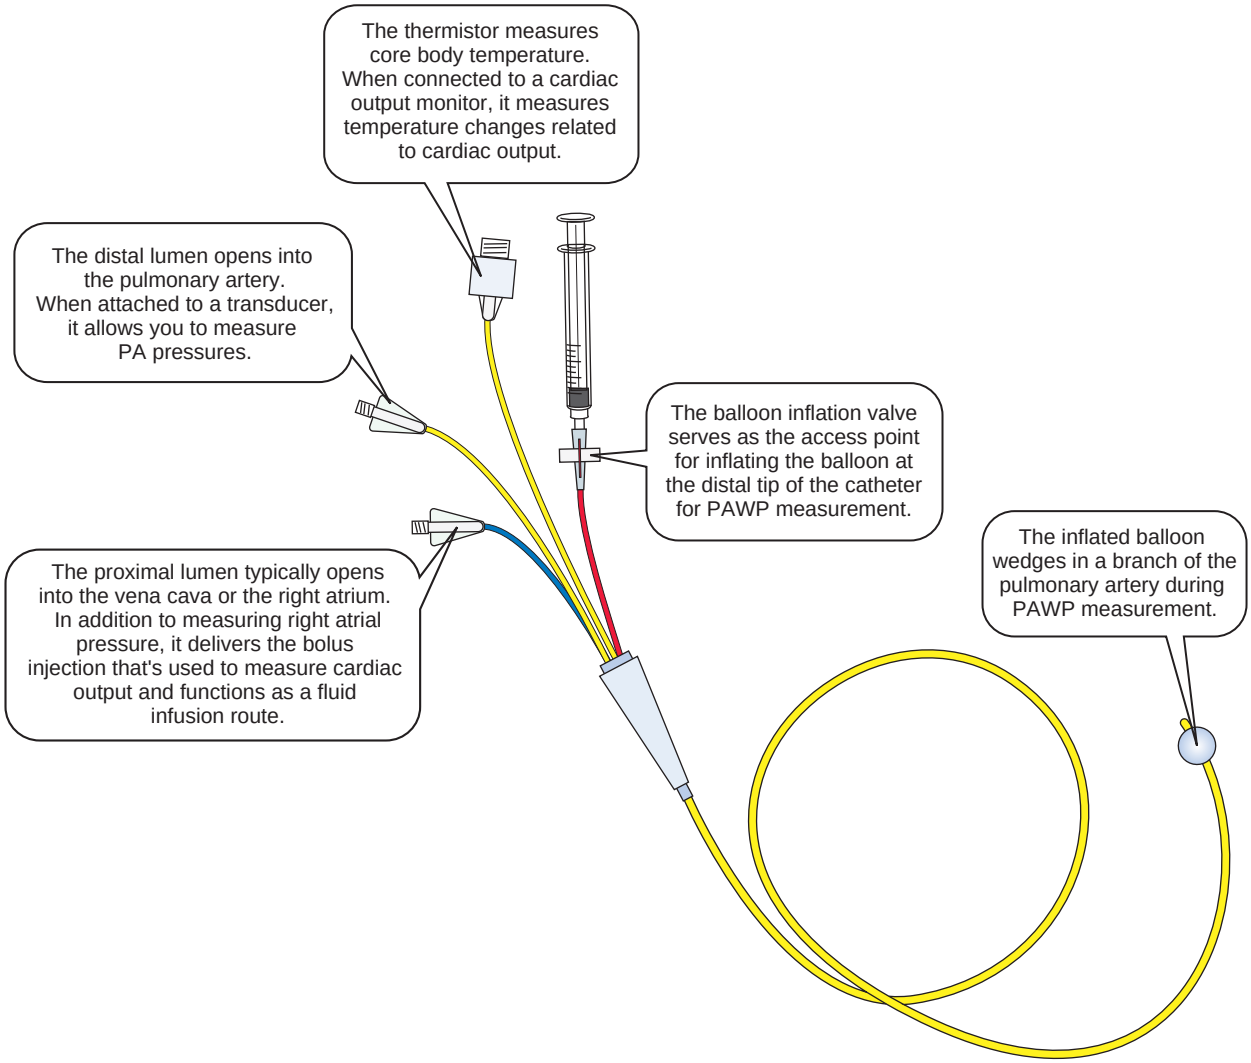

FIGURE 17-43 ▲ Pulmonary artery catheter. PA, pulmonary artery; PAOP, pulmonary artery occlusion pressure. (Courtesy of Edwards Lifesciences, LLC.)

Pulmonary Artery Catheter Insertion

Before the PA catheter is inserted, all necessary equipment should be assembled and prepared according to institution policies. The flushed pressure monitoring system is placed at the zero reference point, leveled, and zeroed. Each lumen of the PA catheter is flushed with sterile solution from the flush system. (Note that fiber-optic SO_2-monitoring catheters must be calibrated in the calibration cup housed in the sterile tray package before flushing the PA lumens.) The balloon lumen is inflated with air to ensure proper inflation and to check for leaks; it is then deflated before insertion. The PA port is then connected to the prepared pressure tubing, and the other lumens are connected to either a pressure monitoring system or an IV solution.

Strict sterile technique, including a full sterile drape, is required for the insertion procedure. The clinician performing the procedure wears a cap, mask, gown, and gloves. The nurse assisting wears a cap and mask and, if manipulating the catheter, gloves. The PA catheter is inserted into a large vein through an introducer catheter, which is usually placed by a percutaneous approach. The most common insertion sites are the right internal jugular, right or left subclavian, and femoral veins. Occasionally, the antecubital vein is used; this requires a venous cutdown.

Determination of the catheter tip location is established by monitoring the waveform and pressures on the bedside monitor as the catheter passes through the heart chambers and vessels. Black catheter markings occur every 10 cm, with a heavier black line at the 50- and 100-cm points. Distances are identified from the distal tip (ie, the proximal lumen exits 30 cm from the distal tip). These marking are also used during the insertion procedure to assist with catheter tip placement. When the catheter tip is approximately 15 cm into the introducer, the tip has typically exited the sheath and lies in the vena cava and RA junction. Waveforms on the monitor show respiratory excursions.

At this time, the balloon is inflated with the recommended balloon inflation volume of 1.5 mL air or CO_2. The clinician gently but rapidly advances the catheter with the balloon inflated. This helps "float" the catheter into the right atrium, through the tricuspid valve into the right ventricle,

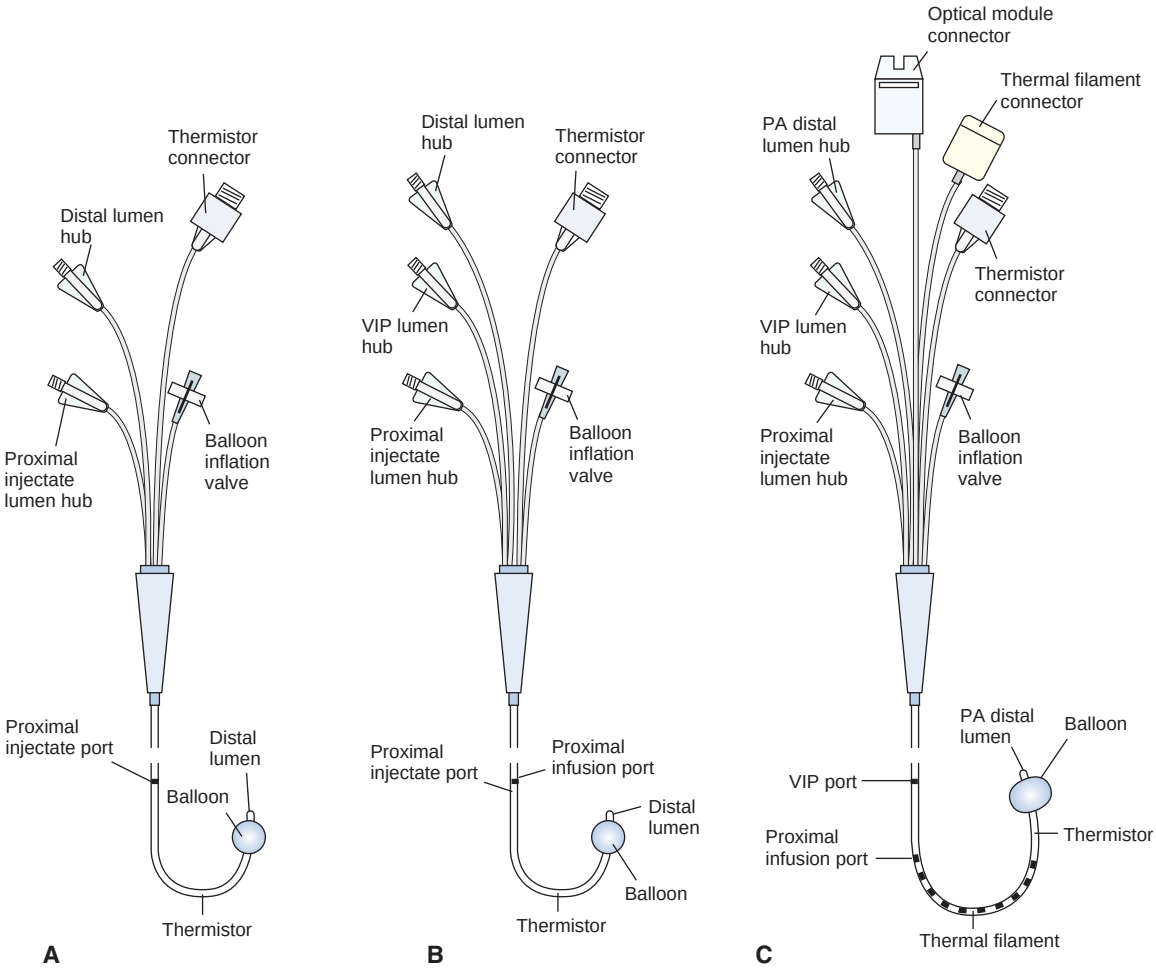

FIGURE 17-44 ▲ Types of PA catheters. **A:** Four-lumen catheter. **B:** Five-lumen catheter that includes an additional venous infusion port (VIP) into the right atrium. **C:** Seven-lumen catheter that includes a VIP port and two additional lumens for continuous cardiac output (CCO) and thermal filament, and continuous mixed venous oxygen saturation (SvO_2) monitoring (optical module connector). An additional option is to combine use of the CCO filament and the thermistor response time to calculate end-diastolic volume monitoring. (Courtesy of Edwards Lifesciences, LLC.)

across the pulmonic valve into the PA, and eventually into the wedged position (Fig. 17-45). The balloon is allowed to deflate passively after the PA wedge waveform is noted on the monitor and return of the PA waveform is confirmed. The PA catheter is slowly pulled back 1 to 2 cm to reduce or remove any redundant length or loop in the right atrium or right ventricle. The balloon is then reinflated to determine the minimum inflation volume required to obtain a wedge tracing. The catheter should be in position where the full or near full inflation volume (1.25 or 1.5 mL for a 7- or 8-F PA catheter) is required to obtain a wedge pressure tracing. Again, the balloon is passively deflated, and return of the PA tracing is observed. The PA catheter is made of a material that softens in vivo. This additional step during insertion helps decrease distal migration of the PA catheter after it has been placed. The PA catheter is then secured, and a sterile dressing is placed over the insertion site. Catheter position is also verified with a chest radiograph after the insertion.

Nursing responsibilities during the insertion procedure include ensuring use of sterile technique, monitoring the changes in hemodynamic waveforms, recording the pressures in each chamber of the heart as the catheter is passed through, and monitoring the patient for complications. Ventricular dysrhythmias are the most common complications during PA catheter insertion (see section on Complications on pages 277–279). Therefore, it is advisable to have a lidocaine bolus and defibrillator available for the insertion procedure.[20]

Waveform Interpretation

All hemodynamic pressures and waveforms are generated by pressure changes in the heart during the various phases of the cardiac cycle. Electrical activity (depolarization and repolarization) precedes mechanical activity of systole and diastole. Therefore, interpretation of the hemodynamic waveforms depends on the correlation of mechanical to electrical activities using the ECG. There are three categories of hemodynamic waveforms: atrial, which includes RA, left atrial, and PA wedge (that indirectly reflects the left atrial waveform); ventricular, which includes left and right ventricular; and arterial, which includes PA and systemic arterial. The waveforms in each category are similar because

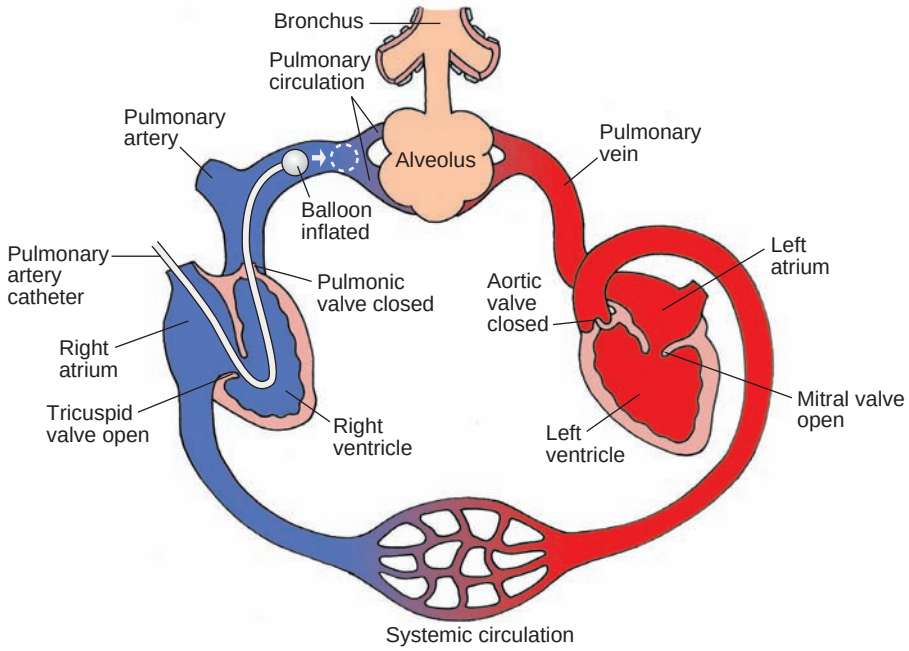

FIGURE 17-45 ▲ Position of the PA. When the balloon is inflated and the catheter is in the wedge position, there is an unrestricted vascular channel between the tip of the catheter and the left ventricle in diastole. PAOP thus reflects left ventricular end-diastolic pressure, an important indicator of left ventricular function. (Courtesy of Philips.)

they result from the same cardiac events. The measurements are different because the pressures generated in the right side compared with the left side of the heart differ.

Right Atrial Pressure

The right atrium is a low-pressure chamber, receiving blood volume passively from the venae cavae. Normal pressure is 2 to 6 mm Hg. Both atrial waveforms have three positive waves: a, c, and v. The a wave reflects the increase in atrial pressure during atrial systole. The c wave results from a small increase in pressure associated with closure of the AV valve and early atrial diastole. The v wave represents atrial diastole and reflects the increase in pressure caused by filling of the atrium with blood. It also occurs during ventricular systole. Figure 17-46 shows the RA waveform.

Accurate identification of the a, c, and v waves requires correlation of the waveform with the ECG. On the ECG, the P wave represents atrial depolarization, which causes RA and then left atrial (LA) contraction. Therefore, the a wave occurs after the P wave and usually in the PR interval. The QRS complex represents ventricular depolarization and causes ventricular contraction. Simultaneously, the atria relax and fill with blood. The v wave generated by these events thus falls after the QRS complex and in the T-to-P interval.

Atrial pressure tracings also have two primary negative waves or descents: x and y. The x descent follows the a or c wave if present and represents a decrease in pressure caused by atrial relaxation at the beginning of atrial diastole. The y descent follows the v wave and represents the initial, passive atrial emptying into the ventricle as the AV valve opens.[20–22]

Right Ventricular Pressure

The RV is a low-pressure chamber. RVEDP is usually 0 to 8 mm Hg. When the tricuspid valve is open, the RAP and the RVEDP are similar. Right ventricular systolic pressure is normally 20 to 30 mm Hg because the RV must generate only enough pressure to open the pulmonic valve and move blood through the low-pressure pulmonary vasculature.

The RV waveform has a distinctive "square root" configuration. Figure 17-46 shows the RV waveform. The initial rapid increase in RV pressure represents isovolumetric contraction, which follows the QRS complex of the ECG. The RV pressure continues to increase as the tricuspid and pulmonic valves are closed until the ventricular force generated exceeds the PA pressure. Rapid ejection occurs when the pulmonic valve opens. After ventricular systole, the pulmonic valve closes, and the right ventricular pressure rapidly decreases, creating a diastolic dip. Next in the cardiac cycle, the tricuspid valve opens and the RV passively fills with blood from the RA. Right ventricular diastole occurs within the period from the T wave to the next Q wave on the ECG. The point on the waveform just before the rapid increase in pressure represents RVEDP.[20–22]

Pulmonary Artery Pressure

The pulmonary vasculature is a relatively compliant low-resistance, low-pressure system in healthy people. Normal PA systolic pressure is 20 to 30 mm Hg. Normal diastolic PA pressure is 8 to 15 mm Hg, with a mean of 10 to 20 mm Hg. Systolic PA pressure and the peak of the PA waveform are generated by RV systolic ejection; therefore, the PA systolic pressure and the RV systolic pressure are the same as long as the pulmonic value is not stenotic. The PA waveform characteristics are similar to the systemic arterial waveform previously described (see Fig. 17-46). The dicrotic notch in the downward slope of the PA waveform corresponds with pulmonic valve closure at the beginning of RV diastole and is the beginning of the PA diastolic phase. PA diastolic pressure reflects the resistance of the pulmonary vascular bed and, to a limited degree, LVEDP. In normal conditions, with no obstructions or resistance from the PA to the left ventricle, PA diastolic pressure theoretically is an indirect measure of

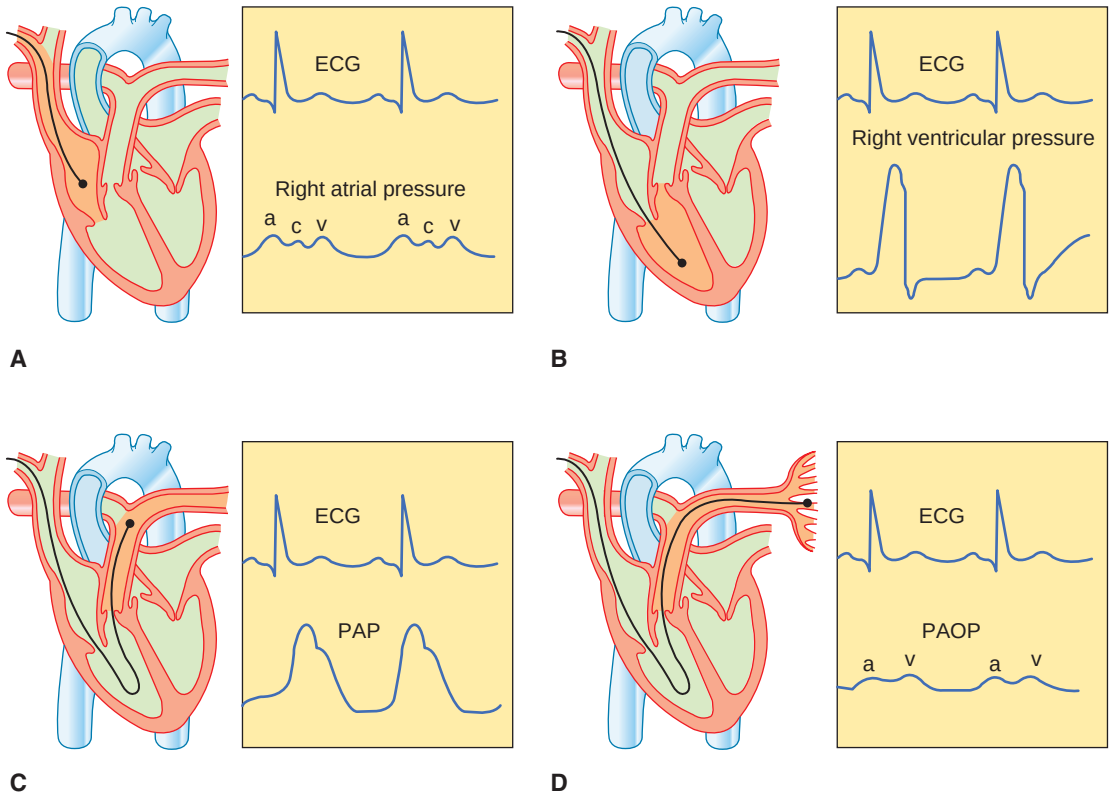

FIGURE 17-46 ▲ Normal PA waveforms. During PA insertion, the waveforms change as the catheter advances through the heart. **A:** When the catheter enters the right atrium (RA), a waveform with three small upright waves appears. The a waves represent the RA systole; the v waves, RA filling. **B:** When the catheter reaches the right ventricle, a waveform with sharp systolic upstrokes and lower diastolic dips appears. **C:** When the catheter "floats" into the PA, a PA pressure (PAP) waveform appears. Note that the upstroke is smoother than on the right ventricle waveform. The dicrotic notch indicates pulmonic valve closure. **D:** When the catheter "floats" into a distal branch of the PA, the balloon wedges where the vessel becomes too narrow for it to pass, and a PAOP waveform, with two small upright waves, appears. The a wave represents left atrial systole; the v wave, left atrial filling. ECG, electrocardiogram. (Courtesy of Edwards Lifesciences, LLC.)

LVEDP because the pulmonary vasculature, left atrium, and open mitral valve allow equalization of pressure from the left ventricle back to the tip of the PA catheter.[20–22]

Pulmonary Artery Occlusion Pressure

When the PA catheter is properly positioned, the PAOP (also called pulmonary artery wedge pressure [PAWP]) is obtained by inflating the balloon at the catheter tip. The balloon occludes forward flow in the branch of the PA, decreasing the influence of pulmonary vascular resistance (PVR) on the pressure reading, and creates a static column of blood from that portion of the PA through the LA, an open mitral valve during diastole, and the LV. In this way, the PAOP reflects LVEDP. Normal PAOP is 8 to 12 mm Hg. The PAOP more closely measures LA pressure and LVEDP than the PA diastolic pressure.

Inflation of the PA balloon causes the PA waveform on the monitor to become a PAOP tracing. No more than 1.5 mL of air is used to inflate the balloon. If less than 1 to 1.25 mL of air generates a PAOP tracing, the PA catheter has migrated distally and with the balloon passively deflated, needs to be withdrawn slightly. Depending on institution policies, a physician or advanced practice clinician performs this procedure.

An LA tracing has a, c, and v waves and x and y descents. The electrical and mechanical events of the heart generating these waves are identical to those of the RA waveform. The a wave corresponds to LA contraction, and the v wave corresponds to LA filling and LV contraction. With a direct LA line, the c wave is typically visible as in an RA tracing. The c wave is rarely visible on the PAOP tracing because the slight increase in pressure from backward bulging of the mitral valve is difficult to observe.

The ECG may be correlated with the PAOP waveform just as with the RA waveform. The primary difference between the PAOP and the RA waveforms is the slight delay of a and v waves in PAOP relative to the ECG because of the distance from the left side of the heart to transmit pressures to the catheter placed in the right side. The a wave now falls more closely in line with the QRS complex, although it may be within the PR interval. The v wave correlates with the T-to-P interval.[20–22]

Figure 17-47 shows the normal values and waveforms during a PA catheter insertion. Note that the RA pressure is equivalent to the RVEDP, the RV systolic pressure is equivalent to the PA systolic pressure, and the PA diastolic pressure is equivalent to the PAOP. Observe the diastolic value during insertion; it increases when the PA catheter "floats" into the PA, and the systolic pressures from the RV to the PA are similar.

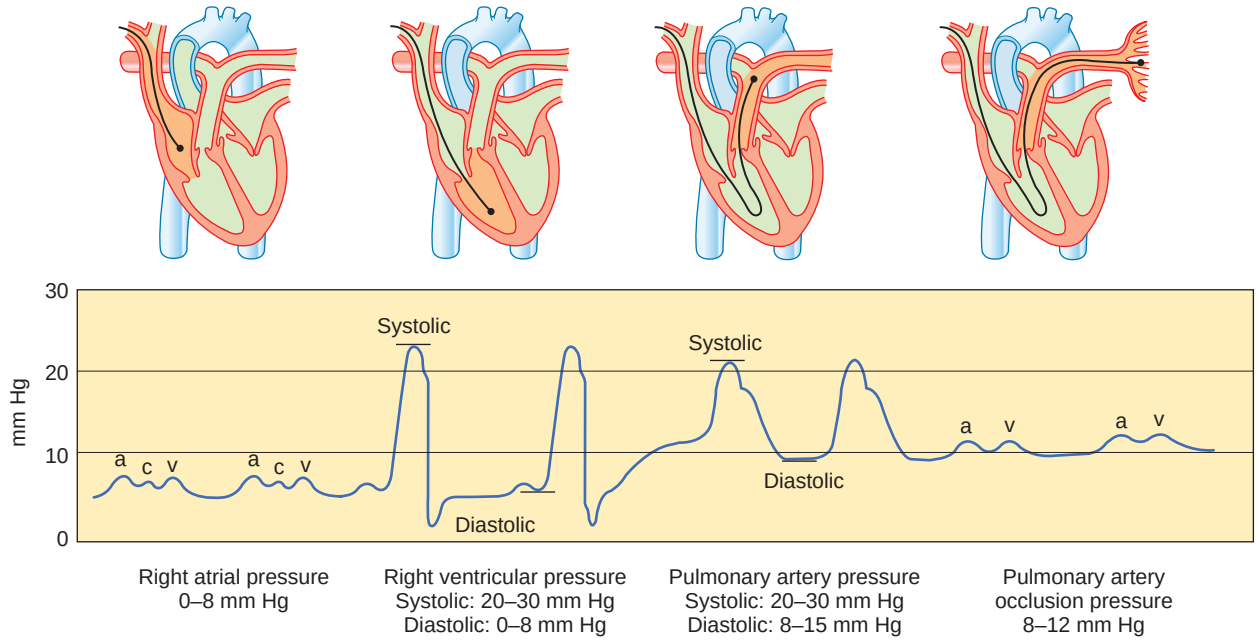

FIGURE 17-47 ▲ Normal values and wave configurations produced by the PA catheter.

Physiological Causes of Abnormal Waveforms

Hemodynamic waveform analysis provides valuable additional information for differential diagnosis. Specific conditions produce abnormalities in the a, c, and v waves, in the x and y descents, or in a combination of both. Clinical assessment, coupled with waveform analysis and interpretation of hemodynamic pressure, enhances the skills of the critical care nurse. Table 17-17 summarizes the causes of abnormal hemodynamic pressures.

Abnormalities of RA waveform include large, elevated a or v waves. Increased resistance to RV filling and impaired atrial emptying cause an elevated a wave. Examples of pathological causes of large a waves are tricuspid stenosis and RV failure. Elevated v waves are related to regurgitant flow from the ventricle back into the atrium during ventricular contraction. Examples of pathological causes of large v waves are tricuspid valve insufficiency and RV failure. Elevations in either the a or v wave cause the mean RA pressure to be higher.

Increased PA pressures may be systolic or diastolic or both. Because PA systolic pressure is a reflection of RV systolic pressure, factors that increase RV pressures such as increased PVR, hypervolemia, LV failure, and mechanical ventilation can produce an increased PA systolic pressure. Left ventricular failure, hypervolemia, and increased PVR cause increased PA diastolic pressure. Increased PVR may result from acute respiratory distress syndrome, primary pulmonary hypertension, or pulmonary embolus.

Left ventricular dysfunction and mitral valve disease occur more frequently than RV or tricuspid valve disorders, and therefore abnormal PAOP waveforms are more common than abnormal RA waveforms. Abnormalities of the PAOP waveform usually are large, elevated a or v waves. Increased resistance to LV filling and impaired atrial emptying cause elevated a waves. Examples of pathological causes of large a waves are mitral stenosis and LV failure. Elevated v waves relate to regurgitation from an incompetent mitral valve, allowing blood to flow from the ventricle back into the atrium during ventricular contraction. In both these valvular diseases, the PAOP does not accurately reflect LVEDP. Left ventricular failure usually causes elevation of both the a and v waves and significantly increases the PAOP because of reduced contractility and forward blood flow. Elevated PAOP frequently is due to LV dysfunction or hypervolemia. In some cases, such as in acute respiratory distress syndrome or with mechanical ventilator settings that generate extremely high intrathoracic pressure, PAOP is elevated because of noncardiogenic causes. In these cases, the normal PA diastolic pressure/PAOP gradient of 1 to 4 mm Hg widens. A widened pressure gradient is a differential diagnostic sign of pulmonary hypertension or increased PVR.[20,22]

Complications

Generally, most complications that occur with use of the PA catheter relate to the process of percutaneous central venous access. The other complications such as infection, thrombus, and air embolus are discussed in the earlier section on CVP.

Pneumothorax

Pneumothorax is a complication from vessel access through the subclavian vein. Anatomical factors can make placement of a PA catheter difficult, particularly if the patient is obese or has torturous subclavian veins. The needle or introducer sheath may pass through the vessel wall and puncture the lung during insertion, causing an apical pneumothorax. Signs and symptoms of a pneumothorax and routine postinsertion chest radiograph are used to diagnose this complication.

Table 17-17 Interpreting Hemodynamic Monitoring Pressures

Pressure and Description	Normal Values	Causes of Increased Pressure	Causes of Decreased Pressure
Central Venous Pressure (CVP) or Right Atrial Pressure (RAP)			
The CVP or RAP reflects right ventricular function and end-diastolic pressure.	Mean pressure: 2–8 mm Hg	• Right-sided heart failure • Volume overload • Tricuspid valve stenosis or insufficiency • Constrictive pericarditis • Cardiac tamponade • Pulmonary hypertension • Right ventricular infarction	Reduced circulating blood volume
Right Ventricular Pressure			
Typically, right ventricular pressure monitored only on initial pulmonary artery catheter insertion. Right ventricular systolic pressure normally equals pulmonary artery systolic pressure; RAP reflects right ventricular end-diastolic pressure.	Systolic pressure: 20–30 mm Hg Diastolic pressure: 0–8 mm Hg	• Mitral stenosis or insufficiency • Pulmonary disease • Hypoxemia • Constrictive pericarditis • Chronic heart failure • Atrial and ventricular septal defects • Patent ductus arteriosus	Reduced circulating blood volume
Pulmonary Artery Systolic Pressure			
Pulmonary artery systolic pressure results from right ventricular systolic pressure and reflects right ventricular function.	Systolic pressure: 20–30 mm Hg Mean pressure: 8–15 mm Hg	• Left-sided heart failure • Increased pulmonary blood flow (left or right shunting, as in atrial or ventricular septal defects) • Any condition causing increased pulmonary arteriolar resistance (such as pulmonary hypertension, volume overload, mitral stenosis, or hypoxia)	Reduced circulating blood volume
Pulmonary Artery Diastolic Pressure			
Pulmonary artery diastolic pressure is an indirect reflection of left ventricular end-diastolic pressure (LVEDP) in a patient without significant pulmonary artery disease.	Diastolic pressure: 8–12 mm Hg	• Any condition causing increased pulmonary arteriolar resistance (such as pulmonary hypertension, volume overload, mitral stenosis, or hypoxia)	Reduced circulating blood volume
Pulmonary Artery Occlusion Pressure (PAOP) or Left Atrial Pressure			
PAOP indirectly reflects left atrial and LVEDPs, unless the patient has obstructions from the tip of the pulmonary artery catheter to the left ventricle. Changes in PAOP reflect changes in left ventricular filling pressure.	Mean pressure: 8–12 mm Hg	• Left-sided heart failure • Mitral stenosis or insufficiency • Pericardial tamponade	Reduced circulating blood volume
Pulse Pressure (PP)			
PP is the difference between systolic and diastolic arterial pressure. PP can be used to assess the patient's stroke volume (SV).	Normal range: 40–60 mm Hg with a wider range of 30–100 mm Hg	• Increased SV • Decreased vascular resistance • Peripheral vascular disease • Aortic insufficiency	Decreased SV Severe vasodilation in conditions such as late sepsis, various shock states

Modified from Springhouse: Critical Care Made Incredibly Easy. Springhouse, PA: Author, 2004, p 170.

Infection

Systemic infection and sepsis are caused by contamination of the PA catheter, insertion site, or pressure monitoring system. Careful attention to sterile technique during pressure tubing assembly, using the maximum sterile barrier for insertion, and dressing changes helps prevent infection.[24] Protocols for changing the PA catheter and monitoring system should be followed carefully. Diagnosis of PA catheter-related sepsis is based on blood cultures, WBC count, and fever in the absence of other sources of infection.

Ventricular Dysrhythmias

Ventricular dysrhythmias may occur during the insertion of a PA catheter. As the catheter passes through the right ventricle, it may irritate the endocardium and cause premature ventricular complexes and occasionally ventricular tachycardia. The dysrhythmias typically resolve when the catheter is advanced into the PA. After the PA catheter is in proper position, it may become dislodged if it is not well secured, and the tip may "fall back" into the right ventricle. The patient may experience dysrhythmias, and the hemodynamic pressures and waveform reflect those of the right ventricle. Usually in this situation, because of potential contamination at the insertion site, the catheter is withdrawn or occasionally by inflating the balloon, the catheter may "refloat" into the PA. It is essential to have ready access to emergency drugs and equipment in case the ventricular dysrhythmias persist. Many introducer kits contain sterile sheaths; when placed over the PA catheter, they provide additional protection from contamination.

Pulmonary Artery Rupture or Perforation

A rare but very serious and potentially fatal complication is rupture or perforation of the PA. Perforation of the PA may occur during insertion, manipulation, or upon subsequent rewedging of the PA catheter. Patients with friable PAs may be at some risk. However, proper advancement of the catheter with the balloon fully inflated with 1.5 mL of air and avoidance of advancing the catheter too far into a small artery minimize the chance of PA perforation. Close observation of the PA waveform as the balloon is inflated and filling the balloon only with the amount of air necessary to obtain a PAOP tracing prevent overdistending a small PA. As previously stated, the catheter should become wedged when inflated with 1.25 to 1.5 mL of air. If less air is required to obtain the PAOP waveform, the catheter has migrated out of proper position.[1]

Nursing Considerations

Nursing care of the patient undergoing PA pressure monitoring is complex. Critical care nurses must be able to interpret waveforms and pressure data as well as be alert to potential complications. It is necessary to ensure accurate readings and minimize operator error. Consistency of leveling and measurement techniques is especially important because small variations in the zero reference point elicit large and erroneous changes in the pressures observed. Table 17-16 outlines problems and troubleshooting strategies associated with hemodynamic pressure monitoring. Evidence-Based Practice Highlight 17-3 on page 271 summarizes current evidence related to obtaining accurate measurement of PA pressures.

Measurement of all hemodynamic pressures is most accurate when obtained at the end of expiration in the respiratory cycle. In the healthy person, intrathoracic pressure at end expiration is about equal to atmospheric pressure. During the end-expiration period, there is minimal airflow and little variation in pleural pressures that influence cardiac pressures. Thus, end expiration provides a standard reference point for obtaining measurements. Spontaneous breathing causes negative intrathoracic pressure during inspiration, which produces a decline in the waveform. The waveform used for measurement is the last clear wave occurring just before the inspiratory dip. Mechanical ventilation causes increased intrathoracic pressure during inspiration, which produces an inspiratory "push" or rise in the waveform. The end-expiratory wave used for measurement is the last clear wave occurring just before the inspiratory rise (Fig. 17-48).

Closely set alarm parameters alert the nurse to potential physiological or technical complications. For example, one indication of a pulmonary embolus is an acute increase in PA pressures. Distal migration of the PA catheter may cause the catheter to wedge spontaneously without balloon inflation, and PA pressures may decrease to that of a PAOP. With properly set alarms, conditions such as these are detected.[20,22]

▲ Determination of Cardiac Output

CO is the volume of blood ejected from the heart per minute, expressed in liters per minute. Normally, CO is 4 to 8 L/min at rest. CO is a function of heart rate and SV. The left ventricle must generate enough pressure in systole to overcome aortic pressure and systemic vascular resistance (SVR) and eject sufficient blood volume to perfuse the organs of the body. The determination of CO and assessment of its determinants are important adjuncts to the care of critically ill patients. Routine evaluation of CO is essential when any CO monitoring technology is used.

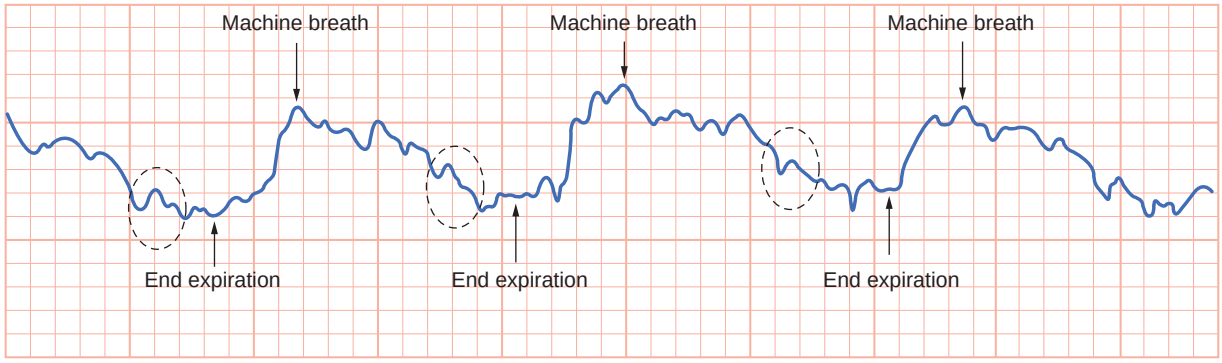

FIGURE 17-48 ▲ PAOP tracing showing respiratory variation from positive pressure mechanical ventilation. Measurement of PAOP is made at the last clear tracing before the inspiratory rise as identified by the open circles.

Cardiac index relates CO to body size. Normally, the cardiac index is 2.5 to 4 L/min/m^2. To obtain it, the CO is divided by the patient's body surface area (BSA). Standard bedside monitors and CO computers automatically calculate the cardiac index when the patient's height and weight are entered. The BSA is also used to index other valuable hemodynamic parameters (Table 17-18).

Factors That Determine Cardiac Output

CO is determined by heart rate and SV as described in Chapter 16. Alterations in CO are caused by changes in heart rate, preload, afterload, and contractility. Analysis of each of these is essential in directing interventions to address the underlying pathophysiological process. One strategy to consider is to evaluate CO, then systematically assess the determinants of heart rate, SV with preload first, afterload second, and finally contractility.

An increased or decreased CO provides global information only and needs to be evaluated in light of the components affecting it. Bradycardia due to conduction defects or medications can cause CO to decrease. An increase in heart rate can produce an increase in CO; however, this may be a compensatory physiological response to emotional or physiologic stress, or to a decreased SV. Tachycardia increases myocardial oxygen demands and may place a compromised patient at risk for myocardial ischemia. Tachycardia also may decrease CO because of shortened diastole and decreased filling time of the ventricles. If the elevated heart rate is due to external stimuli, identify the cause and direct interventions to eliminate or decrease the stimuli. Conditions to assess for are pain, fever, stress, and hypermetabolic states.

Table 17-18 Calculation of Cardiac Hemodynamic Parameters

Parameter	Definition	Formula	Normal Values
Cardiac Output (CO)	The number of liters pumped by the heart per minute.	Heart rate × SV	4–8 L/min
Cardiac Index (CI)	CO indexed to the patient's body surface area (BSA).	CO/BSA	2.5–4 L/min/m^2
Stroke Volume (SV)	The mL of blood ejected from the ventricle with each contraction.	CO/HR × 1,000	60–100 mL/beat
Stroke Volume Index (SVI)	SV indexed to the patient's BSA.	CI/heart rate	33–47 mL/beat/m^2
Mean Arterial Pressure (MAP)	The calculated average arterial pressure over a full cardiac cycle.	[Systolic BP + (diastolic BP × 2)]/3	70–105 mm Hg
Right Atrial Pressure (RAP)	Pressure created by volume of blood in the right heart.	Direct measurement	0–8 mm Hg
Left Atrial Pressure (LAP)	Pressure created by volume of blood in the left heart.	Direct measurement	6–12 mm Hg
Pulmonary Artery Occlusion Pressure (PAOP)	Pressure measured in the pulmonary artery when the pulmonary artery catheter's balloon is inflated.	Direct measurement	8–12 mm Hg
Right Ventricular End-Diastolic Volume Index (RVEDVI)	Amount of volume in the right ventricle at the end of diastole.	SVI/RV ejection fraction	60–100 mL/m^2
Left Ventricular End-Diastolic Volume Index	Amount of volume in the left ventricle at the end of diastole.	SV/LV ejection fraction	40–80 mL/m^2
Systemic Vascular Resistance (SVR)	Refers to the resistance to blood flow offered by the systemic vasculature.	[(MAP – RAP) × 80]/CO	800–1,200 dyne/s/cm^{-5}
Systemic Vascular Resistance Index (SVRI)	SVR indexed to patient's BSA.	[(MAP – RAP) × 80]/CI	1,360–2,200 dyne/s/cm^{-5}
Pulmonary Vascular Resistance (PVR)	Refers to the resistance to blood flow offered by the pulmonic vasculature.	(MPAP – PAOP) × 80/CO	<250 dyne/s/cm^{-5}
Pulmonary Vascular Resistance Index (PVRI)	PVR indexed to patient's BSA.	(MPAP – PAOP) × 80/CI	<425 dyne/s/cm^{-5}
Left Ventricular Stroke Work Index (LVSWI)	A measure of work performed by the left ventricle each beat.	SVI (MAP–PAOP) × 0.0136	40–70 g/m^2/beat
Right Ventricular Stroke Work Index (RVSWI)	A measure of work performed by the right ventricle each beat.	SVI (MPAP – RAP) × 0.0136	5–10 g/m^2/beat
Stroke Volume Variation	Variation in SV over a respiratory cycle.	SV maximum – SV minimum/SV mean	<10%–15%

SV, the volume of blood ejected by each ventricular contraction, is influenced by preload, afterload, and contractility (see Chapter 16 for detailed discussion). Preload is the degree of stretch on the myocardial muscle fibers at end-diastole and is determined by ventricular filling (end-diastolic) volume. Within physiological limits, increases in end-diastolic volume cause stretch of the myofibrils and increase the force of the next ventricular contraction (Frank-Starling law of the heart). Preload is primarily influenced by total blood volume. Because the PA catheter measures pressure, not volume, assumptions are made that volume and pressure can be equated. Many factors alter the pressure–volume relationship; therefore, the use of pressures (eg, CVP or PAOP) to evaluate preload must be considered in light of factors that can affect pressures, such as mechanical ventilation or ventricular compliance. A specialized PA catheter is able to provide right ventricular ejection fraction and volumetric data. Indirect assessment of preload uses the RAP or CVP for the right ventricular preload, and the PA diastolic pressure, left atrial pressure, and PAOP for the left ventricular preload.[20–22]

Decreases in preload can be due to hypovolemia, secondary to blood loss, dehydration, or third spacing of fluids. Preload is also reduced related to massive vasodilation, for example in septic, anaphylactic, or neurogenic shock. Hypovolemia or decreased venous return associated with mechanical ventilation and elevated intrathoracic pressures can cause a decreased preload.

Afterload is often defined as the impedance or resistance to ejection of blood from the ventricles. PVR is a clinical assessment of right ventricular afterload. Left ventricular afterload is clinically evaluated by calculating SVR. PVR and SVR can be indexed to body size using the patient's BSA (see Table 17-18, p. 280). Primary factors affecting afterload are semilunar valve abnormalities and vascular resistance.

Vasoconstriction causes elevated afterload and has several causes. Increased SVR may be a compensatory response to hypovolemia caused by vasoconstriction to maintain peripheral perfusion in this state. An increase in afterload occurs with some medications, hypothermia, and the compensatory vascular response to cardiogenic shock. This increase in afterload may also be accompanied by a decrease in CO and an increase in myocardial oxygen demand and work. A decrease in afterload due to vasodilation reduces resistance to ejection of blood, thus increasing CO. Vasodilating medications, septic states, and allergic and anaphylactic reactions are all causes of vasodilation and thus increased CO.

Contractility, the third determinant of SV, is an inherent property of the heart. It is not affected by preload or afterload and cannot be directly measured. Indices used to assess contractility include determining SV and calculating the stroke work index for both the left and right ventricles. Myocardial oxygen supply and demand balance, electrolytes, and minerals (eg, calcium) influence myocardial contractility.

Reduction in contractility decreases CO. Examples include insufficient oxygen delivery to the myocardium, causing myocardial ischemia and infarction; medications, such as beta-blocking agents; or metabolic imbalances, such as low serum levels of calcium, phosphorus, or magnesium. Positive inotropic agents or correction of impaired myocardial oxygenation or metabolic derangements may cause enhanced contractility, most often resulting in increased CO.[20–22]

Obtaining Cardiac Output Values

Several methods for evaluating CO are available. These include invasive, minimally invasive, and noninvasive technologies. All techniques have certain assumptions and limitations that need to be considered to provide an understanding of the indications and applications of each. This section discusses the more common methods of CO monitoring used in the critical care areas.

Fick's Method for Cardiac Output Determination

The Fick method, originally developed in the 1800s by Adolf Fick, is the historical laboratory gold standard. The Fick method is based on the principle that the uptake or release of a substance by an organ divided by the arterial and venous concentration of that substance is the product of flow or CO. The classic method of determining CO uses oxygen as the substance and the lungs as the organ. In order for this relationship to be valid, simultaneous samples of arterial and venous blood must be obtained and accurately measured. In addition, inspired and expired oxygen concentration must be measured by indirect calorimetry to determine the oxygen consumption. Other technologies use these principles; however, they use carbon dioxide as the measured substance.

Indicator-Dilution Methods for Cardiac Output Determination

Stewart proposed the principles of the indicator-dilution method, and Hamilton further refined them. The Stewart-Hamilton equation is based on use of a known indicator as a signal and determination of the dilution rate of that signal over a given period of time. Three indicators in clinical use are dye, thermal, and small doses of lithium. The indicator is injected into the venous system, and a time–concentration curve is generated from a blood sample obtained from the arterial system. Analysis of the curve allows CO calculation.[20–22]

Thermodilution is the most common method used to measure CO and is considered the clinical gold standard. Cold or room temperature solution is the indicator and is injected into the RA port of the PAC. A thermistor near the end of the catheter continuously measures the temperature of blood flowing past it. A dilution curve is generated by the change in blood temperature after indicator injection. Based on this curve, CO is calculated by the computer.

Determination of CO through thermodilution is obtained either on an intermittent or continuous basis. Intermittent CO requires the injection of a known amount of "cooler than blood" injectate, and a single CO curve is produced. Specialty catheters house thermal filaments and, with a dedicated thermal cable and computer, emit energy as the indicator. The "warmer than blood" signal is measured at the thermistor, and thermodilution curves are produced on a 30- to 60-second frequency for continuous CO assessment.[20]

Procedure for Intermittent Thermodilution Cardiac Output Determination

A computation constant, based on the catheter size, volume, and temperature of the injectate, as well as injection method, is set on the computer or programmed into the bedside CO

module. Five or ten milliliter of sterile D_5W or normal saline solution is used as the injectate solution and volume. The injectate syringe used should be part of a closed system that remains intact and attached to the RA port by a stopcock (Fig. 17-49). Iced (0°C to 4°C) or room-temperature solution may be used. A temperature difference between the patient's blood temperature and the injectate of at least 10°C improves accuracy. In most conditions, room-temperature injectate with a 10-mL volume provides accurate results. With hypothermia or very low CO states, iced solution and a 10-mL injectate volume provide a greater signal and increased accuracy.

Steps for performing a manual CO determination vary according to bedside monitor or CO computer manufacturer. See specific operations manuals for directions for use. General steps include:

- Ensuring the accurate amount of injectate volume in the syringe
- Injecting the volume in a smooth and rapid manner, in less than 4 seconds
- Waiting approximately 1 minute between injections to allow the catheter thermistor to return to baseline

When injected, the solution passes a temperature probe in the closed system and flows through the right atrium and right ventricle, past the thermistor at the tip of the PAC. A curve is produced and used for determining the CO. The average of several CO determinations is required to obtain a final measurement. Serial measurements and averaging are necessary because of the number of physiological variables and the performance of the technical procedure. Three or more consecutive measurements are usually necessary. Measurements included in the averaging process should be within 10% to 15% of the mean, and each one should be associated with a normal CO curve. Abnormal curves are eliminated from the CO averaging process.

Interpretation of Cardiac Output Curves

Many bedside monitors and CO computers are equipped with a means of visualizing the CO curves. Normal CO curves have a smooth upstroke from the rapid injection followed by a gradual decline (Fig. 17-50). The area under the curve is inversely proportional to the CO. Curves associated with a high CO have a small area under the curve, with a steeper upstroke and more rapid return to baseline, and curves associated with a low CO have a greater area under the curve, with a more sloped upstroke and slower return to baseline.

Arterial Pressure- and Waveform-Based Cardiac Output Determinations

Uses of arterial pressures, arterial waveforms, or both are other methods for determining CO and SV. The basic premise relates to the proportionality relationship of PP to SV and the inverse relationship of PP to aortic compliance. As PP widens, SV increases and aortic compliance decreases (becomes more rigid, less elastic). Other factors considered with this relationship are the impact of conditions that change vascular tone: larger vessel compliance and peripheral vessel resistance.[25,26]

General components required for these methods are an existing arterial line, a special sensor, and a specific monitor

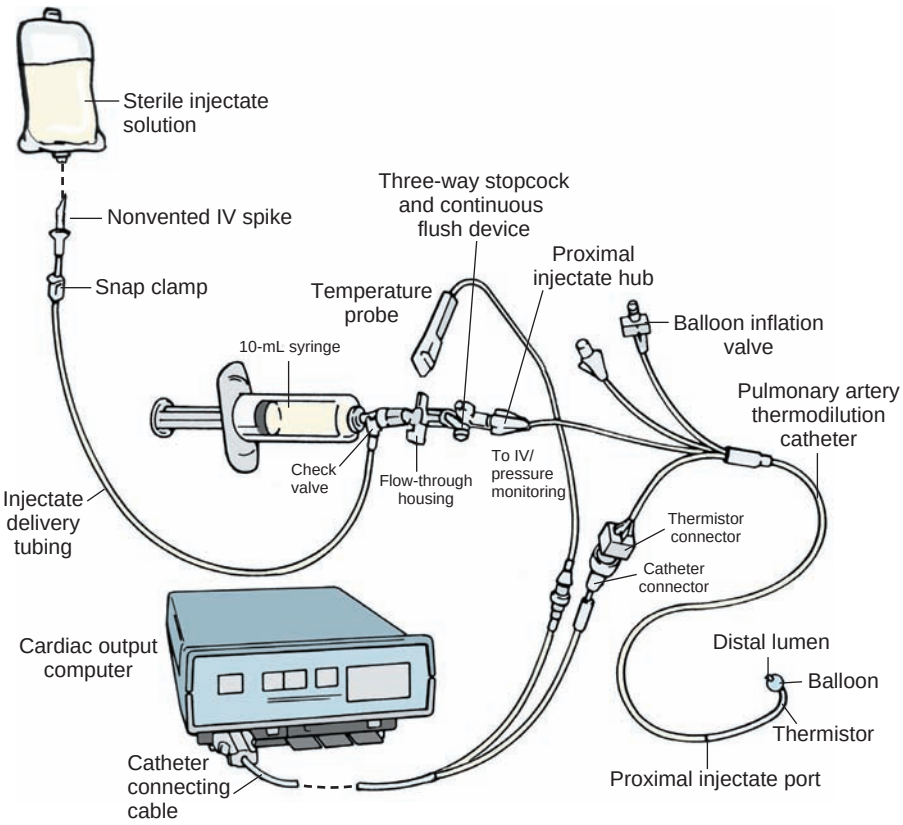

FIGURE 17-49 ▲ A closed room-temperature injectate system for measurement of cardiac output (CO). (Courtesy of Edwards Lifesciences.)

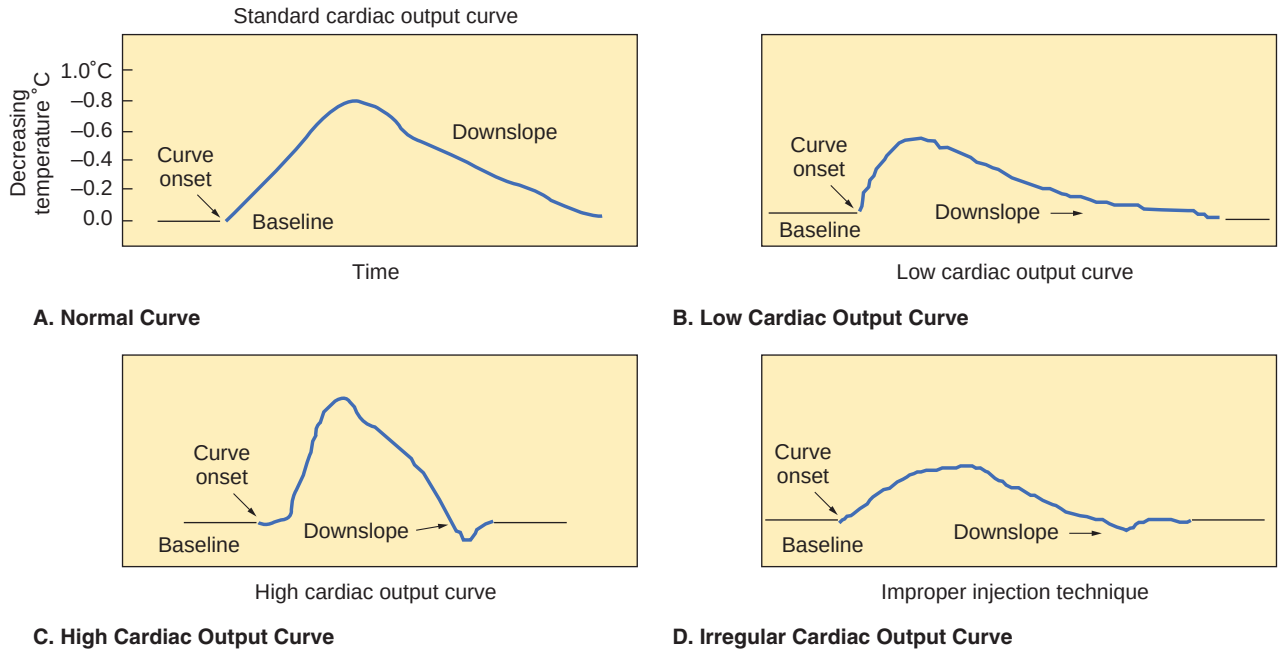

FIGURE 17-50 ▲ Examples of thermodilution curves observed on a bedside monitor or strip chart recorder. **A:** Normal curve with smooth upstroke and gradual decline to baseline. Note that the temperature change is actually lower than patient baseline temperature; however, the graph is shown in an upright orientation. **B:** Low CO produces a greater area under the curve. The upstroke is normal with a more gradual decline. **C:** A high CO has a smaller area under the curve. The upstroke is more rapid with a faster return to baseline. **D:** Irregular curve shows an erroneously low CO probably due to irregular or uneven emptying of the injectate syringe. (Courtesy of Edwards Lifesciences.)

that uses a unique algorithm for the SV and CO determinations. Some systems use the shape of the arterial wave to determine the dicrotic notch location, which signifies the end of systole. This method is referred to as pulse contour.[27] The area under the curve then represents the amount of volume ejected into the arterial vascular bed and reflects SV. Other systems assess the systolic and diastolic pressure to obtain a mean value to arrive at SV. This method is described as pulse power.[28] Another method samples the full waveform for pressures and uses waveform characteristics for CO determinations. This method is termed arterial pressure–based CO.[29] External calibration with either thermodilution or lithium is required for both the pulse contour and pulse power methods. The arterial pressure–based CO method does not require external calibration. Figure 17-51 depicts the various methods for obtaining SV from the arterial pulse wave.

Once the SV is determined, the pulse rate, assessed by the arterial waves, reflects the heart rate; SV × heart rate = CO. All the technologies, regardless of the specific algorithm used to determine the CO value, use the arterial pressure. This requires obtaining of accurate values and ensuring optimal waveforms.

Other parameters obtained with an arterial pressure system include stroke volume variation (SVV) or its surrogate, pulse pressure variation (PPV), and systolic pressure variation (SPV). These parameters evaluate the difference between the maximum and minimum values of systolic pressure, PP, or SV during a respiratory cycle. They are called dynamic parameters and are better predictors of fluid responsiveness than static measures such as CVP/RAP in the critically ill. A natural phenomenon occurs during the respiratory cycle in which the arterial pressure falls during inspiration and rises during expiration. The variation is a result of changes in intrathoracic pressure during respiration; a negative pressure during inspiration results in a fall in systolic pressure, and a relatively higher intrathoracic pressure during expiration causes a rise in systolic pressure. The normal variation during a respiratory cycle is 5 to 10 mm Hg. When the difference is greater, the condition is termed *pulsus paradoxus*. Reverse pulsus paradoxus is the same phenomenon that occurs during

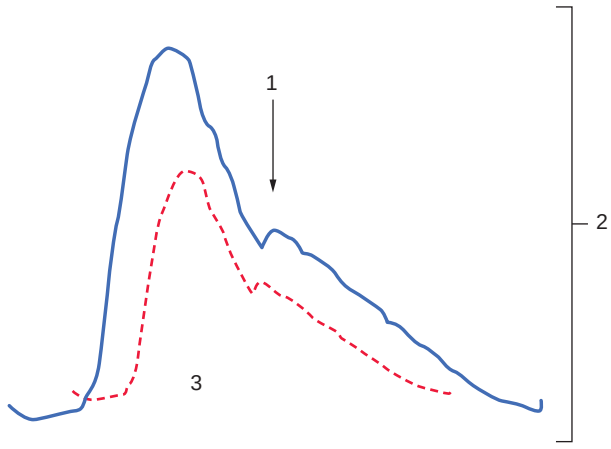

FIGURE 17-51 ▲ Methods to obtain stroke volume using arterial pulse wave. 1. Pulse Contour: Identification of dicrotic notch required. 2. Pulse Power: Mean determined, systolic and diastolic extrapolated. 3. Pulse Pressure/Flow: Full wave measured for pressure and waveform shape assessed.

controlled mechanical ventilation. The mechanics are opposite of spontaneous breathing in that the arterial pressure rises during inspiration and falls during expiration.[20,25,29]

SPV, PPV, and SVV can be calculated from the arterial tracing as long as the respiratory cycle is noted. In addition, other technologies to obtain this value include bedside physiological monitors with special software and the pulse oximetry plethysmographic waveform.[30,31]

Nursing Considerations

Patient assessment includes assessing for pulsus paradoxus that occurs during cardiac tamponade, obstructive lung diseases, and hypovolemic states. A SVV greater than 10% to 15% has a high level of sensitivity and specificity for determining the need for fluid and in predicting preload responsiveness. A patient is preload responsive if after a fluid bolus their SV or CO increases by 10% to 15%. Technical considerations for the use of arterial pressure–based technologies include those that affect the accuracy of the arterial waveform. Optimal pressure system maintenance and leveling of the device is required. Limitations to using variation parameters relate to factors that cause changes in intrathoracic pressure and those that affect ventricular filling time. Any cardiac dysrhythmia can affect the overall value because of irregular ventricular responses and therefore the value should be used with caution in those conditions. Intravascular volume resuscitation increases preload, which in turn increases CO.[20,22,25]

Impedance-Based Cardiac Output Determination

Impedance (Z) is resistance to flow of an electrical current. Impedance decreases in the presence of fluid. Two types of impedance-based CO technologies are available for clinical use: bioreactance and impedance cardiography (ICG) (also called thoracic electrical bioimpedance). Both provide noninvasive, continuous, real-time CO and other hemodynamic data using pairs of skin electrode-sensors at the upper and lower thorax.

Bioreactance technology delivers a small alternating current via the upper electrodes and analyzes the changes in frequency of the electrical impulses as they traverse the chest. The frequency changes are related to aortic blood flow and thus can be used to calculate SV and CO. CO derived from bioreactance is comparable to those from PAC, ICG, and Fick.[32]

ICG also uses a very small electrical current injected through skin electrodes placed at the base of the neck and the lower thorax (Fig. 17-52). These electrodes also sense the change in impedance due to pulsatile blood flow in the descending aorta during systole and diastole. The change in impedance over time (dZ/dt) directly reflects left ventricular contractility (Fig. 17-53) and is mathematically converted into SV and CO.[33]

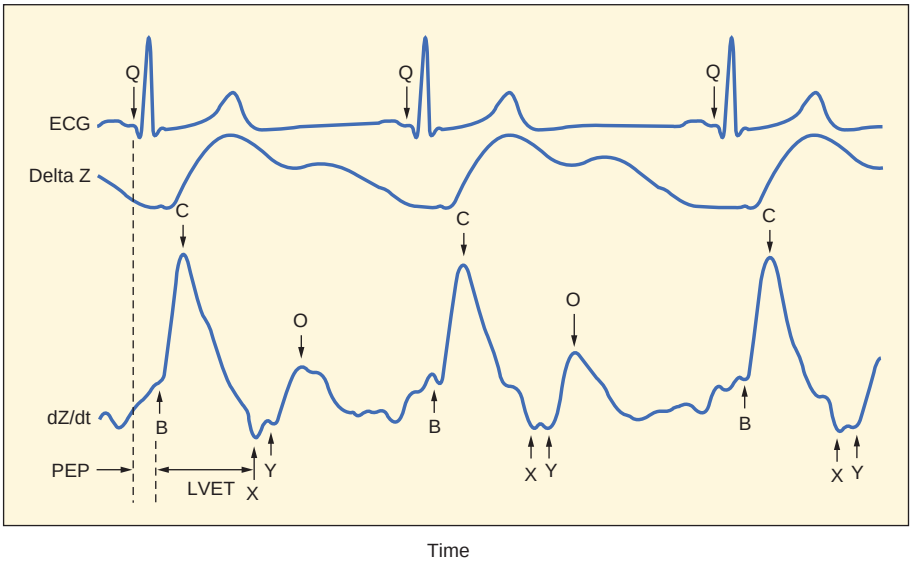

FIGURE 17-53 ▲ ECG and normal change in impedance over time (dZ/dt) waveform. Q, start of ventricular depolarization; B, opening of aortic and pulmonic valves; C, maximum deflection of dZ/dt (dZ/dt_{max}); X closure of aortic valve; Y, closure of pulmonic valve; O, mitral opening snap and early ventricular diastolic filling. (Courtesy of Cardiodynamics International, Inc.)

Both bioreactance and ICG monitors provide traditional hemodynamic determinations such as CO, SV, and SVR, if a blood pressure and CVP or RAP are entered into the monitor. Since aortic blood flow causes the most significant change in impedance, these technologies provide more direct indices of left ventricular contractility that are not available from a PAC. They also provide a baseline impedance, the thoracic fluid content, which reflects all of the fluid in the thorax (interstitial, intravascular, or intracellular). In some instances, when thoracic fluid content is very high, ICG determination of SV and CO may be affected.[33] CO values from bioreactance technology appear to be less influenced by pleural fluid, pulmonary edema, and chest wall movement than ICG.[32]

Nursing Considerations

Because ICG and bioreactance are noninvasive technologies, nurses in any inpatient or outpatient setting can initiate this type of hemodynamic monitoring.[33] Thus, the clinical applications are broad. For example, ICG parameters are used to evaluate patients with heart failure, hypertension, and permanent pacemakers in the emergency department, outpatient clinic, or physician office.

Because electrical impedance is reduced in the presence of fluid, the thoracic fluid content measurement is useful in the differential diagnosis of heart failure or chronic obstructive pulmonary disease as well as in the assessment and management of patients with heart failure who may have pulmonary congestion or pulmonary edema. Adjustment in diuretics, inotropic agents, and vasodilators can be fine-tuned based on impedance parameters. Similarly, patients with chronic and resistant hypertension can be managed more closely and more aggressively on an outpatient basis using ICG or bioreactance hemodynamic parameters as opposed to using blood pressure alone. Continuous noninvasive CO and hemodynamic parameters are also used to optimize the settings of atrial–ventricular (A-V) sequential cardiac pacemakers to adjust the time for A-V delay to allow appropriate ventricular filling to achieve optimal SV and CO.

Doppler-Based Cardiac Output Determination

Doppler-based technology uses the aortic blood flow velocity waveform to calculate SV and CO. The pulsatile velocity waveform directly reflects left ventricular contractility as well as the patient's intravascular volume status (preload).

The esophageal Doppler monitor (EDM) is a minimally invasive hemodynamic monitoring device that incorporates a Doppler transducer into a nasogastric tube. When placed in the esophagus, EDM monitors the descending aortic blood flow velocity[31,34] (Fig. 17-54). Continuous CO and SV determinations are calculated in real time relative to changes in blood flow using the Doppler waveform configuration.

USCOM is a noninvasive hemodynamic monitor that determines CO by continuous-wave Doppler ultrasound.[31,35] Data is obtained using a probe placed on the chest in either the left parasternal position to measure transpulmonary blood flow or the suprasternal notch to measure transaortic blood flow. USCOM does not provide continuous hemodynamic data. Information is obtained intermittently as desired by the clinician.

Both EDM and USCOM provide traditional parameters such as CO, SV, and SVR, if a blood pressure and CVP or RAP is entered into the monitor. Additional parameters derived from the waveform include: peak velocity, an indicator of myocardial contractility, and flow time, which reflects systolic ejection time and thus changes in preload.

Nursing Considerations

A valuable aspect of Doppler-based technology is use of the waveform shape to determine changes in myocardial contractility and intravascular volume (preload) because the waveform displayed on the monitor reflects the volume and velocity of blood in the aorta. The normal waveform is triangular, consisting of the beginning of systole, peak systole, and end-systole (Fig. 17-55). As flow from the left ventricle increases, the shape of the waveform changes, becoming a larger, higher, and wider triangle. Conversely, decreased contractility is reflected in a smaller waveform; hypovolemia causes the waveform to become more narrow at the base. The baseline shape of the waveform, as well as changes in response to therapy, can significantly contribute to hemodynamic assessment. Thus Doppler-based data and waveform analysis can guide the clinician in evaluating the patient's need for therapy and responses to fluid administration and titration of vasopressors and inotropes.[34]

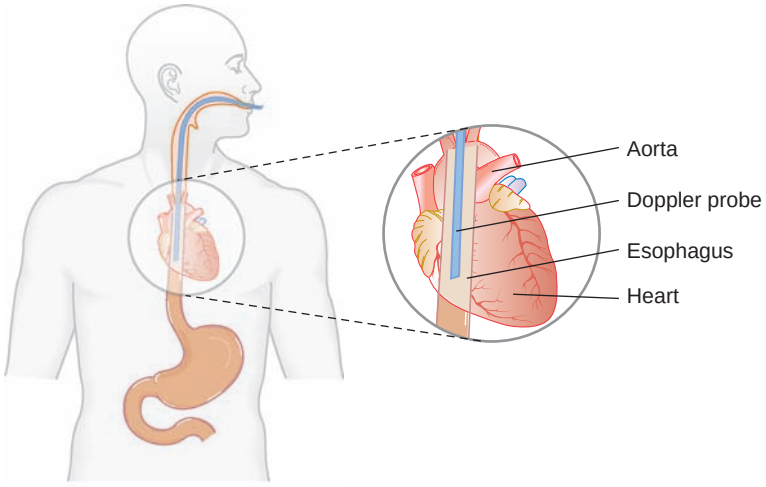

FIGURE 17-54 ▲ Location of the esophageal Doppler probe in the esophagus in relation to the heart and descending aorta. (Courtesy of Deltex Medical, Inc.)

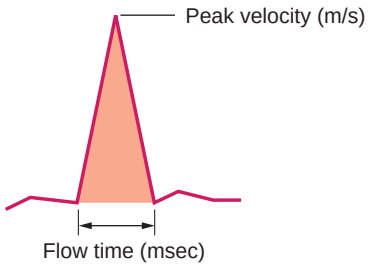

FIGURE 17-55 ▲ Esophageal Doppler waveform showing peak velocity and flow time. (Courtesy of Deltex Medical, Inc.)

EDM usually requires the patient to be sedated; therefore it is most often used in the critical care unit, operating room, postanesthesia care unit, and the emergency department. USCOM is noninvasive technology; clinicians in any inpatient or outpatient setting can use this type of hemodynamic monitoring. However, training is required and the data obtained depends on proper technique.

▲ Evaluation of Oxygen Delivery and Demand Balance

One of the primary objectives of hemodynamic monitoring is to use the data in the evaluation of oxygen delivery or transport and the consumption of oxygen by the tissues and organs. Adequate oxygen delivery to the body's organs is essential for maintenance of cell, tissue, and ultimately organ function. Insufficient oxygen delivery and consumption to meet the cellular requirements for oxygen, or oxygen demand, result in hypoxia and the accumulation of an oxygen deficit. Persistent oxygen deficit causes cell and organ dysfunction and eventually leads to cell death and organ failure.[36] Table 17-19 lists the parameters that are used to evaluate oxygen delivery and demand balance, the formulas, and normal values.

Determinants of Oxygen Delivery

Arterial oxygen delivery (DaO_2) is the amount of oxygen transported to the tissues. DaO_2 depends on arterial oxygen content and CO.

Oxygen Content

Oxygen content is the total amount of oxygen in the blood that is available to the cells. The two primary determinants of oxygen content are hemoglobin and oxygen saturation. Most of the available oxygen in arterial blood (>95%) is reversibly bound to hemoglobin in the form of oxyhemoglobin and is measured by arterial oxygen saturation (SaO_2). A very small amount of oxygen (<5%) is dissolved in plasma and measured as PaO_2. A sufficient amount of hemoglobin is required to ensure adequate oxygen-carrying capacity.

Cardiac Output

CO is required to deliver oxygenated blood to the cells of the body. DaO_2 is assessed by evaluating the adequacy of CO and arterial oxygen content. In nonstressed states, normal DaO_2 is 1,000 mL O_2/min, or indexed to BSA, 600 mL O_2/min/m^2. Increases in the body's oxygen demand associated with injury or illness are initially and primarily met by a compensatory increase in CO. Deficiencies of hemoglobin, arterial saturation, or CO decrease DaO_2 to cells and threaten the adequacy of cellular oxygenation.[37]

Determinants of Oxygen Consumption

Oxygen consumption (VO_2) is the amount of oxygen used by the tissues of the body. The primary determinants of VO_2 are the cellular demand for oxygen, the delivery of adequate amounts of oxygen, and the extraction of oxygen from the blood for use by the cells.

Oxygen Demand

Oxygen demand is the requirement of cells for oxygen and is not directly measurable. Any stress increases the oxygen demand (eg, surgery, infection, mobilization, pain, anxiety). Reduced oxygen demands are associated with lower metabolic rates (eg, hypothermia, sedation, pharmacological paralysis). Oxygen demands are met through adequate delivery of oxygen and cellular extraction of oxygen.[36,37]

Oxygen Delivery

Cellular use of oxygen depends on an adequate supply of oxygen. This is termed delivery-dependent oxygen consumption (Fig. 17-56). As oxygen delivery increases, oxygen consumption also increases to meet the oxygen demand. When the requirement for oxygen is met, further increases in oxygen delivery do not increase consumption. The level of critical oxygen delivery is the point at which a decrease in oxygen delivery results in decreased VO_2 because of an insufficient oxygen supply.[36,37]

Oxygen Extraction

Oxygen extraction ($CaO_2 - CvO_2$) is the amount of oxygen removed from the blood for use by the cells. It is measured by comparing the arterial oxygen content to venous oxygen content. Like arterial oxygen content, venous oxygen content (CvO_2) is primarily determined by the amount of hemoglobin that is saturated with oxygen. Venous saturation is obtained by withdrawing a mixed venous blood gas sample from the distal port of the PA catheter, or by using an SvO_2 or $ScvO_2$ monitoring central venous catheter or PA catheter, as discussed later in this section.

In normal circumstances, provided that oxygen is supplied in adequate amounts, the cells extract the oxygen they need to support tissue and organ function. Increased demand for oxygen results in a compensatory increase in oxygen extraction as more oxygen is "unloaded" from the hemoglobin for cellular use. The decreased amount of oxygen in venous blood means that the $CaO_2 - CvO_2$ difference is larger. Conversely, as oxygen demands decrease, less oxygen is required and extracted from the blood, and the $CaO_2 - CvO_2$ difference becomes smaller.[37]

Oxygen Supply and Demand Imbalance

An imbalance of oxygen supply and demand occurs whenever oxygen delivery is inadequate to meet cellular demand or the cells are unable to extract sufficient quantities of

Table 17-19 Oxygen Utilization Variables

Parameter	Definition	Formula	Normal Values
Arterial Oxygen Content (CaO_2)	The amount of oxygen carried by hemoglobin in a deciliter of arterial blood.	$(Hb \times 1.37 \times SaO_2) + (0.003 \times PaO_2)$	20 mL O_2/dL
Venous Oxygen Content (CvO_2)	The amount of oxygen carried by hemoglobin in a deciliter of venous blood.	$(Hb \times 1.37 \times SvO_2) + (0.003 \times PvO_2)$	15 mL O_2/dL
Arterial Oxygen Delivery Index (DaO_2I)	The amount of oxygen transported in the blood from the left ventricle through the arteries and capillaries to tissues/organs, in 1 min, indexed to the patient's BSA.	$CI \times CaO_2 \times 10$	500–600 mL O_2/min/m^2
Venous Oxygen Delivery Index (DvO_2I)	The amount of oxygen in the blood returned to the right ventricle in 1 min, via the veins from tissues/organs, indexed to the patient's BSA.	$CI \times CvO_2 \times 10$	375–450 mL O_2/min/m^2
Mixed Venous Oxygen Saturation (SvO_2)	The oxygen saturation of venous blood, measured in the pulmonary artery.	Direct measurement	60%–80%
Central Venous Oxygen Saturation ($ScvO_2$)	The oxygen saturation of venous blood, measured in the superior vena cava.	Direct measurement	65%–85%
Partial Pressure of Oxygen, venous blood (PvO_2)	Reflects the amount of oxygen dissolved in the plasma of venous blood.	Direct measurement	35–45 mm Hg
O_2 extraction	Amount of oxygen that is removed (extracted) from hemoglobin for use by cells/tissues/organs.	$CaO_2 - CvO_2$	3–5 mL O_2/dL
Oxygen Extraction Ratio (OER)	The percent of oxygen delivered that is removed (extracted) from hemoglobin for use by cells/tissues/organs.	$\frac{(CaO_2 - CvO_2)}{CaO_2}$	22%–30%
Oxygen Consumption Index (VO_2I)	The amount of oxygen used by cells/tissues/organs every minute, indexed to the patient's BSA.	$(CaO_2 - CvO_2) \times CI \times 10$	120–170 mL/min/m^2
Arterial pH (pHa)	The acidity (pH) of arterial blood.	Direct measurement	7.35–7.45
Base Excess/Base Deficit (BE/BD)	Amount of base required to titrate one liter of arterial blood to a pH of 7.40. Decreases with metabolic acidosis.	Direct measurement	–2 to +2
Lactate	A metabolic byproduct of Krebs cycle that increases with anaerobic metabolism.	Direct measurement	0.5–2.2 mmol/L

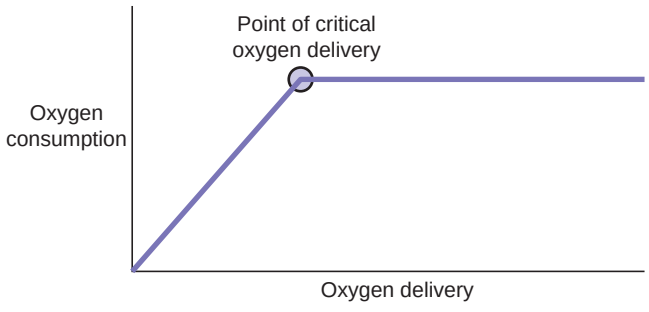

FIGURE 17-56 ▲ Delivery-dependent oxygen consumption curve reflecting the change in oxygen consumption related to oxygen delivery. At the point of critical oxygen delivery, oxygen delivery is sufficient to meet oxygen demand, and oxygen consumption does not increase further. However, any decrease in oxygen delivery from this point results in a decrease of oxygen consumption due to an inadequate supply of oxygen.

oxygen. Specific threats to the balance of oxygen supply and demand are decreased CO, hemoglobin, or arterial saturation; impaired cellular extraction of oxygen; or oxygen demands that are so great that they cannot be met by increased oxygen delivery or extraction.

Metabolic Indicators of Oxygen Delivery and Utilization Imbalance

Inadequate oxygen consumption causes an anaerobic state and cellular hypoxia. Cells deprived of oxygen become hypoxic and dysfunctional. Over time, cell damage becomes irreversible and cell death results. Cellular hypoxia is a major cause of multisystem organ dysfunction and failure. If an oxygen deficit is identified before irreversible cell injury has occurred, it may be reversed by increasing oxygen availability.

Several metabolic parameters can be measured to evaluate cellular hypoxia. When these indicators are used in conjunction with hemodynamic monitoring of oxygen delivery and consumption, therapies may be more specifically directed to achieve a balanced oxygen supply and demand.

Because hypoxia and oxygen debt are associated with anaerobic metabolism, the byproducts of anaerobic metabolism can be used to assess the presence of an oxygen deficit and cellular hypoxia. Lactic acid accumulation causes a metabolic acidosis in a hypoxic state. Therefore, laboratory measurement of lactate levels, serum pH, and base deficit/excess are means to evaluate if oxygen supply is sufficient to meet cell requirements. Serum pH and base deficit/excess are routinely measured and reported with blood gas analysis. Elevated lactate levels (>2.2 mm/L) or metabolic acidosis (pH < 7.35 with normal $PaCO_2$) correlate with oxygen debt, particularly when the patient has a low or even normal level of DaO_2 and VO_2. As with all assessment parameters, lactate levels, pH, and base deficit should not be viewed in isolation; they should be evaluated in conjunction with other assessment parameters.[20–22]

Monitoring of Mixed Venous and Central Venous Oxygen Saturation

Mixed venous oxygen saturation (SvO_2) reflects the level of oxyhemoglobin in desaturated blood returning to the right ventricle and PA. Venous oxygen saturation can also be measured in the superior vena cava ($ScvO_2$). SvO_2 or $ScvO_2$ can be monitored at the bedside by specialized central venous catheters or PACs containing fiber-optic filaments in one of the lumens ending at the distal end. The information is updated every few seconds; thus, a continuous SvO_2 or $ScvO_2$ reading is obtained.

Both SvO_2 and $ScvO_2$ are useful to evaluate the global balance of oxygen supply, oxygen utilization, and oxygen demand. The SvO_2 or $ScvO_2$ is significantly lower than arterial saturation because of the extraction of oxygen by the cells and the unloading of oxygen from hemoglobin.

SvO_2 or $ScvO_2$ is influenced by the degree of arterial saturation, the quantity of hemoglobin, the CO (the determinants of oxygen delivery), and the amount of oxygen extracted and consumed by the cells. Under normal conditions of oxygen delivery, oxygen consumption, and oxygen demand, approximately 25% of the available oxygen is extracted and used to meet demand. In this situation, the SvO_2 or $ScvO_2$ is in the normal range: SvO_2 of 60% to 80%, or $ScvO_2$ of 65% to 85%. If oxygen delivery is reduced by a decrease in arterial saturation, hemoglobin, or CO, then more oxygen is extracted from the blood to meet cellular demand. The blood returning to the right side of the heart and PA has had a greater quantity of oxygen removed and is more desaturated, which is reflected by a decrease in $ScvO_2$ or SvO_2. Similarly, if oxygen demand increases but oxygen delivery does not increase to meet this requirement, additional oxygen is extracted from the blood and consumed by the cells. Therefore, oxyhemoglobin is reduced in the venous blood, decreasing SvO_2 or $ScvO_2$. Persistently low SvO_2 or $ScvO_2$ is a warning that cellular hypoxia and an oxygen debt may be developing because of inadequate oxygen delivery or a high oxygen demand not met by the oxygen supply.[37,38]

Three general conditions result in increasing SvO_2 or $ScvO_2$:

- An oxygen delivery that is much greater than the oxygen demand; only a small percentage of the delivered oxygen is extracted, causing SvO_2 or $ScvO_2$ to increase.
- A low metabolic rate and oxygen demand; the need for oxygen is reduced, and less oxygen is extracted and consumed. SvO_2 or $ScvO_2$ reflects the decrease in extraction as greater amounts of oxyhemoglobin are returned to the right side of the heart.
- Pathological states in which the cells cannot extract oxygen from the blood or in which tissue beds are not well perfused with oxygenated blood; oxygen is not extracted from the blood despite the cellular oxygen demand. The SvO_2 or $ScvO_2$, returning to the right side of the heart and PA, is therefore higher because of the decreased oxygen consumption.[37,39]

Although the SvO_2 or $ScvO_2$ may be in the normal range, cells in the body may not use or receive the oxygen they require. In these instances, cells become reliant on anaerobic metabolism because of the reduced cellular oxygen extraction or the shunting of oxygenated blood past tissue beds. Thus, a normal SvO_2 or $ScvO_2$ may be misleading when viewed in isolation. Table 17-20 summarizes factors that cause SvO_2 or $ScvO_2$ to increase or decrease.

Lactate, base deficit and excess, and SvO_2 or $ScvO_2$ are measures of global tissue oxygenation status. In shock states, blood is shunted from the splanchnic tissue bed and from the extremities to vital organs. Therefore, assessment of perfusion

Table 17-20 Examples of Causes of Increasing or Decreasing Central Venous Saturation

↓ $ScvO_2$	↑ $ScvO_2$
Increased oxygen extraction	*Decreased oxygen extraction*
1. Increased oxygen demand Causes: Stress, pain, anxiety, fever	1. Decreased oxygen demand Causes: Sedation, pain relief, hypothermia
2. Oxygen delivery insufficient to meet oxygen demand Causes: Decreased CO, Hgb, SaO_2	2. Increased oxygen delivery Causes: Increased CO, Hgb, SaO_2
	3. Impaired cellular oxygen extraction Causes: cytotoxicity, sepsis, cell death

CO, cardiac output; Hgb, hemoglobin; SaO_2, arterial saturation.

in these specific tissue beds can be useful in the early detection of reduced oxygen delivery and/or utilization.

Near-infrared spectroscopy is a noninvasive technology to monitor tissue oxygen saturation (StO_2) in muscle. It uses an infrared light emitting and sensing "patch" over the thenar muscle (located at the base of the thumb on the palm of the hand) to measure oxygen saturation in the microcirculation below the sensor. (Fig. 17-57) As tissue perfusion is reduced, especially when associated with hypovolemia or decreased CO states, StO_2 decreases. StO_2 values that trend downward and are less than 75% are associated with higher morbidity and mortality.[40] In patients with sepsis and septic shock, StO_2 is lower compared with patients who meet SIRS criteria[41] but has not been shown to be superior to $ScvO_2$ in the sepsis population.[42]

Gastric tonometry and sublingual CO_2 monitoring are methods to evaluate perfusion of specific tissue beds that have early susceptibility to hypoperfusion.[43] In early shock or shock states, compensatory diversion of blood flow from the splanchnic bed and digestive tract to vital organs causes the gastric mucosa and upper gastrointestinal tract to be underperfused. Anaerobic metabolism produces increased amounts of CO_2 and lactate; thus, measuring the CO_2 level or pH of these tissue beds can provide an early indicator of oxygen supply and demand mismatch.

Gastric tonometry uses a nasogastric tube with a gas-permeable balloon near the distal end. CO_2 diffuses from the gastric wall into the balloon. Sampling the contents allows measurement of the PCO_2 and gastric mucosal pH. Normal gastric mucosal pH is 7.35 to 7.45, and normal gastric mucosal PCO_2 is 35 to 45 mm Hg. Decreasing gastric mucosal pH or an increasing gastric PCO_2 out of the normal range suggests hypoperfusion and is an indication that oxygen delivery and consumption should be analyzed and optimized. Medications that neutralize gastric pH, such as H-2 blockers may also affect the gastric tonometer values.

Sublingual capnometry is based on the same physiological principles as gastric tonometry. Blood flow to the upper digestive tract, including the area under the tongue, is reduced in response to shock or hemorrhage. Sublingual capnometry uses a handheld device similar to a thermometer to measure PCO_2 using a sensor that is placed under the tongue.

FIGURE 17-57 ▲ Placement of the StO_2 sensor over the thenar muscle.

Nursing Considerations

When patients are critically ill, careful evaluation of the adequacy of oxygen delivery, oxygen extraction, and consumption with respect to oxygen demand is paramount. Scrutiny of each determinant of CO (heart rate, preload, afterload, and contractility parameters), oxygen content (arterial saturation and hemoglobin), oxygen consumption (VO_2 and $CaO_2 - CvO_2$), and oxygen debt (lactate, pH, base deficit and excess, SvO_2 or $ScvO_2$) is important to critical care nursing.

Numerous interventions are used to enhance oxygen delivery. Measures to increase CO include the addition of intravascular volume to increase preload as well as the administration of positive inotropic agents to improve contractility and vasodilating agents to reduce afterload. Interventions that may increase arterial oxygenation and oxygen content include changes in mechanical ventilator settings; chest physiotherapy; positioning and mobilization; and, in nonmechanically ventilated patients, coughing and deep-breathing exercises. Administration of packed red blood cells increases hemoglobin and oxygen-carrying capacity. In all cases, it is necessary to manage both the treatment modalities and assess the patient's response to therapy.

Many of the interventions used to decrease oxygen demand and increase oxygen consumption are important tenets of nursing care. For example, appropriate management of the environment, pain, and anxiety reduces stress, thus decreasing the demand for oxygen. Maintaining normothermia by control of the patient's temperature may decrease oxygen requirements associated with fevers and facilitate impaired perfusion and oxygen consumption associated with hypothermia.

SvO_2 or $ScvO_2$ monitoring may be a helpful guide in nursing interventions. For example, endotracheal suctioning may cause a temporary decrease in arterial oxygenation and increase discomfort and anxiety. Monitoring SvO_2 or $ScvO_2$ allows the nurse to judge the impact of this activity on the patient's oxygen supply and demand. A decreasing SvO_2 or $ScvO_2$ during suctioning is usually caused by increased oxygen demand and decreased arterial oxygenation. Hyperoxygenating and hyperventilating before, during, and after suctioning helps lessen the negative effects on oxygen demand and arterial oxygenation. Before proceeding to another activity such as repositioning, the nurse should monitor the SvO_2 or $ScvO_2$ and wait until the value normalizes, thereby avoiding an additional stressor and further increase on oxygen demand.

$ScvO_2$ monitoring has been incorporated into the early, goal directed management guidelines for patients with sepsis and septic shock. A goal is to maintain an $ScvO_2$ of at least 70% by increasing oxygen delivery.[44] The use of a sepsis bundle and protocol that includes $ScvO_2$ is associated with improved morbidity and mortality.[45]

▲ Clinical Applicability Challenges

CASE STUDY

Mr. T. is a 69-year-old male, 6′1″, 97.6 kg (BSA 2.22) whose medical history revealed questionable hypertension with noncompliant use of medication and absent regular medical treatment.

Mr. T. arrived at the emergency department with complaints of increasingly severe abdominal pains. The abdomen was tender upon palpation and distended. Initial vital signs were: blood pressure 190/104 mm Hg, heart rate 86 beats/min, normal sinus rhythm, respiratory rate 22 breaths/min, and SpO_2 96%.

Laboratory results showed Hgb 11 g/dL, Hct 33%, white blood cell (WBC) 9,840, and lactate 2.2 mmol/L.

A preliminary differential diagnosis of acute appendicitis versus abdominal aortic aneurysm was made. The physical examination and laboratory test findings were inconclusive so a computed axial tomography scan was performed. Results of the scan showed a 9-cm abdominal aortic aneurysm.

Mr. T.'s condition worsens rapidly after the scan with complaints of increased abdominal pain, severe respiratory distress with an SpO_2 value decreasing to 89%, and a sudden decrease in his blood pressure to 108/64 mm Hg. Respiratory rate increased to a rate of 36 and he exhibited shallow breathing. Heart rate remained in a sinus rhythm, however it increased to 98.

Due to Mr. T.'s worsening respiratory status and blood pressure, he was intubated and placed on controlled mechanical ventilation. To assist with ventilation synchronization management, he was sedated. Mr. T. was subsequently admitted to the intensive care unit (ICU) for stabilization and additional monitoring.

Upon admission to the ICU an arterial line was placed and he was attached to a less invasive CO monitoring device to measure and monitor CO and other dynamic variables, such as stroke volume variation (SVV). In addition, to provide ready access to his central circulation, a central line was placed in his right internal jugular vein. The specific catheter used was one that monitors continuous central venous oxygen saturation values to provide an assessment of his overall oxygenation balance status.

Additional hemodynamic and oxygenation values obtained in the ICU were: cardiac index 2.8 mL/min/m^2, SV variation 13%, and $ScvO_2$ 72%. All of these variables are within the normal value range. Care included continued monitoring of Mr. T.'s status.

About an hour after admission to the ICU Mr. T.'s condition continued to deteriorate. His reprofiled parameters were: blood pressure 98/48 mm Hg, HR 126 beats/min, CI 2.1 L/min/m^2, SVV 24% and $ScvO_2$ 54%.

The profile Mr. T. now presents can be one of acute hypovolemia, hemorrhage, or potentially both. The cardiac flow indices are low. With a cardiac index of 2.1 and a heart rate of 126, the SV is only 37. These are significant changes from the earlier set of parameters that showed a SV of 63. The $ScvO_2$ value in addition decreased from 72% to 54%, again a clinically significant change. Factors to assess when the $ScvO_2$ value changes are those conditions that alter either oxygen delivery; arterial oxygen saturation, hemoglobin, or CO, and those that affect oxygen consumption; metabolic demand, pain, shivering, and fever.

SVV as a dynamic indicator of fluid responsiveness suggested that since Mr. T. is on controlled mechanical venation, he would respond favorably to fluid.

A repeat laboratory hemoglobin and hematocrit sample showed Mr. T.'s blood count to have dropped from Hgb 11/Hct 33 to Hgb 9/Hct 27. This significant drop along with the indicators of a hypovolemic state resulting from potential bleeding from the aortic aneurysm led the surgical team to perform an emergent abdominal aortic aneurysm repair.

The remaining course of hospitalization was unremarkable and Mr. T. did well. Discharge was within 5 days.

1. What were the symptoms that caused concern on initial assessment?

2. How did the additional parameters, CI, SVV, and $ScvO_2$, assist in the identification of the clinical problem?

3. What would be a course of action for improving CO, $ScvO_2$, and SVV?

18 Patient Management: Cardiovascular System*

Barbara Leeper, Marla J. De Jong, Vicki J. Coombs, Kenneth J. Rempher, Dulce Obias-Manno, and Conrad Gordon

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Compare and contrast commonly used fibrinolytics, anticoagulants, and platelet inhibitors used to affect the thrombotic process.
2. Describe the four classes of antiarrhythmic drugs.
3. Explain how inotropic drugs improve myocardial function.
4. Discuss the rationale for using phosphodiesterase III inhibitor, angiotensin-converting enzyme inhibitor, and vasodilator drugs for patients with cardiovascular disease.
5. Compare and contrast the four major classes of antihyperlipidemic drugs.
6. Compare and contrast the indications and contraindications for percutaneous coronary interventions (PCIs), including percutaneous transluminal coronary angioplasty and intracoronary stenting.
7. Summarize interventions for complications associated with PCI procedures.
8. List potential nursing diagnoses and the interventions for each diagnosis in the patient undergoing an interventional cardiology procedure.
9. Discuss the indications for percutaneous balloon valvuloplasty.
10. Describe the physiological effect of intra-aortic balloon pump (IABP) counterpulsation therapy.
11. Explain indications for and contraindications to IABP therapy.
12. Describe a ventricular assist device and its indications and mechanism of action.
13. Discuss nursing interventions for the patient receiving IABP therapy or ventricular circulatory assistance.
14. Describe the indications, procedure, and nursing management for electrical cardioversion.
15. Explain the indications, procedure, and nursing management for radiofrequency catheter ablation.
16. Describe the indications for a permanent pacemaker.
17. Explain the components, functions, and modes of a pacemaker.
18. Explain complications of pacing and appropriate interventions.
19. Discuss the nursing management of the patient with a pacemaker.
20. Describe the indications, components, and function for an implantable cardioverter–defibrillator (ICD).
21. Explain the nursing management of a patient with an ICD.
22. Describe causes of cardiopulmonary arrest.

(continued)

*Opinions or assertions contained herein are the private views of the authors and are not to be construed as official or as reflecting the views of the Department of the Air Force or the Department of Defense.

LEARNING OBJECTIVES *(Continued)*

23. Explain steps of cardiopulmonary resuscitation and the role of each member of the resuscitation team.
24. Explain indications, procedure, and nursing management for defibrillation.
25. Discuss the rationale for using hypothermia as part of cardiopulmonary arrest management.
26. Describe pros and cons of having family members present in a cardiopulmonary arrest situation.

PHARMACOLOGICAL THERAPY

Cardiovascular disease continues to be the leading cause of disease-related death for men and women in the United States. However, recent and remarkable pharmacological advances have reduced morbidity and mortality related to cardiovascular disease.

Critical care nurses are responsible for administering medications that affect the patient's cardiovascular function. Furthermore, nurses continuously evaluate the effects of these drugs and use detailed patient assessment data to guide the titration of these drugs.

This section provides a summary of medications used in critical care settings to treat patients with cardiovascular disease. Critical care nurses need to know drug indications, effects, contraindications, dosage, method of administration, and adverse effects. Additionally, many patients require treatment with numerous cardiovascular drugs; therefore, it is important to consider how drugs interact with other drugs.

▲ Fibrinolytics, Anticoagulants, and Platelet Inhibitors

Atherosclerotic plaque rupture or vascular endothelium damage initiates platelet activation resulting in platelet aggregation and adhesion. This process initiates the production of thrombin through the activation of the coagulation cascade. Thrombin converts fibrinogen to fibrin resulting in the formation of a nonsoluble fibrin thrombus. For further information about the coagulation process, see Chapter 45. An arterial thrombus may transiently or persistently occlude coronary artery blood flow, causing acute coronary syndrome (ACS). For further information about ACS, see Chapter 21. Fibrinolytic, anticoagulant, and platelet inhibitor drugs affect different phases of the thrombotic process.

Fibrinolytics

Fibrinolytic agents are indicated for patients with acute ST-segment elevation myocardial infarction (STEMI). The drugs are not effective and should not be administered to patients without ST-segment elevation or to patients with nonspecific electrocardiogram (ECG) changes.[1,2] Fibrinolytic agents either directly or indirectly convert plasminogen to plasmin, which in turn lyses the thrombus. Early fibrinolytic therapy has been shown to dissolve the thrombus, reestablish coronary blood flow, minimize infarction size, preserve left ventricular (LV) function, and reduce morbidity and mortality.[1] Table 18-1 summarizes commonly used fibrinolytic agents.

The decision to administer fibrinolytic therapy is based on the patient's cardiovascular physical assessment data and ECG. Unless contraindicated (Box 18-1), fibrinolytics should be given to patients with acute STEMI whose symptoms began within the previous 12 hours and who have ST-segment elevation greater than 0.1 mV in two or more contiguous (adjacent) leads, or who have a new-onset left bundle branch block (BBB).[1] Fibrinolytic therapy produces the greatest reduction in mortality when initiated within the first 0 to 4 hours of symptom onset; however, fibrinolytics may be administered up to 12 hours after symptom onset. The goal is to administer a fibrinolytic drug within 30 minutes of the patient's arrival in the emergency department. Patients are at risk for recurrent thrombus formation in the coronary artery; therefore, aspirin and heparin are given to most patients who receive fibrinolytic therapy.[1,3]

Reperfusion may be manifested by decreased or resolved ST-segment elevation, abrupt cessation of chest pain, early peak of serum cardiac biomarkers, and reperfusion dysrhythmias, such as premature ventricular contractions, ventricular tachycardia (VT), accelerated idioventricular rhythm, and atrioventricular (AV) blocks. In contrast, reocclusion may be evidenced by recurrent chest pain and ST-segment elevation, further myocardial ischemia or infarction, lethal dysrhythmias, cardiogenic shock, or death. The most common adverse effects of fibrinolytic therapy are bleeding, intracranial hemorrhage, stroke, and reperfusion dysrhythmias. For more details about the use of fibrinolytic therapy for acute myocardial infarction (AMI), see Chapter 21.

Anticoagulants

Anticoagulants, such as unfractionated heparin, low-molecular-weight heparins (LMWHs), direct thrombin inhibitors, and warfarin (Coumadin) limit further fibrin formation and help prevent thromboembolism.[3]

Unfractionated heparin, the most commonly used anticoagulant drug for acute conditions, is indicated for ACS, venous thromboembolism, percutaneous coronary interventions (PCIs), and patients receiving reteplase or tenecteplase. Heparin prevents clot formation by combining with antithrombin III and inhibiting circulating thrombin. However, unfractionated heparin does not lyse thrombi and is not an optimal anticoagulant because of its narrow therapeutic range, its low bioavailability, the varied anticoagulant response, the requirement for parenteral administration, the need for monitoring the activated partial thromboplastin

Table 18-1 Fibrinolytic Drugs

	Action	Indications	Dose	Half-Life (min)
Alteplase	Binds to fibrin in a thrombus and converts plasminogen to plasmin	Acute ischemic stroke	0.9 mg/kg (max 90 mg) IV over 60 min. 10% of total drug administered via bolus and the remaining dose via infusion.	<5
		Acute massive PE	100 mg infused over 2 h	
		Peripheral thrombus	100 mg infused over 2 min	
		Cathflo Activase only: to restore function of a central venous access device (for patients 30 or more kg, instill 2 mg in 2 mL solution into blocked catheter; dose may be repeated if first dose is not effective after 2 h)		
Reteplase	Catalyzes the cleavage of plasminogen to generate plasmin	AMI	10 U + 10 U IV bolus (each 10 U given over 2 min; second bolus given 30 min after first bolus)	13–16
Tenecteplase	Binds to fibrin and converts plasminogen to plasmin	AMI	Weight-based dose IV over 5 s: >60 kg = 30 mg 60 or more to <70 kg = 35 mg 70 or more to <80 kg = 40 mg 80 or more to <90 kg = 45 mg 90 kg or more = 50 mg	20–24
Streptokinase	Binds with plasminogen to produce a complex that converts plasminogen to plasmin	Acute arterial thrombosis or embolism (slowly instill 250,000 IU in 2 mL solution into occluded cannula and clamp for 2 h)		
		Occluded arteriovenous cannulas		

AMI, acute myocardial infarction; DVT, deep venous thrombosis; IV, intravenous; PE, pulmonary embolism.

time (APTT), the risk for bleeding, possible heparin-induced thrombocytopenia (HIT), and hypersensitivity reactions.

The dosage for unfractionated heparin varies according to its indication and administration route. When used with reteplase (Retavase) or tenecteplase (TNKase), the recommended heparin dosage is 60 U/kg intravenous (IV; maximum 4,000 U) bolus given when the fibrinolytic infusion is started, followed by an infusion of 12 U/kg/h (maximum 1,000 U/h) for ST-segment elevation AMI.[1,4] When IV heparin is administered for non–ST-segment elevation myocardial infarction (NSTEMI) and unstable angina, an initial IV bolus of 60 to 70 U/kg (maximum 5,000 U) followed by a 12 to 15 U/kg/h infusion is recommended.[4] The heparin infusion rate is adjusted to maintain an APTT of 50 to 70 seconds for 48 hours. Protamine sulfate reverses the effects of heparin; however, protamine may cause a life-threatening anaphylactic reaction.

BOX 18-1 Contraindications for Fibrinolytic Therapy

- Active internal bleeding
- Any history of intracranial hemorrhage
- Ischemic stroke within 3 months
- Intracranial neoplasm, arteriovenous malformation, or aneurysm
- Recent intracranial or intraspinal surgery
- Recent closed-head or facial trauma within 3 months
- Suspected aortic dissection
- Severe uncontrolled hypertension
- Bleeding diathesis

LMWHs, such as enoxaparin (Lovenox) and dalteparin (Fragmin), are small fragments derived from unfractionated heparin and are alternatives to heparin for patients with unstable angina, NSTEMI, or deep venous thrombosis. Table 18-2 summarizes these drugs, which inhibit clot formation by blocking Factor Xa and thrombin. Investigators have shown that enoxaparin is superior to unfractionated heparin for patients with STEMI, unstable angina, and NSTEMI.[5–8]

The advantages of LMWHs are their longer half-life, more predictable anticoagulation effect, greater bioavailability, and cost-effectiveness. In addition, LMWHs are administered subcutaneously twice daily and do not require APTT monitoring.

The most common adverse effects of LMWHs include bleeding, thrombocytopenia, elevated aminotransferase levels, and pain, erythema, ecchymosis, or hematoma at the injection site. Because LMWHs have different molecular weight distribution profiles, activities, and plasma clearance rates, they must not be used interchangeably with each other or unfractionated heparin.

Bivalirudin (Angiomax), a direct thrombin inhibitor, may be administered as an alternative to unfractionated heparin in low-risk patients who undergo PCI or patients with HIT.[9] The IV bolus dose for bivalirudin is 0.75 mg/kg, followed by an infusion of 1.75 mg/kg/h for the duration of the PCI procedure. An additional bolus dose of 0.3 mg/kg may be given

Table 18-2 Low-Molecular-Weight Heparins

	Indications	Absolute Bioavailability	Dose for Patients With USA or Non–Q-Wave AMI	Peak Effect	Half-Life
Dalteparin	USA (with aspirin) Non–Q-wave AMI (with aspirin) Prophylaxis of DVT	87%	120 IU/kg (maximum 10,000 IU) SC every 12 h	4 h	3–5 h
Enoxaparin	USA (with aspirin) Non–Q-wave AMI (with aspirin) Prophylaxis and treatment of DVT	100%	1 mg/kg SC every 12 h	3–4.5 h	4.5 h

AMI, acute myocardial infarction; DVT, deep venous thrombosis; SC, subcutaneous; USA, unstable angina.

in 5 minutes depending on results of the activated clotting time (ACT). The infusion may be continued for 4 hours after the PCI procedure.

Lepirudin (Refludan) is a direct thrombin inhibitor used to prevent thromboembolic complications for patients with HIT and thromboembolic disease. After an IV bolus dose of 0.4 mg/kg (maximum 44 mg), an infusion is initiated at 0.15 mg/kg/h (maximum 16.5 mg/h). The infusion rate is adjusted to maintain an APTT ratio of 1.5 to 2.5 times the baseline value. As with other anticoagulants, the major adverse effects of lepirudin are bleeding complications.

Argatroban (Acova) is another direct thrombin inhibitor indicated for prophylaxis or treatment of thrombosis in HIT. The recommended initial dose is 2 mcg/kg/min given as a continuous infusion. Dose adjustments are made to maintain an APTT ratio of 1.5 to 3.0 times the baseline value.

Warfarin, an oral drug used for chronic anticoagulation therapy, interferes with the synthesis of vitamin K–dependent clotting factors, such as factors II, VII, IX, and X. The most common cardiovascular indications for warfarin include post-AMI anticoagulation for high-risk patients, dilated cardiomyopathy, atrial fibrillation (AF), heart failure (HF), venous thromboembolism, mobile mural thrombus, and presence of a prosthetic heart valve. Studies show that warfarin plus aspirin combination therapy is associated with decreased recurrent AMI, stroke, and revascularization but with increased major bleeding.[10] Although high-intensity oral anticoagulation (international normalized ratio [INR]: 3.0 to 4.0) and moderate-intensity anticoagulation (INR: 2.0 to 3.0) plus aspirin lower the risk for untoward outcomes such as AMI, stroke, and death, warfarin treatment regimens are more inconvenient and place patients at greater risk for significant bleeding.[11] Thus, oral anticoagulants are not routinely administered after infarction.

Contraindications for warfarin include uncontrolled hypertension; severe hepatic or renal disease; bleeding diathesis; gastrointestinal (GI) or genitourinary (GU) bleeding; cerebral or dissecting aortic aneurysm; recent central nervous system, eye, or other major surgery; recent trauma; pregnancy (first and third trimesters); pericarditis; pericardial effusion; spinal puncture; and recent diagnostic procedures with the potential for uncontrolled bleeding. Patients must be able and willing to adhere to this somewhat complicated therapy.

Warfarin is usually started at 5 mg daily but should be decreased for the elderly and patients with liver or renal impairment and HF. The dose is titrated according to the patient's INR. Because warfarin levels do not peak for 3 to 4 days, acute anticoagulant therapy is continued until the INR is at the desired level for the patient's condition, usually 2.5 to 3.5. Once the INR is therapeutic on a stable warfarin dose, less frequent INR monitoring is appropriate. Elevated INR levels predispose the patient to bleeding, warfarin's most common adverse effect.[12]

Patient education is an important part of warfarin therapy. Warfarin interacts with numerous drugs and foods; safe treatment depends on the patient's knowledge of therapy.

A new class of anticoagulants called Factor Xa inhibitors is emerging as an alternative to warfarin therapy. These inhibitors seem to have fewer adverse events related to bleeding. Routine frequent blood testing is not required to monitor the effects.

Two recently approved Factor Xa inhibitor agents are rivaroxaban (Xarelto) and dabigatran (Pradaxa). There are no laboratory tests that will evaluate the effectiveness of the Factor Xa inhibitors. If bleeding occurs, laboratory coagulation tests can be used as a qualitative assessment to determine if the medication is contributing to the event. Additionally, there are no reversal agents should severe bleeding occur. Supportive care and control of bleeding are the cornerstones of therapy in this situation.

Platelet Inhibitors

Aspirin, the most widely used platelet inhibitor, inhibits thromboxane A_2, a platelet agonist, and prevents thrombus formation and arterial vasoconstriction. Aspirin is used to decrease mortality for patients with AMI; to reduce incidence of nonfatal AMI and mortality for patients with stable angina, unstable angina, or previous myocardial infarction (MI); and to prevent graft closure after coronary artery bypass graft (CABG) surgery and coronary artery thrombus after PCI. Aspirin is also indicated to reduce the risk for nonfatal stroke and death in patients with a history of ischemic stroke or transient ischemia resulting from platelet emboli. Aspirin is not indicated for primary prevention of AMI. Patients with a history of aspirin intolerance, GI or GU bleeding, peptic ulcers, severe renal or hepatic insufficiency, or bleeding disorders should not take aspirin.

Common aspirin dosages range from 75 to 325 mg daily. Depending on the indication, patients may take aspirin for a few weeks or indefinitely. Unless contraindicated, patients with symptoms of ACS should immediately chew 160 to 325 mg of non–enteric-coated aspirin. A 325-mg aspirin suppository is recommended for patients unable to take oral drugs or for patients with severe nausea, vomiting, or upper GI disorders. Aspirin may cause stomach pain, nausea, vomiting, GI bleeding, subdural or intracranial hemorrhage, thrombocytopenia, coagulopathy, and a prolonged prothrombin time (PT).

The adenosine diphosphate receptor antagonists clopidogrel (Plavix) and ticlopidine (Ticlid) prevent platelet

activation and platelet aggregation, resulting in an irreversible inhibition of platelet function.

- Clopidogrel is indicated to reduce new AMI, new stroke, and vascular death in patients with ACS (both STEMI and NSTEMI) or atherosclerosis as documented by recent stroke, recent AMI, or established peripheral arterial disease (PAD).
- Ticlopidine is used generally for patients who cannot tolerate aspirin.

Guidelines recommend that patients receive a loading dose of clopidogrel at least 6 hours before PCI.[9,10] Patients with a drug-eluting stent (DES) should take clopidogrel for a minimum of 12 months after PCI and in some cases, longer.[9] The dosage for clopidogrel is 75 mg daily with or without food. A loading dose of 300 to 600 mg is often used to achieve a rapid onset of action. The effects of clopidogrel begin immediately; steady-state platelet inhibition is achieved after 3 to 7 days of therapy. Once clopidogrel is discontinued, bleeding times and platelet function normalize within 3 to 7 days. Recently, a subgroup of patients has been identified with altered metabolism, which causes a suboptimal clinical response to clopidogrel. The Federal Drug Administration has identified the need for pharmacogenomic testing to identify patients' altered clopidogrel metabolism.[13] Major adverse effects include bleeding disorders, GI upset, thrombotic thrombocytopenic purpura, and neutropenia. Patients receiving clopidogrel have less GI upset, hemorrhage, and abnormal liver function than patients receiving aspirin. If CABG is planned within 1 week, clopidogrel should be withheld.

With ticlopidine, a dosage of 250 mg is administered twice daily with food to increase absorption and minimize GI irritation. A loading dose of 500 mg can be given to achieve platelet inhibition more quickly. Maximal platelet aggregation inhibition occurs after 4 to 7 days of therapy. Once ticlopidine is discontinued, bleeding times and platelet function normalize within 2 weeks. Major adverse effects include bleeding, neutropenia, agranulocytosis, thrombotic thrombocytopenic purpura, elevated liver aminotransferases, and GI irritation.

Three GP IIb/IIIa inhibitors include abciximab (ReoPro), tirofiban (Aggrastat), and eptifibatide (Integrilin; Table 18-3). These drugs inhibit the GP IIb/IIIa receptor, the final common pathway for platelet aggregation, preventing platelet aggregation and thereby inhibiting thrombus formation. These three drugs are all administered with either enoxaparin or unfractionated heparin. Box 18-2 lists the contraindications to GP IIb/IIIa inhibitors. Adverse effects for this class of drugs include bleeding, thrombocytopenia, stroke, and allergic reactions.

Practice guidelines for PCI intervention recommend a GP IIb/IIIa inhibitor for patients with ACS or NSTEMI who undergo PCI.[14] Guidelines for managing patients with STEMI recommend abciximab as early as possible before PCI.[10]

▲ Antiarrhythmics

Antiarrhythmic drugs are used to restore the heart to a regular rhythm. Many of these medications have serious side effects. Caution must be used to prevent complications. Antiarrhythmics are classified by their effect on the cardiac action potential—whether they block β-receptors; or sodium, potassium, or calcium channels. The action of these drugs is complex; drugs within the same class can work differently, and actions of those in different classes may overlap (Table 18-4). Table 18-5 on page 300 summarizes antiarrhythmic drugs that are commonly used in critical care settings. Refer to Chapter 16 for more specific information regarding the cardiac action potential.

Class I Antiarrhythmic Drugs

Class I antiarrhythmics stabilize the cell membrane by blocking the influx of sodium into the cell. Class I drugs are further categorized on the basis of the action and effects of the specific medications.

Class IA antiarrhythmics include quinidine (Quinate), procainamide (Pronestyl), and disopyramide (Norpace). These drugs are effective for treating atrial rhythms in the short term but may cause life-threatening dysrhythmias by prolonging the QTc interval. They also interact with other drugs commonly used for cardiovascular disease.

Class IB antiarrhythmics are lidocaine and mexiletine (Mexitil). Lidocaine, a less effective but acceptable alternative to procainamide for ventricular dysrhythmias, is no longer used routinely to prevent ventricular dysrhythmias.

Class IC antiarrhythmics are flecainide (Tambocor) and propafenone (Rythmol). Because these drugs are prodysrhythmic and may increase mortality, they are not commonly prescribed.

In general, research data do not support the effectiveness of class I antiarrhythmics. The current trend is to treat ventricular dysrhythmias with class II and class III antiarrhythmics, cardioversion, ablative techniques, and implantable cardioverter–defibrillators (ICDs).[15]

Class II Antiarrhythmic Drugs

β-Adrenergic blockers are class II drugs that interfere with sympathetic nervous system stimulation, contributing to decreased heart rate, prolonged AV node conduction, decreased myocardial contractility, and decreased myocardial oxygen demand. This class of drugs has a broad spectrum of activity and an established safety record and is currently the best class of antiarrhythmics for *general* use.[16] This is the only class of medications shown to reduce the incidence of sudden cardiac death following AMI and HF.

β-Blockers are categorized as cardioselective (inhibition of β_1 receptors) or nonselective (inhibition of β_1 and β_2 receptors). Inhibition of β_1 receptors causes decreased heart rate, slowed conduction through the AV node, and depressed cardiac function. Inhibition of β_2 receptors causes bronchoconstriction, vasoconstriction, and decreased glycogenolysis. Table 18-6 on page 302 indicates the β activity of selected β-blockers.

Unless contraindicated, β-blockers should be given indefinitely to all patients with a history of AMI, ACS, or LV dysfunction with or without symptoms of HF.[14] Other indications include tachydysrhythmias, unstable angina, hypertension, and HF. Acebutolol, esmolol, propranolol, and sotalol are approved to treat dysrhythmias. All β-blockers, except esmolol and sotalol, are indicated for hypertension.

Unless contraindicated, β-blockers should be a part of early treatment for patients with ACSs.[17,18] Metoprolol

Table 18-3 Glycoprotein IIb/IIIa Inhibitors

	Indications	Dose	Concurrent Aspirin and Heparin Therapy	Half-Life
Abciximab	Adjunct to PCI USA that does not respond to conventional therapy and when PCI is planned within 24 h	PCI: IV bolus of 0.25 mg/kg 10–60 min before PCI; then continuous IV infusion of 0.125 mcg/kg/min (maximum 10 mcg/min) for 12 h USA with planned PCI: IV bolus of 0.25 mg/kg; then 10 mcg/min IV infusion for 18–24 h, concluding 1 h after PCI	Yes	First phase, <10 min; second phase, 30 min; remains in circulation up to 10 d in a platelet-bound state
Eptifibatide	ACS: Non–Q-wave AMI or USA, including patients who are managed medically or with PCI PCI	ACS: 180 mcg/kg bolus IV, then 2 mcg/kg/min infusion up to 72 h, discharge, or CABG; if PCI performed, continue IV infusion up to discharge or for up to 18–24 h post-PCI (whichever comes first), allowing up to 96 h of therapy; for patients with a creatinine between 2 and 4 mg/dL, reduce infusion to 1 mcg/kg/min PCI: 180 mcg/kg IV bolus immediately before PCI; then 2 mcg/kg/min IV infusion and a second 180 mcg/kg bolus IV 10 min after the first bolus; continue infusion until discharge or for up to 18–24 h; a minimum of 12 h of infusion is recommended; for patients with a creatinine level between 2 and 4 mg/dL, 180 mcg/kg IV bolus immediately before PCI, then 1 mcg/kg/min IV infusion, and a second 180 mcg/kg bolus IV 10 min after the first bolus	Yes	2.5 h; platelet function returns to normal approximately 4 h after stopping the infusion
Tirofiban	ACS: Non–Q-wave AMI or USA, including patients who are managed medically or with PCI	0.4 mcg/kg/min IV for 30 min, then 0.1 mcg/kg/min IV infusion through angiography or for 12–24 h after PCI; for patients without signs of refractory ischemia who do not proceed to angiography and angioplasty, continue infusion for at least 48 h; for patients with severe renal insufficiency, give half the usual rate of infusion.	Yes	1.4–2.2 h; platelet function returns to near baseline 4–8 h after stopping the infusion

ACS, acute coronary syndrome; CABG, coronary artery bypass grafting; IV, intravenous; PCI, percutaneous coronary intervention; USA, unstable angina.

(Lopressor), atenolol (Tenormin), timolol, and nadolol (Corgard) are approved for angina, whereas metoprolol and atenolol are indicated as first-line drugs for AMI. The first dose may be given intravenously, and successive doses are usually given orally.

β-Blockers are contraindicated in patients with severe asthma or bronchospasm, severe chronic obstructive pulmonary disease, cardiogenic shock, severe LV failure, bradycardia (<60 beats/min), or second- and third-degree heart block. Cardioselective β-blockers are sometimes used with caution for patients with pulmonary disease. It is important to remember that cardioselective drugs lose their selectivity at higher doses.

Adverse effects of β-blockers include bradycardia, heart block, hypotension, HF, bronchospasm, cold extremities, insomnia, fatigue, decreased libido, and depression. Some patients who experience these adverse effects may respond better to a different β-blocker.

Class III Antiarrhythmic Drugs

Class III antiarrhythmic drugs include amiodarone (Cordarone), sotalol (Betapace), ibutilide (Corvert), and dofetilide (Tikosyn). It is important to know each drug's unique properties because individual agents contain unique properties not shared by other class III drugs.

Amiodarone is indicated for treating VT as well as AF and flutter. The advanced cardiac life support (ACLS) algorithms include amiodarone as a first-line option for treating ventricular fibrillation (VF), pulseless VT, wide-complex tachycardia, and AF associated with Wolff-Parkinson-White (WPW)

BOX 18-2 Contraindications for Glycoprotein IIb/IIIa Inhibitors

- Internal bleeding
- Bleeding diathesis within 30 days
- Intracranial neoplasm, arteriovenous malformation, or aneurysm
- Stroke within 30 days or any hemorrhagic stroke
- Thrombocytopenia with prior exposure to tirofiban
- Aortic dissection
- Major surgery or severe trauma within the previous month
- Severe hypertension
- Pericarditis (tirofiban)
- Concurrent use of another glycoprotein IIb/IIIa inhibitor
- Dependence on dialysis or serum creatinine 4.0 mg/dL or more (eptifibatide)

syndrome.[19] Limitations of amiodarone include its variable onset of action, long half-life, intolerable adverse effects, dangerous drug interactions, and life-threatening complications associated with chronic therapy.[15,16]

Ibutilide (Corvert) and dofetilide (Tikosyn) are class III drugs that are indicated for the pharmacological conversion of AF and atrial flutter. Ibutilide inhibits potassium current and enhances sodium current, prolonging repolarization. Dofetilide blocks the rapid potassium current channel, prolonging the action potential duration and refractory period. These drugs may cause a prolonged QT interval and torsades de pointes. Therefore, close monitoring of the QTC is required upon initiation of the medication. These medications have fewer systemic adverse effects than amiodarone and sotalol.

Class IV Antiarrhythmic Drugs

The class IV calcium channel blocker antiarrhythmics, verapamil (Calan) and diltiazem (Cardizem), decrease automaticity of the sinoatrial (SA) and AV nodes, slow conduction, and prolong the AV nodal refractory period. These agents have negative inotropic and peripheral vasodilation effects. In addition, they have antiplatelet and anti-ischemic effects. Calcium channel blockers are primarily indicated for angina, hypertension, and supraventricular tachycardia (SVT). Verapamil and diltiazem are contraindicated for usual forms of VT, severe sinus bradycardia, sick sinus syndrome, WPW syndrome with AF, digoxin toxicity, hypotension, HF, AV conduction defects, and severe aortic stenosis, and they are not standard therapies for AMI. Adverse effects include hypotension, AV block, bradycardia, headache, dizziness, peripheral edema, nausea, constipation, and flushing.

Calcium channel blockers do not decrease mortality after AMI, and in some cases, these medications may be harmful. Calcium antagonists, in general, should be used only in the setting of AMI when β-blockers are contraindicated or maximal dosage has been reached without effect.[20]

Unclassified Antiarrhythmic Drugs

Adenosine is a first-line antiarrhythmic that effectively converts narrow-complex paroxysmal supraventricular tachycardia (PSVT) to normal sinus rhythm by slowing conduction through the AV node. This agent is effective in terminating dysrhythmias due to reentry involving the SA and AV nodes; however, it does not convert AF, atrial flutter, or VT to sinus rhythm. It is also used to differentiate between VT and SVT, treat rare forms of idiopathic VT, and reveal latent pre-excitation in patients with suspected WPW syndrome.[16] The dose is 6 mg rapid IV bolus followed by a rapid saline flush. If the 6-mg dose is ineffective, a dose of 12 mg may be administered twice. The half-life of adenosine is less than 10 seconds; therefore, adverse effects are short-lived.

Magnesium sulfate is the drug of choice for treating torsades de pointes. Magnesium is also used for refractory VT and VF, as well as for life-threatening dysrhythmias from digitalis toxicity. Its mechanism of action is unclear; however, it has calcium channel blocking properties and inhibits sodium and potassium channels. The dose for patients in

Table 18-4 Classification of Antiarrhythmic Medications

Class	Action	Medication Examples
IA	Inhibits fast sodium channel, decreases automaticity, depresses phase 0, and prolongs the action potential duration	Quinidine Procainamide Disopyramide
IB	Inhibits fast sodium channel, depresses phase 0 slightly, and shortens action potential duration	Lidocaine Mexiletine
IC	Inhibits fast sodium channel, depresses phase 0 markedly, slows His-Purkinje conduction profoundly leading to a prolonged QRS duration	Flecainide Moricizine (plus IA and IB effects) Propafenone
II	Depresses phase 4 depolarization, blocks sympathetic stimulation of the conduction system	Esmolol Propranolol Sotalol (plus Class III effects) Acebutolol
III	Blocks potassium channel, prolongs phase 3 repolarization, prolongs action potential duration	Amiodarone Sotalol Ibutilide Dofetilide
IV	Inhibits inward calcium channel, depresses phase 4 depolarization, lengthens repolarization in phases 1 and 2	Verapamil Diltiazem

Table 18-5 Selected Antiarrhythmic Medications

Drug	Antiarrhythmic Indications	Antiarrhythmic Dose	Route	Effect on ECG	Major Adverse Effects
Procainamide	VT, VF; SVTs including WPW syndrome, AF, atrial flutter	IV: 20 mg/min IV infusion (maximum total dose 17 mg/kg). Then infusion of 1–4 mg/min to maintain therapeutic drug level PO: up to 50 mg/kg/d given in divided doses every 3 h to maintain therapeutic drug level	IV, PO	→ QRS → QTI	Hypotension with IV use, asystole, ventricular fibrillation, positive antinuclear antibody test, lupus syndrome, rash, fever, heart block, torsades de pointes, headache, agranulocytosis
Lidocaine	VT, VF	1.0–1.5 mg/kg IV bolus; may repeat 0.5–0.75 mg/kg IV every 5–10 min for total of 3 mg/kg. Then infusion of 1–4 mg/min	IV; ETT if no patent IV (2–4 mg/kg)	None	Bradycardia, blurred vision, hypotension, tremors, dizziness, tinnitus, convulsions, mental status changes
Flecainide	AF and PSVTs (AVNRT, AVRT) in patients without structural heart disease; life-threatening ventricular dysrhythmias (VT)	100–200 mg PO every 12 h	PO	→ PRI → QRS 0/→ QTI	Ventricular dysrhythmias, dizziness, dyspnea, headache, fatigue, nausea, palpitations
Esmolol	SVT including AF and atrial flutter; noncompensatory ST	500 mcg/kg/min IV loading dose for 1 min. Then 50 mcg/kg/min infusion for 4 min. Repeat loading dose every 5 min and increase infusion by 50 mcg/kg/min increments until desired therapeutic effect or maximum of 300 mcg/kg/min.	IV	↓ HR 0/→ PRI 0/← QTI	Hypotension, nausea, diaphoresis, dizziness, headache, weakness, somnolence, heart block, bronchospasm, thrombophlebitis from extravasation
Sotalol	Life-threatening ventricular dysrhythmias (VT, VF); maintenance of NSR in patients with symptomatic AF or atrial flutter who are currently in NSR	80 mg PO twice a day; may be increased to 240–640 mg/d given in two to three divided doses	PO	↓ HR → PRI 0/→ QTI	Bradycardia, AV block, dizziness, HF, bronchospasm, gastric pain
Ibutilide	AF, atrial flutter	1 mg IV infusion over 10 min (<60 kg, 0.01 mg/kg). May repeat either dosage in 10 min	IV	→ QTI	Hypotension, torsades de pointes, VT, BBB, bradycardia, nausea
Dofetilide	AF, atrial flutter; maintenance of NSR after conversion	125–500 mcg PO twice a day depending on creatinine clearance	PO	→ QTI	Torsades de pointes, bradycardia
Amiodarone	Recurrent VF or hemodynamically unstable VT in patients refractory to other drugs; unlabeled uses: AF and maintenance of NSR; SVTs including WPW syndrome; rate control in AF or atrial flutter when other therapies ineffective	IV: Loading infusion of 150 mg over 10 min; 360 mg over next 6 h; 540 mg over next 18 h. May follow with maintenance infusion of 0.5 mg/min. For breakthrough VF or VT, supplemental infusions of 150 mg IV over 10 min PO: Loading dose of 800–1,600 mg daily for 1–3 wk. Then 600–800 mg daily for 1 mo. Maintenance dose 100–400 mg/d	IV PO	→ PRI → QTI	Heart block, cardiac arrest, bradycardia, hypotension, VT, pneumonitis, liver disease, hypothyroidism or hyperthyroidism, photosensitivity, solar dermatitis, blue discoloration of skin, malaise, paresthesias, nausea, vomiting, constipation, visual disturbances, anorexia

Verapamil	PSVTs including WPW syndrome; ventricular rate control in AF, atrial flutter	IV: 5–10 mg over 2 min; may give 10 mg 30 min after first dose PO: 240–480 mg/d in 3–4 divided doses	IV PO	↓ HR → PRI	Hypotension, heart block, HF, bradycardia, headache, dizziness, edema, nausea, constipation
Diltiazem	Ventricular rate control in AF, atrial flutter; PSVT including WPW syndrome	IV: 0.25 mg/kg over 2 min; may give 0.35 mg/kg after 15 min. May follow with an infusion of 5–15 mg/h for up to 24 h	IV for antiarrhythmic indications	↓/0 HR → PRI	Bradycardia, heart block, edema, hypotension, nausea, dizziness, flushing, headache, fatigue
Adenosine	PSVT including WPW syndrome; idiopathic VT; used diagnostically to evaluate VT, SVT, latent pre-excitation	6 mg IV over 1–2 s followed by rapid saline flush. After 1–2 min, may give 12 mg. A second 12-mg dose may be given in 1–2 min if needed.	IV	→ PRI	Facial flushing, light-headedness, headache, bradycardia, dyspnea, heart block, asystole, chest pain, nausea
Atropine	Symptomatic sinus bradycardia, AV block, asystole, bradycardic PEA	Asystole or PEA: 1 mg IV push; repeat every 3–5 min to maximum of 0.04 mg/kg; bradycardia: 0.5–1.0 mg IV every 3–5 min to maximum of 0.04 mg/kg	IV; ETT if not patent IV (1–2 mg)	↑ HR	Palpitations, tachycardia, blurred vision, dry mouth, altered taste, nausea, urinary retention
Digoxin	Ventricular rate control in AF	IV: loading dose of 0.4–0.6 mg with additional doses of 0.1–0.3 mg every 4–8 h. Maintenance dose of 0.125–0.5 mg/d PO: loading dose of 0.5–0.7 mg with additional doses of 0.125–0.375 mg every 6–8 h. Maintenance dose of 0.125–0.5 mg/d	IV PO	↓ HR → PRI ← QTI	Heart block, bradycardia, weakness; toxicity: dysrhythmias, anorexia, nausea, vomiting, headache, fatigue, depression, confusion, hallucination

AF, atrial fibrillation; AV, atrioventricular; BBB, bundle branch block; ECG, electrocardiogram; ETT, endotracheal tube; HF, heart failure; HR, heart rate; IV, intravenous; NSR, normal sinus rhythm; PEA, pulseless electrical activity; PO, oral; PSVT, paroxysmal supraventricular tachycardia; ST, sinus tachycardia; SVT, supraventricular tachycardia; VF, ventricular fibrillation; VT, ventricular tachycardia; WPW, Wolff-Parkinson-White; ↑, increased; ↓, decreased; →, prolonged; ←, shortened; 0, little or no effect; AVNRT, atrioventricular nodal reentrant tachycardia; AVRT, atrioventricular reentrant tachycardia.

Table 18-6 Selected β-Blockers

Medication	Cardioselective	Nonselective
Acebutolol	X	
Atenolol	X	
Betaxolol	X	
Bisoprolol	X	
Carvedilol		X
Esmolol	X	
Labetalol		X
Metoprolol	X	
Nadolol		X

Propranolol		X
Sotalol		X
Timolol		X

cardiac arrest is 1 to 2 g diluted in 10 mL of D_5W given by IV push. Adverse effects include hypotension, nausea, depressed reflexes, and flushing.

Atropine, a parasympatholytic agent, is a first-line drug used to treat symptomatic bradycardia and slowed conduction at the AV node. It is also indicated for asystole or bradycardic pulseless electrical activity (PEA). Atropine reduces the effects of vagal stimulation, thereby increasing heart rate and improving cardiac function. It is important not to increase the heart rate excessively in patients with ischemic heart disease because this may increase myocardial oxygen consumption and worsen ischemia.

Digoxin (Lanoxin) is a mild positive inotrope with antidysrhythmic and bradycardic actions. It inhibits the sodium–potassium pump, causing a rise in intracellular sodium. This rise promotes calcium influx and ultimately enhances myocardial contractility. Digoxin also activates the parasympathetic system, decreasing heart rate and increasing AV nodal inhibition. Digoxin is primarily indicated for patients with both HF and chronic AF.[21] In addition, digoxin may be used to control a rapid ventricular rate associated with non-pre-excitation AF or atrial flutter and in combination with verapamil, diltiazem, or β-blockers for patients without HF.[19,21] Digoxin is not currently used for paroxysmal AF, acute SVTs, or acute LV failure, or as part of inotropic therapy regimens.[21]

The doses and therapeutic blood levels for digoxin are controversial. No longer is it common to administer loading doses.[21] Most patients on digoxin benefit from a low dose, which also reduces the incidence of toxicity.[21] Toxicity is a common occurrence and is frequently associated with serious dysrhythmias. Routine doses are individualized based on the patient's diagnosis, symptoms, underlying disease processes, age, response to therapy, and blood levels. Levels of 0.5 to 1.0 ng/mL are recommended for patients with HF, and levels of 0.8 to 2 ng/mL for those with dysrhythmias.

Signs and symptoms of digitalis toxicity include palpitations, syncope, dysrhythmias, elevated digoxin level, anorexia, vomiting, diarrhea, nausea, fatigue, confusion, insomnia, headache, depression, vertigo, facial pain, and colored or blurred vision. Digitalis levels may be increased by the concurrent use of quinidine, verapamil, amiodarone, captopril, diltiazem, esmolol (Brevibloc), propafenone (Rythmol), indomethacin (Indocin), quinine, or ibuprofen (Motrin). Finally, hypokalemia, hypomagnesemia, and hypothyroidism may predispose patients to digitalis toxicity. Blood serum levels are analyzed if toxicity is suspected.

▲ Inotropes

Cardiovascular function is regulated by two divisions of the autonomic nervous system, the sympathetic and parasympathetic systems. Refer to Chapter 32 to review this information.

Adrenoreceptor stimulation leads to a variety of effects; therefore, it is important to understand which receptors each drug stimulates (Table 18-7).

Inotropic drugs are used to increase the force of myocardial contraction and cardiac output. Inotropic drugs include sympathomimetics, such as dopamine (Intropin), dobutamine (Dobutrex), epinephrine, isoproterenol (Isuprel), and norepinephrine, and the phosphodiesterase inhibitor milrinone (Primacor). These drugs are commonly given to patients with impaired myocardial contractility or cardiogenic shock. Enhanced ventricular contraction increases stroke volume, cardiac output, blood pressure, and coronary artery perfusion. As the ventricles empty more completely, ventricular filling

Table 18-7 Adrenergic Receptors Affecting Cardiovascular Function

Receptor	Location	Effects of Stimulation
β_1	Heart	Positive inotropic (increases contractility) and chronotropic action (increases rate)
β_2	Bronchial smooth muscle	Bronchodilation
	Vascular smooth muscle	Vasodilation
	AV node	Positive dromotropic action (increases conduction velocity)
α_1	Vascular smooth muscle	Vasoconstriction
	Heart	Weak positive inotropic and chronotropic actions
α_2	Presynaptic sympathetic nerve endings	Inhibition of norepinephrine release
Dopaminergic	Kidney and splanchnic vessels	Renal and splanchnic vessel vasodilation

pressures, preload, and pulmonary congestion are decreased. However, as contractility and heart rate increase, myocardial oxygen demand also increases. Myocardial ischemia can occur if a myocardial oxygen supply–demand mismatch develops. The nurse must closely monitor the patient for evidence of ischemia, angina, and onset of dysrhythmias.

Dopamine

Dopamine, the most widely used inotropic drug, is administered to patients with conditions that cause hypotension, decreased cardiac output, and oliguria. Dopamine directly stimulates dopaminergic, β-adrenergic, and α-adrenergic receptors and promotes release of norepinephrine from sympathetic nerve terminals. Dopamine is given by continuous IV infusion, and its dose is titrated to achieve the desired effect. Increased myocardial contractility results from dosages of 3 to 10 mcg/kg/min. Higher dosages predominantly cause vasoconstriction and increased blood pressure. Dopamine is usually given through a central line to enhance its distribution and to avoid extravasation, which may cause local vasoconstriction and tissue necrosis. Adverse effects include tachycardia, palpitations, dysrhythmias, angina, headache, nausea, vomiting, and hypertension.

Dobutamine

Dobutamine acts on β_1 receptors and increases myocardial contractility. Dobutamine also stimulates the β_2 receptors as well as the α_1 receptors. The result is slight vasodilation. Dobutamine is used after cardiac surgery, during some cardiac diagnostic stress procedures, and for patients with HF, shock, or other conditions that cause poor cardiac contractility or a low cardiac output. The dosage for dobutamine is 2 to 20 mcg/kg/min by continuous IV infusion. Adverse effects include tachycardia, dysrhythmias, blood pressure fluctuations, headache, and nausea.

Epinephrine

Epinephrine stimulates α_1, β_1, and β_2 receptors and is given for a variety of indications, including cardiac arrest, symptomatic bradycardia, severe hypotension, anaphylaxis, and shock. In the intensive care unit (ICU), epinephrine is given by continuous IV infusion through a central line, as an IV bolus, or through an endotracheal tube. Continuous IV dosages of 1 to 2 mcg/min stimulate β_1 receptors to increase cardiac output by increasing heart rate and myocardial contractility. At higher dosages, epinephrine stimulates α receptors, causing profound vasoconstriction, increased blood pressure and systemic vascular resistance (SVR), and decreased renal and splanchnic perfusion. Epinephrine may cause dysrhythmias, tachycardia, cerebral hemorrhage, pulmonary edema, headache, dizziness, nervousness, myocardial ischemia, and angina.

Vasopressin is now used as an alternative to epinephrine for treating shock-refractory VF, asystole, or PEA.[19] Vasopressin promotes smooth muscle contraction and increases peripheral vascular resistance. The dosage for patients with cardiac arrest is 40 U given by IV push. The drug may also be given as an infusion. Adverse effects include dysrhythmias, myocardial ischemia, angina, MI, tremors, vertigo, sweating, and water intoxication.

Isoproterenol

Isoproterenol (Isuprel) stimulates β_1 and β_2 receptors to increase myocardial contractility, cardiac output, heart rate, and blood pressure. Currently, isoproterenol is used mainly to increase heart rate after cardiac transplantation. Other indications include refractory torsades de pointes, β-blocker overdose, and symptomatic bradycardia when an external pacemaker is not available. The IV dosage is 0.5 to 10 mcg/min by continuous infusion. Isoproterenol causes a variety of adverse effects, including dysrhythmias, tachycardia, palpitations, myocardial ischemia, hypotension, pulmonary edema, bronchospasm, headache, nausea, vomiting, and sweating.

Norepinephrine

Norepinephrine (Levophed) primarily affects α_1 receptors, causing peripheral vasoconstriction, increased blood pressure, and increased SVR. The increased SVR may actually increase myocardial oxygen demand and work, thus decreasing cardiac output. Norepinephrine is used for patients with cardiogenic shock and significant hypotension accompanied by a low SVR. The dosage is 2 to 12 mcg/min by continuous IV infusion. Adverse effects include tachycardia, bradycardia, dysrhythmias, headache, hypertension, and tissue necrosis from extravasation.

▲ Phosphodiesterase III Inhibitor

The phosphodiesterase III inhibitor milrinone (Primacor) increases contractility, venous vasodilation, and peripheral arterial vasodilation by inhibiting an enzyme that breaks down cyclic adenosine monophosphate. There is a reduction of ventricular filling pressures and a slight reduction of arterial pressure; however, there is minimal affect on the heart rate.

Milrinone is frequently used for the short-term treatment of acute HF. Some patients with HF may be on a milrinone infusion long term at home. The IV bolus dose of 50 mcg/kg is given over 10 minutes and is followed by a maintenance IV infusion of 0.375 to 0.75 mcg/kg/min. Patients who receive milrinone may experience ventricular dysrhythmias, hypotension, headache, bronchospasm, and thrombocytopenia.

▲ Vasodilators

Vasodilators decrease preload and afterload. Preload is the distending force that stretches the ventricular muscle at the end of filling. The greater the stretch, the better the contraction. However, if the cells are overstretched, contractile force decreases. Afterload is the force against which the heart has to work to eject its contents. If afterload is too low, blood pressure and tissue perfusion may be low. If afterload is too high, the heart has to work harder.

Nitrates

Patients with myocardial ischemia or infarction may have an increased preload and afterload, which further strains their

hearts. Nitrates cause peripheral vasodilation, which in turn decreases venous return to the heart and reduces preload. These drugs promote coronary artery vasodilation, improve collateral blood flow, reduce platelet aggregation, enhance perfusion to ischemic myocardium, and decrease myocardial oxygen demand, thus reducing ischemia, chest pain, and infarct size. Nitrates reduce blood pressure and previously elevated pulmonary vascular resistance, SVR, and central venous and pulmonary artery occlusion wedge pressures. At high doses, nitrates reduce afterload by arterial vasodilator effects.

Nitrates are indicated for unstable angina; large anterior AMI; AMI associated with acute and chronic HF, acute pulmonary edema, or hypertension; angina unresponsive to other therapies; and prophylaxis of effort angina. Nitroglycerin has been shown to raise the threshold for VF in the setting of AMI. Contraindications to IV nitrates include, but are not limited to, hypotension, uncorrected hypovolemia, hypertrophic obstructive cardiomyopathy, and pericardial tamponade. When a right ventricular (RV) AMI is suspected, nitrates are used with extreme caution because these patients require an adequate venous return to maintain cardiac output and blood pressure. Patients should not receive nitrates for 24 hours after sildenafil (Viagra), vardenafil (Levitra), or tadalafil (Cialis) use because the resulting drug interactions predispose patients to life-threatening hypotension.

Nitrates are available in a variety of dosage forms. In the ICU, nitrates are often given by the IV, sublingual, or topical routes. An IV nitroglycerin drip is initiated at 5 to 20 mcg/min and increased every 5 to 15 minutes, up to 200 mcg/min, to achieve the desired effects. When used to treat or prevent angina, a 0.3- to 0.6-mg tablet is placed under the patient's tongue and may be repeated twice at 5-minute intervals. The usual dose for nitroglycerin ointment is 1 to 2 inches every 8 hours; however, treatment is often initiated with 0.5 inch and increased gradually to achieve the desired effects.

The adverse effects of nitrates include headache, hypotension, syncope, and tachycardia. Tolerance may develop to the antianginal, hemodynamic, and antiplatelet effects of nitrates, especially with continuous or high-dose therapy; however, dosing regimens that allow for nitrate-free intervals for at least 12 hours may prevent this occurrence.[4]

Sodium Nitroprusside

Nitroprusside (Nipride) is a potent arterial and venous vasodilator that is used to treat severe LV HF, hypertension after CABG, hypertensive crisis, and dissecting aneurysm. Nitroprusside decreases SVR and increases cardiac output. The usual IV infusion dosage is 0.5 to 10 mcg/kg/min; however, to prevent cyanide toxicity, the maximal dose should not be given for longer than 10 minutes. The dose is titrated to effect; if blood pressure does not respond after 10 minutes, the drug is discontinued. Because nitroprusside is sensitive to light, the infusion bag must be covered with an opaque material to prevent the drug's degradation. Adverse effects include hypotension, myocardial ischemia, nausea, vomiting, abdominal pain, and cyanide toxicity.

Nesiritide

Nesiritide (Natrecor), a recombinant form of human B-type natriuretic peptide, is identical to the hormone produced by the left ventricle in response to volume overload and increased wall stress. A venous and arterial vasodilator, nesiritide reduces preload and afterload and increases cardiac output without increasing heart rate. Nesiritide is indicated for acutely decompensated HF with dyspnea at rest or with minimal activity and is often used with IV diuretics. The bolus dose is 2 mcg/kg/min, followed by an IV infusion of 0.01 to 0.03 mcg/kg/min. Contraindications include cardiogenic or distributive shock, valvular stenosis, constrictive pericarditis, and restrictive or obstructive cardiomyopathy. Adverse effects include hypotension, bradycardia, ventricular dysrhythmias, angina, dizziness, and apnea. Nesiritide should not be infused through heparin-coated catheters or IVs containing furosemide (Lasix), insulin, hydralazine (apresoline), enalapril (Vasotec), and bumetanide (Bumex).

▲ Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme (ACE) inhibitors are indicated to treat HF, hypertension, AMI with or without LV dysfunction or failure, and asymptomatic LV dysfunction. They are also used to decrease morbidity and mortality for patients at high risk for AMI, stroke, or cardiovascular death. Unless contraindicated, patients with a STEMI with anterior infarction, pulmonary congestion, or LV ejection fraction (EF) less than 40% should receive an ACE inhibitor within 24 hours of admission to the hospital.[1]

The ACE inhibitors block the conversion of angiotensin I to the potent vasoconstrictor angiotensin II, reduce aldosterone synthesis, and may promote fibrinolysis.[22–29] As a result, these agents mitigate LV remodeling, increase cardiac output, and decrease sodium retention, blood pressure, central venous pressure, SVR, pulmonary vascular resistance, and pulmonary capillary wedge pressure. Numerous research trials conducted in the late 1980s through the early 2000s showed that ACE inhibitors prevent HF, prevent hospitalization due to HF, and decrease mortality.[23–30]

All ACE inhibitors are contraindicated in pregnancy, angioedema, bilateral renal artery stenosis, and pre-existing hypotension. They should be used with caution for patients with renal failure or hyperkalemia. Patients with impaired renal function, hypotension, or concurrent diuretic use should receive a lower dosage. Adverse effects of ACE inhibitors include hypotension, dizziness, angioedema, cough, headache, fatigue, nausea, vomiting, diarrhea, hyperkalemia, and impaired renal function.

▲ Antihyperlipidemics

Cholesterol reduction is an important part of therapy for patients with cardiovascular disease. Patients are encouraged to modify their diet and lifestyle before reverting to drug therapy. The pharmacological management of hyperlipidemia decreases morbidity and mortality from coronary heart disease (CHD).[30–32] Recent evidence suggests

that intensive statin therapy can regress coronary atherosclerosis. The primary target of antihyperlipidemic therapy is low-density lipoprotein (LDL) cholesterol.[32] The goal LDL cholesterol level is (1) less than 160 mg/dL for patients with zero or one risk factor, (2) less than 130 mg/dL for patients with two or more risk factors, and (3) less than 100 mg/dL for patients with documented CHD or diabetes, stroke, and or PAD.[32] An LDL cholesterol goal of less than 70 mg/dL may be preferred for patients at highest risk.

A total cholesterol level of less than 200 mg/dL is desirable, and a high-density lipoprotein (HDL) cholesterol less than 40 mg/dL is considered low. Drug therapy with LDL cholesterol–lowering drugs is recommended for patients with (1) zero or one risk factor and an LDL cholesterol level greater than or equal to 190 mg/dL, (2) two or more risk factors and an LDL cholesterol level greater than or equal to 130 mg/dL, and (3) documented CHD or CHD risk equivalents and an LDL cholesterol level greater than or equal to 100 mg/dL.[32] Drug therapy is also appropriate when triglycerides are 200 mg/dL or greater.[32] Finally, patients with borderline-high triglycerides (150 to 199 mg/dL) and CHD or CHD risk equivalents may receive drugs to raise the HDL cholesterol.

The four major classes of antihyperlipidemic drugs are the following:

- Hydroxymethylglutaryl coenzyme-A reductase inhibitors (statins) decrease total and LDL cholesterol, decrease triglycerides, and increase HDL cholesterol by inhibiting the rate-limiting enzyme that promotes cholesterol biosynthesis.
- Nicotinic acid inhibits lipolysis in adipose tissue and inhibits hepatic production of very-low-density lipoprotein (VLDL) cholesterol, thus decreasing cholesterol, triglycerides, VLDL cholesterol, and LDL cholesterol, as well as increasing HDL cholesterol.
- The bile acid sequestrants bind bile acids in the intestine and form an insoluble complex that is excreted in the feces. Because bile acids are not absorbed, there is ultimately an increased hepatic synthesis of bile acids from cholesterol that may be evident by a slightly increased triglyceride level. However, plasma total and LDL cholesterol actually decrease owing to an increased clearance rate.
- The fibrates inhibit peripheral lipolysis and decrease the hepatic extraction of free fatty acids, which reduces triglyceride production. These agents decrease total cholesterol, triglycerides, and VLDL cholesterol, and they increase HDL-C.

Ezetimibe (Zetia) is a cholesterol absorption inhibitor that selectively inhibits the intestinal absorption of cholesterol. It is used more effectively when combined with a statin to further reduce LDL cholesterol.

Combination drugs have become increasingly popular; therefore, it is essential that nurses know which drugs may be contained within one tablet or capsule. For example, currently available combinations include aspirin and pravastatin (Pravachol), lovastatin (Mevacor) and extended-release niacin, and ezetimibe (Zetia) and simvastatin (Zocor). Future "polypills" may include one pill that contains a statin, an ACE inhibitor, and aspirin.

PERCUTANEOUS CORONARY INTERVENTIONS AND PERCUTANEOUS BALLOON VALVULOPLASTY

▲ Percutaneous Coronary Interventions

Historical Background

Cardiovascular disease is the number one cause of death in the United States. The American Heart Association (AHA) estimates that 81,100,000 Americans have one or more types of cardiovascular disease.[1] The estimated treatment cost of cardiovascular disease to Americans is $503.2 billion per year.[1]

The first major advance in the palliative treatment of coronary artery disease (CAD) was the implantation of an aortocoronary saphenous vein bypass graft in 1967. Since that time, the CABG procedure has been refined and has been the treatment of choice for many patients with CAD. However, the first percutaneous transluminal coronary angioplasty (PTCA), performed by Andreas Gruentzig in 1977, marked another major innovation in CAD treatment.

Since the late 1970s, techniques to treat CAD have expanded beyond PTCA. Today, the term PCI is used to describe less invasive procedures to treat CAD and includes PTCA, laser angioplasty, atherectomy, and stenting. These interventions are described in this chapter.

The path to PCI began in 1964, when Dotter and Judkins introduced the concept of mechanically dilating a stenosis in a blood vessel with a technique of inserting a series of progressively larger catheters to treat peripheral vascular disease. After experimenting with this technique, Gruentzig modified the procedure by placing a polyvinyl balloon on the tip of a catheter; the balloon was passed into a narrowed vessel and then inflated. This revised procedure produced a smoother luminal surface with less trauma than the Dotter-Judkins approach and reduced the risk for complications, including vessel rupture, subintimal tearing, and embolism. Gruentzig performed successful dilation of more than 500 peripheral lesions. He subsequently designed a smaller version of the dilation catheter for use within the coronary arterial tree. Gruentzig performed the first human PTCA in 1977.[2] Improvements in technique and device technology during the past three decades have made PCI the treatment of choice for managing CAD. In 2006, some 1,313,000 PCIs (76% utilizing drug-eluting stents) and 448,000 CABGs were performed in the United States.[1] PTCA is a nonsurgical technique used as an alternative to CABG in treating obstructive CAD. When indicated and if successful, PTCA can alleviate myocardial ischemia, relieve angina pectoris, and prevent myocardial necrosis. PTCA is the hallmark procedure and serves as the basis of almost all other percutaneous intracoronary interventions. During PTCA, a coaxial catheter system is introduced into the coronary arterial tree and advanced into an area of coronary artery stenosis. A balloon attached to the catheter is then inflated, increasing the luminal diameter and improving blood flow through the dilated segment. Several inflations ranging from 30 to 300 seconds may be performed.

Physiological Principles

The process that leads to successful dilation is complex and not clearly defined. Angiographic evaluation and animal and human histological studies indicate that PTCA stretches the vessel wall, leading to fracture of the inelastic atherosclerotic plaque and to tearing or cracking within the intima and media of the vessel. This cracking or slight dissection of the inner lumen of the vessel may be necessary for successful dilation.[2]

Comparisons Between PCI and CABG

As an alternative treatment for CAD, PCI compares favorably with CABG in terms of risk, success rate, the patient's physical capacity after the procedure, length of hospital stay, and cost.[3]

Mortality rates associated with first-time PCI and CABG are somewhat similar. According to the National Healthcare Cost and Utilization Project Statistics in 2007, the in-hospital death rate for patients undergoing PCI was 0.80% as compared to CABG in-hospital death rates of 1.95%.[1] In the event that a second surgical procedure becomes necessary to alleviate the symptoms of progressive CAD, the mortality and complication rates for the bypass procedure are significantly greater than for a second PCI. Seven-year survival data in the Bypass Angioplasty Revascularization Investigation trial revealed that CABG offers a survival benefit to diabetic patients compared with PTCA (76.4% vs. 55.7%). There was no difference in the survival rates of nondiabetic patients with CABG versus PTCA (86.4% vs. 86.8%).[4,5] Three-year outcome data after stenting compared with CABG for the treatment of multivessel disease revealed similar mortality rates.[6,7]

Successful PCI, which is defined as a significant reduction of the luminal diameter stenosis without in-hospital death, MI, or CABG, ranges from 80% to 100%, depending on the severity of the patient's angiographic and clinical presentation. In a study by Bentivoglio and colleagues, the cumulative 2-year survival rates were 96% and 95% among patients with stable and unstable angina, respectively, with event-free survival (ie, no death, MI, or CABG) in 79% and 76%, respectively.[8] Among patients with multivessel PCI, the actuarial survival rates were 97% at 1 year and 88% at 5 years in a study by O'Keefe et al.[9] Seven years after PTCA, Dorros et al[10] reported a survival rate of 90% in patients with simple single-vessel angioplasty and 95% in patients with simple multivessel angioplasty. Long-term survival data in the era of stenting revealed that survival rates remain approximately the same (92% to 97%)[7,11] Data regarding long-term survival in patients who have received DES are being collected at this time.

In the Coronary Artery Surgery Study, graft patency after CABG was 90% at 2 months, 82% at 18 months, and 82% at 5 years. The 10-year survival rate was 82%.[12]

Restenosis or patency data differ greatly between CABG and PCI. Within 6 months after angioplasty, 20% to 30% of lesions recur or restenose. Bare metal intracoronary stenting reduces the incidence of restenosis by an additional 5% to 10%. DES placement further reduces the risk for restenosis to approximately 2%.[13–15] Recently, late loss, defined as late restenosis following DES, has been observed. Stent manufacturers are addressing the concern of late loss through DES platform design and a variety of drug coatings applied directly to the stent. The mean occlusion rate for bypass grafts is approximately 18% during the first 5 years and 4% to 5% in 5 to 10 years.[7]

Psychological advantages of PTCA over surgery may argue favorably for the less invasive procedure. The emotional stress of awaiting dilation is less than that of awaiting surgery. However, this reduction in anxiety is partly offset by the risk for psychological crisis if the angioplasty fails and surgery—especially emergent (immediate) surgery—is needed. The psychological impact of this discouraging situation is significant, but it occurs in a relatively low percentage of cases.

Barring complications with either procedure, PCI requires a hospital stay of 8 to 24 hours, whereas CABG requires a stay of 3 to 7 days. Because the average hospital stay is shorter with PCI and because it is performed in the cardiac catheterization laboratory with the patient receiving local anesthesia, the average cost of PCI may be substantially lower than that of CABG. However, the following factors can increase the cost of PCI:

- Complications occurring during the procedure that necessitate emergency surgery (eg, coronary perforation, acute closure)
- Lesions that recur, requiring repeat dilation, or bypass surgery
- Lesions that require multiple devices to alleviate the lesion
- Complications associated with the anticoagulation regimen or arterial and venous access
- Long-term anticoagulation or antiplatelet therapy

In general, after a PCI, patients can expect a faster return to work (5 to 7 days) as opposed to patients who have had CABG (6 to 8 weeks). Depression in patients following CABG is common, although reports of quality of life in both groups are similar.[16]

In conclusion, the major advantages of PCI compared with CABG may include reduced mortality and morbidity, shorter convalescence, and lower cost to the patient and third-party payers.

Diagnostic Tests for Patient Selection: PCI and CABG

Before deciding between PCI and CABG, all objective evidence of coronary insufficiency must be documented. Noninvasive methods of evaluation that may be used before and after PCI include standard treadmill stress testing and thallium stress and redistribution myocardial imaging. These tests allow the physician to discover the areas of ischemia in the myocardium when the patient is subjected to stress (ie, exercise; see Chapter 17 for a discussion of these tests). It is necessary that nurses familiarize themselves with the results of thallium stress tests because an understanding of the patient's diagnosis, related symptoms, and indications for PCI promotes informed patient care.

Coronary angiography performed by cardiac catheterization, another method of documenting coronary insufficiency, is performed if the previous tests suggest the presence of CAD. Although this procedure is more invasive than treadmill testing and thallium imaging, it is the gold standard test to pinpoint the location of any stenoses and the degree of involvement of the artery or arteries (see Chapter 17 for a

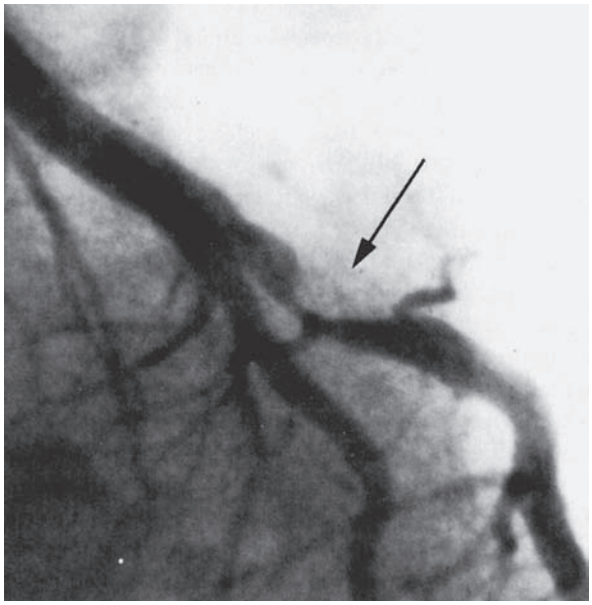

FIGURE 18-1 ▲ An eccentric stenosis in the left anterior descending artery. The term *eccentric* defines a plaque involving only one side of the intraluminal wall. (Courtesy of John B. Simpson, MD, Palo Alto, CA.)

discussion of this test). This procedure yields a 35-mm or digital image of the coronary artery anatomy. The physician can then analyze the areas of narrowing (stenosis) and gain precise information to decide the appropriate treatment (Figs. 18-1 and 18-2).

Equipment Features

Since the introduction of the PCI procedure, the device technology has been refined and improved, resulting in fewer contraindications, lower rates of mortality, and fewer incidences of emergent bypass surgery. The guiding catheters used to direct and support the advancement of the dilation catheter into the appropriate coronary artery ostium have an outer diameter of 5 to 10 French (Fr). The tips of the guiding catheters have curves that are preshaped for selective access to either the right or left coronary artery.

Balloon dilation systems have evolved since Gruentzig's original design, in which the guide wire tip and catheter shaft were integral. In the early days of PTCA, physicians were limited by catheter performance and could address lesions only in the proximal anatomy. In 1982, Simpson introduced a coaxial "over-the-wire" system, an improvement that has become predominant in current catheter designs. The main innovation is an independently movable guide wire within the balloon dilation catheter. This guide wire can be manipulated to select the correct vessel despite side branches and permits safe advancement of the dilation catheter across the lesion. Currently, the available guide wires measure between 0.010 and 0.018 inch in diameter and thus usually pose little threat of interference with the blood flow through a stenosis.

Coronary balloon dilation catheter shafts range in size from 2.0 to 4.2 Fr, small enough for easy passage through the guiding catheter and for visualization around the catheter during contrast injection. Figure 18-3 shows the contrast injection through the guiding wire to verify position. The balloon dilation catheter has one or more radiopaque markers that can be imaged by fluoroscopy, allowing the interventional cardiologist to position the balloon accurately across the lesion. The inflated balloon size ranges from 1.5 to 5 mm wide and from 10 to 40 mm long.

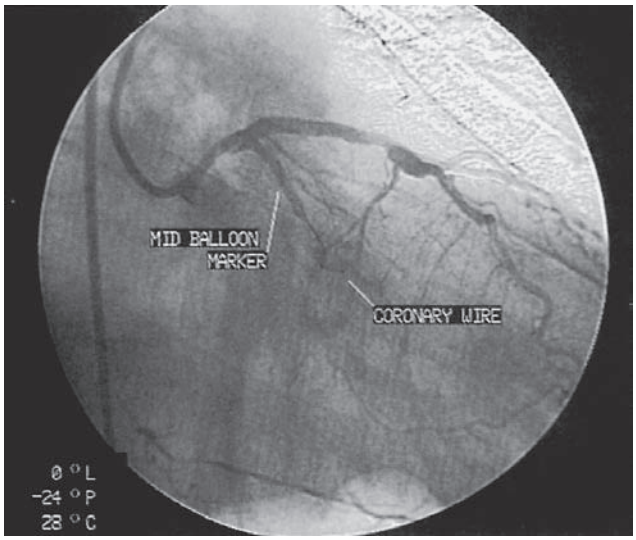

FIGURE 18-3 ▲ Contrast injection through the guiding catheter to verify position. The coronary guide wire tip is located at the occlusion of the circumflex artery, and the coronary balloon is positioned in the proximal vessel. FIGURE 18-4 ▲ Percutaneous transluminal coronary angioplasty (PTCA) balloon dilation catheter illustrating the key components of the system. (Reprinted with permission of Advanced Cardiovascular Systems [ACS] Inc., Santa Clara, CA.)

The size (inflated diameter) of the balloon to be used for a particular PCI procedure is usually the same as the smallest-diameter segment of the coronary artery proximal or distal to the stenosis (ie, 3-mm vessel, 3-mm balloon). Lesion and balloon length also are approximated. Figure 18-4 shows the key components of the PTCA balloon dilation catheter.

The interventional cardiologist manually inflates the balloon with a contrast-filled, disposable inflation device that connects to the side arm or balloon lumen of the coronary dilation catheter. The device incorporates a pressure gauge that indicates the amount of pressure exerted against the balloon wall during inflation. Balloon pressure is measured in pounds per square inch (psi) or atmospheres (atm). The average initial inflation is between 60 and 150 psi or 4 to 10 atm and lasts from 30 to 180 seconds. Longer inflations may promote a smoother, more regular vessel wall as assessed by angiography and are used primarily for treating major dissections and abrupt closure. Extended inflations are performed safely with perfusion catheters that simultaneously dilate and perfuse the coronary artery.

Many factors must be considered when selecting the most appropriate equipment for performing PCI. Technological advances in balloon dilation catheter systems have improved the success and safety associated with PCI and have expanded the clinical and anatomical indications for these procedures.

Many interventional cardiologists consider the coaxial "over-the-wire" system a workhorse catheter because it can approach any anatomy well. However, the interventional cardiologist might select a rapid-exchange system to accomplish more easily the dilation of a bifurcation lesion. This type of device incorporates a "rail" system that facilitates the exchange process. A fixed-wire catheter is used to reach and dilate lesions in distal, tortuous anatomy, and its small shaft also makes it an option for the use of two coronary dilation catheters in one guiding catheter when the strategy calls for side-by-side balloons; this is also referred to as a "kissing balloon" technique.

Each PCI intervention also encompasses an inflation strategy. The main elements of an inflation strategy are the duration and pressure of balloon inflation required to open a lesion. Today, balloons that can withstand greater pressure for treating calcific lesions are available.

The outcome of any PCI procedure is greatly affected by (1) the selection of a guiding catheter that provides a platform for the advancement of the dilation system while preserving flow to the coronary artery and (2) the selection of a balloon dilation system and intracoronary DES that best address the vessel's anatomy and the lesion's location and characteristics.

Indications for and Contraindications to PCI

Indications

When choosing to treat with PCI, the physician's purpose is to alleviate angina pectoris unrelieved by medical treatment and to reduce the risk for MI in symptomatic patients and asymptomatic patients with significant stenosis. Indications for PCI have expanded as device technology, techniques, and operator experience have improved.

PCI may be indicated in coronary arteries that have at least a 70% narrowing. Arteries with less narrowing may not be considered appropriate for PCI because they are equally at risk for abrupt closure, which can have serious consequences. Patients with surgical risk factors, such as severe underlying noncardiac diseases, advanced age, and poor LV function, are particularly suited for PCI because successful dilation obviates the need for an operation that would be poorly tolerated.

An example of the wide spectrum of candidacy for PCI is the accepted practice of treating patients with multivessel disease. The common technique for dilating multiple lesions is to dilate the most critical stenosis first. With successful dilation of this "culprit" lesion, remaining lesions are dilated in stages (ie, at different intervals during the procedure or over several days). However, dilation of multiple vessels is technically more demanding and carries a higher risk for complications.

Another expanded indication is the approach to treating the patient with a totally occluded vessel. Early in PCI practice, acute and chronic total occlusions disqualified a patient for the procedure because the stenosis could not be crossed with the guide wire and balloon dilation catheter without causing severe trauma to the artery. Refinement of device technology and the increased physician experience have allowed dilation of total occlusions attempts in appropriate candidates. Total occlusions of short duration (ie, 3 months or less) are easier to cross and dilate successfully than total occlusions of longer duration (chronic total occlusions).

Additional candidates for PCI are those who have undergone CABG in whom symptoms have recurred because of stenosis and graft closure or progression of coronary disease in the native vessels or in vein grafts. For these candidates, successful PCI makes second surgery, with its increased potential for complications, unnecessary. It is thought that the proliferative disease in the graft wall generates fibrous stenosis that is much less dense than most fibrotic tissue in the native vessels, so certain vein graft stenoses respond favorably to percutaneous intervention.

Historically, patients experiencing an AMI as documented by significant ST-segment elevation, increased cardiac enzyme levels, and pain unrelieved by thrombolysis,

surgery, or pharmacological treatment were treated with complete bed rest in a coronary care unit. Today, if thrombus and underlying stenosis are causing the infarction, thrombolytic therapy, PCI, or both offer alternatives. If a blood clot has impeded flow to the distal myocardium and precipitates an ischemic episode, a thrombolytic agent can be administered intravenously or directly into the coronary artery. On successful lysis of the thrombus, dilation of the underlying stenosis often further enhances blood flow to the reperfused myocardium, reducing the risk for rethrombosis or critical narrowing caused by normal or spastic vasomotion superimposed on an organic stenosis.

Primary PCI is a dilation of an infarction-related coronary artery during the acute phase of an AMI without prior administration of a thrombolytic agent. Meyer et al[17] first used PTCA in the AMI setting in 1982. They reported an 81% success rate in PTCA of the infarction-related artery after intracoronary thrombolytic therapy. In 2006, the TRITON TIMI 38 trial reported a PCI with stenting success rate of 95% and a patency rate of 53% 1 year post PCI.[18] Parameters routinely assessed in patients selected to receive primary angioplasty are depicted in Box 18-3.

In the setting of AMI, PCI may benefit patients deemed ineligible for traditional medical therapy. Such patients include those in cardiogenic shock, those believed to be at high risk for bleeding complications (CVA, prolonged cardiopulmonary resuscitation [CPR], bleeding diathesis, severe hypertension, or recent surgery), and those of advanced age (>75 years). Primary PCI does not preclude the use of thrombolytic therapy if residual thrombus is observed. In fact, AMI patients deemed high risk (extensive ST-segment elevation, new-onset left BBB, previous AMI, Killip Class 2 or greater, anterior MI, or EF ≤ 35%) who receive fibrinolytic therapy at a non-PCI hospital should be transferred as soon as possible to a PCI-capable facility for evaluation and possible intervention. Patients who are not deemed to be at high risk and who receive fibrinolytic therapy at a non-PCI hospital may also be transferred as soon as possible to a PCI-capable facility.[19]

Primary PCI may offer distinct advantages in reducing the length of hospital stay and eliminating the need for additional intervention in many cases. Indications for PCI are summarized in Box 18-4.

Complications of primary PCI include retroperitoneal or vascular hemorrhage, other bleeding requiring transfusion, late restenosis, and early acute reocclusion (subacute thrombosis). These complications occur at approximately the same rate as those experienced in routine elective PCI.

BOX 18-3 Parameters Evaluated in Patients Selected to Receive Primary Angioplasty

- Age
- Hemodynamic status
- Angiographic anatomy:
  - Single-, double-, or triple-vessel disease
  - Vessel involvement: left anterior descending artery (LAD), right coronary artery (RCA), left circumflex artery (LCX)
  - Lesion location ostial: proximal, mid, or distal disease
  - Percent grade stenosis
  - Thrombolysis in myocardial infarction flow: 0, I, II, III
- Left ventricular (LV) ejection fraction (EF) (%)
- Presence of chest pain consistent with acute myocardial infarction (AMI)
- Electrocardiogram (ECG) evidence of AMI:
  - 1-mm ST-segment elevation in two contiguous leads
  - or
  - 1-mm ST-segment depression believed to represent reciprocal changes to an area of infarction

BOX 18-4 Indications and Contraindications for Percutaneous Coronary Intervention

Indications	Contraindications
Clinical	
Symptomatic (angina unrelieved by medical therapy)	
Asymptomatic but with severe underlying stenosis	
Stable/unstable angina	
Acute myocardial infarction	
High-risk surgical candidates	
Anatomical	
Severe stenosis (70% or more)	Mild stenosis (<70%)
Proximal and distal lesions	
Single and multivessel disease	
Bifurcation lesions	
Ostial lesions	
Totally occluded vessels	
Bypass graft lesions	
"Protected" and unprotected left main coronary artery (previous LAD or LCX coronary artery bypass graft)	

LAD, left anterior descending artery; LCX, left circumflex artery.

Contraindications

There are very few contraindications to PCI. Patients with left main CAD were once not considered candidates for PCI. The obvious drawback of PCI in left main artery disease is the possibility of acute occlusion or spasm of the left main artery during the procedure, which would result in severe LV dysfunction. Patients who have a "protected" left main artery (ie, have had previous bypass surgery to the left anterior descending or circumflex arteries with patent grafts present) are often candidates for PCI. One-year clinical outcomes of protected and unprotected left main coronary artery stenting revealed that those who had unprotected left main stenting had increased major adverse cardiac events, and their survival was decreased at 1 year. However, left main stenting should be considered in the absence of other options.[20] For high-risk patients (ie, patients with left main vessel disease, severe LV dysfunction, or dilation of the last remaining patent artery), percutaneous support devices may improve the safety of PCI. These devices include perfusion balloons, intra-aortic balloon counterpulsation, coronary sinus retroperfusion, and cardiopulmonary support.

Procedure

The PCI procedure is carried out in a sterile fashion, with the use of local anesthesia and either the Judkins (percutaneous

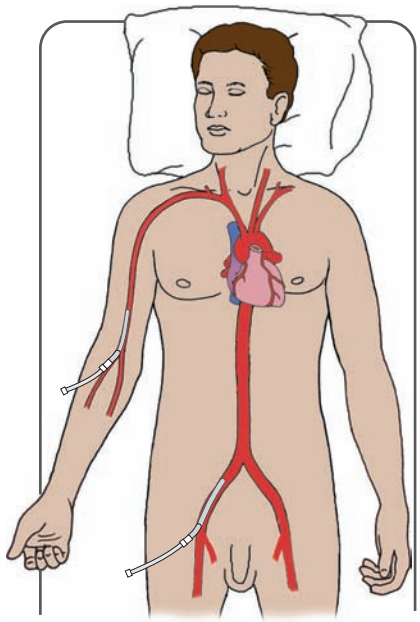

FIGURE 18-5 ▲ Two approaches to left heart catheterization. The Sones technique uses the brachial artery, and the Judkins technique uses the femoral artery. With either method, the catheter is passed retrograde through the ascending aorta to the left ventricle. (Reprinted with permission of Advanced Cardiovascular Systems [ACS] Inc., Santa Clara, CA.)

femoral) approach or, less often, the Sones (brachial cutdown) approach (Fig. 18-5). With the Judkins approach, the interventional cardiologist cannulates the femoral vein and artery percutaneously by inserting a needle (usually 18-gauge) containing a removable obturator. The obturator is then removed to confirm by the presence of blood flow that the outer needle is within the lumen of the vessel. Once proper placement is established, a guide wire is introduced through the outer cannula into the artery to the level of the diaphragm. The cannula then is removed and replaced by a valved introducer sheath. The sheath provides hemostasis and support at the puncture site in the groin and reduces potential arterial trauma if multiple catheter exchanges are necessary. The guiding catheter is preloaded with a 0.038-inch J-wire and introduced into the sheath. The 0.038-inch J-wire is advanced over the arch, and the guiding catheter is advanced over the wire. The 0.038-inch J-wire is removed, and the guiding catheter is rotated precisely to the appropriate coronary ostium. The procedure also may be accomplished by the Sones approach, in which a brachial cutdown is used to isolate the brachial vein and artery. A small arteriotomy is made, and the catheter is passed to the level of the aortic arch.

Regardless of the mode of access, coronary angiography is then carried out in both the left anterior oblique (30 degrees) and right anterior oblique (60 degrees) views. These views allow for visualization of the heart along its transverse and longitudinal planes. Opposing views provide a thorough assessment of both the lesion and the anatomical approach. A "freeze frame" of each view is obtained as a road map or guide throughout the procedure. A final lesion assessment is made, confirming lesion severity and vessel diameter for appropriate balloon and stent sizing.

If PCI is indicated, the patient may be anticoagulated with 5,000 to 10,000 U of heparin to prevent the formation

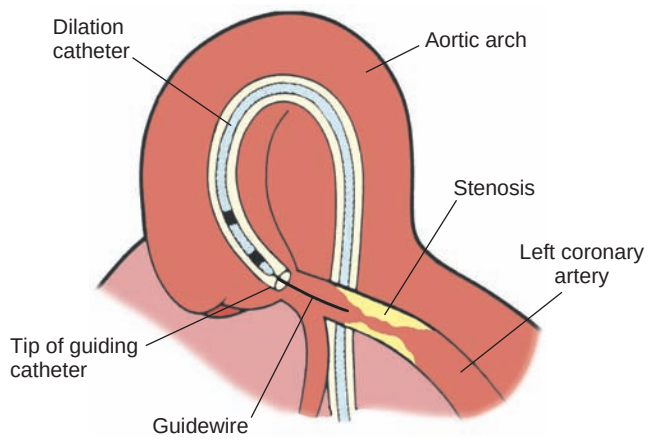

FIGURE 18-6 ▲ The advancement of the coronary dilation catheter to the tip of the guiding catheter, which is positioned in the left coronary artery, is facilitated by fluoroscopy. (Reprinted with permission of Advanced Cardiovascular Systems [ACS] Inc., Santa Clara, CA.)

of clots on or in the catheter system during the procedure. Intracoronary nitroglycerin is kept on the sterile field throughout the procedure and given intermittently as needed for vasospasm and for dilation to facilitate visualization of the culprit coronary artery.

The balloon dilation catheter and intracoronary stent system is introduced into the guiding catheter through a bifurcated adapter that provides access and is a port for contrast injections and aortic pressure measurement. The balloon dilation catheter, stent, and guide wire are advanced to the tip of the guiding catheter while their position is checked by fluoroscopy (Fig. 18-6). The guide wire then is advanced and manipulated to negotiate the branches of the coronary artery. Proper advancement can be confirmed by injecting contrast through the guiding catheter and fluoroscopically visualizing the coronary tree.

Once the guide wire is positioned safely beyond the stenosis, the balloon dilation catheter (with or without a stent) can be advanced slowly over the guide wire into the narrowing without risk for injury to the intima (Fig. 18-7).

Exact placement of the dilation balloon and stent in the stenosis is facilitated under fluoroscopy by the radiopaque marker on the balloon and by contrast injections for visualization. Initially, the balloon is inflated at 1 to 2 atm of pressure to confirm its position. Many PTCA balloon catheters expand at both ends and not in the center, where they are pinched by the stenosis (Figs. 18-8 and 18-9). The central indentation usually disappears as the stenosis is dilated. After each inflation, the interventional cardiologist injects a small bolus of contrast medium to assess any changes in coronary blood flow through the stenosis and to assess any increase in luminal diameter. At this time, the need for additional inflations is determined. Complications, such as vessel recoil and abrupt closure, occur most often during this early phase; however, their incidence is low, and redilation can be performed readily at this time. After dilation is complete, the guiding catheter, balloon dilation catheter, and stent delivery platform are removed. Postdilation angiography is performed to define more clearly the results of the PCI procedure.

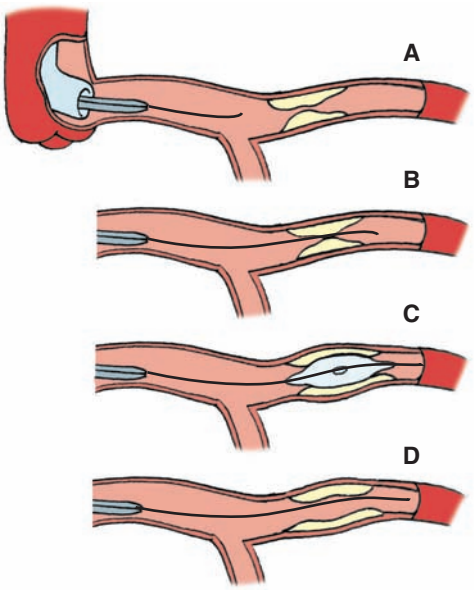

FIGURE 18-7 ▲ **A:** PTCA dilation catheter and guide wire exiting the guiding catheter. **B:** Guide wire advanced across the stenosis. **C:** Dilation catheter advanced across the stenosis and inflated. **D:** Dilation catheter pulled back to assess luminal diameter. (Reprinted with permission of Advanced Cardiovascular Systems [ACS], Inc., Santa Clara, CA.)

Reasons for failure to complete a PCI procedure include inability to cross the target lesion with a guide wire or dilation catheter due primarily to chronic total occlusions, inability to dilate the lesion due to rigid lesions or severe dissection, and embolization of friable vein graft material or of thrombus.

Successful dilation of a lesion commonly is defined as a reduction of the luminal diameter stenosis by about 40% or 50%. Clinical success commonly is defined as angiographic success with clinical improvement and without significant in-hospital complications, such as death, MI, or CABG or repeat PCI for abrupt closure.

Angiography after successful PCI demonstrates an immediate increase in the intraluminal diameter of the involved vessel (Fig. 18-10). Clinical improvement of the patient is demonstrated by improved or normalized myocardial perfusion deficits, as shown by comparison of a post-PCI thallium stress image with the pre-PCI stress image. Post-PCI treadmill test results compared with the preprocedure test results reveal increased exercise endurance and a decrease in exercise-induced angina or angina equivalent.

Results

Excellent short- and long-term results have been achieved in patients undergoing PCI. The results vary depending on the patient's clinical presentation (ie, stable or unstable angina) and angiographic characteristics (ie, subtotal or total occlusion). Among patients undergoing either single-vessel dilation or multivessel dilation, in-hospital clinical success has ranged from 85% to 100%.[8–10] In-hospital complications have been low, with a reported mortality rate of 1% to 2% in both these patient groups.[13] Long-term survival rates have been high, although repeat PCI may be necessary for recurrent or progressive disease. The frequency with which this occurs with DES has decreased dramatically.

Patients with high-risk clinical or angiographic presentations have lower success rates. However, PCI is often

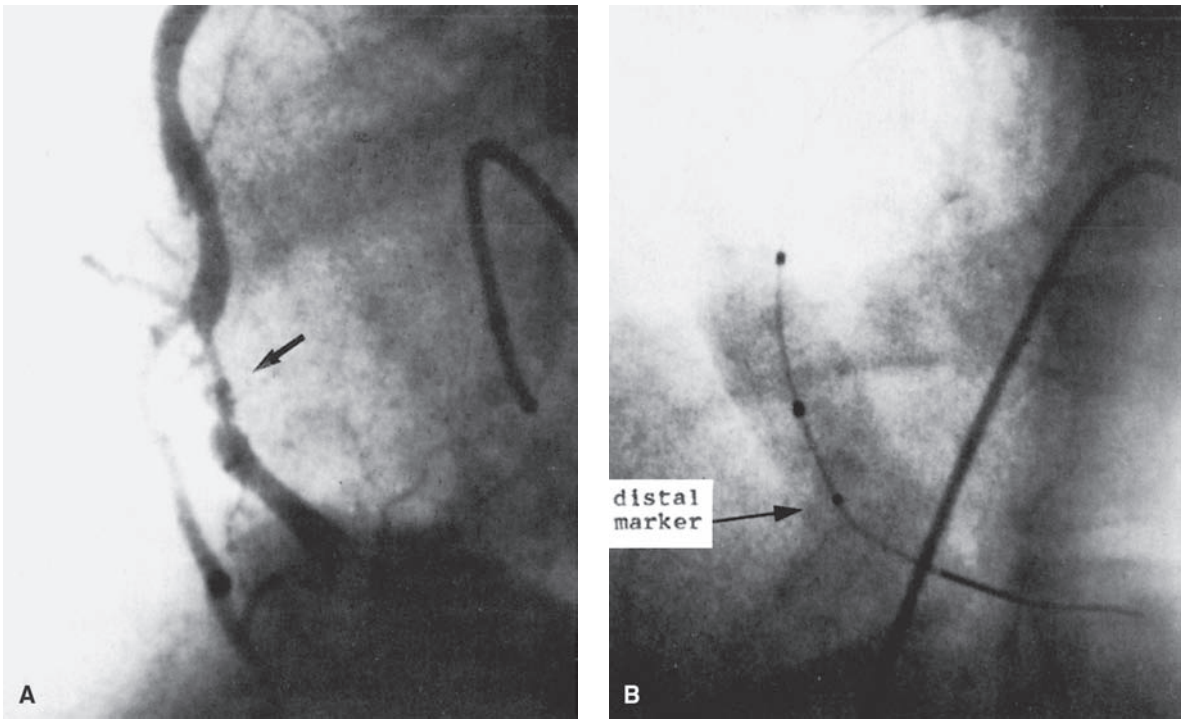

FIGURE 18-8 ▲ Thirty-five-spot frames showing (**A**) stenosis involving the midright coronary artery and (**B**) the first and second radiopaque markers revealing the position of the dilation balloon across the stenosis, with the distal marker referring to the tip of the catheter beyond the narrowing. preferable to surgical revascularization because of the latter's increased risk for mortality in patients, such as older adults or those with depressed LV function. On the other hand, success of a PCI procedure can be defined angiographically, procedurally, or clinically.

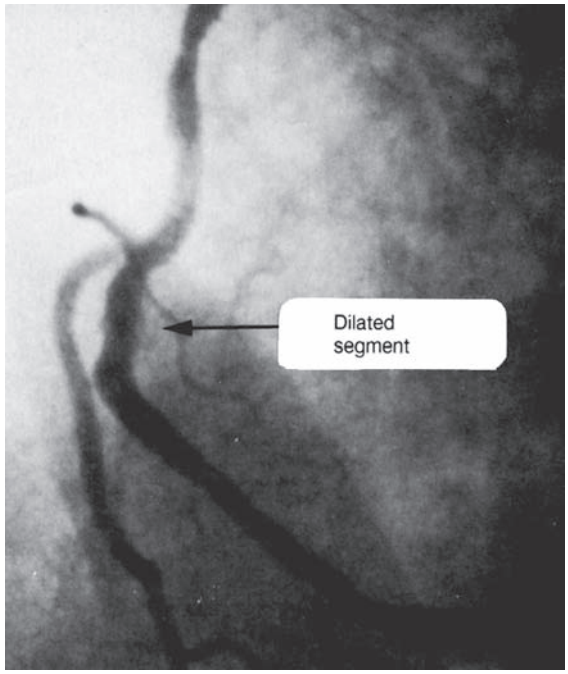

FIGURE 18-10 ▲ Repeat angiography after PTCA of a right coronary artery stenosis showing increased flow and increased diameter of the dilated segment. (Courtesy of John B. Simpson, MD, Palo Alto, CA.)

According to a joint statement by the American College of Cardiology (ACC) and the AHA[19] (2009), these successes are defined as:

1. Angiographic success: A successful PCI procedure is one in which the minimum residual vessel stenosis is less than or equal to 20%.
2. Procedural success: Angiographic success without complications (ie, death, CABG, MI) during the procedure or initial hospitalization.
3. Clinical success: Anatomical and procedural success with relief of the signs of symptoms of myocardial ischemia. Long-term success requires that the relief of the signs and symptoms persists for more than 6 months after the procedure. Restenosis is the principal cause of failure to achieve long-term success.[20]

Assessment and Management

Patient Preparation

When the decision has been made to proceed with any PCI procedure, the patient typically is admitted to the hospital the day of the procedure.

LABORATORY TESTS. The nurse monitors all preliminary laboratory tests, including cardiac enzymes, serum electrolytes, and coagulation studies (PT and partial thromboplastin time), serum potassium, creatinine, and blood urea nitrogen (BUN) levels.

Potassium levels must be within normal limits because low levels result in increased sensitivity and excitability of the myocardium and subsequent dysrhythmias. The cardiac

muscle also is sensitive and becomes irritable when the flow of oxygen-rich blood decreases, as it does for a controlled period of time during placement and inflation of the dilation balloon and stent across the lesion. The irritability arising from hypokalemia, ischemia, or both can give rise to life-threatening ventricular dysrhythmias.

Elevation in the levels of serum creatinine, BUN, or both may indicate problems in kidney function. Good kidney function is important because during PCI, radiopaque contrast material (which permits fluoroscopic visualization of the coronary anatomy and of catheter placement) is introduced into the bloodstream.[21] This contrast material is a hyperosmotic solution that the kidneys must filter and excrete from the blood. High levels of creatinine and BUN may reflect decreased renal filtration capability and vulnerability of the kidney in processing the extra load of radiopaque solution. Instances of acute renal failure have resulted from high doses of radiopaque contrast agent. A study by Rihal et al reported a 3.3% incidence rate of contrast-induced renal failure following PCI. Contrast-induced renal failure occurs more frequently in patients who are diabetic, in patients who are dehydrated, and in patients with higher baseline creatinine levels.[22] The nurse ensures that the patient is adequately hydrated, either orally or with IV solutions, to avoid falsely high electrolyte levels. Trends in creatinine and BUN levels, in conjunction with measurement of urine output, can be used to monitor kidney function.

INFORMED CONSENT. The informed consent for the PCI procedure is obtained from the patient before the procedure after a detailed discussion of the potential complications, anticipated benefit, and alternative therapies. This discussion should be conducted before any preoperative sedation. The nurse plays an important role in answering any questions that the patient and his or her family may have regarding the procedure and follow-up care.

PREOPERATIVE MEDICATIONS. Twenty-four hours before the procedure, the patient's medications should include aspirin, 325 mg once a day, for its antiplatelet effect. Diabetic patients taking metformin should be advised to discontinue this medication before their procedure because it is contraindicated with intravascular contrast agents. Anticoagulants, such as warfarin, are often withheld for a number of days before the PCI procedure. Studies show that administration of clopidogrel before and after a PCI decrease adverse events such as acute closure and subacute thrombosis.[23,24]

SURGICAL STANDBY. Surgical standby for PCI is controversial at this time. Surgical availability is required, but the degree to which the operating room is held for availability varies according to the patient's risk factors, patient acuity, and hospital policies. Many smaller community hospitals across the United States are performing PCI procedures without in-house surgical standby. These patients are typically low risk and reside near larger academic centers that can accept the patient by immediate transfer if complications arise during the PCI. A comparison of patients treated with PCI at hospitals without on-site cardiac surgery with those treated only with thrombolytic therapy reveals that the former group has better clinical outcomes at 1, 3, and 6 months.[25]

Nursing Management During PCI

Both before and during the procedure, nurses in the cardiac catheterization laboratory are responsible for understanding all aspects of equipment use and patient care. They should be experienced in ACLS and be knowledgeable about the proper administration of emergency medications and the correct application of emergency equipment, including the defibrillator, the intra-aortic balloon pump (IABP), the ventilator, and the temporary pacemaker. They observe and communicate with the patient intermittently and report any changes in patient status to the physician. The nurse monitors the ECG and arterial pressure, noting significant changes that may accompany the administration of drugs, symptoms of ischemia, or chest pain. The nurse must recognize signs and symptoms of contrast sensitivity, such as urticaria, blushing, anxiety, nausea, and laryngospasm. The nurse should understand the proper assembly and use of all PCI equipment and should be able to troubleshoot any situation that might arise.

The patient's anticoagulation status during the PCI procedure is of utmost importance. Subtherapeutic levels may result in serious complications, including acute closure or thrombotic events. An ACT should be measured in the catheterization laboratory at baseline (before the PTCA), 5 minutes after the heparin bolus (usually 5,000 to 10,000 U), and every 30 minutes thereafter for the duration of the procedure. ACT levels of 250 to 300 seconds are desirable after the initial heparin bolus. Subsequent boluses of 2,000 to 5,000 U of heparin may be required to achieve and maintain these ACT levels during the PCI procedure.

Patients at high risk for abrupt closure or with unstable lesions, such as in the setting of AMI, may be administered a platelet GP IIb/IIIa antagonist in addition to aspirin and heparin. This is referred to as a "facilitated PCI." These agents are typically initiated just before or during PCI. Eptifibatide (Integrilin) or tirofiban (Aggrastat) should be administered, in addition to aspirin and either unfractionated heparin or LMWH, to patients with continuing ischemia, an elevated troponin, or other high-risk features in whom an invasive management strategy is not planned.[25]

After the PCI is complete, the nurse instructs the patient in the precautions necessary to prevent bleeding from the puncture site (see Box 18-5).

After the procedure, the patient is transferred to a telemetry unit or catheterization recovery area for observation. Common nursing diagnoses for patients undergoing PCI are listed in Box 18-6.

BOX 18–5 TEACHING GUIDE *Precautions for Patients Post-Percutaneous Transluminal Coronary Angioplasty*

The nurse needs to remind the patient to:
- Remain on bed rest for 4 to 6 hours.
- Maintain the involved leg in a straight position (for Judkins technique).
- Avoid an upright position.
- Avoid vigorous use of the abdominal muscles, as in coughing, sneezing, or moving the bowels.

BOX 18–6 EXAMPLES OF NURSING DIAGNOSES

For the Patient Having PCI or Percutaneous Balloon Valvuloplasty (PBV)

- Decreased Cardiac Output related to mechanical factors that affect preload, afterload, and LV function
- Decreased Cardiac Output related to electrical factors affecting rate, rhythm, or conduction
- Decreased Cardiac Output related to structural changes (dissection, thrombus, or arterial spasm at PCI site), resulting in myocardial ischemia or infarction
- Decreased Cardiac Output related to increased preload and pulmonary congestion related to temporary mechanical factors (eg, balloon inflation during PBV)
- Decreased Cardiac Output related to left-to-right shunt with mitral PBV or late cardiac tamponade
- Ineffective Peripheral Tissue Perfusion related to hematoma, thrombus formation, or infection associated with cannulation site
- Acute Pain related to angina or stretching of the valve during dilation
- Deficient Fluid Volume related to renal sensitivity to contrast material or diuretic therapy
- Deficient Knowledge related to illness and impact on patient's future
- Anxiety/Fear related to lack of knowledge of PCI/PBV, acute care environment, and potential for surgery

Nursing Management After PCI

The nurse in the catheterization laboratory recovery area, coronary care, or telemetry unit, plays an important role in observing and assessing the patient's recovery. Post-PCI care is designed to monitor the patient closely for signs and symptoms of myocardial ischemia. The most overt symptom of a possible complication, early recurrence of angina pectoris, requires prompt nursing action.

As soon as possible on receiving the patient from the cardiac catheterization laboratory, the nurse attaches the ECG monitor, which allows a quick initial cardiac assessment and establishes a baseline if the patient's condition should change suddenly. The nurse assesses the patient's status from head to toe, noting the overall skin color and temperature and carefully observing the level of consciousness. After the patient is transferred to the bed and attached to the monitor, the nurse listens closely to heart and breath sounds. The nurse evaluates the peripheral circulation by noting peripheral skin color and temperature and the presence and quality of dorsalis pedis and posterior tibial pulses.

Because the Judkins technique is used most often in PCI to access the vasculature, most patients have an entry port in either the right or the left groin through which sheaths have been placed percutaneously in a vein and artery. If the Sones technique is used, there is an arterial catheter in the brachial area (see Fig. 18-5, p. 310). A variety of mechanical devices and clamps may be used to facilitate hemostasis after sheath removal. The insertion of collagen plugs or the application of a surgical suture around the opening of the blood vessel is also routinely performed to obtain hemostasis. After sheath removal, the nurse pays careful attention to the area distal to the puncture site, checking pulses frequently and reporting immediately to the physician any changes that may indicate bleeding. Bleeding at the sheath site may result in a major hematoma that can require surgical evacuation or compromise distal blood flow to the lower extremity. To prevent excessive bleeding and to aid hemostasis, the physician may order that a 5-pound sandbag be placed over the puncture site after sheath removal if hemostasis is achieved with manual compression.

The nurse instructs the patient on the importance of keeping the involved leg straight and the head of the bed angled at 45 degrees or less. To prevent clotting in the lumens of the introducing sheaths, an IV infusion is attached to the venous sheath, and a pressurized arterial flush is attached to the arterial line. This arrangement also ensures patency should an immediate return to the cardiac catheterization laboratory be necessary because of a complication. The physician chooses both the type of solution to be infused through the venous sheath and the rate of infusion. His or her decision depends on the patient's fluid volume status.

Although initial post-PCI laboratory blood tests vary by institution, they may include coagulation studies, cardiac enzymes, and serum electrolytes. Elevation of the cardiac enzymes can indicate that a silent MI has occurred (ie, infarction unannounced by chest pain). If a cardiac enzyme laboratory value is abnormal, the nurse notifies the physician immediately because the patient's postoperative care might need to be modified to prevent further injury.

The nurse plays a significant role in observing and assessing angina that recurs soon after a PCI procedure. Any chest pain demands immediate and careful attention because it may indicate either the start of vasospasm or impending subacute thrombosis. The patient may describe angina as a burning, squeezing heaviness or as sharp midsternal pain. Other signs and symptoms of myocardial ischemia include ischemic ECG changes (elevation of the ST segments or T-wave inversion), dysrhythmias, hypotension, and nausea. The nurse notifies the physician immediately of any such change in the patient's condition because it is impossible to tell merely by observation whether the change indicates a transient vasospastic episode, which can be resolved with vasodilation therapy, or an acute occlusion requiring emergent intervention (repeat PCI or CABG).

If vasodilation therapy is indicated, it may be administered as described subsequently unless the patient is hypotensive; in that case, vasodilation is contraindicated. At the first sign of vasospasm, the nurse gives oxygen by mask or nasal cannula. For fast, temporary (and possibly permanent) relief, 0.4 mg of nitroglycerin, 5 mg of isosorbide (Imdur), or 10 mg of nifedipine (Procardia) is administered sublingually. In addition, the IV drip of nitroglycerin should be titrated to maintain a blood pressure adequate to ensure coronary artery perfusion and to alleviate chest pain.

With the onset of the chest pain, a 12-lead ECG reading is recorded to document any acute changes. If the angina resolves and any acute ECG changes caused by medical therapy disappear, it is safe to assume that a transient vasospastic episode occurred; however, if the angina continues and the ECG changes persist, redilation or emergency bypass surgery should be considered.

If the post-PCI course is uncomplicated, the sheaths are removed after 2 to 4 hours, and a pressure dressing is applied to the site. A variety of mechanical clamps or hemostasis

BOX 18-7 CONSIDERATIONS FOR THE OLDER PATIENT

Before and After PCI

- Assess whether the patient will have assistance in the home with meals, cleaning, self-care, and transportation to medical appointments.
- Closely monitor kidney function before and after PCI because elderly patients may be sensitive to small amounts of radiocontrast material.
- Monitor vital signs frequently, including temperature, because elderly patients are prone to excessive body heat loss.
- Assess all preexisting comorbidities: arthritis, peripheral vascular disease, diabetes, and so forth.
- Provide clear, precise, written instructions in preparation for discharge.
- Assess patient's ability to purchase/afford required medications.

devices may be used to facilitate hemostasis after sheath removal. Many times, the sheaths are removed before the patient leaves the cardiac catheterization laboratory, and a hemostasis device is utilized. The patient must continue complete bed rest for 4 to 6 hours after the sheaths are removed. A normal, low-sodium, or low-cholesterol diet may be resumed, depending on the preference of the physician and the needs of the patient.

During the recovery period, the nurse can introduce the patient to the rehabilitation process, emphasizing lifestyle modifications to combat the advance of CAD. Efforts should be made during this instruction to reinforce the importance of aerobic conditioning with regular, moderate exercise. Risk factor and secondary prevention are also discussed, including stress reduction, weight loss, and smoking cessation. See Box 18-5 for instructions for the patient after PCI. Box 18-7 describes implications for the older patient.

After PCI, the patient is asked to take medications that help prevent thrombus formation and maintain maximal dilation at the culprit lesion site. Routinely, when all patients are sent home, they should be taking aspirin for the antiplatelet effect. Aspirin is continued indefinitely. Clopidogrel (Plavix) should be administered to patients who receive one or more DESs. Clopidogrel should be continued for at least 12 months and may be administered indefinitely.[23–25] However, in patients taking clopidogrel in whom elective CABG is planned, the drug should be withheld for 5 to 7 days. Often, long-acting nitrates, calcium channel blockers, ACE inhibitors, and lipid-lowering agents are added to the medical regimen. The nurse may be responsible for explaining to the patient the indications for the specific medications ordered by the physician, including side effects and signs of overdose. The nurse should also answer any questions that the patient may have regarding his or her follow-up care. Box 18-8 summarizes medications currently associated with PCI.

Four to six weeks after the patient's discharge, an exercise treadmill stress test and a thallium imaging study may be performed to test the efficacy of the PCI. Compared with the pre-PCI tests, an increase in exercise capacity and a decrease in or disappearance of exercise-induced chest pain (without ST-segment changes) suggest improved blood flow and normalization of cardiac function in the previously hypoperfused muscle. Treadmill stress testing should be repeated at 6 months and then annually after PCI.

Complications

The indications for PCI have expanded to include patients with more severe CAD (ie, total occlusions, multivessel disease, recent or ongoing MI, poor LV function). The rate of complications associated with PCI has not increased. Major complications that can result in ischemia and possible severe LV dysfunction necessitating emergent CABG include angina unrelieved by maximal administration of nitrates and calcium channel blockers (Box 18-8), MI, coronary artery spasm, abrupt closure of a dilated segment, coronary artery dissection leading to occlusion, and restenosis. See Box 18-6 on page 314 for nursing diagnoses for the patient having PCI or percutaneous balloon valvuloplasty (PBV).

Angina, Myocardial Infarction, and Vasospasm

Some degree of angina is anticipated during the PCI procedure owing to the temporary occlusion of the involved vessel during dilation. This angina is handled with intracoronary nitroglycerin or removal of the balloon dilation catheter while the guide wire is left across the lesion. Evidence of persistent chest pain after PCI, reflected in changes in heart rate and blood pressure and elevated ST segments, indicates ischemia predisposing to an insult to the myocardium and requiring immediate intervention. Coronary artery spasm sometimes requires emergent surgical intervention (CABG) when the vasoconstriction, occlusion, or ischemia cannot be reversed by administering nitrates.

Abrupt Closure of Dilated Segment

Abrupt closure is a serious complication of coronary artery dilation that occurs in approximately 3% of those undergoing angioplasty.[15] An estimated 70% to 80% of abrupt closures occur while the patient is still in the cardiac catheterization laboratory. Approximately one third to one half of those patients whose vessel abruptly closes undergo a successful repeat dilation. Abrupt closure can be caused by coronary artery dissection, coronary artery spasm, and thrombus formation. Treatment options include immediate repeat dilation, emergent CABG surgery, or pharmacological therapy. To maintain blood flow through the occlusion while the patient is being prepared for emergent CABG surgery, the physician can use a perfusion balloon catheter, which has side holes along its shaft to allow blood to flow through the catheter at the site of occlusion and perfuse the distal myocardium.

Coronary Artery Dissection

Coronary artery dissection or an intimal tear in the coronary artery can be visualized in the form of intraluminal filling defects or extraluminal extravasation of contrast material. Mild interruptions in the intraluminal wall are an expected result of the splitting and stretching of the intima on inflation of the balloon dilation catheter at the lesion site. However, a dissection may cause a major luminal obstruction associated with coronary artery occlusion, leading to deterioration in

BOX 18-8 Summary of Medications Most Often Associated With PCI

Anticoagulants/Antiplatelets

Aspirin
Indications: Prophylaxis of coronary and cerebral arterial thrombus formation
Actions: Blocks platelet aggregation
Dosage: 80 to 325 mg daily, PO
Adverse effects: (Usually well tolerated) nausea, vomiting, diarrhea, headache, and vertigo occasionally

Heparin (fractionated)
Indications: Prophylaxis of impending coronary occlusion and prophylaxis of peripheral arterial embolism
Actions: Inhibits clotting of blood and formation of fibrin clots; inactivates thrombin, preventing conversion of fibrinogen to fibrin; prevents formation of a stable fibrin clot by inhibiting the activation of fibrin stabilizing factor; inhibits reactions that lead to clotting but does not alter normal components of blood; prolongs clotting time but does not affect bleeding time; does not lyse clots
Dosage: Varies with indications; IV or intra-arterial: 10,000 U at start of PCI
Adverse effects: Uncontrollable bleeding, hypersensitivity

Low–Molecular-Weight Heparin (Enoxaparin Sodium, Dalteparin Sodium)
Indications: Treatment of unstable angina and myocardial ischemia, complete and non–Q-wave myocardial infarction (MI).
Action: Prevents clotting of blood and formation of thrombin.
Dosage
Enoxaprin: 1 mg/kg SC every 12 hours for 2 to 8 days
Dalteparin sodium: 120 mcg/kg SC every 12 hours for 5 to 8 days
Adverse effects: Thrombocytopenia, hematoma, pain or reaction at the injection site, rash, hemorrhage, fever.

Glycoprotein IIb/IIIa Antagonists (Abciximab, Eptifibatide, Tirofiban)
Indications: Prevention of clotting and abrupt closure during interventional procedures and prevention of restenosis.
Action: Blocks the receptor on the platelet membrane that leads to the final common pathway of platelet aggregation.
Dosage
Abciximab: 0.25 mg/kg IV bolus followed by 0.125 mcg/kg/min infusion for 12 to 24 hours after PCI
Eptifibatide: 135 mcg/kg IV administered immediately before PCI followed by 0.5 mcg/kg/min for 20 to 24 h
Tirofiban: 180 mcg/kg IV bolus followed by 1.2 to 2 mcg/kg/min infusion for 72 to 96 hours after PCI
Adverse effects: Thrombocytopenia, hemorrhage, nausea, hematoma

Clopidogrel (Plavix)
Indications: Reduction of atherosclerotic events (AMI, stroke, and vascular death) in patients with atherosclerosis documented by a recent stroke or AMI or established peripheral arterial disease
Action: Blocks platelet aggregation
Dosage: 75 mg once daily
Adverse effects: Diarrhea, rash, gastrointestinal (GI) disturbances, hemorrhage, neutropenia.

Coronary Vasodilators

Isosorbide Dinitrate (Isordil, Sorbitrate)
Indications: Prophylaxis of angina
Actions: A nitrate that acts as a smooth muscle relaxant; causes coronary vasodilation without increasing myocardial oxygen consumption; secondary to general vasodilation, blood pressure decrease
Dosage
Sublingual: 2.5 to 10 mg every 2 to 3 hours PRN angina
Oral: 5 to 40 mg four times daily.
Sustained-action oral: 40 mg every 6 to 12 hours
Adverse effects: Cutaneous vasodilation that can cause flushing; headache, transient dizziness, and weakness; excessive hypotension

Nitroglycerin
Indications: Control of blood pressure and angina pectoris
Actions: Potent vasodilator; affects primarily the venous system; selectively dilates large coronary arteries increasing blood flow to ischemic subendocardium
Dosage
Sublingual: 0.3 to 0.4 mg PRN chest pain
Topical (patch): 2.5 to 10 mg/d; indicated for primary, secondary, or nocturnal angina due to more sustained effect
Intravenous: 5 mcg/min to start—titrate to patient response (no fixed dose due to variable response in different patients)
Adverse effects: Excessive and prolonged hypotension; headache; tachycardia, palpitations; nausea, vomiting, apprehension; retrosternal discomfort

Calcium Channel Blockers

Nifedipine (Procardia), Diltiazem (Cardizem)
Indications: Treatment of angina pectoris resulting from coronary artery spasm and fixed vessel disease; hypertension; dysrhythmias
Actions: Inhibits calcium ion flux across the cell membrane of the cardiac muscle and vascular smooth muscle without changing serum calcium concentration; decreases afterload through peripheral arterial dilation and
1. Reduces systemic and pulmonary vascular resistance
2. Vasodilates coronary circulation
3. Decreases myocardial oxygen demands and increases myocardial oxygen supply

Dosage
Nifedipine: 10 to 30 mg three to four times daily, PO
Diltiazem: 30 to 90 mg three to four times daily, PO
Adverse effects: Contraindicated in patients with sick sinus syndrome; hypertension after IV use; GI distress; headache, vertigo, flushing; peripheral edema, occasional increase in angina, tachycardia

See pages 297–302 for full discussion of antiarrhythmic medications.

blood flow with resultant severe ischemia or MI that requires emergent bypass surgery.

Stent Thrombosis

As the number of stent implantations increased, so has the incidence of stent thrombosis. The Food and Drug Administration (FDA) met in 2006 and concluded that there appeared to be an issue of late stent thrombosis with drug-eluting stents, but the magnitude was deemed uncertain, and off-label use of the DES, as with bare metal stents, is associated with increased risk when compared with on-label use. The panel also agreed that, in the future, new DES studies should have longer follow-up, enroll greater numbers of patients, and include stent thrombosis as a study end point. The advisory panel concurred with the joint clinical practice guideline recommendation for 12 months of dual antiplatelet therapy after placement of a DES in patients who are not at high risk of bleeding.[23]

There is some evidence, however, that DESs may be susceptible to an event known as "late stent thrombosis." Late stent thrombosis is defined as a blood clot inside the stent that occurs 1 or more years after stent implantation. While this has been seen rarely in both the Taxus and Cypher stents, thrombosis is extremely dangerous, even fatal. To prevent subacute thrombosis (SAT), poststent antiplatelet therapy is crucial, and patients should be carefully and repeatedly instructed not to stop taking aspirin, Plavix, or Ticlid without consulting their interventional cardiologist. The FDA concluded that more information is needed, especially in the use of devices in off-label settings. However, when DESs are used as directed, no greater risks of death or heart attack are reported. Current recommendations and guidelines suggest that antiplatelet medications (aspirin and Plavix or Ticlid) must be continued for a minimum of 1 year assuming the patient has no history of bleeding complications.

The development of devices to remove atherosclerotic plaque (atherectomy catheters) and implantable devices to maintain the opening mechanically (stents) has provided effective adjuncts or alternatives to PTCA for the problem of recurring lesions. Restenosis of de novo lesions after atherectomy is similar in character and prevalence to that in PTCA; however, intracoronary stenting has resulted in a lower restenosis rate in native and vein graft lesions of approximately 10%.

The cause of restenosis still is unclear. It appears to be the result of an excessive healing response to balloon dilation that exposes the subintimal structures of the vessel to circulating blood. These exposed areas are then potential sites for platelet adhesion and aggregation and for thrombus formation. The degree of this "healing" response varies from lesion to lesion and may be influenced by the clinical and angiographic factors associated with restenosis that were discussed previously. Factors associated with increased incidence of restenosis are listed in Box 18-9.

Other Complications

Other major complications of PCI requiring medical intervention are coronary perforation, which may be treated with a sheathed stent to stop the leak of blood into the pericardium; bradycardia, which requires temporary pacing; VT or VF, which requires immediate defibrillation; and a central nervous system event causing transient or persistent neurological deficit.

Peripheral vascular complications occurring primarily at the catheter site include arterial thrombosis, excessive bleeding that causes a significant hematoma, pseudoaneurysm, femoral arteriovenous fistula, and arterial laceration. If any of these complications persists or compromises distal blood flow to the involved extremity, surgical intervention may be required.

Table 18-8 summarizes the complications that may result from PCI, including general signs of the complications and possible interventional actions.

Box 18-10 provides a complete outline of care for the patient undergoing PCI.

BOX 18-9 Factors Associated with Increased Incidence of Restenosis

Clinical Factors
Severe angina
Noncompliance with antiplatelet regimen
Diabetes
Smoking cigarettes
Substance abuse
Uncontrolled hyperlipidemia

Angiographic Factors
Lesion location
Lesion length
Lesion severity before and after PCI
Adjacent arterial diameter
Gaps between overlapping stents

Other Interventional Cardiology Techniques

The immediate and long-term efficacy of PCI in treating symptomatic patients with single-vessel disease has been well established. In many centers, PTCA also is routinely and successfully used in patients with multivessel disease. The safety and efficacy with which angioplasty has been used have fostered research into treating patients with unstable angina, AMI, and cardiogenic shock.

Technologies have been developed to address the challenges associated with complex PCI. These include laser angioplasty, thrombectomy devices, atherectomy devices, DES, brachytherapy, and distal protection devices.

Laser Angioplasty

The acronym LASER stands for "light amplification through stimulated emission of radiation." Through a series of mirrors and lenses, the laser beam is directed into a catheter containing numerous glass fibers. These fibers transmit the light energy through the catheter to the plaque that is to be ablated.[26] The laser is used to ablate plaque or as an adjunct to other PCI procedures to make a pathway in total occlusions to facilitate the passage of a PTCA balloon or stent.

Laser angioplasty is performed much like a standard PCI procedure. The guide catheter is advanced to the ostium

Table 18-8 Complications of PCI

Complications	General Signs/Symptoms	Possible Interventions
Angina	Chest pain or anginal equivalent	CABG or repeat PCI
Myocardial infarction (MI)	Dysrhythmias: tachycardia, bradycardia, VT/fibrillation, ST elevation	Redo PCI Oxygen
Abrupt reclosure Dissection/intimal tear	Marked hypotension Acute ECG changes (ST-segment change)	Medications: vasodilators (nitrates), calcium channel blockers, analgesics, anticoagulants, vasopressors
Hypotension	Nausea/vomiting	Intra-aortic balloon pump (IABP)
Coronary branch occlusion	ST-segment elevation	Possible repeat PCI
Restenosis	Angina pectoris Positive exercise test	Redo PCI Coronary artery bypass graft
Marked change in heart rate: bradycardia, VT, ventricular fibrillation	Rate below 60 beats/min Rate above 250 beats/min No discernible cardiac rhythm Pallor Loss of consciousness Hypotension	Temporary pacemaker Defibrillation Medications: antiarrhythmics, vasopressors
Vascular: excessive blood loss	Hypotension Decreased urine output (from hypovolemia) Decreased hemoglobin/hematocrit Pallor Hematoma at puncture site	Possible surgical repair Fluids Transfusion Oxygen Flat in bed
Allergic	Hypotension, urticaria, nausea/vomiting, hives, laryngospasm, erythema, shortness of breath	Medications: antihistamines, steroids, antiemetics Clear liquids/NPO Oxygen With anaphylaxis: fluids for volume expansion, epinephrine, vasopressors for hypotension
Central nervous system events	Changes in level of consciousness Hemiparesis Hypoventilation/respiratory depression	Oxygen Discontinue/withhold sedatives Medication: narcotic antagonist as a respiratory stimulant Computed tomography, magnetic resonance imaging

Miscellaneous complications: conduction defects, pulmonary embolism, pulmonary edema, coronary air embolism, respiratory arrest, febrile episode, nausea, minor bleeding.

BOX 18–10 *COLLABORATIVE CARE GUIDE for the Patient Undergoing PCI*

Outcomes	Interventions
Oxygenation/Ventilation	
Patient will maintain normal arterial blood gases, or pulse oximeter reading.	• Provide supplemental oxygen per face mask or nasal cannula per hospital post-PCI protocol. • Monitor blood gases/pulse oximeter per protocol. • Auscultate breath sounds when taking vital signs. • Monitor for signs of pulmonary edema or respiratory distress.
Circulation/Perfusion	
The patient will have stable vital signs following PCI.	• Monitor blood pressure, heart rate, respiration rate, arterial puncture site, distal pulses, and distal motor function and sensation: every 15 min × 4, every 30 min × 4 every 1 h × 4, then every 4 h
There is no evidence of post-PCI myocardial ischemia or infarction due to coronary reocclusion (eg, no ECG changes or angina).	• Monitor cardiac rhythm in leads specific to myocardium most affected by PCI location. • Administer medications to treat coronary artery spasms (eg, nifedipine and nitroglycerin).
There is no evidence of cardiac dysrhythmias after PCI.	• Administer heparin per protocol. • Report type and frequency of dysrhythmias. • Administer antiarrhythmic medication as indicated and ordered. • Temporary transvenous or external pacemaker and defibrillator are readily available.

(*continued on page 319*)

BOX 18–10 *COLLABORATIVE CARE GUIDE for the Patient Undergoing PCI (Continued)*

Outcomes	Interventions
There is no evidence of bleeding at the puncture site.	• Monitor site for hematoma as above with vital signs. • Assess for tenderness, ecchymosis, and warmth over puncture site. • Apply direct pressure to puncture site for 15–30 min after sheath is removed. • Apply sandbag to puncture site if oozing continues, per hospital protocol. • Apply a pressure dressing to puncture site when oozing has stopped. • Monitor activated clotting time, prothrombin time, partial thromboplastin time, and platelets, reporting coagulopathies per protocol.
There is no evidence of arterial occlusion at puncture site.	• Monitor involved extremity with vital signs for mottling, coolness, pallor, diminished pulses, numbness, tingling, pain, and so forth.
Fluids/Electrolytes	
Patient is euvolemic.	• Monitor intake and output. • Obtain type and cross-match, complete blood count, electrolytes prior to PCI. • Maintain IV patency.
Renal function is maintained after administration of radiographic IV contrast agent.	• Obtain pre-PCI and post-PCI blood urea nitrogen, creatinine, and electrolyte levels. • Closely monitor urine output; report if <30 mL/h. • Monitor urine specific gravity or osmolarity for clearance of IV contrast. • Administer diuretic agents as ordered.
Mobility/Safety	
	• The patient is on bed rest for 4–6 h post-PCI per hospital protocol. • While sheath is in place and while on bed rest, keep head of bed <45 degrees.
Skin Integrity	
Patient's skin will remain intact.	• Assess skin immediately after PCI for pressure areas. • Reposition to relieve pressure from bony prominences, maintaining alignment of extremity involved in procedure. • Consider pressure relief/reduction mattress.
Nutrition	
Nutritional intake is reestablished.	• Resume oral fluids and diet per protocol. • Monitor swallowing and protective airway reflexes while patient is receiving sedatives or narcotics.
Patient does not experience nausea or vomiting after PCI.	• Monitor nausea and vomiting. • Administer antiemetic medication as appropriate.
Comfort/Pain Control	
Patient will not experience anginal pain.	• Instruct patient to verbally report discomfort and pain. • Evaluate severity and location of pain, distinguishing angina from other causes of discomfort. • Administer nitrates or narcotics per order or protocol for angina. • Evaluate patient response to medication.
Patient will not experience pain from mobility restrictions.	• Reposition patient frequently, keeping involved extremity straight. • Use mattress overlay or egg crate for comfort. • Administer analgesics as appropriate, after distinguishing joint or muscular pain from angina.
Psychosocial	
Patient and family state risks associated with PCI. Patient uses personal support systems to reduce anxiety.	• Provide information for informed procedural consent. • Encourage verbalization of questions, concerns, and fears. • Encourage significant other to visit in early postprocedural recovery phase. • Validate patient/significant others' understanding of surgery and illness. • Initiate referrals to social services, clergy, and so forth as necessary.
Teaching/Discharge Planning	
Patient and family are prepared for possibility of emergent repeat PCI or cardiac surgery. Patient cooperates with post-PCI mobility restrictions. Patient states lifestyle changes required to reduce risk for worsening coronary artery disease.	• Preprocedure teaching includes discussion regarding causes for coronary reocclusion or perforation and rationale for surgery or repeat PCI. • Provide preprocedure and postprocedure instruction and rationale for bed rest and limited movement of involved extremity. • Provide verbal and written instruction/information regarding risk factors and pathophysiology, activity, diet, stress reduction, medication administration, and appropriate times/indications to seek medical attention.

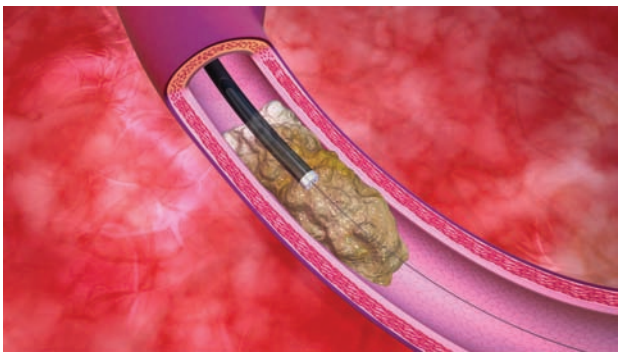

FIGURE 18-11 ▲ LASER ablation of a coronary artery stenosis.

of the coronary artery targeted by fluoroscopy. Once the lesion location is ascertained through contrast injection, a guide wire is advanced up and through the lesion. Before the laser is activated, everyone in the room (including the patient) must don protective eyewear. The laser catheter is then advanced through the guide wire and brought into contact with the lesion. Depending on anticipated lesion morphology, energy settings are chosen that will presumably suffice to ablate the plaque. The laser settings include the fluency (millijoules per square millimeter) to be delivered and the repetition rate (pulses per second). The plaque is then vaporized by the laser energy. Several passes down the length of the lesion may be performed. Laser success is determined by fluoroscopy and coronary injections with contrast dye. If there is residual stenosis after use of the laser, adjunctive PCI procedures, including stenting, can be performed to achieve an optimal final result (Fig. 18-11).

Stenotic lesions best suited for laser angioplasty include those that are long and diffuse (longer than 15 to 20 mm), ostial in location, highly calcified, in vein grafts, and totally occluded. Risks associated with laser angioplasty include perforation of the coronary artery, dissections, and aneurysms. Now considered a "niche" procedure, laser angioplasty is performed less frequently in the percutaneous treatment of cardiovascular disease.

Atherectomy

Atherectomy is the process of removing atherosclerotic plaque from the coronary artery by cutting or ablating and thus "debulking" the lesion. Atherectomy devices include directional coronary atherectomy (DCA) and rotational ablation (Rotablator).

Potential complications of all atherectomy devices include perforation of the coronary artery, abrupt closure, embolization distal to the lesion site, and MI. The rate of restenosis and other complications is comparable to that with standard balloon angioplasty and less successful than those results achieved with DESs.

Directional Coronary Atherectomy

The directional coronary atherectomy (DCA) device is a cutting catheter that is inserted over a guide wire into the coronary artery across the stenotic lesion. It is positioned so that the opening for the blade faces the lesion. A low-pressure balloon on the opposite side of the catheter is inflated, thus forcing the atherosclerotic plaque into the opening near the cutting blade. The cutting blade turns at approximately 1,200 revolutions/min (rpm) and is then slowly advanced along the length of the lesion, cutting the plaque and collecting it in the catheter nosecone. The DCA catheter is turned a complete 360 degrees in the artery to shave all sides of the atherosclerotic plaque with repeated passes. The procedure is repeated until the atherosclerotic plaque is sufficiently removed. The catheter, laden with plaque, is then withdrawn from the patient.

Rotational Ablation Device

The Rotablator device (Boston Scientific, Natick, MA) is a high-speed rotating, abrasive, burr-tipped catheter that ablates the atherosclerotic plaque in the coronary artery. The Rotablator has proved especially effective for complex stenotic lesions that are calcified, tortuous, small in diameter, ostial, or diffuse in character. The device consists of a football-shaped, diamond-studded burr attached to a drive shaft. The Rotablator is advanced over a guide wire to the lesion site. The burr rotates at 160,000 to 190,000 rpm and pulverizes the atherosclerotic plaque into microparticles that are absorbed into the patient's circulatory system. The spinning burr is advanced across the lesion several times to debulk the stenotic lesion. Adjunctive balloon angioplasty may be performed after use of the Rotablator device.

The AngioJet device (Possis) is a thrombectomy system used to extract clot from coronary arteries, saphenous vein grafts, or peripheral arteries. The system consists of three components: (1) the drive unit (Fig. 18-12A); (2) the pump set, which achieves isovolumetric balance between the fluid and thrombus that is removed from the artery and the fluid that is delivered (see Fig. 18-12B); and (3) the catheter, which is disposable and 4- to 6-Fr compatible (see Fig. 18-12C). The AngioJet System has been shown to be safe and effective in removing fresh clot from patients undergoing PCI for AMI[27] and in instances in which there is clot in saphenous vein grafts.[28]

Stents

Intracoronary stents are hollow stainless steel tubes that act as "scaffolding" in the coronary artery. After predilation with a PTCA balloon catheter, most stents are premounted on a balloon catheter and inserted through the guide catheter along a guide wire to the lesion site. Once placed across the stenotic lesion, the balloon is inflated, and the stent is expanded and left in the coronary artery.

Traditional and older stent designs are bare metal. Because many bare metal stent designs use stainless steel, they are potent thrombogenic prostheses. Stent thrombus is a major short- and long-term complication. Success of the stenting procedure depends on endothelialization of the stent to provide a smooth flow of blood in the coronary artery and through the stent yet controlled to prevent stent thrombosis. Anticoagulation and antiplatelet medication regimens are crucial to successful stenting and long-term prognosis. Stenting has been shown in numerous trials to reduce restenosis rates and improve long-term prognosis. Stents made of newer alloys and compounds are currently undergoing investigation. There are three main

components to a DES: (1) the type of stent that carries the drug coating, (2) the method by which the drug is carried (eluted) to the blood vessel wall, and (3) the drug itself. DESs are coated with drugs such as heparin, paclitaxel, sirolimus, or rapamycin. It is believed that the gradual release of these drugs into the coronary vasculature at the site of the atherosclerotic plaque inhibits restenosis by limiting smooth muscle cell proliferation and inflammation but allowing reendothelialization to proceed normally. At this time, the FDA-approved DESs include a sirolimus-coated stent known as Cypher (Johnson & Johnson, Cordis) (Fig. 18-13). Another stent, known as Endeavour (Medtronic), uses a cobalt chrome Driver stent with a phosphorylcholine coating of zotarolimus. Xience V (vee) (Guidant, Abbott) uses an L605 cobalt chrome ML Vision stent and adds a fluoropolymer multilayer coating with the drug everolimus and the paclitaxel-coated stent called Taxus (Boston Scientific) (Fig. 18-14).

The interventional cardiologist must make several important decisions that lead to a successful stent implantation. These include:

- Correct sizing of the stent length to match the length of the lesion
- Correct sizing of the stent diameter to match the thickness of the normal sections of the coronary artery

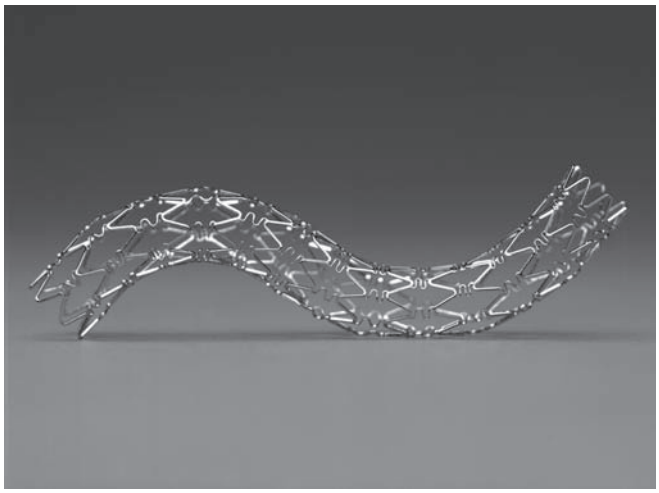

FIGURE 18-13 ▲ Fully expanded Cypher stent. Used with permission of Cordis Corporation.

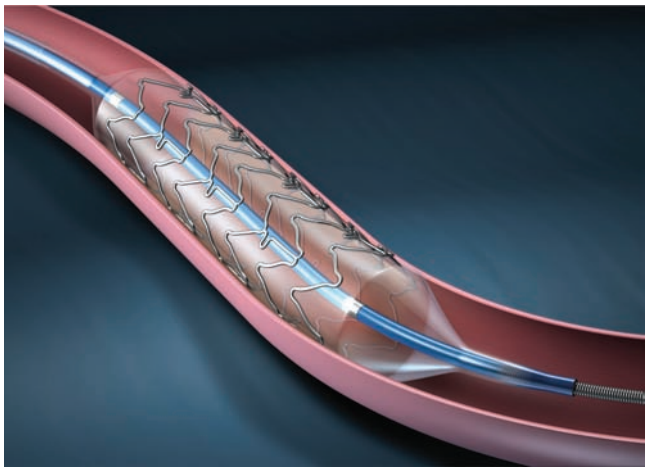

FIGURE 18-14 ▲ XIENCE V everolimus-eluting coronary stent. (Courtesy of Abbott Vascular. © Abbott Laboratories. All rights reserved.)

- Accurate and complete deployment of the stent. Underexpansion of the stent can result in tiny gaps between the stent and arterial wall, which can lead to serious problems such as SAT. Other complications following implantation of bare metal stents or DESs may include bleeding at the access site, stent migration, coronary artery dissection, and abrupt closure.

Brachytherapy

Intracoronary radiation (brachytherapy) is potentially a potent antiproliferative therapy that is currently being investigated for use with PCI and might therefore provide a means for effective reduction of restenosis. The radiation therapy is emitted in the form of temporarily implanted or inserted radioactive sources, such as seeds, radioactive stents, or radioactive liquid–filled balloons. Radiation works particularly well in inhibiting new growth by attacking the newer, more aggressive neoplastic cells, while often having little effect on normal tissue.[29] In brachytherapy, endovascular low-dose radiation is applied at the site of balloon dilation or stent implantation by a catheter system. Two types of radiation are used to treat restenosis: gamma and beta emitters. Gamma emitters create a radiation field for a considerable distance away from their source. This requires that the treatment be conducted in a heavily lead-shielded cardiac catheterization laboratory. Gamma-emitter intensity is lower than that of beta emitters, and gamma emitters must be left in place 14 to 45 minutes, depending on the strength of the source used. Beta sources, with a higher intensity of radiation near the source, can be more concentrated, enabling the brachytherapy to last only 3 to 10 minutes. The beta source can be shielded only with approximately 0.5 inch of polymerized methyl methacrylate (Lucite). The FDA currently approves the use of brachytherapy only for in-stent restenosis.

Distal Protection Devices

Distal embolization of particulate matter can complicate PCI and peripheral interventional procedures. Tiny microemboli can be showered distally (downstream of the lesion) during revascularization procedures. This can cause end-organ ischemia, AMI, serum cardiac enzyme elevation, stroke, and LV dysfunction. Distal protection devices are designed to reduce or eliminate distal embolization during PCI and peripheral interventions. Distal protection devices are often used during PCI of saphenous vein grafts and during carotid procedures.

To date, the only distal protection devices approved by the FDA are the PercuSurge GuardWire (Medtronic, Santa Rosa, CA) and the FilterWire (Boston Scientific) (Fig. 18-15). The PercuSurge device consists of a guide wire with a low-pressure occlusive balloon on the distal end. The balloon is inflated to prevent distal embolization, and an aspiration catheter removes the debris from the treated vessel before the balloon is deflated and antegrade flow is restored. The FilterWire device contains a low-profile filter mounted on an angioplasty wire. The filter contains small holes that permit antegrade blood flow while trapping microemboli and thus providing distal protection. Because these distal protection devices are quickly becoming the standard of care for degenerated saphenous veins grafts and carotid stenting, device manufacturers may seek indications for use in ACS interventions and other peripheral procedures in the near future.

▲ Interventions for Peripheral Arterial Disease

PAD is a condition that affects approximately 12 million Americans.[30] The disease results from the accumulation of plaque in the arteries. It constricts normal blood flow and can result in heart attack, stroke, extremity amputation, and death if left untreated. Patients with PAD have a 5-year mortality rate of 30%.[31] Refer to Chapter 19 for a discussion of aortic aneurysms and PAD and Chapter 22 for surgical management of carotid disease (endarterectomy). Until recent advances in technology made minimally invasive and percutaneous approaches possible, medical or surgical intervention for these cardiovascular diseases was the only option.

Remote endarterectomy is a minimally invasive endovascular procedure for complete superficial femoral artery revascularization. It provides treatment of lower extremity arterial disease and serves as an alternative to bypass surgery. The benefits of the remote endarterectomy approach are (1) preservation of the native vessel, (2) less invasive than surgery, (3) no limitation of future surgical options, (4) potentially faster and easier recovery for the patient compared with bypass procedures, and (5) comparable long-term clinical outcomes to surgical endarterectomy.

Percutaneous treatment is an emerging approach in PAD management. Angioplasty, atherectomy, and stenting of the carotid arteries, aorta, renal arteries, iliac and femoral arteries, and upper extremities are routinely performed in many medical institutions. Before undergoing a percutaneous intervention, most patients require magnetic resonance angiography, arterial duplex mapping, or angiography. Percutaneous

transluminal angioplasty of the peripheral arteries involves placing a balloon in the blood vessel at the site of the blockage and inflating the balloon to open the blood vessel. Stents can also be inserted into the blocked vessel to serve as scaffolding in opening it. Thrombolytic therapy can also be delivered to the site of the blockages before initiating angioplasty or stenting. Atherectomy, or debulking the peripheral blood vessels, has also been shown to be beneficial in some cases before angioplasty or stenting.

Abdominal aortic aneurysms and thoracic aortic aneurysms can also be treated percutaneously. Endovascular stent grafts are metal-lined fabric tubes that reinforce an aneurysm in a blood vessel. It essentially relines the blood vessel and decreases the incidence of aneurysm rupture. The stent graft seals tightly above and below the aneurysm (Fig. 18-16). The graft is stronger than the weakened aorta and permits blood to pass through without exerting pressure on the aneurysm. Patients are candidates for endovascular stent grafting if aneurysms measure 5 cm wide, the aneurysm and aorta contour are conducible to stent grafting, and the blood vessels are large enough to pass guiding catheters, angioplasty balloons, and the stent graft. Potential complications of endovascular stent grafting include endoleaks (leaking of blood around the graft), migration of the stent graft, infection, and restenosis.

Postprocedure care of the patient with PAD is similar to that of patients undergoing PCI of the coronaries. Groin incision observation, extremity assessment, and vital sign measurement are important components of postprocedure care. Patient education and discharge planning should include aggressive management of cardiovascular risk factors, such as smoking cessation, reduction of blood glucose levels, exercise regimens, and lowering of blood pressure and cholesterol level. Antiplatelet therapy is also indicated for the patient undergoing percutaneous treatment of PAD.

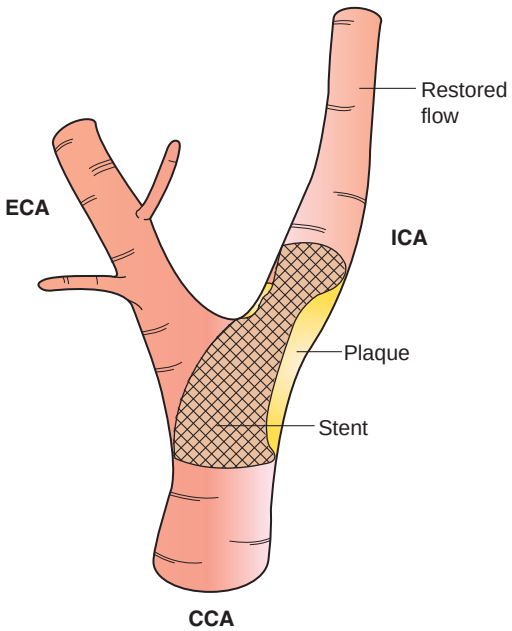

FIGURE 18-16 ▲ Endovascular stent graft (AAA). CCA, common carotid artery; ECA, external carotid artery; ICA, internal carotid artery.

With the various tools and technologies available to the interventional cardiologist, as well as improved adjunctive pharmacological therapy, the future should bring further improvement in the efficacy and predictability of PCI and in the long-term patency of involved atherosclerotic vessels in the coronary system and in the peripheral arterial system.

▲ Percutaneous Balloon Valvuloplasty

PBV is a nonsurgical technique for increasing blood flow through stenotic cardiac valves using dilation catheters. This procedure is similar to PCI procedures in that a catheter system is inserted percutaneously and advanced to the region of narrowing using fluoroscopic guidance. A dilation catheter then is inflated to increase the valvular opening and improve blood flow.

Historical Background

The first cases of balloon dilation of stenotic cardiac valves were reported in 1979 and 1982, when physicians successfully dilated pulmonary valve stenoses. This technique was considered an effective alternative to open heart surgery, although long-term results could not yet be evaluated. Because surgical commissurotomy was successful in treating mitral valve stenoses and because of the initial success with pulmonary valve dilation, physicians began percutaneous dilation of mitral valves in 1984 to avoid the need for thoracotomy. These procedures improved cardiac function with no serious procedural complications.

The number of PBVs does not approach the volume of PCI procedures. This is due partly to the lesser incidence of valve disease compared with CAD.

Assuming patients have long-term clinical improvement associated with PBV, the advantages compared with surgery are similar to those of PCI versus CABG. PBV is less traumatic, requires no anesthesia, is associated with lower morbidity and a shorter hospital stay, causes no scarring, and is less expensive. Minimally invasive surgical procedures are also available and include mini-thoracotomy approaches.

Pathophysiology of Stenotic Valves

Stenotic valves are caused by calcific degeneration, congenital abnormalities, or rheumatic heart disease. Calcific aortic and mitral valve degeneration now appears to be the most frequent causes of valve disease requiring surgical treatment. Refer to Chapter 22 for a discussion of the pathophysiology and surgical management of specific stenotic valves.

Diagnostic Tests for PBV and Valve Replacement

Before deciding on the appropriate intervention, the physician evaluates the patient for evidence and severity of valvular stenosis. A variety of noninvasive tests allow the physician to determine the degree of left atrial or LV hypertrophy, pulmonary venous congestion or hypertension, valvular rigidity,

and transvalvular gradient. In a 12-lead ECG, the magnitude of the R wave in the left precordial leads reflects the presence of LV hypertrophy associated with AV stenosis. The presence of broad, notched P waves in leads I, II, and aVL reflects left atrial hypertrophy associated with mitral valve stenosis. A chest radiograph illustrates the presence of calcium in or around the valve, LV or atrial hypertrophy, and pulmonary venous congestion or HF. A two-dimensional echocardiogram is used to scan the cardiac valves and chambers. A Doppler ultrasound study allows measurement of the transvalvular gradient, indirect calculation of valve area, and assessment of valvular regurgitation. With this information, the physician is able to (1) estimate the size of the valve orifice, (2) visualize the degree of valve leaflet movement, and (3) determine the extent of LV or atrial hypertrophy.

Right and left heart catheterization is performed if the previous tests indicate valvular disease. Although this procedure is invasive, it is required to determine the pressures within each of the cardiac chambers and to confirm transvalvular gradients. Once the pressures and gradients are obtained, a series of radiographs may be taken by injecting radiopaque contrast medium, either in the aorta to visualize aortic regurgitation or in the left ventricle to visualize mitral regurgitation. This procedure yields a cineangiogram illustrating the function of the cardiac valves and chamber sizes.

After this series of tests, the physician can analyze the valves closely, gaining precise information with which to decide the treatment mode. The nurse should be familiar with the results of these tests because a better understanding of the patient's diagnosis and related symptoms, and thus of the reasons for intervention, promotes better care.

Equipment Features

Although PBV and PCI catheters are based on similar designs, there are important differences, primarily because of the larger diameters of heart valves compared with coronary arteries. One major difference is the outer diameter of the catheters. PBV catheter shafts range from 7 to 9 Fr PBV balloons range from 15 to 25 mm in diameter when inflated. A 10- to 14-Fr introducing sheath may be used at the arterial or venous puncture site to allow for introduction of the valve dilation catheter.

A large guide wire, 0.035 to 0.038 inch, also is used to provide the added stiffness and support required to introduce the dilatation catheter. PBV dilation catheters have radiopaque markers similar to PCI catheter systems for fluoroscopic imaging.

Indications for and Contraindications to PBV

The use of PBV initially was limited by the fear of embolization of calcific debris, disruption of the valve ring, acute valvular regurgitation, and valvular restenosis. The incidence of these complications continues to be a concern. Both major and minor complications have been reported in numerous early studies; however, these complications must be assessed in terms of the patient population in which the procedure is performed.

BOX 18-11 Indications and Contraindications for PBV

Clinical Indications
- High-risk surgical patients (advanced age, severe pulmonary hypertension, renal failure, pulmonary dysfunction, LV dysfunction)
- Unstable presurgical patients
- Patients not candidates for chronic anticoagulation

Anatomical Indications
- Moderate to severe valvular narrowing
- Moderate to severe valvular calcification
- Mild valvular regurgitation

Anatomical Contraindications
- Inability to access vasculature
- Thrombus
- Severe valvular regurgitation
- History of embolic events

Although surgical valve replacement is an effective treatment for those with aortic valve stenosis and operative mortality rates are low, the operative mortality rate significantly increases in patients with multisystem disease (often, these are older patients). PBV initially has been proved a safe and efficacious alternative for these patients. It also is an effective therapy for children who are high surgical risks because it delays the need for surgery until the child is older and can better tolerate an operation. In addition, the longevity of both mechanical and bioprosthetic valves is approximately 10 to 20 years, so PBV delays or prevents the need for a second operation. Also, the long-term anticoagulation therapy required with mechanical valve prostheses is undesirable in younger patients and pregnant women. PBV also is effective for stabilizing those with poor LV function before surgery; it is contraindicated in patients with moderate to severe valvular regurgitation due to a small but significant risk for increasing valvular insufficiency with the procedure (Box 18-11).

A complication associated with PBV is excessive bleeding at the puncture site due to the large catheters required to perform dilation. The development of smaller catheters may reduce the incidence of bleeding. As with PCI, PBV catheters are being refined continually to increase procedural safety, time, and efficacy.

Procedure

The procedure is performed in the cardiac catheterization laboratory and involves many of the same steps as PCI (see earlier section on PCI procedure). Right and left heart catheterization is repeated to evaluate hemodynamic status and to obtain baseline transvalvular gradients. Coronary angiography, when indicated, is repeated to determine whether the patient still meets the criteria for valvuloplasty. Thorough repeat evaluation is necessary because a patient's status can change, precluding treatment with this intervention.

The angiographic catheter is replaced either by an introducing sheath or a dilation catheter. In mitral PBV, a venous puncture is made in the right femoral vein. During both aortic and mitral PBV, maintaining patent IV and radial or

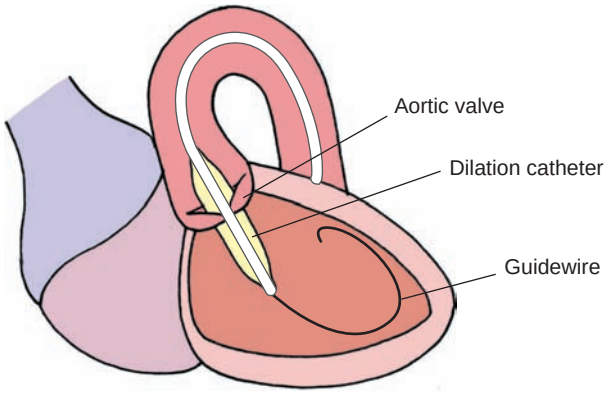

FIGURE 18-17 ▲ Cross-sectional view of heart illustrating guide wire and dilation catheter positions across the aortic valve. The guide wire is curved to prevent ventricular dysrhythmias or puncture.

femoral arterial lines is important to administer medications and draw blood samples.

In aortic PBV, once the sheaths are in place, the patient is anticoagulated with 5,000 to 10,000 U of heparin to prevent clot formation in the catheter system. The dilation catheter and guide wire then are advanced to the root of the ascending aorta. The guide wire is advanced across the stenotic aortic valve, and the dilation catheter is advanced over the guide wire (Fig. 18-17). Exact placement of the dilation catheter is facilitated by fluoroscopy and radiopaque markers on the balloon.

In mitral PBV, a pacing catheter may be positioned through a separate venous sheath at the level of the inferior vena cava or right atrium and placed on standby. The mitral valve then is approached either by way of the femoral artery and aortic valve or, in most cases, through the right heart by perforating the atrial septum to enter the left atrium. Once the mitral valve has been accessed, the patient is anticoagulated with 5,000 to 10,000 U of heparin. The dilation catheter is then advanced over the guide wire through the atrial septal puncture and across the mitral valve (Fig. 18-18). Again, exact placement of the dilation catheter in the valve is facilitated by fluoroscopy and radiopaque markers on the balloon.

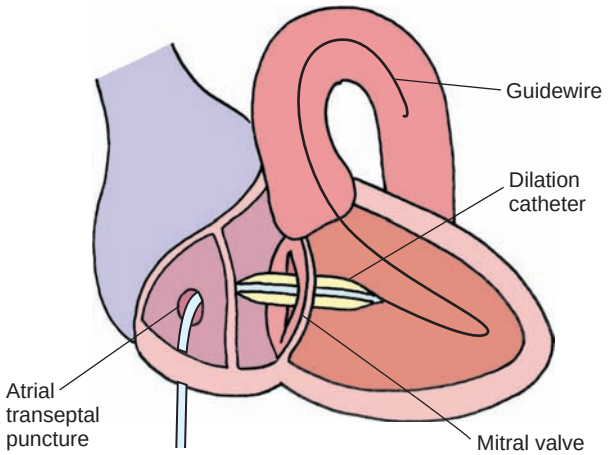

FIGURE 18-18 ▲ Cross-sectional view of heart illustrating guidewire and dilation catheter placed through an atrial transseptal puncture and across the mitral valve. The guide wire is extended out the aortic valve into the aorta for catheter support.

Average inflation time of the dilation catheter is 15 to 60 seconds in aortic valvuloplasty and 10 to 30 seconds in mitral valvuloplasty. During dilation of either valve, the nurse monitors blood pressure closely because of the imposed decrease in cardiac output. Once the dilation catheter has been deflated, blood pressure should return to normal. During dilation of the mitral valve, there is a temporary increase in the pulmonary artery occlusion pressure (PAOP; formerly known as pulmonary artery wedge pressure [PAWP]). Once the dilation catheter has been deflated, the PAOP should return to baseline. Dysrhythmias, such as VT, VF, or sinus bradycardia, also may occur during dilation.

Once maximal dilation has been obtained, the catheter is removed. Hemodynamic measurements, including transvalvular gradients, are repeated to determine efficacy of the procedure. Repeat angiography is performed to assess for valvular regurgitation. When the procedure is complete, the anticoagulant effects of heparin are reversed to prevent bleeding complications associated with the large puncture site.

Results

Aortic PBV is associated with a decrease in pressure gradient and end-systolic volume and an increase in aortic valve area, EF, and cardiac output. Although there is an increase in the aortic valve area, it is not as great as with surgical valve replacement. In addition, the restenosis rate associated with PBV is high. Therefore, aortic valvuloplasty is indicated primarily for older and high-risk surgical patients and generally is considered a palliative, not a curative, procedure.

Results of mitral valvuloplasty are more dramatic. There is a more significant increase in valve area and cardiac output and a decrease in valve gradient, PAOP, and mean pulmonary arterial pressure. Three mechanisms have been postulated for improving valvular function due to PBV: (1) fracture of calcific nodules adherent to leaflets (most frequent), (2) separation of fused commissures, and (3) stretching of the annulus and leaflet structure.

Assessment and Management

Patient Preparation

The patient is admitted to the hospital the day of the PBV procedure. The goal of nursing care is to reduce the cardiac workload, monitor fluid and electrolyte balance, and reduce psychological stress so that the patient remains hemodynamically stable.

In most cases, the patient does not have invasive pressure monitoring lines in place before the procedure. The nurse therefore carefully monitors signs and symptoms of HF: narrowing in the arterial pulse pressure, more frequent increases in heart rate during activity, peripheral edema, presence of a cough, complaints of dyspnea, or rales in lung fields. The nurse also must note any changes in sensorium, color, skin temperature, and pulse volume, and any decrease in urinary output. To monitor fluid and electrolyte balance, the nurse obtains a baseline serum electrolyte level and baseline body weight. In addition, daily fluid intake and output are recorded.

The patient's medications before admission may have included diuretics, digoxin, and anticoagulants. Before the procedure, any anticoagulant medication is discontinued because of the possibility of emergency surgery. Therefore, patients with chronic AF who have the potential for systemic embolization due to thrombus should be monitored closely. The nurse also monitors preliminary laboratory tests and notifies the physician of any abnormalities. (See the section on patient preparation for PTCA for further information on these tests.)

After the patient fully understands the procedure, the physician must obtain an informed consent for PBV, anesthesia, and surgery. Surgical standby usually is provided during PBV due to possible complications requiring emergency valve replacement.

Nursing Assessment and Management During PBV

The nurse continuously monitors pulmonary artery pressure and PAOP and is aware of changes in tracings that may suggest symptoms of HF or pulmonary edema. In the presence of severe hypotension, the nurse should be prepared to start an IV infusion of dopamine or norepinephrine (Levophed). In the case of ventricular dysrhythmias, a lidocaine drip should be available for infusion.

Nursing Assessment and Management After Percutaneous Balloon Valvuloplasty

The nurse is important in the patient's recovery. The goal of postvalvuloplasty nursing care is to maintain adequate cardiac output, maintain fluid and electrolyte balance, and verify hemostasis at the puncture site. Alterations in cardiac output can be caused by dysrhythmias secondary to valve manipulation, resulting in edema near the bundle of His; left-to-right atrial shunt through the transseptal puncture created during mitral valvuloplasty; cardiac tamponade; alteration in circulating fluid volume; or blood loss. Alteration in fluid and electrolyte balance results from diuretic therapy and contrast medium used during catheterization. Bleeding at the puncture site is secondary to the combined effect of systemic anticoagulation and the large diameter of catheters used.

Because fluids are important in the hemodynamic balance of the patient with valvular disease, the volume of IV fluids is recorded to establish an accurate intake and output. The decreased circulating volume from diuretic medications given before PBV, combined with improved stroke volume after successful PBV, can be reflected as a decrease in cardiac output. Therefore, careful monitoring of central venous pressure, pulmonary artery pressure, PAOP, and blood pressure, in addition to heart rate, urinary output, and electrolyte balance, is essential in the evaluation and assessment of circulating fluid volume and cardiac pumping status.

In addition, the nurse assesses the patient's status from head to toe, noting overall skin color and temperature and carefully observing the level of consciousness and neurological signs. The nurse also listens closely to heart and breath sounds. Circulation distal to the puncture site is evaluated by noting peripheral skin color and temperature in addition to the presence and quality of the dorsalis pedis and posterior tibial pulses.

Finally, any drainage appearing on the puncture site dressing or tenderness during palpation should be noted to establish a baseline for the possibility of increased pericatheter bleeding. The nurse reports immediately any changes that may indicate excessive bleeding. Bleeding at the sheath site may result in a hematoma requiring surgical evacuation. To prevent excessive bleeding and to aid hemostasis, the physician may order a sandbag or clamp placed over the puncture site.

If the patient has documented CAD, the physician also may request a serum cardiac enzyme panel. Particular attention should be paid to creatine kinase (CK) and CK isoenzymes (see Nursing Management After Percutaneous Coronary Interventions). The nurse should be aware of the signs and symptoms of myocardial ischemia in addition to the appropriate interventions.

The nurse instructs the patient about the importance of keeping the involved leg straight for the first few hours after valvuloplasty.

Post-PBV laboratory evaluation may include PT, hemoglobin and hematocrit, coagulation studies, serum electrolytes, CK, ECG, and chest radiograph. Box 18-6, under Nursing Management During Percutaneous Coronary Interventions, lists nursing diagnoses and collaborative problems for patients undergoing PBV. Teaching points for home care for the patient after PCI or PBV are described in Box 18-12.

Complications

A common in-hospital complication associated with PBV is bleeding at the arterial puncture site due to the large diameter of the catheters needed to dilate the valve annulus. In addition, in mitral PBV, a common complication is left-to-right shunting secondary to septal dilation, again due to the large diameter of the dilation catheters. Systemic

BOX 18–12 TEACHING GUIDE *Advising the Cardiac Patient After PCI or PBV*

Physiological Teaching Points

- Restrict physical activities during the first week after PCI/PBV.
- Avoid lifting more than 10 pounds the first 2 weeks after PCI.
- Resume exercise program after undergoing an exercise stress test.
- Follow prescribed low-fat diet.
- Consider cardiac rehabilitation.
- Limit alcohol to three drinks per week.
- Notify physician of any oozing, bleeding, or pain at puncture site.
- Notify physician of fever or other signs of infection.
- Notify physician or call 911 for any chest discomfort not relieved with three nitroglycerin tablets taken 5 minutes apart.
- Begin a weight loss program if indicated.

Psychosocial Teaching Points

- Stop smoking, if appropriate, and avoid exposure to second-hand smoke.
- Resume sexual activities after completing an exercise stress test.
- Begin stress management activities.
- Recognize signs of depression.
- Comply with medication regimen.
- Schedule and keep medical appointments

BOX 18-13 PATIENT SAFETY

Serious Complications of PBV That Need Intervention

- Embolization of calcific debris
- Valve ring disruption
- Valvular regurgitation
- Valvular restenosis
- Bleeding at arterial puncture site
- LV perforation
- Severe hypotension
- Transient ischemia
- Vascular trauma
- Atrial septal defect (with mitral PBV)
- Aortic dissection
- Aortic rupture
- Cardiac tamponade
- Chordae tendineae rupture

embolization in both mitral and aortic PBV is a potential and significant complication, although its incidence is low. There have been few reports of significant increases in valvular regurgitation. Complications associated with PBV are listed in Box 18-13.

INTRA-AORTIC BALLOON PUMP COUNTERPULSATION AND MECHANICAL CIRCULATORY SUPPORT

▲ Intra-Aortic Balloon Pump Counterpulsation

Harken and colleagues of Boston originally described the concept of counterpulsation in 1958 when, in an attempt to increase coronary artery perfusion, they used femoral access to remove blood during systole and replace it during diastole. IABP counterpulsation was first introduced clinically by Kantrowitz and associates in 1967. This therapeutic approach was instituted for treatment of two patients with LV failure after AMI. Since that time, IABP has become a standard treatment for medical and surgical patients with acute LV failure that is unresponsive to pharmacological and volume therapy.

IABP counterpulsation is designed to increase coronary artery perfusion pressure and blood flow during the diastolic phase of the cardiac cycle by inflation of a balloon in the thoracic aorta. Deflation of the balloon, just before systolic ejection, decreases the impedance to ejection (afterload) and thus LV work, with subsequent decreased myocardial oxygen consumption. Inflation and deflation counterpulse each heart beat. With improved blood flow and effective reduction in LV work, the desired results are increased coronary artery perfusion and decreased afterload with subsequent increase in cardiac output. Goals are directed toward increasing oxygen supply to the myocardium, decreasing LV work, and improving cardiac output. Before IABP, no single therapeutic agent was capable of meeting these three goals.

The ACC/AHA guidelines for management of AMI consider IABP counterpulsation therapy a class I recommendation for the following conditions: (1) hypotension, defined as systolic blood pressure less than 90 mm Hg, or 30 mm Hg below baseline mean arterial pressure (MAP), in patients with STEMI who do not respond to other interventions; (2) low output state in patients with STEMI; and (3) cardiogenic shock that has not been quickly reversed with pharmacological agents in patients with STEMI.[1] The ACC/AHA guidelines also regard IABP counterpulsation to be a class I recommendation when used with other medical therapy for patients with STEMI and recurrent ischemic-type chest discomfort with signs of hemodynamic instability, poor LV function, or a large area of myocardium at risk.[1]

While IABP therapy remains an ACC/AHA class I recommendation, recent studies challenge the current recommendations and suggest that a review and update of the clinical practice guidelines are necessary.[2]

Physiological Principles

Greater work is required to maintain cardiac output in the failing heart. With this added work requirement, oxygen demand increases. These circumstances may occur at a time when the myocardium already is ischemic and coronary artery perfusion is unable to meet the oxygen demands. As a result, LV performance diminishes even further, resulting in decreased cardiac output. A vicious cycle ensues that is difficult to interrupt (Fig. 18-19). Without interruption of the cycle, cardiogenic shock may be imminent. This cycle can be broken with IABP therapy by increasing aortic root pressure during diastole through inflation of the balloon. With increased aortic root pressure, the perfusion pressure of the coronary arteries is increased.

Effective therapy for the patient in LV failure also involves decreasing myocardial oxygen demand. Four major determinants of myocardial oxygen demand are afterload, preload, contractility, and heart rate. IABP counterpulsation therapy can have an effect on all these factors. It decreases afterload directly and affects the other three determinants indirectly as cardiac function improves. Because IABP therapy assists the left heart, only the left ventricle is discussed here.

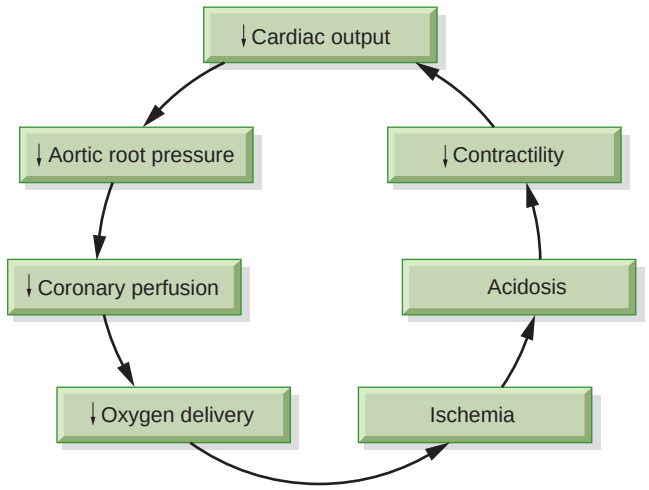

FIGURE 18-19 ▲ Cycle leading to cardiogenic shock.

Afterload and Preload

The greatest amount of oxygen required during the cardiac cycle is for the development of afterload (see Chapter 16). With greater impedance to ejection, afterload increases, resulting in increased myocardial oxygen demand. Impedance to ejection is caused by the aortic valve, aortic end-diastolic pressure, and vascular resistance. Greater aortic end-diastolic pressures require higher afterload to overcome impedance and ejection. Vascular resistance increases impedance when vessels become vasoconstricted. Vasodilation or lower vascular resistance decreases afterload by decreasing impedance to ejection. Deflation of the balloon in the aorta just before ventricular systole lowers aortic end-diastolic pressure. This decreases impedance to ejection and decreases LV workload. In this way, IABP can effectively decrease the oxygen demand of the heart.

A person in acute LV failure has increased volume in the ventricle at end-diastole (preload; see Chapter 16) as a result of the heart's inability to pump effectively. This excessive increase in preload increases the workload of the heart. IABP therapy helps decrease excessive preload by decreasing impedance to ejection. With decreased impedance, there is more effective forward flow of blood and more efficient emptying of the left ventricle.

Contractility

Contractility refers to the velocity and vigor of contraction during systole. Although vigorous contractility requires more oxygen, it is a benefit to cardiac function because it ensures good, efficient pumping, which increases cardiac output. In the patient with HF, cardiac contractility is depressed. The biochemical status of the myocardium directly affects contractility. Contractility is depressed when calcium levels are low, catecholamine levels are low, and ischemia is present with resultant acidosis.

IABP counterpulsation can increase oxygen supply, thereby decreasing ischemia and acidosis. In this way, IABP therapy contributes to improved contractility and better cardiac function (see Fig. 18-19).

Heart Rate

Heart rate is a major determinant of oxygen demand because the rate determines the number of times per minute the high pressures must be generated during systole. Normally, myocardial perfusion takes place during diastole. Coronary artery perfusion pressure is determined by the gradient between aortic diastolic pressure and myocardial wall tension. PAOP estimates wall tension and resistance to perfusion by approximating LV end-diastolic volume. It can be expressed by the following equation:

Coronary perfusion pressure =
aortic diastolic pressure – myocardial wall tension

Tension in the muscle retards blood flow, which is why approximately 80% of coronary artery perfusion occurs during diastole. With faster heart rates, diastolic time becomes shortened, with very little change occurring in systolic time. A rapid heart rate not only increases oxygen demand but decreases the time available for oxygen delivery. In acute ventricular failure, a person may not be able to maintain cardiac output by increasing the volume of blood pumped with each beat (stroke volume) because contractility is depressed. Cardiac output is a function of both stroke volume and heart rate:

Cardiac output = stroke volume × heart rate

If stroke volume cannot be increased, heart rate must increase to maintain cardiac output. This increase is very costly in terms of oxygen demand.

By improving contractility, IABP therapy helps improve myocardial pumping and the ability to increase stroke volume. Decreasing afterload also increases pumping efficiency. With improved myocardial function and cardiac output, the need for compensatory tachycardia diminishes. IABP counterpulsation increases coronary artery perfusion pressure by increasing aortic diastolic pressure during inflation of the balloon, resulting in improved blood flow and oxygen delivery to the myocardium.

The physiological effects of IABP therapy are summarized in Box 18-14. Proper inflation of the balloon increases oxygen supply, and proper deflation of the balloon decreases oxygen demand. Timing of inflation and deflation is crucial and must coincide with the cardiac cycle.

BOX 18-14 Direct Physiological Effects of Intra-Aortic Balloon Pump (IABP) Therapy

Inflation
↑ Aortic diastolic pressure
↑ Aortic root pressure
↑ Coronary perfusion pressure
↑ Oxygen supply

Deflation
↓ Aortic end-diastolic pressure
↓ Impedance to ejection
↓ Afterload
↓ Oxygen demand

Equipment Features

The intra-aortic balloon catheter and the balloon mounted on the end are constructed of a biocompatible polyurethane material. Filling of the balloon is achieved with a pressurized gas that enters through the catheter. Because of its low molecular weight, helium is the pressurized gas of choice. Balloon size should be determined by the patient's physical stature to optimize counterpulsation (Table 18-9). With inflation, the addition of the balloon volume into the aorta acutely increases aortic pressure and retrograde blood flow

Table 18-9 IABP Balloon Size Guidelines

Patient Height	Balloon Volume	Body Surface Area
<5′4″	30 mL	1.8 m^2 or less
5′4″–6′0″	40 mL	<1.8 m^2
>6′0″ (or aortic diameter >20 cm)	50 mL	>1.8 m^2

BOX 18-15 Indications for IABP Therapy

- Cardiogenic shock after acute infarction
- LV failure in the postoperative cardiac surgery patient
- Severe unstable angina
- Postinfarction ventricular septal defect or mitral regurgitation
- Short-term bridge to cardiac transplantation

back toward the aortic valve. With deflation, the sudden evacuation of the balloon volume acutely decreases aortic pressure. Catheters have a central lumen with which aortic pressure can be measured from the tip of the balloon.

Indications for Intra-Aortic Balloon Pump Counterpulsation

Two major applications of IABP therapy are for treatment of cardiogenic shock after MI and for low cardiac output following cardiac surgery. Other applications of IABP therapy for patients with cardiac pathophysiological conditions are noted in Box 18-15.

Cardiogenic Shock

Treatment of cardiogenic shock is complicated, and the mortality rate remains high. Cardiogenic shock develops in approximately 15% of patients with MI.

Initially, patients are treated with various inotropic drugs, vasopressors, and volume. A lack of, or minimal response in, cardiac output, arterial pressure, urine output, and mental status after this therapy indicates a need for assisted circulation with IABP therapy. Once hypotension is present, the self-perpetuating process of injury is in effect. Control of further injury and improvement in survival require early reversal of the shock state.

After IABP therapy is instituted, improvement should be observed within 1 to 2 hours. At this time, steady improvement should be seen in cardiac output, peripheral perfusion, urine output, mental status, and pulmonary congestion. With improved cardiac function, a decrease in central venous pressure and PAOP also should be seen. Average peak effect should be achieved within 24 to 48 hours.

Postoperative Low Cardiac Output

The primary indication for use of IABP therapy in the perioperative cardiac surgery patient is low cardiac output refractory to traditional inotropic support.[3] IABP therapy is also used preoperatively in patients who have sustained mechanical injury resulting from AMI as well as those with refractory angina.

IABP counterpulsation therapy can be used to wean patients from cardiopulmonary bypass (CPB) and to provide postoperative circulatory assistance until LV recovery occurs. In these situations, early recognition of failure is evidenced by the heart's inability to support circulation after CPB. Early recognition and treatment are crucial if LV failure is to be reversed.

In addition to providing circulatory assistance, outcomes in cardiac surgery patients have been positively influenced by IABP through other properties as well. For example, the pulsatile blood flow produced by IABP therapy during CPB has been shown to decrease activation of the systemic inflammatory response through inhibition of endothelial activation.[4] IABP therapy has also been associated with improvements in whole body perfusion during CPB.[5]

Unstable Angina

IABP counterpulsation therapy may be used during PCI for patients with unstable angina or mechanical problems. In this situation, PCI procedures usually are followed by emergency cardiac surgery. Patients in this category include those with unstable angina, postinfarction angina and postinfarction ventricular septal defects, or mitral regurgitation from papillary muscle injury with resultant cardiac failure. IABP counterpulsation therapy has been used successfully to control the severity of angina in patients in whom previous medical therapy has failed. The use of IABP therapy for patients with cardiac failure after ventricular septal rupture or mitral valve incompetence aids in the promotion of forward blood flow, which decreases shunting through the septal defect and decreases the amount of mitral regurgitation.

Contraindications to IABP Counterpulsation

There are few contraindications to the use of IABP therapy. A competent aortic valve is necessary if the patient is to benefit from IABP therapy. With aortic insufficiency, balloon inflation would only increase aortic regurgitation and offer little, if any, augmentation of coronary artery perfusion pressure. In fact, the patient's HF could be expected to become worse.

Severe peripheral vascular occlusive disease also is a relative contraindication to the use of IABP therapy. Occlusive disease would make insertion of the catheter difficult and possibly interrupt blood flow to the distal extremity or cause dislodgment of plaque formation along the vessel wall, resulting in potential emboli. In patients who absolutely require IABP therapy, insertion can be achieved through the thoracic aorta, thus bypassing diseased peripheral vessels. Any previous aortofemoral or aortoiliac bypass graft contraindicates femoral artery insertion.

In addition, the presence of an aortic aneurysm is a contraindication to the use of IABP therapy. A pulsating balloon against an aneurysm may predispose the patient to dislodgment of aneurysmal debris with resultant emboli. A more serious complication is rupture of the aneurysm; it is possible for the catheter to perforate the wall of the aneurysm during insertion.

Procedure

Insertion

Proper positioning of the balloon is in the thoracic aorta just distal to the left subclavian artery and proximal to the renal arteries (Fig. 18-20). The most commonly used method of catheter placement is percutaneous insertion using a Seldinger technique, although other approaches have been

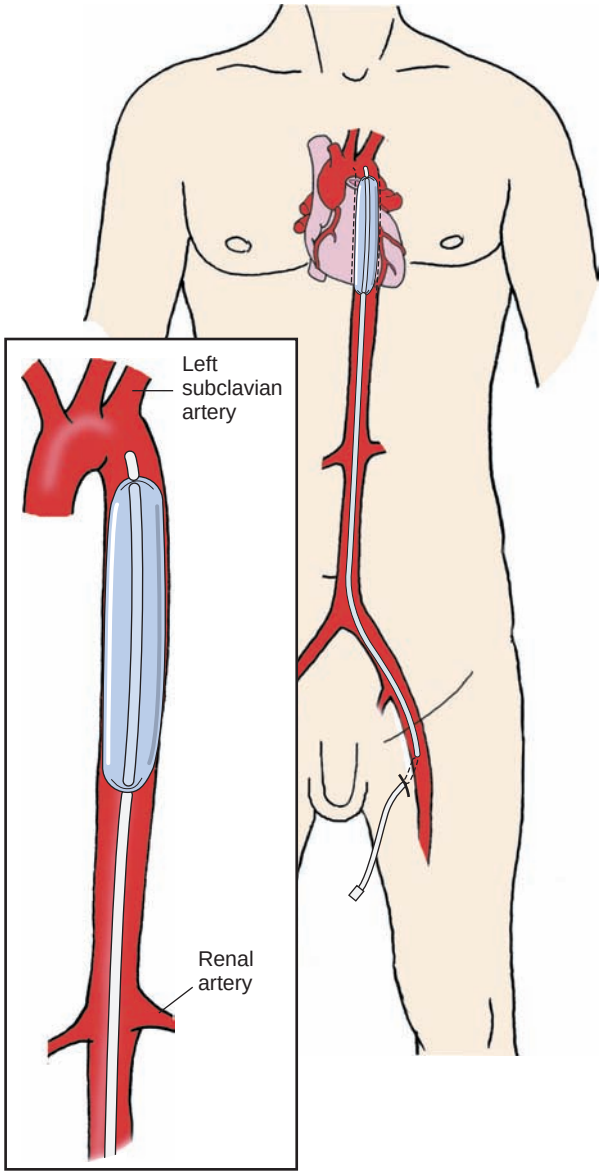

FIGURE 18-20 ▲ Proper position of the balloon catheter; illustrating percutaneous insertion.

described. The most common alternative is direct insertion into the thoracic aorta. Because this requires a median sternotomy incision, it is restricted to cardiac surgical patients whose chests have been opened for the surgery.

Once in place, the catheter is attached to a machine console that has three basic components: a monitoring system, an electronic trigger mechanism, and a drive system that moves gas in and out of the balloon. Monitoring systems have the capability of displaying the patient's ECG and an arterial waveform showing the effect of balloon inflation–deflation. Consoles also are capable of displaying a balloon waveform that illustrates the inflation and deflation of the balloon itself. The standard trigger mechanism for the balloon pump is the R wave that is sensed from the patient's ECG. This trigger signals the beginning of each cardiac cycle for the drive system. Other possible triggers include systolic arterial pressure or pacemaker spikes on the ECG. Adjustment of exact timing is controlled on the machine console. The drive system is the actual mechanism that drives gas into and out of the balloon by alternating pressure and vacuum.

Timing

Two primary methods of timing can be used with IABP therapy: conventional timing and real timing. Conventional timing uses the arterial waveform as the triggering mechanism to determine both inflation and deflation of the balloon. Real timing uses the same point of reference (the dicrotic notch on the arterial waveform) for balloon inflation but uses the ECG signal as the trigger for balloon deflation. Real timing is discussed briefly after conventional timing.

CONVENTIONAL TIMING. The first step to proper timing of the balloon pump using conventional timing is the identification of the beginning of systole and diastole on the arterial waveform. Systole begins when LV pressure exceeds left atrial pressure, forcing the mitral valve closed.

There are two phases of systole: isovolumetric contraction and ejection. Once the mitral valve is closed, isovolumetric contraction begins and continues until enough pressure is generated to overcome impedance to ejection. When ventricular pressure exceeds aortic pressure, the aortic valve is forced open, initiating ejection, or phase 2. Ejection continues until pressure in the left ventricle falls below pressure in the aorta. At this point, the aortic valve closes, and diastole begins.

Closing of the aortic valve creates an artifact on the arterial waveform that is called the dicrotic notch. The dicrotic notch is used as a timing reference to determine when balloon inflation should occur. Inflation should not occur before the notch because systole has not been completed.

After the aortic valve closes, two phases of diastole begin: isovolumic relaxation and ventricular filling. After the aortic valve closes, there is a period in which neither the aortic nor mitral valve is open. The mitral valve remains closed because LV pressure still is higher than left atrial pressure. This phase is isovolumic relaxation. When LV pressure falls below left atrial pressure, the mitral valve is forced open by the higher pressure in the left atrium. This begins the filling phase of diastole. Balloon inflation should continue throughout diastole. Deflation should be timed to occur at end-diastole, just before the next sharp systolic upstroke on the arterial waveform.

Figure 18-21 illustrates the cardiac cycle with left atrial, LV, and aortic pressures superimposed on one another.

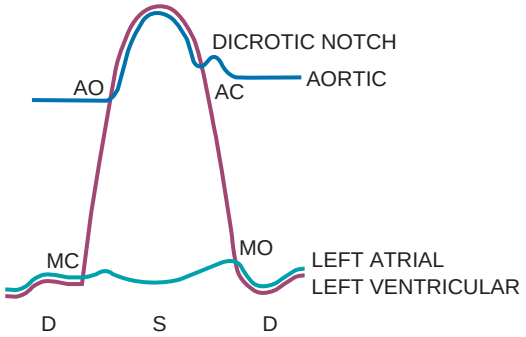

FIGURE 18-21 ▲ Cardiac cycle of the left heart with aortic, left ventricular (LV), and left atrial pressure waveforms. AC, aortic valve closure; AO, aortic valve opening; D, diastole; MC, mitral valve closure; MO, mitral valve opening; S, systole.

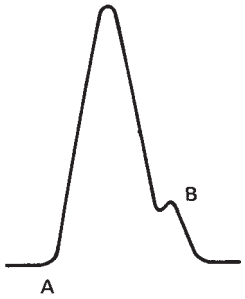

FIGURE 18-22 ▲ Arterial waveform, with *A* representing the point of balloon deflation before the systolic upstroke, and *B* representing balloon inflation at the dicrotic notch, at diastole.

Figure 18-22 illustrates a radial artery waveform with the beginning of systole and diastole marked.

REAL TIMING. The main difference between the two timing methods is balloon deflation and the triggering mechanism used. Real timing uses the ECG as the trigger signal for balloon deflation. The QRS complex is recognized as the onset of ventricular systole, and balloon deflation occurs at this time. Triggering off the R wave allows for balloon deflation to occur at the time of systolic ejection and not before (as with conventional timing). This timing mechanism is more effective in patients with irregular heart rhythms because balloon deflation occurs on recognition of the R wave (systolic ejection). It does not need to be approximated by the operator or an algorithm, as in conventional timing. Both a rapid deflation mechanism and a reliable ECG signal are necessary for IABP using real timing to augment blood pressure effectively. Balloon inflation with real timing occurs at the onset of diastole as triggered by the dicrotic notch on an arterial waveform, just as in conventional timing.

Advances in IABP technology have led to the development of automatic timing mechanisms currently available in some IABP models. Automatic timing therapy is possible because of special IABP catheters that have fiber optic pressure sensors in the tip.[3] These pressure sensors, capable of transmitting real-time pressure signals at the speed of light, use Windkessel model algorithms to calculate real-time aortic flow from aortic pressure.[6] This allows the balloon pump to determine the precise time when the aortic valve closes with each contraction of the heart, regardless of the patient's heart rhythm. The closure of the aortic valve signals the onset of diastole, and balloon inflation occurs.

Interpretation of Results

Waveform Assessment

Analysis of the arterial pressure waveform and the effectiveness of IABP therapy is an important nursing function. Nurses must be able to recognize and correct problems in balloon pump timing. Figure 18-23 illustrates the five points that are assessed on the waveform.

STEP 1. The first step in timing assessment is the ability to recognize the beginnings of systole and diastole on the arterial waveform, as shown in Figure 18-23. Systole begins at point A, where the sharp upstroke begins. Point B marks

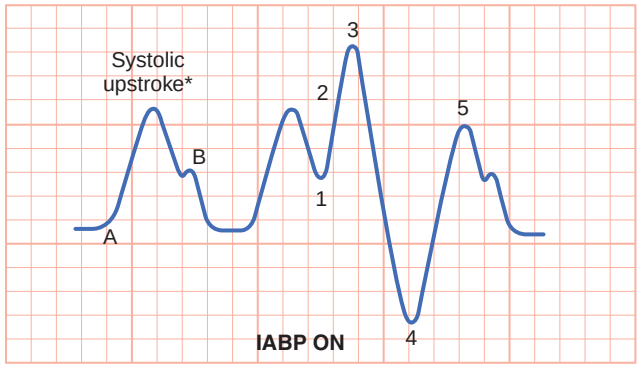

FIGURE 18-23 ▲ Inspection of the arterial waveform with intra-aortic balloon assistance should include observation of (*1*) inflation point, (*2*) inflation slope, (*3*) diastolic peak pressure/diastolic augmentation, (*4*) end-diastolic dip, and (*5*) next systolic peak.

the dicrotic notch, which represents aortic valve closure. At this point, diastole begins, and the balloon should be inflated. Balloon deflation occurs just before point A, at end-diastole.

Box 18-16 lists five criteria that can be used to measure the effectiveness of IABP therapy on the arterial pressure waveform. To evaluate the waveform effectively, the patient's unassisted pressure tracing must be viewed alongside the assisted pressure tracing. This can be accomplished through adjustment of the console so that the balloon inflates and deflates on every other beat (ie, a 1:2 assist ratio). Most patients tolerate this well for a brief period of time. Machine consoles are capable of freezing the waveform on the console monitor so that it is necessary to assist at a 1:2 ratio only for one screen. Another alternative is to obtain a strip recording of the 1:2 assistance for analysis.

STEP 2. After identification of the patient's dicrotic notch, a comparison is made with the assisted tracing to see that inflation occurs at the point of the dicrotic notch. Inflation before the dicrotic notch shortens systole abruptly and increases ventricular volume as ejection is interrupted. Late inflation, past the dicrotic notch, does not raise coronary artery perfusion pressure. The peak-diastolic pressure may not be as high as it would be with proper timing.

STEP 3. Next, the slopes of systolic upstroke and diastolic augmentation (also known as diastolic peak pressure) should be compared. The diastolic slope should be sharp and parallel

BOX 18-16 Criteria for Assessment of Effective IABP Therapy on the Arterial Pressure Waveform

- Inflation occurs at the dicrotic notch.
- Inflation slope is parallel to the systolic upstroke and is a straight line.
- Diastolic augmentation peak is greater than or equal to the preceding systolic peak.
- An end-diastolic dip in pressure is created with balloon deflation.
- The following systolic peak (assisted systole) is lower than the preceding systole (unassisted systole).

the systolic upstroke, as shown in Figure 18-23. The slope always should be a straight line. The greater the peak in diastolic pressure, the greater the increase in aortic root pressure. For this reason, balloon assistance is adjusted until the highest peak possible is achieved.

STEP 4. Deflation should occur just before systole, causing an acute drop in aortic end-diastolic pressure. This quick deflation displaces approximately 40 mL of volume. The result is an end-diastolic dip in pressure that reduces the impedance to the next systolic ejection. The end-diastolic pressure without the balloon assistance should be compared with the end-diastolic pressure with the dip created by balloon deflation. Optimally, a pressure difference of at least 10 mm Hg should be obtained. Better afterload reduction is achieved with the lowest possible end-diastolic dip.

The point of deflation also is crucial. Deflation that is too early allows pressure to rise to normal end-diastolic levels preceding systole. In this situation, there is no decrease in afterload. Deflation that is too late encroaches on the next systole and actually increases afterload because of greater impedance to ejection from the presence of the still-inflated balloon during systolic ejection. Figure 18-24 demonstrates possible errors in timing.

STEP 5. Finally, if afterload has been reduced, the next systolic pressure peak will be lower than the unassisted systolic pressure peak. This implies that the ventricle did not have to generate as great a pressure to overcome impedance to ejection. This may not always be seen because the systolic pressure peak also represents the compliance of the vasculature. If the vasculature is noncompliant due to atherosclerotic disease, the systolic peak may not change very much.

Balloon Fit

The fit of the balloon to any particular patient's aorta determines how well these criteria are met. Ideally, approximately 80% of the aorta is occluded with balloon inflation. In a dilated aorta, in which less than 80% occlusion occurs, the effect of inflation and deflation is not as dramatic on the waveform. When a patient is hypotensive or hypovolemic, the balloon does not have as pronounced an effect on the waveform because there is less volume displacement as the balloon inflates or deflates. See Table 18-9 on page 328 for a review of balloon size guidelines.

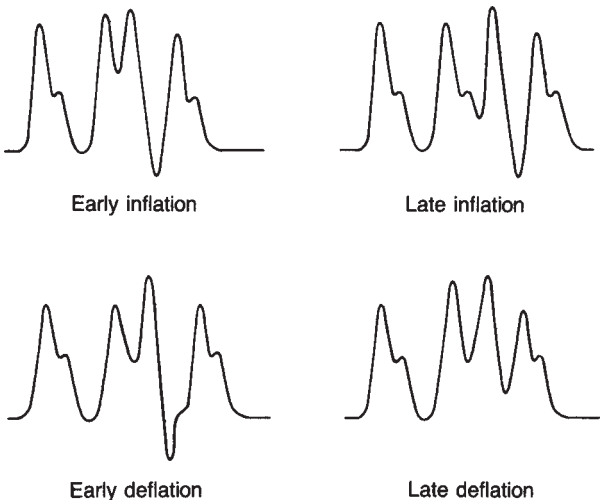

FIGURE 18-24 ▲ Illustration of possible errors occurring with timing.

Assessment and Management

Patients requiring IABP are managed much like any other critically ill patient in cardiogenic shock or acute LV failure. Nursing assessment and management of these conditions are discussed in Chapter 54. Additional nursing skills and assessment considerations specific to IABP therapy must be included in the care of these patients. These are summarized in Box 18-17. Nursing diagnoses for patients with an IABP are listed in Box 18-18.

Monitoring the Cardiovascular System

Monitoring the cardiovascular system is extremely important in determining the effectiveness of IABP therapy. The basis for this assessment includes vital signs, cardiac output, heart rhythm and regularity, urine output, color, perfusion, and mentation.

VITAL SIGNS. Three important vital signs with respect to IABP therapy are heart rate, MAP, and PAOP. Effective IABP therapy causes a decrease in all three parameters. Acute changes in the MAP may indicate volume depletion. Critically ill patients tolerate little change in their volume status. The PAOP is an important parameter for monitoring volume and provides the clinician with an early indication of volume depletion or overload.

Blood pressure readings require special consideration. Because the balloon inflates during diastole, peak-diastolic pressure may be higher than peak-systolic pressure. Most IABP consoles have monitoring systems capable of distinguishing systole from peak diastole; however, some monitoring equipment can distinguish only peak pressures from low-point pressures. For this reason, a monitor's digital display of systolic pressure actually may represent peak-diastolic pressure. It is advisable to record blood pressure as systolic, peak-diastolic, and end-diastolic, that is, 100/110/60. These pressures can be read from a strip recording of the arterial waveform.

HEART RHYTHM AND REGULARITY. Heart rhythm and regularity are important considerations. Early recognition and treatment of dysrhythmias are crucial for effective IABP support. Irregular dysrhythmias may inhibit efficient IABP therapy with some types of consoles because timing is set by the regular R-R interval on the ECG. A safety feature of all balloon pump consoles is automatic deflation of the balloon for premature QRS complexes. One particular IABP model tracks real time versus any average of beats, so it more effectively tracks dysrhythmias. If the dysrhythmia persists and timing is ineffective, another alternative might be use of the systolic peak on the arterial waveform as the trigger mechanism for balloon inflation. The primary goal is to treat the dysrhythmia.

OTHER OBSERVATIONS. Urine output, color, perfusion, and mentation all are important assessment parameters for determining the adequacy of cardiac output. All should

BOX 18-17 NURSING INTERVENTIONS

For IABP Counterpulsation and Ventricular Assist Devices (VADs)

IABP Nursing Interventions

- Verify correct timing using assist ratio of 1:2 and document settings hourly.
- Reevaluate timing for any change in the heart rate greater than 10 beats/min.
- Maintain proper balloon volume and refill as needed every 2 to 4 hours. Use automatic filling mode if available. Avoid hip flexion, which may impair gas movement in and out of IABP catheter.
- Maintain good arterial waveform and adequate ECG signal for evaluation of timing.
- Transduce aortic arterial line to the IABP per unit protocol.
- Reduce or eliminate situations that will interfere with the IABP's ability to maintain proper assist ratio. Notify physician of the development of tachycardias or irregular rhythms, and treat dysrhythmias with drug therapy or pacing as ordered. Use appropriate trigger (ie, ECG, arterial pressure, pacing).
- Use pacer modes only if the patient is 100% paced.
- Notify physician of significant changes in balloon pressure waveform.

VAD Nursing Interventions

- Assess and maintain adequate filling pressures during immediate postoperative phase.
- Monitor and assess heart rate, blood pressure, mean arterial pressure, pump flow, urine output, and neurological status hourly. Treat changes as ordered.
- Assess and change equipment level for devices that require specific placement of equipment for adequate pump flow.
- Evaluate pump flow and rate of VAD in relation to native heart rate and activity level of patient.
- Manage VAD function and volume status as ordered to maintain adequate device output.

General Nursing Interventions

- Monitor and record temperatures every 4 hours and PRN.
- Observe all insertion sites and incisions for signs of infection. Maintain sterile technique with dressing changes.
- Change any dressing that is wet or not intact.
- Change all infusion lines and infusion bags per unit protocol.
- Culture any site with suspicious drainage, redness, or swelling.
- Notify physician of elevation in white blood cell count.
- Treat patient with antibiotics as ordered.
- Auscultate and document breath sounds every 2 to 4 hours.
- Assist patient with pulmonary toilet (ie, coughing, deep breathing, frequent turning). Suction intubated patients as needed.
- Use pulse oximeter to monitor patients with abnormal blood gas levels, excessive secretions, or respiratory difficulty.
- Extubate patient and increase activity level as tolerated—particularly for patients with VADs.
- Document quality of peripheral pulses and neurological status before IABP or VAD insertion. Assess and document quality of pulses, skin perfusion, and neurological status per protocol. Evaluate peripheral perfusion with any complaints of leg or foot pain by patient.
- Notify physician of any changes in pulses or neurological status.
- Maintain anticoagulation as ordered.
- Avoid hip flexion, which might obstruct flow to the affected extremity, by keeping the cannulated leg straight and the bed at angle less than 30 degrees.
- Always maintain balloon motion to avoid thrombus formation on the balloon.
- Assess skin integrity, and document any redness and ulcerations over bony prominences.
- Use sheepskin, foam pads, and specialty beds as needed. Turn patient every 2 hours.
- Ensure that skin remains clean and dry.
- Maintain adequate nutrition by encouraging oral intake or implementing use of parenteral or enteral nutrition when necessary.
- Maintain alarm volumes, monitor noise at lowest level possible, and minimize unnecessary noise in the room.
- Talk with and orient patient to date and time frequently.
- Encourage family visits.
- Explain all procedures and activities to the patient.
- Organize care to allow for periods of uninterrupted sleep. Turn the lights off in room at night if possible.
- Sedate patient if necessary and as tolerated per physician orders.

BOX 18-18 EXAMPLES OF NURSING DIAGNOSES

For the Patient Requiring Circulatory Support With an IABP

- Decreased Cardiac Output related to alterations in preload
- Decreased Cardiac Output related to alterations in afterload
- Decreased Cardiac Output related to alterations in heart rate and rhythm
- Ineffective Peripheral Tissue Perfusion related to LV failure
- Ineffective Peripheral Tissue Perfusion related to unstable angina
- Ineffective Peripheral Tissue Perfusion related to improper IABP timing
- Risk for Infection related to invasive procedure
- Impaired Bed Mobility related to dependency on mechanical device
- Risk for Impaired Skin Integrity related to decreased perfusion
- Disturbed Sleep Pattern related to disruption in circadian rhythm
- Deficient Knowledge with IABP related to lack of history with device

improve in patients responsive to IABP therapy. Any deterioration in these signs also might indicate a fall in cardiac output. Cardiac output measurement is indicated when deterioration is evident, when a major change in volume or pharmacological therapy has been instituted, and during weaning from IABP support.

The left radial pulse and the cannulated extremity should be frequently assessed. A decrease, absence, or change in character of the left radial pulse may indicate that the balloon has advanced up the aorta and may be partially obstructing or has advanced into the left subclavian artery.

The presence of the balloon catheter in the femoral or iliac artery predisposes the patient to impaired circulation of the involved extremity. The affected extremity needs to be kept relatively immobile. Because flexion of the hip may kink the catheter and impair balloon pumping, it may be helpful to use a knee immobilizer to remind the patient to avoid hip flexion. The head of the bed also should not be elevated more than 30 degrees. Hip flexion also contributes to decreased perfusion to the distal extremity. Extremities should be checked hourly for

pulses, color, and sensation. Any deterioration in the affected extremity should be reported to the physician. Severe arterial insufficiency necessitates removal of the catheter.

Physicians advocate the use of heparin therapy to prevent possible thrombus formation around the catheter and vascular insufficiency, especially in medical patients. Each physician determines whether the risks of anticoagulation outweigh the benefits for the specific patient. Low-molecular-weight dextran is another possible choice of therapy to prevent thrombus formation. This agent impairs platelet function and prevents triggering of the coagulation cascade. Low-molecular-weight dextran is usually preferred in the cardiac surgical patient for the first 24 hours.

Monitoring the Pulmonary System

Many patients on IABP therapy require intubation and ventilatory assistance. Some of these patients may have respiratory insufficiency secondary to fluid overload associated with HF. The immobile, intubated patient is always at risk for respiratory infections and the development of atelectasis. Turning the patient is appropriate provided modifications are implemented to keep the extremity cannulated by the balloon catheter straight. Daily chest radiographs are needed to follow pulmonary status and to inspect IV catheter placement. The position of the balloon catheter also can be determined in this manner.

Monitoring the Renal System

Patients in cardiogenic shock or severe LV failure are at risk for the development of acute renal failure. In the shock state, the kidneys suffer the consequences of hypoperfusion; therefore, urine output and quality should be monitored closely. Serum BUN, creatinine, and creatinine clearance are monitored daily to assess renal function. Creatinine clearance indicates renal dysfunction and possible failure much earlier than elevated serum creatinine. Any acute, dramatic drop in urine output may be an indication that the catheter has slipped down the aorta and is obstructing the renal arteries.

Weaning

INDICATIONS FOR WEANING. Weaning patients from balloon assistance usually can begin 24 to 72 hours after insertion. Some patients require longer periods of support. Weaning can begin when there is evidence of hemodynamic stability that does not require excessive vasopressor support. Ideally, vasopressor support is minimal when weaning begins. After the balloon is removed, it is much easier to increase vasopressor support than to reinsert a balloon catheter for hemodynamic support.

The patient should exhibit signs of adequate cardiac function, demonstrated by good peripheral pulses, adequate urine output, absence of pulmonary edema, and improved mentation. Good coronary artery perfusion is indicated by an absence of ventricular ectopy and no ECG evidence of ischemia or injury.

Complications may require abrupt cessation of IABP. This may or may not result in reinsertion of another balloon catheter. Severe arterial insufficiency, evidenced by a loss of pulses in the distal extremity, pain, and pallor, is definitely an indication to remove the balloon catheter from that particular insertion site. Any balloon that develops a leak also requires removal. The physician may choose to reinsert the balloon catheter in another extremity or to replace the faulty balloon if the patient is hemodynamically unstable. Depending on the philosophy of the institution and physician, a deteriorating, irreversible situation also might be an indication for weaning or discontinuing balloon pump support. Box 18-19 lists major indications for weaning from IABP therapy.

BOX 18-19 PATIENT SAFETY

Indications for Weaning Patient From IABP

To ensure patient safety when weaning him or her from IABP, the nurse should be alert for the following:

- Hemodynamic stability
  - Cardiac index greater than 2 L/min
  - Pulmonary artery occlusion pressure less than 20 mm Hg
  - Systolic blood pressure greater than 100 mm Hg
- Minimal requirements for vasopressor support
- Evidence of adequate cardiac function
  - Good peripheral pulses
  - Adequate urine output
  - Absence of pulmonary edema
  - Improved mentation
- Evidence of good coronary perfusion
  - Absence of ventricular ectopy
  - Absence of ischemia on the ECG
- Severe vascular insufficiency
- Deteriorating, irreversible condition

APPROACHES TO WEANING. Weaning is commonly achieved by decreasing the assist ratio from 1:1 to 1:2 and so on until the minimal assist ratio is achieved on any particular console. A patient may be assisted at the first decrease for up to 4 to 6 hours. The minimal amount of time should be 30 minutes. During this time, the patient must be assessed for any change in hemodynamic status. An increase in heart rate, a decrease in blood pressure, and a decrease in cardiac output indicate deterioration in hemodynamic status. Weaning should be discontinued temporarily, and therapy should be adjusted before another weaning attempt is made. If the first decrease in assist ratio is tolerated, the assist ratio is decreased to minimum, with 1 to 4 hours allowed for each new assist ratio. The patient must be assessed continually for any indications of intolerance to the process. Although less common, weaning can also occur by decreasing balloon volume, which is controlled from the console in many models.

Complications Specific to IABP Therapy

Patients with IABP counterpulsation need to be monitored for development of poor blood flow to the cannulated extremity, which could lead to compartment syndrome. It may occur within the first 24 hours of support or not until several days after catheter insertion. Compartment syndrome is caused by a rise in the tissue pressure in one of the compartments of the affected lower extremity. Bone, muscle, nerve tissue, and blood vessels all are enclosed by a fibrous membrane called the fascia, and this enclosed space is called a compartment. It is nonyielding, so a rise in volume in the compartment increases the pressure in the compartment. The patient with IABP in whom

Table 18-10 Injuries Secondary to Balloons

Injury	Assessment Findings	Nursing Intervention
Balloon rupture	Presence of bright red blood or flecks of dried blood in the catheter or helium delivery line Gas alarm sounds Decreased augmentation Signs of embolic event Entrapment (may be the first indication)	Immediate removal of the catheter by the appropriate personnel Before removal: Turn pump off Clamp the line Place the patient on left side in Trendelenburg position
Balloon entrapment	Balloon pressure waveform indicates leaks Small amounts of blood in tubing or flecks of dried blood in tubing	Surgical removal is usually indicated Physician may consider pharmacological dissolution of clot with thrombolytics Physician may consider use of Fogarty embolectomy to remove fresh clot

limb ischemia develops from decreased capillary flow can suffer cellular and capillary damage that leads to increased capillary permeability. The resultant transudation of fluid into the closed compartment space increases tissue pressure to a level that can interfere with capillary blood flow. When this degree of tissue pressure is reached, tissue viability may be threatened. Treatment is directed at improving blood flow. Pressure release by fasciotomy may be needed to prevent tissue death.

Decreased circulating platelets in the first 24 hours of IABP therapy and a minimal decrease in red blood cell count have been reported; however, these problems are not thought to be significant. There is a low incidence of balloon leakage and rupture. These complications may result from balloon inflation against a calcific, atherosclerotic plaque in the aorta. This disruption in the balloon surface may be as small as a pinhole or may be a large tear. The associated danger is gas embolism. In addition, the risk for entrapment is minimal but still exists. Table 18-10 provides additional details about injury secondary to balloons.

Insertion of the catheter in cases of severe atherosclerotic vascular disease may result in arterial perforation or occlusion. Any leak is an indication for immediate balloon removal. Iatrogenic dissection of the aorta is rare but has been reported. Arterial insufficiency is the most common complication of IABP therapy. Arterial insufficiency may be permanent, or it may be relieved by aortofemoral or ileofemoral bypass grafting. Neuropathy in the catheterized extremity is another reported complication.

▲ Mechanical Circulatory Support

When there is profound myocardial injury, the augmentation of systemic blood pressure by IABP counterpulsation may not be adequate for patient survival. Use of IABP for circulatory support requires that a patient have a functioning left ventricle because IABP augments cardiac output only by 8% to 10%. Patients with severe, acute LV failure after a MI, after a surgical procedure, or from end-stage HF may need a mechanism for replacing LV function. Circulatory support with a ventricular assist device (VAD) has become a successful treatment for patients with cardiac failure refractory to pharmacological therapies, revascularization procedures, and IABP counterpulsation. These devices are capable of supporting circulation until the heart recovers or a donor heart is obtained for transplantation. As of 2008, 80% of all VAD placements were for bridge to transplant.[7]

Interest in the research and development of artificial circulatory support devices has existed since the 1930s. CPB, an early example of these efforts, was successfully implemented in the 1950s. A National Institutes of Health initiative helped organize and support these efforts on a national level. Michael DeBakey became the first clinician to support a postcardiotomy patient with a LV bypass pump successfully in 1966. An impetus for continued research during the 1960s and 1970s was the limited early success with heart transplantation. At that time, the focus of research was the development of a device that could support the failing heart until sufficient cardiac function had returned. Current research focuses on the use of these devices as a bridge to heart transplantation and as a method of permanent cardiac support for patients with end-stage cardiac disease.

Physiological Principles

Patients who are candidates for ventricular assistance suffer from HF resulting from ischemic or myopathic heart disease. Both disease processes lead to a reduction in cardiac output and oxygen delivery. The physiological response of the body to this low output state is vasoconstriction and increased SVR. Although these compensatory mechanisms are meant to protect and preserve cardiovascular function in the short term, a vicious cycle develops that is characterized by compromised cardiac contractility and a low ventricular EF. Hypotension ensues, leading to hemodynamic instability requiring the use of pharmacological agents and possibly IABP therapy for cardiovascular support. Should the patient continue to deteriorate despite drug therapy and IABP, a VAD may be necessary for survival. Hemodynamically, these patients usually demonstrate a cardiac index of less than 2 L/min/m^2, a PAOP of greater than 20 mm Hg, and a systolic blood pressure of less than 80 mm Hg despite pharmacological therapies and the use of IABP counterpulsation.

Restoration of adequate blood flow and preservation of end-organ function are the fundamental goals of short- or long-term VAD use. Hemodynamics and perfusion improve as the VAD assumes the workload of the failing ventricle. Ventricular assistance may involve supporting one or both ventricles depending on the extent of myocardial damage and ventricular failure.

LV support usually requires cannulation of the left ventricle with a conduit that leads to the device. The ascending aorta, which receives the output from the device, is also cannulated with a conduit. In certain situations, the left atrium may be cannulated instead of the left ventricle. Circulation in the patient supported by a left ventricular assist device (LVAD) is similar to the normal circulatory process. Venous blood returns to the right heart, passes through the lungs to be oxygenated, and then returns to the left atrium through the pulmonary veins. Blood then passes from the left atrium through the left ventricle and into the LVAD. The LVAD then ejects blood into the ascending aorta during pump systole.

In situations that necessitate biventricular support, two pump units function in synchrony to assume the roles of the native right and left ventricles. One pump supports right heart circulation while the other supports left heart circulation. The addition of RV assistance requires cannulation of the right atrium for inflow to the pump and the pulmonary artery for outflow from the right ventricular assist device (RVAD). During biventricular assistance, blood is diverted from the right atrium to the lungs through the RVAD, bypassing the right ventricle. Circulation continues to the left heart, where the LVAD undertakes support of systemic circulation. Univentricular or biventricular assistance relieves the ventricles of its workload by acting as the primary pump supporting pulmonary circulation or systemic blood pressure. Reducing ventricular workload decreases cardiac oxygen demand.

Devices

Several VADs are available for use. Certain devices are commercially available, whereas others require special exemption for investigational purposes. Although no universal classification system exists, the devices can be categorized according to four general functional characteristics: the intended duration of support (short term vs. long term), the type of support provided (univentricular vs. biventricular), the actual physical placement of the device (internal vs. external), and the type of blood flow produced (pulsatile vs. nonpulsatile). Short-term support usually refers to assistance for patients expected to recover from episodes of acute LV failure secondary to MI or surgical procedures. Long-term ventricular assistance may be an option for people awaiting heart transplantation, or it may provide an alternative method of permanent cardiac support.

Nonpulsatile Pumps

Centrifugal and roller pumps are examples of nonpulsatile VADs capable of providing univentricular (to either ventricle) or biventricular support. Centrifugal pumps introduce blood near the center of a rapidly spinning disk that accelerates blood toward the periphery of the disk. They are primarily used for short-term ventricular assistance when myocardial recovery is expected. These devices have been used, infrequently, as bridges to transplantation. Both types are approved by the FDA and are commercially available. Centrifugal and roller pumps are extracorporeal devices designed to support circulation of the patient's blood. Because these devices do not generate pulsatile blood flow, IABP is often used in conjunction with them to create a pulse. Blood is transported from the cannulated chamber to an external pump console that circulates the blood back to the corresponding great vessel by a separate cannula. Should right ventricular failure (RVF) be identified after placement of an LVAD, an RVAD can be added for additional support with these devices.

These devices can be inserted relatively quickly and are adequate methods of deploying short-term circulatory assistance. Methods of cannulation and physical placement of the equipment limit the mobility and activity level of the patient. Patients supported by these VADs are usually sedated and paralyzed. A commonly used centrifugal pump is the BioMedicus.

Axial pumps, another type of nonpulsatile pump, use corkscrew-type impellers that propel blood by rapid rotation. These pumps are much more compact than centrifugal pumps and can be used short or long term.[7] In addition, they weigh less than centrifugal pumps, are more compact, and therefore are more comfortable for patients.

Extracorporeal membrane oxygenation (ECMO) or CPB systems are alternative methods of temporary CPR involving circulatory support and oxygenation of the patient's blood. CPB is primarily used for operative situations but has demonstrated effectiveness as a mechanism of support for patients unable to wean from the pump perioperatively or for those requiring cardiopulmonary support refractory to conventional efforts. Circulation of blood between the patient and an external pump is supported by cannulation of the femoral vessels. Venous blood is diverted from central venous circulation; pumped through a membrane oxygenator, where oxygen and carbon dioxide are exchanged; and returned to the arterial circulation through the femoral artery cannula. A heating mechanism in the pump console helps maintain body temperature during circulatory support.

Rapid deployment without the need for surgical intervention and the ability to provide hemodynamic stabilization for a brief period are the major advantages of these resuscitative devices. CPB and ECMO allow time for further assessment and intervention during episodes of acute hemodynamic decompensation. Disadvantages include the need for continuous anticoagulation and the inability to provide extended circulatory support. The presence of occlusive peripheral vascular disease could be a contraindication to use of these devices.

Pulsatile Pumps

IMPLANTABLE PULSATILE PUMPS. Implantable pumps were designed with the intention of providing long-term LV support while allowing the patient a certain amount of physical independence. A few devices have successfully supported a patient for greater than 1 year while awaiting heart transplantation. Many patients with the implantable devices have been physically rehabilitated by participating in regular physical therapy programs and normal activities of daily living while being supported with a VAD. This might better prepare them physically to endure the transplantation process. Examples of the implantable devices are the HeartMate IP and the Novacor left ventricular assist system (LVAS). The Novacor device operates on electricity, whereas the HeartMate IP operates as a pneumatic unit.

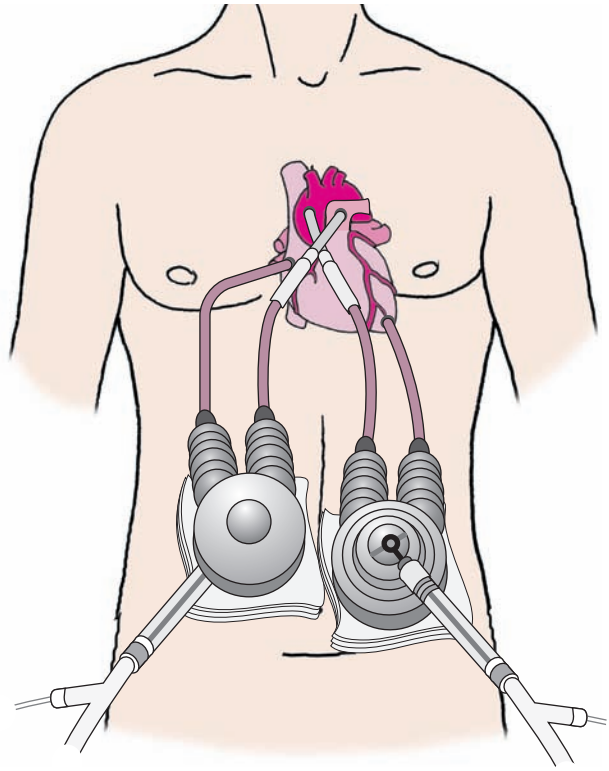

FIGURE 18-26 ▲ Thoratec pneumatic ventricular assist device. External placement with biventricular assist capabilities. (Courtesy of Kathy J. Vaca, RN, Department of Surgery, St. Louis Health Sciences Center, St. Louis, MO.)

Surgical implantation of the VAD necessitates a sternotomy and the use of CPB. Device placement is in an abdominal pocket just below the left diaphragm. Typically, the inflow conduit is tunneled through the diaphragm and anastomosed to the apex of the left ventricle. The outflow conduit is brought around the diaphragm and is anastomosed to the ascending aorta. Drivelines extending from the implanted device are tunneled through the patient's skin and connected to a portable, external power source. This power source may be a portable console or battery pack that is worn by the patient (Fig. 18-25). Either situation allows the patient mobility and independence during the recovery period.

Pump units of the implantable VADs are encapsulated in rigid housing and consist of a blood pump sac and single or dual pusher plates (depending on the particular device). Inflow and outflow conduits have valves that support unidirectional blood flow. These devices work on the principle of converting electrical or pneumatic energy to mechanical energy. This mechanical energy activates the pusher plates, causing them to compress the blood sac at the appropriate time. Blood sac compression causes ejection of the blood out of the pump sac and into the ascending aorta through the outflow conduit. These devices have stroke volumes of 70 to 83 mL and can support pump outputs of greater than 10 L/min. Depending on the device implanted, long-term anticoagulation may be necessary to prevent thromboembolic events.

EXTERNAL PULSATILE PUMPS. Two commonly used external pulsatile devices are the Thoratec VAD and the Abiomed pump. Both devices have successfully supported patients postcardiotomy and patients bridged to heart transplantation.

The Thoratec VAD is a pneumatically driven device that is positioned externally on the recipient's upper abdomen. Placement of this device requires a sternotomy incision and use of CPB. The structure of the pump drive, the inflow and outflow conduits, and the cannulation techniques of the chambers and great vessels are all similar to that of the implantable devices. A major difference is that the cannulas supporting the blood flow pass through the patient's chest wall to the externally positioned pump. One advantage of this device is the ability to provide univentricular or biventricular support, depending on the extent of HF. Figure 18-26 is an example of biventricular support. Another advantage is that due to its external placement, small patient body size is less of a contraindication when considering the need for ventricular assistance.

Another external VAD, the Abiomed pump, is designed for short-term univentricular or biventricular support. It has been used in patients when myocardial recovery is expected and as a bridge to transplantation. Components consist of cannulas for venous and arterial access, blood pumps to support unidirectional blood flow and systemic circulation, and a pneumatically driven console that provides the power source. Cannulation sites for this device are either atria, the pulmonary artery, and the ascending aorta. Filling of the blood pumps occurs passively by gravity; therefore, the blood pumps must be positioned securely below the level of the heart to promote adequate blood flow into their chambers (Fig. 18-27). The internal bladders operate in a fill-to-empty mode. Pumps positioned too high fill insufficiently, and pumps that are too low have a prolonged filling time, each adversely affecting patient hemodynamics.

Nursing interventions specific to the Abiomed include monitoring and adjusting the level of the blood pumps and monitoring filling pressures to ensure adequate volumes

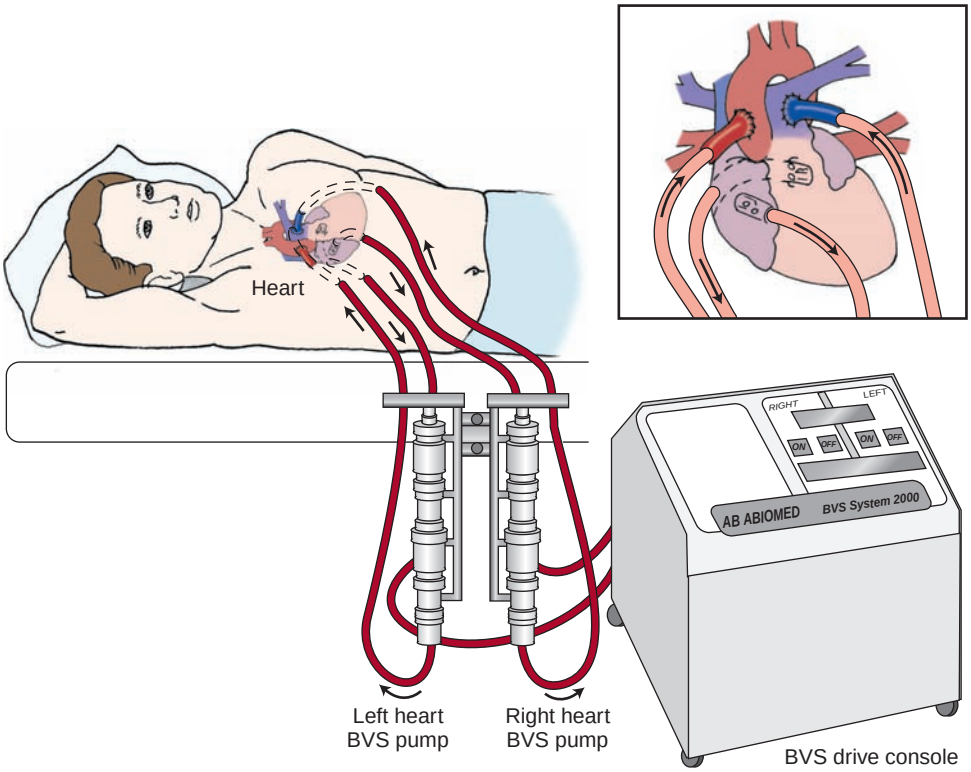

FIGURE 18-27 ▲ Abiomed biventricular support system. (Artwork courtesy of ABIOMED Cardiovascular, Inc., Danvers, MA.)

necessary to support optimal flow through the system. Use of this device significantly impairs patient mobility.

ADVANCES IN MECHANICAL CIRCULATORY SUPPORT. There have been many advances in mechanical circulatory support in the last decade. In November 2002, the FDA approved the Thoratec HeartMate SNAP-VE LVAS for permanent implantation, also known as "destination therapy," in patients with end-stage HF who are not candidates for traditional heart transplantation. Since October 2003, the Centers for Medicare and Medicaid Services have provided coverage for patients who meet specific criteria. The HeartMate SNAP-VE LVAS is an implantable electric pump that allows patients to ambulate and participate in cardiac rehabilitation programs, making it an appropriate system for in-home use by specific HF populations.

Additional advances in VAD technology have been introduced through third-generation devices that use rotary pumps to create a centrifugal flow with the help of magnetically levitated propellers. The use of magnetic bearings over traditional blood-coated bearings has positive effects including extended operating life, improved reliability, and decreased blood damage.[8]

Another recent advance in mechanical circulatory support has been the introduction of very small pumps that can be incorporated into a transvascular catheter. Major surgical procedures are required for implantation of all other models of VADs, whereas catheter-based LVADs can be placed percutaneously. Several such devices have been developed, including the Tandem Heart LVAD, which is an extracorporeal centrifugal LVAD. Table 18-11 provides a comprehensive review of VADs.

Table 18-11 Ventricular Assist Devices

Device	Manufacturer	Duration of Support	Physical Placement	Flow	Drive System
Abiomed BVS 5000	Abiomed	Short term Intermediate term	External	Pulsatile	Pneumatic
Biomedicus	Medtronic-Biomedicus	Short term	External	Nonpulsatile (centrifugal)	Electric
HeartMate IP	Thoratec	Long term	Implantable	Pulsatile	Pneumatic
HeartMate VE	Thoratec	Long term	Implantable	Pulsatile	Electric
Novacor	World Heart	Long term	Implantable	Pulsatile	Electric
TandemHeart	Cardiac Assist	Short term	Percutaneous	Nonpulsatile (centrifugal)	Electric
Thoratec ventricular assist device	Thoratec	Short term Long term	External	Pulsatile	Pneumatic

Table 18-12 Total Artificial Heart

Device	Manufacturer	Flow	Drive System
Abiocor	Abiomed	Pulsatile	Hydraulic
CardioWest	SynCardia	Pulsatile	Pneumatic

Artificial hearts have been approved in the United States by the FDA for investigational use (Table 18-12). Abiomed has developed the first fully implantable replacement heart known as the AbioCor TAH (totally artificial heart).[9] Devices such as the AbioCor are designed for use in patients ineligible to receive a VAD, such as those with both right- and left-sided HF. The AbioCor received Humanitarian Device Exemption from the FDA in September of 2006. In addition, SynCardia Systems has developed the CardioWest device, which is an implantable pneumatic artificial heart. Blood and air in each of the heart's ventricles are separated by a polyurethane sheath and triggered by compressed air from the external console.[8]

Whereas the AbioCor is a self-contained device, the CardioWest device is designed such that patients are connected to a large console by tubes through their chest wall.

MODES OF OPERATION. With the exception of the Abiomed device, the pulsatile pumps have several modes of operation. Two primary modes depend on the patient's ECG or the rate of blood flow through the pump during each cardiac cycle. In the ECG trigger mode, the pump initiates blood ejection in conjunction with the patient's QRS complex; the R wave acts as the trigger for pump systole. The second mode is a dynamic mode that allows the pump to respond to the changing heart rate, depending on patient activity level. Pump systole and cardiac output depend on the blood flow sensed by the device, which is programmed to respond to changes in pump filling rate as blood passes from the left ventricle into the blood sac of the pump drive. This ability is particularly important as a patient's level of activity increases during the recovery phase after implantation. A third mode of operation, rarely used clinically, is a fixed-rate mode that functions independently of the native heart.

Nursing Implications

Historically, VAD recipients have received care in the ICU, usually intubated and sedated. Evolution of the technology and the use of portable devices as bridges to transplantation have changed the mode of care. Now, patients are encouraged to be independent, pursue physical rehabilitation, and engage in normal activities of daily living when possible (Fig. 18-28). Certain patients may even be discharged from the hospital. Nurses have an opportunity to be instrumental in the coordination of patient care and outcome management in this new patient population.

During the immediate postoperative phase, the critical care nurse must be cognizant of the physiological responses expected and the common postoperative complications associated with device implantation. The nurse determines whether the equipment is functioning appropriately by monitoring parameters associated with adequate tissue perfusion and improved end-organ function because these are the primary goals of VAD implantation. Hemodynamic instability and the maintenance of adequate filling pressures are critical issues in the immediate postoperative period. Other issues the critical care nurse encounters include, but are not limited to, dysrhythmias, bleeding complications, infections, thromboembolic events, and possible mechanical problems associated with the devices.

FIGURE 18-28 ▲ Wearing the portable LV assist system, a patient is able to enjoy the independence of outdoor activities. Some patients may take day trips or be discharged from the hospital. (Photograph courtesy of Emory University.)

Psychosocial issues and patient education dominate the nursing focus during periods of extended support with a VAD; most of these patients require minimal direct nursing care once stabilized and discharged from the ICU. Increased independence in activities of daily living, continued physical rehabilitation, and patient education are emphasized. All aspects of the rehabilitation phase should include the recipient's family members or identified support person. As patients are discharged, they and their primary care givers need to be educated about the operation of the equipment and how to troubleshoot malfunctions. A person capable of operating the VAD needs to accompany the patient at all times. Nursing must facilitate the integration of the patient's lifestyle with the boundaries created by having a VAD implanted for extended support. Feelings of isolation may unfold because investigational device protocols governed by the FDA may restrict the patients' social activity and geographical mobility.

An advanced-practice nurse is in a pivotal position to assume the role of case manager facilitating the implementation of clinical paths, protocols, and procedures related to patient progress from the acute to chronic phases of rehabilitation. Nursing education facilitated by a clinical nurse specialist

is vital to patient care as increasing numbers of nurses on the general floors, and possibly the outpatient setting, are exposed to this patient population. As more patients receive the portable devices and approach the possibility of hospital discharge, case management will be a principal facet of patient care.

▲ Complications Associated With IABP Therapy and Circulatory Support

Bleeding

Prolongation of bleeding times is a side effect of exposure to CPB, which is normally reversed in the early postoperative period. With the use of mechanical circulatory support, the continued exposure of blood to an artificial surface causes trauma to platelets. A cascade of events involving the platelets, white blood cells, fibrinolytic system, and complement system occurs. The frequency and severity of bleeding associated with artificial circulatory devices have been reduced by improved surgical techniques and methods of maintaining hemostasis, the reversal of heparin, the infusion of coagulation factors (platelets, fresh frozen plasma), and continued experience with the equipment. Episodes of severe bleeding are usually corrected within the first 24 hours after surgical implantation of a VAD.

Factors associated with increased postoperative bleeding in VAD recipients are preoperative and postoperative use of anticoagulants; coagulopathies secondary to cardiogenic shock, HF, and extended CPB exposure; and the use of multiple cannulation sites. Hemodynamic instability, a reduction in native cardiac output and device output, a risk for ischemia to target organs, and possible cardiac tamponade are all deleterious events associated with uncontrolled bleeding in the patient supported with a VAD. In the patient receiving IABP therapy, bleeding is usually related to use of continuous anticoagulation or the development of coagulopathies. Bleeding commonly occurs at the insertion site of the balloon catheter. In both patient populations, nursing interventions include observing external cannulation sites for oozing, monitoring changes in vital signs (particularly hemodynamic parameters, such as filling pressures for VAD recipients) and laboratory values, and regularly assessing adequate tissue perfusion.

Thromboembolic Events

Placement of IABP puts a patient at risk for thromboembolic events. At the time of insertion, plaque may become dislodged from the vessel wall, or emboli may break off a thrombus that has formed on the indwelling catheter or balloon. Both situations can impair circulation to distal extremities and other vital organs or cause a stroke. Continuous anticoagulation with a heparin infusion is required during IABP therapy; dextran infusions may also be used.

The development of a thrombus and the migration of emboli have been reported with the use of mechanical circulatory support. Anticoagulation regimens and the prevention of embolic events are unresolved issues in the clinical management of VAD recipients. Currently, anticoagulation therapy is managed differently depending on the device that is inserted. Devices used for short-term support require prophylactic use of low-dose heparin infusions. Similar to IABP, dextran infusions may be used in conjunction with heparin. Patients who are supported with the Novacor, HeartMate, and Thoratec devices and who require long-term support are at greater risk secondary to extended periods of exposure to the device. These patients are usually managed with heparin infusions in the immediate postoperative phase. During the extended support period, the heparin is weaned, and warfarin (Coumadin) therapy is initiated to maintain the PT at an INR of 2.5 to 3.5.[10] Antiplatelet agents, such as dipyridamole (Persantine), may be used with warfarin therapy. Obtaining baseline and postimplantation neurological assessments; monitoring peripheral pulses, especially those distal to cannulation sites; and assessing tissue perfusion are critical to the early recognition and intervention of any embolic event.

Right Ventricular Failure

RVF is a significant contributor to morbidity and mortality in patients who have undergone LVAD placement. In an effort to detect risk for RVF in patients who are candidates for LVAD placement, researchers at the University of Michigan have developed a preoperative risk assessment instrument.[11] The risk score is calculated using preexisting clinical data and has been scientifically proven to effectively stratify the risk of RVF and death after LVAD implantation.[11]

RVF becomes a problem for patients with LVADs when the pumping capabilities of the device exceed those of the impaired left ventricle, systemic circulation and RV preload increase, subsequently increasing RV workload. RV output is increased in a patient with a healthy right ventricle. However, a patient with underlying RVF may not be able to handle this augmentation in circulatory volume. Evidence of primary RV dysfunction may not become apparent until the right heart is challenged by the cardiac output of the LVAD. When RVF develops after LVAD implantation, vasodilators and IV inotropes, such as prostaglandin E_1, isoproterenol (Isuprel), and epinephrine, are used to reduce pulmonary pressures and improve RV contractility. It may be possible to add an RVAD for additional support if pharmacological intervention is unsuccessful. Clinical practice has shown that the addition of an RVAD after LVAD placement is a poor prognostic indicator.[12]

Infection

People requiring mechanical circulatory assistance and IABP therapy are at increased risk for infection secondary to the surgical procedures and the presence of external cannulas, pumps, drivelines, and so forth. Many of these patients suffer from chronic illness that renders them more immunocompromised. Infection may be related to surgical wounds after device insertion, invasive monitoring lines, drain placement, pulmonary status, or nutritional status. Early recognition of signs and symptoms of infection and early intervention can prevent the development of sepsis. Early detection is particularly important because some of these patients await heart transplantation, and an infection could preclude transplantation. Diligent handwashing, changing or removing invasive lines or drainage tubes when appropriate, adherence to sterile

dressing techniques and schedules, and the use of appropriate prophylactic antibiotics are effective barriers to the development of infection. Early extubation and mobilization are goals for patients with the implanted devices. Primary nursing interventions include monitoring invasive sites for signs of infection, encouraging good pulmonary toilet, increasing activity level as tolerated, and promoting adequate nutrition.

Dysrhythmias

Most patients with cardiomyopathy who require some form of circulatory assistance experience dysrhythmias before insertion of a device. These dysrhythmias often continue after device implantation and may hinder device function, depending on the rhythm. Dysrhythmias should be treated when they occur, and attempts should be made to restore sinus rhythm.

Circulatory assistance with IABP is affected by dysrhythmias. Diastolic augmentation and systolic assistance decrease in the presence of irregular rhythms, such as AF or sinus rhythm with frequent ectopy. These rhythm changes make it difficult to manage the timing of balloon inflation and deflation. Lethal ventricular dysrhythmias need to be treated conventionally because IABP is designed only to augment existing cardiac output.

RV function and the maintenance of adequate pump output are of primary concern in LVAD recipients with lethal ventricular dysrhythmias. These patients may lack sufficient RV function to support cardiac output during ventricular dysrhythmia even though LV function has been assumed by the LVAD. Although LVAD flow and mean blood pressure have been known to decrease by approximately 20%, it has been demonstrated that patients with LVADs do tolerate sustained lethal ventricular dysrhythmias without the need for RVAD support. Symptoms associated with these rhythms and low-flow states are usually weakness and palpitations.[13] Patients receiving biventricular support should be able to maintain adequate device outputs despite the dysrhythmia because left and RV function has been taken over by the VAD. AF is usually tolerated by these patients even though it may have some effect on right heart function. Severe bradycardia and tachydysrhythmia need to be addressed because they will change pump flow and output. Cardiac rhythms require close monitoring for any acute changes.

Nutritional Deficits

Nutritional status is an important element of any recovery process. Many patients have had end-stage HF and are nutritionally depleted before any surgical intervention, placing them at a higher risk for nutritional deficits during the postoperative phase. Adequate nutrition is necessary for wound healing. Obtaining dietary consultation, encouraging increased oral intake, and providing flexibility with meals will assist these patients in meeting their nutritional goals. Patients who are supported by IABP and VADs and who require intubation and sedation require parenteral or enteral feedings. Those with implanted devices eventually progress to a regular diet but may need smaller, more frequent meals. Experiencing feelings of fullness or early satiety is not uncommon for these patients due to the abdominal placement of the device.

Psychosocial Factors

Balloon and VAD insertion are usually unplanned, emergent interventions for a deteriorating condition. Abundant monitoring is frightening for both patient and family; therefore, explanations of procedures and surroundings are very important. Family members need to be prepared before visiting their loved one immediately after device insertion. The goal is to alleviate anxiety and to help the patient and family feel more secure in a foreign environment. Honest communication is important. This helps the family members recognize changes in their loved one's condition and make informed, realistic decisions regarding the patient's care. Putting the family in contact with nonmedical personnel who can objectively provide emotional support is often beneficial. Issues that families and patients struggle with include fear, hopelessness, and death.

Critically ill patients often suffer from disorientation and sleep deprivation. Immobility and unfamiliar noises of the ICU tend to increase stress and anxiety. Mechanisms to help alleviate this stress and anxiety include frequent reorientation by the nursing staff and contact with family members. Better organization of time and procedures also reduces stress because it allows the patient longer periods of uninterrupted rest.

MANAGEMENT OF DYSRHYTHMIAS

▲ Electrical Cardioversion

Electrical cardioversion is used to convert sustained supraventricular or ventricular tachydysrhythmias to sinus rhythm, especially when the patient has an unstable rhythm that causes hemodynamic collapse. It may be used electively for recent-onset dysrhythmias that do not respond to antiarrhythmic drugs. As opposed to defibrillation, which delivers an unsynchronized current to the heart, cardioversion delivers a shock that is synchronized with the heart's activity. By setting the automated external defibrillator (AED) to the synchronized mode, the device detects the patient's R wave and delivers the shock during ventricular depolarization. As a result, there is no danger of causing VF, which can occur when a shock is delivered during ventricular repolarization (on the T wave). Indications for synchronized, external cardioversion and recommendations for initial joules (J) used are listed in Table 18-13.[1,2] Precautions and relative contraindications for cardioversion are listed in Table 18-14.

Table 18-13 Indications and Energy Requirements for Cardioversion

Indications	Energy in Joules (J) Monophasic Waveform*
Monomorphic VT with a pulse	100–360
Atrial flutter	50
Atrial fibrillation	200 initially

*The energy requirement when using a biphasic waveform defibrillator varies but is usually less compared with a monophasic waveform automatic external defibrillator.

Table 18-14 Precautions/Relative Contraindications to Cardioversion

Condition	Complications
Digitalis toxicity	Ventricular irritability, asystole
Hypokalemia	Ventricular irritability/fibrillation
AF with slow ventricular response	Postcardioversion asystole
AF of unknown duration with inadequate anticoagulation	Thromboembolization
Pacemaker dependency	Rise in thresholds with loss of capture
Low-amplitude R wave	Synchronization on T wave leading to ventricular fibrillation

The energy needed to convert monomorphic VT with a pulse may be as low as 100 J initially, followed by 200, 300, or 360 J, as necessary for conversion.[1] The energy required for conversion of atrial flutter may start at 5 to 50 J when a biphasic waveform defibrillator is used.[2] The energy required to convert AF is greater, starting at 200 J.[3] After conversion to sinus rhythm, antiarrhythmic therapy may be initiated for rhythm maintenance. Although recommendations are made for the amount of joules needed to convert various rhythms, the actual energy needed may vary depending on the duration of the dysrhythmia, transthoracic impedance, and the waveform morphology of the defibrillator (ie, monophasic vs. biphasic).[2]

Procedure

The steps for cardioversion follow:

1. Explain the procedure to the patient and obtain informed consent.
2. Restrict the patient's food and water for 6 to 8 hours before cardioversion, unless emergency cardioversion is required.
3. If the patient is on chronic digitalis, confirm that digoxin levels are therapeutic. Patients with digitalis toxicity should not undergo elective cardioversion until levels are normalized.
4. Record a 12-lead ECG and vital signs, establish an IV line, monitor blood oxygen saturation levels, and ready all necessary resuscitation equipment.
5. Turn on the defibrillator and monitor, and attach the monitoring electrodes to the patient's chest. Avoid placing the electrodes in the area where the defibrillation paddles will be positioned. Some devices permit both monitoring and defibrillation through disposable defibrillation patches.
6. Select a monitoring lead that provides a good ECG pattern with a tall R wave. If monitoring by way of the disposable defibrillator patches, select "paddles" lead.
7. Turn on the synchronizer mode button. The size of the R wave or the monitored lead may need to be adjusted until the synchronization marker appears on each R wave.
8. Sedate the patient, and maintain an adequate airway.
9. Remove paddles from the defibrillator and apply a generous amount of electrode gel to the metal surface. Take care not to smear electrode gel between the two paddles on the chest. Disposable pregelled defibrillator patches may be selected rather than standard paddles.
   a. If hands-free gel patches are used, disconnect the paddles from the defibrillator and connect the terminal pin of the patches to the defibrillator using an adaptor. Place the sternum patch to the right of the sternum, just below the clavicle, and the apex patch below the anterior/axillary margin of the left chest. Apply each patch firmly from the center to the periphery, ensuring that there are no air pockets, which can cause electrical arcing and skin burns.
   b. If using paddles, apply firmly, one just below the right clavicle and the other over the apex of the heart. Make sure paddles or patches are away from electrode wires or from an implanted pacemaker or ICD generator.
10. Set the desired energy level.
11. Press the charge button. A light will flash until paddles are fully charged.
12. Reconfirm the synchronization markers on the R waves on the monitor.
13. Call out "clear" and visually check to make sure no one is touching the patient or the bed.
14. While applying 25 pounds of firm pressure on the paddles, push and hold both paddle discharge buttons until the defibrillator discharges. Maintain contact on the chest wall until the machine has delivered the shock. There will be a momentary delay from the pressing of the discharge button to delivery of the shock because of the synchronization with the R wave. Failure to keep the paddles on the chest can result in failure to cardiovert and burns to the chest.
15. Assess the patient's rhythm, airway, and vital signs.
16. Subsequent shocks may need to be delivered. If so, be certain to select the synchronized mode.
17. If the patient's rhythm deteriorates to VF, turn off the synchronizer and immediately defibrillate the patient, starting with 200 J and increasing to 360 J as needed.
18. After cardioversion, observe the patient for changes in rhythm, blood pressure, and respirations. Patients with AF converting with sinus pauses may have underlying tachy–brady syndrome. Be prepared for transcutaneous pacing if needed, or have atropine sulfate readily available. If a patient has a pacemaker, the pacemaker may need to be interrogated or reprogrammed because a temporary rise in capture thresholds may follow cardioversion. Older pacemaker models may revert to a reset or backup mode.
19. Antiarrhythmic agents may need to be initiated to maintain sinus rhythm.
20. Monitor the patient's respiratory status and level of consciousness because sedation was delivered before the procedure. Inspect the chest wall for any signs of burns and treat appropriately.
21. Clean the paddles thoroughly before storing them.
22. Document the procedure, the outcomes of the procedure, and the patient's status in the medical record.

▲ Catheter Ablation

Catheter ablation is an invasive procedure used for treating tachydysrhythmias. The technique involves percutaneously inserting a catheter into the heart via a vein or artery, and applying radiofrequency or cryoablation. Delivery of the catheter electrode tip to targeted areas responsible for initiating or conducting the dysrhythmia limits the tissue damage.

Clinical use of catheter ablation of cardiac tissue started in the early 1980s with direct current shocks delivered through a catheter attached to a defibrillator. Because this technique was associated with significant risk, safer means to ablate tissue were investigated.

Radiofrequency energy, the primary source of energy used to ablate cardiac tissue, is produced by alternating current (AC) delivered at 500 kHz through the tip of the catheter in unipolar fashion. The circuit is completed through a grounding pad applied on the patient's skin. Resistive heat is created as the energy dissipates around the active electrode, which results in a small localized lesion in cardiac tissue. Tissue temperatures of 50°C or higher lead to irreversible tissue injury. If properly targeted, this localized area of damage can prevent the initiation of the dysrhythmia (the "focus") or interrupt the conduction (the "accessory pathway") of the dysrhythmia. The size of the resulting lesion depends on the electrode temperature, power delivered, and duration of the AC used. When tissue temperature exceeds 100°C, formation of coagulum and char at the electrode tissue interface prevents further energy delivery and adds the risk for steam venting to the endocardial tissue, possibly causing perforation. Electrode cooling (eg, through saline irrigation) reduces the risk for overheating and allows for larger lesion size delivered by higher power. The size, shape, and electrode material of the ablating catheter also influence the resulting lesion.[4]

Indications for Ablation

A PSVT can be treated with radiofrequency ablation. Most PSVTs are caused by either atrioventricular nodal reentrant tachycardia (AVNRT) or by atrioventricular reentrant tachycardia (AVRT). PSVT also can be caused by intra-atrial reentrant tachycardia. Recurrent symptomatic or life-threatening ventricular dysrhythmias also may be indications for ablation. Indications for catheter ablation procedures are included in the AHA and Heart Rhythm Society (formerly North American Society of Pacing and Electrophysiology; NASPE) policy statement on catheter ablation.[5]

The most common mechanism for SVT is reentry[3] which occurs when conduction of an impulse through myocardial tissue is initially blocked (or functionally refractory, unresponsive to stimuli) in one direction. The advancing wave front proceeds through an alternate slower route. As the previously refractory pathway recovers, the electrical impulses return through that pathway and then find their way back down to the alternate slower route. As a result, a circuitous reentrant pattern of conduction occurs.

Atrioventricular Nodal Reentrant Tachycardia

The compact AV node can utilize two functional pathways for conduction—slow and fast—setting the stage for AVNRT. When this phenomenon is observed in the electrophysiology (EP) laboratory, the AV node is described as having dual physiology. AVNRT, the most common type of PSVT, occurs when an AV node with dual physiology is stimulated by a premature atrial contraction. The fast pathway, which is preferentially used in normal sinus rhythm, has not recovered, so the impulse travels down the slow pathway and activates the ventricles. On surface ECG, this initiating rhythm would be viewed as a premature atrial contraction with a long PR interval. The impulse then returns back up to the atria from the ventricles through the fast pathway, which has now recovered excitability, then back down again to the ventricles through the slow pathway, causing the reentrant circuit to perpetuate. Selective ablation of the slow pathway is the preferred method of treating AVNRT. The fast-pathway ablation sites are closer to the compact AV node, and ablation of the fast pathway may be complicated by high-grade AV block.

Atrioventricular Reentrant Tachycardia

In the normal heart, the AV node and the bundle of His serve as the connection between the atria and the ventricles for the conducting system. AVRT rhythms are characterized by the presence of additional accessory pathways that link conduction between the atria and the ventricles. Conduction through accessory pathways may start from the atria to the ventricles (antegrade conduction), from the ventricles to the atria (retrograde conduction), or in both directions. AVRT rhythms result when circular movement of the impulse occurs because of the ability of the accessory pathways to conduct signals in either direction.

In WPW syndrome, an electrocardiographic pattern associated with PSVT and sometimes associated with Ebstein's anomaly of the tricuspid valve, the person has one or more anomalous conduction accessory pathways linking the atria and the ventricles. Because of these accessory pathways, the person with WPW syndrome is prone to AVRT and AF with rapid ventricular response. When rapidly conducting, these PSVTs may deteriorate into VF. Ablation of the accessory pathways is used to interrupt the rapid limb of the reentrant circuit and eliminate the offending dysrhythmias.

Atrial Fibrillation or Flutter

Ablation may be indicated for patients with AF or flutter with a rapid ventricular response that has not been controlled by pharmacological therapy. The AV junction may be ablated, completely disrupting communication from the atria to the ventricles. Successful ablation results in complete heart block with a ventricular rate of 40 to 60 beats/min. A permanent pacemaker is implanted after AV junction ablation to ensure the presence of a reliable rhythm and adequate rate as well as to reduce the risk for bradycardia-dependent torsades de pointes.

In addition, ablation for AF can be performed by creating lines of block around the anatomical triggers (eg, around the orifice of the pulmonary vein), or when the focus is identified, by electrically isolating the foci. The various techniques require special catheters and mapping equipment.[6] However, not all types of AF are amenable to this procedure; the etiology and trigger of the dysrhythmia need to be elucidated before a decision is made to carry out the ablation.

Ablation therapy for primary atrial flutter is indicated in those patients who have reentrant circuits within the right atrium. Ablation lesions are directed at creating a line of block usually along a narrow isthmus between the inferior vena cava and tricuspid annulus to interrupt the circuit.[7] When successful, atrial flutter ablation can provide a permanent cure. Unlike AV node ablation, atrial flutter ablation does not require permanent pacemaker implantation.

Ventricular Dysrhythmias

The success of ablation for the treatment of VT depends on the cause of the dysrhythmia. Radiofrequency ablation has been effective in patients with VT in structurally normal hearts and in patients with VT due to bundle branch reentry. The technique also has had some limited success in patients with hemodynamically stable, monomorphic VT associated with a healed myocardial scar. However, it is not unusual to have multiple morphologies (forms) of VT in this population, and some unstable morphologies may not be amenable to ablation.

Procedure

Before an ablation, the patient undergoes an electrophysiological study (EPS) to evaluate the electrical activity of the heart. The EPS is an invasive test in which catheters are placed in the heart to record intracardiac electrograms (IC-EGM). The test provides information about the sequence of electrical activation of the heart in sinus rhythm and any abnormal sequence of activation during an induced dysrhythmia. An electrical map is inferred from the electrical recordings to help identify the focus of a dysrhythmia or locate an accessory pathway. The map guides the placement of the ablating catheter.

After the catheters are positioned, ECG recordings are made from the surface electrodes on the patient's chest and electrograms (EGMs) from the intracardiac electrodes. Programmed electrical stimulation (PES) is then performed to induce the dysrhythmia so that its mechanism and pathway can be evaluated. Once a diagnosis of the dysrhythmia is confirmed, an ablating catheter is positioned in the targeted area of the heart. Additional catheters are positioned to stimulate atrial and ventricular tissue. The ablation catheter contains multiple electrodes designed to localize the site of the dysrhythmia and to deliver the ablation current. The distal tip of the catheter can be flexed to facilitate access to the tissue and to ensure direct contact. Fluoroscopy and the EGM pattern from the catheter, as well as special mapping equipment and intracardiac ultrasound, help the physician determine the appropriate target area. The clinical ECG of the tachycardia is a useful template of the target dysrhythmia when several morphologies are induced.

When the appropriate site is identified, the radiofrequency current is applied for several seconds until the target tip temperature is achieved. Longer application time is allowed when a cooled or irrigated catheter tip is used. Several lesions may be required to eliminate the abnormal conducting tissue. Successful elimination of the target site is determined by examining the ECG and EGM tracings and confirmed when the dysrhythmia is no longer inducible. When the procedure is finished, the intracardiac catheters and venous or arterial sheaths are removed, and efforts to attain hemostasis at the insertion site are implemented.

Nursing Management

The nurse plays a vital role in the care of the patient undergoing radiofrequency ablation. In consultation with the electrophysiologist, the nurse provides information to the patient and family about what to expect before, during, and after the procedure. The psychosocial support provided by the nurse may be key in helping the patient and family cope with the uncertainties of dysrhythmia management.

Preablation

The nurse participates in educating the patient and family about radiofrequency ablation (Box 18-20). During the preablation period, the nurse records a 12-lead ECG, continuously monitors the patient's cardiac rhythm, and treats any dysrhythmias per the physician's orders. Other baseline data obtained include vital signs, breath sounds, fluid status, serum chemistries, PT, and complete blood counts. Antiarrhythmic drugs may be discontinued 2 to 3 days before the procedure to allow provocation of the dysrhythmia during the procedure. The patient receives nothing by mouth for about 8 hours before the procedure. It is important to verify that a female patient is not pregnant because of x-ray exposure during the test. No activity restrictions are imposed before the procedure.

During Ablation

The nurse in the EP laboratory is responsible for monitoring the patient throughout the procedure and assisting the physician with necessary interventions. The nurse must be competent in ACLS so that an emergency situation can be handled appropriately.

In the laboratory, the nurse explains each intervention to the patient and helps put the patient at ease. The nurse

BOX 18-20 TEACHING GUIDE Preablation

Points the patient needs to know before the ablation procedure include the following:

- Purpose of the procedure
- The patient's dysrhythmia and how the procedure will help
- Interventions that will occur before transport to the electrophysiology (EP) laboratory
- The appearance of, equipment, and personnel in the EP laboratory
- The use of IV conscious sedation, including the amnesic/analgesic effect of conscious sedation and possible side effects, such as nausea, vomiting, or hypotension
- Sensations associated with the procedure, such as:
  - Cool sensation from cleansing agents
  - Pressure sensation from catheter insertion
  - Palpitations, dizziness, or other sensations when dysrhythmia is induced
  - possible mild burning sensation during ablation
  - Restlessness or back discomfort from lying immobilized
- Anticipated length of the procedure
- Potential for placement of a permanent pacemaker
- Anticipated after effects, such as:
  - Skipped beats or faster than usual resting rate may be felt initially
  - Mild chest discomfort or burning may occur for a few days
  - A "skin effect," a dark outline of the grounding or defibrillation pad, which may persist indefinitely

connects the patient to a cardiac monitor and physiological recorder and applies a grounding pad for the radiofrequency catheter, AED patches, automatic blood pressure device, and pulse oximeter. Oxygen is provided by nasal cannula. If not already in place, an IV line is inserted. IV conscious sedation is administered to ensure patient comfort. A urinary catheter is inserted if the procedure is anticipated to be lengthy. Both groins and the right subclavian vein sites are shaved and the skin prepared. A sterile field is established and maintained throughout the procedure. A lead apron may be placed under the patient's lower back to block fluoroscopy radiation from penetrating the reproductive system.

Throughout the procedure, the nurse monitors hemodynamic status, activated clotting time (ACT) if heparin is used, sedation level, and patient comfort. Communication with the patient is essential so that the patient is kept informed about the progress of the procedure, and anxiety and fear are minimized. The nurse also warns the patient that a burning sensation may be felt for a brief time during the actual ablation.

Postablation

Thorough assessment and monitoring of the patient are continued after the ablation procedure. Essential components of the assessment include vital signs, cardiac rhythm, catheter insertion sites, peripheral pulses, and level of consciousness. The patient may remain drowsy for several hours and experience nausea and vomiting as a result of the medications. When an arterial site has been used, leg immobilization and bed rest are maintained for about 6 hours. If only venous sites were used, the patient may begin ambulation in about 4 hours. The nurse assesses the patient for any pain or discomfort and provides comfort measures if indicated. Fluid volume status is checked, and when the patient's condition is stable, the urinary catheter is removed.

During the postablation period, the nurse carefully assesses the patient for any evidence of complications. Table 18-15 lists potential complications of radiofrequency ablation and associated signs and symptoms.

Table 18-15 Potential Complications of Radiofrequency Ablation and Associated Signs and Symptoms

Complications	Signs and Symptoms
Cardiac perforation	Tachycardia, hypotension, dyspnea, pleuritic chest pain
Cardiac tamponade	Hypotension, distended neck veins, muffled heart sounds, pulsus paradoxus, change in level of consciousness
Coronary artery spasm	Chest pain, ECG changes
Pneumothorax	Dyspnea, decreased oxygen saturation decreased breath sounds
Cerebral embolus	Slurred speech, blurred vision, headache, seizures
Pulmonary embolus	Chest pain, dyspnea, tachycardia
Femoral artery dissection	Bruit at site of pulse, hematoma, retroperitoneal bleed
Deep venous thrombosis	Swelling of leg at site of catheter insertion, calf pain

▲ Cardiac Pacemakers

Electrical stimulation of the heart was tried experimentally as early as 1819. In 1930, Hyman noted that he could inject the right atrium with a diversity of substances and restore a heartbeat. He devised an "ingenious apparatus" that he labeled an artificial pacemaker, which delivered a rhythmic charge to the heart. In 1952, Zoll demonstrated that patients with Stokes-Adams syndrome could be sustained by the administration of current directly to the chest wall. In 1957, Lillehei affixed electrodes directly to the ventricles during open heart surgery.

From 1958 to 1961, implantable pacemakers became accepted treatment for complete heart block. In the 1970s and 1980s, AV synchrony and "physiological" pacing became available. At the start of the first decade of the 21st century, clinical trials on right and LV (biventricular) pacing made tremendous progress. Biventricular pacing is achieved by positioning an additional lead in one of the coronary sinus branches to stimulate the left ventricle, nearly simultaneous with the right ventricle. Commonly referred to as cardiac resynchronization therapy (CRT), biventricular pacing is used for symptom improvement and treatment of HF in patients with moderate to severe LV dysfunction and BBB. Biventricular pacing corrects intra- and interventricular delay; CRT has been shown to improve functional class and quality of life in select HF populations.[8]

Currently, technological advances have resulted in smaller pacemakers with longer battery life and numerous programmable options in most models. Furthermore, the goal of individualized, physiological pacing has been achieved with recent advances.

Indications for Cardiac Pacing

Cardiac pacing is most commonly indicated for conditions that result in failure of the heart to initiate or conduct an intrinsic electrical impulse at a rate adequate to maintain perfusion. Pacemakers are necessary when dysrhythmias or conduction defects compromise the electrical system and the hemodynamic response of the heart. The original pacemakers were designed for antibradycardia. Today's pacemakers also monitor and treat tachydysrhythmias and facilitate electrical remodeling. Further research and advances in technology have allowed the use of pacemakers in heart conditions such as congestive heart failure, long QT syndrome, and neurocardiogenic syncope.[9]

Critical care nurses work with members of the health care team to assess potential pacemaker patients who may exhibit dysrhythmias, atherosclerotic heart disease, AMI, or other conditions that alter the conduction of the heart. To assist medical professionals in determining the clinical criteria for pacemaker implantation, a Joint Committee of the ACC, AHA, and Heart Rhythm Society (formerly NASPE) was formed to establish uniform criteria for pacemaker implantation.[9] The committee divided its recommendations for implantation into three classes of indications. Class I indication recommends implantation, includes conditions for which there is evidence or general agreement that treatment is

useful and effective. Class II indication includes conditions for which there is conflicting evidence or a divergence of opinion about the usefulness or efficacy of a procedure or treatment. (In class IIa conditions in which treatment is reasonable, and in class IIb conditions in which treatment may be considered) Class III includes conditions for which there is evidence or general agreement that the procedure or treatment is not useful or effective and in some cases may be harmful. The most common indications for pacemaker implantation with recommended pacing modes are summarized in Box 18-21.[9]

The Pacemaker System

The pacemaker system, which consists of a pulse generator and one to three leads with electrodes, performs two main functions: diagnosis and treatment. The diagnostic function is to sense intrinsic cardiac activity; the treatment function is to emit an electrical impulse that excites endocardial cells and produces a wave of depolarization in the myocardium. Clinical terminology related to pacemakers is listed in Box 18-22.

Permanent Pacing Systems

THE PULSE GENERATOR. The pulse generator for a permanent pacemaker is composed of a lithium iodide battery source and electronic circuits enclosed in a hermetically sealed metal container. The generator weighs 20 to 30 g and is 5 to 7 mm thick (Fig. 18-29). The longevity of most permanent pacemakers is about 6 to 12 years, depending on the percentage of pacing the heart requires over time. Most permanent pulse generators are inserted in a subcutaneous pocket in the pectoral region below the clavicle (Fig. 18-30).

BOX 18-21 Indications for Permanent Cardiac Pacing*

Acquired Atrioventricular (AV) Block in Adults

Class I: Third-degree and advanced second-degree AV block at any anatomical level, associated with any one of the following conditions: (1) symptomatic bradycardia; (2) asystole greater than or equal to 3.0 seconds or any escape rate less than 40 beats/min in awake, symptom-free patients; (3) dysrhythmias and other medical conditions that require drugs that result in symptomatic bradycardia; (4) post-AV node ablation; (5) postoperative AV block that is not expected to resolve after cardiac surgery; and (6) neuromuscular diseases with AV block, (7) atrial fibrillation with pause of 5 seconds or greater, and (8) exercise-induced AV block in the absence of myocardial ischemia

Class IIa: (1) Asymptomatic third-degree AV block at any anatomical site with average awake ventricular rates of 40 beats/min or faster without cardiomegaly (2) asymptomatic type II second-degree AV block with a narrow QRS; (3) asymptomatic type I second-degree AV block at intra- or infra-His levels found at EPS (4) first- or second-degree AV block with symptoms similar to those of pacemaker syndrome.

Class IIb: (1) Neuromuscular diseases, such as myotonic muscular dystrophy, Kearns-Sayre syndrome, Erb's dystrophy (limb-girdle), and muscular atrophy, with any degree of AV block (including first-degree AV block) with or without symptoms. (2) AV block in the setting of drug use when the block is expected to occur even after the drug is withdrawn

Class III: Asymptomatic first-degree AV block and type I second-degree AV block, transient AV block

Chronic Bifascicular Block

Class I: (1) Intermittent complete heart block, (2) type II second-degree AV block, and (3) alternating bundle branch block

Class IIa: (1) Syncope not demonstrated to be due to AV block when other likely causes have been excluded, specifically VT; (2) prolonged His–ventricular interval on EPS; (3) incidental finding of pacing-induced, nonphysiological infra-His block at EPS

Class IIb: (1) Neuromuscular diseases, such as myotonic muscular dystrophy, Kearns-Sayre syndrome, Erb's dystrophy (limb-girdle), and peroneal muscular atrophy, with any degree of fascicular block with or without symptoms

Class III: Fascicular block without AV block or symptoms and asymptomatic fascicular block with first-degree AV block

AV Block After AMI

Class I: (1) Persistent type II second-degree AV block with alternating bundle branch block (BBB) or third-degree AV block (2) transient advanced (second- or third-degree) infranodal AV block and associated BBB; (3) persistent and symptomatic second- or third-degree AV block.

Class IIb: (1) Persistent second- or third-degree AV block at the AV node level

Class III: Transient AV block

Sinus Node Dysfunction (SND)

Class I: SND (1) with documented symptomatic bradycardia (2) symptomatic chronotropic incompetence (3) occurring spontaneously or as a result of required drug therapy for a medical condition

Class IIa: SND (1) with heart rate less than 40 beats/min, (2) syncope of unexplained origin with provoked SND during EPS

Class IIb: In minimally symptomatic patients, chronic heart rate less than 40 beats/min while awake.

Class III: Asymptomatic SND; SND with symptomatic bradycardia due to nonessential drug therapy; symptoms occur in the absence of bradycardia

Hypersensitive Carotid Sinus Syndrome and Neurocardiogenic Syncope

Class I: Recurrent syncope caused by spontaneous carotid sinus stimulation and asystole of more than 3 seconds induced by minimal carotid sinus pressure.

Class IIa: Recurrent syncope without clear, provocative events and a hypersensitive cardioinhibitory response of 3 seconds or longer

Class IIb: Significantly symptomatic neurocardiogenic syncope associated with bradycardia documented spontaneously or at head-up tilt

Class III: (1) A hyperactive cardioinhibitory response to carotid sinus stimulation in the absence of symptoms or in the presence of vague symptoms such as dizziness, light-headedness, or both and (2) situational vasovagal syncope in which avoidance behavior is effective

*Box does not include indications for special population and specific conditions.

A report of the American College of Cardiology/American Heart Association task force on practice guidelines (ACC/AHA/NASPE 2002 guideline update for implantation of cardiac pacemakers and antiarrhythmia devices). Heart Rhythm 5:e7–e19, 2008

BOX 18-22 Clinical Terminology Related to Pacemakers

Active fixation lead: A pacing lead with some design at the lead tip (corkscrew, coil) that allows the tip to be embedded in heart tissue, thus decreasing the likelihood of dislodgment
Asynchronous pacing: A pacemaker that fires at a fixed rate regardless of the intrinsic activity of the heart
Bipolar lead: A pacing lead containing two electrodes. One electrode is at the tip of the lead and provides stimulation to the heart. A second electrode is several millimeters proximal to the tip and completes the electrical circuit. Both electrodes provide sensing of the intrinsic cardiac activity.
Capture: The depolarization of a cardiac chamber in response to a pacing stimulus
Chronotropic incompetence: Inability of the sinus node to accelerate in response to exercise
Demand pacing (inhibited pacing): A pacemaker that withholds its pacing stimulus when sensing an adequate intrinsic heart rate
Dual-chamber pacing (physiological pacing): Pacing in both the atria and the ventricles to restore artificially AV synchrony
Electromagnetic interference: Electrical or magnetic energy that can interfere with or disrupt the function of the pulse generator
Milliamperage (mA): The unit of measure used for the electrical stimulus (output) generated by the pacemaker
Multisite pacing: The ability to stimulate more than one site in a chamber (eg, right ventricle and left ventricle stimulation in biventricular pacing/cardiac resynchronization therapy [CRT])
Overdrive pacing: A method to suppress a tachycardia by pacing the heart at a rate faster than the patient's intrinsic rate
Oversensing: Inhibition of the pacemaker by events other than those that the pacemaker was intended to sense. These may include tall T waves and EMI.
Pacing threshold: The minimal electrical stimulation required to initiate atrial or ventricular depolarization consistently
Passive fixation lead: A pacing lead that lodges in the trabeculae of the heart without actually penetrating the cardiac wall
Rate-responsive (rate-adaptive, rate-modulated) pacing: A pacemaker that alters pacing rate in response to detected changes in the body's metabolic demand
Sensing: The ability of the pacemaker to detect intrinsic cardiac activity and respond appropriately. How the pacemaker responds depends on the programmed mode of pacing.
Sensing threshold: The minimal atrial or ventricular intracardiac signal amplitude required to inhibit or trigger a demand pacemaker
Situational vasovagal syncope: Syncope associated with bradycardia by vagal stimulation during coughing, micturition, or severe pain
Triggered: A response to sensing in which the pacemaker fires a stimulus in response to intrinsic cardiac activity. In pacemaker terms, triggered is the opposite of inhibited.
Undersensing: Failure of the pacemaker to sense the heart's intrinsic activity. As a result, the pacemaker fires inappropriately.

THE LEAD SYSTEM. The lead is a wire that provides the communication network between the pulse generator and the heart muscle. One or more electrodes are at the distal end of the lead and provide sensing and pacing of the heart muscle. In a bipolar lead, the negative electrode (cathode) is at the tip, and the positive electrode (anode) is about 1 to 3 cm proximal to the tip (Fig. 18-31).

The permanent pacemaker lead is typically inserted either through a subclavian vein or a cephalic vein through the chest wall. Alternate insertion sites include the external jugular, internal jugular, and rarely, femoral vein. The lead is then positioned with fluoroscopic guidance and affixed in the right atrial appendage or in the apex of the right ventricle, or in both locations. A third lead may be inserted in a coronary sinus branch to stimulate the left ventricle for biventricular pacing. The leads must provide adequate electrical stimulation, sufficient insulation, and the endurance to withstand pulsatile turbulence.

The permanent pacemaker lead tip can be affixed to the myocardium with a lead fixation mechanism. Over time, fibrotic tissues anchor the tip to the myocardium securing placement and ensuring proper function of the electrode.

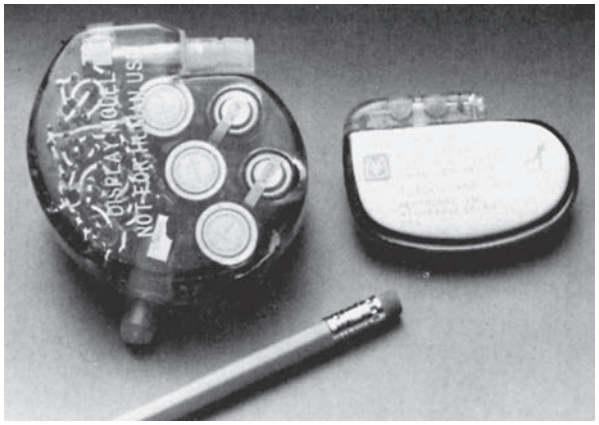

FIGURE 18-29 ▲ Permanent pulse generators, old (*left*) and new (*right*) models. Note the decrease in size and weight that has been achieved over the years. The smaller unit is an example of an activity-responsive pulse generator and is four times smaller than the larger 1,968 U.

Temporary Pacing Systems

Temporary pacemaker systems are used in emergency and elective situations. In life-threatening situations, a temporary pacemaker serves as a bridge to permanent pacemaker

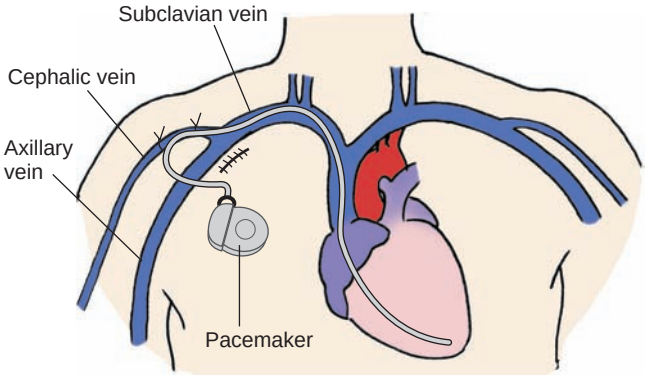

FIGURE 18-30 ▲ Transvenous installation of a permanent pacemaker. For dual-chamber pacing, a separate pacing wire would be in the atrium.

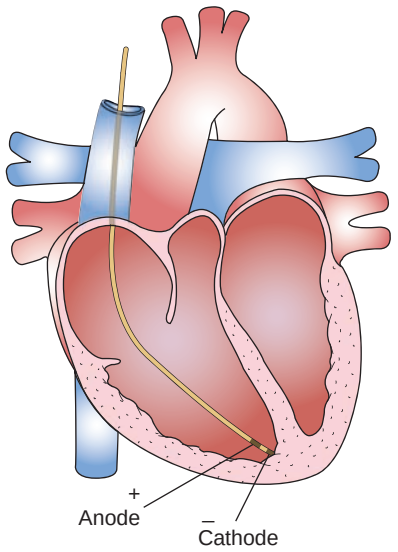

FIGURE 18-31 ▲ Transvenous bipolar pacing catheter in place.

implantation or until resolution of a reversible cause. Electively, temporary pacemakers may be used for overdrive or pace-termination of tachydysrhythmias. Temporary pacing systems can be transvenous, epicardial, transcutaneous, or transthoracic.

TRANSVENOUS TEMPORARY PACING SYSTEMS. A transvenous pacemaker system consists of an external pulse generator and a temporary transvenous pacing lead. The lead system usually includes the use of a bipolar catheter with a paired negative distal and positive proximal electrode at the endocardial surface. The lead terminal pins are attached to a connecting cable and the corresponding negative and positive ports of the pulse generator.

For temporary transvenous pacing, the clinician uses local anesthesia and then introduces the catheter/lead into a superficial vein. The brachial, internal or external jugular, subclavian, and femoral veins may be used. The subclavian and internal jugular sites allow greater lead stability and patient mobility. The transvenous lead is threaded through a sheath in the vein, into the vena cava and the right atrium, through the tricuspid valve, and into the right ventricle. The lead tip is placed in contact with the endocardial surface of the RV apex for stability and reliability. For atrial pacing, an atrial bipolar catheter is placed in the right atrial appendage. There are also pulmonary artery balloon flotation catheters with atrial and ventricular pacing ports for dual-chamber pacing. Balloon flotation catheters are useful in the critical care setting because they provide thermodilution and cardiac output determination and do not require fluoroscopy for positioning.

After placement, the leads are affixed at the skin entry site with nonabsorbable suture. The sheath should be sutured and attached to a continuous drip if used for drawing blood or administering drugs. To maintain sterility at the connection site and terminal tip of the catheter, a sterile protective sleeve over the catheter can be used before insertion and then connected to the end of the sheath after satisfactory position is confirmed. The sheath entry site should be covered with an antiseptic ointment and a self-adhesive, semipermeable transparent dressing. A small label above the dressing, initialed by the nurse, should indicate time and date of application.

EPICARDIAL TEMPORARY PACING SYSTEMS. Placement of epicardial wires provides another method for temporary pacing. This method can be accomplished by thoracotomy or through a subxiphoid incision with the placement of pacing electrodes directly on the outer surface of the heart. Epicardial wires often are used as a temporary adjunct during and after open heart surgery. The pacing wires are attached to the epicardial surface of the heart, and the proximal end is brought outside through the chest incision and either connected to a temporary pacemaker generator or capped and then connected if the need for pacing arises. The wires are extracted without reopening the incision, even after scar tissue has formed over the tips.

TRANSCUTANEOUS TEMPORARY PACING SYSTEMS. Another method of temporary pacing is known as external transcutaneous pacing. This method involves placing large gelled electrode patches directly on the chest wall. The cathode or negative electrode is applied anteriorly to the left of the sternum, and the anode or positive electrode is applied straight posteriorly on the patient's back and then connected to an external transcutaneous pacemaker (Fig. 18-32). Transcutaneous pacing can cause significant discomfort, and the patient should be informed and adequately sedated, if necessary. Transcutaneous pacing is used when temporary transvenous pacing is not immediately available. In patients with profound asystolic arrest, the transcutaneous pacemaker should not be relied on indefinitely.

TRANSTHORACIC TEMPORARY PACING SYSTEMS. Transthoracic pacing is a temporary pacing method used as a last resort in an emergency situation. This method involves introduction of a pacing needle in the anterior wall of the heart. Transthoracic pacing has limited success rates and a high potential for complications.

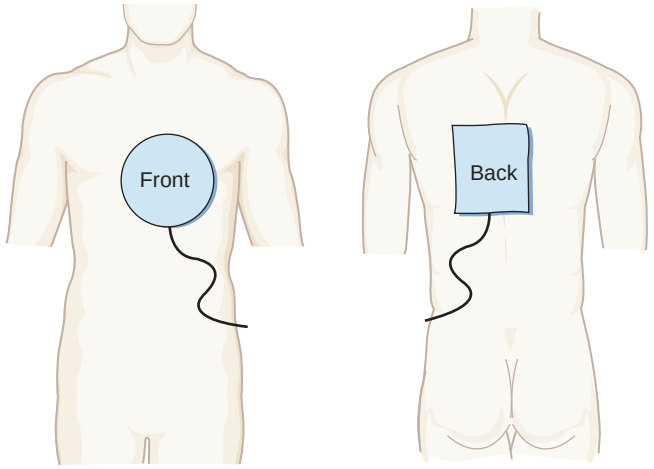

FIGURE 18-32 ▲ Transcutaneous pacing. Electrodes are placed on anterior and posterior chest walls and attached to the external pacing unit.

FIGURE 18-33 ▲ A dual-chamber temporary pacemaker. (Courtesy of Medtronic, Minneapolis, MN.)

EXTERNAL PULSE GENERATOR. The temporary pulse generator is an external device powered by a 9-V alkaline or lithium replaceable battery (Fig. 18-33). Often called a temporary pacemaker, the device contains several controls that regulate the current output, rate, sensitivity, and the mode of pacing; and for dual-chamber pacing, base and upper rate, AV interval and refractory period settings can be chosen. A dual-chamber pulse generator has separate terminals for the atrial and ventricular inputs. The use of a connecting cable allows the lead tips to tighten into the connector block and a locking mechanism to the pulse generator. Cables should be labeled appropriately near the distal lock: atrial or ventricular so as to avoid interchanging the leads when attaching to the atrial or ventricular port of the pulse generator. Nursing assessment and intervention guidelines for temporary transvenous pacemaker placement are summarized in Box 18-23.

Pacemaker Functioning

When the pacemaker system functions appropriately, it senses and treats the heart rhythm dysfunction. The sensing function is the ability of the pacemaker to detect the heart's intrinsic activity, and the sensing amplitude is the largest intrinsic signal that is consistently detected by the pacemaker electrode (eg, the R wave is usually the largest signal sensed by the ventricular lead). At the site of the sensing electrode, the amplitude of the intrinsic depolarization wave is measured in millivolts (mV). The smallest number on the sensor control represents the most sensitive setting, in mV, indicating the smallest signal the pacemaker will sense. If the heart's intrinsic amplitude is smaller than the sensitivity setting,

BOX 18-23 NURSING INTERVENTIONS

For the Patient With a Temporary Transvenous Pacemaker

Assessment

- During insertion:
  - Vital signs, O_2 saturation, peripheral pulses
  - Level of sedation/sedative agents used
  - Continuous cardiac rhythm monitoring
  - Date, time, method, and site of insertion
  - Location of wire inserted (atrial, ventricular, atrial and ventricular)
  - Measured values: capture (mA) threshold and intrinsic amplitude (mV)
  - Patient's tolerance of procedure
  - Complications
  - 12-lead ECG
  - Final settings: mode, rate, output, and sensitivity
- After insertion:
  - Rate setting, mV setting, mA setting, mode of operation (demand, asynchronous) and AV interval (if appropriate)
  - Pacemaker turned off or on
  - Rhythm strip, capture and intrinsic, if appropriate; 12-lead ECG
  - Status on insertion site and sutures (if present)
  - Chest x-ray performed, results on chart
- Every change of shift:
  - Pacemaker turned off or on
  - Pacemaker secured appropriately to patient
  - All connections are secure
  - Setting for rate, mA, sensitivity, mode of operation, AV interval (if appropriate)
  - Rhythm strip (and with any clinical change or intervention)
  - Sensing and capture thresholds (compare to baseline)
  - Presence/absence of hiccupping or muscle twitching
  - Status of insertion site and sutures (if present)
  - Signs of infection (redness, pain, fever, pus)
  - Pulse perfusion distal to insertion site (if appropriate)
  - Connective ends of pacer wires covered (as appropriate)

Intervention

- Continuous cardiac monitoring
- Pacemaker generator:
  - Verify replacement 9-volt battery available.
  - Verify connections are intact.
- Wear rubber/latex gloves when handling the connective ends of pacer wires.
- Cover connective ends of pacer wires to prevent microshock hazard.
- Label epicardial pacer wires *atrial* or *ventricular*.
- Clean and dress pacer wire insertion site(s) daily with gauze dressing or transparent dressing per institutional protocol. Label time and date of dressing change and initial.

Documentation

- Document in Critical Care Flow Sheet/Nursing Notes:
  - Assessments
- Instructions to patient/family
  - Pacing wire insertion site care
  - Pacing and sensing thresholds (print ECG strips)
  - Pacing problems, nursing interventions, and results of interventions
  - Complications/problems

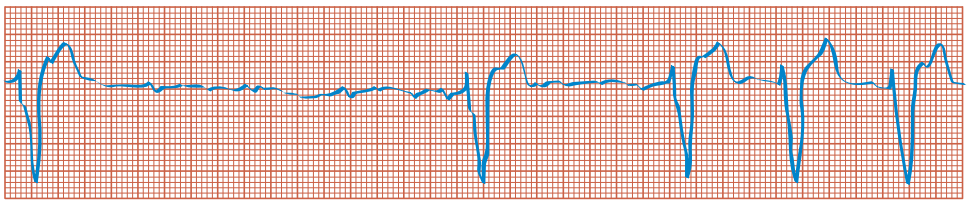

FIGURE 18-34 ▲ Failure to discharge or oversensing with pacing inhibition. In the first half of the strip, the sensing amplifier may have detected electrical noise (oversensing) causing pacemaker inhibition.

undersensing occurs. This can occur when the electrode has inadequate contact with the heart tissue. The drawback in setting pacemaker sensitivity at its most sensitive setting is that oversensing may occur, such as when the pacemaker senses extraneous signals (eg, T waves) or signals from the other chamber. If oversensing occurs, the pacemaker stimulus may be inhibited (Fig. 18-34).

When intrinsic heart rate is adequate, the pacemaker responds by inhibiting a pacing stimulus. When intrinsic heart rate drops to the programmed minimum rate, the pacemaker delivers a stimulus through the lead. When the pacemaker discharges, an artifact known as a pacing spike appears on the ECG, as shown in Figure 18-35. As a result of this stimulus, the cardiac chamber containing the pacemaker lead is depolarized. *Capture* is the term used to indicate depolarization of the atria or ventricle in response to a pacing stimulus. The minimal amount of voltage required from the pacemaker to initiate consistent capture is known

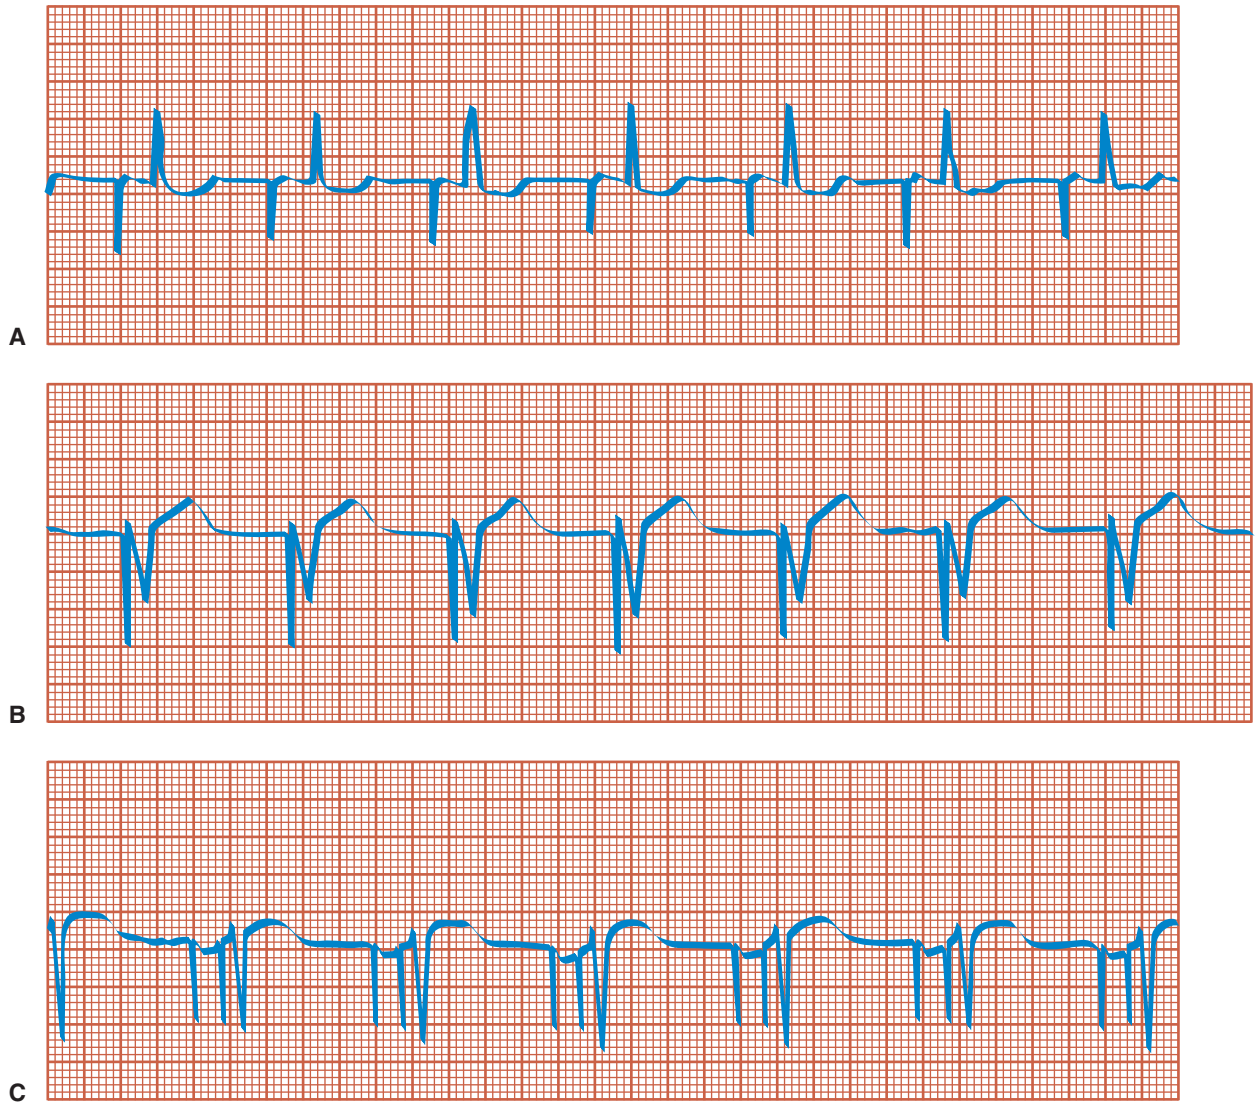

FIGURE 18-35 ▲ Strip **A** shows an atrial pacemaker. Note that each pacing stimulus is followed by a P wave. Strip **B** shows a ventricular pacemaker. Note that each pacing stimulus is followed by a wide QRS complex. Strip **C** shows a dual-chamber pacemaker. Note that the first spike is followed by a P wave and the second spike is followed by a QRS complex. All strips show 1:1 capture.

as the pacing threshold. This threshold level is determined by establishing successful pacing at higher energy and then gradually decreasing the energy output of the generator until capture ceases. The pacing threshold is expressed as milliamperage (mA) in the temporary generator and voltage (V) in the permanent pulse generator, within a given pulse width duration. The generator output is then set at two or three times the threshold level to allow for an adequate safety margin.

Many factors affect the pacing threshold. These include hypoxia, hyperkalemia, antiarrhythmic drugs, catecholamines, digoxin toxicity, and corticosteroids.

The Pacemaker Code

Since the initial use of cardiac pacemakers, the technology has become so complex and diverse that a coding system has been formed to identify the various modes of pacemaker operation. Initially developed in 1974, the pacemaker coding system has undergone several revisions. The most recent version of the code was developed in 2002 through the joint efforts of the AHA and Heart Rhythm Society (formerly NASPE) and the British Pacing and Electrophysiology Group (BPEG).[10] The NASPE/BPEG Generic (NBG) Pacemaker Code is shown in Table 18-16 and is simply called the NBG pacemaker code.

The first letter describes the chamber or chambers of the heart in which pacing occurs: A, atrium; V, ventricle; and D, dual chamber.

The second position of the code indicates the chamber or chambers in which intrinsic cardiac activity is sensed: A, atrium; V, ventricle; and D, dual chamber.

The third position of the code denotes the pacemaker's response to sensed intrinsic cardiac activity. The letter "I" means that the pacemaker is inhibited from firing in response to a sensed intrinsic event. For example, if the pacemaker is set to a rate of 70, and if the patient's intrinsic rate exceeds 70 beats/min, the pacemaker will not fire. The pacemaker fires only if the patient's intrinsic heart rate drops below the programmed rate. Thus, the pacemaker functions on demand and is known as a demand pacemaker. Because the pacemaker is inhibited by adequate intrinsic heart activity, there is no danger of the pacemaker firing at an inappropriate time that could initiate a dangerous cardiac dysrhythmia, such as VT. The letter "T" indicates a pacemaker that triggers pacing stimuli in response to a sensed intrinsic beat. In a patient with complete AV block, a dual-chamber pacemaker is capable of sensing intrinsic atrial activity and triggering ventricular pacing stimulus in response to a sensed atrial event. The letter "D" designates a dual response (inhibited pacing output and triggered pacing after sensed event). The letter "O" in the third position designates a mode in which the pacemaker does not respond to sensed intrinsic activity. Pacemaker insensitivity to intrinsic activity is known as asynchronous pacing. This can be achieved by setting the sensitivity to the highest number or programming to asynchronous mode (ie, DOO, VOO).

Permanent pacemakers also may be switched temporarily to an asynchronous mode by placement of a large magnet over the pulse generator. This maneuver causes the pacemaker to fire without regard to intrinsic rate (fixed pacing), allowing assessment of firing and capture while the patient's rhythm is overridden by the fixed pacing pulse.

The fourth position of the code describes the presence or absence of rate modulation. The letter "O" denotes no rate modulation, and the letter "R" means that rate modulation is active. This is a feature in which the pacing rate varies in response to a physiological variable reflecting activity levels. The physiological variables used are mechanical vibration, acceleration, or minute ventilation. When patients increase their activity, the pacer detects the physiological response (eg, muscle vibration, increased respiratory rate) and increases the pacing rate to meet increased metabolic demands.

The fifth position of the code describes whether multisite pacing is present: "A" in the atrium, "V" in the ventricle, "D" in both atrium and ventricle, and "O" means that no multisite pacing is present.

In clinical parlance, the absence of a fourth or fifth letter designation signifies no rate modulation and no multisite pacing. The first three positions are required when describing pacemaker mode, although all positions may be indicated for completeness.[8]

Pacing Modes

Knowledge of the pacemaker code helps the critical care nurse determine the type of implanted device, the intended mode of operation, and the actual mode of operation.

Table 18-16 The NBG Pacemaker Code

Position: Category				
I: Chamber(s) Paced	**II: Chamber(s) Sensed**	**III: Response to Sensing**	**IV: Rate Modulation**	**V: Multisite Pacing**
O = none	**O** = none	**O** = none	**O** = none	**O** = none
A = atrium	**A** = atrium	**T** = triggered	**R** = rate modulation	**A** = atrium
V = ventricle	**V** = ventricle	**I** = inhibited		**V** = ventricle
D = dual (A +V)	**D** = dual (A + V)	**D** = dual (T + I)		**D** = dual (A + V)

Adapted from North American Society of Pacing and Electrophysiology/British Pacing and Electrophysiology Group. The revised NASPE/BPEG generic code for antibradycardia, adaptiverate, and multisite pacing. Pacing Clin Electrophysiol 25(2):260–264, 2002.

Modes of operation can be classified as single- and dual-chamber modes.

AAI and VVI are single-chamber modes of operation in the atrium or ventricle. An AAI is a mode of operation for atrial pacemakers. With this mode of operation, there is **a**trial pacing, **a**trial sensing, **i**nhibited response to sensed events, and no rate modulation. Temporary atrial pacemakers most often are set to an AAI mode and are particularly useful in overdrive pacing of atrial dysrhythmias.

DDD mode provides **d**ual-chamber pacing, **d**ual-chamber sensing, **d**ual response to sensed events (inhibited or triggered). Dual-chamber modes allow physiological pacing, in which atria and ventricles are sequentially sensed or paced. DDDR mode has the additional feature of rate modulation. VDD mode paces only in the ventricle, but this mode senses atrial and ventricular events and has dual response to sensed events. Therefore, an atrial event (P wave) will trigger a ventricular event. If an intrinsic R wave is sensed, ventricular pacing is inhibited. This mode is particularly useful in patients with intact sinus node function but with high-grade AV block.

Pacemaker Malfunction

Permanent Pacemaker Malfunction

Pacemaker malfunction can be a result of inappropriate programming (pseudomalfunction) or true component malfunction. Although pacemakers are now manufactured to provide more complex capabilities and are generally considered to be more reliable, unanticipated pacemaker malfunction (eg, "advisories") do occur.[11] For this reason, it is important for the patient to know the manufacturer, model, and serial number of his or her pacemaker components (pulse generator and leads) and to ascertain that they have been appropriately registered with the manufacturer. This is usually provided to the patient after the implant procedure, and the patient is given an implanted device identification card.

Advisories are issued when devices of a certain lot or model are associated with component or battery failure. Most manufacturers have toll-free telephone numbers that can provide information on advisories. However, it is important that the patient contact his or her physician, who can provide counseling on appropriate interventions for the advisory. At times, simple programming or monitoring may be all that is needed.

Temporary Pacemaker Malfunction

Temporary pacemaker malfunction should be addressed systematically. First and foremost, immediate action is required to restore pacemaker capture when the patient has no underlying rhythm. These steps are to be followed:

1. Increase pulse generator output (in mA) to the highest setting, asynchronous mode (VOO, DOO).
2. Check patient hemodynamics, simultaneous multiple ECG lead recordings; intervene if appropriate with transcutaneous pacing, atropine sulfate, or isoproterenol.
3. Check all connections.
4. Replace pulse generator or battery; be prepared for transcutaneous pacing backup during change.

Proceed with troubleshooting if the patient's condition is stable. Table 18-17 describes troubleshooting strategies for temporary pacemaker malfunction.

Types of Malfunction

FAILURE TO DISCHARGE. If stimulus discharge from the pacemaker causes an artifact, or "spike," to appear on the ECG, failure to discharge may be manifested by absence of the artifact and unexplained loss of pacing. The cause of this failure may be within the generator itself, either processor or battery failure. Processor failure is not common, but battery failure is more prevalent among patients who are noncompliant with follow-up or unaware of the longevity of their pacemaker battery. This may be evaluated by measuring the output values of the generator through a programmer. In extreme cases, the generator fails to communicate with the programmer. If the situation is emergent, the physician may insert a temporary transvenous pacemaker to support the patient hemodynamically until the permanent pacemaker problem can be corrected.

FAILURE TO CAPTURE. Failure of the pacing stimulus to capture the ventricles or atria is noted by the absence of the QRS or P wave immediately after the pacemaker artifact on the ECG (Fig. 18-36). Failure to capture may be caused by elevated threshold, a lead dislodgment, or impending battery depletion. These conditions may create insufficient output delivery to meet the capture threshold. If the patient is pacemaker dependent and becomes symptomatic, drug therapy (atropine, isoproterenol), transcutaneous pacing, or CPR may be required until the cause of the problem is found and corrected.

OVERSENSING. Oversensing occurs when the pacemaker detects events other than those intended. For example, in VVI pacing, if large T waves are sensed in addition to the R wave, the pacemaker is inhibited, and pacing at a slower than programmed rate may be noted. Similarly, electromagnetic interference (EMI) may result in inappropriate sensing and as a result, incorrectly activate the inhibited or triggered mode of a dual-chamber pacemaker. Oversensing may be caused by electrode displacement, inappropriate sensitivity settings, EMI or impending lead fracture. A partially fractured lead often allows signals to saturate the sensing amplifier, causing oversensing and inhibition of pacing output in demand mode. On the surface ECG, oversensing mimics failure to discharge because oversensing may cause inhibition of the pacing stimuli; for example, in a DDD pacemaker, a sensed P wave usually triggers a ventricular stimulus after completing the timed P-V interval; however, if the ventricular lead senses an intrinsic signal (eg, oversensing noise), the ventricular stimulus is inhibited. The only way to confirm oversensing is to examine IC-EGM through a programmer. If noise is recorded on the IC-EGM, then the problem is due to oversensing.

To correct suspected oversensing in a temporary pacemaker system, the nurse should check the connection between the temporary pacemaker and the lead. Electrical noise from an improperly connected lead could cause oversensing. EMI should be investigated, and the grounding wires of all electrical equipment should be checked. Unipolar leads are particularly prone to EMI because of the broad sensing field from the tip of the lead (negative pole) to the generator (ground). The sensitivity may be decreased by turning the dial toward asynchronous, toward

Table 18-17 Troubleshooting a Temporary Pacemaker

Problem	Cause	Intervention
Failure to discharge: No evidence of pacing stimulus, patient's heart rate below programmed rate	Due to battery depletion or pulse generator failure, output or timing circuit failure	Replace battery or generator.
	Due to loose cable connection	Check all connections for tightness.
Failure to capture: Pacing stimulus not followed by ECG evidence of depolarization	Due to lead dislodgment	Review chest film, turn patient to left lateral decubitus position until lead can be replaced.
	Due to broken connector pins or fractured extension connecting cable	Connect wire directly to generator to diagnose cable problem, replace connecting cable.
	Due to incompatibility of wire pins with cable or to generator	Ascertain a secure fit of the exposed pin to the cable or the generator, adjust connection or replace pulse generator.
	Due to output setting (mA) too low	Check capture thresholds and adjust output to a two- to threefold safety margin.
	Due to perforation	Review 12-lead ECG, report signs of perforation, stabilize hemodynamics.
	Due to lead fracture without insulation break	Check intracavitary ECG; if evidence of fracture in one pole, unipolarize lead; if total fracture, replace lead.
	Due to increase in pacing threshold from medication or metabolic changes	Check laboratory test results, correct metabolic alterations, review medications and vital signs, increase output.
Oversensing: Device detects noncardiac electrical events and interprets them as depolarization	Due to oversensitive setting	Reduce sensitivity (value [in millivolts] should be larger to make pacer less sensitive); if patient is pacer dependent (no intrinsic R wave), program to asynchronous mode until problem is corrected.
	Due to device detecting tall T waves and interpreting them as R waves	Increase ventricular refractory period beyond T wave.
In dual-chamber pacing, cross-talk is a form of oversensing: The device detects signals from the other chamber and inhibits; in atrial channel, R waves are detected as P waves.	Caused by atrial lead dislodgment	Recheck atrial capture thresholds; if high, dislodgment is probable.
In ventricular channel, atrial pacing stimulus afterpotential is detected as an R wave, with V pacing inappropriately inhibited	Due to high output from atrial channel	Reduce output from atrial channel, decrease ventricular channel sensitivity (higher millivolt value).
	Due to electrical interference, improperly grounded electrical devices	Remove nongrounded equipment.
Undersensing: Device fails to detect intrinsic cardiac activity and fires inappropriately	Due to asynchronous mode setting (VOO, DOO, AOO)	Reprogram to synchronous mode (VVI, DDD, AAI).
	Due to small intrinsic amplitude	Increase sensitivity (turn sensitivity dial toward lower millivolt value).
	Due to lead dislodgment	Recheck capture thresholds; if high, lead probably dislodged and needs repositioning.
	Due to lead insulation break	Check lead with pacing system analyzer, if impedance too low (<200 Ohms), insulation break is likely, and lead needs to be replaced or can be temporarily placed in unipolar configuration

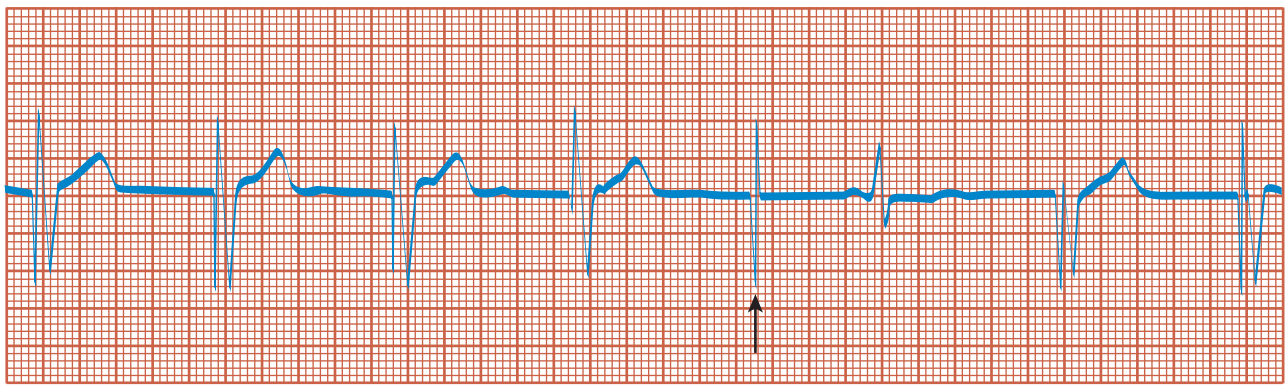

FIGURE 18-36 ▲ Electrocardiogram (ECG) strip showing evidence of failure to capture. Note that pacing stimulus is not followed by a QRS complex.

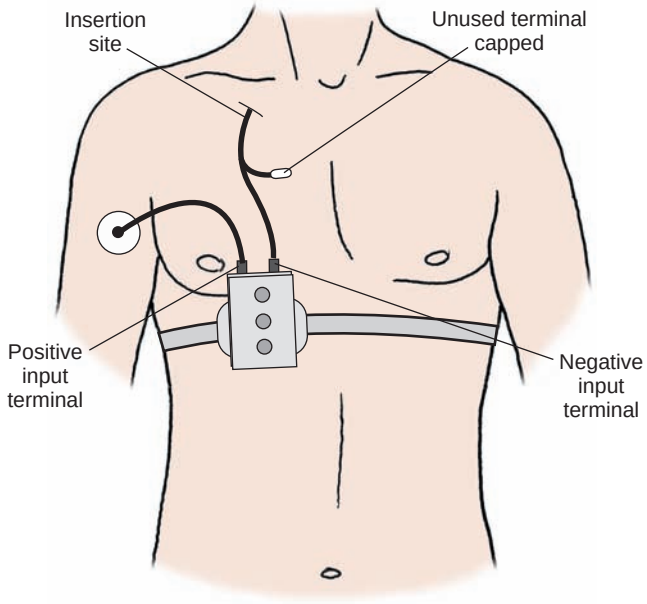

FIGURE 18-37 ▲ Unipolarizing a temporary bipolar lead. This uses an older-style generator with positive and negative terminal input and is for single-chamber pacers only.

a higher mV value. Oversensing due to partial wire fracture in a temporary transvenous bipolar catheter may also be corrected by converting to a unipolar system. To diagnose, an intracavitary ECG is obtained by connecting a single pole to a surface V lead using an alligator clamp connector and obtaining a unipolar V1 precordial recording. The recording should show a large voltage artifact amplitude and an elevated ST segment. A complete fracture shows a flat tracing. Noise on the recording that is not related to intrinsic ECG or diminished artifact amplitude demonstrates partial fracture. If one of the poles is intact, this lead is unipolarized by inserting the terminal tip of the intact pole into the negative port of the generator terminal. The tip of an external ECG single wire electrode applied on the skin is inserted into the positive port of the generator, serving as the ground (Fig. 18-37). The unused pole terminal of the lead is shielded with rubber tubing. Since a unipolarized bipolar lead in temporary pacemakers is subject to EMI, it should not be used indefinitely. The safest intervention for a fractured lead is replacement.

UNDERSENSING. Failure of the pacemaker to sense intrinsic beats is known as undersensing and results in inappropriately placed pacemaker artifacts on the ECG (Fig. 18-38). Undersensing may be a result of lead dislodgment, lead insulation defect, lead wire fracture, or inappropriately programmed sensitivity. Ventricular dysrhythmia caused by the pacemaker firing during the vulnerable phase of the T wave is of concern with undersensing. The most likely cause of sensing failure in the temporary pacemaker is lead displacement.

To correct undersensing problems in the temporary pacemaker, the nurse must first ascertain that the lead is properly connected to the temporary pacer. Undersensing may also be corrected by increasing the sensitivity of the device, which is done by turning the dial to a lower millivolt value (ie, detect a smaller signal). If problems persist, the physician may need to reposition or replace the lead. In permanent pacemakers, undersensing can sometimes be corrected by reprogramming to a more sensitive setting or by switching bipolar to unipolar mode.

Pacemaker Complications

Numerous possible complications are associated with cardiac pacemakers. The critical care nurse plays a vital role in the early detection and management of these complications.

Pneumothorax

Insertion of a transvenous lead through the subclavian vein can be complicated by traumatic injury to the lung by the exploring needle, allowing air to escape into the pleural cavity, because of the proximity of the subclavian vein to the apex of the lung. The symptoms may occur suddenly or may insidiously present up to 48 hours after the procedure. The symptoms include pleuritic pain, hypotension, respiratory distress, or hypoxia. A chest radiograph can reveal the extent of the trauma. When severe, placement of a chest tube allows for lung reexpansion.

Ventricular Irritability

Ventricular irritability at the site of the endocardial catheter tip is occasionally encountered in temporary pacing systems after initial catheter insertion. The premature ventricular complexes usually appear similar in configuration to the pacemaker complexes (Fig. 18-39). Irritability from the catheter as a foreign body usually disappears after a few hours. Persistent ventricular irritability may indicate lead dislodgment in both temporary and permanent pacing systems.

Perforation of Ventricular Wall or Septum

Perforation of the ventricular free wall or septum by the transvenous catheter occurs in a few patients. This may or may not result in cardiac tamponade. Elderly patients and patients on chronic corticosteroid or anticoagulant therapy are at highest risk. Perforation can be suspected if the patient demonstrates a change in precordial lead morphology on cardiac monitoring. RV apical pacing often results in a negative QRS in a V1 lead on a 12-lead ECG

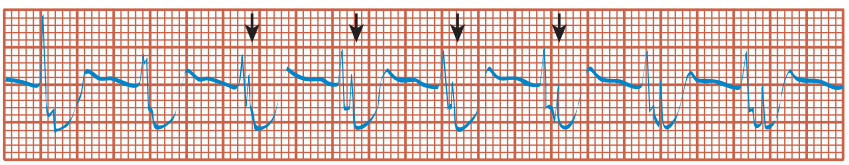

FIGURE 18-38 ▲ ECG strip showing evidence of undersensing. Failure of the ventricular demand pacemaker to detect the intrinsic rhythm is shown by pacemaker spikes at inappropriate intervals after spontaneous QRS complexes.

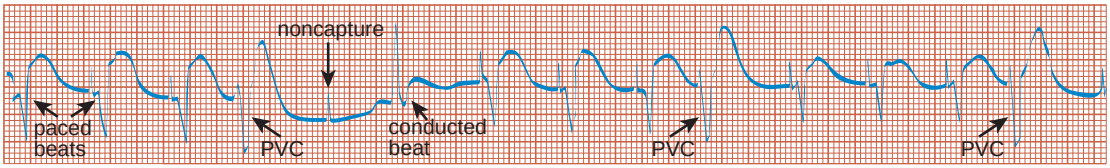

FIGURE 18-39 ▲ Ventricular demand pacemaker with premature ventricular contractions. This strip also shows one noncaptured pacemaker spike followed by a spontaneous conducted beat.

recording. Ventricular perforation may result in pacing from the left ventricle, and the QRS becomes positive in polarity. When ventricular wall perforation is suspected, pericardial tamponade, causing a decrease in blood pressure and an increase in sinus rate, can be confirmed by two-dimensional echocardiography.

Catheter or Lead Dislodgment

Dislodgment of the pacing catheter or lead may occur resulting in oversensing, undersensing, or failure to capture. A chest radiograph usually confirms the findings. Catheter or lead dislodgment usually requires repositioning.

Infection and Phlebitis or Hematoma Formation

Infection and phlebitis can occur at the temporary pacemaker insertion site, and infection or hematoma may occur at the site of permanent generator implantation. These sites must be inspected for swelling and inflammation and kept dry. Infection in permanent pacemakers needs immediate attention by a physician. In most cases, pacemaker pocket infection requires removal of the entire pacemaker system and replacement at a different site, after systemic antibiotics have been given. In temporary pacing sites, sterile technique must be used to prevent infection when dressings are changed.

Abdominal Twitching or Hiccups

Abdominal twitching or hiccups occur occasionally as a result of electrode placement against a thin RV wall and resultant electrical stimulation of the abdominal muscles or diaphragm. In patients with a LV lead for biventricular pacing, abdominal twitching may be due to phrenic nerve stimulation (PNS) by the LV lead in the lateral branch of the coronary sinus vein. PNS is usually uncomfortable for the patient but can sometimes be corrected by programming the lead polarity or reducing the output of the generator.[12]

After acute implantation, diaphragmatic stimulation may sometimes be associated with perforation. A drop in the patients' blood pressure and high capture thresholds accompanying diaphragmatic stimulation warrants critical observation and evaluation.

Pocket Erosion

Erosion at the implantation site occurs rarely in the early postimplantation period and is more often regarded as a late complication of permanent pacemaker implantation. At times, erosion heralds a fulminant infection. However, at other times, erosion may be due to poor skin integrity or pressure of the generator on thinning tissues. When pre-erosion is detected, prompt reoperation for pocket relocation can protect the patient from a potentially malignant cause of systemic infection and salvage the device. Once a pacemaker system erodes, an aggressive infection occurs throughout the lead system into the heart, making complete system removal a necessary course of action.

Nursing Management

Critical care nurses play a key role in caring for patients with a pacemaker. The nurse is responsible for comprehensive assessment of the patient, patient and family education, ECG monitoring, and patient safety. For intervention guidelines for patients with a temporary transvenous pacemaker, see Box 18-23 on page 349, and for a list of nursing diagnoses for the patient with a pacemaker, see Box 18-24 below.

Patient Assessment

The critical care nurse may be the first to detect the patient's dysrhythmia that necessitates pacing. Knowing the indications for pacing and how to initiate emergent transcutaneous pacing is essential for the critical care nurse. After a comprehensive assessment and stabilization of the patient, the critical care nurse may need to assist the physician in inserting a transvenous or permanent pacing system.

An important aspect of preimplantation of a pacemaker includes an assessment of the patient's medical and social history. For example, knowledge of a previous fracture to the clavicle may lead to avoidance of implantation on the same side of the fractured clavicle because of potential anatomical distortion. A subclavian approach may be avoided in a person with a history of a collapsed lung or previous lobectomy. A patient with a right arm arterial-venous fistula is best served with a left-sided implant. For social history, avocations such as hunting, professional sport activities, and even just preferential arm dexterity come into consideration. For example, the right pectoral region should not be used in a right-handed tennis player.

BOX 18-24 EXAMPLES OF NURSING DIAGNOSES

For the Patient With a Pacemaker

- Anxiety related to life-threatening cardiac disease requiring pacemaker
- Deficient Knowledge related to newly diagnosed condition
- Risk for Infection related to invasive procedure and presence of foreign body
- Decreased Cardiac Output related to pacemaker syndrome or absence of AV synchrony

To assess patients with pacemakers accurately, the nurse must understand the pacemaker code to know the type of pacer used and the intended mode of the device. The nurse must be aware of the patient's underlying rhythm so that if the pacemaker fails, the nurse is prepared to treat any life-threatening dysrhythmias.

A thorough assessment also helps the nurse determine the patient's physiological response to pacing therapy. Important parameters to assess include pulse rate, underlying cardiac rhythm, blood pressure, activity tolerance, and evidence of dizziness, syncope, dyspnea, palpitations, or edema. The nurse should be attentive to results of chest radiographs, blood tests, and other relevant laboratory tests. If a permanent pacemaker has been implanted, the incision is examined for swelling, redness, drainage, hematoma, and tenderness.

Psychosocial assessment is another essential component of comprehensive care of the patient with a cardiac pacemaker. Patients' psychosocial responses to the need for cardiac pacing may differ. Some may be relieved to have a device that supports the functioning of their heart, whereas others may be anxious about the technology and express fears of dying. If a permanent pacemaker is implanted, patients and families should be encouraged to join support groups where they can share their fears and concerns with others who depend on pacing technology.

Patient and Family Education

A planned and systematic approach to teaching the patient and family about cardiac pacing is a vital part of nursing care. Teaching a patient about pacemakers begins at the time the decision for pacemaker insertion is made. The nurse can begin by eliciting the patient's previous knowledge of pacemakers and clarifying any misconceptions. Nothing is assumed about the patient's understanding. If appropriate, the difference between heart block and heart attack is clarified. The patient may confuse cardiac monitoring with pacing and become anxious when the monitoring electrodes are removed.

The patient and family should be told why the pacemaker is necessary. The anatomy of the heart is discussed in general terms when explaining the need for pacing and how the pacemaker takes the place of or complements spontaneous rhythm. The insertion procedure and the immediate postinsertion care that can be expected are explained.

Many booklets and media presentations are available to aid the nurse in teaching the pacemaker patient. Visual and written guidelines are helpful for the patient and family to review after discharge from the hospital.

The depth of teaching that is appropriate and the teaching tools used may depend on the patient's age, intellect, attention span, vision, and interest in learning. Initial teaching should be confined to the positive aspects of life with a pacemaker. Knowledge of the function and care of the pacemaker are of no interest until the patient is able to accept it as part of life. Box 18-25 provides a guide for teaching patients and families about living with a pacemaker.

Electrocardiogram Monitoring

Careful monitoring of the ECG of the patient with a cardiac pacemaker is an essential component of comprehensive patient assessment. The first step in the analysis involves examining the strip for evidence of pacemaker stimulation. This evidence is noted by the presence of pacing spikes on the strip. Unipolar pacing spikes are usually tall and visible, but bipolar pacing spikes may not be visible in certain leads. Each pacing spike should result in capture. If the pacing lead is in the atria, a pacing spike is followed by a P wave. If the pacing wire is in the ventricle, the spike is followed by a wide QRS complex (Fig. 18-40). However, a narrower QRS following a pacing spike does not necessarily mean there is pacemaker malfunction. When fusion is present, the patient spike appears right before the intrinsic QRS (see Fig. 18-40A). Biventricular pacing (pacing both ventricles) for cardiac resynchronization in HF also results in a narrower QRS.

The sensing function of the pacemaker is evaluated next. If the pacemaker does not sense intrinsic cardiac activity (undersensing), inappropriate pacemaker spikes may appear throughout the underlying rhythm. An oversensing problem can be detected when the pacemaker senses events other than the intrinsic rhythm and is inappropriately inhibited in that chamber or causes a triggered response in the other chamber.

The third step in evaluating the ECG is to measure various intervals in milliseconds (ms). Each small box on the ECG paper represents 40 ms, and one large box represents 200 ms. The duration of each interval is compared with the programmed setting for that interval.

The first interval, the pacing interval, is the amount of time between two consecutive pacing spikes in the chamber being paced. This interval is used to determine the pacing rate. To calculate the pacing rate, the nurse counts the number of milliseconds between two consecutive atrial spikes or two consecutive ventricular spikes (Fig. 18-41). To convert from milliseconds to beats per minute, the following formula is used: 60,000 ms/min divided by the number of milliseconds between pacing spikes equals the pacing rate.

The next interval to measure is the AV interval, also known as the AV delay. This interval is analogous to the PR interval on the ECG. The AV interval is measured from the beginning of an intrinsic P wave or an atrial pacing spike to the beginning of the intrinsic QRS complex or the ventricular pacing spike (see Fig. 18-41).

The third interval to measure is the ventriculoatrial (VA) interval, also called the atrial escape interval. The VA interval is the amount of time from a ventricular paced or sensed event to the next atrial paced stimulus (see Fig. 18-41). The sum of the AV and the VA interval equals the pacing interval.

Patient Safety

Electrical safety precautions must be observed when the patient has a temporary pacemaker. Electrical equipment in the room is kept at a minimum and must be properly grounded. Use of a nonelectric bed is preferable. If an electric bed is used, it must be properly grounded or remain disconnected from AC. Only battery-operated electric shavers, toothbrushes, or radios are recommended. An AC-powered television may be used if it is operated by someone who is not in contact with the patient. The nurse should avoid simultaneous contact with the patient and any electrical equipment.

BOX 18-25 TEACHING GUIDE *Living With a Pacemaker*

Patient Activity
- Start passive and active range-of-motion exercises on the affected arm 48 hours after implantation to avoid "frozen shoulder." For those with new leads implanted, avoid abduction of the affected arm above the shoulder level for 4 to 6 weeks to prevent lead dislodgment.
- Avoid activities that may result in high impact or stress at the implantation site.
- Return to work at the discretion of your physician after discussing the type of work you do and what your job entails.
- Return to whatever degree of sexual activity you prefer.
- Your pacemaker will set off the alarm on metal-detector devices in airports, so avoid going through the detector gates. Show your pacemaker identification card. A manual search may be done or a magnetic wand may be used. Do not allow the wand to linger at the pacemaker site for an indefinite amount of time because the magnet in the wand may temporarily put the pacemaker into asynchronous mode. The metal detector or wand will not cause any permanent damage to your pacemaker.

Signs of Pacemaker Malfunction
- Be alert for symptoms of pacemaker malfunction: those associated with decreased perfusion of the brain, heart, or skeletal muscles. Be particularly mindful of return of symptoms you experienced before pacemaker implantation.
- Report any dizziness, fainting, shortness of breath, undue fatigue, or fluid retention. Fluid retention includes sudden weight gain, "puffy ankles," "tightness of rings," and so forth.
- Take your pulse once daily upon awakening. Report a pulse rate over 5 beats/min slower than that at which pacemaker is set.
- Be aware that your pulse may be somewhat irregular with a demand pacemaker and has some spontaneous beats and paced beats. This does not signify pacemaker malfunction.

Signs of Infection
- Report any redness, swelling, warmth, drainage, or increase in soreness at the implantation site.
- Report a fever of undetermined source.

Medications
- Antibiotics are usually given within 24 hours of pacemaker implantation. Report any unusual reactions to your physician.
- Medications that were withdrawn before pacemaker implantation may need to be restarted. Check with your physician about such medications as beta blockers, digitalis, or blood thinners. Know the name of the medication and the dose, frequency of administration, side effects, and use of each medication.
- If warfarin (Coumadin) therapy is restarted, warfarin blood levels should be rechecked after reinitiation of the medication.

Considerations for Home Care
- Carry a pacemaker identification card at all times. This card shows the brand and model of your pacemaker, the date of insertion, and the implanting physician.
- Wear a medical identification bracelet or necklace stating that you have a pacemaker.
- Adhere to a schedule of follow-up visits with your physician or clinic. The follow-up visit will include an interval history and ECG recording. Many pacemaker clinics have specialized equipment available to determine pacemaker and lead performance and to predict battery longevity. Some clinics have the capability for obtaining some of this information by telephone, reducing the necessity for travel to the clinic. However, when pacemaker follow-up is done by phone transmission, have the pacemaker checked at least once a year in the pacemaker clinic. Many problems related to the pacemaker pocket or intermittent failure of components cannot be picked up through telephone transmission tests.
- If you have any symptoms similar to those you had before pacemaker insertion, have the pacemaker checked. Be alert for other symptoms of malfunction, such as unexplained dizzy spells, fatigue, or a slow pulse.
- Inform any physician or dentist of the pacemaker and of the medications you are taking.

Pulse Generator Replacement
- Follow-up is intensified when the pacemaker battery approaches its elective replacement indicator. Avoid extended absences or vacations without consulting your physician at this time.
- Be aware that when the battery depletes, the generator stops working.
- The battery cannot be removed from the generator, so the entire generator is replaced when the battery is low.
- Generator replacement can be done within a 24-hour stay, as long as the leads are in good condition. Usually only the generator needs to be replaced.

Considerations for the Older Patient
- Report any changes in skin condition at the pacemaker site. Sudden weight loss or poor nutritional status may predispose elderly patients to pocket erosion.
- Report symptoms, such as fatigue, neck pulsations, and lack of energy. Loss of AV synchrony in patients with single-chamber VVI pacemakers may result in pacemaker syndrome.
- If the pacemaker feels like it is "flipping" inside the pocket, report it to your doctor and do not reposition it. When the skin is loose or when the patient "twiddles" with the pacemaker, the leads can become tangled and coiled and may fracture.

The patient's bed must be kept dry at all times. Diathermy and electrocautery equipment should not be used because their output may be sensed by and inhibit the demand pacemaker.

The literature on ensuring electrical safety in temporary pacemaker wires has been sparse; however, manufacturers have been guided by the FDA to increase vigilance over patient safety. Currently manufactured leads have no exposed areas after they are inserted tightly into the connecting cable. The use of rubber gloves to handle temporary pacing lead terminal pins is often recommended. Most manufacturers supply connecting cables with the pulse generator to ensure compatibility. Some connecting cables are nonsterilizable, and integrity may be compromised by resterilization. Care should also be taken to ensure that nonsterile cables are not in close proximity with the sterile field during insertion.

FIGURE 18-40 ▲ Pacemaker initiated beats. **A:** The pacemaker artifact is followed by intrinsic QRS complex deflection. **B:** Pacemaker capture (ventricular capture) beats with typical widening of QRS complex.

When using the older pulse generator model, the hard plastic cover over the dials of the temporary generator must be secured in place to prevent inadvertent change in settings. The generator should be attached to the patient's arm or visibly pinned to the patients' gown. The catheter should be taped securely to the patient's skin without direct tension on the catheter. Motion of the extremity nearest the catheter entry site should be minimized, especially if the femoral site has been used.

According to manufacturers of permanent pacemaker generators, very few electrical hazards are associated with the permanent generators currently in use. These generators are shielded from external electrical sources and usually are not affected by microwave ovens or small appliances. There have been rare reports of unipolar pacemakers being affected by large electromagnetic fields and radiofrequency signals, such as radio transmitters. Precautions should be taken to avoid large magnetic fields or use a cellular phone in close proximity (<6 inches) to the device.

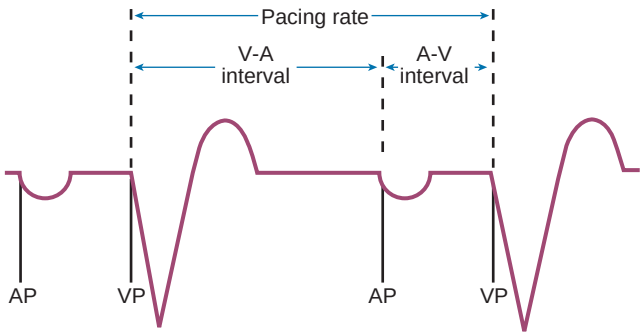

FIGURE 18-41 ▲ The intervals measured on an ECG strip for a patient with a pacemaker. The pacing interval is the amount of time between two consecutive atrial pacing spikes or two consecutive ventricular pacing spikes. The atrioventricular (AV) interval is measured from the beginning of a P wave or an atrial pacing spike to the beginning of an intrinsic QRS complex or the ventricular pacing spike. The ventriculoatrial (VA) interval is measured from a ventricular pacing or sensed beat to the next atrial pacing spike. The sum of the AV and VA intervals equals the pacing interval.

▲ Implantable Cardioverter–Defibrillators

Sudden cardiac arrest continues to be a leading cause of death in the United States.[13] Sudden death may be caused by the rapid loss of heart function due to VF. VT and fibrillation can be corrected when treated within minutes with electrical cardioversion or defibrillation.

In the late 1960s, Dr. Michel Mirowski and Dr. Morton Mower developed a device called an ICD to treat patients at risk for sudden death due to ventricular dysrhythmia. In 1980, the first device was implanted successfully in a person. The device was found to be safe and effective and, as a result, received FDA approval in 1985. Since its initial use in 1980, the ICD generator and lead technology have undergone many improvements in design and function. With these improvements, as well as with expanded indications and increased understanding of patients at risk, ICD implantation has rapidly increased.

Indications for Implantable Cardioverter–Defibrillators

Uniform criteria for ICD implantation were established by the Joint Committee of the ACC, AHA, and Heart Rhythm Society by class indications.[9] Class I indication recommends implantation. Class II includes conditions for which ICDs may be used, with less than sufficient evidence or divergence of opinion regarding the necessity of insertion. Class III includes conditions for which there is evidence that ICD implantation is unnecessary or may be harmful. Box 18-26 lists the indications for use of ICD therapy.

The Implantable Cardioverter–Defibrillator System

The purpose of an ICD is to monitor the patient's rhythm continuously, diagnose rhythm changes, and treat life-threatening ventricular dysrhythmias. Similar to a pacemaker, the ICD consists of a lead system and a pulse generator containing the battery, capacitors, and circuits. The lead system and the pulse generator have undergone significant changes in design and function since their initial use in 1980.

The Pulse Generator

Early ICD pulse generators were large and heavy in comparison to the pacemaker pulse generator. Because of their size and weight, these ICD pulse generators required implantation in the patient's abdomen. Currently used ICD pulse generators are not much larger than the earlier models of pacemakers and can be implanted in the pectoral area. The size of the device is shown in Figure 18-42. Lithium silver vanadium oxide (Li/SVO) batteries provide the power source for ICDs. Improved circuit design has expanded the capabilities and functions of the ICD.

The Lead System

Lead systems sense the life-threatening ventricular dysrhythmia and deliver a shock to convert the dysrhythmia. Initially,

BOX 18-26 Indications for Implantable Cardioverter–Defibrillators (ICDs)*

Class I: Conditions Where ICD is Effective/Beneficial

1. Survivors of cardiac arrest due to ventricular fibrillation (VF) or ventricular tachycardia (VT), after evaluation to exclude transient or reversible causes
2. Spontaneous sustained VT associated with structural heart disease
3. Syncope of undetermined origin with induced sustained VT or VF at electrophysiological study
4. LV dysfunction with EF less than 35% due to prior MI more than 40 days, and NYHA functional class II or III
5. Nonischemic dilated cardiomyopathy (ND-CM) with an EF less than or equal to 35% and in NYHA functional class II or III

Class IIa: Conditions Where ICD is Reasonable

1. Patients with unexplained syncope, significant LV dysfunction and ND-CM
2. Sustained VT and normal or near normal ventricular function
3. Hypertrophic cardiomyopathy with one or more major risk factors for sudden cardiac death (SCD)
4. Arrhythmogenic right ventricular dysplasia cardiomyopathy with one or more risk factors for SCD
5. Syncope and/or VT while on beta blockers in patients with long QT
6. Nonhospitalized patients awaiting transplantation
7. Brugada syndrome with syncope
8. Brugada syndrome with documented VT that has not resulted in cardiac arrest
9. Catecholaminergic polymorphic VT with syncope and/or sustained VT while on beta blockers
10. Cardiac sarcoidosis, giant cell myocarditis, or Chagas disease

Class IIb: Conditions Where ICD may be Considered

1. Nonischemic heart disease with an EF less than or equal to 5% with NYHA functional class I
2. Long QT syndrome and risk factors for SCD
3. Syncope and advanced heart disease in which thorough evaluations have failed to define a cause
4. Familial cardiomyopathy associated with sudden death
5. LV noncompaction

Class III: Conditions Where ICD is not Useful or may be Harmful

1. Conditions that meet Class I, IIa, and IIb but with expected survival less than 1 year
2. Incessant VT or VF
3. Patients with significant psychiatric illnesses that may be aggravated by device implantation or preclude follow-up
4. NYHA Class IV patients with drug-refractory congestive heart failure (HF) and not candidates for cardiac transplantation or CRT-D
5. Syncope of undetermined cause in a patient without inducible VT and without structural heart disease
6. VT or VF amenable to surgical or catheter ablation
7. VT due to reversible cause in the absence of structural heart disease

*Box does not include indications for children, adolescents, and patients with congenital heart disease.

Adapted from Epstein AE, DiMarco JP, Ellenbogen KA, et al: ACC/AHA/HRS 2008 Guidelines for device-based therapy of cardiac rhythm abnormalities: Executive summary. A report of the American College of Cardiology/American Heart Association task force on practice guidelines (ACC/AHA/NASPE 2002 guideline update for implantation of cardiac pacemakers and antiarrhythmia devices). Heart Rhythm e37–e38, 2008.

the lead system consisted of a pair of epicardial patches for energy delivery and epicardial coils for sensing. The leads were often implanted at the time of CABG surgery, when indicated, or by the subxiphoid approach. The sensing coils were later replaced with a long transvenous lead positioned in the RV endocardium. These leads were tunneled down from the subclavian insertion site to the generator in the abdomen. Improved lead design and smaller generators paved the way for prepectoral implantation. At this time, previously implanted epicardial leads are used only with replacement of ICD generators, when the leads are deemed to be usable. Newer implants use bipolar or tripolar transvenous leads for sensing and defibrillation. The sensing electrodes are bipoles at the tip of the lead. One unipolar coil in the distal portion of the ventricular lead serves as the defibrillation cathode, whereas another coil in the mid-proximal portion or the ICD generator serves as the defibrillation anode, giving rise to the term "active can" or "hot can." With dual-chamber ICDs, an additional bipolar electrode in the right atrium provides atrial sensing and pacing. In biventricular ICDs, a third lead is inserted in the coronary sinus and positioned in the lateral vein for LV stimulation and resynchronization of the ventricles.

FIGURE 18-42 ▲ Implantable cardioverter–defibrillators (ICDs), old and new models. Note the decrease in size and weight that has been achieved with the newer generation, allowing prepectoral implantation. (Courtesy of Medtronic Inc. Minneapolis, MN.)

Ideally, the ICD generator is implanted in the left pectoral area so that the heart is central to the vector of the defibrillation current (Fig. 18-43). Improvements in lead design have allowed ease of implantation not very dissimilar to that of permanent pacemaker implantation. It is no longer unusual for a patient to be discharged a day after ICD implantation.

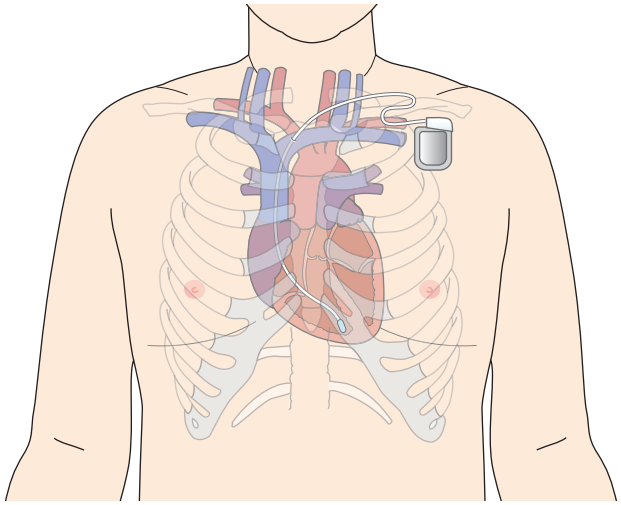

FIGURE 18-43 ▲ The ICD mechanical system consists of a generator and a sensing/pacing/defibrillating electrode.

Implantable Cardioverter–Defibrillator Functioning

ICDs have been categorized into "generations," based on their functionality. The first-generation ICDs were nonprogrammable devices that used a factory-specified rate criterion to detect ventricular dysrhythmias and delivered a shock at a preset energy level. In the mid-1980s, the second generation of the device became available and included programmable features, among them bradycardia and antitachycardia pacing and synchronized cardioversion. These features allowed the use of tiered therapy, the term used to describe different levels of therapy to treat a dysrhythmia. Table 18-18 illustrates the concept of tiered therapy. The first tier of therapy is usually antitachycardia pacing, which involves the carefully timed delivery of pacing stimuli. If antitachycardia pacing is not successful, the second tier of therapy is initiated by synchronized cardioversion. The joules for cardioversion can be programmed anywhere from 1 to 36 J, with the highest output dependent on device specifications. Current devices use ATP while charging to minimize painful shocks. If cardioversion is not successful, the third tier of therapy, defibrillation, is used. The energy delivered for defibrillation can be programmed to a maximum of 36 J, again depending on the model and capacity of a device. The number of defibrillation attempts varies with different devices, but six attempts is usually the maximum. If the patient is successfully converted to a life-compatible rhythm, but the rate is slow, ventricular demand pacemaker is initiated. Bradycardia pacing is usually intended for brief periods of pacing until normal rhythm resumes. However, with CRT, 100% biventricular pacing is desirable.

Table 18-18 Implantable Cardioverter–Defibrillator: Tiered Therapy

Type of Therapy*	Mode/Energy Level	Condition(s)
Antibradycardia pacing/Biventricular pacing	VVI/DDD/VDD	Bradycardia CHF
Antitachycardia pacing (ATP)	Burst/ramp ATP	AT†/VT (120–200 bpm)
Cardioversion‡	10–36 J	VT (180–230 bpm)
Defibrillation	30–36 J	VF (>230 bpm)

*Therapy and detection intervals (rate of tachycardia detected) are programmable.

†AT therapies limited to certain models.

‡ATP while charging allows painless therapy.

CHF, congestive heart failure; AT, atrial tachycardia; VT, ventricular tachycardia; VF, ventricular fibrillation.

Today's ICDs have many programmable features that allow the physician to tailor the device to the patient's needs. Bradycardia pacing therapies with biventricular pacing are common features of current ICDs. The availability of an atrial sensing lead allows for a more specific SVT discrimination algorithm. To improve discrimination of tachydysrhythmias, the device allows programming of discrimination algorithms, which withhold VT therapy when PSVT is confirmed. Some devices also have separate tiers of therapy for atrial tachycardia and AF or flutter.

All current ICDs are "noncommitted"; that is, therapy is aborted if the tachycardia terminates even while the ICD is charging. Patients with nonsustained VT need not suffer the discomfort of an inappropriate shock. Third-generation defibrillators have additional features, including memory and event retrieval. Event retrieval may involve successive R-wave analysis or the recording of an EGM during therapy. These methods document the dysrhythmia before and after the therapy, allowing the physician to analyze the problematic rhythm. These data can be correlated to the patients' symptoms to help further diagnose the dysrhythmia.

Current devices also have the ability to deliver PES using a programmer. PES, a noninvasive method similar to EPS, is used to induce a dysrhythmia to determine the device's ability to successfully terminate it with programmed therapies. It can also be used to ascertain the integrity of the shocking coil, to determine whether a suspected lead problem exists, and to define the defibrillation threshold (DFT) of a patient. The DFT is the lowest amount of energy tested that successfully converts VF. Certain antiarrhythmic drugs can increase DFTs. For the sake of patient safety, the device should be capable of delivering at least 10 J above the patients' DFT.

PES minimizes the need to test the device in a laboratory situation where catheters are placed in the patient's heart to induce the rhythm disturbance. Testing is done through the device itself, thus reducing the risk associated with the invasive procedure.

The Implantable Cardioverter–Defibrillator Code

The cardiac pacemaker code previously discussed has limited ability to describe modes of ICD function. As a result, in 1993, the AHA and Heart Rhythm Society (formerly NASPE) and BPEG developed the NASPE/BPEG Defibrillator Code.[14]

Table 18-19 The NBD Defibrillator Code

Position: Category			
I: Shock Chamber	**II: Antitachycardia Pacing Chamber**	**III: Tachycardia Detection**	**IV: Antibradycardia Pacing Chamber***
O = None	**O** = None	**E** = Electrogram	**O** = None
A = Atrium	**A** = Atrium	**H** = Hemodynamic	**A** = Atrium
V = Ventricle	**V** = Ventricle		**V** = Ventricle
D = Dual (A+V)	**D** = Dual (A+V)		**D** = Dual (A+V)

*Added in NBG code format (VVI, DDD).

Adapted from The NASPE/BPEG Defibrillator Code. Pacing Clin Electrophysiol 16(9):1776–1780, 1993.

Known as the NBD defibrillator code, it is similar to the NBG pacemaker code in describing ICD capabilities and operation. The four positions in the code are designated as: (I.) shock chamber, (II.) ATP location, (III.) means of tachycardia detection, (IV.) antibradycardia pacing chamber (Table 18-19).

Nursing Management

The critical care nurse plays a key role in the preimplantation and postimplantation management of patients with an ICD. Patient teaching is one of the most important tasks of the critical care nurse. Topics for discussion are included in the Box 18-27. Patients and families need to understand why an ICD is indicated, the purpose of an ICD, the basic parts of the ICD system, and how the ICD functions. Once the physician has determined the type of system to be used, the nurse reinforces the physician's explanation of how the device will be implanted and where the leads and pulse generator will be placed. The patient and family should be informed of the expected length of hospitalization and plans for follow-up care. Many resources for patient education are available from manufacturers of ICDs, including printed materials and videotapes. In addition, the patient and family may find it helpful to meet with a person who has an ICD. This person may be able to alleviate any fears or clarify misconceptions about living with an ICD.

BOX 18-27 TEACHING GUIDE *Implantable Cardioverter–Defibrillator*

When teaching patients receiving an ICD, be sure to include the following points:

- The purpose of an ICD and why it is indicated
- Components of an ICD
- How the ICD works
- How a shock feels
- How the ICD will be implanted
- The expected length of hospitalization
- Activities of daily living that can be tolerated postimplantation
- Rate cutoff and therapies programmed in the ICD
- Plans for follow-up care and when to call the doctor
- Importance of carrying an ICD identification card and/or wearing medical identification devices, such as a bracelet or necklace
- Need for carrying a list of current medications and dosages
- Safety precautions
- Importance of keeping emergency phone numbers readily available and calling the physician after receiving a shock, especially when not feeling completely recovered
- Importance of calling the physician immediately if you receive more than one shock or several in succession
- What the patient and family should do if a shock occurs
- Information the family, significant others, coworkers, and traveling companions should know about the ICD
- Precautions to be taken when traveling by air and informing airline security personnel of the ICD
- Encouraging of family members to take a cardiopulmonary resuscitation (CPR) course
- Benefits of support groups

In the postimplantation period, the nurse continuously monitors the patient for the development of any ventricular dysrhythmias and intervenes if necessary. If the patient experiences a sustained VT and no therapy is delivered, it may be that the rate of the tachycardia is below the programmed rate cutoff or that undersensing of the tachydysrhythmias is occurring. Knowledge of the parameters of the ICD and the rate of the patient's dysrhythmia can help the critical care nurse assess this situation correctly. A patient who has an ICD and who has a sustained, hemodynamically unstable rhythm should not be treated any differently from one without an ICD. External cardioversion can be given in an emergency in the absence of therapy from the patient's ICD. Care should be taken not to apply paddles near or above the ICD generator.

The nurse must be aware of the programmed settings and features of the patient's ICD to provide safe and competent care. Device information should be readily available at the bedside and clearly documented in the patient's chart. If the device fires, the status of the patient and the patient's rhythm is assessed and documented. When a device fires in the absence of dysrhythmias, there is a high probability of oversensing due to a dislodged lead, loose connection at the header, or an oversensitive setting. Immediate intervention by the EP service is necessary to avoid further discomfort to the patient.

Other immediate postoperative care (wound care, activity instructions) is very similar to that of the patient after pacemaker implantation (see Box 18-25, p. 357). Furthermore, because the operative approach is almost identical to that of a pacemaker, the complications that one might expect from a pacemaker implant can also be encountered after ICD implantation.

After consulting with the implanting physician, the nurse provides discharge instructions about resuming daily activities. Patients are usually cautioned against swimming or boating alone, climbing ladders, and operating equipment that may produce sparks or cause EMI. Patient and family teaching points (Box 18-27) should be reviewed with the patient and family with discharge instructions.

Discussion of psychosocial issues regarding living with an ICD also should be part of the discharge preparation. Although the emotional adjustment varies with each patient, many have fears about receiving their first shock. Other potential patient concerns include alterations in body image, return to work, participation in recreational activities, and reaction of family and friends to the device. If support groups are available, the patient and family should be encouraged to join.

CARDIOPULMONARY RESUSCITATION

The acuity of patients in an ICU requires the nurse to be especially vigilant for subtle signs of change in the patient's status. The numerous technologies and monitoring devices assist the nurse in delivering effective interventions, but physical assessment skills must be continually practiced and improved.

In any ICU, there is an increased chance that the patient's condition will deteriorate. The cessation of breathing and circulation is known as cardiopulmonary arrest. This condition is also referred to as sudden cardiac arrest, or SCA. When a patient is determined to be in cardiopulmonary arrest, seconds matter. Unless definitive action is taken within 4 to 6 minutes, the patient will suffer irreversible brain injury. Prompt intervention is necessary if the patient is going to have a chance of survival. Immediate and effective CPR often prevents fatal complications. CPR is divided into basic life support (BLS), which is discussed in this chapter, and ACLS.[1] The ACLS guidelines developed by the AHA can be found in Appendix A. This section of the chapter outlines assessment, procedures, interventions, and roles of the nurse in the cardiopulmonary arrest situation. Box 18-28 defines some common terms used during CPR.

▲ Causes of Cardiopulmonary Arrest

Box 18-29 outlines some of the causes of cardiopulmonary arrest. There are many additional causes of cardiopulmonary arrest. Determination of the cause of the arrest is secondary to rapid intervention. Once intervention to preserve life has been initiated, the cause of the arrest can then be ascertained, and any specific interventions designed to correct the underlying cause can be added to the BLS and ACLS measures.

BOX 18-28 Common Terms in Cardiopulmonary Resuscitation

Cardiac arrest: Abrupt cessation of effective cardiac pumping activity, resulting in cessation of circulation
Code: Informal term for emergency resuscitation
Crash cart: Emergency cart (see Table 18-20)
Resuscitation: Restoration of vital signs by mechanical, physiological, and pharmacological means
Clinical death: Absence of vital signs
Biological death: Irreversible cellular changes

BOX 18-29 Causes of Cardiopulmonary Arrest

Cardiac Causes
- Myocardial infarction
- Heart failure
- Dysrhythmia
- Coronary artery spasms
- Cardiac tamponade

Pulmonary Causes
- Respiratory failure secondary to respiratory depression
- Airway obstruction
- Impaired gas exchange, such as in acute respiratory distress syndrome
- Impaired ventilation, such as pneumothorax
- Pulmonary embolus

Electrolyte Imbalances
- Hyperkalemia
- Hypomagnesemia
- Hypercalcemia/hypocalcemia

Procedural Causes
- Pulmonary artery catheterization
- Cardiac catheterization
- Surgery

Miscellaneous
- Drug toxicity and drug side effects

▲ Assessment and Management of the Patient in Cardiopulmonary Arrest

Before implementing the resuscitative measures in a code situation, the patient must first be assessed. A myriad of technological monitoring devices are used in the ICU, but it is the everyday physical assessment skills used by nurses that are most accurate in determining a patient's status. The nurse needs to ensure that the alarm parameters of the bedside monitors are set accurately for each patient. The default settings are not always appropriate.

Determine Responsiveness

The nurse first determines the patient's responsiveness before initiating CPR. The nurse should take no more than 10 seconds to check for breathing and a pulse before initiating CPR. If the patient is unresponsive, the nurse calls for help ("initiate a code") and initiates BLS measures. In the new AHA Guidelines for CPR, the new acronym to guide resuscitative efforts is C-A-B, rather than A-B-C as in previous years. Box 18-30 summarizes the priority interventions of resuscitation.

BOX 18-30 Circulation, Airway, Breathing

Circulation	• Compress chest at rate of at least 100/min • Compress chest to a depth at least 2 inches • Place backboard or use CPR setting on bed • Watch ECG monitor to assist with ensuring rate • Palpate pulses (radial, femoral, pedal) to determine effectiveness of compressions • Measure blood pressure manually
Airway	• Open patients airway using head tilt–chin lift maneuver (jaw thrust for cervically injured patients) • Place oropharyngeal airway (if possible) • Provide suction as necessary
Breathing	• Use Ambu bag, set for 100% oxygen • Aim for compression to breath ratio 30:2 • Deliver breaths at rate of 6–8/min once advanced airway is in position • Maintain seal around patient's mouth and nose • Observe for chest rise and fall • Pulse goniometry • Auscultate for bilateral breath sounds

Circulation

Chest compressions provide blood flow to the brain and vital organs. Even with an apneic patient, there is still enough oxygen bound to hemoglobin to allow for oxygen delivery. This change in the interventions required is based on numerous studies compiled by the International Liaison Committee on Resuscitation (ILCOR) that have shown that in out-of-hospital cardiac arrest situations, early initiation of chest compressions have improved survival rates. Too much time was being lost assessing for breathing, positioning the patient, opening the airway and delivering two rescue breaths before initiating chest compressions. Additional changes to the CPR protocol are: (1) Compressions must be delivered at a rate of at least 100/min, and (2) the adult sternum should be depressed at least 2 inches for adult patients.

The arrival of a second rescuer allows for compressions to continue unabated while the second rescuer can open the airway and be ready to deliver breaths via a bag-valve device when the initial rescuer has completed a 30-chest compression cycle. External cardiac compression is a simple technique performed by standing at either side of the patient, placing the heel of one hand two to three fingerbreadths above the xiphoid process, and placing the heel of the other hand over the first. Firm compressions are applied directly downward, and the sternum is depressed *at least* 2 inches and released abruptly. The chest must be allowed to fully recoil between compressions. This rhythm is maintained at the rate of at least 100 times/min. A 30:2 compression–ventilation ratio is used, with a pause to provide the ventilation. If the patient is mechanically ventilated, there is no need for an interruption in compressions.[1] To be effective, these techniques must be learned correctly and applied skillfully[1] (Fig. 18-44). A recent study indicates that compressions-only CPR is favorable to conventional CPR in an out-of-hospital arrest situation.[2]

If one person must apply both ventilation and compression, the rescuer gives 30 chest compressions, then gives two breaths via a bag-valve device (also known as an Ambu bag). This routine may be maintained until additional members of the team arrive. When help arrives, one person delivers breaths using the bag-valve device, while another performs chest compressions. The patient's radial, carotid, or femoral pulse is checked at regular intervals to determine the adequacy of compressions. If compressions are being delivered effectively, a pulse should be felt in these regions. This circulation check should be performed by a third rescuer; there should be no interruption of CPR for a pulse check.[1] CPR considerations for the older patient are found in Box 18-31.

Position the Patient

The patient should be placed in a supine position on a firm, flat surface. This position enables the rescuer to open the

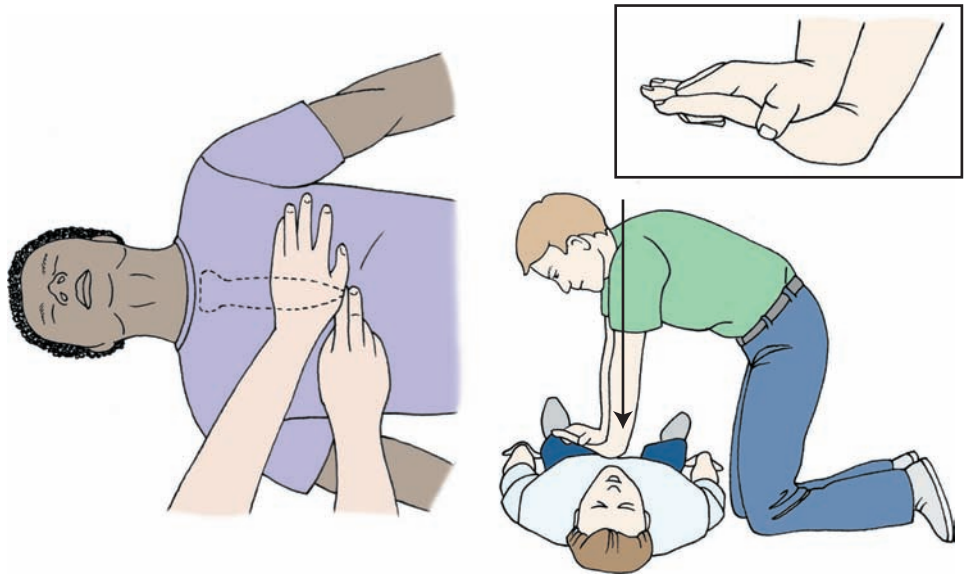

FIGURE 18-44 ▲ External chest compression. *Left,* proper hand position over lower portion of sternum. *Right,* correct rescuer position.

BOX 18-31 CONSIDERATIONS FOR THE OLDER PATIENT

Cardiopulmonary Resuscitation

- Assess for fractured sternum after CPR. Continue with CPR even if fracture occurs.
- Be certain the health care team implements the patient's desire for *do not resuscitate* or *do not intubate* orders.
- Consider family presence during code.
- Keep in mind the effect of medications due to delayed clearance and altered metabolic response.

airway and assess for the presence and effectiveness of any spontaneous breathing. If the patient is in a standard hospital bed, a resuscitation board is placed under his or her torso when help arrives. If the patient is in a specialty bed, the CPR setting on the bed is selected.

If the patient is found to be breathing effectively and there is no evidence of trauma, the patient is placed in the recovery position. The recovery position is used to reduce the possibility of airway obstruction by the tongue or by secretions or emesis. To place the patient in the recovery position, the rescuer kneels next to the shoulder of the patient. The rescuer lifts the arm of the patient nearest the rescuer and bends it at the elbow. The arm is then positioned so that the patient's palm of the hand is turned upward and moved toward the patient's face. The rescuer then lifts the leg of the patient furthest from the rescuer and crosses it over the patient's body, moving it toward the rescuer. One hand of the rescuer supports the patient's head during turning and the second hand is used to turn the patient's hips toward the rescuer (Fig. 18-45). Caution must be used when moving patients with suspected or actual spinal cord injuries. One rescuer should ensure that the patient's head remains in a neutral position.

Airway

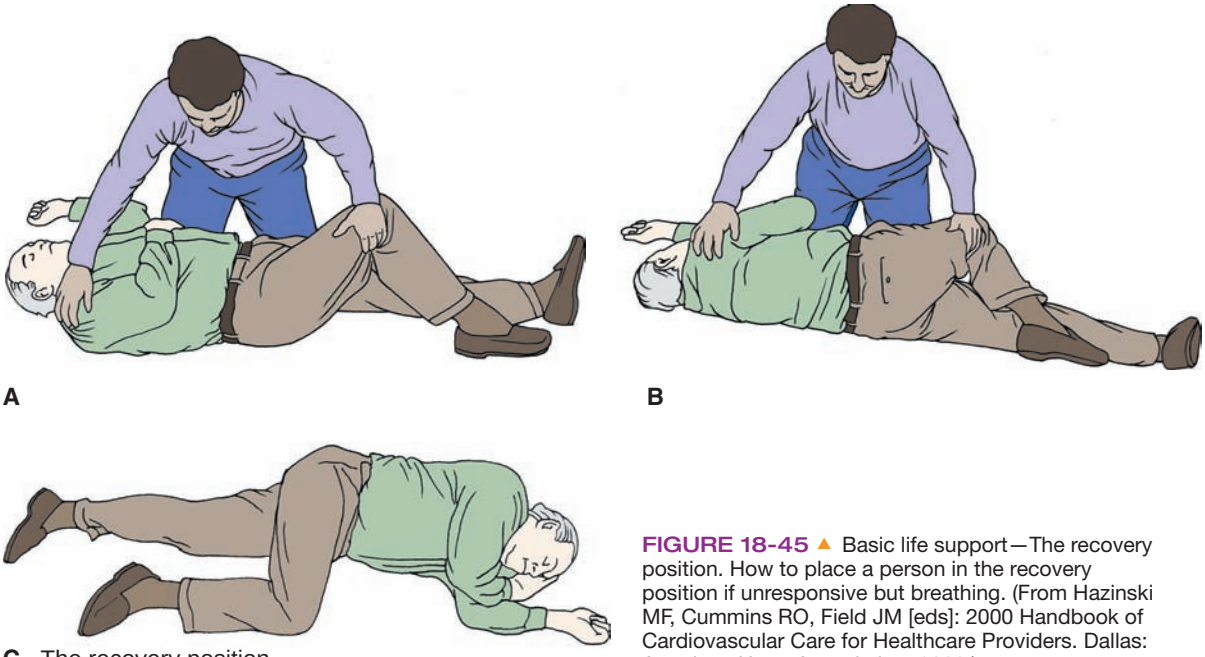
The nurse assesses for an adequate airway. The patient is positioned to ensure an open, patent airway. The patient is placed in the supine position, and the airway is opened using the head tilt–chin lift method. In this method, the head is tilted back, and the chin is raised to stretch the airway and advance the tongue in preparation for ventilation (Fig. 18-46).

In the case of patients with confirmed or suspected cervical spine injuries, the jaw thrust method is used (Fig. 18-47). The patient's head and neck must not be moved to ensure that no damage is done to the cervical spinal cord. Keeping the head in a neutral position, the rescuer places a hand on each side of the patient's head behind the temporomandibular joint and gently pushes the jaw forward. This will open the airway enough to allow for ventilation.

If spontaneous respirations have not returned once a patent airway has been established, then the patient must be assisted with breathing.

Breathing

Using a bag-valve device, the rescuer can deliver oxygen as rescue breaths. The bag-valve device is connected to 100% high-flow oxygen, and the mask portion is placed over the patient's mouth and nose. If the patient has an endotracheal tube or tracheostomy tube, there is an adapter that allows breaths to be delivered through an artificial airway. The bag reservoir is then squeezed to deliver the breaths. The adapter must be fitted properly; this allows the rescuer to deliver breaths using both hands to squeeze the Ambu bag. Observation of the patient's chest is necessary to determine whether the delivered breaths are actually ventilating the lungs. A second person assisting with CPR should auscultate all lung fields to confirm that the delivered breaths



A B C The recovery position

FIGURE 18-45 ▲ Basic life support—The recovery position. How to place a person in the recovery position if unresponsive but breathing. (From Hazinski MF, Cummins RO, Field JM [eds]: 2000 Handbook of Cardiovascular Care for Healthcare Providers. Dallas: American Heart Association, 2000.)

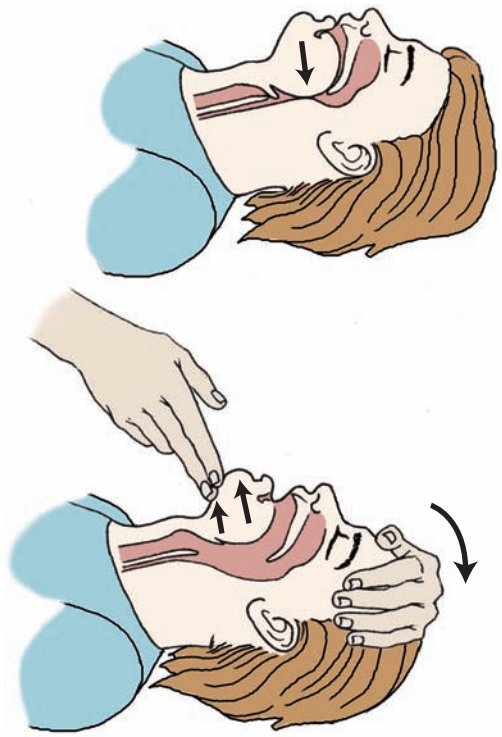


FIGURE 18-46 ▲ Opening the airway with the back head tilt–chin lift maneuver.

are reaching the lungs. Pulse oximetry is used to determine oxygenation.

When one person is performing CPR, two slow breaths are delivered initially. Caution must be used to ensure that the breaths are not going into the patient's stomach. Air in the stomach may lead to vomiting, which in turn could result in aspiration. The ratio of compressions to breaths is 30:2.

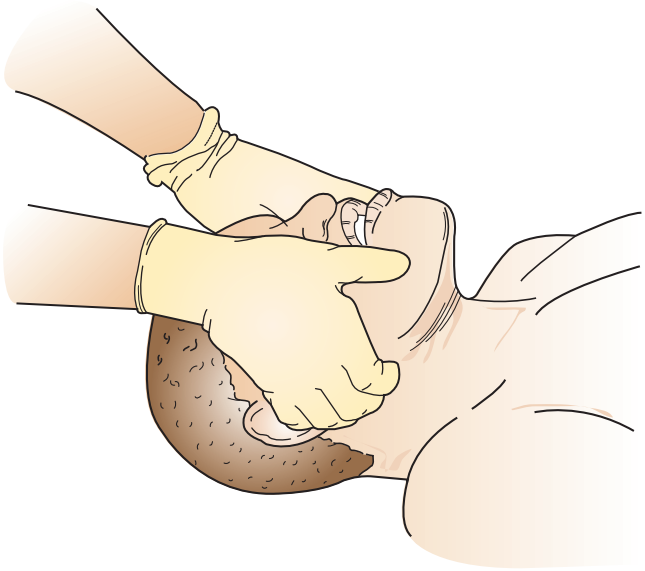

FIGURE 18-47 ▲ The jaw thrust maneuver without head extension is used if cervical spine trauma is suspected.

Once an advanced airway has been placed, and position of the artificial airway confirmed, the compressions and breaths may be delivered asynchronously. Accurate placement of the artificial airway and effectiveness of delivered breaths should be confirmed using an end tidal carbon dioxide monitor (see Chapter 25 for additional information on endotracheal intubation). The breaths are then delivered at a rate of 1 breath every 6 to 8 seconds (8 to 10 breaths/min).

▲ Role of Resuscitation Team Members

When a cardiopulmonary arrest ("code") is called, various members of the emergency response team are notified. Each institution has its own policies regarding who responds. In many teaching hospitals, residents, medical students, and other students may respond. Box 18-32 outlines the roles and responsibilities of the code team members. Some institutions now have Rapid Response Teams that respond in cases of cardiopulmonary arrest (see Chapter 14).

BOX 18-32 Roles and Responsibilities of Code Team Members

Director of the Code (Physician/Nurse Practitioner/ Advanced Cardiac Life Support (ACLS) Qualified Personnel)
- Make diagnosis.
- Direct treatment.

Primary Nurse
- Provide information to code director.
- Contact attending physician.

Second Nurse
- Coordinate use of emergency cart.
- Prepare medications.
- Assemble/pass equipment.
- Defibrillate.

Medication Nurse
- Administer medications.

Charge Nurse
- Coordinate personnel performing CPR.

Nursing Supervisor
- Control crowd.

Anesthesiologist/Nurse Anesthetist
- Intubate patient.
- Manage airway/oxygenation.

Respiratory Therapist
- Assist with manual ventilation.
- Draw arterial blood for blood gas analysis.
- Assist with intubation.
- Set up mechanical ventilator.

Recorder
- Record events and document personnel involved.

▲ Equipment Used in Cardiopulmonary Arrest

The equipment used in resuscitative efforts is kept in a central location in what is commonly referred to as the "crash cart." Most hospitals have rolling carts in easy-to-access locations throughout the hospital. These carts are stocked in a standard way so that all hospital personnel are familiar with the contents and layout of the equipment. The carts must be inventoried daily to ensure their contents are complete and available in the event of a cardiopulmonary arrest. The cart consists of several drawers, a flat top for the storage of larger equipment, an oxygen tank rack, and space for storing a backboard. The drawers and intubation tray are locked with a numbered lock in most cases to ensure that all vital equipment remains in place and undisturbed unless needed for an emergency situation. When any of the locks are broken to access the equipment, resupply of the cart must be performed at the earliest convenience.

The drawers are labeled to assist personnel in locating specific equipment. The intubation tray is separate from the rest of the crash cart because intubation may be the only measure required to treat an individual in respiratory distress, or in whom there is the potential for a compromised airway. In addition to the intubation tray, a cardiac monitor–defibrillator (preferably with transcutaneous pacing capabilities) is on the top of the cart. An oxygen tank, oxygen tubing, and a bag-valve device are found on the outside of the cart for the same reason, as is portable suctioning equipment. Table 18-20 details the contents and the rationale for the equipment and medications found inside the cart.

Table 18-20 Resuscitation Equipment Cart

Equipment	Rationale
Intubation equipment (usually a separate locked container) Straight and curved blades Endotracheal tubes Syringes Oropharyngeal airways Nasopharyngeal airways Suction catheters	• Provides adequate, patent airway, thus ensuring oxygenation of the lungs during resuscitation • Allows for patient to be placed on mechanical ventilation • Reduces chances for gastric distention, aspiration, or vomiting • Permits suctioning • Allows for the administration of oxygen in high concentrations • Provides route for certain medications (NAVEL)*
Oxygen source (separate tank)	• Ensures that oxygen is available if wall oxygen unavailable
Bag-valve device (Ambu bag)	• Provides seal over patient's mouth and nose; reduces risk to rescuer
Suctioning equipment	• Ensures suctioning available if wall suction unavailable
Suctioning source	• Clears oropharyngeal (nasopharyngeal) airway before intubation
Suctioning catheters	
Suction tubing	
IV fluids and tubing	• Improves hypotension
Nitroglycerin tubing	• Prevents precipitation of IV nitroglycerin
Medications (ACLS drugs as a minimum)	• Amiodarone • Lidocaine • Atropine • Epinephrine • Sodium bicarbonate • Calcium chloride • D_{50} • Premixed dopamine infusion
Drip chart (attached to outside of cart)	• Allows for rapid titration of ACLS/Critical Care drugs during and after resuscitation without having to perform complex calculations
Blood tubes	• Allows for the rapid drawing and sending of blood for analysis • Red—chemistries • Blue—coagulation studies • Purple—hematology (complete blood count) • Green—troponin
Arterial blood gas kits	• Allows for rapid drawing and sending of arterial blood gases
Peripheral IV supplies	• Ensures access for fluid and IV drug administration
Prefilled flush syringes (normal saline solution)	• Allows for faster flushing of IV lines
Needles	• Allows for drawing up of medications

(Continued on page 367)

Table 18-20 Resuscitation Equipment Cart *(Continued)*

Equipment	Rationale
Decompression (cardiac) needles	• Used in cardiac tamponade
Clipboard with paper and pen; code sheets	• Used to document the arrest
Pressure bags	• Used for rapid infusion of fluid boluses
Manual blood pressure cuff	• Provides dedicated equipment to monitor resuscitative effectiveness
Gloves (latex, nonlatex, sterile)	• Provides protection for rescuers • Provides sterile gloves for invasive/sterile procedures
Defibrillator/transcutaneous pacemaker	• Used in defibrillation, cardioversion, and temporary transcutaneous pacing

*NAVEL is a mnemonic for drugs that may be administered by endotracheal tube: naloxone, atropine, diazepam, epinephrine, lidocaine.
ACLS, advanced cardiac life support; IV, intravenous.

▲ Medications

Numerous pharmacological interventions are used during and immediately after a cardiopulmonary arrest situation. These drugs should be readily available in the crash cart and include antiarrhythmics, inotropes, vasoconstrictors, and electrolyte replacements. Table 18-21 lists these medications, the indications for their use, and their dosages.

▲ Defibrillation

All patients in an ICU are connected to a cardiac monitor that provides useful information during a cardiopulmonary arrest. Once BLS procedures (ie, CPR) have been initiated, further intervention may be necessary. The nurse assesses the ECG rhythms on the monitor throughout the resuscitation. If the patient is in VF or pulseless VT, preparations for

Table 18-21 Medications Used to Treat a Patient in Cardiopulmonary Arrest

Drug	Class	Uses	Dosages
Adenosine	Antiarrhythmic	SVT, AF	6 mg rapid IV followed by 10 mL NS flush Repeat twice with 12 mg Maximum dose: 30 mg
Amiodarone	Antiarrhythmic	VT, SVT, AF, VF	150–300-mg bolus, 1 mg/min for 6 h, then 0.5 mg/min for 18 h
Atropine	Anticholinergic	Bradycardia, PEA	0.5–1.0 mg IV Maximum dose: 3 mg
Bretylium tosylate	Antiarrhythmic	VT, VF	
Calcium chloride	Electrolyte	Hyperkalemia, hypocalcemia, calcium channel blocker toxicity	Syringe 10 mL of 10% solution (100 mg/mL), 2–4 mg/kg
Dobutamine	Inotrope; β_1 agonist	Decreased cardiac output	5–20 mcg/kg/min
Dopamine	Inotrope; β_1 agonist	Hypotension	5–20 mcg/kg/min
Epinephrine	Catecholamine	VF	Syringe 1:10,000, 1-mg bolus IV Repeat every 3–5 min
Isoproterenol	Catecholamine; β agonist	VT, VF	Drip 0.5–5 mcg/min
Lidocaine	Antiarrhythmic	VT, VF	Bolus 1–1.5 mg/kg Drip 20–50 mcg/kg/min
Magnesium sulfate	Electrolyte	Torsades de pointes	Drip 1–2 g/50 mL NS solution
Nitroglycerin	Coronary vasodilator	MI, angina	5–100 mcg/min
Procainamide	Antiarrhythmic	VT, VF	Bolus 5–10 mg/kg over 8–10 min Drip 20–30 mg/min
Sodium bicarbonate	Alkalinizer	Acidosis	50 mEq syringe Normal dose is 1 mEq/kg
Verapamil	Calcium channel blocker	SVT	2.5–5 mg IV over 2 min Repeat 5–10 mg in 15–30 min

AF, atrial fibrillation; NS, normal saline; PEA, pulseless electrical activity; SVT, supraventricular tachycardia; VF, ventricular fibrillation; VT, ventricular tachycardia.

defibrillation need to be started immediately to avoid death. It is paramount that compressions and ventilations continue during the defibrillation preparation time. The myocardium needs oxygen and electrolytes provided during compressions. The delivery of an electrical impulse by an external defibrillator simultaneously depolarizes most of the ventricular cells during VF and the reentry abnormalities of VT. If the conditions are right, and there has not been too much damage to the heart's intrinsic electrical conduction system, the SA node may resume its function as the pacemaker of the heart.

If indicated, an external countershock should be applied as soon as the instrument is available. The defibrillator paddles (or pads) are positioned so that the heart is in the current pathway. The anterior apex, also known as the anterolateral or sternum–apex position, is used most often. The anterior paddle is placed firmly on the patient's upper right chest below the clavicle and to the right of the sternum. The apex paddle is positioned firmly on the patient's lower left chest in a midaxillary line (Fig. 18-48).

A growing body of evidence indicates that early defibrillation can convert a patient's rhythm from VF more than 90% of the time. In a change to previous defibrillation protocols, defibrillation should be attempted using one shock, with immediate resumption of CPR. If a monophasic defibrillator is used, it should be set at 360 J. If a biphasic device is used, it should be set at either 120 or 200 J; this initial setting is device specific, so familiarity with which defibrillator is on the unit is very important.[1]

Following this first shock, five cycles of CPR should be performed. If the patient remains in a shockable rhythm, then a second shock should be delivered.[1] After each subsequent shock, five more cycles of CPR should be performed before assessing whether the patient has remained in a shockable rhythm. All personnel are advised to avoid touching the patient or bed when the shock is delivered. Immediate resumption of artificial circulation and ventilation (CPR) should occur after each countershock if no pulse returns. Box 18-33 outlines the indications and procedure for defibrillation.

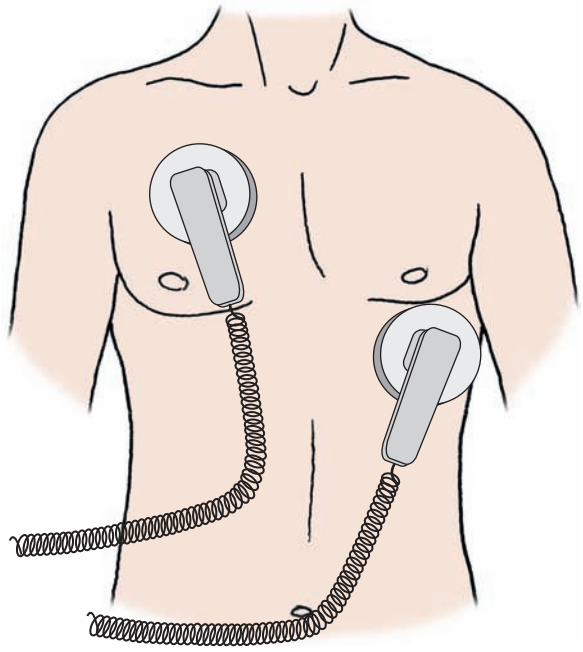

FIGURE 18-48 ▲ Standard positioning of defibrillator paddles.

BOX 18-33 Indications and Procedure for Defibrillation

Indications
- Pulseless VT
- Ventricular fibrillation

Procedure
1. Apply defibrillator pads to patient.
2. Turn on defibrillator.
3. Charge defibrillator to 200 J for *monophasic* device; for *biphasic* defibrillation, change to 120 or 200 J, depending on device.
4. Ensure all personnel are not touching patient or bed.
5. Deliver shock.
6. Determine effectiveness of treatment. Check pulse and observe patient's rhythm.
7. Continue CPR.
8. Be prepared to deliver subsequent shocks per ACLS protocol.

Defibrillators are classified based on the type of waveform used by the defibrillator. Since the early 1970s, monophasic defibrillators have been used. This type of defibrillator provides a shock that flows in one direction from one paddle or electrode pad to the other. In more recent years, newer technology has been developed that changes the way the electrical current flows during defibrillation. Known as a biphasic defibrillator, this newer type delivers the current in two phases. The current initially flows in one direction, then flows in the opposite direction. The biphasic wave uses less peak current, so there is less damage to the heart during defibrillation.[3] ICDs are devices that are designed to shock patients out of potentially fatal dysrhythmias. ICDs have used biphasic technology for more than a decade. Currently, transthoracic biphasic defibrillation is also possible.

▲ Automatic External Defibrillator

Studies show that the sooner a patient in VF is defibrillated, the greater the chance for survival.[5] The development of the AED has improved the survivability of individuals suffering from potentially life-threatening dysrhythmias. The AED allows for defibrillation to be performed in a variety of settings by personnel trained in the use of the AED but not BLS or ACLS.

The AED consists of a computerized detection system that recognizes the patient's inherent heart rhythm and delivers a defibrillatory countershock when necessary. This cycle of rhythm analysis followed by countershock lasts approximately 30 seconds. AEDs are now found in airports, train stations, sports stadiums, office buildings, and shopping malls. AEDs are also available in most hospitals in common areas, general floors, and laboratories. The widespread availability of these devices allows for a much quicker response time when a person experiences cardiac arrest.[4]

▲ Transcutaneous Pacing

A combination defibrillator–transcutaneous pacemaker is usually found on top of the crash cart. The large pacing electrodes ("combination pads") used in defibrillation can also be used to pace a patient transcutaneously. Transcutaneous pacing may be used as a "bridge" (temporary measure) until either a transvenous or permanent pacemaker can be placed.

A nurse, nurse practitioner, or physician quickly and easily initiates transcutaneous pacing. This procedure is noninvasive and therefore is low risk and saves time during an arrest situation. Indications for transcutaneous pacing include new complete (third-degree) heart block or symptomatic bradycardia (unresponsive to drug therapy). The pacing electrodes are also placed when the patient's rhythm changes to a new second-degree, Mobitz II heart block. Transcutaneous pacing also is used when invasive (transvenous) pacing is unsuccessful or contraindicated, such as after the use of thrombolytics and for the patient with sepsis.

The transcutaneous pacemaker is used in a "demand mode" for bradycardia and asystole; it paces the heart only when needed. This mode is safer because the chance of firing on the T wave ("R-on-T phenomenon") is greatly reduced. When the pacemaker is used in an asynchronous mode, the heart is paced at a fixed rate, regardless of the heart's intrinsic rate or rhythm. The pacemaker may fire on the T wave, producing either AF or VT. Box 18-34 outlines the indications and procedure for transcutaneous pacing.

The nurse must ensure that a conscious patient understands what is happening. Much technical jargon and various personnel are involved when a patient is having noninvasive temporary pacing. The nurse is responsible for placing the pacing pads in an anteroposterior configuration, which allows for more effective pacing. Figure 18-49 shows the proper placement of the electrodes. The skin is not shaved, which means that there is no skin irritation. No alcohol or adhesive should be used so that the electrical current is not compromised. The nurse sets the pacing rate and stimulation threshold. Blood pressure should be taken using the right arm to avoid interference from the pacemaker.

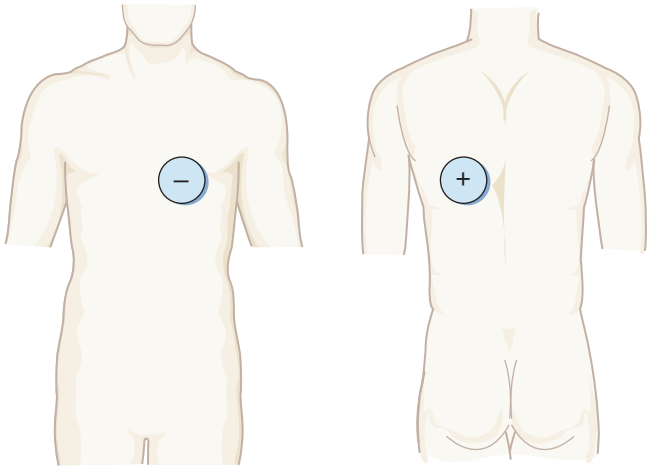

FIGURE 18-49 ▲ Standard position of transcutaneous electrodes.

Transcutaneous pacing requires diligent monitoring by the nurse. A loss of capture can occur if the electrodes fail to keep good contact with the skin. Inappropriate pacing may result if the pacemaker cannot detect the heart's intrinsic rhythm. In either case, the nurse must recognize the problem and reposition the patient or the electrodes to ensure efficacious transcutaneous pacing.

BOX 18-34 Indications and Procedure for Transcutaneous Pacing

Indication

- Complete (third-degree) heart block

Procedure

1. Explain procedure to patient.
2. Clip excess hair from chest. Ensure skin is dry.
3. Apply anterior electrode to chest at the fourth intercostal space to the left of the sternum.
4. Apply posterior electrode to patient's back in the area of the left scapula.
5. Connect pacing electrodes to transcutaneous pacemaker.
6. Set pacemaker mode, heart rate, and output.
7. Turn unit on.
8. Assess for effectiveness of pacing:
   - Observe for pacemaker spike with subsequent capture.
   - Assess heart rate and rhythm.
   - Assess blood pressure.
   - Check level of consciousness.
   - Observe for patient anxiety and/or pain and treat accordingly.

▲ Therapeutic Hypothermia

Unconscious adult patients who suffer out-of-hospital cardiac arrest caused by VF and are resuscitated in the field may benefit from induced mild hypothermia. During cardiac arrest, blood flow to the brain is compromised, and even prompt interventions may not counteract the deleterious effects of this hemodynamic compromise. The cerebral metabolic rate for oxygen, or $CMRO_2$, is reduced when the body temperature is reduced. Apoptosis (programmed cell death) and the production of free radicals are reduced in a hypothermic state. Studies have shown that the cooling of the patient after cardiac arrest may preserve neurological function. This therapy is currently contraindicated in children of any age, although research continues. There is evidence that supports hypothermic therapy for cardiac arrest caused by dysrhythmias.[5]

Many institutions are now implementing therapeutic hypothermia protocols. Common among these protocols is the systematic lowering of a patient's temperature to 32°C to 34°C. This can be accomplished by various methods, including ice packs, cooling blankets, and endovascular cooling devices. The patient remains in this hypothermic state between 8 and 12 hours. Rewarming is then allowed to occur over the next 8 to 12 hours.[5–7]

Nursing care during therapeutic is intense. In addition to the monitoring of cardiac rhythm and MAP, potassium levels and blood glucose must also be tracked. In most cases,

the patient is intubated and on mechanical ventilation, so arterial blood gases and ventilator settings must be evaluated periodically. The nurse must ensure that medications, such as sedatives, neuromuscular blockade medications, and analgesics, are administered in accordance with the established protocols. Care must include skin assessment to check for possible damage caused by the cooling devices, as cooling injuries are a realistic complication that is not often seen in an ICU. The patient's core body temperature is monitored, usually using a bladder catheter.

Research continues as to the optimal temperature, means of cooling, and method of rewarming. Investigative studies are now being conducted as to the efficacy of therapeutic hypothermia in cases of cerebral vascular accidents. One of the major controversies surrounding therapeutic hypothermia is the patient's quality of life following rewarming, as well as the long-term costs if the patient recovers, but with resulting neurological deficits.[8]

▲ Family Presence in Cardiac Arrest Situations

One aspect of the treatment of cardiopulmonary arrest that has gained attention in recent years is the issue of family presence during a code. Nurses have voiced strong opinions for both sides of the issue. Health care institutions have become more flexible, and they are more accommodating of families and visitors. Some emergency departments and ICUs have protocols in place regarding having loved ones at the bedside while resuscitation efforts are taking place. Every effort must be made to have a knowledgeable person explain to the family what measures are being implemented and the rationale. By involving the family in this manner, they can make more informed decisions about the continuation of resuscitation.[9]

Many family members express a desire to be with the patient during CPR for various reasons. Some want to be reassured that all resuscitative efforts were attempted. There are those who want to have a chance to say goodbye at the moment of death, rather than in the hours or days after death. One of the most often cited reasons for wanting to be with the patient is to make sure that the death is painless.

When discussing advanced directives with patients and their families, the techniques of resuscitation are often described. In the event of a cardiac arrest situation, some family members have seen these measures taking place and make the determination to terminate resuscitation.

The recognition of families after a successful resuscitation must be experienced to appreciate it. When the family sees a team of health care professionals working against time to save a patient, they express the realization that nurses, physicians, respiratory therapists, and others combine to provide excellent and compassionate care.

Many nurses and physicians believe that family presence during CPR detracts from their performance and that individuals who have an emotional attachment to the patient hinder their efforts. Rules must be in place to escort family members from the room if the rescuers cannot perform resuscitative measures effectively.

▲ Clinical Applicability Challenges

CASE STUDY

P.M., a 77-year-old female recovering from sudden cardiac arrest, myocardial infarction, and status post placement of an implantable cardioverter–defibrillator, is a "full code." She has visitors at this time, her daughter and son-in-law. The nurse is outside at the nurse's station, documenting morning assessments. The sound of a cardiac monitor alarm begins as the nurse hears P.M.'s daughter yell: "Someone come quick! There's something wrong with my mother!" The nurse enters the room and notes that the monitor is showing ventricular fibrillation.

1. What are the immediate actions the nurse must perform?
2. When more health care team members arrive, what are the various roles to be performed and actions to be taken?
3. What should be done with the family members in the room?

19 Common Cardiovascular Disorders

Clifford C. Pyne and Sue Apple

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Differentiate between pericarditic and ischemic chest pain.
2. Explain the long-term effects of endocarditis on the heart valves.
3. Discuss key differences in the clinical management of dilated and hypertrophic cardiomyopathy.
4. Describe key differences in clinical presentation between arterial and venous peripheral vascular disease.
5. Compare and contrast the clinical findings of chronic aortic aneurysm with those of acute aortic dissection.
6. Construct a plan of care for the patient in hypertensive crisis covering the first hour of treatment.

The first intensive and coronary care units were developed in the mid-1960s to treat patients with acute myocardial infarction (MI). Since those early days, critical care nurses have expanded their knowledge base to include care of patients with a wide spectrum of cardiovascular diseases. In addition to acute MI, these disorders include inflammation and infections of the heart muscle, pericardium, and valves; dilation and/or thickening of the ventricular walls; and diseases involving the aorta and peripheral vascular system. This chapter reviews several common cardiovascular disorders, including pericarditis, myocarditis, endocarditis, cardiomyopathies, peripheral vascular disease, aortic diseases, and hypertensive crisis.

▲ Infection and Inflammation of the Heart

Infectious and inflammatory diseases of the heart have multiple etiologies, making diagnosis and treatment a clinical challenge. Patients may present with acute pain mimicking MI, or may seek medical attention because of fatigue and vague flu-like symptoms that fail to resolve over a period of weeks. Because of the permanent damage these diseases can cause to structures of the heart, patients often face serious long-term cardiac disability.

Pericarditis

The pericardium surrounds the external surface of the heart and the roots of the great vessels. It is composed of two layers: an outer tough fibrous pericardium and an inner serous layer.[1,2] The serous pericardium has two layers: the parietal and the visceral. The parietal layer lines the internal surface of the fibrous membrane. The parietal pericardium extends to the great vessels, where it then folds over on itself to form the inner visceral layer, also known as the epicardium (Fig. 19-1). From 10 to 50 mL of clear serous fluid lies between these layers and acts as a lubricant. The pericardium helps restrain the heart and isolate it from infections in the surrounding structures.[3,4]

Pericarditis is inflammation of the pericardium. Acute pericarditis is pericarditis that lasts no longer than 1 or 2 weeks.[4,5] Inflammation often involves the adjoining diaphragm. Pericarditis can be a primary disease or occur secondarily as the result of some other disorder, such as acute MI or renal failure.[5,6] The etiology of pericarditis varies. However, in almost 90% of patients diagnosed with acute pericarditis, the exact cause is unknown (idiopathic).[4,5] Causes of pericarditis are listed in Box 19-1. Dressler's syndrome refers to the development of pericarditis, malaise, fever, and elevated white blood cell count appearing weeks to months after a MI. This syndrome is believed to be the result of an autoimmune reaction that occurs after the infarction.[3] Infectious pericarditis remains a problem in the immunocompromised patient.[7]

Repeated episodes of pericarditis can lead to the formation of adhesions between the layers of the pericardium or between the pericardium and adjacent structures, resulting in constrictive pericarditis.[8] In constrictive pericarditis, the primary problem is failure of the heart to fill during diastole because of its inability to expand. Unless the diseased pericardium is removed surgically, diastolic filling continues to be impaired, eventually leading to a decrease in cardiac output and systemic signs of heart failure. Even with successful surgical removal of the diseased pericardium, the long-term survival rate is poor.[4,8]

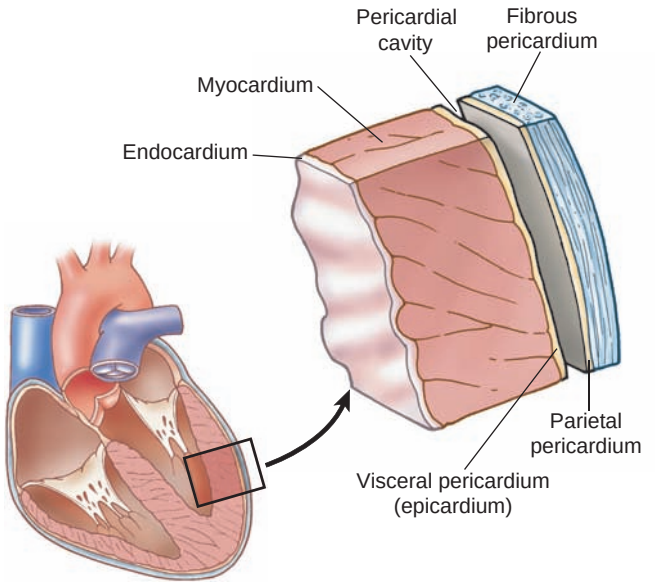

FIGURE 19-1 ▲ Layers of the heart, showing the visceral pericardium, pericardial cavity, parietal pericardium, fibrous pericardium, myocardium, and endocardium. (From Porth CM: Pathophysiology, Concepts of Altered Health States, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 459.)

BOX 19-1 Causes of Pericarditis

- Idiopathic (usually presumed to be viral)
- Infectious
- Bacterial
- Tuberculosis
- Autoimmune or inflammatory
- Systemic lupus erythematosus
- Drugs
- Vaccinations
- Neoplasms
- Radiation therapy
- Following device implantation, such as an implantable defibrillator
- Acute myocardial infarction
- Trauma to the chest wall or myocardium, including cardiopulmonary surgery
- Chronic renal failure requiring dialysis

Assessment

Important clues to the diagnosis of pericarditis can be obtained from the history and physical examination. The primary symptom in acute pericarditis is chest pain.[4,6] The pain tends to be pleuritic in nature and classically is made worse by breathing deeply or lying supine. Because of pain from breathing, patients frequently complain of dyspnea. Relief is often obtained by sitting up, leaning forward, and taking shallow breaths. The chest pain of pericarditis may be difficult to distinguish from ischemic chest pain.[5] Differential vdiagnoses of chest pain are summarized in Table 19-1. One clue in the differentiation is that ischemic chest pain is not relieved by a change in the patient's position.

There may also be general symptoms of an infection, such as a low-grade fever, tachycardia, or malaise. The presence of a pericardial friction rub confirms the diagnosis; however, absence of a rub does not rule out pericarditis. The classic friction rub produces a rasping or scraping, high-pitched sound that varies with the cardiac cycle. The rub may wax and wane and may even transiently disappear during the course of the illness. It is best heard with the diaphragm of the stethoscope placed over the lower to middle left sternal edge.[3,6]

There are no specific guidelines for evaluating or managing acute pericarditis. The electrocardiogram (ECG) is the most important test in establishing the diagnosis.[4] It classically shows diffuse ST-segment elevation with an upward concavity and PR-segment depression (Fig. 19-2). This contrasts with the ECG seen in acute myocardial injury, which typically shows upward convexity in leads facing the infarction zone (Fig. 19-3).[4–6] The chest radiograph may not be helpful. Although the echocardiogram is usually normal in acute pericarditis, it is indicated in patients with suspected pericardial disease.[9]

Laboratory tests include complete blood count, cardiac enzyme levels (which may be elevated if the inflammation extends to the myocardium), rheumatoid factors, and antinuclear antibody titers. Blood cultures may be indicated if there is evidence of infection. Viral studies may be obtained if the rest of the diagnostic workup is negative.

Table 19-1 Differential Diagnosis of Chest Pain

Diagnosis	Onset of Pain	Quality of Pain	Relieved by
Angina pectoris	Sudden, after heavy meal or exertion	Crushing Squeezing Choking	Rest, nitrates
Acute myocardial infarction	Varies, may be associated with feeling of doom	Similar to angina, but more severe	No relief with rest
Pericarditis	Varies, may be preceded by "flu-like" symptoms for several days to weeks	Pleuritic Sharp, stabbing	Sitting up Shallow breathing NSAIDs
Acute aortic dissection	Sudden, may be associated with syncope Intense from the onset	Ripping Tearing Worst pain in patient's life	No relief

NSAIDs, nonsteroidal anti-inflammatory drugs.

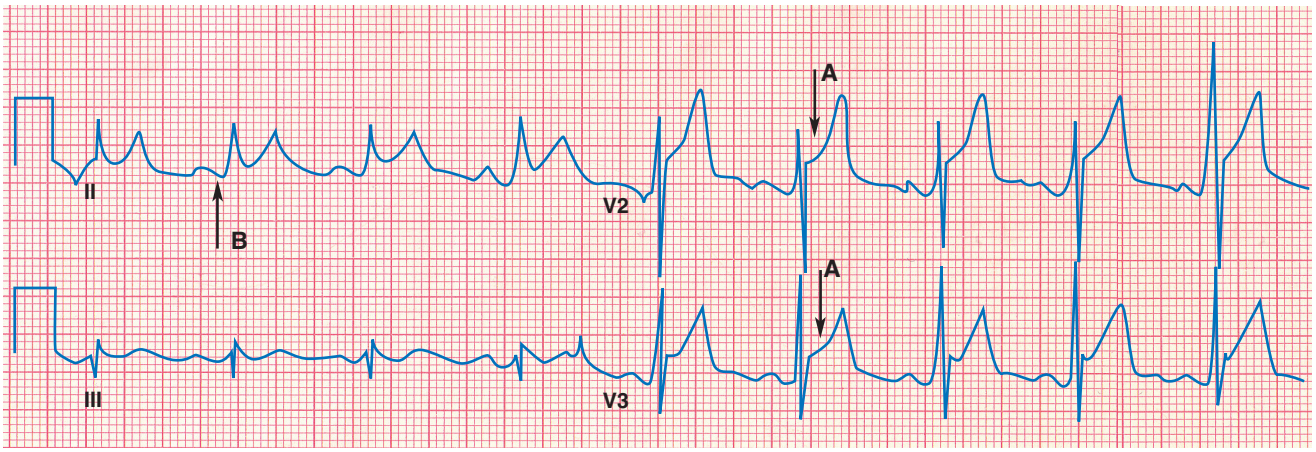

FIGURE 19-2 ▲ The 12-lead electrocardiogram in acute pericarditis. Note the diffuse upward concavity ST changes (*A*) and the PR-segment depression (*B*).

Management

Treatment goals for the patient with pericarditis are to relieve symptoms, eliminate any possible causative agents, and monitor for complications, such as constrictive pericarditis or pericardial effusions that could lead to cardiac tamponade.[3,6] Symptom relief includes the use of nonsteroidal anti-inflammatory drugs (NSAIDs), such as aspirin or ibuprofen. Steroids may be indicated in resistant cases in which infectious causes have been excluded. Anticoagulants should be avoided in the patient recovering from MI. Most episodes of pericarditis abate over 2 to 6 weeks. Rarely do patients experience recurrent episodes.

Myocarditis

Myocarditis is an inflammation of the myocardium.[3,10] Primary myocarditis is believed to be related to an acute viral infection or an autoimmune response to the infection. Secondary myocarditis is inflammation related to a specific organism. Potential causes of both types, which can occur in any age group, are listed in Box 19-2. The prevalence is unknown because the clinical presentation is so varied and often subacute.[11] Myocarditis can be a devastating illness that evolves into a chronic, progressive disease with a poor prognosis. The disorder may result in dysrhythmias, congestive heart failure, or death.[10] It is also recognized as a cause of sudden death in young athletes.[12]

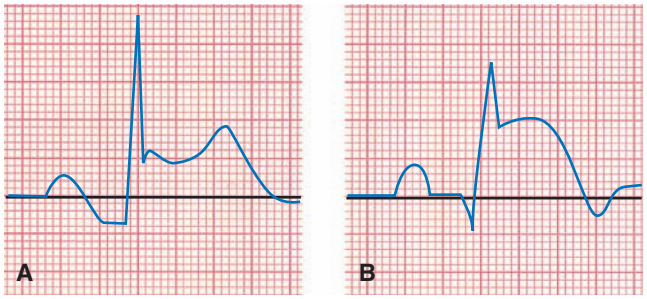

FIGURE 19-3 ▲ ST-segment changes seen in (**A**) acute pericarditis and (**B**) myocardial infarction.

Assessment

The clinical presentation of myocarditis is variable. With viral myocarditis, typically, there is a delay before the onset of cardiac symptoms, such as congestive heart failure or dysrhythmias.[3,10] The presence of symptoms, such as fatigue, dyspnea, palpitations, and precordial discomfort, accompanied by a slight rise in serum enzyme levels and nonspecific ST-T wave changes on the ECG suggests a diagnosis of myocarditis. Definitive diagnosis requires a positive endomyocardial biopsy.[10,11] However, lack of a positive biopsy does not rule out myocarditis. Current research focuses on finding a more reliable and safe method of diagnosing this complex disease.[10]

Management

Management of myocarditis depends on the etiology and clinical presentation; however, treatment is largely supportive.[3] Although myocarditis evokes a severe inflammatory response, treatment with corticosteroids or immunosuppressive agents has not been effective in changing the clinical course.[10,11] Some

BOX 19-2 Potential Causes of Myocarditis

Viruses
- Coxsackie virus
- Adenovirus
- Human immunodeficiency virus
- Influenza virus

Bacteria
- *Clostridium* species
- *Corynebacterium diphtheriae*
- Streptococci
- Spirochetes (Lyme's disease)

Fungi
- *Aspergillus* species
- *Candida* species

Toxins
- Tricyclic antidepressants
- Phenothiazines

BOX 19-3 EXAMPLES OF NURSING DIAGNOSES

- Acute Pain related to inflammation of the myocardium
- Fatigue related to deteriorating myocardial function
- Ineffective Coping related to sudden onset of a critical disease
- Ineffective Family Coping related to sudden onset of a critical disease
- Powerlessness related to medical regimen
- Grieving related to loss of former lifestyle

episodes of myocarditis resolve without further sequelae. In other patients, a subacute disease develops with persistent laboratory findings of inflammation (eg, an increased white blood cell count or an elevated sedimentation rate). Athletes with myocarditis should withdraw from competitive sports for a period of at least 6 months following the onset of disease. Return to training and competition depends on normalization of cardiac function and absence of any significant clinical findings, such as dysrhythmias.

Box 19-3 lists nursing diagnoses for a patient with myocarditis. Many of the skills required by the nurse to care for the patient with myocarditis are similar to those needed in the care of the patient with heart failure. In addition, the nurse must be prepared to help the patient and family deal with the unexpected reality of a potentially lethal disease that often has no cure and may require heart transplantation.[3]

Endocarditis

Endocarditis is an infection of the endocardial surface of the heart, including the valves, caused by bacterial, viral, or fungal agents.[13,14] Infectious endocarditis (IE) is a serious illness associated with considerable morbidity and mortality. The incidence of IE varies with the specific population under study, but overall, the incidence appears to be increasing.[3,13] Children with congenital heart disease, a group known to be at risk for IE, have increasingly higher survival rates, and this may contribute to the rise of IE in the pediatric population.[15] Adults at risk for IE include those with mitral valve prolapse or rheumatic heart disease, those who use illicit intravenous drugs, and patients with prosthetic valves or long-term indwelling devices (Box 19-4).[3,13,16,17] Common infectious organisms include streptococci, enterococci, and *Staphylococcus aureus*.

BOX 19-4 Risk Factors for Endocarditis

Native Valve Endocarditis
- Mitral valve prolapse
- Congenital heart disease
- Rheumatic heart disease
- Degenerative valve disease (such as aortic stenosis)
- Age greater than 60 years
- Intravenous drug abuse

Prosthetic Valve Endocarditis

Early (Within 60 Days of Surgery)
- Nosocomial infections
- Indwelling catheters
- Endotracheal tubes

Late (After 60 Days)
- Dental, genitourinary, or gastrointestinal manipulations

The development of IE is a complex process that requires the occurrence of several critical elements.[3,13,17] First, there must be endothelial damage that exposes the basement membrane of the valve to turbulent blood flow. Next, this exposure, especially in patients in a hypercoagulable state, must lead to the development of a platelet and fibrin clot on the valve leaflet. These clots, or vegetations, must be exposed to bacteria by way of the bloodstream, such as occurs after dental manipulations or urological procedures. Finally, bacterial proliferation must take place. Bacteria proliferate on these vegetations for two reasons: (1) the turbulent blood flow across the valves helps concentrate the numbers of bacteria near the vegetation and (2) the vegetation itself covers the bacteria with layers of platelets and fibrin, protecting the bacterial colony from the body's natural defense mechanisms. The infected vegetation interferes with normal valve function and eventually damages the valve structure. These incompetent valves eventually lead to severe heart failure. Particles from the infected vegetation or severely damaged valve can break loose and cause peripheral emboli.[3,13,14,17]

Assessment

Symptoms of endocarditis usually occur within 2 weeks of the precipitating bacteremia and are related to four underlying processes: bacteremia or fungemia, valvulitis, immunologic response, and peripheral emboli (Box 19-5).[13,16] Nonspecific complaints, such as general malaise, anorexia, fatigue, weight loss, and night sweats, are common. Because symptoms are nonspecific, a careful history focusing on risk factors for IE and a physical examination are needed to alert the nurse to the potential diagnosis of endocarditis.[3] Fever and a new or changed heart murmur are present in almost all patients.[13] The nurse should suspect IE in any patient with these clinical findings.[3,14]

Definitive diagnosis of IE includes persistent bacteremia caused by typical IE pathogens and evidence of myocardial involvement such as echocardiographic visualization of a vegetation or new or worsening murmur (Duke criteria).[18,19] Blood is usually drawn for three separate sets of cultures; meticulous site preparation is necessary to avoid contamination.[3]

BOX 19-5 Clinical Features of Endocarditis

- Fever
- Heart murmurs
- Splenomegaly
- Petechiae
  - Splinter hemorrhages
  - Osler's nodes (small, raised, tender nodules that occur on the fingers or toes)
  - Janeway's lesions (small erythematous or hemorrhagic lesions on the palms or soles)
- Musculoskeletal complaints
- Systemic or pulmonary emboli
- Neurological manifestations
  - Headache
  - Mycotic aneurysms

Management

Rapid diagnosis of IE, initiation of appropriate treatment, and early identification of complications are the keys to good patient outcomes.[3,16] Antibiotic therapy is based on the results and the clinical setting (ie, native valve vs. prosthetic valve IE). Recommended therapies have been revised to account for a dramatic increase in drug resistance among common IE organisms.[16] Treatment should not be delayed while waiting for identification of the specific organism but should begin as soon as blood culture specimens are drawn. Immediate surgical intervention is indicated in the presence of severe congestive heart failure secondary to valve dysfunction, uncontrolled infections, and prosthetic valve dysfunction or dehiscence.

Cure of IE is difficult and requires complete eradication of the bacterial colony from the vegetation. This usually involves a prolonged course of antibiotic therapy.[3,16]

▲ Cardiomyopathies

The cardiomyopathies are diseases of the heart muscle that cause cardiac dysfunction resulting in heart failure, dysrhythmias, or sudden death.[20–22] Since 1995, the cardiomyopathies have been separated into distinct categories: dilated, hypertrophic, restrictive, arrhythmogenic right ventricular cardiomyopathy, and unclassified.[23] However, advances in molecular genetics and improvements in diagnostic imaging reveal that the cardiomyopathies are more heterogeneous, which has led to the proposal of a new definition and classification scheme (Box 19-6).[20] See Spotlight on Genetics 19-1 for information about familial restrictive cardiomyopathy.

BOX 19-6 Cardiomyopathies and Their Classification

Definition

"Cardiomyopathies are a heterogeneous group of diseases of the myocardium associated with mechanical and/or electrical dysfunction that usually (but not invariably) exhibit inappropriate ventricular hypertrophy or dilatation and are due to a variety of causes that frequently are genetic. Cardiomyopathies either are confined to the heart or are part of generalized systemic disorders, often leading to cardiovascular death or progressive heart failure–related disability."[20]

Classification

Primary cardiomyopathies are solely or predominantly confined to heart muscle. Primary cardiomyopathies are classified according to etiology and include genetic (such as hypertrophic cardiomyopathy), mixed genetic and nongenetic (such as dilated cardiomyopathy), and acquired (such as inflammatory or peripartum cardiomyopathy).

Secondary cardiomyopathies have myocardial involvement as part of systemic disorders (such as amyloidosis or diabetes).

Adapted from Maron BJ, Towbin JA, Thiene G, et al: Contemporary definitions and classification of the cardiomyopathies: An American Heart Association scientific statement from the Council on Clinical Cardiology, Heart Failure and Transplantation Committee; Quality of Care and Outcomes Research and Functional Genomics and Translational Biology Interdisciplinary Working Groups; and Council on Epidemiology and Prevention. Circulation 113:1807–1816, 2006.

SPOTLIGHT ON GENETICS 19-1

FAMILIAL RESTRICTIVE CARDIOMYOPATHY

- The least common of the cardiomyopathies, the heart muscle is stiff and cannot fully relax after each contraction.
- Is caused by mutations in the *TNNI3* gene, which helps regulate contraction and relaxation of the heart muscle.
- *TNNI3* gene mutations associated with familial restrictive cardiomyopathy result in the production of a defective troponin I-cardiac isoform protein. The altered protein disrupts the function of the troponin protein complex and does not allow the heart muscle to fully relax
- Genetic testing for the *TNNI3* gene-**r**elated familial restrictive cardiomyopathy is available

Sen-Chowdhry S, Syrris P, McKenna WJ. Genetics of restrictive cardiomyopathy. Heart Fail Clin 6(2):179–186, 2010.

This section focuses on the most common types of primary cardiomyopathies in Western countries: dilated and hypertrophic cardiomyopathies (Table 19-2).

Exactly how cardiomyopathy develops is not completely understood. Current theories under investigation suggest that ischemic, immune, mechanical, and neurohormonal effects on the pericardium, myocardium, and endothelium lead to structural changes that result in functional changes. Structural changes at the cellular level include replacement of contractile and elastic muscle cells with fibrotic elements, which leads to stiffness of the ventricles and smooth muscle layers in the arteries. In hypertrophic cardiomyopathy (HCM), the heart muscle becomes thickened, with increased mass and poor relaxation. In dilated cardiomyopathy (DCM), the ventricular chamber dilates, thins, and changes from a normally elliptical shape to a less efficient spherical shape, reducing contractility and impairing emptying. Both stiffness and spherical remodeling may occur in the same heart, leading to a compromised cardiac output from impaired relaxation and impaired emptying. Stiffening of arteries seen in aging, atherosclerosis, and arteriosclerosis decreases stroke volume and exacerbates the ventricular wall stress by overfilling the ventricle. The heart attempts to maintain cardiac output in the face of a decreased stroke volume by increasing heart rate, which decreases relaxation time and impairs filling. This endless spiral of dysfunction is manifested by the progressive nature of heart failure.

The resulting decrease in cardiac output leads to activation of the renin–angiotensin–aldosterone system and the release of catecholamines. As previously described, these neurohormones were meant to respond to temporary decreases in blood pressure, such as hemorrhage, but in cardiomyopathy, the problem is chronic. Consequently, the neurohormonal effects, which were intended to be temporary, become permanent and become part of the problem instead of the solution to a decreased cardiac output.

The persistence of these neurohormones is hypothesized to be the mechanism by which the ventricle remodels from an elliptical shape to spherical, further decreasing its pumping efficiency. The realignment of the muscle fibers has been attributed to long-term exposure to aldosterone. Furthermore, long-term exposure to catecholamines leads to downregulation of β-adrenergic receptors and contributes to decreased contractility.

Table 19-2 Primary Cardiomyopathies

Cardiomyopathy	Pathology	Clinical Manifestations	Management
Dilated cardiomyopathy (DCM)  	Systolic dysfunction Chamber dilation with normal left ventricular wall thickness	• Congestive heart failure • Fatigue, weakness • Dysrhythmias • Systemic or pulmonary emboli	• Identify and eliminate potential causes such as alcohol • Symptomatic treatment • Manage heart failure, dysrhythmias • Biventricular pacing or implantable cardioverter defibrillator (ICD) in selected patients • Genetic testing • Family screening to identify asymptomatic members with DCM
Hypertrophic (HCM)  	Diastolic dysfunction Marked hypertrophy of left ventricle, occasionally also of right ventricle, and usually (but not always) disproportionate hypertrophy of septum	• Dyspnea • Angina • Fatigue • Syncope • Palpitations • Dysrhythmias • Congestive heart failure • Sudden death	• Symptomatic treatment • Medications • ICD • Septal wall ablation or surgery in select patients • Volume reduction surgery • Genetic testing • Family screening to identify asymptomatic members with HCM

Images adapted from the Anatomical Chart Company: Atlas of Pathophysiology. Springhouse, PA: Springhouse, 2010, p 45.

Dilated Cardiomyopathy

DCM is characterized by increased myocardial cavity size in the presence of normal or reduced left ventricular wall thickness and impaired systolic function.[20,21] The heart gradually assumes a globular shape accompanied by ventricular chamber dilation.[22] A decrease in contractility may occur for many reasons, including ischemia, alcohol abuse, endocrine disorders, pregnancy, viral infections, and valvular disease. The result of the decrease in contractility (ejection fraction <40%) is an increase in end-systolic volume. Over time, the ventricle dilates to accommodate the increased intraventricular volumes (preload). The increased preload in a normal heart would lead to an increase in stroke volume, but in the dilated heart, the increased volume leads to a decreasing stroke volume. As ventricular dilation progresses, mitral and tricuspid insufficiency develop as the valve leaflets are stretched and separated. Dysrhythmias, such as ventricular tachycardia, as well as conduction defects commonly occur.

DCM is the third most common cause of heart failure, the most common cause of heart failure in the young, and the most frequent cause of heart transplantation.[20] It occurs most frequently in middle-aged men, and 20% to 35% of cases are familial.[20,22] In most cases, the specific cause is unknown. The etiology of DCM is various, including familial and genetic factors, viral infections (ie, past episodes of viral myocarditis), immunological defects, and exposure to toxins.[20,21,24] Many researchers believe that alcohol is the most prevalent toxic cause of DCM.[21] DCM can be further divided into two types: ischemic and nonischemic.

Ischemic Cardiomyopathy

Ischemic cardiomyopathy is the result of oxygen levels that are inadequate to meet the metabolic demands of the myocardial cells. It occurs when there is obstruction in the coronary arteries and may be acute or chronic. Oxygen is essential to the function of cells. It is necessary for the metabolism of nutritional substrates and the formation of adenosine triphosphate (ATP), which powers all intracellular processes. When oxygen is inadequate, ATP becomes insufficient, and the calcium, sodium, and potassium pumps fail, leading to interruptions in both the mechanical and electrical function of the cells. The net result is a decrease in contractility and dysrhythmia. If oxygen is restored to the muscle cells, function returns and the dysrhythmia disappears.

If the ischemia is severe or persists, the muscle tissue dies, causing an MI. Dead muscle cannot regenerate and is replaced with scar tissue. The larger the scar, the greater the dysfunction. The decrease in muscle mass leads to decreased energy for pumping blood and therefore decreased cardiac output. The goal in treating unstable angina and acute MI is preservation of muscle mass to prevent systolic dysfunction.

If an MI is small, the damage may be insufficient to cause heart failure because there is still enough muscle to meet the body's demands for oxygen at rest and with exercise. The ejection fraction may still be within the normal range, although it may be decreased somewhat owing to the myocardial damage. However, repeated damage from subsequent infarctions or persistent ischemia in other areas of the heart muscle may exhaust the reserve function. "Hibernating" myocardium is an area of myocardial cells that are not dead (MI) but lack sufficient oxygen and nutrient substrates to contract. Once a patient's condition is stable after an MI, it is important to identify any viable myocardium that may be hibernating because of reversible ischemia. If perfusion can be restored to this viable but underperforming myocardium, ventricular function can be improved.

If an MI is very large, or critical structures such as the chordae tendineae are involved, then the consequences may be life-threatening. Damage or rupture of the chordae may

lead to acute, severe mitral regurgitation and profound heart failure. The loss of ventricular pumping function that results from a massive MI or smaller repeated MIs may produce such an acute loss of pump function that all the body's compensatory mechanisms are not effectively able to overcome the deficit in cardiac output.

This condition represents cardiogenic shock, in which cardiac output is severely inadequate and the left ventricle empties poorly (see Chapter 54). Consequently, left ventricular end-diastolic pressure increases, pulmonary artery pressures increase, and pulmonary edema results. End-organ damage caused by inadequate oxygen begins to occur depending on the function of the organ. The skin becomes cool, perhaps clammy and pale. The respiratory rate increases to supply as much oxygen as possible to the blood being pumped because the pulmonary edema severely decreases the effective area for gas transport. The pulmonary edema makes the lungs heavy and less compliant and reduces the effective tidal volume. Increases in respiratory rate are necessary to maintain minute volume. In addition, the tissues that are not adequately supplied with oxygen begin to produce lactic acid, leading to metabolic acidosis. The short-term compensation for metabolic acidosis is an increase in minute volume, or hyperpnea. The patient complains of feeling short of breath even at rest and may not be able to breathe in any recumbent position.

The hierarchy of protection in times of inadequate perfusion preserves most of the cardiac output for the brain, heart, and kidneys. Autoregulation mechanisms are present in all these organs to preserve pressure gradients and blood flow even when blood pressure and flow are compromised in other areas such as the skin, muscle, and gut. Indications that the brain is inadequately perfused are confusion, disorientation, somnolence, and agitation. Early indications of inadequate renal flow are an increase in blood urea nitrogen (BUN) and creatinine. Early on, the normal 10:1 to 20:1 ratio of BUN to creatinine increases to greater than 20:1; this signals the onset of prerenal azotemia. If perfusion is restored to the kidney at this time, the BUN and creatinine levels return to normal, as does kidney function. If the poor perfusion is profound or prolonged, the kidneys become damaged, and the BUN and creatinine continue to increase, although the ratio returns to normal. This ischemic damage to the kidneys is known as acute tubular necrosis and may be reversible.

If cardiogenic shock persists uncorrected for an extended period, the damage cannot be reversed, and the patient will die. Even if the patient is treated appropriately, further damage may occur in areas where the oxygen demand is lower than that of the brain and kidneys. Prolonged episodes of low cardiac output may lead to ileus, bowel infarction, liver failure, and increased risk for pneumonia and skin breakdown.

Patients who survive the initial episode of acute heart failure may recover completely if an intervention such as angioplasty or coronary artery bypass restores perfusion to the heart muscle and the damage to the remaining muscle is not severe. Chronic heart failure eventually develops in many patients and is characterized by the same symptoms as acute heart failure, but usually at a lower intensity; the body has had time to compensate for the decreased cardiac output. Usually, chronic heart failure does not have the intense limitations associated with acute heart failure. Patients often modify their activity to match the limited reserve of cardiac output available.

Nonischemic Cardiomyopathy

Nonischemic cardiomyopathy results from several causes. A large number of people have idiopathic DCM. For some as yet unknown reason, their hearts dilate, remodel, and become ineffective pumps. Others have myocarditis, often due to viral infection of the myocardium, hypothyroidism or hyperthyroidism, valvular disease, human immunodeficiency virus (HIV), or hemochromatosis. In addition, myocarditis may be bacterial or idiopathic. Nonischemic cardiomyopathy may also result from pregnancy, heavy alcohol use, hypertension, and tachycardia. Heart failure that results from hypothyroidism or hyperthyroidism, hemochromatosis, valvular disease, and tachycardia is reversible and disappears when these problems are corrected.

Nonischemic cardiomyopathy, like ischemic cardiomyopathy, may be acute or chronic. Patients with chronic disease are often quite limited in their ability to carry out everyday activities. The mechanism by which the dilation is triggered and progresses is not well understood. DCM, whether ischemic or nonischemic, produces symptoms after all the compensatory mechanisms have been exhausted.

Consequently, unless the onset of symptoms is acute, pathological changes may be quite advanced before activity is sufficiently limited and the patient seeks medical care. However, myocarditis frequently has an acute onset. The patient feels fine and is free of symptoms before fatigue and dyspnea on exertion, or, occasionally, pulmonary edema, suddenly develop. Dysfunction results from inflammation of the heart muscle. Metabolic function of inflamed muscle cells is impaired; the cells do not contract properly, leading to decreased cardiac output. Severity of the condition ranges from cardiogenic shock to mild limitation of activity. Once the initial acute phase passes, the patient has a low ejection fraction, with varying levels of physical limitation of activity and shortness of breath, or chronic heart failure.

Alcoholism, hypertension, and idiopathic etiologic factors are nonischemic conditions that may lead to DCM over longer periods—months to years as opposed to days to weeks with acute onset. As the ventricle begins to dilate, compensatory mechanisms, including the previously described catecholamines and other neurohormonal factors, begin to work. The proposed mechanism by which the ventricle remodels from the normal, efficient elliptical dimensions to a thin-walled, inefficient spherical shape involves constant exposure of the myocardium to these neurohormones. The natural progression is from dilation without symptoms to compensated heart failure, to uncompensated heart failure, and to refractory heart failure. Patients most often present when their heart failure is no longer compensated and symptoms interfere with normal daily activities. At this point, medication may relieve all or most symptoms. However, the structural changes that occur are progressive, and, even with medication, symptoms worsen over time. Medication can be adjusted to treat the worsening symptoms, but eventually, the medications will not be enough, and the patient dies. Usually mortality is due to worsening of the cardiac output, leading to system failure or sudden death from ventricular dysrhythmia. Before the stage of refractory heart failure is reached, much can be done to control the patient's symptoms, improve activity tolerance, control the progression of the disease, and improve quality of life.

ASSESSMENT. The natural history of DCM is not well defined. Some patients remain asymptomatic or have minimal clinical findings. Symptoms usually develop gradually and are typically related to left ventricular heart failure. The presence of right-sided heart failure is associated with poor prognosis.[3,21] Laboratory tests include screening for potentially reversible causes, including HIV. The echocardiogram is needed to differentiate the primary abnormality and determine the ejection fraction. Cardiac catheterization may be needed to rule out coronary artery disease.[3,21,24]

MANAGEMENT. Treatment goals include identifying and eliminating potential causes of DCM. Patients and their families should be questioned carefully about alcohol consumption because myocardial damage related to ingesting alcohol is reversible if detected early and the patient abstains from further drinking.[3,21,24] Clinical management is focused on control of heart failure and other problems such as dysrhythmias or intracoronary thrombus. Biventricular pacing may be helpful in medically refractory patients with severely symptomatic heart failure and a prolonged QRS on the ECG, dilated left ventricle, and poor ejection fraction.[25] Implantable cardioverter defibrillators (ICDs) may also be indicated in select patients to prevent sudden death associated with lethal dysrhythmias.[25] Only heart transplantation and some medical therapies have been shown to prolong life.[21]

Hypertrophic Cardiomyopathy

HCM is distinguished by a hypertrophied, nondilated left ventricle that is not related to any obvious cause, such as hypertension or aortic valve stenosis.[20,21] The most characteristic feature of HCM is diastolic dysfunction. The heart can contract but cannot relax and remains abnormally stiff in diastole. In a few patients, septal wall hypertrophy occurs, leading to a left ventricular outflow tract obstruction during systole.[3,21,26]

HCM is probably the most frequently occurring cardiomyopathy in the United States. It appears to be a common autosomal dominant genetic malformation; indeed, it is probably the most common genetic cardiovascular disorder, affecting approximately 1 in 500 of the population.[20,22,26]

Sudden death is a catastrophic outcome of HCM, usually from a ventricular dysrhythmia, in asymptomatic or mildly symptomatic people of any age group. In the United States, HCM is a leading cause of sudden death in competitive athletes as well as in people participating in recreational sports.[10,27] The risk for sudden death is constant; mortality is higher in younger patients.[3] Early identification of patients at risk for HCM (and therefore, sudden death) is imperative. However, there is no agreement on the best method to identify people at high risk at this time.[21,26]

Assessment

Many patients with HCM are asymptomatic or have only mild complaints.[3,21,24] The condition is often found unexpectedly during investigation of heart murmurs or family screening. The most common symptom is dyspnea, which may be exacerbated with exertion. Presyncope and syncope also frequently occur. Left ventricular hypertrophy (LVH) present on the echocardiogram confirms the diagnosis. Borderline LVH may be a normal finding in competitive athletes.[20]

Management

The goals of management include controlling symptoms, preventing complications, and reducing the risk for sudden death.[3,21] Genetic screening and counseling are also indicated.[26] Most symptomatic patients can be medically managed. ICDs are indicated in patients who have survived an episode of sudden death or have documented potentially lethal ventricular dysrhythmias.[25] In patients with symptoms resulting from septal hypertrophy, percutaneous ablation with ethanol or surgery to remove a portion of the septum may be necessary.[3,21]

Psychosocial concerns are important as patients and families try to cope with this debilitating and potentially fatal illness. They must deal with feelings of uncertainty and loss of control as well as the financial impact of a serious chronic illness.

▲ Peripheral Vascular Disease

Peripheral vascular disease includes a group of distinct disorders involving the arteries, veins, and lymphatic vessels of the peripheral circulation—the noncardiac diseases that affect the circulation as a whole.[28,29] The next section focuses on peripheral arterial and venous disease.

Peripheral Arterial Disease

Peripheral arterial disease (PAD) refers to processes that obstruct the blood supply of the lower or upper extremities.[28,29,30] The incidence of PAD depends on the population studied and the method used to establish the diagnosis. In general, symptomatic PAD is a disease of the elderly found more commonly in men aged 70 years and older.[28,29] Although the incidence of PAD increases steadily with age, the disease is more likely to occur in patients of any age with risk factors for atherosclerosis, such as smoking or diabetes. Other risk factors for PAD include hypertension, lipid disorders, family history, postmenopausal state, and hyperhomocysteinemia.[28,29] With the aging of the US population, management of PAD is a major focus not only of prevention and cure but also of maintenance of quality of life and independence (Box 19-7).

Atherosclerosis is the most common cause of PAD. The disease develops in major bifurcations and areas of acute angulations (Fig. 19-4). In people with diabetes, there is greater involvement of the smaller and more distal vessels. Upper extremity involvement is less common than lower extremity involvement.[28]

BOX 19–7 CONSIDERATIONS FOR THE OLDER PATIENT

Peripheral Arterial Disease

- Management of peripheral arterial disease (PAD) in older adults is often more complicated because of the presence of comorbidities, polypharmacy, financial concerns, physical and cognitive limitations, inadequate social support or isolation, and depression and anxiety.
- The incidence of symptomatic PAD increases with age, directly affecting quality of life.
- Conservative management (eg, smoking cessation, walking, foot care) can reduce symptoms and significantly improve quality of life in people of any age.

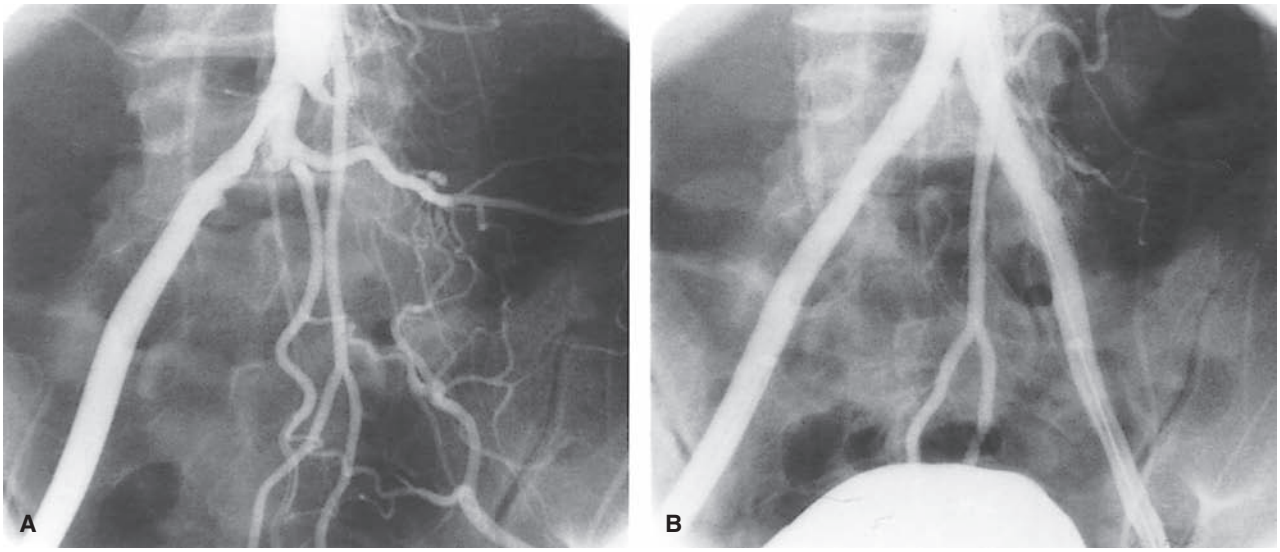

FIGURE 19-4 ▲ **A:** A baseline angiogram demonstrating a total occlusion of the left iliac artery. In addition, there is a significant stenosis of the right common iliac artery and occlusion of the internal iliac arteries. **B:** The final result following angioplasty and stenting of the right and left common iliac arteries with Palmaz stents. (Reprinted from Laird JR, Lansky AJ: Percutaneous transluminal angioplasty for the treatment of peripheral vascular disease. In Apple S, Lindsay J Jr (eds): Principles and Practice of Interventional Cardiology. Philadelphia, PA: Lippincott Williams & Wilkins, 2000, p 196, with permission.)

Thromboangiitis obliterans, or Buerger's disease, is a severe, chronic inflammatory disease affecting the intermediate and small arteries of the extremities. It may also involve adjacent veins and nerves. The etiology is unknown, but it is associated with heavy smoking, especially in young people. The chronic inflammatory process is often followed by thrombosis, with vascular lesions and fibrous obliteration of the vessel.[29] See Evidence-Based Practice Highlight 19-1.

Assessment

Clinical signs of PAD reflect the blood's inability to circulate freely to the extremity. Symptoms depend on the extent of the disease and the presence of collateral circulation. The classic symptom of PAD is intermittent claudication, experienced as a cramping, burning, or aching pain in the legs or buttocks that is relieved with rest.[28–31] Symptoms do not correlate with the extent of the disease. If the PAD is extensive and multilevel, the patient may present with "rest pain," that is, a sensation of burning or numbness in the foot or toes. Patients also experience trophic changes, such as hair loss on the extremities, thickening of the nails, and drying of the skin. Acute arterial obstruction, such as occurs with an embolism, results in the sudden onset of extreme pain and other signs of acute arterial obstruction (Box 19-8).[28–30]

Practice guidelines should be incorporated in the evaluation of the patient at risk for PAD.[28] This includes a careful vascular examination of the extremities and assessment of all peripheral pulses, including the measurement of segmental pressures in the legs and the ankle/brachial index (ABI). The ABI is the ratio of ankle to brachial systolic blood pressure. A normal ABI should be 1.0 or greater. Patients with critical limb ischemia may have an ABI of less than 0.518 (Fig. 19-5).[28,29]

EVIDENCE-BASED PRACTICE HIGHLIGHT 19-1

Heart Failure in Adults With Peripheral Arterial Disease

△ Risk Factors for Heart Failure in the Adult

- Atherosclerotic coronary artery disease and or myocardial infarction or ischemia
- Presence of pressure overload including hypertension or obstructive valvular disease
- Genetic or familial disorders, infiltrative disorders
- Advanced age
- Toxins (ie, alcohol)

△ Initial Evaluation of Patients

- Evaluation of exercise tolerance including walking
- Comprehensive physical evaluation including lungs, heart, and vascular systems
- Personal and family history including family history of heart failure or sudden death. History of drug or alcohol use

Excerpted from Jessup M, Abraham WT, Casey DE, et al: ACCF/AHA Guidelines for the Diagnosis and Heart and Lung Transplantation Guidelines Developed in Collaboration With the International Society for Cardiology Foundation/American Heart Association Task Force on Practice Management of Heart Failure in Adults: A Report of the American College of Foundation/American Heart Association Task Force on Practice Guidelines Developed in Collaboration With the International Society for Heart and Lung Transplantation. J Am Coll Cardiol 53:1343–1382, 2009.

BOX 19-8 Clinical Features of Vascular Obstruction

Acute Arterial Occlusion
- Pain
- Pulselessness
- Pallor
- Paresthesia
- Paralysis

Deep Venous Thrombosis
- Pain in calf with dorsiflexion of foot (Homans' sign)
- Pain when standing
- Inflammation
- Swelling
- Tenderness
- Redness, soreness

Treadmill exercise testing can provide an objective measurement of the patient's walking ability as well as an evaluation of possible coronary artery disease. Noninvasive imaging, such as magnetic resonance or computed tomography (CT), may be required to evaluate the extent of disease fully. Angiography is usually limited to revascularization procedures (see Fig. 19-4) or presurgical evaluation.[28,29]

Management

PAD is associated with an increased risk for atherosclerotic adverse events; the mortality rate is high in symptomatic patients.[29,30] Therefore, treatment goals include modifying or eliminating risk factors (especially smoking), improving leg symptoms, and maintaining limb viability. Risk factor modification incorporates national guidelines; these include immediate smoking cessation as well as aggressive treatment of hypertension, diabetes, and lipid disorders, with medication, if necessary. Other pharmacological agents include antiplatelets (aspirin or clopidogrel [Plavix]) to reduce the risk for MI and stroke and cilostazol (Pletal) to increase walking distance. In patients with claudication, exercise improves overall walking ability. Peripheral interventional procedures, such as balloon angioplasty, are successful in restoring circulation in many cases. Surgical bypass may be required when severe or diffuse arterial obstruction is present.[28–30]

Venous Disease

Phlebitis is inflammation of the vessel wall occurring as the result of direct injury to the vein or as a complication of varicose veins. It can lead to the formation of a thrombus, a solid

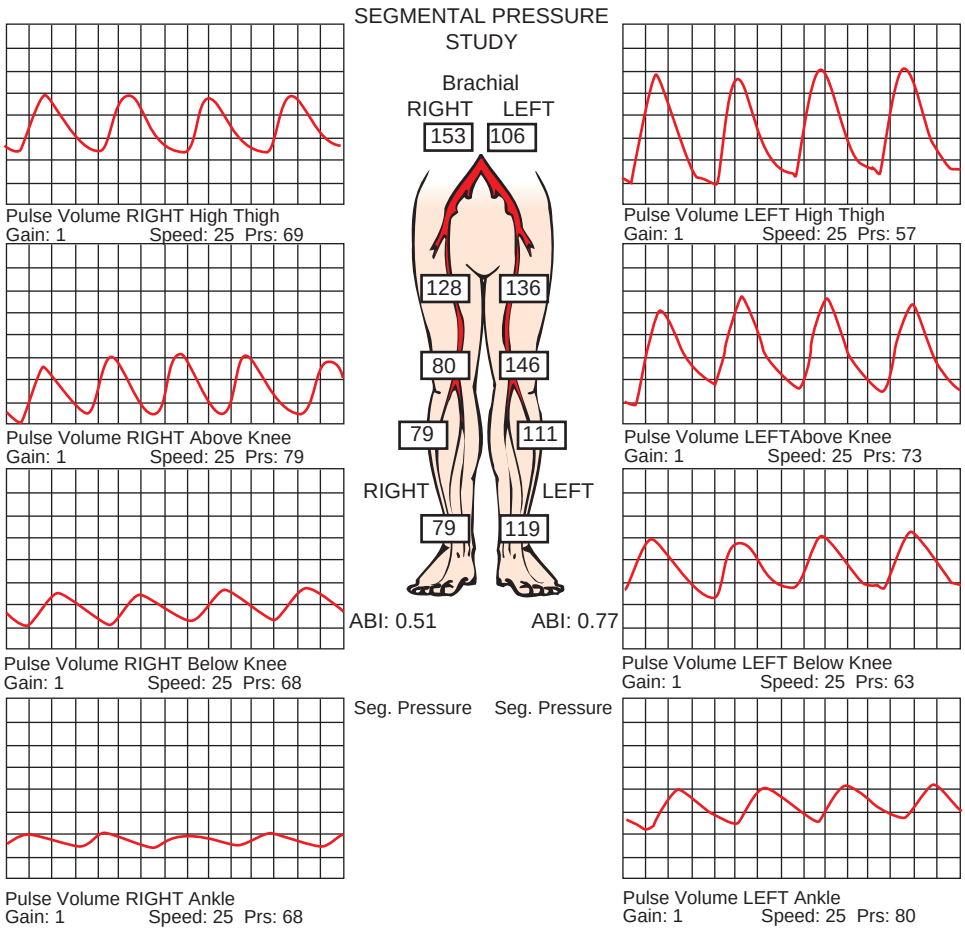

FIGURE 19-5 ▲ Segmental pressures and ankle/brachial indices indicating bilateral lower extremity occlusive disease with more severe involvement of the right lower extremity. There is also a probable significant stenosis of the left subclavian artery, which explains the difference between the right and left brachial pressures. Prs, pressures. (Reprinted from Saucedo JF, Laird JR: Peripheral vascular disease. In Apple S, Lindsay J Jr [eds]: Principles and Practice of Interventional Cardiology. Philadelphia, PA: Lippincott Williams & Wilkins, 2000, p 47, with permission.)

obstruction within the vein that can break loose and form a venous thromboembolism (VTE).[32,33] Factors that predispose a patient to thrombus formation are vessel wall injury, stasis of blood, and increased blood coagulability (Virchow's triad).[32,34] These three conditions have been recognized as causative factors in the development of thrombophlebitis since 1846.

An estimated 100,000 to 300,000 cases of VTE occur in the United States each year.[32,34] This incidence increases with aging.[34,35] More than half of the cases of VTE involve deep vein thrombosis (DVT),[34] and others include pulmonary embolism. Because VTE is associated with significant morbidity and mortality, it is important for the nurse to be familiar with risk factors for VTE as well as current recommendations for treatment. (See Chapter 26 for more information concerning pulmonary embolism.[33,36])

Assessment

DVT is characterized by pain, swelling, tenderness, and increased temperature over the affected area (see Box 19-8). The patient also exhibits a positive Homans' sign (pain in the calf with passive dorsiflexion of the foot).[32] However, these clinical findings are not specific for DVT. Accurate diagnosis usually requires diagnostic testing such as compression ultrasonography.[34]

Management

The focus of care for the patient with VTE is to relieve symptoms, increase blood flow, and prevent complications. Patients with DVT are at high risk for pulmonary embolism. Treatment strategies include anticoagulant therapy to prevent the formation of emboli, followed by long-term warfarin (Coumadin) use to prevent recurrence. Specific therapy depends on the patient's history and clinical setting.[33] Bleeding is the most common complication of therapy. Patient teaching includes safe administration of home anticoagulants as well as behaviors to decrease the recurrence of DVT.[32] Prevention of VTE is discussed in Evidence-Based Practice Highlight 19-2.

▲ Aortic Disease

The aorta is the longest and strongest artery in the body.[37] However, over time, congenital, degenerative, hemodynamic, and mechanical factors stress this elastic vessel. The result is dilation of the aortic wall, leaving the patient at risk for aortic dissection or rupture.[38]

Aortic Aneurysm

Aortic aneurysms are defined as a localized dilation of the aorta to a size greater than 1.5 times its normal diameter.[37] Aneurysms are classified according to their shape, morphology, and location (Fig. 19-6). Fusiform aneurysms, the more common type, are diffuse dilations of the entire circumference of the artery. Saccular aneurysms are localized balloon-shaped outpouchings. Aneurysms may be thoracic or abdominal; rarely, they are both.

True aneurysms involve the entire vessel wall and are classified as fusiform or saccular. False aneurysms are not actually aneurysms but are formed when blood leaks through the wall of the aorta and is contained by the surrounding tissues (a contained rupture).[37]

Abdominal Aortic Aneurysm

Abdominal aortic aneurysms (AAAs), which are more common than thoracic aortic aneurysms, occur more frequently in men. Smoking is the leading risk factor for AAAs, followed closely by age, hypertension, lipid disorders, and atherosclerosis.[37] Atherosclerosis is probably a major cause of AAAs, but other factors, such as genetic and environmental influences, almost certainly contribute to their development.[39] The major risk from AAAs is rupture, which is associated with a high rate of mortality.

ASSESSMENT. Most patients with AAAs are asymptomatic; they are typically identified during health screening for another problem. Abdominal or back pain is the most common complaint. Worsening of symptoms is usually related to expansion or rupture of the aneurysm.

Detection of AAAs by physical examination is difficult, especially in obese patients. The abdomen is examined for the presence of bruits or masses, and peripheral pulses are carefully evaluated. Abdominal ultrasonography is the most practical method of confirming the diagnosis.[37–39]

MANAGEMENT. Management of AAAs includes control of hypertension and elimination of risk factors, such as smoking. The patient should be followed with serial noninvasive tests, such as ultrasonography. Treatment of aneurysms involves surgical repair, which is usually indicated for AAAs larger than 5.5 cm (Box 19-9).[40]

In addition to surgery, AAAs may be repaired by a minimally invasive approach using an endovascular graft. This approach involves placement of a graft through the femoral artery. The graft is then anchored to the wall of the aorta by means of self-expanding or balloon-expanded stents. Endovascular repair has become the treatment of choice for high-risk patients with AAAs.[41]

Thoracic Aortic Aneurysm

Thoracic aortic aneurysms occur relatively infrequently and are classified by the involved segment of the aorta (root, ascending, arch, or descending). The location is important because the etiology, natural history, and treatment differ for each segment.[37,39] Most ascending thoracic aortic aneurysms are due to cystic medial degeneration. Ascending thoracic aortic aneurysms are also associated with connective tissue disorders, genetic disorders, bicuspid aortic valve, infections, inflammatory diseases, chronic aortic dissection, and trauma.[37–39]

ASSESSMENT. Like most patients with AAAs, most patients with thoracic aortic aneurysms are asymptomatic at the time of diagnosis. Symptoms are related to the size and location of the aneurysm; these include aortic insufficiency and signs of pericardial tamponade if the aneurysm involves the aortic root.[37] Rupture or acute dissection of a thoracic aneurysm can be fatal. Fewer than half of patients with rupture survive until they are hospitalized, and by 24 hours, mortality is almost 80%.[37]

MANAGEMENT. For most ascending thoracic aortic aneurysms, surgical repair is indicated at a diameter of

EVIDENCE-BASED PRACTICE HIGHLIGHT 19-2
Venous Thromboembolism Prevention

Expected Practice

- Assess all patients upon admission to the ICU for risk factors of venous thromboembolism (VTE) and anticipate orders for VTE prophylaxis based on risk assessment. [Level D]
- Clinical eligibility and regimens for VTE prophylaxis include:
  - Moderate-risk patients (medically ill and postoperative patients): low dose unfractionated heparin, low-molecular-weight heparin (LMWH), or fondaparinux [Level B]
  - High-risk patients (major trauma, spinal cord injury, or orthopedic surgery): LMWH, fondaparinux, or oral vitamin K antagonist [Level B]
  - Patients with high risk for bleeding: mechanical prophylaxis including graduated compression stockings and/or intermittent pneumatic compression devices [Level B]
  - Mechanical prophylaxis may also be anticipated in conjunction with anticoagulant-based prophylaxis regimens.
- Review daily—with the physician and during multidisciplinary rounds—each patient's current VTE risk factors including clinical status, necessity for central venous catheter (CVC), current status of VTE prophylaxis, risk for bleeding, and response to treatment. [Level E]
- Maximize patient mobility whenever possible and take measures to reduce the amount of time the patient is immobile because of the effects of treatment (eg, pain, sedation, neuromuscular blockade, mechanical ventilation). [Level E]
- Ensure that mechanical prophylaxis devices are fitted properly and in use at all times except when being removed for cleaning and/or inspection of skin. [Level E]

Supporting Evidence

- Multiple medical and surgical risk factors leading to VTE formation have been identified.[1] Iatrogenic risk factors for VTE include immobilization, sedation/neuromuscular blockade, CVCs, surgery, sepsis, mechanical ventilation, vasopressor administration, heart failure, stroke, malignancy, previous VTE, and renal dialysis; a vast majority of patients in critical care units have 1 or more major risk factors.[1–4] In five prospective studies, the rate of VTE in patients in critical care not receiving prophylaxis ranged from 13% to 31%.[5–8] Because signs and symptoms of VTE are frequently silent and can lead to fatal pulmonary embolism, multiple professional organizations recommend VTE prophylaxis for at-risk patients.
- Randomized trials indicate that both low dose unfractionated heparin and LMWH are efficacious in preventing VTE in moderate-risk critical care patients.[5–8,19] For patients at higher risk, such as those who have major trauma or have had orthopedic surgery, LMWH has been shown to provide superior protection over low dose unfractionated heparin.[1] Direct thrombin inhibitors can be used in place of LMWH or unfractionated heparin for patients with documented of suspected heparin-induced thrombocytopenia.[1,21–22] Numerous studies suggest that aspirin alone is not an efficacious means of VTE prophylaxis for any patient group.[23–27]
- Although examined less rigorously than anticoagulant-based methods, mechanical methods of prophylaxis (including graduated compression stockings, intermittent compression devices, and venous foot pumps) have been shown to reduce the risk of VTE.[28–38] One study involving non–lower extremity trauma patients compared the efficacy of intermittent pneumatic compression devices and venous foot pumps. VTE rates among the venous foot pump group were three times greater when compared with the rates of the intermittent pneumatic compression group. The researchers concluded that intermittent pneumatic compression devices provided superior prophylaxis in this patient population.[36]
- In general, mechanical prophylaxis is less efficacious when compared to anticoagulation-based therapy.[33–35,37–39] Reduction in risk of death or pulmonary embolism has not been attributed to mechanical methods of prophylaxis.[1] In one study involving below-the-knee graded stockings, 98% of commercially available stockings failed to produce an ideal pressure gradient and 54% were found to produce a dangerous reverse pressure gradient.[40] Mechanical prophylaxis methods are a desirable option because they do not pose bleeding concerns.[1] A combination of mechanical prophylaxis and chemoprophylaxis is thought to potentiate overall efficacy but this combination has not been tested in the critical care setting.[41]
- Written policies for VTE prophylaxis in conjunction with either preprinted or computerized ICU admission orders have been shown to increase compliance with prophylaxis measures.[42] One study found that implementation of a daily goals form, which included VTE prophylaxis in the ICU, resulted in a significant improvement in the percentage of residents and nurses who understood the patient's daily goals for care and decreased ICU length of stay by 1.1 days.[19,43,44]
- The presence of a CVC is an independent risk factor for upper extremity VTE in the general population.[45]
- Several studies involving a variety of patient populations with diagnostically confirmed VTE have identified immobility either as a comorbidity or independent risk factor.[46–48]
- Improperly fitted graduated compression stocking producing a reversed pressure gradient were associated with a statistically higher incidence of VTE compared with stockings that produced a proper gradient.[35] Studies evaluating compliance with intermittent pneumatic compression devices demonstrated rates of noncompliance ranging from 22% to 81% in at-risk patients.

AACN Evidence Leveling System

Level A Meta-analysis of quantitative studies or metasynthesis of qualitative studies with results that consistently support a specific action, intervention, or treatment.
Level B Well-designed, controlled studies with results that consistently support a specific action, intervention, or treatment.
Level C Qualitative studies, descriptive or correlational studies, integrative review, systematic reviews, or randomized controlled trials with inconsistent results.
Level D Peer-reviewed professional organizational standards with clinical studies to support recommendations.
Level E Multiple case reports, theory-based evidence from expert opinions, or peer-reviewed professional organizational standards without clinical studies to support recommendations.
Level M Manufacturer's recommendations only.

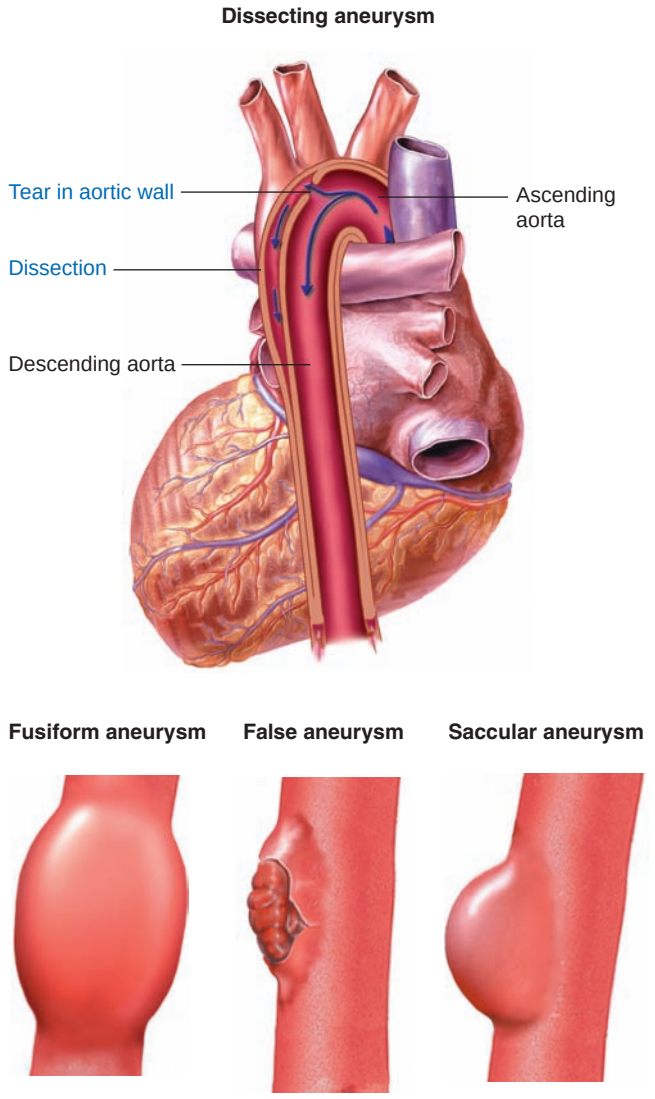

FIGURE 19-6 ▲ Types of aortic aneurysms. (Anatomical Chart Company: Atlas of Pathophysiology. Springhouse, PA: Springhouse, 2010, p 39.)

5.5 cm or more.[39] These indications vary according to the clinical situation and the existence of comorbidities. Repair of descending thoracic aneurysms is recommended when the diameter is 6 cm or more.[39]

Aortic Dissection

Acute aortic dissection is the most common and the most lethal process involving the aorta. Mortality rates are very high, approaching 1% per hour for this catastrophic event.[37] Death usually occurs from rupture of the aorta. The incidence is highest in men older than age 60 with a history of hypertension. Other risk factors include cystic medial degeneration, pregnancy, and trauma.[37,38]

Pathophysiology

Dissection involves a longitudinal separation of the medial layers of the aorta by a column of blood. The dissection begins at a tear in the aortic wall, usually at the proximal end of the dissection. Blood pumped through this tear creates a false channel, or lumen, that rapidly becomes larger than the true aortic lumen. Dissections are typically classified according to location, as illustrated in Figure 19-7.

BOX 19-9 General Indications for Surgical Repair of Aortic Aneurysms

Abdominal
- Diameter 5.5 cm of more (men)
- For women, 4.5 to 5.0 cm (due to greater incidence of rupture)
- Diameter 4.5 to 5.5 cm; clinical setting, patient preference

Ascending Thoracic
- Diameter 5.5 cm or more (5 cm in patients with Marfan's syndrome)
- Symptoms suggesting expansion or compression of surrounding structures

Other
- Rapidly expanding aneurysms (growth rate more than 0.5 cm over a 6-month period)
- Symptomatic aneurysm regardless of size

Assessment

More than 90% of patients present with sudden, intense chest pain. Frequently, the pain is described as "ripping" or "tearing" and may be accompanied by syncope (see Table 19-1). In most patients, the diagnosis can be determined with a careful history and physical examination. The clinician should

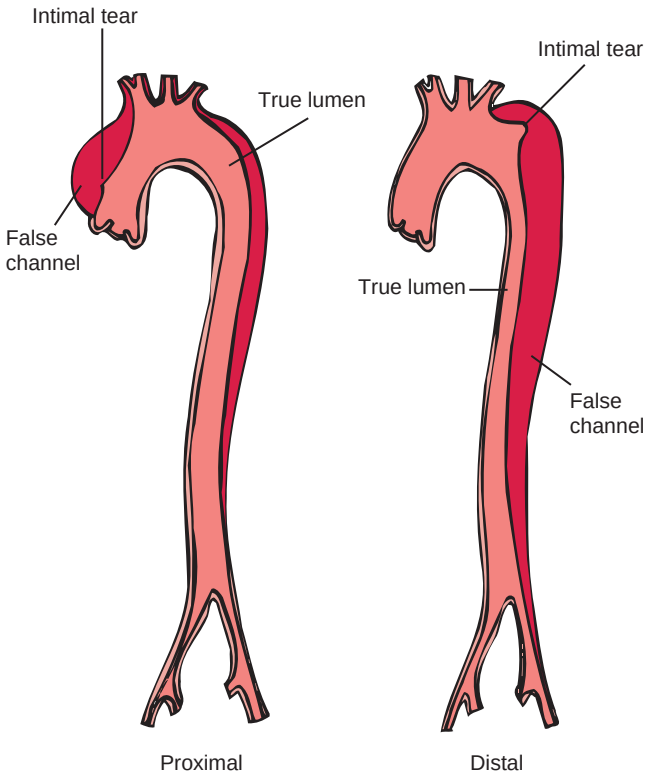

FIGURE 19-7 ▲ Two major patterns of aortic dissection. Blood pumps through a tear in the wall, creating a false channel or lumen. The false channel rapidly becomes larger than the true lumen.

look for the murmur of aortic regurgitation or alteration of the peripheral pulses in patients with known risk factors, such as hypertension. The chest radiograph may show a widened mediastinum. Cardiac ischemia may be present if the dissection involves the coronary arteries. Cardiac tamponade may be another complication of dissection involving the aortic root. Neurological deficits may occur if the aortic arch vessels are involved. Dissections involving the renal arteries result in elevated serum creatinine, decreased urine output, and severe hypertension that is difficult to manage. To confirm the diagnosis of acute aortic dissection, transesophageal echocardiography or contrast medium–enhanced CT may be ordered.[37–39]

Management

Survival of the acute phase depends on the location of the dissection, the severity of the complications, and the rapidity with which the diagnosis is confirmed. Clinical management focuses on controlling blood pressure and managing pain. Surgery is the treatment of choice when the dissection involves the ascending aorta.[37,38]

▲ Hypertensive Crisis

Hypertension affects approximately 50 million people in the United States and is a major controllable risk factor for the development of cardiovascular diseases.[42,43] Recognition of the extent of this risk led to the inclusion of a new category in the classification of hypertension, prehypertension, which includes individuals with a systolic blood pressure of 120 to 139 mm Hg or a diastolic blood pressure of 80 to 89 mm Hg (Table 19-3). People with prehypertension should be counseled to adopt healthy lifestyle modifications to reduce their risk for cardiovascular disease.

Patients with high blood pressure are at risk for experiencing a hypertensive crisis. A hypertensive crisis or emergency is defined as an acute elevation of blood pressure (>180/120 mm Hg) that is associated with acute or imminent target organ damage.[42] This rare but potentially fatal condition strikes about 1% to 2% of hypertensive patients, occurring more frequently in African American men and in elderly patients.

Pathophysiology

A hypertensive crisis is characterized by a marked rapid increase in blood pressure that initially leads to intense vasoconstriction as the body attempts to protect itself from the elevated pressure. If the blood pressure remains critically high, compensatory vasoconstriction fails, resulting in increased pressure and blood flow throughout the vascular system. In the cerebral circulation, this may quickly lead to hypertensive encephalopathy.[42,43] Hypertensive crisis is associated with a variety of clinical situations (Box 19-10).

Table 19-3 Classification of Blood Pressure for Adults

Blood Pressure Classification	Systolic (mm Hg)	Diastolic (mm Hg)
Normal	<120	and <80
Prehypertension	120–139	or 80–89
Stage 1 hypertension	140–159	or 90–99
Stage 2 hypertension	≥160	or ≥100

BOX 19-10 Summary of Hypertensive Crisis

Causes
- Acute or chronic renal disease
- Exacerbation of chronic hypertension
- Sudden withdrawal of antihypertensive medications

Associated Clinical Situations
- Acute cerebrovascular syndrome
  - Acute stroke
  - Hypertensive encephalopathy
  - Acute cardiovascular syndromes
  - Myocardial infarction
  - Unstable angina
  - Pulmonary edema
- Aortic dissection
- Extensive burns
- Postoperative period
- Pheochromocytoma
- Eclampsia

Management
- Intravenous medications with continuous arterial pressure monitoring
- Goal is to reduce mean arterial blood pressure over 1 hour by no more than 25% while avoiding hypoperfusion

Assessment

Most patients who present with hypertensive crisis are critically ill and in need of immediate treatment. Clinical findings depend on the degree of vascular injury.[43] Signs of encephalopathy include headache, visual disturbances, confusion, nausea, and vomiting. Examination of the eyes may reveal cotton–wool exudates and hemorrhages, indicating damage to retinal nerves and rupture of retinal blood vessels; papilledema is diagnostic of increased intracranial pressure. Chest pain may represent acute coronary syndrome or aortic dissection. Depending on the damage to the kidneys, the patient may present with decreased urine output (oliguria) or azotemia (excess urea in the blood).[43,44]

Management

The goal is to reduce the mean blood pressure within 1 hour of starting treatment and to prevent or reverse target organ damage.[42,45,46] Several intravenous medications are indicated in treating hypertensive crises; the choice depends on availability and the clinical situation (Table 19-4). Constant monitoring is necessary to avoid lowering the blood pressure too quickly. This is best accomplished with an intra-arterial catheter.

Once the blood pressure has been stabilized, treatment goals depend on the etiology of the crisis. All patients require careful long-term management to control their blood pressure and prevent future episodes.

Table 19-4 Intravenous Medications in Hypertensive Emergencies*

Drug	Class	Onset of Action	Adverse Effects
Sodium nitroprusside	Vasodilator	Immediate	Hypotension, nausea, vomiting, muscle twitching, thiocyanate and cyanide toxicity, methemoglobinemia
Nitroglycerin	Vasodilator	1–2 min	Hypotension, reflex tachycardia, headache, tolerance with prolonged use
Labetalol	Adrenergic blocker	<5 min	Nausea, vomiting, bronchospasm, heart block
Fenoldopam	Vasodilator	<5 min	Reflex tachycardia, headache, nausea
Esmolol	Adrenergic blocker	Immediate	Hypotension, heart block
Nicardipine	Calcium channel blocker	5–6 min	Reflex tachycardia, headache, nausea, vomiting, flushing
Enalaprilat	Angiotensin-converting enzyme inhibitor	10–15 min	Hypotension, renal failure
Hydralazine	Vasodilator	15–30 min	Reflex tachycardia, headache, exacerbation of angina pectoris

*Choice of drug depends on the etiology of the hypertensive emergency and the clinical setting.

Adapted from Mansoor GA, Frishman WH: Comprehensive management of hypertensive emergencies and urgencies. Heart Dis 4:358, 2002; and Tuncel M, Ram VCS: Hypertensive emergencies: Etiology and management. Am J Cardiovasc Drugs 3(1):21–31, 2003.

▲ Clinical Applicability Challenges

CASE STUDY

Mr. S. is a 21-year-old Caucasian man who is being evaluated in the emergency room with a 2-day history of chest pain. The patient describes the chest pain as a sharp burning pain in the center of his chest that gets worse with deep inspiration and better when he changes position. He reports a history of a recent upper respiratory viral infection. He is physically active, does not smoke, and has no family history of premature heart disease. An ECG performed in the emergency room shows diffuse ST-segment elevations and PR-segment depression.

Physical examination reveals a normal S1 and S2 and no murmurs or gallops. There is a friction rub that is heard most prominently at the apex and varies with the cardiac cycle. Prior laboratory values obtained during the emergency room visit revealed potassium, 4.2 mEq/L; blood urea nitrogen, 20 mg/dL; creatinine, 1.0 mg/dL; brain natriuretic peptide, 50 pg/mL; troponin I, 0.10 ng/mL × 1 cycle; white blood cells, 9.0×10^3 mL; hemoglobin, 13.0 g/dL; and hematocrit, 43.3%. A C-reactive protein level was 10 mg/L. Results of a posteroanterior and lateral chest x-ray were unremarkable.

Mr. S. is admitted to your telemetry floor with a diagnosis of acute pericarditis for monitoring and cycling of his cardiac enzyme levels. Prior to your shift, an echocardiogram reveals an ejection fraction of 65% (normal 50% to 70%), normal valve structure and function, and normal myocardial wall motion. He was taking no medication prior to his admission. He received 30 mg of ketorolac (Toradol) IV while in the emergency room and was started on ibuprofen 800 mg by mouth every 8 hours.

During morning report, you learn that Mr. S. is very concerned about the diagnosis of pericarditis. He has questions regarding the long-term prognosis and the length of time he may be required to take medication and its impact on his ability to play sports. He does not care for the hospital food and wants to know when he can go home.

1. What are the priority medical problems for Mr. S.?
2. What are the priority nursing actions for Mr. S.?
3. What are some potential long-term problems facing Mr. S.?

20 Heart Failure

Kay Blum

LEARNING OBJECTIVES

Based on the content in this chapter, the reader should be able to:

1. Define heart failure.
2. Describe the classification systems used to define heart failure.
3. Explain the physiological basis for the clinical manifestations of heart failure.
4. Describe expected clinical assessment findings for patients with heart failure.
5. Explain the standard pharmacological therapies for chronic heart failure and acute exacerbation of chronic heart failure, and their rationale.
6. Describe the nonpharmacological therapies for management of heart failure.
7. Define expected outcomes for therapeutic management of patients with heart failure.
8. Formulate a teaching plan for patients and families regarding heart failure.

Approximately 5.8 million Americans live with heart failure. About 550,000 new people receive the diagnosis of heart failure each year. The incidence of heart failure approaches 10 per 1,000 population after age 65 years, and 75% of patients have antecedent hypertension. Incidence and prevalence statistics indicate that heart failure is a common occurrence in certain patient populations, most notably elderly patients and patients with a history of hypertension, myocardial infarction (MI), or both. Although other cardiovascular mortality and morbidity statistics have decreased, the incidence of new-onset heart failure has continued to increase.[1,2] An estimated 1,106,000 patients were discharged with heart failure in 2006.

Heart failure is a common diagnosis in the intensive care unit (ICU) because the onset is sudden. An acute MI or an acute exacerbation of chronic heart failure is often life threatening. Sudden cardiac death occurs six to nine times as often in patients with heart failure as it does in the general population. Overall, the 5-year mortality rate for heart failure is 59% for men and 45% for women. Hospitalization is associated with high financial costs; for 2010, the direct and indirect costs were estimated to be $39.2 billion.[1,3] In addition, the physical and emotional burdens of inpatient care are great both for patients and their families.

Management of patients with heart failure requires a collaborative effort on the part of physicians, nurses, pharmacologists, dietitians, and other allied health professionals. The care of patients with heart failure extends across all parts of the health care system. Patients with heart failure may be located in home care, ambulatory care, acute care, critical care, and rehabilitation facilities. As patients take charge of their own disease management, the home serves as a critical location. As emphasis on self-care increases, more and more disease management programs are partnering with patients at home to prevent hospitalization.

▲ Definition

Heart failure is a clinical syndrome characterized by shortness of breath, dyspnea on exertion (DOE), paroxysmal nocturnal dyspnea (PND), orthopnea, and peripheral or pulmonary edema. Not all patients have all these clinical indicators. Heart failure is a general term used to describe the general clinical syndrome regardless of the kind of heart failure or the etiology that produces the symptoms. Congestive heart failure is so named because the interruption in circulation related to failure of the heart to function normally leads to congestion in the vascular beds of the lungs and peripheral tissues, resulting in respiratory symptoms and peripheral edema. The revised guidelines recently published by a joint American College of Cardiology (ACC) and American Heart Association (AHA) task force use the preferred term *heart failure* rather than congestive heart failure because patients with chronic heart failure rarely demonstrate the rales and alveolar edema associated with congestion.[2] For this reason, it

is important to look at the way heart failure is classified because the pathophysiology and etiology are keys to appropriate management.

▲ Classification

Heart failure is more difficult to understand when signs and symptoms are common to more than one type of failure and when types of heart failure are used interchangeably. Several categories are used to describe and classify heart failure. Using these categories to organize information about heart failure and for discussion of any individual patient case makes diagnosis, management, and outcome evaluation clearer.

Acute Versus Chronic

The terms *acute* and *chronic* describe both the onset of symptoms of heart failure and the intensity of symptoms. Heart failure of acute onset refers to the sudden appearance of symptoms, usually over days or hours. Acute symptoms have progressed to a point at which immediate or emergency intervention is necessary to save the patient's life. Heart failure of chronic onset refers to the development of symptoms over months to years. Chronic symptoms represent the baseline condition, the limitations the patient lives with on a daily basis. If the cause of the acute onset or the acute symptoms is not reversible, then the heart failure may become chronic. For example, a patient who has an acute MI with severe damage to the left ventricle has acute heart failure with pulmonary edema, causing lasting damage to the left ventricle. As a result, the patient has poor contractility (and therefore DOE) after the MI has resolved. The patient's acute onset of heart failure has left him or her with chronic symptoms. Chronic heart failure does not disappear when the symptoms are controlled or absent. People with heart failure demonstrate various levels of compensation, meaning that they have enough reserve to "compensate" for the loss of function and they appear to be asymptomatic, usually at rest. The lack of symptoms, or compensation, should not be mistaken for absence of disease. Like most chronic conditions, heart failure is characterized by relatively stable periods interrupted by episodes of acute decompensation. Acute decompensation is often life threatening and frequently requires critical care. A common cause of acute decompensation is inadequate treatment for chronic heart failure. The following discussion will focus on evidence-based care for chronic heart failure and then diagnosis and management of acute decompensated heart failure (ADHF).

Left-Sided Heart Failure Versus Right-Sided Heart Failure

Left-Sided Heart Failure

Left-sided heart failure refers to failure of the left ventricle to fill or empty properly. This leads to increased pressures inside the ventricle and congestion in the pulmonary vascular system. Left-sided heart failure may be further classified into systolic and diastolic dysfunction.

SYSTOLIC DYSFUNCTION (HEART FAILURE WITH REDUCED LEFT VENTRICULAR FUNCTION). Systolic dysfunction is defined as an ejection fraction of less than 40% and is caused by a decrease in contractility. Left ventricular function is estimated by ejection fraction, or the percentage of the left ventricular end-diastolic volume (LVEDV) that is ejected from the ventricle in one cycle. If the LVEDV is 100 mL and the stroke volume is 60 mL, the ejection fraction is 60%. Normal ejection fraction is 50% to 70%. The ventricle does not empty adequately because of poor pumping, and the result is decreased cardiac output.

DIASTOLIC DYSFUNCTION (HEART FAILURE WITH PRESERVED LEFT VENTRICULAR FUNCTION). Diastolic dysfunction is less well defined and more difficult to measure. Diastolic dysfunction is caused by impaired relaxation and filling. Left ventricular filling, a complex process that occurs during diastole, is a combination of passive filling and atrial contraction. Pumping is normal or even increased, with an ejection fraction as high as 80% at times. If the ventricle is stiff and poorly compliant (due to aging, uncontrolled hypertension, or volume overload), relaxation is slow or incomplete. If the heart rate is fast, diastole is short, or if the patient has atrial fibrillation, there is no organized atrial contraction. These mechanisms all reduce filling of the ventricle and contribute to diastolic dysfunction, thereby decreasing cardiac output.

Right-Sided Heart Failure

Right-sided heart failure refers to failure of the right ventricle to pump adequately. The most common cause of right-sided heart failure is left-sided heart failure, but right-sided heart failure can exist in the presence of a perfectly normal left ventricle and does not lead to left-sided heart failure. Right-sided heart failure can also result from pulmonary disease and primary pulmonary artery hypertension (cor pulmonale). Pulmonary embolus is a common cause of acute right-sided heart failure.

Classification Systems

New York Heart Association Functional Classification

The New York Heart Association (NYHA) Functional Classification is a measure of how much the symptoms of heart failure limit the activities of patients (Box 20-1). Although ejection fraction is used to define left ventricular

BOX 20-1 New York Heart Association (NYHA) Functional Classification of Heart Failure

Class I: No limitation of physical activity. Ordinary physical activity does not cause undue fatigue or dyspnea.
Class II: Slight limitation of physical activity. Comfortable at rest, but ordinary physical activity results in fatigue or dyspnea.
Class III: Marked limitation of physical activity without symptoms. Symptoms are present even at rest. If any physical activity is undertaken, symptoms are increased.
Class IV: Unable to carry on any physical activity without symptoms. Symptoms are present even at rest. If any physical activity is undertaken, symptoms are increased.

BOX 20-2 American College of Cardiology (ACC)/American Heart Association (AHA) Guidelines for Stages of Heart Failure*

A Patients at high risk for heart failure because of the presence of conditions that are strongly associated with the development of heart failure. Such patients have no identified structural or functional abnormalities of the pericardium, myocardium, or cardiac valves and have never shown signs or symptoms of heart failure.
B Patients who have structural heart disease that is strongly associated with the development of heart failure but who have never shown signs or symptoms of heart failure.
C Patients who have current or prior symptoms of heart failure associated with underlying structural heart disease.
D Patients with advanced structural heart disease and marked symptoms of heart failure at rest despite maximal medical therapy and who require specialized interventions.

*New York Heart Association classification is applicable only to stages C and D.

function, ejection fraction is poorly correlated with the patient's functional capacity or prognosis.[4]

American College of Cardiology/American Heart Association Guidelines

The ACC/AHA Guidelines outline four stages of heart failure that are useful for organizing the prevention, diagnosis, management, and prognosis for patients with heart failure[2] (Box 20-2). These stages are not meant to replace the NYHA functional classification but rather to augment it. Only stages C and D are applicable to the NYHA functional classification system. See also Evidence-Based Practice Highlight 20-1.

▲ Factors That Determine Cardiac Output

The underlying result of all types of heart failure is insufficient cardiac output. That is, the volume of blood pumped by the heart in 1 minute is inadequate. Some patients may have a normal cardiac output at rest, but they do not have the reserve function to increase cardiac output to meet the increased demands of exercise, hypoxemia, or anemia. Therefore, it is important to understand the physiological basis of cardiac output and review the mechanisms of compensation of decreased cardiac output. (See Chapter 16 for a review of cardiovascular physiology.)

Oxygen Demand

The required cardiac output is determined by the body's metabolic demand for oxygen. At rest, the body needs sufficient oxygen to burn calories to support cellular function, as measured by basal metabolic rate. Oxygen delivery to the tissues depends on arterial oxygen content (CaO_2) and cardiac output. CaO_2, a combination of arterial oxygen saturation (SaO_2) and hemoglobin (Hgb), is constant in healthy people. Any factor that increases metabolic demand for oxygen, such as exercise, fever, hyperthyroidism, or trauma, increases cardiac output. If CaO_2 is decreased, as it is in hypoxemia or anemia, then cardiac output increases to ensure sufficient oxygen to meet the metabolic demand. Exercise or fever in a patient with anemia puts a tremendous burden on the heart to supply sufficient oxygen to meet the metabolic demands.

A person with a healthy heart has sufficient reserve to meet this increased metabolic demand and increase cardiac output. At best, a patient with myocardial ischemia, cardiomyopathy, valvular disease, dysrhythmia, or lung disease

EVIDENCE-BASED PRACTICE HIGHLIGHT 20-1

Management of Heart Failure

It is recommended that heart failure disease management programs include the following components, based on patient characteristics and needs (strength of evidence = B):
- Comprehensive education and counseling individualized to patient needs
- Promotion of self-care, including self-adjustment of diuretic therapy in appropriate patients (or with family member or care giver assistance)
- Emphasis on behavioral strategies to increase adherence
- Vigilant follow-up after hospital discharge or after periods of instability
- Optimization of medical therapy
- Increased access to providers
- Early attention to signs and symptoms of fluid overload
- Assistance with social and financial concerns

It is recommended that heart failure disease management include integration and coordination of care between the physician and heart failure care specialists and with other agencies, such as home health and cardiac rehabilitation (strength of evidence = C).

It is recommended that patients in a heart failure disease management program be followed until they or a family member or care giver demonstrates independence in following the prescribed treatment plan, adequate or improved adherence to treatment guidelines, improved functional capacity, and symptom stability. Higher-risk patients with more advanced heart failure may need to be followed permanently. Patients who experience increasing episodes of exacerbation or who demonstrate instability after discharge from a program should be referred again to the service (strength of evidence = B).

Note: Rating scheme for the strength of the evidence: A, randomized, controlled, clinical trials (may be assigned based on results of a single trial); B, cohort and case-control studies (post hoc, subgroup analysis, and meta-analysis; prospective observational studies or registries); C, expert opinion (observational studies—epidemiological findings; safety reporting from large-scale use in practice).

may not be able to meet the metabolic demand for oxygen associated with exercise. At worst, the patient with one or more of these problems may not be able to meet the basal metabolic demand for oxygen and becomes symptomatic, even at rest.

Mechanical Factors and Heart Rate

Cardiac output equals stroke volume multiplied by heart rate.

This relationship between stroke volume, heart rate, and cardiac output is critical to understanding why heart failure may be present long before it produces the symptoms that cause patients to seek help. Preload, afterload, and the contractile force of the left ventricle determine stroke volume (see Chapter 16). These three components are in a constant and dynamic relationship. A decrease in one or more components is compensated by an increase in the others designed to maintain a constant stroke volume at rest. Catecholamines and other neurohormones contribute to the complex balance that preserves stroke volume over a wide range of supply and demand for oxygen at the tissue level. Relatively minor increases in stroke volume are possible because of neurohormonal regulation of reserve fluid volume stored in the liver and venous system until needed. The largest increase in cardiac output comes, not from increased stroke volume, but through increases in heart rate. Cardiac reserve is the ability to significantly increase oxygen delivery in response to increased demand. Reserve is meant to meet demand that exceeds that of rest. Patients with heart failure need their reserve just to function at rest. When that reserve is exhausted, they have symptoms even at rest. The increase in catecholamines increases the risk of dysrhythmias such as ventricular tachycardia and sudden death.

Heart Rate

As stated earlier, cardiac output equals stroke volume multiplied by heart rate. Therefore, just doubling the heart rate doubles cardiac output without changing stroke volume. The immediate response to a decrease in stroke volume, a decrease in arterial oxygen content, or an increase in metabolic demand is an increase in heart rate. However, at a certain point, increasing the heart rate can actually decrease the stroke volume and, therefore, cardiac output as well. Because the ventricle fills during diastole, preload becomes compromised at higher heart rates because of the shortened diastolic filling time. A decrease in preload compromises contractility.

The physiological role of heart rate in the regulation of cardiac output involves more than just the absolute rate. Cardiac rhythm is important. As previously stated, rapid tachycardia can compromise stroke volume. Any rhythm that does not include a rhythmic atrial contraction, such as atrial fibrillation and flutter, junctional rhythms, ventricular rhythms, and ventricular pacing, can compromise filling and therefore stroke volume and cardiac output. A heart rate that is too slow, such as that which occurs in third-degree atrioventricular (AV) block or sick sinus syndrome, may compromise cardiac output, not by decreasing stroke volume, but by decreasing overall cardiac output.

Neurohormonal Mechanisms

Metabolic demand for oxygen is the primary factor in the regulation of cardiac output, and the mechanical relationships between loading and contractility provide a means to regulate it. Neurohormones are the messengers that initiate, coordinate, and mediate the complex processes that meet the dynamic need for cardiac output[5–7] (Fig. 20-1).

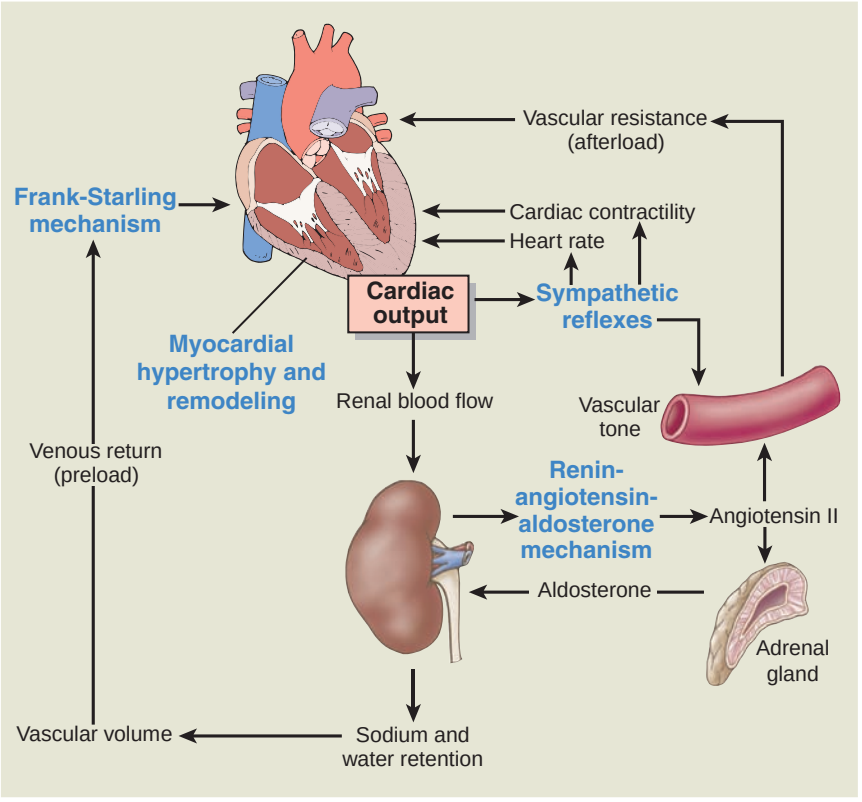

FIGURE 20-1 ▲ Compensatory mechanisms in heart failure. The Frank-Starling mechanism, sympathetic reflexes, renin–angiotensin–aldosterone mechanism, and myocardial hypertrophy work to maintain cardiac output in the failing heart. (From Porth CM: Pathophysiology: Concepts of Altered Health States, 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009, p 613.)

Catecholamines

Catecholamines are released from the adrenal medulla as part of the primitive "fight or flight" response to any stressor. Stressors can be physiological or psychological. Epinephrine and norepinephrine as well as cortical hormones, such as cortisol and aldosterone, are released.

Epinephrine and norepinephrine are the key catecholamines involved in the regulation of the cardiovascular system. The heart and blood vessels contain α- and β-adrenergic receptors that bind with these hormones to support cardiac output and blood pressure. Norepinephrine has almost exclusively α-adrenergic properties that increase vascular resistance and therefore blood pressure. Epinephrine has both α- and β-adrenergic properties. β-Agonist effects include increased heart rate, increased contractility, and vasodilation. The net effect of epinephrine is increased cardiac output; it increases stroke volume by increasing contractility and decreasing afterload. The increases in heart rate and stroke volume together produce a greater increase in cardiac output than either would alone.

Renin–Angiotensin–Aldosterone System

One of the most important mechanisms of blood pressure control in relation to heart failure is the renin–angiotensin–aldosterone system. Fluids, such as blood, flow down pressure gradients (ie, from higher pressure to lower pressure). Consequently, pressure in the aorta is higher than pressures distal to it, including the arteriolar and capillary levels. Arterial blood pressure is critical to the delivery of blood (and therefore oxygen) to the cells to support cellular function. Several mechanisms maintain normal blood pressure across variable body fluid volumes, in different positions (sitting or standing vs. supine), and with cardiac output demands.

Renin is an enzyme produced in the kidney in response to even small decreases in blood pressure. Renin has a direct effect on the kidney, causing increased reabsorption of salt and water. Much of the renin travels to the lung to act enzymatically on angiotensinogen to form angiotensin I. In the presence of angiotensin-converting enzyme (ACE) in the lung, angiotensin I is converted to angiotensin II.

A powerful vasoconstrictor, angiotensin II increases arterial resistance quickly and profoundly, providing immediate support for blood pressure and maintaining perfusion in the short term until a longer-term strategy can be implemented. Although angiotensin II has a much more modest effect on venous resistance, it does increase venous resistance and therefore venous return. Angiotensin II also stimulates the adrenal cortex to release aldosterone. Aldosterone then acts on the kidney to increase salt reabsorption in the distal tubule, and this salt increases water reabsorption in the kidney, resulting in increased circulating volume. Increased circulating volume is the longer-term strategy. The renin–angiotensin–aldosterone system initiates a process that assumes any decrease in blood pressure is a volume loss (eg, hemorrhage), and the long-term strategy is to replace that loss.

▲ Pathophysiology

The physiological principles discussed in the previous section form the basis for understanding the patient's signs, symptoms, responses, and compensation for the disease process as well as the basis for management strategies. Heart failure has many causes (Table 20-1).

Table 20-1 Causes of Heart Failure

Impaired Cardiac Function	Excess Work Demands
Myocardial Disease	**Increased Pressure Work**
Cardiomyopathies Myocarditis Coronary insufficiency Myocardial infarction	Systemic hypertension Pulmonary hypertension Coarctation of the aorta
Valvular Heart Disease	**Increased Volume Work**
Stenotic valvular disease Regurgitant valvular disease	Arteriovenous shunt Excessive administration of intravenous fluids
Congenital Heart Defects	**Increased Perfusion Work**
	Thyrotoxicosis Anemia
Constrictive Pericarditis

Cardiomyopathy

The distinguishing pathophysiological factor in heart failure is a cardiomyopathy, but cardiomyopathy is not synonymous with heart failure.[2] Literally, cardiomyopathy is a progressive pathological process in the heart muscle. Cardiomyopathy may be congenital or acquired. Hypertrophic, nonobstructive cardiomyopathy and dilated cardiomyopathy are the two most common forms. Hypertrophic cardiomyopathy is an increase in muscle mass in the ventricle resulting in a measurable increase in the thickness of the ventricular wall. Hypertrophy is a response to a prolonged increase in resistance (afterload). Dilated cardiomyopathy is an increase in the size of the ventricular chamber without an increase in wall size and is a response to decreased contractility. For a more detailed discussion of cardiomyopathies, see Chapter 19; see also Figure 20-2.

Dysrhythmia

Heart failure is commonly associated with dysrhythmias, both atrial and ventricular. The structural and metabolic changes that occur in heart failure frequently lead to dysrhythmia, and the dysrhythmia itself may lead to heart failure.

Atrial Dysrhythmias

Atrial tachycardias may cause heart failure in two ways. First, the shortened diastole leads to decreased filling and may cause or aggravate diastolic dysfunction, resulting in decreased cardiac output and the symptoms of heart failure. When the tachycardia is caused by atrial fibrillation, the loss of atrial kick increases the impact of the atrial dysrhythmia on left ventricular dysfunction. In one study, systolic dysfunction developed in 11% of patients with atrial fibrillation, and 6% of the patients died.[7]

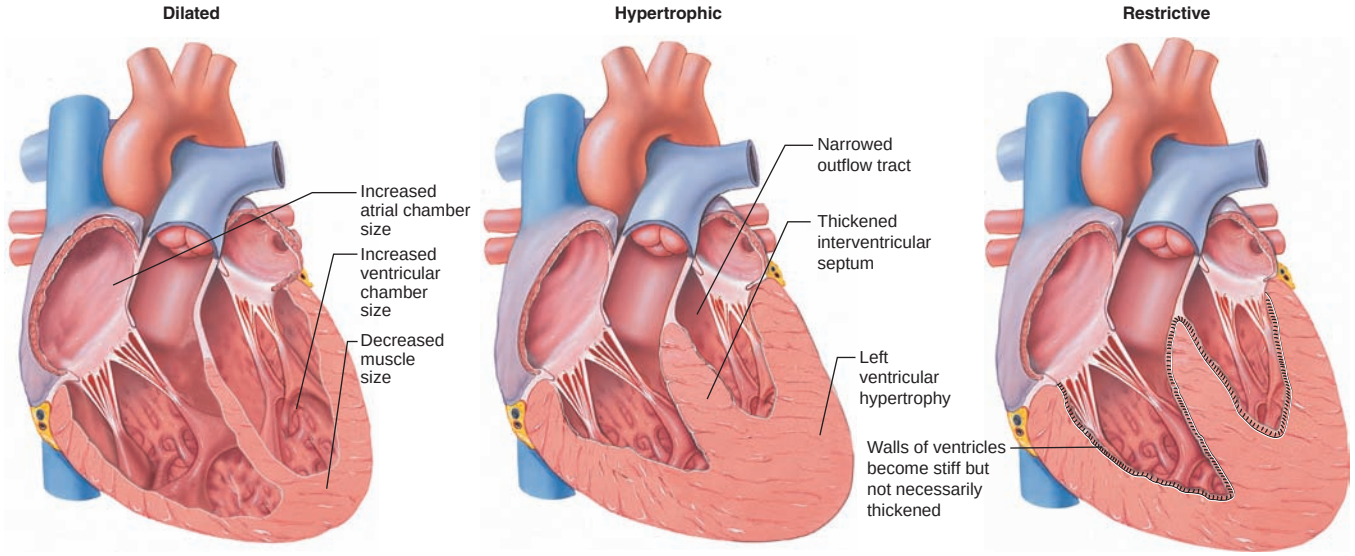

FIGURE 20-2 ▲ Patterns of ventricular hypertrophy and remodeling in various forms of cardiomyopathy. (Anatomical Chart Company: Atlas of Pathophysiology. Springhouse, PA: Springhouse, 2010, p. 45.)

Atrial fibrillation is a significant problem in patients with heart failure. The most common sustained dysrhythmia, atrial fibrillation, affects 2.2 million Americans. The median age for atrial fibrillation is 75 years; it affects 8.8% of Americans older than 80 years. The risk for stroke is increased five times in patients who have this dysrhythmia.[8] The incidence of both atrial fibrillation and heart failure increases with age, increasing the likelihood that patients with heart failure will also have atrial fibrillation at some time.

Ventricular Dysrhythmias

Ventricular dysrhythmias, in particular premature ventricular beats and nonsustained ventricular tachycardia (NSVT), are common in patients with dilated cardiomyopathy, whether ischemic or nonischemic. Prior to the common use of implantable cardioverter–defibrillators (ICDs), sudden death from ventricular dysrhythmia or bradycardia accounted for 30% to 40% of deaths associated with heart failure.[9–11] Since the widespread use of ICDs, the death rate from sudden cardiac death has decreased to 12.7%.[10] The presence of premature ventricular beats or even NSVT has not been shown to reliably predict risk for sudden death for any particular patient. However, the presence of these dysrhythmias does appear to reliably reflect a globally impaired myocardium.

Several mechanisms play a role in the development of ventricular dysrhythmias. The low ejection fraction leads to stretch of the myocardial fibers, thus increasing excitability. Excitability is also affected by the presence of increased catecholamines; increased sympathetic tone; and, on occasion, antiarrhythmic drugs. Activation of the renin–angiotensin–aldosterone system contributes to the overall environment that generates dysrhythmia. Ischemia leads to failure of the sodium–potassium pump, and the loss of potassium from the cell increases the risk for premature ventricular beats. Scar tissue from previous infarctions and surgery can stimulate dysrhythmia. Electrolyte shifts involving potassium, calcium, and magnesium are often associated with prolonged or aggressive diuretic use. Lung disease such as emphysema or chronic bronchitis is often comorbid with heart failure, and the lung disease may lead to hypoxemia, which contributes to the genesis of ventricular dysrhythmias. The traditional sources of ventricular dysrhythmia that occur in patients without heart failure, such as reentry, enhanced automaticity, and delayed after-potentials, may also be involved.

Acute Decompensated Heart Failure

Chronic disease is characterized by variable periods of relative stability or compensation interrupted by periods of exacerbation or decompensation. Patients with chronic heart failure may live from day to day with no symptoms of heart failure or well-controlled symptoms. However, chronic heart failure may become acutely worse, resulting in an increase in symptoms and limitations associated with left ventricular dysfunction. Several factors may lead to an exacerbation or ADHF.[12] Current therapy for ADHF is not guideline driven, and there is poor agreement on the appropriate course. There is agreement that most of the therapies available to treat ADHF, such as inotropes and loop diuretics, hasten the course of heart failure by destroying myocytes and stimulating the renin–angiotensin system. Unfortunately, they are often the only tools available. Consequently, one of the fastest growing areas of clinical research is directed toward understanding ADHF and developing better therapies to treat it based on accumulated evidence.[13]

Alcohol, anemia, hypoxemia, hypertension, ischemia, and worsening left ventricular function may trigger acute decompensation. Any factor that increases oxygen demand, and therefore demand for increased cardiac output beyond the ability of the ventricle to function (eg, hypertension, tachycardia, anemia, exercise), causes an exacerbation. Similarly, any factor that depresses the function of the already compromised ventricle leads to exacerbation (eg, alcohol, drugs that exert a negative inotropic effect, such as calcium channel

blockers and β-blockers). As the ventricle is called on to work harder, it works less efficiently, and the left ventricular end-diastolic pressure increases, leading to increased pulmonary artery pressures. The increased pulmonary artery pressures, in turn, lead to orthopnea, possibly pulmonary edema, elevated venous pressures, liver congestion, lower extremity edema, and PND. Patients may also present with lower blood pressures, more rapid heart rates, and prerenal azotemia. Potentially, the acute decompensation is reversible if treated quickly and aggressively.

▲ Assessment

Heart failure has long been defined by the presence of pulmonary edema characterized by bibasilar rales or crackles. At one time, the absence of crackles ruled out heart failure. However, chronic heart failure is a persistent, not episodic, condition, and it rarely includes pulmonary edema and crackles even in early decompensation. History, physical examination, diagnostic procedures, and hemodynamic evaluation all contribute to diagnosing heart failure, perhaps determining its cause, and evaluating the success of therapy.

History

The symptoms of heart failure are nonspecific (ie, they are common to many disease processes). The health history is used to put the symptoms into a context that may lead to their interpretation as heart failure and not pulmonary disease, deconditioning, or other conditions that produce shortness of breath, DOE, fatigue, and swelling of the lower extremities. History alone does not confirm the diagnosis, but it helps determine follow-up examinations and diagnostic tests that may be appropriate.

Onset

The basic question is, "When did the symptoms start?" The answer to this question helps categorize the condition as acute or chronic. Most patients indicate an acute onset of 2 weeks or fewer if this is their first visit for their symptoms. If they are asked additional questions about their activity tolerance for the past year or so, patients with chronic heart failure note a gradual slowing of activity to match the amount of energy available or to control symptoms. The recent identification of symptoms indicates that the patient is now aware of them or they have become unbearable. Acuity is important because reversible ischemia is a potentially life-threatening etiology that may present acutely. When identified and treated, chronic heart failure can be avoided, and perhaps a patient's life may be saved.

Duration

It is important to know whether the symptoms are persistent and independent of activity or come and go with activity, change of position, food ingestion, or other events. This helps differentiate between heart failure and other conditions that can cause the same symptoms. Heart failure symptoms typically worsen with activity and improve with rest. Cough and shortness of breath may increase when lying down and improve with sitting up. Hiatal hernia and gastric reflux may produce shortness of breath, chest pain, and cough but typically occur after eating and more often in the evening. Lung disease or sleep apnea may also cause the shortness of breath that occurs at rest or awakens the patient at night, characteristic of heart failure.

Severity

Severity of symptoms is important to determine because it is the basis for establishing functional class (see Box 20-1, p. 392). Severity of symptoms is also an important standard for evaluating the success of therapy. A major goal of therapy is symptomatic improvement or, if possible, elimination of symptoms. The evaluation of severity requires that patients be asked certain questions about their symptoms (Table 20-2).

Comorbid Diseases

Many patients with heart failure have comorbid disorders that contribute to or aggravate their heart failure. The most common of these diseases are coronary artery disease (CAD), hypertension, diabetes mellitus, chronic obstructive pulmonary disease (COPD), and chronic renal insufficiency. Worsening of one or more comorbid diseases may lead to an exacerbation of stable chronic heart failure. In the case of CAD, hypertension, and diabetes, heart failure may be the long-term result of complications of these disease processes. Identification and tight control of these comorbid diseases contribute to the control and treatment of the symptoms of heart failure.

Medications

It is very important to obtain a complete list of the patient's medications and dosages. The list should include prescription and nonprescription medications. In cases of new-onset heart failure, even old medications may contribute to the severity of symptoms. For example, patients who have been treated with a calcium channel blocker for hypertension and now present with a decreased ejection fraction and heart failure may improve when the medication is changed and does not depress myocardial function. Other medications may contribute to heart failure. Patients taking over-the-counter medications, such as nonsteroidal anti-inflammatory drugs (NSAIDs), may present with worsening heart failure and renal function because of the effect of the NSAIDs on renal blood flow. NSAIDs block the effect of prostaglandins, which the body secretes to maintain renal blood flow in the context of decreased cardiac output. Cold medicines with systemic decongestants can lead to increased blood pressure that precipitates worsening symptoms of heart failure.

Psychosocial Factors

Noncardiac factors may also affect patients with heart failure. Because many affected patients are elderly, they may have problems remembering to fill prescriptions or take medications. Financial hardships may force some patients to choose between buying medication and buying food. Transportation may depend on friends or family who may be unreliable. Housekeeping may be difficult or impossible because of

Table 20-2 Assessment of Severity of Heart Failure

Symptom	Measure(s)	Questions
Orthopnea	Number of pillows patient sleeps on regularly	How many pillows do you sleep on at night? If more than one, is it for comfort or because you cannot breathe with one or two?
Dyspnea on exertion	Number of blocks patient can walk without stopping to rest or catch breath Number of flights of stairs patient can climb without stopping to rest or catch breath Number of times patient must rest while doing activities of daily living such as toileting or minor housework	How many blocks and flights of stairs can you walk without stopping to rest or catch your breath? Do you stop because you cannot go further or because you want to avoid getting short of breath? For patients who are limited by peripheral vascular disease or orthopedic problems: Do you stop because you cannot breathe or because of pain? Which comes first?
Paroxysmal nocturnal dyspnea	Average number of times per night or week	After you go to bed, do you ever have to sit up suddenly to catch your breath? How much time passes before you can breathe normally? Do you need to do anything besides sit up to relieve the shortness of breath?
Dizziness or lightheadedness	Presence or absence (of real concern when symptom occurs when the patient is standing and persists or occurs with activity)	Do you ever become dizzy or lightheaded? What are you doing when this occurs?
Chest pain or pressure*	Presence or absence	Do you have chest pain or pressure? Do you become short of breath with the chest pain or pressure? Which comes first, the pain or the shortness of breath?†

*Chest pain should be fully investigated to determine whether active ischemia is present. This is especially true in patients who are presenting for the first time for evaluation of symptoms of heart failure. Once ischemia has been ruled out, patients may still have chest pain, and it should be evaluated by using these assessment questions.

†Chest pain that comes after shortness of breath is often caused by the heart failure.

fatigue and shortness of breath. Patients living on the second or third floor of buildings without elevators may become isolated and lonely. Depression is not uncommon; the exact incidence is not known. Ongoing family dysfunction and family members who depend on the patient for care and financial support (eg, grandchildren, dependent adult children, spouses or partners) add a burden to the patient's management. Illiteracy is still prevalent; even patients who can read may not comprehend medication instructions correctly. Some patients may skip diuretic doses when visiting places where they are uncertain about access to bathroom facilities; they may not take the diuretic when they return home.

Although many of these factors are significant, they may not be obvious until the patient has visited the same health care facility many times. Early case management and skillful discharge planning depend on recognizing these problems before they lead to repeated hospitalizations and increased mortality.

Substance Abuse

Alcohol and drug (eg, cocaine) use is also important because it may contribute to the development and progression of heart failure. If alcohol use is the cause of cardiomyopathy, abstinence may lead to complete reversal. Patients who have substance abuse problems often forget to buy or take medication. They may be homeless, which increases the likelihood that they will not return to the health care facility for regular follow-up.

Physical Examination

The physical findings in heart failure differ depending on whether the patient has (1) acute or chronic heart failure or (2) systolic or diastolic dysfunction. When the physiological changes of left ventricular dysfunction occur over a long period, the body adapts and compensates. Consequently, many of the findings on physical examination are normal, despite moderate to severe disease. However, when the problem occurs acutely, there is no time for compensation or adaptation, and the symptoms and consequences are severe. Patients who have chronic heart failure from systolic dysfunction and who have abnormal findings, have them persistently. Patients with diastolic dysfunction may have abnormal findings only during an exacerbation.

One or more of the following findings characterizes acute decompensation. The patient may be volume overloaded by 5 to 50 pounds over dry weight; dry weight is the patient's weight when he or she is euvolemic. Patient self-monitoring is often geared to maintenance of dry weight. In many cases, maintaining dry weight within 1 to 2 pounds can prevent decompensation. A second finding, often, is renal insufficiency characterized by an increase in both blood urea nitrogen (BUN) and creatinine levels, with a ratio of BUN to creatinine of greater than 20:1. The third finding is decreased cardiac output manifested by increased DOE and decreased exercise tolerance in general, often described as "fatigue."

Patients may also complain of increased orthopnea, PND, or both. Some patients have all of the findings, and it is not unusual for patients to be short of breath at rest (NYHA class IV) or demonstrate Cheyne-Stokes respirations.

General Findings

Patients with acute heart failure or acute decompensation of chronic heart failure appear ill; they are often breathing rapidly, looking anxious, and either sitting up straight or leaning forward and resting their arms on a table or their knees. Patients with stable, chronic heart failure may be quite comfortable but may have evidence of cachexia, muscle wasting, and thin skin.

Vital Signs

Patients with systolic dysfunction may have quite low, but asymptomatic, blood pressures (systolic, 80 to 99 mm Hg; diastolic, 40 to 49 mm Hg). Heart rates may be rapid (90 beats/min or more), or lower at rest. Patients with diastolic dysfunction may or may not be hypertensive.

Serial weights are very important in following fluid status. Daily weights, when performed properly on a calibrated scale, are more accurate estimates of fluid status than intake and output. Daily weights can be used to evaluate fluid status because 1 liter of water weighs 1 kg. Overnight fluctuations in weight are always related to water retention or diuresis.

Neck

Jugular venous pressure is an estimate of right heart filling pressures. When either the total-body fluid volume or the right atrial pressure increases, the jugular venous pressure increases, and the vein dilates. Jugular venous pressure is estimated by identifying the internal jugular vein and measuring the height of the pulse from the level of the clavicle in centimeters. The patient's head is elevated to 45 degrees. It is important not to use the external jugular vein, which often appears distended and prominent in patients with normal volume and pressure.

Lungs

It is necessary to determine the respiratory rate and observe the depth of respiration as well as the respiratory rhythm. It is not unusual for patients with severe NYHA class IV heart failure to have a Cheyne-Stokes respiratory pattern.[14] The heart failure may be chronic and persistently rated as class IV heart failure or may represent an acute exacerbation.

Results of chest auscultation may be completely normal. Because patients with increased pulmonary artery pressures have increased lymph drainage over time, fluid does not collect in the alveoli. Rales or crackles are sounds made by air bubbling through water in the alveoli, and if no water is present, the sounds are not audible. When pressures increase suddenly, water is forced into the alveoli by increased hydrostatic pressure. Consequently, in acute heart failure and acute decompensation, in which pulmonary edema is common, bibasilar crackles occur. Unilateral crackles or nondependent crackles are indicative of a pulmonary process, not heart failure. Pulmonary edema can cause wheezing that may be difficult to distinguish from reactive airway disease, such as asthma.

Heart

Progressions from left-sided heart failure to left-sided and right-sided heart failure or chronic elevations of pulmonary artery pressure often result in a visible, palpable right ventricular or pulmonary artery pulsation at the left sternal border. The point of maximal impulse may be extremely displaced. In advanced heart failure, the maximal impulse may be at the posterior axillary line and at the fifth or sixth intercostal space.
